# Preface

---

Only 25 years ago, a multidisciplinary group of some three dozen individuals met for the first time in Vero Beach, Florida, under the auspices of the National Institute of Child Health and Human Development (NICHD) to discuss a recently identified immunoglobulin, secretory IgA. Since that historic workshop, seven international congresses have been held to discuss secretory immunoglobulins and mucosal immunology, and there have been a number of scientific meetings on immunological mechanisms in such mucosal sites as respiratory tract, gut, genital tract, mammary glands, and periodontal tissues. The last International Congress of Mucosal Immunology, held in 1992 in Prague, Czechoslovakia, was attended by nearly 1000 participants.

The recognition that defenses are mediated via mucosal barriers dates back several thousand years. Ingestion of *Rhus* leaves to modify the severity of reactions to poison ivy is a centuries old practice among native North Americans. The modern concepts of local immunity, however, were developed by Besredka in the early 1900s, followed by the discovery of IgA in 1953 and its isolation and characterization in 1959. Studies in the early 1960s demonstrated the presence of IgA in a unique form in milk and, shortly thereafter, in other external secretions. These studies were followed by the discovery of the secretory component and the identification of the J chain. These remarkable observations were soon complemented by the characterization of the bronchus-associated lymphoid tissue (BALT) and the gut-associated lymphoid tissue (GALT), the observation of circulation of antigen-sensitized or reactive IgA B cells from BALT and GALT to other mucosal surfaces such as the genital tract and the mammary glands, and the definition of mucosal T cells. In the past decade, our concept of the mucosal immune system has been expanded to include M cells and mechanisms of mucosal antigen processing, regulatory T lymphocytes and other effector cell mechanisms, neuropeptides, and the network of interleukins and other cytokines. Finally, the biological significance of the mucosal immune system increasingly is being realized in the context of human infections acquired via mucosal portals of entry, including conventional infections as well as new syndromes such as acquired immune deficiency associated with infection by HIV.

Despite the tremendous progress made in the acquisition of new knowledge concerning the common mucosal immune system, mucosal infections, and oral immunization, no single text covering the entire spectrum of mucosal immunity was available. Therefore, this handbook was organized to develop a perspective of the basic biology of the components that constitute the framework of the common mucosal immune system, as well as of the infectious and immunologically mediated disease processes of the mucosae. Virtually all chapters have been authored by original investigators responsible for key observations on which current concepts are based.

Part I, Cellular Basis of Mucosal Immunity, provides an introductory overview and a historical perspective of the mucosal immune system (Chapter 1), followed by 10 comprehensive chapters (Section A) on development and physiology of mucosal defense (Chapters 2–11). These chapters address structure and function of mucosal epithelium, cellular basis of antigen transport, mucosal barrier, innate humoral factors, bacterial adherence, development and function of mucosal immunoglobulin, and epithelial and hepatobiliary transport. Section B (Chapters 12–19) focuses on cells, regulation, and specificity in inductive and effector sites. The inductive site chapters discuss characteristics of mucosa-associated lymphoid tissue (MALT), Peyer's patches, regulation of IgA B cell development, diversity and function of mucosal antigen-presenting cells, oral tolerance, peptidergic circuits, role of B-1 cells, and lymphocyte homing. The chapters on effector sites (Section C) present information about cytokines, mucosal Ig-producing cells, regulatory T cells, intraepithelial cells, mucosal IgE, inflammation and mast cells, cytokines in liver, cytotoxic T cells in mucosal effector sites, and immunity to viruses (Chapters 20–29). Section D addresses mucosal immunization and the concepts of mucosal vaccines. These chapters discuss passive immunization, vaccine development for mucosal surfaces, antigen delivery systems, mucosal adjuvants, and approaches for generating specific secretory IgA antibodies (Chapters 30–34).

Part II, Mucosal Diseases, addresses the secretory immune system with special reference to mucosal diseases. Section E consists of chapters on the stomach, intestine, and liver, and includes diseases of GALT and intestinal tract,  $\alpha$  chain

and related lymphoproliferative disorders, gastritis and peptic ulcer, malabsorption syndrome, food allergy, intestinal infections, and diseases of the liver and biliary tract (Chapters 35–42). Section F covers selected areas of lung and lower airway and includes chapters on BALT and pulmonary diseases, mucosal immunity in asthma, respiratory infections, and inhalant allergy (Chapters 43–46). Section G presents information on the oral cavity, upper airway, and mucosal regions in the head and neck (Chapters 47–50), as well as ocular immunity, tonsils and adenoids, and middle ear. Sections H and I are devoted to mammary glands and genitourinary tract, respectively. These sections consist of chapters on milk, immunological effects of breast feeding (Chapters 51–52), IgA nephropathy, immunology of female and male reproductive tracts, endocrine regulation of genital immunity, mucosal immunopathophysiology of HIV infection, and genital infections relative to maternal and infant disease (Chapters 53–58).

The information reviewed in the different chapters in this handbook will be of considerable interest to diverse groups of clinicians, basic and clinical immunologists, biologists, veterinarians, and public health workers interested in understanding the application of basic biology to virtually all immunological or infection-mediated disease processes of external mucosal surfaces. This handbook will be of particular importance to students of medicine and pediatrics, including individuals studying gastroenterology and pulmonology, ophthalmology, gynecology, infectious disease, otolaryngology, periodontal disease, sexually transmitted disease, and especially mucosal immunology.

# Introduction: An Overview of the Mucosal System

Thomas B. Tomasi

The concept of a mucosal immune system first developed almost 30 years ago as a result of quantitative immunochemical studies of the various immunoglobulin isotypes in human mucosal fluids (Chodirker and Tomasi, 1963). The initial and most striking findings showed that external fluids that bathe mucosal surfaces contained predominantly IgA, in contrast to the low concentration of this immunoglobulin in comparison to IgG. Moreover, the IgA in saliva appeared to be different in molecular size from IgA in serum (serum IgA was primarily a 7S monomer with a smaller amount of 10S and larger polymers, whereas salivary IgA was mainly 11S). Importantly, salivary IgA was found to contain an additional component that we called the secretory piece and later termed the secretory component (SC; Tomasi *et al.*, 1965). Using antisera specific for IgA and for SC in immunofluorescent studies of the gastrointestinal tract and other tissues, large numbers of IgA cells were found in the lamina propria in close anatomical relationship with the mucosal surface, whereas SC was localized to epithelial cells. These findings suggested that the source of IgA in external secretions (secretory or SIgA) was regional and that SC was added during transport. This hypothesis was verified further by our studies showing that <sup>125</sup>I-labeled 7S IgA administered intravenously (iv) did not appear in significant amounts in saliva. However, the saliva of patients with agammaglobulinemia contained free SC, indicating that the transport of SC occurred in the absence of the specific ligand. As shown by South *et al.* (1966), the administration of large amounts of IgA to agammaglobulinemic patients resulted in the appearance of SIgA in secretions, suggesting that, if local production is diminished or absent and if enough dimeric IgA reaches the lamina propria from the circulation, transport will occur as in the nondeficient state. Similarly, Renegar and Small (1991) showed that polymeric IgA but not monomeric IgA or IgG1 anti-influenza antibodies promote mucosal protection in nonimmune mice. Thus, the absence of transport from serum to secretions in most tissues may be related to the saturation of local transport mechanisms by the regionally produced IgA. Later researchers demonstrated that much of the IgA in certain fluids such as the rat mammary gland (Halsey *et al.*, 1980) and especially rat bile (Fisher *et al.*, 1979) was a result of transport of polymeric 10S IgA from serum. This transport is a primary reason that 10S IgA has such a short apparent half-life in serum (Fisher *et al.*, 1979) in comparison to 7S serum IgA (Chodirker and Tomasi, 1963; Tomasi *et al.*, 1965).

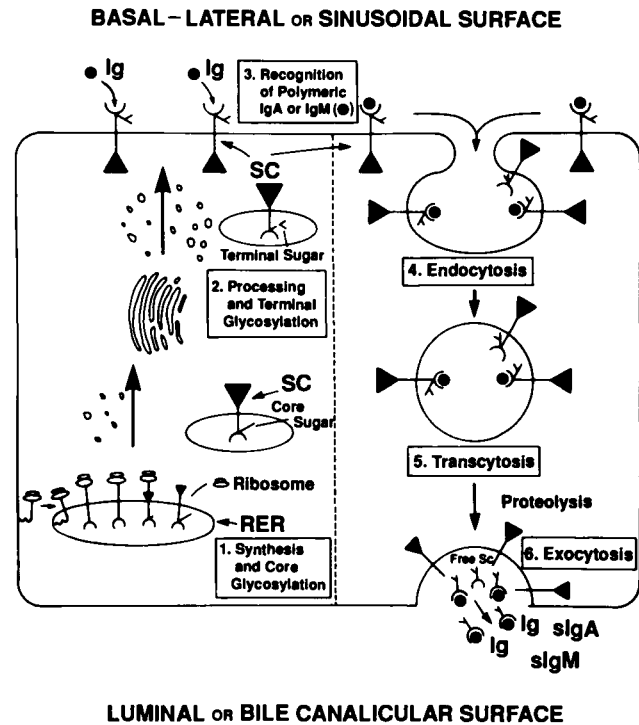

There are two IgA subclasses, IgA1 and IgA2, which differ in several respects, most notably in the absence of a 13-amino-acid proline-rich region in the hinge of IgA2 that is the site of cleavage by IgA proteases. This difference confers resistance to these enzymes on the IgA2 subclass. The IgA proteases are enzymes (virulence factors) produced by a variety of bacteria that inactivate the antibody by a highly specific cleavage in the hinge region; the presence of IgA proteases in virulent strains of bacteria as shown by Plaut (1983) has great medical significance. Teleologically, therefore, having larger proportions of the IgA2 subclass in external secretions, that is, secretions that bathe the mucous surfaces these organisms colonize, would be advantageous. Moreover, after cleavage of IgA1 into Fab and Fc, the Fab portion has been suggested to coat the bacteria and protect these organisms from the destructive action of other antibodies (Kilian *et al.*, 1983).

Most of the monomeric serum IgA (90% IgA1 subclass) is produced in the bone marrow. In humans, small amounts of polymeric IgA are present in serum, probably as a result of synthesis in mucosal sites, although some polymeric IgA also is produced in the marrow. There is a catabolic site in the liver for human IgA1 which involves binding to a hepatic binding protein or the asialoglycoprotein receptor. IgA2 also is produced in bone marrow and peripheral lymphoid tissue, but the major portion appears to be synthesized in mucosal sites. SIgA is a dimer with a molecular weight of approximately 390,000 which, in addition to H and L chains, contains two additional polypeptide chains. J chain, described by Koshland (1985), is synthesized in the same cells that produce the dimeric IgA (i.e., plasma cells) and is a 15-kDa protein with one *N*-glycosylation site. This chain is not homologous to SC or Ig chains and does not appear, by sequence analysis, to be a member of the immunoglobulin superfamily. However, J chain does have a domain structure, probably a  $\beta$  barrel (Pumphrey, 1986), that has similarities to the classical immunoglobulin domain. J chain is involved in and probably necessary for polymer formation in B cells. J chain production occurs in pre-B cells, but its synthesis is stimulated markedly in more mature B cells by antigen contact. Complexing of J chain with the monomeric units of IgA (and IgM) to form the dimer occurs late, just prior to secretion. The complexing of J chain occurs with the penultimate cysteine in the C-terminal tail piece (an 18-amino-acid peptide characteristic of IgA and IgM). Some evidence suggests that the disulfide bridge may be formed with a sulfhydryl

group in a C<sub>H</sub>2 domain of the alpha chain. As shown by Hauptman and Tomasi (1975), J chain lends a conformation to both IgA and IgM that is required for noncovalent complexing (followed by S-S formation) to SC; SC does not interact efficiently with polymers lacking J chain, presumably because of the unique conformation of the IgA<sub>2</sub>-J or IgM<sub>5</sub>-J complex.

## I. POLYIg RECEPTORS AND TRANSPORT

Secretory component is an 80,000 molecular weight glycoprotein that is synthesized in epithelial cells and is bonded covalently through a disulfide linkage between the fifth domain of SC and the C<sub>H</sub>2 domain of one monomer in the human SIgA molecule. SC does not appear to cross-link the two monomeric units or bind to J chain, although the disulfide chemistry is not established completely. Bakos *et al.* (1991) showed that the binding of SC to polymeric IgA is dependent on a highly conserved N-terminal region of SC that may be the primary site of noncovalent interactions between SC and IgA. SC is a member of the immunoglobulin superfamily. This family contains over 40 different molecules present on lymphocytes and a variety of other cells. SC is a component of a larger molecule, the poly Ig receptor (poly IgR), that acts as a receptor on epithelial cells for polymeric molecules of IgA and IgM that contain J chain. The rabbit poly IgR has been cloned and sequenced by Mostov *et al.* (1984); the extracellular region is composed of five domains, four V-like domains and a C-terminal C<sub>H</sub>-like domain close to the plasma membrane. The human poly IgR also has been cloned and shows organization similar to that of the rabbit poly IgR, with which it shares 54% homology (Krajči *et al.*, 1989). As shown in Figure 1, the poly IgR is synthesized on the rough endoplasmic reticulum (RER) as a 95-kDa protein and is then core-glycosylated to a 105-kDa molecule and transported to the Golgi complex, where the carbohydrate is trimmed and the molecule is terminally glycosylated. The 116-kDa protein then is transported in vesicles to the basal lateral surface of the mucosal cell or, in the hepatocyte, to the sinusoidal surface. The receptor has an N-terminal ectoplasmic domain on the outside acting as the receptor for ligand (IgA and IgM), a transmembrane portion, and a 103-amino-acid cytoplasmic tail. The cytoplasmic tail, as shown by Larkin *et al.* (1986), is phosphorylated on a serine residue during its intracellular journey to the membrane to give the 120-kDa mature receptor. Figure 1 illustrates how the binding of dimeric IgA (or pentameric IgM) containing J chain results in endocytosis in coated pits; the ligand-receptor complexes and unbound receptors are sorted, and the ligand-receptor complex is directed across the cells to the apical membrane by a process referred to as transcytosis. Before secretion into the lumen, the receptor is proteolyzed and SC is released from the transmembrane region and cytoplasmic tail and secreted into the lumen, either attached to its ligand or "free." The location and mechanism of proteolysis and the existence of a single specific site or multiple cleavage sites (which appears more likely from the staggered C-terminal ends) are unclear. However, in rat hepatocytes, cleavage appears to occur at the

**Figure 1** Model for transport of IgA and IgM across the mucosal epithelial cell or hepatocyte. The synthesis of secretory component (SC) and the steps in the transport of Ig across the cell are represented. SC is synthesized and core glycosylated on membrane-bound polysomes [rough endoplasmic reticulum (RER)] as an approximately 95,000 molecular weight transmembrane protein and is inserted cotranslationally into the RER. Further processing (including the addition of terminal sugars) may occur in the Golgi. SC then becomes integrated into the basal (and lateral) plasma membranes of the mucosal epithelial cell or the sinusoidal membrane of the hepatocyte. The transmembrane SC ( $\Upsilon$ ) consists of three domains: cytoplasmic ( $\downarrow$ ), membrane-spanning ( $|$ ), and ectoplasmic ( $\Upsilon$ ). The ectoplasmic domain acts as the external receptor for J chain-containing polymeric Igs such as IgA and IgM ( $\bullet$ ). Endocytosis of the complexes and of SC not associated with Ig occurs continuously. Transcytosis of the receptor probably does not fuse with lysosomes but do fuse with the plasma membrane, thus carrying the Ig-receptor complex to the luminal surface. Proteolysis occurs at an unknown stage, removing the cytoplasmic and membrane-spanning portions. The Ig is secreted covalently attached to the ectoplasmic domain (MW  $\sim$ 80,000).

canalicular plasma membrane; the membrane-anchor domain is either internalized or secreted with SC into the bile (Solari *et al.*, 1989). The receptor is presumed to be selectively targeted to the appropriate membrane, as shown for viral and other proteins documented to undergo polarized transport. Biosynthetic studies (Schaerer *et al.*, 1990) indicate selective (rather than random) targeting of the receptor to the basolateral surface. In the Madin-Darby canine kidney (MDCK) cell line, cleavage of the receptor by an endogenous protease is delayed until after its appearance on the membrane, explaining the presence of poly IgR on the apical membrane surface. Thus, the SIgA in human external fluids consists

of the J chain-containing dimer plus the covalently linked ectoplasmic domain of SC. As we first reported (Tomasi and Czerwinski, 1968), the SIgA molecule is protected from proteolysis by the secretory component, which may lend a biological advantage to SIgA functioning in a complex fluid containing many proteolytic and other degradative mechanisms.

### A. Cellular Traffic

As shown by the studies of Owen and Jones (1974; Owen, 1977), antigen is taken up in significant part, although not solely, via the Peyer's patches and moves in pinocytotic vesicles across the attenuated epithelium of the patch dome (called M for microfold cells) to the lymphoid epithelium that lies immediately beneath it. Lymphoid cells in the patch consist of macrophages, dendritic cells, and T cells of several subsets [including CD4<sup>+</sup> helper (Th), CD8<sup>+</sup> suppressor (T<sub>S</sub>), and contrasuppressor (T<sub>CS</sub>)], as well as B cells. The influence of T cells and various lymphokines, as described subsequently, may be involved in determining isotype specificity. In some cases, T<sub>S</sub> cells of CD8<sup>+</sup> phenotype leave the patches to seed peripheral tissues, and are probably responsible for oral tolerance (Tomasi, 1980). After antigen presentation, by mechanisms that are not clear (but probably involve macrophages, dendritic cells, and possibly B cells), B cells become committed to antigen specificity. These cells also are predestined to a migratory journey to mucosal membranes to become IgA plasma cells. This precommitment to IgA and the migration to the lamina propria was described first by Craig and Cebra (1971). We now know that both T and B cells have homing properties and that specific receptors for homing are present at mucosal sites. From the studies of Butcher *et al.* (1980), the high endothelial venule (HEV) appears to be a site at which tissue specific receptors reside; monoclonal antibodies that block *in vitro* attachment of lymphocytes to mucosal tissues such as Peyer's patches (but not peripheral lymphoid tissues) have been described. Similarly, other monoclonal antibodies block the binding of lymphocytes to HEV in peripheral lymph nodes, but not in Peyer's patches. Interestingly, the monoclonal antibodies directed against Peyer's patch HEVs are able to inhibit homing to the lamina propria, suggesting common antigenic determinants in the Peyer's patch and lamina propria HEVs. On the lymphocyte surface, homing may involve receptors for mannose 6-phosphate and/or other sugars. In addition to the homing of Peyer's patch cells to the gut lamina propria, evidence exists for more extensive migratory patterns to and between other sites that collectively, as described by Bienenstock *et al.* (1979), are called the mucosal-associated lymphoid tissues (MALT). Central aggregates that resemble Peyer's patches have been described in the lung and elsewhere (tonsils, appendix); cells from these sites migrate to a variety of mucosal tissues and, with cells derived from Peyer's patches, give rise to the IgA in the secretions of the mammary gland, respiratory tract, gastrointestinal (GI) tract, and salivary, lacrimal, and cervical-vaginal fluids. This common mucosal system has biological and medical implications. For example,

in animal models, immunization via the gut against caries-producing *Streptococcus mutans* has been shown to inhibit caries. Moreover, the important studies by Mestecky *et al.* (1978) have shown that oral immunization with killed *Streptococcus mutans* in capsules can produce significant titers of antibodies in the saliva of normal humans. This procedure could be a mechanism of vaccination in several areas, for example, generating antibodies in tears against trachoma or in vaginal secretions against organisms involved in venereal diseases, including HIV. The classical studies of Ogra and Karzon (1969) showed the importance of oral immunization in protection of mucosal surfaces of the GI tract. These studies form the basis for the concept that the content of local antibodies, particularly of the IgA class, is the first line of defense of mucosal surfaces against colonization of these surfaces by potentially pathogenic microorganisms.

## II. MUCOSAL LYMPHOID CELLS

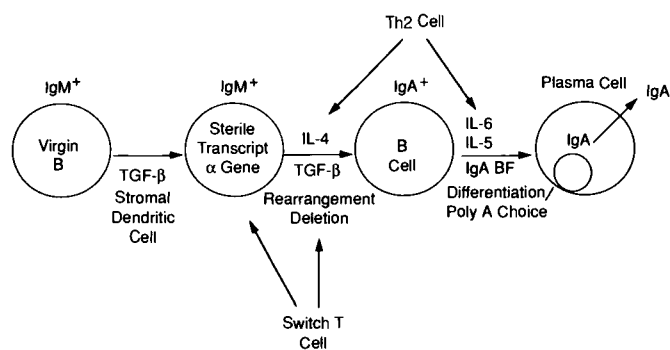

The mucosal immune system comprises three basic kinds of lymphoid tissue that are compartmentalized and, to a large degree, functionally distinct. Central or organized lymphoid tissues constitute the Peyer's patches and related aggregates in the other organs mentioned earlier. The second type of tissue is located diffusely in the various lamina propria of the mucosal system; after receiving B cells from the centralized aggregates which are already precommitted to IgA, they undergo further differentiation and give rise to IgA plasma cells. The third type of lymphoid mucosal tissue consists of cells that lie between the epithelial cells of the various membranes, the so called intraepithelial lymphocytes (IEL). This functionally heterogeneous population contains cells with anti-tumor activity, natural killer (NK) activity, allospecific cytotoxic T lymphocytes (CTL), precursors of CTL, and mast cells. Almost all IEL are granulated (contain sulfated proteoglycans) and about 85% are CD8<sup>+</sup>. Approximately half of the CD8<sup>+</sup> cells are of thymic origin and migrate to Peyer's patches; after antigen exposure, they seed the lamina propria of the gut (Guy-Grand *et al.*, 1991). These cells also bear TCR  $\alpha\beta$ 1 and CD3<sup>+</sup> and their CD8<sup>+</sup> molecules have two chains:  $\alpha$  (Lyt2) and  $\beta$  (Lyt3). A small percentage (~10%) of thymus-dependent CD4<sup>+</sup> cells are also present. The thymus-independent cells arise in the bone marrow and migrate directly to the gut. The high incidence of TCR  $\gamma\delta$  cells in IEL, their restricted specificity (selective use of V <sub>$\gamma$</sub> 7 and a few other  $\gamma$ -gene segments), and their presence in athymic and germ-free mice (which lack TCR  $\alpha\beta$ ) suggest that this unique T-cell subset may be directed against antigens other than conventional bacterial enteroantigens (Bandeira *et al.*, 1990). CD8<sup>+</sup>, Thy1<sup>-</sup>, CD5<sup>-</sup> cells also have been found to be present in IEL of SCID/SCID mice (Croitoru *et al.*, 1990), which lack TCR. Therefore these T cells may arise by a different pathway or may be a unique lineage of cells. Interestingly, intestinal epithelial cells have Class I antigens encoded by TL region genes that are found uniquely in the gut (Wu *et al.*, 1991), suggesting the possibility that the TL region has evolved to generate antigen-presenting cells as a subset of

IEL TCR  $\gamma/\delta$  cells. One hypothesis is that the  $\gamma/\delta$  cells are directed against self-antigens (Guy-Grand *et al.*, 1991; Taguchi *et al.*, 1991), perhaps eliminating altered enterocytes, thereby maintaining the defense function of the epithelia.

### A. Regulation of the Immune Mucosal Response

That T cells are required for an IgA response is well established; in fact, IgA is one of the most T-cell dependent of all the isotypes. T cells may operate in a nonspecific fashion. Immunoglobulin class is determined by the number of mitoses and the distance of the particular gene from the 3' end of the  $C_H$  gene complex. Since the  $\alpha$ -gene chain is located on the most 3' end of the  $C_H$  gene complex, multiple repeated switches may occur with constant exposure to environmental antigens, as first suggested by Cebra *et al.* (1983), and could be a mechanism of the predominance of IgA in the gut. In this respect, most of the IgA antibodies in mucosal fluids are directed toward environmental substances including microbial and nonviable food antigens. The role of IgA antibodies with respect to nonviable food antigens has been shown clearly by Cunningham-Rundles *et al.* (1978) in IgA-deficient patients, who absorb large amounts of food antigens, leading to the production of immune complexes and the resulting autoimmune-like syndromes manifested by these patients.

T cells also may operate in an isotype-specific fashion. Evidence exists for several isotype-specific T cells and T-cell factors. Some of the postulated relationships are shown in Figure 2. T cells are involved in the sequence of switching from an antigen-committed virgin IgM-bearing B cell (with or without IgD) to an IgA B cell with subsequent differentiation to an IgA-producing plasma cell. Switch T cells have been described in Peyer's patches by Kawanishi *et al.* (1983). Other cells bearing  $Fc\alpha$ -receptors ( $Fc\alpha R$ ) are capable of causing IgA-bearing cells to differentiate into plasma cells. These cells produce lymphokines as well as soluble IgA binding factors (IgA-BF) that specifically suppress or enhance the immune response of IgA. Similar factors have been identified in the IgE system by Huff and Ishizaka (1984). In the IgE

**Figure 2** Production of IgA plasma cell via T cells. Postulated T switch cell may be involved in the transition of an IgM-bearing B cell to an IgA B cell. IL-4 and TGF- $\beta$  may be switch factors. The differentiation from an IgA B cell to a plasma cell probably involves IL-5, IL-6, and perhaps IgA-BF.

system, whether the IgE-BF is suppressive or potentiating depends on the degree of glycosylation. Glycosylation in the IgE system is, in turn, dependent on factors secreted by T cells that are either glycosylation inhibiting factors (GIF) or glycosylation enhancing factors (GEF). These factors are produced by two different T-cell subsets. Thus, a complex mechanism in the IgE system determines whether the factors that bind IgE suppress or enhance. Whether such GIF and GEF molecules exist for IgA has not been determined.

The up-regulation of  $Fc\alpha R$  in the presence of IgA may represent a feedback mechanism, since isotype-specific suppressor cells appear in conditions such as IgA myeloma, which shows a high concentration of IgA. These cells inhibit transcription of the heavy chain mRNA of IgA as well as growth of the IgA myeloma cell. A monoclonal antibody to the  $Fc\alpha R$  that blocks binding of IgA to T cells has been described; this antibody could be helpful in eventually cloning the T-cell  $Fc\alpha R$ . Expression cloning of the Fc receptor for IgA on myeloid cells has been reported, but this receptor appears to be myeloid specific; a monoclonal antibody (My43) to it lacks reactivity with lymphocytes (Maliszewski *et al.*, 1990). In our laboratory, Crago *et al.* (1989) have shown that the  $Fc\alpha R$  on T cells may be related to secretory component. We have found that antisera to SC, but not to other cell surface antigens, inhibit IgA binding to its receptor on murine T cells and T-T hybridomas. Thus, SC and  $Fc\alpha R$  are present on different cells, but both bind the Fc region of IgA, suggesting a common evolutionary origin at least in the IgA binding site.

Evidence also suggests that interleukin 4 (IL-4; produced by Th2 cells) probably is involved at an early step and may itself be a switch factor or a factor that enhances switching by a switch T cell. This hypothesis is not unreasonable since IL-4 is known to be a switch factor for IgG1 and IgE (Snapper and Paul, 1987). The work of Berton and Vitetta (1990) has shown that IL-4 alone induces a DNase I hypersensitivity site at the 5' end of the  $\gamma 1$  switch region of resting B cells, as well as germ-line transcripts of the  $\gamma 1$  gene. Thus, IL-4, probably via induction of DNA binding proteins, may enhance transcription by making the switch region more accessible to RNA polymerase and switch recombinases. The work of Strober (1990) on the CH12.LX cell line and by Shockett and Stavnezer (1991) on I.29 $\mu$  suggests that the first step may involve selective isotype (or region)-specific accessibility of transcription factors to switch sites. Antigen (or mitogen) stimulation, in addition to specific factors such as transforming growth factor  $\beta$  (TGF $\beta$ ) and IL-4, may be important in selecting the isotype switch region near which chromatin is relaxed. Other factors, perhaps derived from dendritic cells or stromal cells, also may be central to switching. Their action even may precede the lymphokine effects. Thus, the virgin IgM cell first may become unstable and show transcription of germ-line (unrearranged)  $C_H$  regions. This cell is, in a sense, poised for the isotype switch to be accomplished by recombinant enzymes that loop out the intervening sequences. Precisely how the germ-line "sterile" transcript seen in these cells and the associated deletional events occur in relation to cytokines such as TGF $\beta$ , IL-4, and "switch T cells" is unclear.

Experiments by Coffman *et al.* (1987) also have shown that IL-5, a lymphokine produced by the Th2 subset, enhances the production of IgA. IL-5 appears to act at the IgA<sup>+</sup> B cell and promotes both proliferation and differentiation to plasma cells. Whether IL-5 induces an IgA-BF factor and functions through this mechanism is unclear. The combination of IL-4 and IL-5 enhances the secretion of IgA from Peyer's patch B cells (Murray *et al.*, 1987).

IL-6, an autocrine growth factor for plasma cells, also is involved in IgA formation. IL-6 is produced by plasma cells, T cells, and possibly other cells. One would suspect from current data that Th2 cells (producing IL-4, 5, 6) might be more prominent in the mucosal system, which appears to be the case (Taguchi *et al.*, 1990).

Th1 cells also may play an important role in modulating the immune response at mucosal sites. The IL-2 and interferon gamma (IFN<sub>γ</sub>) produced by Th1 may have important regulatory roles. IL-2 receptors are present on B cells and, in fact, IL-5 up-regulates these receptors and may potentiate the secretion of IgA as well as other immunoglobulins. IFN<sub>γ</sub> has been shown to down-regulate certain immunoglobulin classes (Snapper and Paul, 1987), but whether this down-regulation occurs with IgA has not been established. IFN<sub>γ</sub> also may affect mucosal epithelial by inducing Ia antigens. The work of Mayer and Shlien (1987) suggests that Ia<sup>+</sup> epithelial cells may present antigen; interestingly, the result is primarily a CD8<sup>+</sup> cell, whereas monocyte presentation produces predominantly CD4<sup>+</sup> helper cells. Thus, the predominance of interepithelial CD8<sup>+</sup> cells could be explained by this mechanism. Inflammatory cells produce large amounts of IFN<sub>γ</sub>; increased CD8<sup>+</sup> cells frequently are seen in diseased tissues. Also interesting, as shown by Sollid *et al.* (1987), is that IFN<sub>γ</sub> and tumor necrosis factor up-regulate the synthesis of SC by epithelial cells, which may facilitate the transport of IgA into secretions. Obviously, the interrelationship between lymphokines are very complex and represent an exciting area for future studies.

## B. Molecular Mechanisms of IgA Formation

The switch and differentiation schemes outlined in preceding sections are accompanied by complex intracellular molecular events. For example, switching may involve the formation of a hypothetical intermediate B cell that contains a long primary transcript, as suggested by the work of Perlmutter *et al.* (1984) as well as by work from our laboratory (Woloschak *et al.*, 1986). Such cells would process a primary transcript of about 200 kb in length differentially into messages for IgM and IgA and produce the double-bearing IgM-IgA cells. Solid evidence suggests that the single-bearing IgA<sup>+</sup> B cell and IgA plasma cell have switched by a mechanism involving deletion and rearrangements. As mentioned earlier, cells and factors that induce IgA may affect chromatin structure and methylation, thereby allowing access of critical switch recombinases to the C<sub>H</sub>α gene.

With respect to the differentiation of the mIgA<sup>+</sup> cell to a plasma cell, the molecular events involve the differential RNA processing of the message to that for the secreted form

of the protein. This processing could be accomplished by several mechanisms: (1) termination, (2) splice site choice, and (3) choice of poly A addition sites. Some evidence exists for each of these mechanisms, although most data suggest that cleavage and polyadenylation are the most likely mechanisms, followed by appropriate splicing. Perhaps the cytokines involved in differentiation for example, IL-5 and IL-6, determine the concentration of factors (such as the endonucleases), as suggested by Galli *et al.* (1988), that regulate the site of cleavage and poly A addition.

# Structure and Function of Intestinal Mucosal Epithelium

Tomohiro Kato • Robert L. Owen

## I. INTRODUCTION

The mucosal epithelial layer forms the interface between the external and the internal environments in the gastrointestinal tract. This area is the site for digestion and absorption of various essential nutrients, yet it also must function as a barrier against various harmful agents and infectious pathogens. Protecting against such agents are many nonimmunological factors including gastric acid, pancreatic juice, bile, motility, mucus, glycocalyx, and cell turnover. In addition to these physiological barriers, an immunological barrier is created and maintained by the immune defense system, which includes the gut-associated lymphoid tissue (GALT)—immunoreactive cells distributed throughout the intestinal tract—and the systemic immune system. Much has been learned about GALT, but many questions about its structure and function remain unanswered. The mucosal epithelium in GALT, which functions as the leading edge of the immunological barrier, differs in many ways from the absorptive epithelium elsewhere in the intestinal tract (Figure 1). This chapter first describes the absorptive mucosa and then the GALT mucosa.

## II. INTESTINAL ABSORPTIVE EPITHELIUM

The total mucosal surface in the adult human gastrointestinal tract extends to 200–300 m<sup>2</sup>, the largest area of the body in contact with the external environment. This mucosal surface is covered with a one-cell-thick layer, the mucosal epithelium, that is composed of columnar absorptive cells, goblet cells, undifferentiated crypt epithelial cells, Paneth cells, enteroendocrine cells, tuft cells, cup cells, and intraepithelial lymphocytes. Although not part of the epithelium, mucus on the surface of the mucosa shields the mucosal epithelial cells from direct contact with the intestinal luminal environment. Beneath the mucosal epithelium is the connective and supportive tissue called the lamina propria. In this tissue are various immunocompetent cells including dendritic cells, macrophages, and lymphocytes, which form a functional unit with the mucosal epithelial cells.

## A. Structure of the Absorptive Epithelium

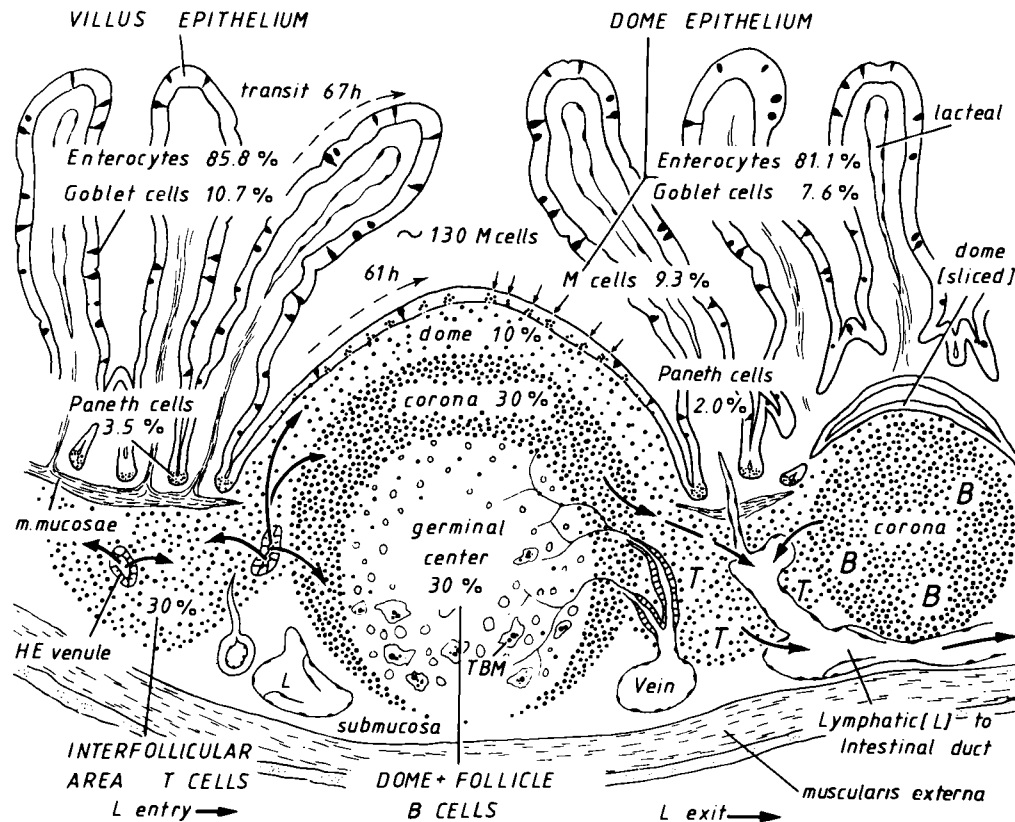

### 1. Mucosal Epithelial Cells

Absorptive epithelial cells (enterocytes)—which are about 25  $\mu\text{m}$  in height, 8  $\mu\text{m}$  in width, and columnar in shape—constitute the majority of the mucosal epithelium. Their surface has numerous tightly packed microvilli that are covered with glycocalyx and a thick mucus layer. The regular longitudinal cores of microvilli are interconnected by a terminal web that is composed of bundles of 20–30 interlacing actin filaments. At their apices, the enterocytes are connected with adjacent epithelial cells mainly by junctional complexes consisting of three major components: tight junctions (zonula occludens), adhesion junctions (zonula adherens), and desmosomes (macula adherens). In addition to the junctional complexes, the lateral membranes interact by means of cell adhesion molecules (CAM), gap junctions, and interdigitations (Boyer and Thiery, 1989). The tight junction, which completely encircles the apical end of absorptive cells as a belt-like band, plays a role in separating the external and internal environments, and functions as a selective barrier. The adhesion junction, located in the apical region of absorptive cells just below the tight junction, is connected to actin filaments in the cytoplasm, and is thought to anchor each cell to adjacent cells. The desmosome functions like the adhesion junction, connected to intermediate filaments in the cytoplasm. Gap junctions, which are located in the basolateral membrane in other epithelial cells and directly mediate cell-to-cell communication, also have been identified provisionally in intestinal absorptive cells (Suzuki *et al.*, 1977; Kataoka *et al.*, 1989).

The glycocalyx, which is the surface layer just above the luminal membrane of the absorptive cell, contains various enzymes and nonenzymatic proteins including disaccharidases, peptidases, receptors, and transport proteins, all of which are necessary for digestion and absorption of nutrients. The major component of the glycocalyx is carbohydrate anchored into the surface of microvilli.

The smooth endoplasmic reticulum and mitochondria are more abundant in the apical than in the basal cytoplasm. The nucleus normally is located in the basal cytoplasm below the rough endoplasmic reticulum, so enterocytes maintain a characteristic polarity. The basolateral membrane, which

**Figure 1** Diagram of an ileal Peyer's patch in the mouse. Peyer's patch lymphoid nodules are composed of three major parts: follicular area (germinal center, corona, and dome), interfollicular (parafollicular) area beneath villi, and dome epithelium. The right follicle beneath villi is sliced tangentially, through the lower slopes of the dome and the lymphocyte corona only. Curved arrows on the left show the influx of lymphocytes across postcapillary high endothelial venules (HEV), which mediate selective immigration of lymphocytes. Arrows on the right show the exit pathway of stimulated lymphocytes into submucosal lymphatics. M cells are difficult to distinguish by light microscopy, and are inferred from the location of groups of lymphoid cells (small arrows) in the follicle epithelium. Migration rates (h) and cell distribution numbers in this figure are from Smith and Peacock (1980) and Abe and Ito (1977). T, T lymphocyte; B, B lymphocyte; TBM, tingible body macrophage; m, muscularis. Diagram courtesy of E. Hamish Batten.

begins below the junctional complex, contains abundant  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase and adenylate cyclase and differs from the apical membrane in function. Interlocking folds are produced by adjacent cells, interdigitating their lateral membranes, which are separated by a 30-nm-wide intercellular space.

The basal membrane also is separated by a 30-nm space from the basal lamina. Junctional structures called hemidesmosomes anchor basal membrane to basal lamina. Hemidesmosomes are thought to connect with intermediate filaments of the cytoplasm, as do desmosomes. The basal lamina has numerous round or oval pores and is composed of collagen, laminin, fibronectin, and glycosaminoglycans (Hay, 1981; Ohtsuka *et al.*, 1992). Ultrastructurally, basal lamina consists of a lamina densa 20–50 nm thick that lies between two thin electron lucent layers: the lamina rata externa below and the lamina rata interna above (Dobbins, 1990). Although the function of the basal lamina is clear, researchers believe it gives polarity to the absorptive cells and guides migration of enterocytes from their crypts of origin to their eventual desquamation sites.

Goblet cells, present in both small and large intestine, increase in number from the proximal to the distal portion of the intestine and are located on villi and in crypts. The goblet cell microvilli are irregular in shape and sparse in number but contain actin filaments. The terminal web is poorly developed in goblet cells, facilitating release of mucus granules from the apical cytoplasm. Mucus granules are synthesized above the nucleus in endoplasmic reticulum and Golgi apparatus and are supported by a goblet-shaped sheath that is composed of inner and outer layers of microtubules and intermediate filaments and keeps its shape before and after release of granules (Specian and Neutra, 1984). Mucus granules are released in response to acetylcholine stimulation, but regulation of release is unclear.

Undifferentiated epithelial stem cells are located in the mid-crypts and produce daughter cells that continuously migrate upward to the crypt mouth and downward to the crypt base. These cells differentiate into absorptive cells and goblet cells above and into Paneth cells and enteroendocrine cells below. The microvilli of crypt cells are shorter and more

sparse than are microvilli of mature absorptive cells. The terminal web and the junctional complex of crypt cells are undeveloped and the tight junction of these cells is structurally irregular, but its density is very high (Marcial *et al.*, 1984). In crypt cells, smooth and rough endoplasmic reticulum are sparse whereas ribosomes, mitochondria, and Golgi apparatus are relatively abundant. Small granules (0.1–1.5  $\mu\text{m}$ ), the functions of which are unknown, are released from crypt cells into the lumen in response to cholinergic stimuli. The undifferentiated crypt epithelial cells mature as they migrate to the summit of the villi, commonly in 3–5 days. From the crypt, cells migrate in a direct line toward the desquamation zone on the villus tip and, similarly, to the apex of the dome in GALT (Schmidt *et al.*, 1985). The migration rate is thought to depend on extraluminal and luminal factors: extraluminal factors consist of hormones, growth factors such as epidermal growth factor (EGF) and transforming growth factor (TGF), cytokines, and neural and vascular factors; luminal factors consist of nutrition, motility, and microflora (Levine, 1991). The crypt is recognized to be a major site of secretion of water and minerals into the lumen (Madara and Trier, 1987).

Paneth cells commonly are located in the crypts of the small intestine, but occasionally appear in the stomach and large intestine in some disease states. Their characteristic features are their pyramidal shape and, in the apical cytoplasm, various secretory granules that contain proteins including lysozyme, tumor necrosis factor (TNF) (Keshav *et al.*, 1990), and cryptdin (Ouellette *et al.*, 1989). These secretory granules are thought to prevent proliferation of crypt microorganisms by their strong antimicrobial action. Paneth cells also contain IgA and IgG, possibly from phagocytosis of immunoglobulin-coated microorganisms (Rodning *et al.*, 1976).

Enteroendocrine cells are distributed throughout the gastrointestinal tract. The main function of these cells is to release hormones into capillaries in the connective tissue in response to changes in the external environment. These cells contain various distinctive kinds of secretory granules and are classified structurally into closed and open types. Both commonly are located in the epithelium adjacent to the lamina propria, surrounded by other mucosal epithelial cells. Open type cells have a narrow apical surface in direct contact with the lumen, and are presumed to react to stimuli from the tissue environment and from the lumen. Closed type cells have no contact with the luminal environment (Dobbins, 1990).

Tuft cells, also called caveolated cells or fibrovesicular cells, have been discovered in the stomach, intestine, and colon of humans, dogs, mice, and rats (Nabeyama and Leblond, 1974; Owen, 1977; Blom and Helander, 1981). These cells are attached to surrounding absorptive cells by regular junctional complexes. On the surface, they have very long microvilli with filaments that are  $\sim 5 \mu\text{m}$  in length, sometimes reaching deep into the cytoplasm. Tuft cells have many caveolae or pits between the bases of microvilli that extend down to the level of the nucleus. The function of these pits is not known, but they are suspected to act as chemical sensors for the luminal milieu.

Cup cells were discovered by Madara (1982) in guinea pig,

rabbit, and monkey intestine but have not yet been reported in humans. These cells stain more lightly than adjacent absorptive cells with toluidine blue stain, have abundant intermediate filaments, and have lower alkaline phosphatase activity on their surfaces than adjacent absorptive cells. Cup cells have shorter microvilli with a cuplike concavity, small mitochondria, and few vesicular bodies. The function of these cells is unknown.

Intraepithelial lymphocytes (IELs) have special characteristics that are distinct from those of other lymphocytes. The average number of IELs per 100 absorptive cells is 20 in normal adult human jejunum and decreases distally in the gut (Dobbins, 1986). These cells are located above the basal lamina in the epithelial layer and are separated from adjacent enterocytes by a 10- to 20-nm space. These lymphocyte–epithelial cell contacts have no junctional structure. Histochemically, almost all IELs are recognized to be CD3<sup>+</sup> (pan T cell). Among these cells, 5–15% express CD4 (helper/inducer phenotype) and the remaining cells express CD8 (cytotoxic/suppressor phenotype). These distributions contrast with other areas such as peripheral blood and lamina propria, where the CD4<sup>+</sup> phenotype is overwhelmingly predominant. Although the T-cell receptors that mediate antigen recognition are composed predominantly of  $\alpha\beta$  chains on lymphocytes, in the intestinal epithelium the proportion of  $\gamma\delta$ -positive lymphocytes is much larger than in the peripheral blood and lamina propria (Jarry *et al.*, 1990). Thus,  $\gamma\delta$ -positive lymphocytes are thought to have a special role in the intestine. The microenvironment within the intestinal epithelium may influence the differentiation of IELs (Guy-Grand *et al.*, 1991). Although the functions of IELs are unclear, some possibilities are cytotoxicity, lymphokine secretion, regulation of renewal of mucosal epithelium, and tolerance (Cerf-Bensussan and Guy-Grand, 1991; see Chapter 24).

## 2. Mucus Layer and Glycocalyx

Mucus is composed of 1% mucin, 1% free protein, 1% dialyzable salts, and >95% water. Mucus contains albumin, immunoglobulin (mainly secretory IgA),  $\alpha 1$ -antitrypsin, lysozyme, lactoferrin, and EGF. In the mucus, the characteristic highly viscous and elastic substance is mucin, which is produced mainly in goblet cells as heavily glycosylated glycoprotein (Rhodes, 1990). Mucus is not digested because of its resistance to various enzymes, and is thought to protect epithelial cells from digestion by enzymes produced by intestinal flora and by pancreatic and biliary juice. The release of mucus from goblet cells is stimulated by neurogenic factors and by alterations in environmental factors, including bacterial infection, parasitic infestation, and the resident intestinal flora. Mucus secretion from goblet cells is triggered by two mechanisms: direct stimulation by immune complexes and chemical agents and indirect stimulation by mediators released by histamine and lymphokines (Snyder and Walker, 1987). Mucus can protect epithelium against the adherence of such organisms as *Entamoeba histolytica*, *Yersinia enterocolitica*, and enteropathogenic *Escherichia coli* by trapping microorganisms and by covering binding sites with mucin and with secretory IgA (Magnusson and Stjernström, 1982;

Chadee *et al.*, 1987; Mantle *et al.*, 1989; Sajjan and Forstner, 1990). Mucin also inhibits the epithelial attachment of such parasites as *Nippostrongylus brasiliensis* and *Trichinella spiralis* (Miller, 1987), whereas other components in mucus, including lysozyme, secretory IgA, and lactoferrin, have antibacterial activity (see Chapters 4 and 11). The glycocalyx on microvilli forms a zone for digestion and absorption. The mucus layer and rapid turnover of absorptive cells are useful for the protection and regeneration of glycocalyx, because some bacteria can digest important proteins in it by direct contact (Jonas *et al.*, 1978; see Chapter 4).

### 3. Resident Microflora

The resident microflora is composed of at least 400 species of bacteria of which major components are streptococci, lactobacilli, *Bacteroides*, and enterobacteria. The upper intestinal bacterial count is low in number ( $<10^5$  cfu/ml) and increases distally (terminal ileum,  $10^6$ /ml; colon,  $10^{11}$ /ml). Intestinal bacterial numbers are regulated by the flow rate of luminal contents (intestinal motility) and by mucus and the antibacterial effects of gastric, pancreatic, and biliary juice. Some of the bacteria produce enzymes that degrade mucin, which is thought to be one of their mechanisms of survival (Rhodes, 1989). Resident microflora are known to coexist within the intestinal tract and maintain a stable environment by precluding attachment of enteropathogens (see Chapter 6). The flora can eliminate foreign pathogens by producing antimicrobial substances (colicins, short chain fatty acids; Iglewski and Gerhardt, 1978; Byrne and Dankert, 1979) and by stimulating the growth of mucosal epithelium (Thompson and Trexler, 1971). Interestingly, bacteria such as *Lactobacillus*, *Bacteroides*, and *Clostridium* have been reported also to exist within the intestinal mucosa. Ultrastructurally, these organisms adhere firmly to the mucus layer in crypts of the distal small intestine (Savage, 1970).

## B. Absorptive Cell Function

### 1. Uptake and Transport of Nutrients, Minerals, Water, and Nonnutrient Materials

Digestion and absorption of nutrients is the primary function of the gastrointestinal tract. Mucosal absorptive cells have digestive and absorptive functions. The apical surface of absorptive cells consists of the glycocalyx and plasma membrane, which contains various enzymes and carriers for digestion and absorption. Sodium is important for the absorption of nutrients and other minerals because its electrical gradient regulates their movement into absorptive cells. The gradient of  $\text{Na}^+$  is regulated mainly by secretion and absorption by  $\text{Na}^+, \text{K}^+$ -ATPase on basolateral membranes;  $\text{Na}^+$  goes in and out with other minerals and nutrients through the brush border membrane. Water and ions are thought to pass through tight junctions (paracellular pathway) in addition to the route across epithelial cells (transcellular pathway).

Pathogens and other harmful agents including bacteria, viruses, parasites, and allergenic macromolecules are mixed

with nutrient materials in the intestine. Despite protective mechanisms, these harmful agents can cross the mucosal barrier via three major routes: the transcellular route, the paracellular route across cell-to-cell junctions including tight junctions, and via M cells, which are specially differentiated epithelial cells in Peyer's patches (see subsequent discussion). Uptake mechanisms are separated into receptor-mediated and non-receptor-mediated pathways. The route of uptake of nonnutrients previously was believed to be only paracellular. However, the transcellular route through absorptive cells has been recognized to play a role in initiating mucosal and systemic infection and, possibly, in antigen presentation, since absorptive cells are the first point of contact for many luminal constituents.

For absorptive cells to function as antigen-presenting cells (APCs), uptake, endosomal degradation, processing, and presentation of antigen to immunocompetent cells (such as T cells and macrophages) restricted by major histocompatibility complex (MHC) Class II proteins would be required. This process of delivery of coherent and recognizable antigenic information also requires cytokines and, possibly, control by hormones and the nervous system. APCs must express MHC Class II proteins on their surfaces to initiate the process of presentation. Normal absorptive cells in humans and rats do, in fact, express MHC Class II proteins on their apical surfaces (Hirata *et al.*, 1986; Mayer *et al.*, 1991; see Chapter 15).  $\text{CD8}^+$  IELs are reported to secrete interferon  $\gamma$  (IFN $\gamma$ ; Cerf-Bensussan *et al.*, 1984), which can stimulate absorptive cells further to express MHC Class II proteins (Hirayama *et al.*, 1987) and protect them against infection by viruses. Further, absorptive cells are reported to produce and secrete an interleukin 1 (IL-1)-like substance, which is an activator of T cells, in response to luminal antigens such as lipopolysaccharide (LPS; Santos *et al.*, 1990). These observations suggest that normal absorptive cells may function as APCs, at least under special circumstances, and that the transcellular route may play a role in immune surveillance.

### 2. Barrier to Entrance of Microorganisms, Particles, and Macromolecules

In the intestinal lumen, pancreatic and biliary juice, mucus, glycocalyx, intestinal motility, and resident microflora interact to limit colonization by enteropathogens. Pancreatic and biliary juices, along with secretory IgA and lysozyme, have antibacterial activities in some species (Williams *et al.*, 1975; Rubinstein *et al.*, 1985; Bassi *et al.*, 1991). Even if pathogens begin to invade the epithelium, the process may be restricted by local mechanisms and terminated as tiny lesions. Protection is provided by the epithelial cell and by the environment surrounding epithelial cells. Turnover of crypt cells increases the rate of epithelial renewal in response to the invasion of harmful pathogens that damage surface cells. Lesions will be washed by mucus and other secretions in conjunction with intestinal motility, and will be repaired by cell migration. Evidence suggests that IELs can kill virus-infected target cells and bacteria in experimental animals (London *et al.*, 1989; Tagliabue *et al.*, 1984), but no information about such a role for IELs in humans is available (see Chapter 24).

Chemical messengers including neuropeptides, gastrointestinal hormones, and lymphokines affect barrier factors. Substance P, somatostatin, and cholecystokinin (CCK) influence the production of mucin and IgA (Stanisz *et al.*, 1986; Freier *et al.*, 1987); IFN $\gamma$  modulates the barrier function of absorptive cells (Madara and Stafford, 1989). Although the roles of these mediators are not elucidated completely, they are thought to contribute to the multifactorial network of nonimmunological mucosal defense mechanisms described earlier and to immunological mechanisms described in subsequent chapters (see Chapters 17, 20, 27).

### III. MUCOSAL EPITHELIUM IN GUT ASSOCIATED LYMPHOID TISSUE

GALT is a general term for lymphoid tissues distributed in intestine, including aggregated lymphoid nodules in Peyer's patches, the appendix vermiformis (Uchida, 1988), colonic patches (Owen *et al.*, 1991), and solitary lymphoid nodules. In its entirety, GALT is one of the largest lymphoid organs in the body.

The typical GALT structures can be observed most easily in Peyer's patches. Peyer's patches are groups of lymphoid follicles in the small intestinal mucosa (Figures 1 and 2). Although their numbers and distribution differ among individuals and in different species, some features are characteristic:

Peyer's patches are located along the antimesenteric side of the small intestine and are most prominent in the terminal ileum, and the number and size of Peyer's patch follicles decrease with age.

#### A. Structure of the Follicle Epithelium

Morphologically, Peyer's patch nodules are separated into three major domains: the follicular area, the parafollicular area, and the follicle-associated epithelium (FAE). Histologically, intestinal lymphoid nodules differ from lymph nodes because they have no capsule, no medulla, no afferent lymphatic ducts, and no clear border. The FAE is a one-cell-thick lining layer that forms the interface between the intestinal lymphoid apparatus and the intestinal luminal environment, and is generated within the crypts that supply enterocytes to villi adjacent to lymphoid nodules. FAE is composed mainly of specially differentiated M cells, columnar epithelial cells, IELs, infrequent mucus-secreting goblet cells, and occasional tuft cells. GALT is described further in Chapter 35.

#### 1. M Cells

By dissecting microscopy, small protruding domes can be distinguished among the villi in Peyer's patches. By scanning electron microscopy (SEM), M cells are found scattered over the dome, surrounded by absorptive cells (Figure 3).

**Figure 2** Scanning electron micrograph of a dome-shaped lymphoid nodule surrounded by numerous finger-shaped villi in human Peyer's patch. Note that surfaces of villi are covered with whitish-colored mucus drops that are absent over the surfaces of the lymphoid nodule. Reprinted with permission from Owen and Jones (1974). Epithelial cell specialization within human Peyer's patches: An ultrastructural study of intestinal lymphoid follicles. *Gastroenterology* 66, 189–203. The Williams and Wilkins Company, Baltimore.

**Figure 3** Scanning electron micrograph of the surface of a human Peyer's patch lymphoid nodule. The M cell in the center is surrounded by polygonal absorptive cells that possess numerous tall, closely packed, regular microvilli on their apices. Note the irregular and short microfolds of the M cell.

Since Schmedtje described M cells (which he termed lymphoepithelial cells) covering dome-shaped lymphoid follicles in the rabbit appendix (Schmedtje, 1965, 1966), similar cells have been discovered in many organs and species. Such cells were identified by Owen and Jones (1974) in human small intestine and termed M cells. M cells also have been found in nonintestinal lymphoid aggregates, including tonsil (Owen and Nemanic, 1978) and bronchi (Bienenstock and Befus, 1984; see Chapter 12; Chapters 43 and 50). M cells occupy ~50% of FAE surface area in rabbit and 10% of intestinal lymphoid follicle surface area in human and mouse.

M cells play an important role in antigen sampling, taking up particles from the intestinal lumen and transporting them to lymphocytes and macrophages enfolded in pockets in the basolateral surfaces of M cells (Trier, 1991). Figure 4 shows M cells typical of the lymphoid follicles in human ileum.

M cells have shared and unique structural features in comparison with other mucosal epithelial cells in the intestine (Figure 5). M cells have tight junctions and desmosomes in contact with adjacent columnar epithelial cells and interdigitating lateral membranes (Figure 6). The processes on their luminal surfaces are spaced more widely and often are shorter and more irregular in shape than the microvilli of absorptive cells; these processes consist of "microfolds" in humans (hence, the name "M" cell; Figure 3). Sometimes longer microfolds reach out to surround microorganisms in the intes-

tinal lumen. M cells in other species were found to have specialized microvilli rather than microfolds. Consequently, the term M cell now denotes "membranous" or "membrane-like," reflecting the role of M cells in separating the luminal and intercellular domains yet facilitating movement from one to the other. Ultrastructurally, microfolds in human M cells and comparable M-cell microvilli in other species have fewer microfilaments such as actin and a less highly developed apical terminal web than do adjacent absorptive cells. The apical cytoplasm of M cells has closely packed mitochondria and numerous rounded, tubular, or oval microvesicles but few lysosomes (Owen *et al.*, 1988a; Figure 7).

The M cell typically has an extracellular space, called the central hollow or pocket, that invaginates its basolateral membrane and surrounds enfolded lymphoid cells (Figure 8). Within these pockets lie one or more lymphocytes, macrophages, plasma cells, or, rarely, polymorphonuclear leukocytes. Often the apical portion of the M cell is compressed into a thin membrane-like band of cytoplasm by the lymphocyte-filled pocket, which also displaces the nucleus of the M cell basally. Golgi apparatus and endoplasmic reticulum are located just above the nucleus in M cells (Figure 4). The well-developed microvesicular system, sparse lysosomes, and enfolded lymphocytes are morphological correlates of the transport function of M cells (see subsequent discussion). No connective junctions are ultrastructurally demonstrable

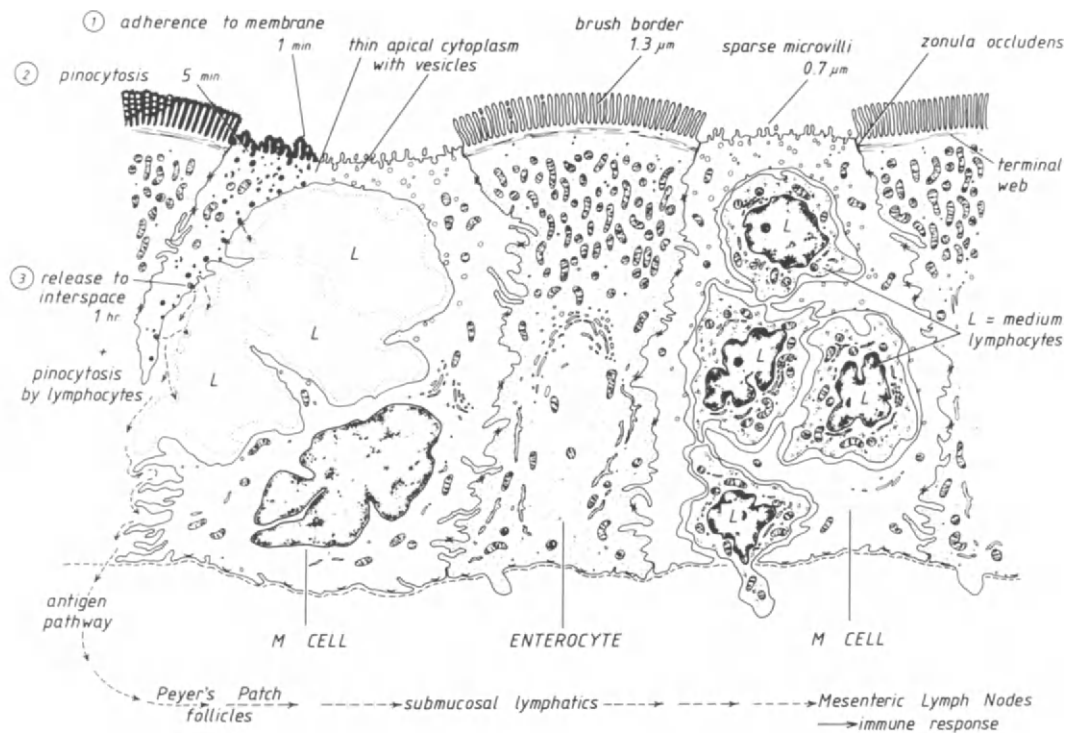

**Figure 4** Transmission electron micrograph of human Peyer's patch follicle epithelium. M cells (M) are shorter than enterocytes (E), which are covered by tightly packed microvilli. The M cells on the right enfold lymphocytes (L) in their pockets, whereas the M cell on the left contains no lymphocyte.

between M cells and enfolded cells, but adhesion molecules, cytokines, and complementary cytoskeletal structures form a complex relationship. Enfolded cells intrude into the M cell from its basal or lateral surface, presumably in response to homing signals, and come in contact with surveillance information in the form of macromolecules, particles, and microorganisms transported from the intestinal lumen by M cells. This lymphoid cell traffic in and out of M cell pockets is facilitated by the numerous holes that can be observed in the basal lamina after removal of mucosal epithelium.

M cells in rabbits have been found to express an unusual pattern of intermediate filaments in their cytoplasm, that is, predominantly vimentin (Gaidar, 1989) with lesser amounts

of cytokeratin (Jepson *et al.*, 1992), compared with other epithelial cells, in which vimentin is absent. This M-cell expression of intermediate filaments that is more typical of cells of mesenchymal origin than of epithelial cells may reflect the phagocytic activity, and accommodation in shape to enfolded cells, in which M cells resemble macrophages.

The layer of glycocalyx and mucus on M cells is quite sparse, compared with that on adjacent columnar cells. Consequently, the microvilli on the surface of M cells can be observed easily by SEM (Figure 3). The surface of M-cell microvilli has more esterase activity and much less alkaline phosphatase activity than the surface of microvilli of adjacent absorptive cells (Owen and Bhalla, 1983). The functional

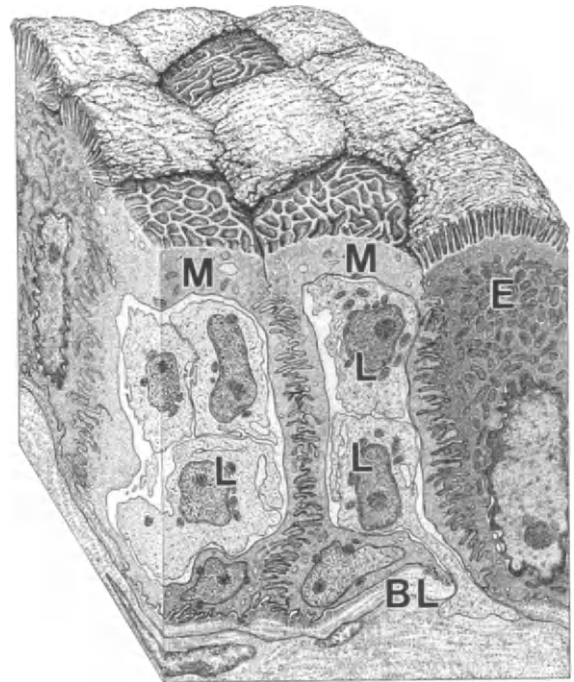

**Figure 5** A diagram of the ultrastructural arrangement of enterocytes (stippled), M cells, and intraepithelial lymphocytes in follicle epithelium of Peyer's patch. On the right, four lymphocytes (L) are enfolded in the central hollow of an M cell. On the left, note the thin apical cytoplasm of the M cell, its lateral interdigitations, and three enfolded lymphocytes (L) shown only in dotted outline. Over the luminal surface, black lines show horseradish peroxidase (HRP) adhering to follicle epithelium 1 min after being injected into mouse ileum. The time sequence (1–3) shows pinocytotic transfer through the M cell into its central hollow, with some uptake by enfolded lymphoid cells (Owen, 1977). Antigens transported by M cells also pass downward through the basal lamina into the lymphoid follicles and are carried into mesenteric lymph nodes for induction of local or systemic immune responses. Diagram courtesy of E. Hamish Batten.

**Figure 7** Diagrammatic model of uptake and transport of luminal antigens by M cells (M). The M cell has only a rare lysosome, compared with numerous lysosomes (arrowhead) in adjacent enterocytes (E). When particulate antigens (asterisks) are taken up by enterocytes, they are diverted into lysosomes and digested. In M cells, antigens escape lysosomal degradation and either are taken up by lymphoid cells (L) in the central hollow or pass into the intercellular space. Reprinted with permission from Owen *et al.*, (1986a) and Wiley-Liss.

significance of this enzymatic pattern is uncertain, but has been used to advantage by Smith and colleagues (1987) in examining patterns of M-cell distribution over follicle domes. Because of their low lysosome content, M cells can transport antigens from the intestinal lumen with little enzymatic degradation (Owen *et al.*, 1986a). The surface of M cells has been found to interact with secretory IgA in uptake of intestinal particles. The surface of the M cell has binding sites for secretory IgA (Roy and Varvayanis, 1987; Weltzin *et al.*, 1989; Kato, 1990; Figure 9), but lacks secretory component (Pappo and Owen, 1988). Immunohistochemically, the human M cell expresses MHC Class II HLA-DR antigen on its apical cytoplasm and basolateral membrane, analogous to the dendritic cell and macrophage which are known to be APCs (Nagura *et al.*, 1991). This feature of M cells, in conjunction with the fact that M cells take up complexes containing secretory IgA, suggests that these cells may function as APCs and as antigen-transporting cells. In fact, M cells from rat jejunal Peyer's patches contain acidic endosomal and prelysosomal structures but few lysosome-like structures (Figure 7) and express MHC Class II determinants, indicating that they have at least some capacity to present endocytosed antigens directly to lymphocytes (Allan *et al.*, 1992).

**Figure 8** Three-dimensional illustration of M cells (M) interdigitating with adjacent enterocytes (E). In their central hollows, M cells enfold several lymphocytes (L), one of which is migrating through a pore in the basal lamina (BL). Reprinted with permission from Owen and Nemanic (1978).

Putative M cells have been recognized morphologically in human fetuses by week 17 of gestation (Moxey and Trier, 1978). Although the origin of the M cell is still controversial, two theories have been proposed. One theory is that M cells develop from mature columnar epithelial cells that overlie Peyer's patches. Another theory is that M cells develop directly from undifferentiated stem cells in crypts that lie between lymphoid domes and adjacent villi (Bhalla and Owen, 1982). This theory is supported by the observations of Bye *et al.* (1984). Morphologically immature M cells, with features shared by mature M cells and crypt cells, can be identified in all regions of the follicle dome. After intraperitoneal injection of [ $^3$ H]thymidine into mice, only crypt cells are labeled for the first 12 hr. Radiolabeled nuclei of immature M cells are first observed near crypt mouths in mice after 24 hr and mature M cells are labeled after 48 hr. M cells are now generally accepted to derive directly from undifferentiated stem cells in the crypts surrounding the dome. Where they go is less clear, however, since more M cells are present on the edges of domes than on the apices, where desquamation and death of enterocytes generally occur.

**Figure 6** Transmission electron micrograph showing the junction between a columnar enterocyte (E) and an M cell (M) in human Peyer's patch. The M cell has characteristic microfolds, absent terminal web, sparse glycocalyx, and numerous pinocytotic vesicles (arrowheads) in its apical cytoplasm compared with the adjacent enterocyte, which has thick glycocalyx, regular microvilli, and microvillus cores extending down into the terminal web (TW). The interface is composed of a tight junction (open arrowhead), several desmosomes (arrows), and lateral interdigitations.

**Figure 9** Immunoelectron micrograph of rabbit Peyer's patch follicle epithelium treated with anti-secretory IgA antibody and horseradish peroxidase-conjugated secondary antibody. Electron-dense areas of enzyme reaction product are prominent over the short irregular microvilli of the M cells (M) with enfolded lymphocytes (Ly), compared with the adjacent enterocytes (E). Reaction product is presumed to show binding sites of secretory IgA on M cells, which may take up IgA-antigen complexes. Reprinted with permission from Kato (1990).

The life-span of M cells is uncertain. According to the study of Bye *et al.* (1984), they migrate from the crypt to the dome base within 24 hr and to the summit of the dome within 72 hr. This life-span is essentially identical to that of the regular villus epithelium. Numbers of cells with labeled nuclei over domes gradually decrease between days 5 and 14 and no labeled cells are present by day 14 (Bye *et al.*, 1984).

GALT in specific pathogen-free (SPF) animals is poorly developed, although its basic structure is present. Exposure to the intestinal flora is essential for the complete development of GALT. M cells also need microbial exposure to proliferate. The total number of M cells is increased in mice after transfer from an SPF to a conventional environment (Smith *et al.*, 1987), whereas the ratio of M cells to FAE is reported not to be changed by such transfer (Siciński *et al.*, 1986). The invagination by lymphocytes had been considered essential to M cell development, but lymphocytes do not seem to be necessary for morphological maturation, since mature M cells can be recognized even in mice depleted of lymphocytes by total lymphoid irradiation (Ermak *et al.*, 1989).

## 2. Other Follicle Epithelial Cells

In addition to M cells, several other kinds of cells are present in FAE: columnar absorptive cells, IELs, and tuft cells. The structure of absorptive cells in FAE resembles that of enterocytes on villi, but these two populations of absorptive cells may differ in surface characteristics and function (Figure 5). In rabbits, secretory component is absent

not only from M cells but also from absorptive cells in FAE (Pappo and Owen, 1988). The majority of IELs in FAE are CD8<sup>+</sup> T cells, as in villus epithelium (see Chapters 23, 24), but the ratio of CD4<sup>+</sup> to CD8<sup>+</sup> lymphocytes in FAE (4:10) is greater than in IELs of villi (0.6:10). Lymphocytes in FAE are often large lymphoblast forms, however, which are thought to be immature and immunologically uncommitted, compared with the mature effector IELs found among enterocytes that cover villi. FAE is involved in induction of helper T cell functions, possibly as a consequence of M-cell uptake and transport of antigens from the intestinal lumen (Bjerke *et al.*, 1988).

## B. M Cell Function

Several important immunological and pathophysiological functions are recognized for M cells. M cells capture antigens from the intestinal lumen and transport them to enfolded lymphocytes and macrophages. Some of these lymphoid cells are presumed to influence IgA production directly in the germinal centers of lymphoid follicles, but this concept has been difficult to prove. Kabok *et al.* (1993) were able to induce production of antiferritin antibody by incubating isolated rabbit Peyer's patch lymphoid follicles with ferritin in organ culture for 7 days. Other stimulated lymphoid cells migrate through lymphatics to mesenteric lymph nodes and via the thoracic duct to the general circulation, then ultimately return by migration and homing receptors to mucosal tissues as IgA-producing plasma cells (Figure 1).

### 1. Mucosal Surveillance

**a. Antigen uptake.** M cells take up and transport a wide variety of sizes and types of intestinal antigens and microorganisms. This unique process may depend in part on factors that include mediators released by immunocompetent cells, hormonal factors, and nervous control. To study M cell function, investigators have focused on M cells of Peyer's patches, often using ligated intestinal segments and high concentrations of organisms to facilitate detection of uptake that, under physiological conditions, would occur less frequently yet would be sufficient for induction of immunological responses. Some of the macromolecules and microorganisms for which uptake and transport by M cells has been confirmed are discussed in the following sections (see also Table I).

*i. Particles and macromolecules.* Native ferritin (rat; Bockman and Cooper, 1973), cationized ferritin (rabbit; Bye *et al.*, 1984), horseradish peroxidase (rabbit; Owen, 1977; von Rosen, 1981), *Ricinus communis* agglutinins I and II (rabbit; Neutra *et al.*, 1987), wheat germ agglutinin (rabbit; Neutra *et al.*, 1987), cholera toxin (guinea pig; Shakhlamov *et al.*, 1981), Picibanil (OK-432, a streptococcal biological response modifier; rabbit; Nagasaki *et al.*, 1988), and 600- to 750-nm diameter latex particles (rabbit; Pappo and Ermak, 1989) have been shown to be transported by M cells.

*ii. Viruses.* Reovirus type 1 and type 3 (mouse; Wolf, 1983), poliovirus type 1 (human; Siciński *et al.*, 1990), human immunodeficiency virus type 1 (HIV-1; mouse and rabbit; Amerongen *et al.*, 1991), and mouse mammary tumor virus

**Table I** Substances and Microorganisms Taken up by M Cells

Particles and macromolecules
Native ferritin
Cationized ferritin
Horseradish peroxidase
<i>Ricinus communis</i> agglutinins I and II
Wheat germ agglutinin
Cholera toxin
Picibanil (OK-432)
600- to 750-nm diameter latex particles
Viruses
Reovirus type 1 and type 3
Poliovirus type 1
Human immunodeficiency virus type 1 (HIV-1)
Mouse mammary tumor virus (MMTV)
Bacteria
<i>Vibrio cholerae</i>
<i>Salmonella typhi</i>
<i>Bacillus Calmette-Guérin</i> (BCG)
<i>Mycobacterium paratuberculosis</i>
<i>Brucella abortus</i>
<i>Streptococcus pyogenes</i>
<i>Campylobacter jejuni</i>
<i>Yersinia enterocolitica</i>
<i>Yersinia pseudotuberculosis</i>
<i>Shigella flexneri</i>
<i>Salmonella enteritidis</i>
<i>Escherichia coli</i> RDEC-1 strain
<i>Escherichia coli</i> 0:124 K:72 strain
Parasites
<i>Cryptosporidium</i>

(MMTV; mouse; Neutra and Kraehenbuhl, 1992) have been shown to be transported by M cells.

iii. **Bacteria.** *Vibrio cholerae* (rabbit; Owen *et al.*, 1986b), *Salmonella typhi* (mouse; Kohbata *et al.*, 1986), BCG (*Bacillus Calmette-Guérin*; rabbit; Fujimura, 1986), *Mycobacterium paratuberculosis* (calf; Momotani *et al.*, 1988), *Brucella abortus* (calf; Ackermann *et al.*, 1988), *Streptococcus pyogenes* (rabbit; Nagasaki *et al.*, 1988), *Campylobacter jejuni* (rabbit; Walker *et al.*, 1988), *Yersinia enterocolitica* (mouse; Grützkau *et al.*, 1990), *Yersinia pseudotuberculosis* (rabbit; Fujimura *et al.*, 1989), *Shigella flexneri* (rabbit; Wassef *et al.*, 1989), *Salmonella enteritidis* (rabbit; Kamoi, 1991), RDEC-1 strain of *Escherichia coli* (rabbit; Inman and Cantey, 1984), and 0:124 K:72 strain of *E. coli* (rabbit; Uchida, 1987) have been shown to be transported by M cells.

iv. **Parasites.** *Cryptosporidium* (guinea pig; Marcial and Madara, 1986) has been shown to be taken up. Even under optimizing conditions, observation of uptake of *Giardia muris* trophozoites has not been possible, although they were found in the pocket within mouse M cells (Owen *et al.*, 1981).

M cells are also capable of reverse transport of some substances into the intestinal lumen, as demonstrated by the fact that injected horseradish peroxidase can be seen to move from the tissue into the lumen through M cells (Bockman and Stevens, 1977).

Information about M cell function in absorption of nutrients is limited; however, no absorption of lipid by M cells of mice was observed (Bye *et al.*, 1984).

Although the range of microorganisms and other particles taken up by M cells is wide, these cells also exhibit selectivity of uptake and specific characteristics impede or facilitate attachment, uptake, and transport. Viable and killed *M. paratuberculosis* are taken up by M cells. Living *V. cholerae* are taken up, transported, and presented (Figure 10), but killed *Vibrio* are scarcely taken up by M cells. When suspensions of  $10^9$  *Vibrio* killed by acidification, formalin treatment, ultraviolet irradiation, or heating were injected into ligated intestinal segments of rabbit intestine containing Peyer's patches, none were taken up after 180 min, although motile noninvasive but colonizing living *Vibrio* of the same strain were taken up readily by M cells when administered in the same concentration (Owen *et al.*, 1988b). Because cholera toxin stimulates a variety of cellular processes, mutant *Vibrio* that produce neither the A nor the B subunit of cholera toxin were administered and found to be taken up by M cells as efficiently as toxigenic strains. In contrast, a toxin-producing but nonmotile strain, CVD 49, was not taken up, indicating that one of the most important determinants of bacterial uptake is whether organisms can reach the M cell surface, either by motility or by lateral spread across the colonized mucosal surface (Owen *et al.*, 1988a).

Even different strains of the same microorganism have very different interactions with M cells. Among *E. coli*, the O:124 K:72 strain is taken up and presented but the O:124 RDEC-1 strain can adhere to the M cell surface without being transported. Reovirus type 1 is taken up by M cells only, but type 3 is taken up by M cells and columnar cells in FAE (Wolf *et al.*, 1983). Further, after passage through M cells, reovirus type 1 passes through the basolateral membrane of these cells to adjacent columnar epithelial cells and proliferates there, finally producing an inflammatory lesion (Weiner *et al.*, 1988).

Whether the relatively weak alkaline phosphatase activity on the apical surface of the M cell has functional significance is unclear, but the very few lysosomes and the well-developed vesicular transport system in its apical cytoplasm contribute to the function of the M cell as the gateway to the immune defense system (Figure 7). This function as a gatekeeper seems to depend on the equilibrium between the motility, colonizing potential, and invasiveness of pathogens and the defensive competence of M cells and associated macrophages. The efficiency and vigor with which M cells function as the gateway for antigen sampling contribute to a pathophysiological role of M cells as entry points for invasion by virulent pathogens. Some types of intestinal infection, particularly typhoid fever and intestinal tuberculosis, occur initially in Peyer's patches. Virulent pathogens such as *S. typhi* and *S. flexneri* invade M cells and subsequently precipitate the destruction of Peyer's patches. Thus, the M cell seems to be a target cell as well as a conduit for some virulent pathogens that cause enteritis in clinical settings.

In M cells, whether initiation of an immune response or systemic invasion occurs may depend on binding to the M-cell apical membrane and on the ability of M cells and associ-

**Figure 10** Transport of tritium-labeled *Vibrio cholerae* by rabbit M cells (M). Vibrios (1) lie in the mucus layer of the intestinal lumen. Vibrio 2 is adherent to M cell microvilli. After uptake, vibrio 3 is transported within a vesicle through the cytoplasm. Finally, vibrio 4 lies within the central hollow, adjacent to an enfolded lymphocyte (L). Reprinted with permission from Owen *et al.* (1988b).

ated phagocytic cells to digest and inactivate microorganisms. The apical membrane of M cells has been shown to have an enhanced capacity to bind secretory IgA, possibly because of its thin glycocalyx compared with adjacent columnar cells (Figure 9). This ability of M cells to bind secretory IgA may protect them against the luminal environment and may accelerate M-cell uptake of luminal antigens that are complexed with IgA to boost an existing immune response. The former possibility is supported by the fact that the mouse intestinal mucosa can be protected against virulent *V. cholerae* and *Salmonella typhimurium* infection by secretion of hybridoma-derived IgA specific to each bacterium (Winner *et al.*, 1991; Michetti *et al.*, 1992). The latter suggestion is supported by the fact that transport of some viruses by M cells is accelerated by monoclonal IgA antibodies directed against proteins of these viruses (Weltzin *et al.*, 1989; see Chapter 34).

The range of mechanisms for capture and uptake of various antigens from the intestinal lumen, and for antigen processing and presentation to enfolded cells, is complex and incompletely understood. Gebert and Hach (1993) have shown that M cells of the rabbit cecum selectively bind lectins specific for fucose and *N*-acetylgalactosamine. These lectins bind to the apical membrane and to the membranes of vesicles in the cytoplasm of M cells. In contrast, rabbit enterocytes selectively bind galactose-specific lectins. In rabbit jejunal Peyer's patches, M cells and enterocytes do not show differences in surface glycoconjugates. Adherence of microorgan-

isms to glycoconjugates on M-cell surfaces may be a critical determinant of variations in microbial uptake and colonization at different levels in the gastrointestinal tract. Even binding sites that are shared by M cells and enterocytes are more accessible for microbial adherence on M cells, which lack mucus and the thick glycocalyx coat present over microvilli of enterocytes. Characterization of M-cell receptor sites that bind microorganisms and antigenic molecules may be critical for the logical development of oral immunizing agents; see Chapters 31 and 32).

**b. Antigen processing.** Using immunohistochemical techniques, investigators have shown that M cells express IL-1 and MHC Class II molecules (Ia antigen in mice, HLA-DR in humans; Nagura *et al.*, 1991). Previously researchers believed that no digestive mechanism was involved in transport through the M cell. However, Allan and associates (1993) showed that M cells possess acidic endosomal, prelysosomal, and lysosomal compartments and express MHC Class II determinants in their prelysosomal and lysosomal structures. These data show that M cells have some potential for processing endocytosed agents and presenting them to the enfolded immunocompetent cells. In mice, IgM plasma cells, macrophages, and T cells that express the CD8 molecule are located in close proximity to M cells and could receive such processed antigen (Jarry *et al.*, 1989). Other APCs such as dendritic cells and macrophages exist beneath the FAE.

These cells extend processes into the FAE and are thought to communicate with M cells in information processing, but their interactions and division of functions remain unclear.

Although the fact that all necessary elements for initiation of intestinal immune responses are present in Peyer's patch follicles has been clearly demonstrated, proving that M cell uptake is an essential step in this process has not been possible. Isolation and culture of M cells, which would be helpful in elucidating their various features, have not yet been accomplished.

## 2. Target for Migration and Homing of Lymphoblasts

Before lymphoblasts can reach FAE to be enfolded within M cells and brought in contact with various antigens in Peyer's patches, they must leave the systemic circulation via postcapillary venules (PCV) (Figure 1). This directed migration is mediated by high endothelial venules (HEV) in Peyer's patches. In homing, lymphocytes are controlled by surface markers peculiar to each mucosal site; the HEVs have receptors recognized by lymphocyte adhesion molecules such as LECAM-1 (in mouse, MEL-14 antigen) and CD 44 (Berg *et al.*, 1989; Hamann *et al.*, 1991; see Chapter 19). Factors that guide the next step of migration, that is, from HEVs in the parafollicular domain to FAE, are only now being investigated. Extracellular matrix components, arrayed along the migration pathway from HEVs to the apices of follicle domes, may provide the physical basis for this directional cell traffic (Ohtsuka *et al.*, 1992). The migratory stimulus for lymphoid cells to move from follicle domes into and out of M cell pockets is unknown.

Lymphocytes of B-cell lineage finally return to the gut mucosa as mature IgA-producing plasma cells. The migration process of these cells from GALT back to the gut is reported to require 4–6 days (Hall, 1979). B lymphocytes from GALT also can go to other mucosal sites such as mammary glands, salivary glands, bronchial tissues, and the genitourinary tract, and there become stationary plasma cells that produce IgA (Bienenstock and Befus, 1980; see Chapters 12, 13, 19, and 21).

# Cellular and Molecular Basis for Antigen Transport in the Intestinal Epithelium

Marian R. Neutra • Jean-Pierre Kraehenbuhl

## I. INTRODUCTION

The mucosal surfaces that line digestive, respiratory, and urogenital systems represent a vast surface area that is covered for the most part by a monolayer of epithelial cells. The importance of secretory antibodies in defense of these surfaces is discussed in detail elsewhere in this volume. Secretory antibodies, primarily of the polymeric IgA type, are designed to interact with their target microorganisms or antigens in external secretions, an environment that is separated by a tight epithelial barrier both from the local cellular assemblies responsible for induction of mucosal immune responses and from the widespread effector cells responsible for production of polymeric IgA antibodies. Epithelial cells thus play important roles in mucosal immune defense apart from their simple function as a barrier (for review, see Neutra and Kraehenbuhl, 1992). A minority population of epithelial cells (the M cells) is highly specialized for transport of antigens to the cells of the mucosal immune system, whereas a major population of diverse epithelial and glandular cells selectively exports polymeric immunoglobulins onto mucosal surfaces. In this chapter, we focus on the basic mechanisms of membrane traffic and the epithelial cell specializations that allow the epithelium in the intestine to function as a gatekeeper that controls access of antigens to the mucosal immune system, while still fulfilling many other complex roles such as digestion, absorption, and maintenance of an effective barrier.

### A. Enterocyte Diversity and Antigen Transport

The phenotype of the intestinal absorptive cell or enterocyte changes during intestinal development of the fetus and neonate, and during differentiation of individual cells along the crypt–villus axis in adults. These changes have important effects on the capacity of the epithelium for endocytosis and transcytosis. Dramatic changes in endocytic activity occur in the entire absorptive enterocyte population during fetal and postnatal development in mammals as they pass through progressive stages of digestive function (Neutra and Louvard, 1989). The cellular heterogeneity of the epithelium that covers the normal adult intestinal mucosa and the changes in cell ultrastructure and function that occur as cells migrate

along the crypt–villus axis have been reviewed in detail elsewhere (Madara and Trier, 1987, Neutra, 1988). In adults, the capacity of individual absorptive enterocytes on intestinal villi to take up intact proteins generally is very limited; endocytic activity and limited transcytosis occur, however, and may vary with the stage of cell differentiation. The functional effect of such transport may be amplified by the immense numbers of cells involved.

Transcytosis by enterocytes would deliver antigens to the basolateral surface of the epithelium that faces a diffuse lymphoid tissue called the lamina propria. This highly vascularized connective tissue contains lymphoid and phagocytic cell populations including sessile antibody-producing cells (mainly IgA-producing plasma cells) as well as various cell types capable of processing and presenting antigens, producing cytokines, and collectively initiating and modulating immune responses. The epithelium itself also harbors intraepithelial lymphocytes (IELs) that are thought to play roles in immune surveillance of foreign antigens, suppression of immune responses, or elimination of damaged or infected epithelial cells. The identity and possible functions of specific lymphoid cell populations in the mucosa and epithelium are addressed in subsequent sections of this volume (see Sections B and C).

### B. M Cells and Antigen Transport

Over specific mucosal sites marked by the presence of organized lymphoid follicles, a unique epithelium occurs. The unusual phenotypes, in particular the M cells that exist only at these sites, are described in Chapter 2. Although M cells represent an exceedingly small minority in the intestinal epithelium, their functional significance is amplified greatly by their unique position over the organized lymphoid tissues that serve as inductive sites for mucosal immune responses and by their ability to transport antigens with great efficiency. Researchers generally agree that M cells play a primary role in transport of antigens to the inductive arm of the mucosal immune system. In M cells as well as in enterocytes, the immunological consequences of antigen uptake and transport are determined in part by the nature and capacity of the intracellular pathways through which antigens are directed. These pathways are driven by the basic mechanisms that govern the direction and rate of membrane traffic in all cells.

## II. GENERAL MECHANISMS OF TRANSEPIHELIAL TRANSPORT

In the past several years, an explosion of new information has become available on the binding of macromolecular ligands and microorganisms to cell surfaces and on the mechanisms by which macromolecules and particles are internalized by endocytosis and phagocytosis. The nature and function of the compartments that compose endocytic pathways, directed either toward the degradative lysosomal compartment or to other destinations, have been elucidated mostly through studies on nonpolarized cells (for review, see Kornfeld and Mellman, 1989). However, attention also has been focused on the endocytic compartments involved in transport of vesicles across polarized epithelial cells (Mostov and Simister, 1985; Schaerer *et al.*, 1991; Sztul *et al.*, 1991). Most studies have exploited relatively simple model cell culture systems such as Madin–Darby canine kidney (MDCK) cells (Brandli *et al.*, 1990; Casanova *et al.*, 1990). Although the nature of specific membrane receptors and the relative importance of various intracellular vesicular pathways clearly differ among epithelial cell types, investigators generally agree that the basic mechanisms operating in one cell type, for example, MDCK, are likely to operate in other cell types such as intestinal enterocytes and M cells. Therefore, some salient findings are reviewed briefly here.

### A. Maintenance of Cell Polarity

In all confluent polarized epithelial cells, the tight junctions that seal the apical poles of the cells not only provide efficient diffusion barriers for many ions, small molecules, and all macromolecules (Madara, 1988), but also prevent lateral diffusion of glycolipids and proteins between apical and basolateral domains of the plasma membrane (Dragsten *et al.*, 1981). The apical domain of epithelial cells, including intestinal cells, contains many components not present in either nonpolarized cell types or the same epithelial cells in culture prior to polarization and junction formation (Louvard *et al.*, 1985; LeBivic *et al.*, 1986; Godefroy *et al.*, 1988; Rodriguez-Boulan and Nelson, 1989; Lisanti and Rodriguez-Boulan, 1990). The basolateral cell surface is divided further into two major subdomains. The lateral subdomain is involved in cell–cell interactions via cell adhesion molecules (Nelson and Hammerton, 1989) and is enriched in  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase, poly Ig receptors, and other components in enterocytes (Slot and Geuze, 1984; Amerongen *et al.*, 1989). The basal subdomain is enriched in receptors that recognize extracellular matrix and basal lamina. In addition, both apical and basolateral plasma membranes can contain specialized microdomains such as microvilli, cell–cell interdigitations, and other sites stabilized by submembrane cytoskeleton and clathrin-coated pits (Mooseker, 1985; Neutra *et al.*, 1988; Nelson and Hammerton, 1989).

Maintenance of the apical and basolateral domains involves at least two types of membrane traffic. First, vesicles derived from the trans-Golgi network and containing newly synthesized, domain-specific proteins can be transported di-

rectly to either the apical or the basolateral domain (Danielson and Cowell, 1985; Caplan *et al.*, 1986; Wandinger-Ness and Simons, 1991). Second, specific components initially inserted into one domain can be re-sorted to the opposite side by “corrective” transcytosis. Studies on the biogenesis of polarized membrane proteins have shown that, in hepatocytes and intestinal enterocytes *in vivo* and in cell culture, certain proteins that are considered residents of the apical domain actually are directed initially to the basolateral domain, but are then endocytosed selectively and carried to the apical domain in transcytotic vesicles (Bartles *et al.*, 1987; Massey *et al.*, 1987; Matter *et al.*, 1990). Corrective transcytosis also may occur in the opposite direction in MDCK cells (Matlin *et al.*, 1983); if this occurs in intestinal cells *in vivo*, such traffic would be expected to provide a potential pathway for uptake of foreign proteins from the lumen.

### B. Endocytosis and Sorting

The initial event in transcytosis is the endocytic uptake of either adsorbed or fluid-phase macromolecules via clathrin-coated or noncoated pits and vesicles (Anderson, 1991). Incoming vesicles fuse to form an “early endosome,” a compartment of distinctive morphology consisting of clear vesicles with attached tubules (for review, see Kornfeld and Mellman, 1989). Studies using ligands tagged with pH-sensitive probes showed that this compartment acidifies to pH 6.0–6.2, a milieu in which certain ligands are released from their receptors (for review, see Maxfield and Yamashiro, 1991). In addition, various receptors may be sorted from each other in the plane of the early endosome membrane. Sorting of receptors in basolateral (sinusoidal) endosomes in hepatocytes was studied by electron microscopic (EM) immunocytochemistry. The images suggested that receptors cluster together and are removed from the endosomal tubules by selective budding of small vesicles destined for transport to three different destinations: rapid return to the same cell surface (recycling), transport along the degradative pathway (ultimately to lysosomes), or transport to the opposite membrane domain (transcytosis) (Geuze *et al.*, 1984, 1987).

The basic molecular mechanisms by which sorting occurs in the endosomal membrane and the exact site at which transcytotic vesicles are formed are not known. Recycling of membrane proteins and vesicle contents can occur not only from early endosomes but also from late endosomes, a population that includes multivesicular endosomes (or transport endosomes) and pre-lysosomal compartments (Hughson and Hopkins, 1990; Rabinowitz *et al.*, 1992). This observation is consistent with the observation that vesicles all along the endosomal pathway have tubular extensions (Neutra *et al.*, 1985; Rabinowitz *et al.*, 1992). However, whether these extensions give rise to transcytotic vesicles all along the pathway, that is from early endosomes, late endosomes, and pre-lysosomes is not known. This idea is of interest since the origin of the vesicles would affect the degree of proteolytic processing that might occur during transcytosis.

In kidney tubular cell lines, intestinal cell lines, and entero-

cytes *in vivo*, distinct sets of apical and basolateral early endosomes are seen (Rodewald, 1980; Fuller and Simons, 1986; Bomsel *et al.*, 1989; Parton *et al.*, 1989; Fujita *et al.*, 1990; Hughson and Hopkins, 1990). Despite many structural and functional similarities, apical and basolateral early endosomes seem to be different functionally and compositionally because, when isolated from MDCK cells, they are unable to fuse with each other *in vitro* (Bomsel *et al.*, 1990). Both types of early endosomes can, nevertheless, fuse with common "late endosomes" isolated from the same cells (Gruenberg *et al.*, 1989; Gruenberg and Howell, 1989; Bomsel *et al.*, 1990); these fusion patterns correspond to the pathways of transfer of apical and basolateral tracer proteins observed in intact MDCK cells (Parton *et al.*, 1989) as well as in intestinal epithelial cells *in vivo* (Rodewald, 1980; Fujita *et al.*, 1990).

Although early endosomes were thought initially to lack degradative enzymes because they lack traditional lysosomal enzyme markers such as acid phosphatase, we now know that certain degradative enzymes are indeed present in very early endosome compartments (Diment and Stahl, 1985; for review; see Courtoy, 1991). In some cell types, these enzymes enter the endosome by receptor-mediated uptake from the outside, but the major source of endosomal proteases seems to be receptor-mediated delivery from the Golgi complex (Brown *et al.*, 1986; von Figura and Hasilik, 1986; Griffiths *et al.*, 1988; Kornfeld and Mellman, 1989). Whether the same enzymes are delivered to early apical and basolateral endosomes in polarized cells is not known. Uptake of extracellular enzymes may be limited to the basolateral side, since cell-surface mannose 6-phosphate receptors on MDCK cells are basolateral (Prydz *et al.*, 1990). Additional hydrolases from the Golgi continue to be delivered along the endocytic pathway; a major delivery site is the late endosome. Although lysosomes generally don't have tubular extensions and have been considered stable dead-end organelles, "resident" glycoproteins of the lysosome membrane have been shown to cycle to the plasma membrane and back via the endocytic pathway (Lippincott-Schwartz and Fambrough, 1987; Braun *et al.*, 1989). In MDCK cells, newly synthesized lysosomal membrane proteins may go to the basolateral plasma membrane on their way to the lysosome (Nabi *et al.*, 1991), implying that digested protein fragments can be re-exposed to both the external and the endosomal milieu.

### C. Transcytosis

Soluble tracers and specific ligands have been used as markers of transcytosis in intact epithelial organs, but since they often enter multiple pathways, the exact transcytotic route and the identity of transcytotic vesicles is not clear. To date, a biochemical analysis of isolated transcytotic carrier vesicles from normal cells has been achieved only by immunaffinity isolation of vesicles from hepatocytes (Sztul *et al.*, 1991). Since access to apical as well as basolateral surfaces generally is restricted in intact organs, the kinetics of internalization and the fates of endocytosed proteins have been analyzed primarily in cultured kidney or intestinal cell lines

grown on permeable supports. Results derived from MDCK cells and Caco-2 or HT29 human colon carcinoma cells have revealed striking differences among these models. In MDCK cells, for example, the amount of internalization of fluid phase proteins from apical and basolateral surfaces was identical, but the subsequent fate of the proteins differed dramatically (Bomsel *et al.*, 1989). Of the horseradish peroxidase (HRP) taken up from the apical side, relatively small amounts were directed to lysosomes; most of the protein was released from the cells—half by recycling and half by transcytosis to the other side. Of the HRP taken up basolaterally, only small amounts were transcytosed to the apical side. Certain membrane proteins also were found to be transported bidirectionally across MDCK cells, indicating that single membrane vesicles may have made the entire transepithelial trip (Brandli *et al.*, 1990). The dominance of the apical-to-basolateral pathway in MDCK cells contrasts with the situation in Caco-2 cells, in which apical-to-basolateral transepithelial transport of HRP was documented by some investigators (Hidalgo *et al.*, 1989) but was found to be limited to paracellular leakage by others (Heyman *et al.*, 1990) or was not observed at all (Hughson and Hopkins, 1990). These discrepancies may have been the result of differences in the Caco-2 cell clones used. In any case, the amount, rate, and direction of transcytosis in cultured epithelial cell lines, although providing useful guidelines, may not reflect transport activity in the various enterocyte phenotypes *in vivo* accurately.

To date, only two receptor systems that mediate transcytosis have been analyzed at the molecular level. These analyses have contributed significantly to our understanding of transcytosis (Breitfeld *et al.*, 1989a; Simister and Mostov, 1989; Apodaca *et al.*, 1991; Hirt *et al.*, 1993). Both these receptor systems operate in the intestinal epithelium. The epithelial Fc receptor mediates apical-to-basolateral transcytosis of maternal immunoglobulins in small intestine of neonatal rodents, but not in neonatal humans (Rodewald, 1980; Simister and Mostov, 1989); the polymeric immunoglobulin (poly Ig) receptor mediates basolateral-to-apical delivery of IgA in a wide variety of epithelial and glandular cells (Kuhn and Kraehenbuhl, 1982; Mostov *et al.*, 1984; Kraehenbuhl and Neutra, 1992a,b). The molecular mechanisms mediating cell surface targeting and trafficking of these immunoglobulin-like receptor molecules through early endosomes and into their respective transcytotic pathways to the opposite cell surface have been studied in epithelial cell lines transfected with either wild-type or mutated receptor cDNAs encoding them (Breitfeld *et al.*, 1989b; Hunziker and Mellman, 1989; Casanova *et al.*, 1990; Hunziker *et al.*, 1990, 1991a; Hirt *et al.*, 1993). Collectively, these studies have shown that the major portion of the targeting information required for the complex itineraries of these proteins resides in the cytoplasmic tails of the receptors, and may be contained both in specific amino acid phosphorylation sites and in motifs of secondary structure (for review, see Apodaca *et al.*, 1991; Schaerer *et al.*, 1991).

Although scientists often assume that transcytotic vesicles directly recognize and fuse with the contralateral cell surface, studies on transfected MDCK cells expressing either the Fc receptor or the poly Ig receptor showed that transcytosed

membrane proteins can recycle between early endosomes and the adjacent cell surface both at their original site of insertion and at their ultimate destination (Breitfeld *et al.*, 1989b; Hunziker *et al.*, 1990), implying that a single population of transcytotic carrier vesicles could shuttle between the apical and basolateral early endocytic compartments. If such a shuttle exists, these vesicles would be competent to fuse with early endosomes at either cell pole.

#### **D. Epithelial Cytoskeleton and Vesicular Traffic**

In epithelial cells, microtubules play an important but controversial role in cell membrane polarity and transcytosis. Researchers generally agree that microtubules serve primarily to move vesicles over "long" distances in cells, but are not required for endocytosis or exocytosis (Schroer and Kelly, 1985; Kelly, 1990). Vesicles carrying newly synthesized cell surface and secretory materials in epithelial cells move from the Golgi region toward the apical surface along microtubules that run parallel to the lateral cell membrane (Specian and Neutra, 1984; Achler *et al.*, 1989; Bacallao *et al.*, 1989). Microtubule-inhibiting drugs interfere with delivery of newly synthesized membrane components to the apical surface of enterocytes *in vivo* (Quaroni *et al.*, 1979; Pavelka *et al.*, 1983) and *in vitro* (Eilers *et al.*, 1989). The minus ends of the microtubules are oriented toward the apical cell surface of cultured epithelial cells (Bacallao *et al.*, 1989); polarized delivery of apically directed vesicles presumably involves a dynein-like motor since these vesicles move toward the minus end (Schroer and Sheetz, 1989; van der Sluijs *et al.*, 1990).

Microtubules also may play a role in transcytosis. For example, microtubules were found to be involved in transcytosis of poly Ig receptors from the basolateral to the apical membrane in transfected MDCK cells (Hunziker *et al.*, 1990). In addition, microtubule-inhibiting drugs reduced the secretion of hepatocyte proteins into bile (Goldman *et al.*, 1983). Endocytosis is not itself microtubule dependent, but movement of peripheral endosomes to more central locations and to lysosomes is mediated in polarized epithelial cells (as in nonpolarized cells) by microtubules (Gruenberg *et al.*, 1989; Bomsel *et al.*, 1990; Hughson and Hopkins, 1990). In this case, vesicles move toward the plus end of the microtubules, presumably via a kinesin-type motor (Schroer and Sheetz, 1989). In transfected MDCK cells expressing both the poly Ig receptor and the epithelial Fc receptor, microtubules were found to be required for basolateral-to-apical transcytosis, whereas apical-to-basolateral transcytosis was microtubule independent (Hunziker *et al.*, 1990). Whether some other type of molecular motor and cytoskeletal "track" facilitate apical-to-basolateral vesicular transport is unknown.

Collectively, new information on the nature of the transcytotic pathway indicates that transport of proteins from one side of an epithelium to the other is not accomplished by simple movement of a vesicle derived from one plasma membrane and subsequent fusion with the opposite side. Rather, this process probably requires a complex series of events including formation and fusion of endosomes and other mem-

brane vesicles and participation of additional organelles and cytoskeleton. The observed alteration in basolateral endosomes that accompanies inhibition of transcytosis of the poly Ig receptor in MDCK cells by the antibiotic brefeldin A supports this general caveat (Hunziker *et al.*, 1991b). Current information about pathways of vesicular traffic must be considered in the interpretation of experiments exploring antigen transport, processing, and presentation by intestinal epithelial cells.

### **III. MEMBRANE TRAFFIC IN INTESTINAL ENTEROCYTES**

Epithelial cells of the intestine constitutively express major histocompatibility complex (MHC) Class I determinants and also express MHC Class II determinants on their surfaces and in internal compartments. Enterocytes isolated from intestine and dispersed *in vitro* have been shown to contain MHC Class II determinants and to be capable of mediating T-cell activation when incubated with predigested antigens and sensitized T cells (Bland and Warren, 1986; Mayer and Shlien, 1987). The hypothesis has been proposed that, in the gut, antigens resulting from digestion in the lumen and transported transepithelially or degraded intracellularly in enterocyte lysosomes could associate with MHC II and be presented to lymphocytes to suppress the systemic immune response to luminal antigens such as products of food digestion (Bland and Warren, 1986; Nedrud and Lamm, 1991; Mayer *et al.*, 1991). On the other hand, other evidence suggests that intact food antigens can be transported across the intestinal epithelium in amounts sufficient to evoke an immune response. The available evidence for these phenomena is discussed in more detail in Chapters 4, 15, and 16. In this chapter, we consider the possible functions of antigen-presenting molecular complexes in enterocytes and the significance of lymphocyte-enterocyte interactions in the light of available information on membrane traffic in enterocytes and the roles of endocytic pathways in antigen presentation.

#### **A. Antigen Exclusion at the Apical Membrane**

Intestinal absorptive cells are well equipped to face an environment rich in foreign proteins and microorganisms. The normal villus and crypt epithelium *in vivo* is sealed by continuous tight junctions that permit charge-selective passage of certain ions, water, and, under some conditions, small organic molecules such as glucose but exclude peptides or macromolecules (Madara, 1988). The apical membrane of enterocytes is a highly differentiated structure dominated by rigid, closely packed microvilli (Moosker, 1985), each of which is coated with a thick layer of membrane-anchored and peripheral glycoproteins called the glycocalyx (Semenza, 1986). This coat impedes the passage of particles such as viruses, bacteria, and macromolecular aggregates between microvilli and can prevent their contact with the microvillus membrane (Gonnella and Neutra, 1985; Amerongen *et al.*,

1991). Lectin binding studies on tissue sections or fixed cells have shown that the glycocalyx is rich in the many saccharides that serve as receptors for lectins or microorganisms. We have shown, however, that on living enterocytes *in vivo* many lectin receptors are masked by the macromolecular assembly of the glycocalyx (Gonnella and Neutra, 1985). Although crypt cell apical membranes may be more accessible, outward fluid flow tends to inhibit passive entry at this site (Phillips *et al.*, 1987). In addition, normal enterocytes can “shed” microvillus membrane in the form of vesicles after cross-linking by lectins (Weinman *et al.*, 1989) and also can shed other adherent macromolecules (Gonnella and Neutra, 1985), perhaps by release of lipid-linked or integral membrane enzymes (Alpers, 1975). Thus, enterocyte-like cell lines and MDCK cells in culture, whose apical surfaces may be less fully differentiated, can provide misleading information concerning antigen or microbial adherence and endocytosis in the normal gut.

The structure of the brush border and glycocalyx also shields the plasma membrane microdomains at the bases of microvilli that are responsible for endocytosis (Neutra *et al.*, 1988). In adult enterocytes, the molecules that can pass between microvilli enter clathrin-coated endocytic pits at this site, which apparently is intended for uptake of physiological ligands such as intrinsic factor–cobalamin complexes (Levine *et al.*, 1984). In suckling rodents, this endocytic domain is expanded to provide access for maternal milk IgG in jejunum and other milk macromolecules in ileum (Rodewald, 1980; Gonnella and Neutra, 1984; Neutra *et al.*, 1988). Note, however, that these specialized cell types and expanded endocytic membrane domains are not present in human intestine beyond the midpoint of gestation (Moxey and Trier, 1979).

### **B. Membrane Traffic in Vacuolated Enterocytes**

During fetal and neonatal development of the mammalian intestine, the epithelium undergoes two major bursts of cytodifferentiation (Neutra and Louvard, 1989). The first involves conversion of the undifferentiated fetal epithelium to a monolayer containing enterocytes that are specialized for active endocytosis of luminal contents. The timing and duration of this “endocytic stage” varies widely among species (Kraehenbuhl *et al.*, 1979): in humans, for example, it begins and ends during the first half of gestation (Moxey and Trier, 1979) whereas in sheep and cattle it begins during fetal life but extends for a few days after birth (Trahair and Robinson, 1986, 1989). This stage has been most studied in rats, whose endocytic enterocytes appear a few days before birth and persist through the 3-week suckling period (Kraehenbuhl *et al.*, 1979). During this stage in rats, specialized enterocytes in proximal intestine conduct receptor-mediated endocytosis and transcytosis of IgG from maternal milk (Rodewald, 1980). IgG uptake is mediated by epithelial Fc receptors that show structural similarities to MHC I, consisting of a membrane-anchored immunoglobulin-like protein associated with  $\beta 2$  microglobulin (Simister and Mostov, 1989). Jejunal enterocytes contain abundant apical endosomes into which both IgG–receptor complexes and soluble proteins from the lumen are

delivered after uptake from clathrin-coated pits located between microvilli (Rodewald, 1980). The apical endosomal system appears to be a sorting compartment, since proteins in the fluid content of the vesicles are directed to lysosomes whereas IgG ligand–receptor complexes enter small transport vesicles that release their content by exocytosis at the lateral cell surface (Abrahamson and Rodewald, 1981).

Enterocytes in more distal regions of suckling rat intestine, and enterocytes throughout the intestines of 10- to 20-week fetal humans and fetuses and newborns of other mammalian species, are specialized cells known as “vacuolated enterocytes” (Moxey and Trier, 1979; Trier and Moxey, 1979). These cells take up large amounts of luminal protein into specialized apical endosomal tubules and vesicles and, hence, into large lysosomal vacuoles (Gonnella and Neutra, 1984). In humans, these cells have been suggested but not proven to conduct transfer of antibodies from amniotic fluid to the fetus (Israel *et al.*, 1989). The endocytic compartments of vacuolated enterocytes have been studied in detail in suckling rats, in which endocytosis allows for intracellular digestion of milk proteins. The apical endocytic complex of rat vacuolated enterocytes is an endosomal system in which hormone and growth factors from milk including epidermal growth factor (EGF), nerve growth factor (NGF), and prolactin are sorted into a transepithelial transport pathway (Siminoski *et al.*, 1986; Gonnella *et al.*, 1987, 1989). A small change in EGF motility on gels after transport suggests that the peptide encounters an intracellular protease, either in endosomes or in transport vesicles (Gonnella *et al.*, 1987).

In both proximal and distal enterocytes of rats, an adherent protein tracer, cationized ferritin, enters transepithelial transport vesicles in small amounts (Abrahamson and Rodewald, 1981; Siminoski *et al.*, 1986), indicating that positively charged peptides or lectins could be transported across these cells in immunologically significant amounts. Soluble proteins, however, are directed efficiently to lysosomes for degradation (Abrahamson and Rodewald, 1981; Gonnella and Neutra, 1984). In other species such as humans and sheep, in which these cells are present during fetal life, transepithelial transport of proteins from amniotic fluid may be conducted by vacuolated enterocytes (Moxey and Trier, 1979; Trahair and Robinson, 1986); these cells contain a specific apical endosomal antigen called endotubin (J. F. Trahair, J. M. Wilson, and M. R. Neutra, unpublished observations). The specificity of transepithelial transport or the nature of the transport vesicles, however, is not known.

Because of their well-developed endocytic compartments, vacuolated enterocytes of suckling rats also have served as models for mapping the interaction of apical and basolateral endocytic pathways. Apical endosomal markers such as the glycoprotein “endotubin” and basolateral membrane receptors such as transferrin appear to cycle in and out of their respective plasma membrane domains and early endosome systems in intestinal cells (Wilson *et al.*, 1987; Godefroy *et al.*, 1988; Hughson and Hopkins, 1990). In vacuolated enterocytes, soluble tracers that enter apical or basolateral endosomes do not mix, but do meet in late endosomes located in the apical cytoplasm and are delivered together to the lysosomal vacuole (Fujita *et al.*, 1990). Whether the transepi-

thelial transport vesicles that carry growth factors and possibly other proteins can transfer protein from apical to basolateral endosomes is not known, but such a pathway would provide an opportunity for interaction of endocytosed antigens with newly synthesized unoccupied MHC II (see Section B).

### C. Membrane Traffic in Adult Enterocytes

In the human fetus, highly endocytic vacuolated enterocytes are replaced at about 20 weeks gestation by cells that are morphologically and functionally analogous to adult enterocytes (Moxey and Trier, 1979). This second stage of cyto-differentiation occurs much later in certain other species (at weaning in rodents and one or more days after birth in cattle, sheep, and pigs; Kraehenbuhl *et al.*, 1979). The dramatic change at this stage has been termed "closure," referring to the halt in maternal Ig transfer and disappearance of specialized endocytic epithelial cells. In humans, other more subtle maturational changes such as increased expression of brush border enzymes (and, perhaps, changes in endocytic activity) continue until after birth. Despite indirect evidence for antigen uptake in neonatal humans, the endocytic and transport activities of individual enterocytes at this age has not been documented. Confluent Caco-2 and HT29 enterocytes in culture, when fully differentiated, are analogous to enterocytes in human fetal colon during the second half of gestation (Huet *et al.*, 1987; Neutra and Louvard, 1989).

Nonspecific tracer proteins, including adherent and soluble molecules, are endocytosed in very small amounts by adult enterocytes and appear to be directed entirely to lysosomes in the apical cytoplasm. If late endosome- or lysosome-derived vesicles are shuttled back to the apical surface, no immunological consequences would ensue. If, however, they are delivered to basolateral endosomes or plasma membrane, processed antigens would be exposed to cells of the immune system, either free or associated with MHC complexes. Such vesicular shuttles operate in nonpolarized cells (Kornfeld and Mellman, 1989). Return of protein from apical endosomes to the basolateral surface was observed in Caco-2 cell monolayers (Hughson and Hopkins, 1990), but the existence of shuttles in normal enterocytes is not established. Nevertheless, transepithelial transport of intact biologically active insulin across normal adult epithelium occurs in some species, and ultrastructural evidence for a vesicular transport pathway has been obtained (Bendayan *et al.*, 1990). Although these studies suggest that transepithelial transport is highly selective, membrane-adherent proteins may be carried along.

### D. Endocytosis and Transport of Cholera Toxin

Certain adherent proteins may be particularly efficient in entering apical endocytic or transcytotic pathways. Cholera toxin is of particular interest in this regard since, unlike most luminal antigens, it binds with high affinity to membrane glycolipid GM1, is endocytosed efficiently, and has profound effects on enterocyte physiology. Using confluent monolayers of polarized T84 cells in culture, Lencer *et al.* (1992)

demonstrated that endocytosis and probably transport of cholera toxin beyond early apical endosomes is required for activation of basolaterally located adenylate cyclase and the resultant chloride secretory response. Others had demonstrated that cholera toxin enters a transepithelial transport pathway in enterocytes *in vivo* (Hansson *et al.*, 1984). Thus, vesicular transport in enterocytes could have important physiological consequences, and endocytic or transcytotic pathways could play a role in the unique modulatory action of cholera toxin in the mucosal immune system (Lycke and Holmgren, 1986; Czerkinsky *et al.*, 1989; Dertzbaugh and Elson, 1991). In addition, cholera toxin has been shown to enhance endocytic activity in other cell types. If this occurs in enterocytes, uptakes of bystander antigens also might be enhanced.

## IV. ANTIGEN-PRESENTING COMPLEXES AND ENTEROCYTE MEMBRANE TRAFFIC

Expression of MHC Class I and II molecules by epithelial cells of the small intestine is both constitutive and cytokine regulated (Bland and Kambarage, 1991). These complexes, which act as receptors for protein antigens, are encoded by the MHC locus. As on all other cells, enterocyte MHC I consists of a highly polymorphic A chain noncovalently associated with  $\beta 2$  microglobulin (for review, see Yewdell and Bennink, 1990). The MHC II complexes on enterocytes are assumed to be identical to those found on "professional" antigen-presenting cells such as B lymphocytes, macrophages, and dendritic cells, consisting of two highly polymorphic transmembrane polypeptides. The assembly of these complexes along the biosynthetic pathway and their interaction with peptides in intracellular compartments has been elucidated greatly by studies on nonpolarized cells. However, how cell polarity and the existence of two separate endocytic pathways might influence their function in intestinal epithelial cells is not yet clear. Further, the access of MHC on epithelial cells to specific T-cell populations may be restricted by the presence of a basal lamina and by the migration patterns of specific T-cell subsets.

### A. MHC I

In enterocytes, MHC Class I determinants are resident noncycling molecules that are restricted to the basolateral membrane (Godefroy *et al.*, 1988), where they could interact readily with CD8<sup>+</sup> IELs. The peptides presented to IELs in the context of MHC I probably would originate in the cytosol of the epithelial cell and might represent, for example, newly synthesized viral proteins. These proteins would be degraded by cytoplasmic proteasomes and the resultant peptides transported into the lumen of the endoplasmic reticulum, probably via transporters that belong to the ABC ATPase family (Spiess *et al.*, 1990). Note that interferon  $\gamma$  (IFN $\gamma$ ), a cytokine that can induce MHC expression in many cells including enterocytes (Bland and Warren, 1986), also up-regulates proteasome production and that protea-

some genes are located adjacent to the MHC region (Brown *et al.*, 1991; Glynn *et al.*, 1991). These peptides thus would associate with newly synthesized MHC Class I determinants in a compartment that also contains MHC Class II molecules, but the latter would be prevented from binding antigen at this point by the presence of the invariant chain (Roche and Cresswell, 1990). Membrane proteins destined for the basolateral cell surface of enterocytes apparently are sorted into vesicles in the trans-Golgi cisternae, and travel directly to the basolateral membrane (Hauri *et al.*, 1985; Matter *et al.*, 1990). Thus, newly synthesized MHC I determinants on infected or damaged enterocytes would induce lysis by intraepithelial CD8<sup>+</sup> T cells, which also would result in production of specific cytokines that might in turn affect epithelial cell proliferation and repair.

### B. MHC II

MHC II determinants have been visualized by immunocytochemistry on basolateral surfaces as well as in intracellular vesicles and on apical membranes of intestinal cells (Mayrhofer and Spargo, 1989, 1990). In nonpolarized cells (and presumably in enterocytes), Class II molecules are synthesized and assembled in the rough endoplasmic reticulum as heterotrimers that include an additional polypeptide, the invariant chain (Brodsky *et al.*, 1989). This complex travels along the secretory pathway to the Golgi, where it may be segregated spatially from MHC Class I molecules (Peters *et al.*, 1991). Whether the MHC II in enterocytes is sorted initially into the apical or basolateral secretory pathway (or both), or whether it initially enters polarized endosomes, is not known. This information will be important in determining whether MHC II picks up lumenally digested antigens or peptides that have "leaked" into the interstitium.

In nonpolarized cells, MHC II enters endosomes on its way to the cell surface (Lotteau *et al.*, 1990; Peters *et al.*, 1991) where a distinct endosomal protease cleaves the invariant chain, exposing the antigen-binding cleft (Brodsky and Guagliardi, 1991). Antigens are taken up by adsorptive or fluid-phase endocytosis into common endosomes and are partially digested by endosomal proteases. The resultant peptides then are able to bind to MHC II and are transported as a complex to the cell surface, where the peptide may be presented to T helper cells that express CD4. In the intestine, how frequently enterocyte basolateral MHC II actually would interact with lamina propria CD4<sup>+</sup> lymphocytes is unclear since these cells generally are found in the lamina propria but not within the epithelium (Brandtzaeg *et al.*, 1988). Both luminal and interstitial antigens could gain access to newly synthesized MHC II if the complex is sorted in both directions, but where antigen-MHC II interaction actually occurs in enterocytes is not known. Both endocytic paths meet at the late endosome in enterocytes, but in some cells MHC II is not present in late endosomes (Peters *et al.*, 1991). The inability of isolated enterocytes *in vitro* to process proteolytically and to present intact proteins suggests that predigestion by proteases in the lumen or by other cell types in the lamina

propria is required (Bland and Warren, 1986). Luminal digestion also would require movement of peptide fragments or MHC II-peptide complexes through the apical-to-basolateral transepithelial transport pathway, a phenomenon that has been suggested but not yet proven to occur. Studies on isolated cells are complicated by the fact that the membrane domains and basolateral endocytic systems of enterocytes are altered rapidly and dramatically after epithelial isolation (Amerongen *et al.*, 1989). Thus, patterns of endocytosis, transport, and proteolysis that occur *in vivo* might not be reproduced by isolated cells.

MHC receptors may mediate several distinct functions in the intestinal epithelium. As noted earlier, enterocyte MHC may restrict antigen presentation *in vitro* (Bland and Warren, 1986; Mayer and Shlien, 1987; Kaiserlain *et al.*, 1989; Pang *et al.*, 1990; Mayer *et al.*, 1991), but no direct evidence is available as yet that antigens absorbed *in vivo* actually are processed and presented to intraepithelial lymphocytes. The small intestine can act as a primary lymphoid organ specifying both the immunoglobulin (Reynaud *et al.*, 1991) and the T-cell repertoire (Guy-Grand *et al.*, 1991). Thus, epithelial MHC molecules also may have an educational role, permitting positive selection of those lymphocytes that recognize "self" MHC molecules. The early development of epithelial and lamina propria cells expressing MHC II, and the early presence of thymus-independent intraepithelial T lymphocytes expressing T cell receptor complexes (TCR) ( $\alpha\beta$  or  $\gamma\delta$ ), suggests that MHC II-positive enterocytes and lamina propria cells cooperate to restrict the diversity of responses to self-antigens in the fetus and to bacterial or food antigens in the neonate. The IELs in the general intestinal epithelium are distinct from those in the follicle-associated epithelium over organized lymphoid tissue such as Peyer's patches (Brandtzaeg *et al.*, 1988; Ermak *et al.*, 1990). These lymphoid cell populations are likely to be organized to respond to transport of different types of antigens by enterocytes or M cells, or to induce very different responses (such as secretory immunity or tolerance) to the same antigen. The dramatic differences observed in epithelial membrane traffic in enterocytes and M cells presumably play a central role in these responses.

## V. MEMBRANE TRAFFIC IN INTESTINAL M CELLS

### A. Adherence of Macromolecules to M Cell Apical Membranes

Studies using various soluble tracers and inert particles have demonstrated rapid endocytosis and transcytosis by M cells (Bockman and Cooper, 1973; Owen, 1977; Lefevre *et al.*, 1978; Pappo and Ermak, 1989). These data suggest that uptake is nonselective, but that the hydrophobicity of particle surfaces could enhance their interaction with M-cell surfaces. Avid binding of cationized ferritin to these cells shows that simple electrostatic interactions also could play a role in binding of bacteria and inert particles (Bye *et al.*, 1984; Neutra *et al.*, 1987). Although these mechanisms clearly play

roles in M-cell uptake they do not explain the M-cell selectivity of binding often observed, since both M-cell and enterocyte surfaces are rich in negatively charged carbohydrates. However, indirect evidence suggests that unique protein, glycoprotein, or glycolipid components are exposed on these cells since certain microorganisms bind selectively to M cells with high efficiency.

Adherent particles, microbes, or macromolecules are concentrated effectively by adherence and may be transcytosed by M cells up to two orders of magnitude more efficiently than nonadherent materials (Neutra *et al.*, 1987). Since adherent antigens tend to elicit strong secretory (and often systemic) immune responses (DeAizpurua and Russell-Jones, 1988) and these responses appear to be initiated in sites such as Peyer's patches, M cell adherence is thought to be a key event in induction of mucosal immunity. M cells also endocytose and transport solutes in the fluid content of endocytic vesicles (Owen, 1977); perhaps transport of very small aliquots of soluble antigens over time may play a role in immune tolerance to soluble food antigens (Mayrhofer, 1984). The exact relationship of M cell transport activity to either mucosal or systemic tolerance, however, is not clear.

### B. Adherence of Microorganisms to M Cells

The pathogenic viruses that adhere selectively to M cells could provide information about the unique features of the M cell apical membrane, but the interacting viral and M cell surface molecules responsible for adherence are not yet identified. The best-known example of M cell-specific adherence is provided by the mouse pathogen reovirus (Wolf *et al.*, 1981). Processing of reovirus by proteases in the intestinal lumen is known to increase viral infectivity through cleavage of the major outer capsid protein  $\sigma 3$  and through a conformational change resulting in extension of the viral hemagglutinin  $\sigma 1$  (Bass *et al.*, 1988; Nibert *et al.*, 1991). Our laboratory has demonstrated that proteolytic processing of the outer capsid also is required for M cell adherence: neither unprocessed virus nor capsidless cores can bind (H. Amerongen, G. Wilson, B. Fields, M. Neutra, unpublished observations). Thus, the virus uses either the protease-resistant outer capsid protein  $\mu 1c$  or the extended  $\sigma 1$  protein to bind to M cells, presumably at a site not involved in serotype-specific cell tropism. M cell binding might be mediated by sialic acid residues, since sialylated glycoproteins serve as viral receptors on other cell types (Paul *et al.*, 1989) and M cell surface components avidly bind wheat germ agglutinin (Neutra *et al.*, 1987). These and other viral adhesins, once identified, could serve as affinity ligands to elucidate the M cell molecules or oligosaccharides responsible for the interaction (Bass and Greenberg, 1992). Studies of other viruses that adhere to M cells, including the neurotropic poliovirus (Siciński *et al.*, 1990) and the retrovirus HIV-1 (Amerongen *et al.*, 1991), are needed to determine whether common molecular motifs are used for M cell binding.

The wide range of gram-negative bacteria that bind selectively to M cells includes *Vibrio cholerae* (Owen *et al.*, 1986b;

Winner *et al.*, 1991), some strains of *Escherichia coli* (Inman and Cantey, 1983), *Salmonella* (Kohbata *et al.*, 1986), and *Shigella* (Wassef *et al.*, 1989). That each organism utilizes a unique type of binding mechanism seems unlikely, since M cells seem to be designed to capture whole classes of pathogens for immunological sampling. Lectin-carbohydrate recognition systems are widely used by bacteria to interact with eukaryotic cells, so these also may operate in M cell adherence. The participating lectin could be a bacterial adhesin such as a pilus or fimbrial protein, or an M cell membrane protein analogous to the mannose or galactose recognition proteins of hepatocytes and macrophages. These possibilities have proven difficult to test in the absence of a system for culture of polarized functional M cells.

Selective M cell adherence could be caused not by the presence of M cell-specific proteins but by the absence of "blocking" molecules. The possible blocking effect of the enterocyte glycocalyx was demonstrated in our laboratory using cholera toxin, a molecule that binds specifically to the glycolipid receptor GM1 that is present on apical membranes of M cells as well as enterocytes. When cholera toxin was applied to Peyer's patch mucosa as single toxin molecules tagged with a fluorescent probe, it bound to all cell surfaces as expected. When the toxin was applied as polyvalent complexes on 15-nm colloidal gold particles, however, the particles failed to bind to enterocytes but still bound avidly to M cells (R. Weltzin, H. Amerongen, W. Lencer, and M. Neutra, unpublished observations). These results suggest that the thick glycocalyx of enterocytes prevents movement of the colloidal gold probe to GM1 binding sites on microvillar membranes, whereas M cell GM1 is more accessible. Since viruses and bacteria also can be considered particulate polyvalent ligands, they too may find their receptors particularly accessible on M cells.

### C. Binding of Immunoglobulins

M cells also have binding sites for immunoglobulins on their apical membranes. Native milk secretory IgA ingested by suckling rabbits accumulates on M cell surfaces (Roy and Varvayanis, 1987). In studies in our laboratory, monoclonal IgA or polyclonal sIgA as well as IgG antibodies were found to bind selectively to M cells and to compete with each other for binding sites (Weltzin *et al.*, 1989). Binding of immunoglobulins appears not to be mediated by known Fc receptors, since antibodies against epithelial and macrophage Fc receptors of other types failed to recognize any M cell component. This binding mechanism would allow M cells to endocytose and transport free IgA as well as IgA-antigen complexes (Weltzin *et al.*, 1989). The role of such transport is not clear; one possibility is that it promotes reuptake of small amounts of antigen into inductive sites. These antigens then might be sampled by intraepithelial or subepithelial antigen-presenting cells to boost an existing secretory immune response. Uptake of IgA also could have other modulatory effects in the mucosal immune system (Kraehenbuhl and Neutra, 1992a; also see Chapter 34).

### D. Mechanisms of Antigen Uptake by M Cells

Adherent macromolecules such as cationized ferritin and lectins are taken up by M cells via clathrin-coated pits and are delivered to tubulovesicular structures in the apical cytoplasm that bear morphological resemblance to early endosomes (Neutra *et al.*, 1987). Early endosomes of other cell types contain a subset of lysosomal enzymes (Diment and Stahl, 1985; Courtoy, 1991). Endosomes of most cells generate an acidic internal milieu (Maxfield and Yamashiro, 1991), although specialized apical endosomes of some epithelial cells were found to be pH neutral (Lencer *et al.*, 1990). In M cells, acid phosphatase-containing compartments were not detected in the apical transepithelial pathway (Owen *et al.*, 1986b), but one study has shown that M-cell endosomes are acidified and that some apical vesicles bear a membrane marker typical of late endosomes and lysosomes (Allan *et al.*, 1992). Viruses appear to be unaltered during transepithelial transport (Wolf *et al.*, 1981; Amerongen *et al.*, 1991). However, whether M cell apical endosomes contain endosomal hydrolases is not known. These enzymes are potentially important because if immunogens are processed by partial proteolysis in the transepithelial pathway, such alteration could affect the specificity of the subsequent mucosal immune response. Whether M cells are able to "present" foreign antigens to cells of the immune system has been controversial, because MHC Class II molecules were detected by immunocytochemistry in rat M cells but not in other species. EM immunocytochemistry has revealed that MHC II localize in apical endosomes of rat M cells (Allan *et al.*, 1992), but the functional significance of this localization is not yet known.

Dense "mature" lysosomes are present deeper in M cells (Owen *et al.*, 1986a), but material taken up from the lumen has not been seen to enter this degradative compartment. Also striking is that transcytotic vesicle traffic in M cells is not directed toward the lateral or basal cell surfaces as it is in enterocytes. Rather, either the endosomal vesicles or the vesicles derived from them fuse directly with the modified invaginated basolateral subdomain lining the intraepithelial pocket (Owen, 1977; Neutra *et al.*, 1987). The "pocket" membrane differs from other areas of the basolateral plasma membrane because it contains very low amounts of Na<sup>+</sup>, K<sup>+</sup>-ATPase (Neutra *et al.*, 1986) and presumably contains adhesion molecules that serve as homing sites for a special subpopulation of lymphocytes (Ermak *et al.*, 1990). The nature of the pocket subdomain and the mechanisms by which endosomes are targeted directly to it are important areas for future study.

The exact mechanism of uptake of adherent particles, viruses, and bacteria by M cells also deserves further scrutiny. Bacteria are taken up by a process that resembles phagocytosis in macrophages. *Vibrio cholerae*, for example, forms broad areas of close interactions with M cells in which the bacterial and eukaryotic cell membranes are separated by a 10- to 20-nm gap under which cytoplasmic actin is reorganized (J. Mack, M. Mekalanos, and M. R. Neutra, unpublished observations). This result implies that specific M cell membrane components are recruited to the interaction site. Evi-

dence from macrophages and nonpolarized cells suggests that adhesion molecules provide direct or indirect links to cytoskeletal elements and to the intracellular signaling machinery that may control local calcium flux (Odin *et al.*, 1992). For bacteria or viruses, which microbial gene products and which M cell membrane components play roles in binding and internalization are not known. The fact that adherent bacteria, viruses, and some macromolecules are released readily into the pocket at the basolateral side implies that initial binding may be accomplished through multiple low affinity interactions that can be reversed by a shift in ionic strength or pH, raising the possibility that the membranes of transport vesicles or the intraepithelial pocket may conduct active transport of protons or other ions.

## VI. CONCLUSION

Design of new mucosal vaccines and rational strategies for enhancing tolerance to mucosal immunogens may be facilitated by a clearer understanding of transepithelial transport by both M cells and enterocytes. Such advances will require more information about the basic mechanisms that direct endocytosed antigens into enterocyte transepithelial pathways and about the nature of the interactions of such antigens with epithelial membrane proteins and with subepithelial and intraepithelial cells. In the case of the M cell, an important goal is elucidating the mechanisms of adherence of the pathogens that efficiently invade at this site and exploiting this information to produce "pseudopathogens" that can serve as efficient oral vaccines.

### Acknowledgments

We thank the current and former members of our laboratories, especially R. Weltzin, J. Mack, L. Winner, H. Amerongen, P. Michetti, F. Apter, W. Lencer, R. Hirt, and E. Schaerer, who contributed to the published and unpublished work discussed in this chapter.

# Mucosal Barrier

Ian R. Sanderson • W. Allan Walker

## I. INTRODUCTION

The primary function of the small intestine is to absorb nutrients into the circulation (Field and Frizzell, 1991). During the course of this activity, the intestine is exposed to a wide variety of antigens derived from foods, resident bacteria and invading microorganisms. These antigens must be limited by a barrier that will allow absorption of nutrient molecules. In addition, the intestine transports macromolecules that are important in growth and development, for example, epidermal growth factor (EGF; Weaver and Walker, 1988; Weaver *et al.*, 1990; Carpenter and Wahl, 1991) and maternal IgG (Rodewald and Kraehenbuhl, 1984; Simister and Rees, 1985). Thus, any mechanism that acts as a barrier must also allow entry of physiologically important molecules the size of which is comparable to that of many antigens.

The lumen of the intestine is capable of harboring harmful microorganisms (Snyder, 1991); to mount an immune response against these potential pathogens, the mucosal immune system must survey antigens in the lumen. Evidence suggests that immunosurveillance by the small intestine depends on transport of antigens across the gut (Winner *et al.*, 1991). However, such transport must occur in a controlled manner to avoid harmful immune responses. Nevertheless, at times the control of antigen entry breaks down and this may lead to an excessive influx of antigens, which ultimately may cause disease (Sanderson and Walker, 1993).

### 1. Macromolecular Absorption

To maintain immunosurveillance, antigens are transported across the intestine in physiological amounts, but pathological transport may occur when the mucosal barrier is breached. This barrier consists of two main components (Figure 1). Extrinsic mechanisms will limit the amount of antigen reaching the surface of the intestine. The intrinsic barrier consists of the structural and functional properties of the intestine itself. Both clinical and experimental evidence suggests that antigens traverse the epithelium and enter the circulation (Warshaw and Walker, 1974; Paginelli *et al.*, 1979). For the most part, this transport is not harmful and may, at times, be beneficial.

Production of immunoglobulins directed against luminal antigens depends on immunologically intact antigen interacting with membrane-bound immunoglobulins on the surface of B cells that are located beyond the intestinal epithe-

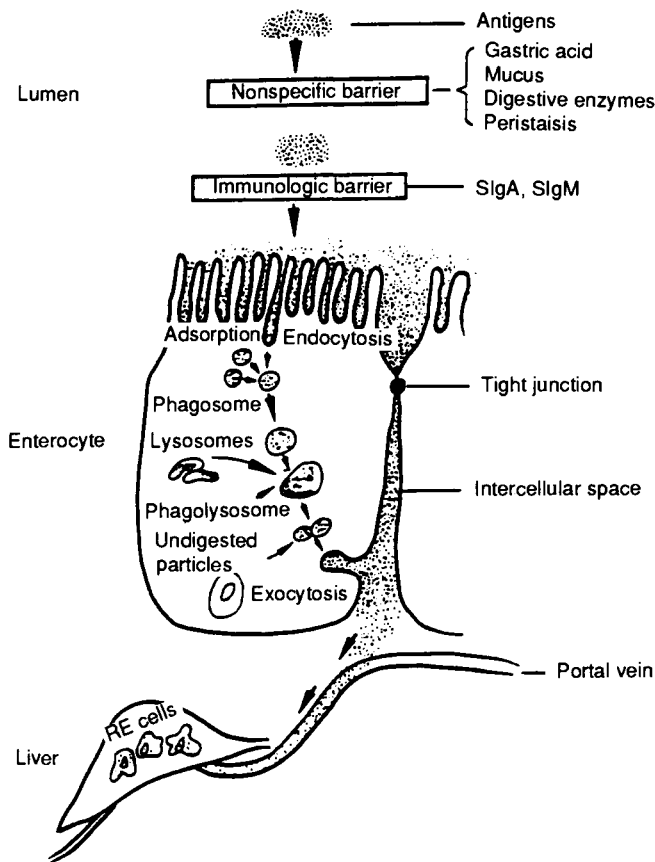

lium (Elson *et al.*, 1986; Kagnoff, 1989). Mechanisms that allow passage of antigen through the intestinal epithelium in controlled amounts are, therefore, an essential prelude to B-cell activation.

T-cell responses, on the other hand, are initiated by presentation of short peptides bound to major histocompatibility complexes (MHC; Unanue, 1984). Since luminal antigen can activate mucosal T cells (as occurs, for example, in celiac disease; Marsh, 1992), the intestine must process luminal antigen to peptides of the correct size to bind to MHC molecules and, in turn, interact with T-cell receptors. Antigens could be processed in two ways by the intestine: first, peptide fragments could be generated during epithelial transport; second, antigen could be processed from whole antigen that has traversed the epithelium and reached antigen-presenting cells in the mucosal immune system. In either case, uptake of antigen by the epithelium is essential. Moreover, the pathway by which the antigen or its product reaches the immune system of the gut may affect critically the type of immune reaction that ensues. Thus, an understanding of the mechanisms by which antigen is handled is central to the study of the mucosal immune response.

## II. PHYSIOLOGIC TRANSPORT

Sampling of luminal antigen by the mucosa is likely to be a physiological phenomenon that will result in appropriate immune responses by the gut. These responses will include the local production of secretory IgA and mechanisms that lead to oral tolerance (Thompson and Staines, 1991). Such reactions are beneficial and are described in other chapters of this volume. At times, however, excessive antigen crosses the intestine, causing more widespread immune reactions. These reactions could result in gastrointestinal disease or even systemic illness (Sanderson and Walker, 1993).

Macromolecules cross intestinal epithelial cells in two ways of which we can be certain: they can be shuttled through absorptive cells on specific receptors, in which case only those macromolecules that bind to a receptor will pass, or they can pass through specialized epithelial cells called M cells (Chapter 2). An additional possibility is that antigenic fragments cross epithelial cells for presentation by MHC Class II molecules at the basolateral surface. Definitive evidence for this mode of uptake is still awaited, but this would constitute a third form of macromolecular transport.

**Figure 1** Barriers to macromolecular absorption. Antigen entry is prevented by nonspecific and immunologic mechanisms in the gastrointestinal tract as well as by the physical structure of the epithelium itself. ## 1. Receptor Bound Transport

Most of the macromolecules that are required for transport can be made *de novo*; however, this is not always the case. For example, certain growth factors including EGF, transforming growth factor  $\alpha$  (TGF $\alpha$ ), and nerve growth factor (NGF) are all polypeptides that are transported across the intestine (Chu and Walker, 1991). IgG also can be transported across the intestine at times (Simister and Rees, 1985). The newborn makes very little immunoglobulin, so most circulating antibody is IgG derived passively from the mother. In humans, IgG is transferred primarily by the placenta during late gestation, whereas in many animals the transfer occurs from maternal milk through the proximal small intestine. The transfer of IgG across the gut is mediated by receptors that are similar to those present in human placenta (Sedmark *et al.*, 1991). These receptors bind the Fc portion of the immunoglobulin molecule.

Macromolecules are transferred by a mechanism that is altogether different from those that transport nutrients such as glucose and amino acids. Nutrient molecules enter the intestinal cell cytoplasm at the apical membrane and exit the

basolateral membrane. Macromolecules, on the other hand, transverse the cell (Figure 2) in membrane-bound compartments that invaginate from the apical membrane. The first step in this process is attachment to receptors on the apical surface of enterocytes.

In young mice, maternal IgG absorption shows features characteristic of membrane-receptor transport: IgG is absorbed selectively (Jones and Waldmann, 1972; Guyer *et al.*, 1976) and its absorption shows saturation kinetics (Brambell, 1966). Binding is pH dependent, occurring at pH 6.5 but not at pH 7.4 (Rodewald, 1976). Since the contents of the upper jejunum are at low pH, the conditions are ideal for binding (Jones and Waldmann, 1972). Moreover, intracellular membrane and components are acidic, so binding would be maintained after invagination of surface membrane and formation of vesicles (Abrahamson and Rodewald, 1981). The IgG receptor has been isolated, its gene has been cloned, and the nucleic acid sequence has been determined. From this sequence, the amino acid sequence has been deduced (Mostov and Simister, 1985). This receptor is a molecule homologous to MHC Class I molecules and is bound in its active form to  $\beta_2$  macroglobulin. Despite the homology, the two molecules have very different functions and their assembly is different.

The mechanisms involved in the transit of membrane-bound ligands to the basolateral pole of the enterocyte are still poorly understood. In electron microscopic studies, the apical membrane of absorptive cells can be seen invaginating to form endosomes (Figure 2). On the inner aspect of these developing membrane compartments appear to be regular arrays of clathrin (Shibata *et al.*, 1983; Gonnella and Neutra, 1984; Knutton *et al.*, 1974), a protein designed to form lattices around membrane vesicles. Clathrin has a central role in the

**Figure 2** Macromolecular endocytosis in enterocytes. Plasma membrane between microvilli invaginates to form vesicles. Clathrin, a protein that forms a membrane lattice, controls the curvature of the membrane. Macromolecules can enter the vesicle bound to surrounding membrane by a particular receptor or by nonspecific attraction; they also can enter free in solution. After entry, the molecules move to the tubulocysternae where they are sorted and pass either to vesicles that travel toward the lysosome or to vesicles that traverse the cell to the basolateral pole. Membrane bound molecules are more likely than those in solution to traverse the cell. [Reprinted with permission from Sanderson and Walker (1993). Copyright © 1993 by American Gastroenterology Association.]

budding and fusion of membrane vesicles (Brodsky, 1984). In particular, clathrin assembly at the surface membrane of cells promotes the endocytosis of external receptors (Steinman *et al.*, 1983).

Transit further into the cell may occur by the movement of separated vesicles (Figure 2). Hopkins and colleagues (1990) have challenged this concept and favor a single transport compartment called the endosomal reticulum that extends from the cell surface. The shape and movement of these intracellular compartments will depend on the structural proteins that make up the cytoskeleton of the cell.

The Fc receptor is able to move across the epithelial cell. This transcytosis occurs in both directions. The receptor is carried with the membrane trafficking from lumen to serosa and returns by another membrane transport mechanism. Some membrane proteins contain specific amino acid sequences that direct the protein within the cell, for example, the polymeric IgA receptor (Casanova *et al.*, 1991) that transports IgA from the basolateral membrane to the apical membrane. However the amino acid sequences that determine the movement of the Fc receptor have not been elucidated.

Transfer of maternal IgG in the neonatal rodent falls markedly at weaning (after 21 days of age, a phenomenon known as closure). This event is now known to be caused by the decrease in the expression of the Fc receptor gene (Mostov and Simister, 1988). Thus, factors in breast milk may affect Fc receptor gene expression. The Fc receptor has been detected in humans in the placenta, and transfers maternal immunoglobulin *in utero* during the later stages of gestation. An observation by Israel and colleagues (1993) suggests that the Fc receptor may be present on small intestinal epithelium in the first trimester and may function early in the transfer of maternal IgG from amniotic fluid to the fetus.

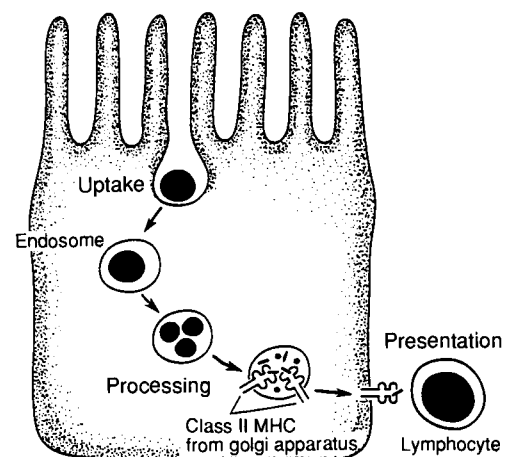

## 2. Cells Specialized for Macromolecular Transport

Generation of secretory immune responses by the intestinal mucosa depends on transfer of antigens across the epithelium. Any loss of the molecular structure of the antibody recognition sites (the epitopes) during transport would render them unrecognizable by B cells. The passage of intact macromolecules across the gut is at variance with the role of the gut as a macromolecular barrier. For macromolecules to cross the gut in a controlled manner, specialized epithelial cells have evolved that overlie lymphoid follicles (Bockman and Cooper, 1973; Owen, 1977). These "M" cells, discussed in detail in Chapters 2 and 3, have features that facilitate controlled entry of antigens and larger particles through the intestinal epithelium.

## 3. Enterocytes as Antigen-Presenting Cells

Effective immune responses to antigenic proteins require the help of T lymphocytes. Stimulation of T cells, in turn, depends on exogenous antigen being presented by antigen-presenting cells (APCs; Unanue, 1984). The APC must internalize, digest, and link a small fragment of the antigen to a surface glycoprotein (the MHC Class II or HLA-D in humans) that interacts with a T-cell receptor. A number of cells of

the immune system can act as APCs including B cells, macrophages, and dendritic cells. The ability of these cells to present antigen depends on the expression of MHC Class II molecules on their surface (Unanue, 1984). MHC Class II determinants are also present in epithelia of the normal small intestine, particularly on villous cells, in humans (Wiman *et al.*, 1978) and in rodents (Kirby and Parr, 1979). *In vitro* studies (Bland *et al.*, 1986; Mayer and Shlien, 1987; Kaiserlian *et al.*, 1989) have demonstrated that isolated enterocytes from rat and human small intestine can present antigens to appropriately primed T cells, raising the possibility that, in the intestine, MHC Class II molecules might present peptides from cellular membrane compartments to cells of the immune system that are localized below the epithelium. In support of this concept, MHC Class II molecules have been detected in adult rat jejunum villi in association with intracellular organelles (Mayrhofer and Spargo, 1990). Class II molecules were not detected in microvillus brush border or in vesicles at the base of microvilli. However, organelles below the terminal web and throughout the apical cytoplasm were stained specifically. Basolateral membranes clearly showed MHC Class II molecules. These molecules are, therefore, in an ideal position for binding with polypeptides that may have been taken up by and processed within the epithelial cell (Figure 3). Interestingly, the expression of MHC Class II molecules in the gastrointestinal epithelium is increased in a number of diseases. In Crohn's disease (Selby *et al.*, 1983; Mayer *et al.*, 1991), enhanced expression occurs on enterocytes from inflamed areas. Moreover, the effect of enterocytes from inflamed tissue is to stimulate helper T lymphocytes (Mayer and Eisenhardt 1990). Increased expression of MHC Class II molecules is also evident in the small intestine

**Figure 3** Model of antigen presentation by enterocyte. Macromolecules can enter membrane-bound organelle of the enterocyte. Instead of binding to the surrounding membrane or being destroyed in lysosomes, antigen is processed within the endosomal component into fragments that can bind to Class II MHC on the inner membrane of the components. Then antigens are presented on the basolateral surface of the cell. Prepared with the help of L. Mayer. [Reprinted with permission from Sanderson and Walker (1993). Copyright © 1993 by American Gastroenterology Association.]

in patients with autoimmune enteropathy (Hill *et al.*, 1991) and in graft-versus-host disease (Mason *et al.*, 1981). Certain gastrointestinal infections increase MHC Class II expression, for example, in the stomach infected with *Helicobacter pylori* (Engstrand *et al.*, 1989) and in the intestine infested with nematode parasites (Masson and Perdue, 1990). If MHC Class II molecules transport peptides derived from luminal macromolecules, these diseases will lead to an increase in the presentation of these peptides to the gastrointestinal immune systems, which may cause further inflammation and further presentation of luminal antigens, leading to a vicious cycle. Some drugs used to treat inflammatory bowel disease reduce Class II expression in epithelial cells. 5-Aminosalicylic acid (5-ASA), for example, reduces the MHC Class II expression that occurs in cultured cells that express MHC Class II in response to interferon  $\gamma$  (Crotty *et al.*, 1992).

### III. BARRIERS PREVENTING PATHOLOGICAL TRANSPORT

Physiological passage of macromolecules is essential for the development of immune responses by the intestine, but uncontrolled penetration of antigens could initiate pathological processes that lead to gastrointestinal disease states. For antigen transport to be controlled, nonspecific entry into the circulation must be limited. This limitation is accomplished in two ways: first, by restricting the amount of antigen reaching the surface of the intestine (extrinsic barrier) and, second, by the physical characteristics of the intestine itself (intrinsic barrier) (Figure 1).

Many barrier mechanisms are not fully developed at birth. Evidence suggests that antigen transport in the neonatal period is less restricted than in adults. In animals, the changes in antigen absorption from the newborn to the adult are particularly evident, a phenomenon known as closure. Initially, the phenomenon was applied to the transport of immunoglobulins (Brambell, 1966), but significant changes in absorption have been documented for antigens that do not have specific transport receptors. Radiolabeled bovine serum albumin (BSA; Udall *et al.*, 1981a) was fed in physiological amounts to rabbits at birth and at 1 week, 2 weeks, 6 weeks, and 1 year of age and the plasma radioactivity measured. The study was designed to insure that the radioactivity measured corresponded to protein absorption. From 1 week of age, a marked fall in the transport of BSA across the intestine was detected. Moreover, in a later study (Udall *et al.*, 1981b) the development of the mucosal barrier was found to depend on the type of feeding during the neonatal period. Naturally fed (breast-fed) rabbits had lower plasma BSA levels than did formula-fed rabbits, suggesting that breast milk affects the development of the mucosal barrier. In this chapter, we review how different components of the barrier develop, particularly since a fall in antigen absorption has been demonstrated in humans also. Milk protein penetrates more readily in infants than in adults. In one study,  $\alpha$ -lactalbumin absorption decreased with age in breast-fed babies (Axelson *et al.*, 1989).

In a second study, formula-fed neonates had greater levels of  $\beta$ -lactoglobulin (BLG) than older infants (Robertson *et al.*, 1982).

#### A. Extrinsic Barrier

##### 1. Proteolysis

Antigen access to the epithelium will be limited in many ways (Figure 1). Proteolysis will destroy the structure of antigens and thus destroy epitopes for immunological recognition. Altering the proteolytic capacity of the gastrointestinal tract affects macromolecular uptake. In everted gut sacs (Walker *et al.*, 1975) of rats who had previously undergone ligation of the pancreatic duct, transport of horse radish peroxidase (HRP) was greater than in sacs from sham-operated animals. Further, prior feeding with pancreatic extract decreased the uptake of HRP. The effects of digestion on macromolecular uptake have been confirmed elegantly by feeding rats aprotinin (a trypsin inhibitor) with lysine vasopressin (Saffron *et al.*, 1979). This peptide hormone, when fed orally, is absorbed through the intestine in sufficient quantities to have a noticeable effect on fluid retention. When given with aprotinin, however, the effects of vasopressin are more marked, implying that more has reached the surface of the intestine because of reduced proteolysis.

Experiments show that neutralizing gastric acidity (which reduces the activity of gastric enzymes) also increases antigen transport. Sodium bicarbonate given to rats orally with BSA increases BSA found in the gut (Walker *et al.*, 1975). These findings have important consequences because deficiencies of pancreatic enzymes occur in various diseases. In cystic fibrosis, in which pancreatic activity is affected severely, an increased incidence of cow milk allergy is seen, presumably because of increased antigen uptake. Also, gastric acidity (Hyman *et al.*, 1985) and pancreatic activity (Lebenthal and Lee, 1982) may be less in the newborn, which may have consequences for the development of the mucosal barrier.

##### 2. Peristalsis

The time available for absorption will depend on the speed of luminal contents down the bowel. A common experience in clinical gastroenterology is that uptake of nutrients in patients with limited absorptive capacity (for example, in short bowel syndrome) is improved by reduced intestinal motility with agents such as loperamide (Remington *et al.*, 1983), providing good reason to believe that antigen absorption also will be limited by peristaltic action. An association between motility and antigen absorption has important implications. First, motility patterns change in development (Bisset *et al.*, 1988), which may contribute to alterations in antigen uptake with age. Second, gastrointestinal disease can affect the motility of the intestine (Mayer *et al.*, 1988) and may result in changes in antigen absorption, although such changes may be small relative to the effect that a disease has on the physical barrier created by the intestine itself. Nevertheless, antibody-antigen complex formation in the mucus coat, coupled with peri-

stalsis, causes rapid expulsion of antigens from small intestine (Snyder and Walker, 1987).

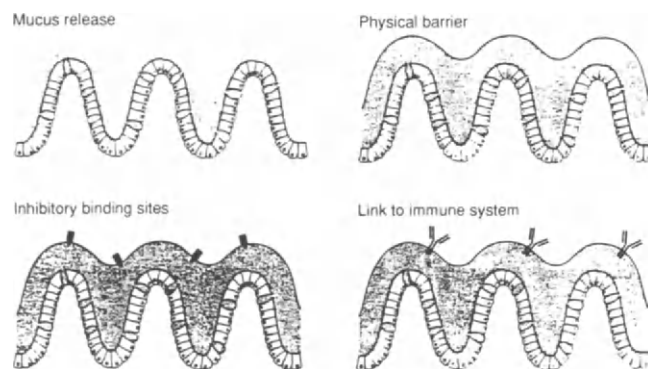

### 3. Mucus Coat

**a. Structure of mucus coat.** The mucus coat lining the intestine is composed of a solution of glycoproteins (mucin) of molecular sizes ranging from one to several million Daltons. Intestinal mucin molecules are made up of carbohydrate side chains (70–80%) bound to a protein skeleton. This protein core has a high proportion of serine, threonine, and proline residues (Forstner, 1978; Allan, 1981); the carbohydrate moieties are attached to it by means of *N*-acetylgalactosamine. Five carbohydrate moieties (*N*-acetylgalactosamine, *N*-acetylglucosamine, fucose, galactose, and sialic acid) are arranged in side chains 2–22 sugars in length.

The exact composition of the molecules of mucin can vary greatly. Clear differences are seen among animal species. Even within localized regions of the intestinal tract, mucus molecules appear to be a heterogeneous group. At least six different mucin species have been identified after separation on DEAE–cellulose chromatography, both from rat and from human (Podolsky, 1985). Each species has distinct carbohydrate and amino acid composition. Marked changes in the composition of mucin occur with development. The mucin from the small intestine of newborn rats contains more protein than does adult rat mucin (Shub *et al.*, 1983). The carbohydrate content also changes as the animals grow. Not only does the total carbohydrate ratio increase with age, but the types of sugar moieties change also: newborn rat mucin has less fucose and *N*-acetylgalactosamine than does mucin from adult rats.

#### b. Function of mucus coat

*i. Viscous coat.* Mucus offers protection to the intestinal wall in a number of ways (Figure 4). First, it provides a mucus blanket. The physical characteristics of this blanket are determined by the chemical structure of the glycoprotein

**Figure 4** Four proposed mechanism for mucus protection: rate and quantity of mucus release, viscous blanket (physical barrier), competitive binding sites, and link to the intestinal immune system. [Reprinted with permission from Snyder and Walker (1981). Copyright © 1981 by Karger.]

molecules themselves. The sticky quality of the mucus is an important mechanism for preventing penetration of organisms. The motility of *Entamoeba histolytica* trophozoites (Leitch *et al.*, 1985), for example, is decreased significantly by mucus. The increased viscosity that mucus provides to the luminal solution enhances the depth of the unstirred layer overlying the surface of the intestine, thus reducing the diffusion of molecules toward the intestinal surface (Strocchi and Levitt, 1991). The effect is most marked for larger molecules, and will limit absorption of antigens rather than nutrient molecules, which are smaller.

*ii. Competitive binding.* The carbohydrate moieties that constitute the majority of the structure of mucus are analogous to the glycoprotein and glycolipid receptors that exist on the enterocyte membrane (Gibbons, 1981). Therefore, they could act as competitors to the binding of proteins and microorganisms at the enterocyte surface. Many infectious agents adhere to epithelial cells through cell-surface appendages (fimbria, pili, and flagella; Freter, 1981) that have carbohydrate binding properties. Indeed, competition between salivary mucus glycoproteins and receptors on buccal epithelium already has been shown for binding of pathogenic streptococci (Williams and Gibbons, 1973). Further, the invasiveness of *Shigella flexneri* in primates, in part, may depend on the lack of barrier function of mucus (Denari *et al.*, 1986). Guinea pig colonic mucus inhibits invasion of HeLa cells by *Shigella*, whereas monkey colonic mucus (and, by implication, human mucus) does not.

*iii. Mucin release.* Release of mucus into the gastrointestinal tract will act as a barrier by generating a stream that draws luminal contents away from epithelial cells. Both nonspecific and immunological agents can initiate mucus release. The role of nonimmunological agents and their relationship to endogenous agents that alter mucus secretion are not well understood (Snyder and Walker, 1987). Cholinergic agents (Specian and Neutra, 1980) and mustard oil (Neutra *et al.*, 1982) cause goblet cell release, but a number of regulatory peptides (including histamine, serotonin, and  $\alpha$ - and  $\beta$ -adrenergic agents; Neutra *et al.*, 1982) had no effect. Nevertheless, immunological phenomena cause goblet cells to release mucus (see subsequent discussion).

### 4. Immunologic Barrier

The adequacy of immune function in the gastrointestinal tract affects the attachment and penetration of bacteria and toxins. This concept was illustrated elegantly (Winner *et al.*, 1991) by implantation of IgA-secreting hybridomas under the skin of infant mice who were then inoculated with cholera. IgA appeared in large amounts in the small intestine as secretory IgA. When hybridomas are implanted that secrete IgA that interacts with the antigen on the surface of *Vibrio cholerae*, mortality from cholera is reduced dramatically.

IgA is also likely to prevent the transfer of antigens across the gut. This hypothesis is supported by studies of patients with selective IgA deficiency. These patients have increased circulating immune complexes and precipitating antibodies to absorbed bovine milk proteins (Cunningham-Rundles *et al.*

*al.*, 1978); peak concentrations occur between 1 and 2 hr after milk ingestion (Cunningham-Rundles *et al.*, 1979).

### 5. Combined Effects of Immunologic and Nonimmunologic Barriers

Both oral and parenteral immunization with specific antigens can reduce their uptake by the intestine (Walker *et al.*, 1972, 1973). These observations may be a combined effect of immunological and nonimmunological components of the mucosal barrier. Proteolysis of intestinal antigens was considerably greater in immunized animal than in nonimmunized controls (Walker *et al.*, 1975). This enhanced proteolysis is likely to be the result of interaction of immune complexes in the mucus coat. This augmented protective process is illustrated in Figure 5.

Another example of combined protection is the increased discharge of goblet cell mucus occurring in intestinal anaphylaxis. Lake and colleagues (1980) have shown, using radiolabeled goblet cell mucus to quantitate release, that IgE-mediated mast cell discharge of histamine results in enhanced mucus release into the intestinal tract, which may explain why parasites eventually are expelled from the intestine in conjunction with mucus (Miller and Nawa, 1979). Figure 4 illustrates possible mechanisms of immune complex-mediated goblet cell mucus release on the intestinal surface.

#### B. Intrinsic Barrier

Once antigens have negotiated the many components of the extrinsic barrier mechanism, a considerable physical barrier to further penetration exists. This barrier is formed by

**Figure 5** Schematic representation of the processing of protein antigen at the surface of the gut. Prior to immunization (*left*), a small portion of ingested protein escapes intraluminal digestion and is taken up by the enterocyte and transported to the intercellular spaces. After immunization (*right*), antibodies present on the gut surface interact with antigen to form complexes, thereby preventing or decreasing the binding of antigen to, and subsequent pinocytosis of antigen by, intestinal epithelial cells. Antigens complexed with antibodies in the mucus coat (glycocalyx) may be degraded by pancreatic enzymes absorbed to the gut surface. Consequently, less antigen is available to intestinal epithelial cells. [Reprinted with permission from Walker *et al.* (1975). Copyright © of the American Gastroenterology Association.]

the surface of the enterocytes and the tight junctions that are formed between the cells. However, this barrier is not impervious to the passage of antigens, as once was thought. The integrity of this barrier often is reduced in diseases of the gastrointestinal tract.

#### 1. Microvillous Structure

Microvilli could constitute a significant barrier because of their size and charge. In the intestinal epithelium of children (Phillips *et al.*, 1979) are 40 microvilli each of diameter 100 nm every 5  $\mu$ m. Thus, if microvilli beat in unison, the distance between them is only 25 nm, which is the same order of magnitude as the dimensions of some macromolecules, for example, albumin at 3  $\times$  13 nm. Microvilli also are negatively charged (they stain easily with ruthenium red; Jacobs, 1983); therefore a charged molecule may be inhibited significantly even if its diameter is less than 25 nm.

The site of invagination of apical plasma membrane has been demonstrated as being between microvilli (Shibata *et al.*, 1983; Gonnella and Neutra, 1984; Knutton *et al.*, 1974). Thus, antigens likely must pass the microvillus "barrier" to enter the cell, a restriction that has direct relevance to disease processes, since any agent that strips off microvilli or affects their formation will alter the barrier function of the intestine. Microvillus structure is altered greatly by infections of cryptosporidia (Phillips *et al.*, 1992) or enteropathogenic *Escherichia coli* (Ulshen and Rollo, 1980).

Additional support for the concept of a microvillous barrier comes from morphological studies on M cells. The function of these cells is macromolecular transport. Unlike absorptive cells, they do not have well-developed microvilli. Since every morphological feature of these cells is in keeping with their function, microvilli are likely to constitute a significant barrier.

#### 2. Enterocyte Surface Membrane

At the base of the microvilli, the surface of the enterocyte consists of plasma membrane. As in other cells, this membrane is composed of a lipid bilayer through which are situated membrane-bound proteins. This bilayer presents a considerable barrier to antigen transport because of its physical structure. In fact, that antigens can cross this lipid bilayer into the enterocyte cytosol is very unlikely. However, invagination of apical membranes occurs regularly, allowing macromolecules to be carried into the cell within membrane-bound compartments (Figure 2). Indeed, a large number of compartments exists beneath the apical surface of the enterocyte into which antigens can be transferred. Some of this activity is physiological and has been described in an earlier section; however, bystander molecules can be carried into the cell by this process, as was demonstrated clearly in electron micrographs that showed HRP inside membrane-bound compartments (Cornell *et al.*, 1971). Stern and Walker (1984) have shown that binding to the surface of the enterocyte is an important determinant of whether macromolecules are transported across the cell. For both BSA and BLG, absorption was nonsaturable and correlated with binding to the intestinal surface. Membrane-bound macromolecular transport can be distinguished from molecules moving freely in

the lumen of compartments of the enterocyte (Gonnella and Neutra, 1984) in newborn rat ileum.

Binding to the surface of the cell depends on the structure of the antigen and the chemical composition of the microvillous membrane. Both these factors can vary. The structure of the antigen depends on the actual antigen itself. BSA binds less efficiently to the surface of the intestine than BLG and, consequently, is transported less readily (Stern and Walker, 1984). In addition, structural alterations in antigen caused by proteolysis also might affect its binding, since this activity will change the physicochemical characteristics of the molecule. For example, the gliadin fraction B3 (Stern *et al.*, 1988) binds less well to microvillous membrane protein than the pure gliadin peptide B3142.

The composition of the microvillous membrane has a marked effect on antigen binding. Plasma membrane consists of both lipids and proteins, and changes in either will affect binding to antigen. Partial digestion of microvillous membrane can alter binding to macromolecules (Stern and Gellerman, 1988). Damage to the protein in membranes is unlikely to occur in healthy individuals since the intestinal surface is protected by mucus. However, if the mucus layer is affected by, for example, resident bacteria, some digestion of the surface membrane might occur, leading to increased antigen binding and transport; such an occurrence, however, is probably rare. Changes in lipid composition, on the other hand, are encountered regularly because lipid composition changes with development. Differences in membrane composition can be detected by electron spin resonance (ESR). In this technique, the movements of the lipid-soluble probe can be followed by a spectrophotometer (Pang *et al.*, 1983). Movements of the probe in the membrane of the newborn rabbit were less confined than in membranes from adults, suggesting a more disorganized membrane structure. Indeed, chemical analysis of the membrane (Chu and Walker, 1988) demonstrated changes in the phospholipid headgroups with age, as well as alterations in protein-lipid ratios (Pang *et al.*, 1983). Changes in membrane fluidity noted by ESR were found to correlate with alterations in lectin binding (Pang *et al.*, 1985). These changes were noted to be under hormonal control, since alterations in the fluidity were affected by both cortisone and thyroxine (Israel *et al.*, 1987).

### 3. Intracellular Organelles and Enzymes

Antigens that enter enterocytes from the lumen are affected by a number of different factors that will influence transport to the basolateral surface. Of primary importance is the rate of vesicular passage to the basolateral membrane, which will depend on the rate of endocytosis, the proportion of vesicles being directed toward the lysosome, and the speed of travel of membrane-bound compartments. The rate of breakdown of products held in membrane compartments is determined by lysosomally derived enzymes that include proteases, such as cathepsin B and D, and enzymes that catalyze carbohydrate breakdown, such as acid phosphatase and mannosidase. The degree to which the organellar contents encounter such enzymes determines the rate of intracellular destruction of macromolecules. This encounter can be in the

lysosome or in endocytic vesicles (Dinsdale and Healy, 1982). We know that such enzymes are present in intestinal epithelial cells at levels of activity that can influence macromolecular transport. In the rat (Davies and Messer, 1984), cathepsin B and D activity can be found throughout the length of intestine, particularly in the mid and distal thirds. Interestingly, this activity peaks in the second week of age and then falls progressively. The ontogeny of macromolecular transport (Udall *et al.*, 1981a) in no way reflects this pattern, emphasizing the importance of *interaction* between membrane-bound compartment flow and enzyme activity. This interaction is seen more clearly in the piglet, in which intestinal cathepsin B and D levels do not change with age (Ekstrom and Westrom, 1991) but closure can be demonstrated clearly in the second day of life.

Although cathepsins are capable of destroying macromolecular biological activity, they may not digest the protein molecule completely so the final steps in digestion of peptides may be by peptidases (Vaeth and Henning, 1982) in the cytoplasm.

### 4. Junctions between Cells

The physical barrier that prevents penetration of antigen across the intestinal epithelium consists of two main components: the epithelial cells (the transcellular route) and the spaces between cells (the paracellular route). The pathophysiology of this latter pathway has been reviewed (Powell, 1981; Gumbiner, 1987; Madara, 1989b, 1990). The pathway consists of the tight junctions (or zonulae occludentes) and the subjunctional space.

The subjunctional space does not act as a significant barrier since molecules as large as HRP can diffuse freely between the serosa and this space. However, the tight junctions offer a substantial barrier to diffusion of large molecules, although they are permeable to water and small ions (Frizzell and Schultz, 1972). Claude and Goodenough (1973) demonstrated a correlation between the structure of the tight junction as seen in freeze fracture preparations and passive electrical permeability in a number of epithelial preparations. The preparations, when viewed under the electron microscope, show a network resembling anastomosing strands. The composition of these strands is unknown, but they are likely to be proteins of high tensile strength. In tight epithelia (such as gall bladder), many such strands are seen, whereas in more permeable epithelia (such as mammalian proximal small intestine), few are found. The relationship between strand density and epithelial resistance has been confirmed in intestinal epithelial cells (Madara and Dharmasathaphorn, 1985), T84 cells, grow as confluent monolayers in culture. In the first 10 days after passage, the junctions become increasingly tight, as judged by transepithelial resistance. This resistance was found to correlate with the number of strands formed between cells.

The barrier formed by tight junctions is preserved even when epithelial cells themselves are extruded at the villous tip. The band from the tight junction moves away from the apex down the lateral aspect of the cell as the cell is extruded (Madara, 1990b). Eventually, younger cells beneath the extruding cell form tight junctions at the very moment that the

old cell is lost. Thus, the preservation of the tight junction network is a function with importance that overrides that of epithelial cell viability.

The tight junction is a dynamic structure with resistance that varies with events taking place in the epithelium and intestinal lumen. Changes in paracellular absorption occur during active transport of nutrients by epithelial cells, particularly in relation to smaller molecules. Pappenheimer and colleagues (Madara and Pappenheimer, 1987; Pappenheimer, 1987; Pappenheimer and Reiss, 1987) have calculated that the rate of uptake of molecules smaller than 5500 Daltons from the lumen was proportional to the rate of fluid absorption—a concept known as solvent drag. The application of an alternating current across isolated intestine, with and without mucosa, gave an estimate of the impedance of the intestinal mucosa. The impedance falls with the stimulation of sodium-coupled solute transport across the enterocyte. Therefore, sodium-coupled solute transport may trigger contraction of cytoskeletal elements of the enterocyte, which in turn pulls open tight junctions. These predictions have been confirmed by electron microscopy (Madara and Pappenheimer, 1987). Sodium-dependent transport of solutes such as glucose and amino acids induces expansion of intercellular spaces associated with condensation of microfilaments of the actinomyosin ring associated the tight junction. Although these observations have enormous importance for the physiology of absorption of nutrients, their impact on our understanding of macromolecular transport has yet to be fully assessed. The calculated pore radius of the open tight junction (5 nm) is similar to that of small macromolecules; sodium-assisted glucose transport will, in fact, allow the passage of polypeptides 11 amino acids long (MP-1; Atisook and Madara, 1991) but larger immunogenic proteins may not pass through this route under physiological conditions. HRP, for example, does not pass the tight junction (Atisook and Madara, 1991) even when these junctions have been rendered permeable to MP-1.

However, pathological insults to the intestine may open these pores sufficiently to allow passage of antigens. The macromolecular permeability of the gut in disease models needs to be reexamined using Pappenheimer's methodology. Macromolecular markers of different sizes, charges, and hydrophilicity all have been used independently *in vivo* in animals and humans, but the physical characteristics of these molecules have not been used to predict pore size in disease. An important model of increased permeability caused by intestinal inflammation is the effect of mast cell dependent reactions in the rat intestine following *Nippostrongylus brasiliensis* infection. Increased amounts of BSA can be detected immunologically in the circulation after infection with the organism, following mild systemic anaphylaxis (Bloch *et al.*, 1979). Similarly, transfer of <sup>51</sup>Cr-labeled EDTA and ovalbumin is enhanced (Ramage *et al.*, 1988). Estimating the physical characteristics of the paracellular pathway during inflammation should be possible.

The permeability of the tight junction can be examined *in vitro*, enabling workers to study the effects of epithelial events that are seen *in vivo*. Monolayers of epithelial cells (T84) have effective tight junctions that produce a resistance

of ~1500 Ω cm<sup>2</sup>. Application of interferon γ (Madara and Stofford, 1989) reduces the resistance and allows easier permeation of large sugars. Interferon γ levels are increased in the mucosa of patients with Crohn's disease because of T-cell activation. Bowel inflammation is characterized by the transepithelial passage of polymorphonuclear neutrophils (PMNs). This phenomenon has been reproduced *in vitro* by placing chemotactic agents and PMNs on different sides of the monolayer (Nash *et al.*, 1987). The passage of neutrophils opens tight junctions, reducing the resistance of the monolayer resistance and allowing transfer of large sugars.

## VI. CONCLUSIONS

The mucosal barrier, like the skin, defines the boundary between an animal and its environment. Unlike the skin, the mucosae of the gut and respiratory tract must absorb substances that are essential for life. To be selective, the intestinal mucosa has developed a complex network containing elements that are extrinsic to the intestine itself and those defined by intestinal structure. The challenges for the future lie in defining the role of these barriers in the establishment of gastrointestinal disease. Examining whether cellular elements in the mucosal immune system can recognize antigens without their needing to penetrate the intestinal epithelium will also be interesting. The observations that members of the immunoglobulin superfamily are found on the surface of the epithelium and that lymphocytes can pass into the intestinal lumen make this a tantalizing possibility.

# Innate Humoral Factors

Kenneth M. Pruitt • Firoz Rahemtulla • Britta Månsson-Rahemtulla

## I. INTRODUCTION

We define the innate humoral factors as those proteins that are secreted onto mucosal surfaces by exocrine glands and are able to carry out their protective functions independent of the presence of specific antibodies. The innate humoral factors are important components of mucosal defense mechanisms. Two families of proteins that function as innate humoral factors—the acidic proline-rich proteins (PRP) and the histidine-rich proteins (HRP)—have not been included in this chapter because of space limitations. The PRPs and HRPs are present in high concentrations in mucosal secretions and participate in a variety of defensive mechanisms. These proteins have been the subject of several reviews (PRP, Hay and Moreno, 1989; HRP, Oppenheim, 1989).

## II. LACTOFERRIN

Lactoferrin (Lf) is found in the exocrine secretions, blood, and leukocytes of many species and has been the subject of numerous investigations. Mammalian Lfs show structural homologies and may have common antigenic determinants (Magnuson *et al.*, 1990). Lfs from different species have similar properties (Shimazaki *et al.*, 1991). A comprehensive review of the vast Lf literature is beyond the scope of this chapter. Here we focus on selected aspects of the biochemistry and biology of human Lf. Human Lf is an 80-kDa glycoprotein composed of a single polypeptide chain of 691 residues. The three-dimensional structure of this molecule has been determined from X-ray crystallographic analyses (Baker *et al.*, 1991). The complete cDNA nucleotide sequence has been reported (Powell and Ogden, 1990; Rey *et al.*, 1990) and the amino acid sequence has been determined (Metz-Boutique *et al.*, 1984; Anderson *et al.*, 1989). The amino acid sequence deduced from cDNA (Rey *et al.*, 1990) was 98% identical to the reported sequence (Anderson *et al.*, 1989). Lf binds  $\text{Fe}^{3+}$  reversibly but with great affinity ( $K_B \sim 10^{20}$ ), but has much less affinity for  $\text{Fe}^{2+}$  ( $K_B \sim 10^3$ ). The molecule has an absolute requirement of binding one  $\text{HCO}_3^-$  with each  $\text{Fe}^{3+}$ .

Apolactoferrin (apo-Lf) and diferric Lf (both  $\text{Fe}^{3+}$  sites occupied) have different three-dimensional structures (Baker *et al.*, 1991). In the diferric form, the molecule is folded into two globular lobes, the N lobe and the C lobe, representing

the N-terminal and C-terminal halves with similar three-dimensional structures. Each lobe contains one  $\text{Fe}^{3+}$  and one  $\text{HCO}_3^-$  binding site located in a deep cleft between two dissimilar domains. Thus, the molecule has a two-lobe four-domain structure. Each lobe has one site of carbohydrate attachment. Although little is known about the structure of the carbohydrate components, one report (Kawasaki *et al.*, 1992) provided evidence that the terminal sialic acid residues in these components are important structural determinants for the Lf inhibition of the binding of cholera toxin to Chinese hamster ovary cells. The two lobes are connected by a three-turn  $\alpha$  helix. In apo-Lf, the N-lobe binding cleft is open wide whereas the C-lobe binding cleft is closed although no  $\text{Fe}^{3+}$  is bound. The molecule is quite flexible, and extensive folding is associated with the binding of  $\text{Fe}^{3+}$ . Deferric Lf has increased conformational stability and increased resistance to unfolding compared with apo-Lf (Harrington, 1992).

An isoform of Lf, hmRNase with high ribonuclease activity against retroviral-like RNAs, has been identified in human milk (Furmanski *et al.*, 1989). Lf and hmRNase comigrate on SDS-PAGE with calculated sizes of 80 kDa, stained similarly with periodic acid-Schiff reagent, had the same pI (8.7) as determined by isoelectric focusing, yielded identical peptide patterns after treatment with trypsin or papain, and had identical NH-terminal amino acid sequences (determined up to 8 residues). Monospecific rabbit antihuman Lf reacted identically with Lf and with hmRNase. In spite of these striking similarities, Lf has no RNase activity and hmRNase does not bind iron. The biological origins of these isoforms of Lf are unknown. Another example of structurally similar and functionally distinct milk proteins, found in bovine, goat, sheep, and human milk in comparable quantities, is the lactoperoxidase enzyme and a nonheme lactoperoxidase that is enzymatically inactive (Allen and Morrison, 1963; Dumontet and Rousset, 1983). These two lactoperoxidase isoforms have the same apparent molecular weight, similar amounts of carbohydrate, similar peptide maps after subtilisin or trypsin treatment, and lines of identity in immunodiffusion experiments. The origin and biological significance of these isoforms of lactoperoxidase are unknown as well.

The iron-binding properties of Lf generally have been assumed to be the basis for its biological functions. The low frequency of iron deficiency anemia in breast-fed infants has been attributed to the transport of iron to the intestinal mucosa of the infant in a readily available Lf-bound form. A human Lf receptor has been isolated from human fetal intesti-

nal brush border membranes (Kawakami and Lönnerdal, 1991). The receptor specifically bound human Lf and showed little affinity for bovine Lf or for human transferrin. However, the data supporting the role of milk Lf in the bioavailability of iron are conflicting (Hurley and Lönnerdal, 1988). Studies of human infants (Roberts *et al.*, 1992) have failed to establish a unique role for Lf in modulating the development of infant fecal flora. Reports (reviewed by Djeha and Brock, 1992) of the effects of Lf on human T-lymphocyte proliferation are complex and conflicting. An interesting hypothesis is that the release of Lf by degranulation of neutrophils may preserve T-cell function at inflammatory sites.

In contrast to the *in vivo* studies reviewed earlier, the *in vitro* antimicrobial properties of Lf have been confirmed by numerous reports. Lf kills or inhibits the growth of many species of microorganisms. The studies summarized in Table I show that, in general, dose-dependent killing or inhibition of microorganisms is caused by apo-Lf but not by iron-saturated Lf. The specific kinetics and quantitative aspects of the dose response depend on the species of microorganism. Human and bovine Lf have similar properties. Both proteins bind to the surface of microorganisms in the apo- and iron-saturated forms. Binding may or may not be correlated with the biological effects, depending on the species of microorganism. Susceptibility of microorganisms to Lf depends on pH, growth phase, temperature, composition of the reaction medium, and methods used to determine viability. Sublethally injured cells of *Escherichia coli* apparently are able to repair damage caused by Lf when the cells are cultured on blood agar, but not when they are enumerated by the pour plate method (Rainard, 1987). Biological effects may be blocked by citrate, by iron salts, and by  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ . Many of the observed biological effects are consistent with the hypothesis that Lf acts by interfering with microbial iron metabolism. However, Lf binding to microbial membranes produces other effects as well, including damage to the outer membrane of gram-negative bacteria resulting in subsequent release of lipopolysaccharides (LPS), increased cell permeability (Ellison *et al.*, 1988), and increased susceptibility to hydrophobic antibiotics (Ellison *et al.*, 1990).

Many bacteria are resistant to Lf. Under conditions that inhibit the growth of *E. coli*, six isolates of *Streptococcus agalactiae* and five isolates of *Streptococcus uberis* were unaffected (Rainard, 1986). Some strains of *E. coli*, *Salmonella wien*, and *Staphylococcus aureus* are resistant to Lf inhibition (Dalmastrri *et al.*, 1988). This resistance may be correlated with the production of enterochelins or aerobactins. Clinical isolates of *E. coli* that do not bind Lf are not inhibited by Lf (Visca *et al.*, 1990). Virulence and Lf resistance may be correlated (Arnold *et al.*, 1980).

The antibacterial properties of Lf are enhanced in the presence of other components of mucosal secretions. Suzuki *et al.* (1989) reported that the growth of *E. coli* strain 011 was inhibited moderately in the presence of egg white lysozyme alone and by bovine apo-Lf alone. No inhibition was observed in the presence of iron-saturated Lf. The combination of lysozyme with either apo-Lf or iron-saturated Lf significantly magnified the growth inhibition. However, these authors also reported that the bacteria were agglutinated by the

lysozyme and iron-saturated Lf mixture. Since these authors measured growth spectrophotometrically, the observed growth "inhibition" could have been a result of a reduction in absorbance as a consequence of agglutination. Ellison and Giehl (1991) found that human lysozyme and human Lf alone were bacteriostatic for strains of *Vibrio cholerae*, *Salmonella typhimurium*, and *E. coli*. However, in combination, lysozyme and Lf were bactericidal for these bacteria. These authors measured the antibacterial effects by serial dilution and plating of aliquots from the reaction mixtures. Therefore, agglutination could have contributed to the observed reduction in the cfu/ml. However, transmission electron microscopic observations showed that *E. coli* cells exposed to the combination of lysozyme and Lf were enlarged and hypodense. Large amounts of cell debris were also present. The latter observations suggest that killing was a consequence of osmotically induced swelling and lysis. This possibility was confirmed by the observation that the effects of lysozyme and Lf could be partially or totally blocked by increasing the media osmolarity. The bactericidal effects were dose dependent, blocked by iron saturation of Lf, and inhibited by high concentrations of calcium. These authors also presented evidence that Lf does not chelate calcium. They concluded that Lf interacts with the outer membrane of these gram-negative bacteria, causing LPS release and increasing membrane permeability. This increase in permeability increases the access of lysozyme to the bacterial cell wall and accounts for the synergistic killing of lysozyme and Lf mixtures.

Increased killing of gram-positive microorganisms by mixtures of Lf and lysozyme also has been reported (Soukka *et al.*, 1991a). Human apo-Lf and human lysozyme alone gave a dose-dependent reduction in viable counts of a strain of *Staphylococcus mutans*. No reduction was observed with iron-saturated Lf. Mixtures of apo-Lf and lysozyme showed an additive but not synergistic reduction in viable counts. The contribution of aggregation to the reduction in viable counts was minimized by subjecting mixtures to vortexing and ultrasonic treatment before plating. The killing of *S. mutans* by Lf and lysozyme was not as dramatic as that reported for gram-negative bacteria. An additive effect of the lactoperoxidase system on apo-Lf killing of *S. mutans* has been reported (Soukka *et al.*, 1991b). These authors also reported that the lactoperoxidase system alone had a bactericidal effect on this bacterium at pH 5.5. Esaguy *et al.* (1991) reported that the 65-kDa heat-shock protein produced by *Mycobacterium leprae* and by *Mycobacterium tuberculosis* is recognized specifically by polyclonal antibodies directed against human Lf, suggesting that these Lf-mimicking bacterial proteins may be responsible for the autoimmune reactions observed in individuals suffering from leprosy and tuberculosis.

The hypothesis that  $\text{Fe}^{2+}$  and apo-Lf can generate hydroxyl radicals ( $\text{OH}^{\cdot}$ ) via an  $\text{H}_2\text{O}_2$  intermediate and that this reaction may contribute to the microbicidal activity of phagocytes is controversial (reviewed by Klebanoff and Waltersdorff, 1990). These authors have described a series of experiments that show that the system is more complex than generally is realized and that the results of experiments intended to generate  $\text{OH}^{\cdot}$  are critically dependent on experi-

**Table 1** Effects of Lactoferrin on Microorganisms<sup>a</sup>

Microorganism	Test medium	Biological effects	Comments	Reference
<i>Actinobacillus actinomycetemcomitans</i>	Simple broth	Bactericidal	Dose-dependent killing by Apo-HLf; Sat-HLf no effect	Kalmar and Arnold (1988)
<i>Aeromonas hydrophila</i> , 28 isolates from clinical specimens and foods	Phosphate-buffered saline	Not reported	Both HLf and BLf bound; specific binding proteins in a representative strain seemed to be cell porins	Kishore <i>et al.</i> (1991)
<i>Bacillus stearothermophilus</i> , <i>Bacillus subtilis</i>	Nutrient agar and broth	Growth inhibited	BLf inhibition reversible; suppressed by addition of Fe <sup>2+</sup>	Oram and Reiter (1968)
<i>Candida albicans</i>	Saline	Fungicidal	Dose-dependent killing by Apo-HLf; Sat-HLf no effect	Arnold <i>et al.</i> (1980)
	0.05 mM KCl	Fungicidal	Dose-dependent killing by Apo-HLf; killing blocked by physiological concentrations of phosphate and bicarbonate; Sat-HLf no effect	Soukka <i>et al.</i> (1992)
Coliforms associated with mastitis ( <i>Klebsiella pneumoniae</i> , <i>Klebsiella</i> spp., <i>Aerobacter aerogenes</i> , <i>Escherichia coli</i> )	Synthetic medium	Dose-dependent growth inhibition of all coliforms by apo-BLf	No growth inhibition by Sat-BLf or when Fe <sup>3+</sup> or citrate was added to Apo-BLf; Apo-BLf (20 mg/ml) killed <i>E. coli</i>	Bishop <i>et al.</i> (1976)
<i>Haemophilus influenzae</i>	Growth medium	Bactericidal	HLf bound to cells in presence and absence of Fe	Dalmastri <i>et al.</i> (1988)
<i>Klebsiella pneumoniae</i>	Growth medium	Bacteriostatic	HLf bound to cells in presence and absence of Fe	Dalmastri <i>et al.</i> (1988)
<i>Escherichia coli</i>	Bovine milk	Bacteriostatic	BLf inhibited growth; effect blocked by citrate, enhanced by bicarbonate	Reiter and Brock (1975); Reiter <i>et al.</i> (1975)
enteropathogen nonenteropathogen	Growth medium Saline	No effect Bactericidal	Apo-HLf and Sat-HLf bound to cells Weak dose-dependent killing by Apo-HLf; sat-HLf no effect	Arnold <i>et al.</i> (1977) Arnold <i>et al.</i> (1980)
enteropathogen	Human milk	Bacteriostatic	Growth slowed for 10 hr, but resumed after 24 hr; effect abolished by addition of iron or enterobactin	Brock <i>et al.</i> (1983)
several strains differing in iron-transport systems	Growth medium	Bacteriostatic	Antimicrobial effects of Zn-Lf > Apo-Lf; strains with only enterochelin Fe transport more sensitive; strains with only aerobactin or both Fe transport systems overcame inhibition by Zn-Lf	Valenti <i>et al.</i> (1985)

Table I (continued)

Microorganism	Test medium	Biological effects	Comments	Reference
mastitic (bovine); 35 isolates	Growth medium	Bacteriostatic	All isolates inhibited by Apo-HLf	Rainard (1986)
serum-resistant strain	Bovine milk—normal, mastitic	Bacteriostatic	Apo-HLf but not Sat-HLf inhibited growth when added to ultrafiltrate from mastitic milk; no inhibition when Apo-HLf added to ultrafiltrate from normal milk	Rainard (1987)
strain 803	Growth medium	Bacteriostatic	Lf bound to cells in presence and absence of Fe	Dalmastrì <i>et al.</i> (1988)
UDP-galactose epimerase-deficient strain	Growth medium	Bacteriostatic	Apo-HLf but not Sat-HLf caused release of LPS from outer membrane; LPS release inhibited by Mg <sup>2+</sup> , Ca <sup>2+</sup>	Ellison <i>et al.</i> (1988, 1990)
K-12, four strains; clinical isolates, five strains	Minimal medium	Bacteriostatic for K-12 strains; no effect on clinical isolates	Apo-HLf and Sat-HLf bind to K-12 strains but not to clinical isolates	Visca <i>et al.</i> (1990)
<i>Legionella pneumophila</i>	Growth medium, human milk	Bactericidal	Dose-dependent killing by Apo-HLf in growth medium but not by Sat-HLf; human milk bactericidal, but effect blocked by addition of iron	Bortner <i>et al.</i> (1986)
	Water	Bactericidal	Susceptibility dependent on growth phase, pH; killing blocked by Ca <sup>2+</sup> , Mg <sup>2+</sup> ; Apo-HLf, Sat-HLf both bind to cells; binding independent of killing	Bortner <i>et al.</i> (1989)
	Growth medium	Intracellular growth in monocytes inhibited	Apo-HLf completely inhibited intracellular multiplication in nonactivated monocytes; Sat-HLf had no effect	Byrd and Horwitz (1991)
<i>Mycobacterium leprae</i> , <i>Mycobacterium tuberculosis</i>	Western blotting (cell extracts), electron microscopy (intact cells, cell fragments)	Polyclonal antibodies against HLf, bind to cell surfaces and cytoplasmic components	Major component in both species binding HLf antibodies is 65-kDa heat-shock protein; may contribute to autoimmune disease in leprosy and tuberculosis	Esaguy <i>et al.</i> (1991)
<i>Neisseria catharralis</i>	Growth medium	Bacteriostatic	HLf bound to cells in presence and absence of Fe	Dalmastrì <i>et al.</i> (1988)
<i>Neisseria gonorrhoeae</i> —40 clinical (human) isolates	Broth	Not reported	All clinical isolates expressed detectable levels of HLf receptors; no correlation between HLf receptor expression and disease state	Lee and Bryan (1989)
<i>Neisseria gonorrhoeae</i> FA19	Defined medium	No inhibition	Bacteria utilized iron bound to HLf; required energy and cell contact	McKenna <i>et al.</i> (1988)
<i>Porphyromonas gingivalis</i> , <i>Prevotella intermedia</i> ,	Phosphate-buffered saline	Not reported	HLf bound to varying extents: <i>P. intermedia</i> > <i>P. gingivalis</i> > <i>P.</i>	Kalfas <i>et al.</i> (1991)

<i>Prevotella melanogenica</i> : human isolates (116 strains) from diseased periodontal pockets			<i>melanogenica</i> ; specific binding to <i>P. intermedia</i> , nonspecific binding to <i>P. gingivalis</i> , <i>P. melanogenica</i> ; binding capacity affected by culture medium; binding components affected by heat, proteases						
<i>Pseudomonas aeruginosa</i>	Agar gel	Bacteriostatic	Apo-HLf (4%) added to agar well inhibited growth; effect abolished by addition of Fe <sup>2+</sup>	Masson and Heremans (1966)					
clinical isolate	Saline	Bactericidal	Dose-dependent killing by Apo-HLf; Sat-HLf no effect	Arnold <i>et al.</i> (1980)					
<i>Salmonella wien</i> 1 (clinical isolate)	Growth medium	Bactericidal	HLf bound to cells in presence and absence of Fe	Dalmastrri <i>et al.</i> (1988)					
<i>Salmonella typhimurium</i> SL696, SH4247	Growth medium	Bacteriostatic	HLf bound to cells in presence and absence of Fe	Dalmastrri <i>et al.</i> (1988)					
<i>Shigella flexneri</i> , <i>Shigella sonnei</i>	Growth medium	Bacteriostatic/bactericidal	Apo-HLf but not Sat-HLf caused release of LPS from outer membrane; LPS release blocked by Mg <sup>2+</sup> , Ca <sup>2+</sup>	Ellison <i>et al.</i> (1988) Ellison <i>et al.</i> (1990)					
<i>Staphylococcus albus</i>	Growth medium	Bacteriostatic	HLf bound to cells in presence and absence of Fe	Dalmastrri <i>et al.</i> (1988)					
<i>Streptococcus mitior</i>	Nutrient agar gel	Bacteriostatic	HLf (0.5%) added to paper discs inhibited growth; effect abolished by addition of Fe <sup>2+</sup>	Masson <i>et al.</i> (1966)					
<i>Streptococcus mutans</i>	Saline	Bactericidal	Dose-dependent killing by Apo-HLf; Sat-HLf no effect	Arnold <i>et al.</i> (1980)					
five serotypes	Growth medium	Bactericidal	Dose-dependent suppression of growth by Apo-HLf; Sat-Lf no effect; Apo-HLf binds to cells	Arnold <i>et al.</i> (1977)					
	Saline	Bactericidal	Dose-dependent killing by Apo-HLf; Sat-HLf no effect	Arnold <i>et al.</i> (1980)					
	Water, glycine buffer, phosphate, HEPES buffer	Bactericidal, reversible inhibition	Growth phase-dependent sensitivity to HLf; killing in water, glycine buffer, but not phosphate or HEPES buffers;	Arnold <i>et al.</i> (1981)					
clinical isolate	Water	Bactericidal	HLf bactericidal effects not limited to iron-deprivation	Arnold <i>et al.</i> (1982)					
strain 6715-13	Growth medium	Bactericidal	HLf bound to cells in presence and absence of Fe	Dalmastrri <i>et al.</i> (1988)					
<i>Streptococcus pneumoniae</i>	Growth medium	Bacteriostatic	Bacteriostasis reversed by saturation of HLf with iron	Visa <i>et al.</i> (1989)					
<i>Streptococcus salivarius</i>	Saline	Bactericidal	Dose-dependent killing by Apo-HLf; Sat-HLf no effect	Arnold <i>et al.</i> (1980)					
	Saline	Bactericidal	Dose-dependent killing by Apo-HLf; Sat-HLf no effect	Arnold <i>et al.</i> (1980)

Table 1 (continued)

Microorganism	Test medium	Biological effects	Comments	Reference
<i>Staphylococcus aureus</i>	Agar gel	Bacteriostatic	Solution of 4% Apo-HLf in agar well inhibited growth; effect abolished by addition of Fe <sup>2+</sup>	Masson and Hereman (1966)
mastitic (bovine) bacteria, 10 isolates	Growth medium	Bacteriostatic	6 isolates inhibited, 4 unaffected by Apo-Lf	Rainard (1986)
mastitic (bovine) isolates: <i>Staphylococcus epidermidis</i> , <i>warneri</i> , <i>hominis</i> , <i>xylosum</i> , <i>hyicus</i> , and <i>chromogenes</i>	Phosphate-buffered saline	Not reported	Specific binding of BLf to all strains; affinity constants varied: 1-12 × 10 <sup>6</sup> liter/mol; BLf binding sites 1900-4700/cell	Naidu <i>et al.</i> (1990)
human clinical isolates (489 strains)	Phosphate-buffered saline	Not reported	HLF binds to 85% of isolates; binding correlated with clinical condition; binding optimal with organisms grown in agar, but abolished by strains grown on carbohydrate and salt-rich agar	Naidu <i>et al.</i> (1991)
<i>Vibrio cholerae</i>	Growth medium	Bactericidal	Dose-dependent suppression of growth by Apo-HLf; Sat-HLf no effect; Apo-HLf binds to cells	Arnold <i>et al.</i> (1977)
	Saline	Bactericidal	Dose-dependent killing by Apo-HLf; Sat-HLf no effect	Arnold <i>et al.</i> (1980)

<sup>a</sup> Abbreviations used: Apo-BLf, iron free bovine lactoferrin; Apo-HLf, iron free human lactoferrin; BLf, bovine lactoferrin; HEPES, N-2-hydroxyethyl-piperazine-N'-2-ethanesulfonic acid; HLf, human lactoferrin; Sat-BLf, iron-saturated BLf; Sat-HLf, iron-saturated HLf.

mental conditions. Klebanoff and Waltersdorff reported that incubation of  $\text{Fe}^{2+}$  with apo-Lf resulted in the formation of oxidants that were toxic to *E. coli*. They obtained evidence for the formation of  $\text{H}_2\text{O}_2$  and  $\text{OH}^\cdot$ . However, precise experimental conditions were required to obtain these results. The microorganisms must be in the early log phase of growth and the following experimental conditions must be met: pH 4.5–5.5,  $[\text{Fe}^{2+}] \sim 10 \mu\text{M}$ , and  $[\text{apo-Lf}] \sim 0.3 \mu\text{M}$ . These investigators explained their results in terms of the following mechanism:

These authors found that the autooxidation of  $\text{Fe}^{2+}$  (reaction 1) was accelerated greatly by apo-Lf at the pH they used (5.0). Formation of  $\text{OH}^\cdot$  was measured by electron paramagnetic resonance detection of the signal from the formation of the complex between the spin-trap DMPO (5,5-dimethyl-1-pyrrolidone-*N*-oxide) and the  $\text{OH}^\cdot$  radical. Evidence for formation of  $\text{H}_2\text{O}_2$  was inhibition of the generation of the DMPO- $\text{OH}^\cdot$  complex and of reduction of toxicity by the addition of catalase. The strict experimental conditions required for generation of  $\text{OH}^\cdot$  and for the observation of toxicity imply that  $\text{OH}^\cdot$  production by Lf may be restricted *in vivo*. The sensitivity of the reactions to experimental conditions may explain why some authors find that Lf enhances  $\text{OH}^\cdot$  production (Ambruso and Johnston, 1981) whereas others report that it does not (Baldwin *et al.*, 1984). Britigan and Edeker (1991) reported that apo-Lf inhibits  $\text{OH}^\cdot$  formation by the hypoxanthine/xanthine oxidase/ $\text{O}_2^\cdot^-/\text{H}_2\text{O}_2$  system. However, diferric transferrin and, to a much lesser extent, diferric Lf, when treated by *Pseudomonas* elastase, induce  $\text{OH}^\cdot$  radical formation by this system. Thus, at sites of *Pseudomonas aeruginosa* infection, alteration of transferrin and Lf by bacterial enzymes may contribute to tissue injury by increasing the local potential for  $\text{OH}^\cdot$  formation. Nakamura (1990) presented evidence that the  $\text{Fe}^{3+}$  bound to diferric Lf may be reduced to  $\text{Fe}^{2+}$  by the NADPH-cytochrome P450 reductase system in the presence of superoxide dismutase, resulting in formation of  $\text{OH}^\cdot$  through reaction of  $\text{H}_2\text{O}_2$  with Lf  $\text{Fe}^{2+}$ . Britigan *et al.* (1991) reported that, when human monocytes were incubated with apo-Lf, cell-associated apo-Lf increased in proportion to apo-Lf concentration in the incubation medium. These investigators estimated  $3.4 \times 10^7$  Lf binding sites per monocyte. Similar results were obtained with diferric Lf. These researchers stimulated  $\text{OH}^\cdot$  formation by exposing the cells to phorbol myristic acetate (PMA) in the presence of ferric nitrilotriacetic acid. The generation of  $\text{OH}^\cdot$  by apo-Lf-loaded monocytes was reduced by 50% compared with controls. Under these conditions, auto-oxidation of cell membranes was reduced 28% in the apo-Lf-loaded cells compared with controls. These authors suggested that Lf may protect tissue *in vivo* from phagocyte-associated  $\text{OH}^\cdot$  generation. The various studies reviewed in this section show that apo-Lf and diferric Lf may contribute to or inhibit the formation of  $\text{OH}^\cdot$ , depending on specific reaction conditions. The chemistry of these reactions is complex and speculations

relating the results of *in vitro* experiments to conditions existing *in vivo* must be considered carefully.

Several studies have been undertaken to determine directly the possible *in vivo* significance of the antimicrobial properties of Lf. Human Lf was administered to 5 human patients receiving chemotherapy for acute myelogenous leukemia (Trumpler *et al.*, 1989). The Lf did not delay the onset of enterogenic infection significantly but reduced its duration and severity. Compared with 9 matched untreated controls, Lf-treated patients had a lower incidence of bacteremia. In animal studies, calves experimentally infected with *E. coli* were treated with a preparation containing the lactoperoxidase system and Lf (Still *et al.*, 1990). Mortality and occurrence and duration of diarrhea were significantly lower in the treated animals than in infected but untreated controls. The latter study did not distinguish between the effects of the lactoperoxidase system and those of Lf. In another study (Zagulski *et al.*, 1989), the survival of mice injected with a lethal dose of *E. coli* was improved significantly when either human or bovine Lf was administered intravenously 24 hr before challenge. Different results were obtained by Czirók *et al.* (1990). These authors confirmed the *in vitro* antibacterial effects of Lf against various strains of *E. coli*, *S. typhimurium*, and *P. aeruginosa*. However, when mice were injected with these same organisms and injected also with Lf using different routes of injection and different time schedules, the results did not establish a consistent pattern for the ability of Lf to protect mice from the lethal effects of injected microorganisms. The latter was a complex study. Some of its conclusions did not seem to be supported clearly by the data presented.

The *in vivo* significance of the many observations of the *in vitro* antimicrobial effects of Lf has yet to be firmly established by direct observation. A comprehensive understanding of the *in vivo* significance of Lf must await the outcome of future studies. However, the evidence reviewed here suggests that the biological activity of Lf must be considered within the context of the concomitant actions of other components of mucosal secretions.

### III. LYSOZYME

Human milk lysozyme appears to be identical to the forms of lysozyme found in other body fluids such as urine and pancreatic juice (Canfield *et al.*, 1971; Jollès and Jollès, 1971; Wang and Kloer, 1985). The concentration of lysozyme in human milk is higher than it is in the milk of most other species. In human milk, lysozyme concentrations are 3000 times higher than in cow milk (Parry *et al.*, 1968). Concentrations vary during lactation. The mean concentration of human lysozyme during the first few days of lactation is approximately 80  $\mu\text{g}/\text{ml}$ , falls to 20–25  $\mu\text{g}/\text{ml}$  at 1 month, and rises to 245  $\mu\text{g}/\text{ml}$  after 6 months of lactation (Goldman *et al.*, 1982, 1983).

Human lysozyme consists of a single polypeptide chain, composed of 129 amino acids, with a molecular mass of 14,600 Da and a pI of 10.5. This protein is cross-linked by four disulfide bridges that give stability to the compact, roughly

ellipsoidal structure (for review, see Jolles and Jolles, 1984). Lysozyme isolated from different species and different organs of the same individual shows the same type of biological activity. However, these enzymes differ in their chemical properties (Jolles and Jolles, 1984) and specific activity (Balkejian *et al.*, 1969). Human salivary lysozyme originates from the salivary glands and oral leukocytes present in the gingival crevices (Petit and Jollès, 1963; Senn *et al.*, 1970; Raeste, 1972; Korsrud and Brandtzaeg, 1982). The salivary concentration of lysozyme ranges from 2 to 80  $\mu\text{g}/\text{ml}$ . Because of its higher specific activity, human lysozyme is considered a more potent antibacterial factor for oral microorganisms than hen egg white lysozyme (Iacono *et al.*, 1980, 1982). Human lysozyme exerts its antibacterial effects by hydrolyzing the peptidoglycans of the bacterial cell wall (muramidase activity) by cleaving the  $\beta(1-4)$  glycosidic bond between *N*-acetylmuramic acid and *N*-acetyl-D-glucosamine (Chipman and Sharon, 1969), by activating bacterial autolysins (Laible and Germaine, 1985), by aggregating bacteria (Pollock *et al.*, 1976) resulting in inhibition of bacterial adherence (Iacono *et al.*, 1980), and by inhibiting acid production by oral streptococci (Twetman *et al.*, 1986; Lumikari and Tenovuo, 1991). Originally, the antibacterial effects of lysozyme were ascribed only to the lytic activity. However, several studies (Laible and Germaine, 1985; Wang and Germaine, 1991) reported that bactericidal and autolytic activities that are independent of the enzymatic activity, as well as the cationic property ( $\text{pI} \sim 10.5$ ) of the molecule, are essential for the bactericidal characteristic of the protein. Although oral streptococci are not lysed directly by lysozyme, the cell walls are damaged by exposure to lysozyme to such an extent that a subsequent addition of anions or detergents results in immediate lysis (Goodman *et al.*, 1981; Cho *et al.*, 1982; Laible and Germaine, 1985; Pollock *et al.*, 1987; Wang and Germaine, 1991). Additionally, the major monovalent anions in saliva, namely bicarbonate, fluoride, thiocyanate, and chloride, all have been demonstrated to activate bacterial lysis at neutral pH, whereas only bicarbonate triggers lysis of oral streptococci at acidic pH (Wilkins *et al.*, 1982; Pollock *et al.*, 1983). Electron microscopic studies have demonstrated that, in the absence of salt or detergent, *S. mutans* treated with high concentrations of lysozyme exhibits areas of cell wall dissolution without cell lysis (Bleiweis *et al.*, 1971; Cho *et al.*, 1982; Iacono *et al.*, 1985). Adsorption of lysozyme to oral bacteria is strongly dependent on pH and ionic strength. Bacteriolysis caused by this cationic molecule therefore may be of physiological significance in an environment such as the oral cavity in which a continuous variation in pH and in ionic strength occurs. However, note that the susceptibility of various serotypes of *S. mutans* to lysozyme varies considerably; for example, *Streptococcus rattus*, serotype b, is highly sensitive whereas *S. mutans*, serotype c, is less sensitive (Iacono *et al.*, 1980).

Several studies have demonstrated a synergistic inhibitory effect of lysozyme and other nonimmunoglobulin defense factors in saliva (Arnold *et al.*, 1984; Soukka *et al.*, 1991a,b; Lenander-Lumikari *et al.*, 1992). A combination of lysozyme and Lf had a bactericidal effect on *S. mutans* (Soukka *et al.*, 1991). Results from our laboratory (Lenander-Lumikari *et al.*, 1992) showed that lysozyme alone slightly stimulated

*S. mutans* glucose uptake. Incubation with 7–15  $\mu\text{mol}/\text{liter}$  HOSCN + OSCN<sup>-</sup> resulted in 20–40% inhibition of glucose uptake. However, when *S. mutans* cells were incubated with lysozyme with subsequent addition of HOSCN and OSCN<sup>-</sup>, glucose incorporation was inhibited completely. The inhibition could be reversed by addition of reducing agents such as 2-mercaptoethanol and dithiothreitol, indicating dependence on the salivary peroxidase (SPO) system. The combined treatment with the peroxidase system and lysozyme did not affect the viability of the bacteria, since no differences in cfu/ml were found between treated and untreated *S. mutans*. When all the components of the SPO system were present with lysozyme in the bacterial suspension, the glucose incorporation of lysozyme-treated bacteria was inhibited totally. However, if the peroxidase enzyme was removed from the HOSCN/OSCN<sup>-</sup> preparation, the inhibition was reduced significantly and was only slightly greater than the inhibition achieved by HOSCN/OSCN<sup>-</sup> alone. A possible explanation is that, when SPO and SCN<sup>-</sup> are present in excess in the bacterial suspension and minimal amounts of H<sub>2</sub>O<sub>2</sub> are produced by *S. mutans*, the H<sub>2</sub>O<sub>2</sub> produced would be sufficient for the continuous generation of HOSCN/OSCN<sup>-</sup>, resulting in the observed effects on the bacteria.

The studies reviewed here show that the biological effects of lysozyme extend beyond the catalysis of the hydrolysis of cell wall components. In part because of its cationic nature, lysozyme is able to bind to bacterial cell surfaces and impair vital membrane functions. Membrane alterations may facilitate the diffusion of products of the SPO system into the cell and amplify oxidative damage to enzymes required for glucose metabolism.

#### IV. PEROXIDASES

Peroxidase activity has been measured in many mucosal secretions (for review, see Tenovuo, 1991): saliva, milk, tears, sweat, and mucus from cervix, intestine, and lung. The activity is derived from enzymes synthesized in exocrine glands and secreted onto mucosal surfaces by the glands. Contributions also come from polymorphonuclear leukocytes (myeloperoxidase) and eosinophils (eosinophil peroxidase). A comprehensive discussion of the numerous studies of the various members of the peroxidase family is beyond the scope of this chapter. We focus our attention on human salivary peroxidase (SPO), human lactoperoxidase (HLPO), and, for comparative purposes, bovine lactoperoxidase (LPO). The latter enzyme has been studied extensively because of its ready availability and has many properties in common with SPO and HLPO.

Peroxidases protect mucosal surfaces from microorganisms by catalyzing the peroxidation of halides (Cl<sup>-</sup>, Br<sup>-</sup>, I<sup>-</sup>) and the thiocyanate ion (SCN<sup>-</sup>) to generate reactive products that have potent antibacterial properties. Myeloperoxidase and eosinophil peroxidase will catalyze the peroxidation of Cl<sup>-</sup>, Br<sup>-</sup>, I<sup>-</sup> and SCN<sup>-</sup>. However, LPO, HLPO, and SPO will not catalyze the peroxidation of Cl<sup>-</sup>. In the absence of halides and SCN<sup>-</sup>, peroxidases can behave as catalases. The catalase and peroxidase activities of these enzymes also pro-

tect mucosal surfaces by preventing the accumulation of toxic products of oxygen reduction.

Preparations of LPO from bovine milk are heterogeneous (reviewed by Paul and Ohlsson, 1985). A major fraction of LPO consists of a single polypeptide chain of 78.5 kDa. Sub-fractions of lower molecular mass are derived by loss of carbohydrate groups and by deamidation of asparagine or glutamine residues. SPO from human saliva is also heterogeneous (reviewed by Månsson-Rahemtulla *et al.*, 1988). At least three major forms of 78, 80, and 280 kDa have been reported. Human milk contains at least two peroxidase enzymes (reviewed in Pruitt *et al.*, 1992), HLPO and myeloperoxidase (MPO). The relative amounts vary widely from sample to sample and depend on the stage of lactation. The properties of HLPO are similar to those of SPO. The MPO is derived from milk leukocytes.

The amino acid sequence of SPO has not been reported. However, Dull *et al.* (1990) used peptide sequences obtained from cyanogen bromide fragments of bovine LPO to design oligonucleotide probes for screening cDNA libraries constructed from bovine and human mammary tissue. The deduced amino acid sequence of bovine LPO was consistent with reported amino acid compositions and was homologous to those reported for myelo-, thyroid, and eosinophil peroxidases. These investigators found that HLPO was homologous to bovine LPO. The C-terminal 324 amino acids of these two peroxidases showed 84% homology. The complete amino acid sequence of bovine LPO, determined by Cals *et al.* (1991), agrees with the deduced sequence reported by Dull *et al.* (1990), except that the latter authors reported aspartate at position 9 and asparagine at position 349 whereas the former reported aspartate or asparagine and arginine, respectively, at these positions. The enzyme consists of a single polypeptide chain containing 612 amino acid residues, with 15 half-cystines and 4–5 potential *N*-glycosylation sites. The odd number of half-cystines is consistent with other evidence suggesting a disulfide bond between the heme and the peptide chain. The sequence of LPO can be aligned with human peroxidases to give the following similarities: myeloperoxidase, 55.4%; eosinophil peroxidase, 54%; and thyroid peroxidase, 44.6%. In these four enzymes, 14 of 15 of the half-cystines are located in identical positions. The sequences of SPO and HLPO are likely to show similar homologies with the other members of the peroxidase family. For comparative purposes, the amino acid compositions of LPO and SPO are listed in Table II. The compositions are generally similar, but significant differences exist. SPO apparently has fewer half-cystine, methionine, and isoleucine residues than does LPO. However, SPO has more alanine, glycine, proline, and serine residues than does LPO. These differences in amino acid composition may account for the differences in the biochemical properties of the two enzymes (Pruitt, *et al.*, 1988).

LPO and SPO also differ in carbohydrate composition (Månsson-Rahemtulla *et al.*, 1988). SPO contains 4.6% and LPO 7% total neutral sugars by weight. The weight ratio of glucosamine to galactosamine is 2 : 1 in SPO and 3 : 1 in LPO. The weight ratios of mannose : fucose : galactose in the two enzymes are 1.5 : 1.4 : 1.0 for SPO and 14.9 : 0.5 : 1.0 for LPO.

No reports have been made of higher order structural studies of SPO and HLPO. Spectroscopic circular dichroism (CD)

studies of bivariate LPO suggest 65%  $\beta$  structure, 23%  $\alpha$  helix, and 12% unordered structure (Sievers, 1980). Bovine LPO probably has an ellipsoidal structure in solution (Paul and Ohlsson, 1985) and has properties in solution that are similar to those of other small globular proteins (Pfeil and Ohlsson, 1986). However, inferences about the higher order structure of SPO can be made based on amino acid composition (Table II) and solution properties. SPO contains 50% nonpolar side chains. These nonpolar side chains exist in part as exposed clusters on the surface of the molecule, since hydrophobic chromatography is an effective means for purification of SPO. The molecule also has exposed positive charges on its surface, as indicated by its affinity for negatively charged ion-exchange resins. The mosaic of hydrophobic and charged groups on the surface of SPO is responsible for its strong affinity for many different kinds of surfaces (Pruitt and Adamson, 1977; Pruitt *et al.*, 1979; Honka *et al.*, 1982).

Since absorbed SPO retains its enzyme activity, attachment to surfaces does not block donor access to the heme group. Thus, the surface binding sites and the heme group are not in immediate proximity on the SPO surface. This separation is consistent with the domain structure proposed for LPO by Pfeil and Ohlsson (1986). Based on their observations and on the general structural similarities between LPO and SPO and HLPO, we may suggest that SPO and HLPO have at least two structural domains that differ in stability.

The ultraviolet and visible spectra of bovine LPO and human SPO are identical (Månsson-Rahemtulla *et al.*, 1988). Therefore the two enzymes probably have the same prosthetic group located in similar environments. The prosthetic group of bovine LPO has been identified as protoheme IX (1,3,5,8-tetramethyl-2,4-divinylporphyrine-6,7-dipropionic acid; Sievers, 1979) and is covalently bound (Nichol *et al.*, 1987; Thanabal and La Mar, 1989; Modi *et al.*, 1990) to the peptide backbone via a disulfide bond at the 8-CH<sub>2</sub> group. The Fe<sup>3+</sup> is held in the porphyrin ring by four bonds to nitrogen; the fifth and sixth axial ligands are thought to be a histidyl residue and a carboxylate ion (Sievers, 1980; Sievers *et al.*, 1983).

Peroxidase kinetics and reaction mechanisms are very complex (for review, see Pruitt and Kamau, 1991). The products of the reactions and the mechanisms depend on the particular enzyme; the particular donor; the relative concentrations of enzyme, peroxide, and donors; the pH; and the temperature. For mucosal defense mechanisms, the most significant peroxidase reactions are those related to catalase activity and to thiocyanate oxidation. The relevant enzymes are SPO (Månsson-Rahemtulla *et al.*, 1988; Pruitt *et al.*, 1988) and HLPO (Pruitt *et al.*, 1992). The actual reactions are complex and include multiple intermediates. The net reactions follow:

1. Catalase activity (occurs in the absence of sufficient donor concentrations)

Subsequent reactions may convert the ferrous enzyme back to the native enzyme.

**Table II** Amino Acid Composition of Bovine Lactoperoxidase and Human Salivary Peroxidase<sup>a</sup>

	Nonpolar side chains		Polar side chains			Basic side chains			Acidic side chains		
	LPO <sup>b</sup>	SPO <sup>c</sup>	LP	SP		LPO	SPO		LP	SP	
Alanine	38	45	Serine	32	47	Arginine	39	35	Asparagine + aspartic acid	71	72
Cystine	15	10	Threonine	32	30	Lysine	33	31	Glutamine + glutamic acid	59	64
Glycine	40	47	Tyrosine	15	13	Histidine	14	11	Total	130	136
Isoleucine	27	19	Total	142	162	Total	86	77			
Leucine	69	72									
Methionine	11	3									
Phenylalanine	31	31									
Proline	42	59									
Tryptophan	14	ND <sup>d</sup>									
Valine	29	23									
Total	316	(309) <sup>e</sup>									

<sup>a</sup> Expressed as the nearest integer per 613 total residues.

<sup>b</sup> LPO, Bovine lactoperoxidase. Data from Cals *et al.* (1991).

<sup>c</sup> SPO, Human salivary peroxidase. Data from Månsson-Rahemtulla *et al.* (1988).

<sup>d</sup> ND, Not determined.

<sup>e</sup> Does not include tryptophan.

## 2. Peroxidation of SCN<sup>-</sup> (occurs under normal *in vivo* concentrations of SCN<sup>-</sup>)

In Compound I, both oxidizing equivalents of peroxide have been transferred to the heme group. The OSCN<sup>-</sup> is in equilibrium with its conjugate acid (HOSCN, pK<sub>a</sub> = 5.3; Thomas, 1981). The net peroxidation reaction may be in an apparent state of dynamic equilibrium *in vivo* (Pruitt *et al.*, 1986) that minimizes the concentration of H<sub>2</sub>O<sub>2</sub> and maximizes the concentration of HOSCN and OSCN<sup>-</sup>.

Both sets of reactions consume toxic H<sub>2</sub>O<sub>2</sub> and generate products that are harmless to the host. HOSCN and OSCN<sup>-</sup> inhibit the growth and metabolism of many species of bacteria (for review, see Pruitt and Reiter, 1985).

The complex dependence of rates of peroxidation on donor concentrations and on pH are consistent with the following mechanism (Pruitt *et al.*, 1988).

1. Oxidation of the native enzyme by H<sub>2</sub>O<sub>2</sub> to generate Compound I. This reaction is independent of pH.
2. Oxidation of SCN<sup>-</sup> by protonated Compound I to produce HOSCN and OSCN<sup>-</sup> and regenerate the native enzyme. This reaction is strongly pH dependent. Compound I must be protonated to react. A second protonation at low pH produces an inactive form.
3. Binding of SCN<sup>-</sup> to the native enzyme to produce an inactive form. This reaction is enhanced by low pH.

The major limiting factor for SCN<sup>-</sup> peroxidation in human saliva is the availability of H<sub>2</sub>O<sub>2</sub>, as has been shown by experi-

ments in which the addition of H<sub>2</sub>O<sub>2</sub> to human saliva *in vivo* (Månsson-Rahemtulla *et al.*, 1983) and *in vitro* (Tenovuo *et al.*, 1981) results in increased concentrations of HOSCN and OSCN<sup>-</sup>. However, concentrations of SCN<sup>-</sup> below 0.6 mM also may be limiting (Pruitt *et al.*, 1982). In human milk, the concentrations of SCN<sup>-</sup> are usually below this level. The low peroxidase concentration in human milk also may be a limiting factor (for review, see Pruitt and Kamau 1991; Pruitt *et al.*, 1992).

The peroxidase system enhances the antibacterial effects of lysozyme and Lf (discussed previously). The reduction of bacterial acid production by the peroxidase system is enhanced in the presence of secretory IgA (Tenovuo *et al.*, 1982a), but this effect does not depend on specific antibodies.

In summary, secretory peroxidase systems in human saliva and in human milk are natural defense mechanisms that do not require specific antibodies for their effectiveness. They protect mucosal surfaces from infection by inhibiting the growth and metabolism of many species of microorganisms. They prevent damage to mucosal surfaces from toxic products of oxygen reduction by converting hydrogen peroxide into products that are nontoxic for host cells but inhibit the growth and metabolism of many species of microorganism.

## A. Thiocyanate

The thiocyanate ion is a critical component of the SPO system. This anion is secreted by salivary, mammary, lacrimal, and gastric glands and can originate from several sources. The major source of SCN<sup>-</sup> is the detoxification reaction of CN<sup>-</sup> (Burgen and Emmelin, 1961), which occurs primarily in the liver through conversion of CN<sup>-</sup> to SCN<sup>-</sup> by the enzyme thiosulfate cyanide sulfur transferase. This

enzyme catalyzes the transfer of a sulfur atom from thiosulfate to a cyanide ion, the result of which is the far less toxic  $\text{SCN}^-$  (for review, see Wood, 1975). Sources of cyanide are dietary, for example, from bitter almonds, cassava, or tobacco smoke. Certain vegetables of the genus *Brassica* also contain appreciable amounts of  $\text{SCN}^-$  (Weuffen *et al.*, 1984). Thiocyanate is found in parotid, submandibular, and whole saliva as well as in gingival crevicular and plaque fluids (for review, see Tenovuo, 1985) and milk (for review, see Pruitt and Kamau, 1991). Average values of  $\text{SCN}^-$  in saliva of nonsmokers has been reported to be in the range of 0.35 to 1.24 mM, whereas the reported range for smokers varies from 1.38 mM to 2.74 mM (Maliszewski and Bass, 1955; Courant, 1967; Tenovuo and Mäkinen, 1976; Azen, 1978; Lamberts *et al.*, 1984; Olson *et al.*, 1985). In human milk, mean values of 0.021–0.122 mM have been reported with large variations from sample to sample (for review, see Pruitt and Kamau, 1991).

Thiocyanate is concentrated 10 to 20-fold from plasma into the salivary glands (Edwards *et al.*, 1954; Fletcher *et al.*, 1956; Logothetopoulos and Myant, 1956; Bratt & Paul, 1983) in humans and animals. Competition experiments provide evidence that iodide, thiocyanate, perchlorate, and nitrate compete as substrates for receptors on the same protein that transports them across the salivary cells (Edwards *et al.*, 1954; Fletcher *et al.*, 1956; Stephen *et al.*, 1973). The concentrating mechanism has been shown to be energy dependent (Fletcher *et al.*, 1956). Thus, this mechanism appears to be active transport. Tenovuo *et al.* (1982b) showed that the concentration of  $\text{SCN}^-$  in whole saliva rises on initial stimulation and then gradually declines. However, in no instance does the  $\text{SCN}^-$  secretion (concentration of  $\text{SCN}^- \times$  secretion rate) in whole stimulated saliva drop below that of unstimulated saliva. These observations indicate that the  $\text{SCN}^-$  transport system is able to maintain  $\text{SCN}^-$  levels despite the increased dilution resulting from stimulation. Thus, active transport of  $\text{SCN}^-$  may be increased by stimulation. Active transport of  $\text{SCN}^-$  into saliva also may provide a recycling mechanism for this important ion. Saliva is swallowed continuously so  $\text{SCN}^-$  would be brought back into the blood by the gastrointestinal transport system and concentrated again in the salivary glands. This recycling mechanism may explain the long half-life (6 days) of  $\text{SCN}^-$  in blood (Junge, 1985).

$\text{SCN}^-$  has been demonstrated to be extremely important in protecting a variety of tissues against tissue destruction that might occur as a result of peroxidase-catalyzed oxidation of  $\text{Cl}^-$  and  $\text{Br}^-$ . For example, in a reaction that accompanies the respiratory burst of leukocytes, the oxidation of the  $\text{Cl}^-$  ion by MPO may generate toxic products. MPO, a major protein of polymorphonuclear leukocytes, will catalyze the oxidation of  $\text{Cl}^-$  by  $\text{H}_2\text{O}_2$  to form water and a highly reactive oxidizing agent, the hypochlorite ion ( $\text{OCl}^-$ ). Hypochlorite will activate latent collagenase, elastase, gelatinase, and cathepsin that are present in leukocytes, and inactivate circulating protease inhibitors, causing tissue injury (Weiss, 1989). The cytotoxic hypohalous acid oxidants also can be produced by eosinophil peroxidase (EPO) through oxidation of halides ( $\text{Br}^-$ ,  $\text{Cl}^-$ , and  $\text{I}^-$ ) in the absence of the pseudohalide  $\text{SCN}^-$ .

Although the hypohalous acid oxidants mediate the killing of bacteria and the extracellular destruction of invading helminthic parasites (Gleich and Adolphson, 1986), these oxidants are also extremely tissue destructive (Slungaard and Mahoney, 1991). However,  $\text{SCN}^-$  has been shown to be the preferred substrate for both MPO and EPO, although it is present in serum in significantly lower concentrations than the other halides (Thomas and Fishman, 1986; Slungaard and Mahoney, 1991). This preference for  $\text{SCN}^-$  results in generation of  $\text{HOSCN}$  and  $\text{OSCN}^-$ , which are nontoxic to human cells and tissues (Hänström *et al.*, 1983; Tenovuo and Larjava, 1984; Thomas and Fishman, 1986; Slungaard and Mahoney, 1991). Note that  $\text{SCN}^-$  is recognized as a useful therapeutic agent for the treatment of sickle-cell crises in sickle-cell anemia patients. The much greater incidence of sickle-cell anemia in African Americans than in tropical Africans has been attributed to the much greater  $\text{SCN}^-$  content of African diets compared with American diets (Agbai, 1986).

Work from our laboratory has shown that patients suffering from leukemia and undergoing chemotherapy have significantly lower  $\text{SCN}^-$  concentrations in saliva than do healthy control subjects. This reduction is correlated with a simultaneous reduction in the number of granulocytes (Månsson-Rahemtulla *et al.*, 1991). These observations have led us to hypothesize that the reduction in  $\text{SCN}^-$  concentration is related to the granulocytopenia resulting from chemotherapy and not from the disease itself. A decrease in  $\text{SCN}^-$  may cause an accumulation of  $\text{H}_2\text{O}_2$  and subsequent damaging effects on the oral mucosa. Hydrogen peroxide has been shown to be toxic to a variety of life forms by causing lysis of normal cells, for example, red blood cells (Weiss *et al.*, 1980), endothelial cells (Sacks *et al.*, 1978), fibroblasts (Simon *et al.*, 1981), lymphoma cells (Nathan *et al.*, 1979), and gingival fibroblasts (Hänström *et al.*, 1983; Tenovuo and Larjava, 1984; Bratt *et al.*, 1991).

### B. Peroxidase Antibodies

Comparative immunological studies of LPO and SPO have been published (Månsson-Rahemtulla *et al.*, 1990). In double immunodiffusion experiments, LPO and SPO showed partial identity to polyclonal antibodies raised against a highly purified preparation of LPO. However, in competitive radioimmunoassays and enzyme-linked immunosorbent assays, LPO replaced the test antigen but SPO did not. The epitopes recognized by the antibodies are present on the protein cores of LPO and SPO. *N*-Linked oligosaccharides were removed from LPO and SPO by treatment with *N*-glycanase. The deglycosylated peroxidases were subjected to SDS-PAGE and transferred to nitrocellulose on which immunodetection was performed. Deglycosylation had no effect on the binding of the antibodies to the protein cores. Structural differences in the core protein of the two enzymes were demonstrated by partial proteolytic digestion and subsequent immunodetection of the peptide fragments. The antibodies did not inhibit the catalytic activity of LPO but did cause partial inhibition of SPO enzyme activity, indicating that sites of the epitopes of the two enzyme were not identical or that they

were distributed differently on the enzyme surface relative to the location of the catalytic sites (Månsson-Rahemtulla *et al.*, 1990). Ongoing studies in our laboratory using a panel of monoclonal antibodies to probe the structures of various peroxidases have indicated that substantial cross-reactivity exists. Of five monoclonal antibodies raised against SPO, four cross-react with LPO, EPO, and MPO whereas one of the three anti-LPO monoclonal antibodies cross-reacts with SPO and EPO (Månsson-Rahemtulla and Rahemtulla, 1989; Kiser *et al.*, 1991).

The studies reviewed here show that antibodies raised against a single peroxidase, for example, LPO, cannot be used for reliable quantitation of other peroxidases (SPO, MPO, EPO) in secretions (saliva and crevicular fluid) in which several peroxidases may be present. These studies also show that the secondary and tertiary structures of LPO and SPO reveal different epitopes and that, relative to the catalytic sites, these epitopes occupy different positions on the exposed surfaces of the two enzymes.

## V. HIGH MOLECULAR WEIGHT GLYCOPROTEINS

Functions that have been proposed for high molecular weight glycoproteins and mucins in saliva include tissue coating and formation of intraoral pellicles, formation of a lubricating film at hard and soft tissue interfaces, selective clearance and adherence of microorganisms and viruses, heterotypic complexing with other salivary proteins, and protection of the oral mucosa against desiccation (for review, see Cohen and Levine, 1989). High molecular weight glycoproteins found in saliva are synthesized and secreted by all major and minor salivary glands. However, high molecular weight mucinous glycoproteins have been localized to cells in the labial, submandibular, and sublingual glands by specific antibodies to these glycoproteins. Further, distinct acinus populations secrete these mucinous glycoproteins (Cohen and Levine, 1989; Cohen *et al.*, 1990). All high molecular weight glycoproteins bear oligosaccharides that are O-glycosidically linked through *N*-acetylgalactosamine-serine/threonine linkages. However, mucinous glycoproteins also may contain *N*-glycosidically linked oligosaccharides (for details see Tabak, 1990,1991).

The agglutinating properties of the high molecular weight glycoproteins have been studied extensively. The first report on salivary-induced aggregation of oral bacteria was by Gibbons and Spinell (1970), who demonstrated that saliva contained a component that adhered to the tooth surface and caused agglutination of bacteria. This component later was isolated from whole saliva and partially characterized as a high molecular weight glycoprotein containing, of the dry weight of the isolated material, 33.3% protein, 19% anthrone-positive carbohydrates, and 2.9% *N*-acetylneuraminic acid. The remaining components were not chemically characterized. Glucosamine and galactosamine were detected in substantial quantities but the proportions were not reported. The amino acid composition revealed that this component was

rich in threonine, serine, and proline. This glycoprotein could cause aggregation of certain oral bacteria, had a high affinity for hydroxyapatite, and had similar properties to a compound isolated from dental plaque. Based on these observations, the authors suggested that the high molecular weight salivary glycoprotein played a significant role in the initial formation of the dental plaque, as well in further development of the bacterial plaque by facilitating binding of the oral microorganisms to each other (Hay *et al.*, 1972).

Several other high molecular weight glycoproteins in saliva have the capacity to agglutinate and prevent oral bacteria from adhering to mucosal and hard tissue surfaces (Ericson *et al.*, 1976; Levine *et al.*, 1978,1985; Eggert, 1980a,b,c,d; Ericson and Rundegren, 1983; Rundegren, 1986). These glycoproteins are dependent on calcium for their agglutinating activity (Gibbons and Spinell, 1970; Eggert, 1980b,c; Rundegren and Ericson, 1981). Agglutinating activity is abolished by removal of carbohydrate chains by beta elimination (Ericson *et al.*, 1976), by removal of sialic acid (Levine *et al.*, 1978), and by treatment with hydrogen peroxide (Ericson and Bratt, 1987). These high molecular weight glycoproteins may modulate the oral microbial flora by favoring attachment and subsequent proliferation of certain microorganisms or by promoting clearance of others. An important question regarding the high molecular weight glycoproteins is whether the molecules partially characterized by investigators mentioned earlier are the same or belong to a family of glycoproteins that occur in several forms originating from transcriptional, translational, and posttranslational modifications. Understanding the origin of the molecules requires a knowledge of the biochemical structure. Work by Ericson and Rundegren (1983) has demonstrated that parotid saliva contains a high molecular weight glycoprotein that can agglutinate *S. mutans* serotype c strain. The chemical characterization of this glycoprotein revealed that it was fucose rich; contained sialic acid, hexosamine, and hexose; and had a total carbohydrate content of 45%. The peptide core of this glycoprotein was rich in aspartic acid, serine, and threonine and low in proline residues. The molecular weight was estimated at  $5 \times 10^6$  Da. After treatment with SDS, the molecular mass was reduced to  $4.4 \times 10^5$ . The purified preparation of this glycoprotein showed agglutinating activity only in the presence of calcium; 0.1  $\mu$ g caused aggregation of  $10^8$  bacteria. Calculations based on these numbers show that only a few agglutinin molecules are required for aggregation of the bacteria. Assuming a molecular weight of  $5 \times 10^6$  Da, 0.1  $\mu$ g corresponds to  $2 \times 10^9$  agglutinin molecules. Therefore, approximately 20 agglutinin molecules per bacterial cell can be estimated to produce aggregation of the cells. More recently, *Streptococcus sanguis* has been demonstrated to contain a receptor that binds purified salivary agglutinin. This protein is highly homologous to a surface antigen expressed by *S. mutans*. The interaction of this receptor was inhibited by neuraminidase digestion of the salivary agglutinin and also by simple sugars containing sialic acid, demonstrating that sialic acid is involved in the binding of this microorganism (Demuth *et al.*, 1988,1990).

The mucinous glycoproteins occur in at least two different forms, a high molecular weight glycoprotein designated MG1

and a low molecular weight glycoprotein MG2. Several studies have demonstrated that the two forms of mucinous glycoproteins are present in submandibular saliva obtained from a wide variety of species (reviewed in Tabak, 1990,1991). MG1 and MG2 share common properties. Both are secreted from labial, sublingual, and submandibular glands. Their amino acid compositions are similar with a preponderance of serine, threonine, and proline and a small number of aromatic amino acids. Bovine mucins (Tabak, 1990) and porcine mucins (Eckhardt *et al.*, 1987; Timpte *et al.*, 1988) contain highly repetitive sequences dominated by serine, threonine, and proline. Both MG1 and MG2 have O-glycosidically linked oligosaccharides with *N*-acetylgalactosamine, *N*-acetylglucosamine, galactose, fucose, and sialic acids. A small amount of *N*-glycosidically linked oligosaccharides has been reported to be present in submandibular mucins (Denny and Denny 1980,1982; Levine *et al.*, 1987). The oligosaccharide side chains of mucinous glycoproteins are sulfated; the sulfate groups are attached to galactose or C4 or C6 of *N*-acetylglucosamine residues (Lombardt and Winzler, 1974; Embery and Ward, 1976; Tabak and Levine, 1981; Green and Embery, 1987; Hofsoy and Jonsen, 1987). The sulfation has been confirmed by demonstration of a sulfotransferase enzyme identified in rat sublingual and submandibular glands. This enzyme catalyzes the transfer of a sulfate ester group from 3'-phosphoadenosine-5'-phosphosulfate to the oligosaccharide chains. Structural studies of the sulfated oligosaccharides have revealed the presence of a sulfate residue on the C6 of *N*-acetylglucosamine (Slomiany *et al.*, 1988,1989). Some of the oligosaccharide side chains of the mucins are related structurally to blood group antigens. The blood group reactive glycoproteins in saliva have been demonstrated to cause aggregation of several strains of oral bacteria (Williams and Gibbons, 1975; Gibbons and Qureshi, 1978; Hogg and Embery, 1979,1982; Ligtenberg *et al.*, 1990a,b).

The mucinous glycoprotein MG1 has a molecular weight in excess of 1 million Da. The molecule consists of several peptide subunits that are disulfide bridged. MG1 had 15% protein and contains only O-glycosidically linked oligosaccharides that are distributed randomly on the protein core. The nonglycosylated regions, referred to as naked regions on the molecule, are highly susceptible to proteases. Approximately 80% of the carbohydrates are located in 292 oligosaccharide side chains consisting of 4–16 monosaccharides per chain. The low molecular weight mucinous glycoprotein MG2 has a molecular weight of 200–250 kDa and an estimated protein content of 30%. The large amount of carbohydrate (approximately 69%) is present as 170 oligosaccharide chains made up of 2–7 monosaccharide residues each. The oligosaccharides are predominantly O-linked through serine/threonine–*N*-acetylgalactosamine bonds, but small amounts of asparagine-linked oligosaccharides are also present (Cohen and Levine, 1989; Tabak, 1990,1991).

The studies reviewed here show that the high molecular weight glycoproteins found in mucosal secretions are heterogeneous. The heterogeneity may arise from transcriptional variations and from translational and posttranslational modifications. These glycoproteins have high affinity for mucosal surfaces and for the surfaces of microorganisms. This affinity

is based on carbohydrate components. These components are probably responsible for the calcium-dependent bacterial clearance and selection, the tissue lubricating, and the protective properties of these glycoproteins.

# Bacterial Adherence and Mucosal Immunity

C. Svanborg

## I. INTRODUCTION

Adhesion is a key to the organized functions of multicellular organisms. Adhesion between eukaryotic cells is a prerequisite for the establishment of tissues and organs. During embryogenesis, tissues evolve from "founder" cells. The progeny remain attached to each other and show greater affinity for cells of the same origin than for other cells. Changes in adhesive properties often accompany the spread of cells to a new site and the development of new functions. Adhesion is also fundamental to the communication between cells that is required for the diversification of cellular functions. For example epithelial cells have elaborate systems for cell-to-cell adhesion. These cells are held together by tight junctions that contribute to the barrier function of the epithelium by limiting the uptake of water-soluble molecules from the lumen. These junctions also maintain the polarity of the cells by limiting the flux of membrane proteins from the apical to the basolateral part of cell.

Bacteria share with eukaryotic cells the requirement for adhesion. The tendency of bacteria to grow attached to surfaces first was observed in aquatic systems (Zobell, 1943). Bacteria that were attached to rocks in a stream multiplied faster than free-floating cells of the same species (Zobell, 1943; Gibbons, 1973). Their likelihood of trapping nutrients was calculated to be enhanced by the attached state (Zobell, 1943; Zafriri *et al.*, 1987). Subsequent studies have shown that attachment between bacteria is essential for the cooperation of cells within a colony, as well as for the exquisitely regulated interactions that make complex bacterial habitats composed of different bacterial species resemble tissues composed of several eukaryotic cell types (Savage, 1984, 1988).

The attachment of bacteria to human cells and tissues lacks the seemingly altruistic quality of adhesion between eukaryotic cells on the one hand and between bacteria on the other. The pro- and eukaryotic cells are unlikely to share any expectations of the outcome of this interaction. Attachment is needed for the bacteria to remain in the human host and to enhance nutrient access. Unattached bacteria are eliminated from mucosal surfaces by the flow of secretions. Attachment also is needed to permit the establishment of the indigenous microflora for the host to benefit from its functions. For example, the microflora has been proposed as a major driving force behind the evolution of genetic polymorphisms in the human host (for review, see Svanborg-Edén and Levin, 1988).

In view of the mutual toxicity of bacteria and host cells, the consequences of attachment may be severe for both parties. Even members of the indigenous microflora contain potent toxins and activators of immunity and inflammation. Pathogens have evolved additional mechanisms to disrupt the organization and function of host tissues (Orskov and Orskov, 1983). A large group of bacteria are considered "coincidental" pathogens (Svanborg-Edén and Levin, 1988). They persist as members of the indigenous flora at one site, apparently without causing damage, but induce disease when they reach a different site within the same host.

The different mechanisms of bacterial adherence may have evolved as a way to reconcile the opposing needs of bacteria and host. The bacteria select habitats in which survival is optimal. This is achieved by the expression of surface molecules—adhesins—that selectively recognize specific habitats, permitting attaching cells to find the appropriate site in each new host and to expand their population there (Leffler *et al.*, 1983). The host directs the establishment of the indigenous flora by expressing variable receptor structures that define the different habitats. By specific attachment to these receptors, the flora is directed to these sites. The toxic effects of the flora may be reduced if the receptors are loosely associated with the cells (Svanborg-Edén *et al.*, 1988a). In contrast, pathogens express adhesins that recognize cell-bound receptors that promote the access of toxin, the invasion of bacteria, and so on. In this way, the specificity as well as the architecture of bacterial adherence will influence the outcome of host-parasite interactions.

## II. MECHANISMS OF ADHERENCE

Adhesive bacterial surface proteins, adhesins, often act as lectins. They bind receptor epitopes provided by host cell glycoconjugates (for review, see Mirelman, 1986). All cells surround themselves with a shell of carbohydrates. Chemical analyses have revealed extensive differences in carbohydrate composition among species, individuals, and tissues within an individual (Berger *et al.*, 1982; Hakomori, 1983). Indeed, blood group antigens that distinguish one individual from the next are often carbohydrate in nature (Berger *et al.*, 1982; Hakomori, 1983). Bacterial cells also use carbohydrates to generate individuality. Isolates of *Escherichia coli* that share the same lipopolysaccharide and capsular polysaccharide antigens are genetically more alike than those with different

carbohydrate structures (Caugant *et al.*, 1985). Polysaccharide capsules help maintain the bacterial self, both as a defense against inflammation and as a mechanism for evasion of the immune response.

The extensive variability of oligosaccharide sequences makes them suitable as receptors for diverse bacterial ligands. Early studies of toxins and viruses showed that microbial ligands can bind glycoconjugate receptors. The influenza virus hemagglutinin recognizes certain acetylneuraminic acid-containing structures (van Heyningen, 1974). Cholera toxin binds specifically to GM1 ganglioside (Paulson, 1985). The fimbriae of gram-negative *E. coli* recognize a variety of host cell glycoconjugates. Adherence consequently might be achieved by the binding of a host lectin to a bacterial glycoconjugate.

### A. *Escherichia coli* P Fimbriae Bind to the Globoseries of Glycolipids

Before the identification of glycolipid receptors, the *in vitro* attachment of bacteria to a given epithelial cell type was known to predict their ability to colonize a mucosal site in the individual. This ability was demonstrated for streptococci with affinity for different mucosal compartments within the oral cavity (Gibbons and van Houte, 1971, 1975) and for uropathogenic *E. coli* that attached to uroepithelial cells but not to small intestinal cells (Leffler *et al.*, 1983; Leffler and Svanborg-Edén, 1980). At the same time, biochemical analyses of intestinal epithelial glycolipids had shown that epithelial cells are highly glycosylated, and that the glycolipid composition varies extensively among species, individuals, and tissues (see Berger *et al.*, 1982; Hakomori, 1983; Leffler *et al.*, 1983; Leffler and Svanborg-Edén, 1986; and references therein). The observation of variability of bacterial attachment and epithelial glycolipid composition led us to study and identify glycolipids as receptors for P fimbriated *E. coli* (Svanborg-Edén and Leffler, 1979; Leffler and Svanborg-Edén, 1980, 1986). The symbol P was chosen for two reasons: (1) P fimbriated *E. coli* are accumulated in patients with acute pyelonephritis (reviewed by Svanborg-Edén *et al.*, 1988b; Johnson, 1991). (2) The globoseries of glycolipids acts as both receptors for P fimbriae and antigens in the P blood group system (Källénus *et al.*, 1980; Bock *et al.*, 1985; Leffler and Svanborg-Edén, 1980).

The initial studies showed that the receptor activity of epithelial cells resided in the globoseries of glycolipids (Leffler and Svanborg-Edén, 1980, 1986). Attachment was inhibited by pretreatment of *E. coli* with those glycolipids. The glycolipids also could induce binding to an inert surface or to a cell that lacked receptor-active glycolipids. Further, attachment was P blood group dependent. Cells from individuals of blood group p, who lack the globoseries of glycolipids, did not interact with P fimbriated *E. coli* (Källénus *et al.*, 1980; Leffler and Svanborg-Edén, 1980). Additional studies have shown variation in receptor activity among members of the globoseries of glycolipids (Leffler and Svanborg-Edén, 1981; Lund *et al.*, 1988; Lindstedt *et al.*, 1989; Strömberg *et al.*, 1990). The P fimbriae constitute a family of adhesins

that recognize the globoseries of glycolipids but differ in the preferred receptor epitope.

The P fimbriae are encoded by the *pap* family of chromosomal gene clusters (Hull *et al.*, 1981). *pap* gene clusters cloned from different *E. coli* strains show extensive sequence homology except for *papA*, which encodes the major fimbriilin subunits, and *papE*, *papF*, and *papG* sequences, which encode the adhesin (Hull *et al.*, 1981; Clegg, 1982; Väisänen-Rhen *et al.*, 1984; vanDie and Bergmans, 1984; Karr *et al.*, 1989). The adhesin complex *papE*–*papG* is located at the tip of the fimbriae (Lindberg *et al.*, 1987; Hanson *et al.*, 1988; Jann and Hoschützky, 1989). *papG* is present in the periplasmic space and has been proposed to act as a chaperone stabilizing the subunits *papE* and *papG* during the transport from the inner membrane to the outer membrane (Huttgren *et al.*, 1989). *papC* has been proposed to form a pore through which the pilus is assembled (Norgren *et al.*, 1987). *papH* terminates fimbrial assembly and helps anchor the fimbriae (Tennent *et al.*, 1990). The roles of *papJ* and *papK* are less clear. The *papJ* gene product has been suggested to facilitate the assembly of *papA* subunits into the pilus structure (Tennent *et al.*, 1990). The *papK* gene product has been suggested to be a pilin-like protein located at the pilus tip (Tennent *et al.*, 1990). *papB* and *papI* encode regulatory proteins involved in positive transregulation of *papA* transcription (Norgren *et al.*, 1984; Uhlen *et al.*, 1985).

The G adhesins of the *papG*<sub>1A2</sub> type dominate in the virulent *E. coli* strains that cause acute pyelonephritis (Johanson *et al.*, 1993). Their adhesins recognize most members of the globoseries of glycolipids, but appear to prefer globotetraosylceramide (Johanson *et al.*, 1992; Strömberg *et al.*, 1990). The G adhesins of the *prsG*<sub>196</sub> type are less prevalent among clinical isolates and show no clear-cut association with disease, except possibly acute cystitis (I. M. Johanson). These adhesins prefer a receptor epitope composed of an *N*-acetylgalactosamine  $\alpha$ -linked to a globoseries core (Karr *et al.*, 1989; Lindstedt *et al.*, 1989; Strömberg *et al.*, 1990). Although these adhesins also recognize globotetraosylceramide on thin-layer chromatogram plates, their binding to uroepithelial cells requires the Forssmann or globo-A glycolipids (Lindstedt *et al.*, 1989; Johanson *et al.*, 1992).

### B. Type 1 Fimbriae

Type 1 or mannose-sensitive (MS) fimbrial adhesins recognize mannose-containing receptors. Their binding is blocked by solutions of D-mannose or  $\alpha$ -methyl-D-mannoside (Duguid *et al.*, 1955, 1979; Ofek *et al.*, 1985). Receptors for type 1 fimbriae are present on a variety of cells from many species (Duguid *et al.*, 1979). Type 1 fimbriae bind mannose epitopes on secreted glycoproteins such as the Tamm–Horsfall protein and secretory IgA (Orskov *et al.*, 1980; Svanborg-Edén *et al.*, 1981; Parkkinen *et al.*, 1988; Wold *et al.*, 1990). When these substances coat uroepithelial cells, they may provide receptor epitopes for bacterial surface colonization. When secreted, they may eliminate type 1 fimbriated *E. coli* strains and prevent colonization or infection. Further, type 1 fimbriae play a complex role in the interaction with human polymorphonuclear leukocytes (PMNs). The adhesion of type 1

fimbriated *E. coli* strains to PMNs may promote bacterial killing (Bar Shavit *et al.*, 1977; Öhman *et al.*, 1982; Svanborg-Edén *et al.*, 1984). The type 1 fimbriae are encoded by the *pil* or *fim* genes of four clusters (Hull *et al.*, 1981; Klemm, 1985). *fimA* encodes the fimbrial subunit protein and can be expressed independent of the *fimH*-encoded adhesin protein (Minion *et al.*, 1986). The *fimA* gene product must be present on the cells to confer the adhesive phenotype, in contrast to what has been found for the P fimbriae.

The expression of fimbriae is subject to phase variation (Brinton, 1965; Eisenstein, 1981; Rhen *et al.*, 1983; Klemm 1986). Changes in temperature, glucose concentration, and other experimental conditions may switch the fimbriae on or off (Uhlin *et al.*, 1985). Little is known about *in vivo* growth conditions that control fimbrial expression. Pere studied the expression of fimbriae in urine directly by immunofluorescence and found that the P fimbriae were expressed whereas the type 1 fimbriae occurred less frequently (Pere *et al.*, 1987).

### C. Other Fimbrial–Carbohydrate Interactions

The fimbria-mediated attachment to oligosaccharide receptor epitopes is common among gram-negative bacteria (Beachey, 1981; Mirelman, 1986). *Haemophilus influenzae* attaches to the respiratory tract mucosa via fimbriae that have been suggested to recognize *N*-acetylglucosamine  $\beta$ (1-3)-galactose-containing glycolipids (van Alphen *et al.*, 1986; Krivans *et al.*, 1988). *Pseudomonas aeruginosa* has both fimbria-associated and independent adherence. Attachment of these cells to nasopharyngeal epithelium is fimbria-mediated and inhibited by acetylneuraminic acid. The attachment to respiratory tract cells is determined by alginate or proteins associated with the alginate that specifically recognize gangliotri- and gangliotetraosylceramide, as well as lactosylceramide (Baker and Svanborg-Edén, 1989; Baker *et al.*, 1990). The attachment of *Vibrio cholerae* to intestinal mucosa is inhibited by fucose, but the receptor epitope remains to be identified (Jones and Feter, 1976). *Neisseria gonorrhoeae* binds to a subset of lactose-containing glycolipids, as does the nonvirulent variant *Neisseria subflava* (Nyberg *et al.*, 1990). *Actinomyces naeslundii* and *Actinomyces viscosus* bind lactosyl ceramide (Strömberg and Karlsson, 1990). The adherence of *Actinomyces* to salivary pellicles was found to be sensitive to *N*-acetylgalactosamine  $\beta$ , but with variation in affinity for different *N*-acetylgalactosamine-containing glycoconjugates (Strömberg and Karlsson, 1990; N. Strömberg, T. Boren, A. Carlén, and J. Olsson, unpublished observations). This list might be extended considerably.

## III. FUNCTIONAL CONSEQUENCES OF ADHERENCE

The simplest outcome of bacterial attachment is the mechanical association of bacteria with the receptor-bearing surface. This result may be sufficient if the attached state

promotes bacterial multiplication and permits the attached cells to reach higher numbers than the unattached bacteria, which are washed away by the flow of secretions (Zobell, 1943; Gibbons, 1973; Zafirri *et al.*, 1987). Attachment is, however, also a way for pathogens to gain access to the host mucosal tissues. Further, attachment may trigger changes in the receptor-bearing target cell such as effacing lesions of microvilli, cytokine production, or invasion into or through epithelial cells (for review, see Gibbons, 1973; Beachey, 1981; Orskov and Orskov, 1983).

### A. Adherence and Toxicity

The crucial role of adherence for virulence first was demonstrated in two models—diarrhea caused by K88-bearing *E. coli* in piglets (Smith and Halls, 1967; Smith and Lingood, 1972; Stirn *et al.*, 1967) and experimental cholera infection in mice (Freter, 1969). *Escherichia coli* causing diarrhea in newborn piglets carried a virulence plasmid encoding the K88 fimbrial adhesin and the exotoxin. Deletion of the plasmid abolished virulence. Mutation of genes encoding the toxin or the K88 adhesin permitted experiments to assess their relative contribution to virulence. The toxin-negative mutant colonized the intestine and caused minor discomfort, but not overt disease, in the piglets. The K88-negative mutant did not colonize or cause disease. Consequently, both adherence and toxin production are required for disease to occur.

Vaccination studies with *V. cholerae* gave similar results. Vaccinated animals were protected against cholera, but carried the same number of *V. cholerae* in their large intestine. However, the bacteria were localized in the lumen rather than adjacent to the mucosal surface (Freter, 1969). Antibodies that prevented adherence protected the animals. Similarly, piglets that received anti-K88 antibodies in milk were protected from infection (Sellwood *et al.*, 1975).

The synergy between adhesin and toxin since has been observed in a variety of models (Sansonettil, 1991; Burroughs *et al.*, 1992). Adherence is presumed to enhance toxicity by approaching the bacteria to the mucosal surface in such a manner that toxin delivery to the epithelial cells becomes more effective (Smith and Halls, 1967; Freter, 1969; Jones and Rutter, 1972; Smith and Lingood, 1972). Adherence also has been shown to enhance the effect of endotoxins. Whereas lipid A alone and P fimbriae alone can trigger a mucosal inflammatory response, the magnitude of the response is enhanced by the combination of P fimbriae and lipid A (Linder *et al.*, 1991).

### B. Attaching Bacteria Elicit Mucosal Cytokine Production

Bacterial products stimulate cytokine production. Molecules such as endotoxin can activate cytokine production in a variety of cells including fibroblasts, monocytes, and lymphocytes. Indeed, many of the clinical signs of gram-negative septicemia may be prevented by compounds that inhibit tumor necrosis factor (TNF) and interleukin 1 (IL-1) (Tracey *et al.*, 1987; Michie *et al.*, 1988; Hirano *et al.*, 1990;

Starnes *et al.*, 1990). Septicemia is, however, a rare event. In most cases, the indigenous gram-negative flora and pathogens are carried at the mucosal level, where they attach and exert the majority of their effects.

The existence of a mucosal cytokine response to gram-negative bacteria first was recognized in patients and in experimental infection models. An IL-6 response occurred in mice within minutes of intravesical instillation of *E. coli* bacteria (de Man *et al.*, 1989). Even mucosal exposure to dead bacteria or isolated P fimbriae elicited an IL-6 response (Linder *et al.*, 1991). No elevation of the circulating cytokine levels was seen (de Man *et al.*, 1989; Hedges *et al.*, 1991). In humans, deliberate colonization of the urinary tract with *E. coli* bacteria caused an increase in the urinary IL-6 and IL-8 levels (Hedges *et al.*, 1991; W. Agace *et al.*, 1993). No concomitant elevation of the serum cytokines was measured, however, and no induction of symptoms was noted. Patients with natural episodes of urinary tract infection also were found to secrete IL-6 into the urine (Hedges *et al.*, 1992). Elevated urinary IL-6 levels were found in most individuals with bacteriuria, regardless of the type of bacteria that caused the infection. Children infected with P fimbriated bacteria had a higher cytokine response than other children (M. Benson, U. Jodal, Å. Karlsson, A. Andreasson, and C. Svanborg, unpublished observations), but no significant difference in mucosal cytokine production related to bacterial adherence was seen in adults. Elevated serum IL-6 levels were seen only in patients with systemic infections who had fever and acute phase reactants. These observations are consistent with the hypothesis that attaching bacteria elicit a local cytokine response and that spread of cytokines from the mucosal site of infection to systemic sites can cause some of the symptoms associated with mucosal infections.

Epithelial cells constitute one source of the mucosal cytokines. Cytokine production was shown for epithelial cell lines in culture and for exfoliated epithelial cells. Their constitutive IL-6 secretion was up-regulated by *in vitro* stimulation with *E. coli* bacteria (Hedges *et al.*, 1990). Cytokine production by epithelial cells has since been analyzed by a variety of techniques (Kvale *et al.*, 1988; Hedges *et al.*, 1990, 1992a,b; Mayer *et al.*, 1992; Moro *et al.*, 1992; W. Agace *et al.*, 1993.) Attaching bacteria elicited a higher cytokine response in epithelial cell lines than did nonattaching bacteria. The IL-6 response was stimulated even by isolated P fimbriae of the F7 type with the ability to bind the globoseries of glycolipids. These organisms triggered a significantly higher IL-6 response than the same fimbriae that had lost the receptor-binding domain (Hedges *et al.*, 1992a). Type 1 fimbriae enhanced the IL-8 response of epithelial cell lines to *E. coli* (W. Agace *et al.*, 1993). These observations suggest that the bacterial adherence properties influence the epithelial cytokine response.

Epithelial cells also respond to cytokine stimulation. Interferon  $\gamma$  stimulation up-regulated the expression of secretory component and HLA-II antigens in HT29 cells (Kvale *et al.*, 1988; Moro *et al.*, 1992). This secondary cytokine production may be relevant in at least two situations. First, the epithelial cell cytokines that are triggered by the bacteria and released at the local site may stimulate adjacent cells. Second, cells

such as lymphocytes, granulocytes, and macrophages, which migrate to the site of infection and release their cytokines at this site, may influence the cytokine profile of the epithelial cells. Epithelial cells therefore play a more active role in the cytokine network than previously has been understood.

#### IV. ANTI-ADHESIVE MUCOSAL DEFENSE MECHANISMS

Early studies demonstrated that secretory IgA antibodies inhibit bacterial attachment. This property of IgA has been discussed as a major protective mechanism of mucosal antibodies (Freter, 1969; Sellwood *et al.*, 1975). Are individuals who lack mucosal antibody production or antibody responses in general overwhelmed by mucosal infections? Clinical observations in such patient groups do not support such an idea. Individuals with hypogammaglobulinemia mainly acquire recurrent upper respiratory tract infections with encapsulated bacteria. IgA-deficient individuals have an increased morbidity in mucosal infections such as traveler's diarrhea but rarely suffer from recurrent mucosal infections (World Health Organization, 1992).

This apparent contradiction probably reflects the fact that the mucosal surfaces are equipped with multiple defense systems that cooperate to control bacterial attachment. Not only sIgA antibodies but also secreted molecules of a nonimmunoglobulin nature interfere with bacterial adherence. Soluble glycoconjugates carry the same oligosaccharide epitopes as cell-bound receptors, but function as competitive inhibitors when secreted. By occupying receptor binding sites on the fimbriae, they prevent subsequent attachment to the cell-bound receptors (Holmgren *et al.*, 1981; Andersson *et al.*, 1986; Askenazi and Mirelman, 1987; Leffler and Svanborg-Edén, 1990; Schrotten *et al.*, 1992).

The anti-adhesive antibodies may act in either of two ways: (1) Antibodies to the receptor binding site of the adhesin competitively inhibit receptor interactions. (2) Antibodies to bacterial surface molecules that are not directly involved in adherence may interfere with the binding. This interference is illustrated by the immune response to bacterial fimbriae. The majority of antibodies elicited by fimbriated bacteria are directed against the antigenically variable fimbrial subunit protein and interferes with attachment only at concentrations high enough to cause agglutination (Svanborg-Edén *et al.*, 1981). A minor fraction of antibodies is directed against the receptor binding lectin and, when purified, such antibodies block adherence (de Ree *et al.*, 1987; Hoschötzky *et al.*, 1989). In either case, the anti-adhesive activity of the antibody is attributed to the specificity of the antigen-combining site.

IgA also can act as a soluble receptor for bacterial adhesins (Wold *et al.*, 1990), a characteristic that is explained by mannose residues on oligosaccharide sequences on the heavy chain (Kornfeld and Kornfeld, 1976). The type 1 fimbriated *E. coli* agglutinates colostral IgA, with a higher titer for IgA2 than IgA1. Type 1 fimbriated *E. coli* also agglutinate IgA2 and IgA1 myeloma proteins, which lack specific antibody

activity against *E. coli* (Wold *et al.*, 1990). The IgA2 myelomas that give the highest agglutination titer with type 1 fimbriated strains were rich in high-mannose oligosaccharides. In contrast, the concentration of such oligosaccharides was low in the less active IgA1 myeloma proteins. The agglutination was inhibited by mannose. Myeloma IgA2 as well as colostral IgA inhibits the attachment of type 1 fimbriated *E. coli* to epithelial cells, providing a mechanism for IgA to be broadly protective regardless of the antigen specificity of the antigen-combining site of the molecule.

Human milk is rich in glycoconjugates and has been used as a source for the purification of nonimmunoglobulin glycoproteins with anti-adhesive activity. Holmgren *et al.* (1981) showed that the nonimmunoglobulin fraction of human milk was able to inhibit the colonization factor antigen-mediated agglutination of human erythrocytes by *E. coli* (Andersson *et al.*, 1986). Askenazi and Mirelman (1987) found similar results for adhesion to guinea pig intestinal epithelia. Human milk was shown to inhibit the attachment of S fimbriated *E. coli* to buccal epithelial cells. The inhibition was suggested to be mediated by carbohydrate residues on secreted mucins of breast milk (Schroten *et al.*, 1992). The molecular mechanisms of these anti-adhesive interactions have, however, not been defined in detail.

Andersson *et al.* (1983) showed that human milk inhibits the adherence of the respiratory tract pathogens *Streptococcus pneumoniae* and *H. influenzae* to human respiratory tract epithelial cells. The anti-adhesive effect is retained after removal of IgA by immunoabsorption. Further, milks from IgA-deficient donors block adherence. Several anti-adhesive components have been identified, including the free oligosaccharides in the low molecular weight fraction and glycoproteins (Andersson *et al.*, 1983) that coprecipitate with casein.

## V. MUCOSAL RECEPTOR REPERTOIRE

Mucosal receptor expression can influence the susceptibility of infection, as was first documented in the *E. coli* K88 piglet diarrhea model. Susceptibility to diarrhea was inherited as an autosomal recessive trait and was determined by the presence of receptors in the *E. coli*-colonized intestine of piglets that expressed the receptors. These piglets were susceptible to infection. The piglets that did not express receptors were not colonized and were resistant to infection (Sellwood *et al.*, 1975).

The double identity of the globoseries of glycolipids as blood group antigens and as receptors for P fimbriae has provided a basis to analyze the role of receptor expression in infection. Individuals of the p blood group phenotype lack a glycosyltransferase required to add the galactose  $\alpha(1-4)$ -galactose  $\beta$  polysaccharide to glycoproteins and glycolipids. Cells from p individuals therefore lack functional receptors for P fimbriated *E. coli*. Unfortunately, the frequency of p individuals is too low to permit a direct evaluation of their relative morbidity and mortality in infections caused by P fimbriated *E. coli*. However, qualitative differences in receptor expression exist among P blood group positive individu-

als. P<sub>1</sub> individuals have a higher intestinal carrier rate of P fimbriated *E. coli* than P<sub>2</sub> individuals. Individuals of the P<sub>1</sub> blood group run an ~11-fold higher relative risk of attracting recurrent kidney infections than P<sub>2</sub> individuals (Lomberg *et al.*, 1983).

The subgroup of P fimbriated *E. coli* that carries the *prs* adhesin also shows host selectivity (Lindstedt *et al.*, 1991). One subgroup of P fimbriae requires globo-A for binding. Although all except the p individuals express the P antigen, only A<sub>1</sub> secretor individuals also express the globo-A glycolipid. The P fimbriae that recognize this receptor structure, attach mainly to uro-epithelial cells from A<sub>1</sub> secretor individuals, and mainly infect A<sub>1</sub> positive individuals (100% blood group A positive compared with 43% in the population at large).

# Mucosal Immunoglobulins

Brian J. Underdown • Jiri Mestecky

## I. INTRODUCTION

Interest in mucosal immunology as a field of study accelerated in the early 1960s with the discovery of IgA and its predominance in mucosal secretions (reviewed by Heremans, 1974; Tomasi, 1968). The subject has broadened considerably since that time, but the study of the structure and function of IgA, as well as the role of other antibody types in the external secretions, are still under active investigation.

Researchers generally agree that antibodies in mucosal secretions, particularly IgA, combine with microorganisms to reduce their motility, growth, and adhesive properties within the mucosal lumen and at its surface (Williams and Gibbons, 1972; Fubara and Freter, 1973; Winner *et al.*, 1991; see Chapter 11). These functions attenuate the ability of microorganisms to attach to the epithelium and subsequently enter the internal environment of the body. More recently, evidence has been presented that indicates that, during their transport to the mucosal lumen, poly IgA (pIgA) antibodies can combine with antigens and viruses that have entered mucosal epithelial cells (Kaetzel *et al.*, 1991; Mazanec *et al.* 1992).

The function of IgA within the blood circulation and lymph is less well established. IgA antibodies are capable of neutralizing viruses and agglutinating bacteria, but the extent to which these antibodies interact with inflammatory cells and the complement system to enhance the elimination and destruction of microorganisms is still under active investigation. Evidence even suggests that in systemic *Neisseria meningitidis* infections, serum IgA1 antibodies to polysaccharide antigens actually may attenuate IgG and complement-mediated destruction of bacteria (Jarvis and Griffiss, 1991). An additional property of circulating IgA appears to be the removal of antigen via the liver (Socken *et al.*, 1981; Russell *et al.*, 1981, 1983).

This chapter reviews current knowledge on the structure and function of IgA, as well as highlighting features of the other immunoglobulin isotypes as they pertain to mucosal secretions.

## II. IMMUNOGLOBULINS OF THE EXTERNAL SECRETIONS

The predominance of IgA in most mucosal secretions compared with blood is now well established. Table I summarizes

some of the data reported in the literature for humans. In general, IgA is present in mucosal secretions in greater concentrations than are other immunoglobulin isotypes. However, note that marked species differences exist with respect to the preponderance of IgA in certain mucosal secretions, notably bile and mammary secretions. These differences (see Section II,C) may be important in the function of the mucosal immune system in particular species and may influence approaches to the study of mucosal immunity in experimental animals.

### A. Secretory IgA

The importance of immunoglobulin A in mucosal secretions was based on two important discoveries: (1) the predominance of immunoglobulin A in intestinal secretions and saliva of humans and (2) the presence of an additional antigenic structure in secretory IgA that came to be known as secretory component (SC; Brandtzaeg, 1985). Subsequently, SC was recognized to be part of the poly Ig receptor (pIgR) that transports IgA from mucosal tissue to its secretions (Mostov *et al.*, 1984). During their ground-breaking work, (Tomasi and Bienenstock, 1968) noted that the IgA in human serum was primarily monomeric whereas in mucosal secretions it was primarily polymeric. Studies of other species indicate that the proportion of serum IgA that is polymeric can vary between less than 10 and 60% (Section II,C). (A schematic representation of the various forms of human serum and secretory IgA is provided in Figures 4 and 5 and is described more fully in Sections VI and VII.)

The majority of secretory IgA in humans is derived from local synthesis and not from the circulation (Jonard *et al.*, 1984). A relatively high proportion of Ig-producing cells in the mucosal lymphoid tissue is committed to the IgA isotype (Table I). This fact, in conjunction with the presence of the specific pIgR expressed on mucosal epithelial cells (Apodaca *et al.*, 1991), accounts for the high relative concentration of IgA in mucosal secretions.

### B. Other Immunoglobulins in Secretions

IgM in the external secretions also is associated with SC, which results from its transport to the secretions by the pIgR (Brandtzaeg, 1985). However, the concentration of secretory IgM is substantially lower than that of secretory IgA because

**Table 1** Isotype Distribution of Immunoglobulin and Cells in Selected Human Fluids and Tissue<sup>a</sup>

Fluid	Immunoglobulin concentration (mg/ml)			Tissue	Distribution of Ig+ cells <sup>b</sup>		
	IgG	IgA	IgM		IgG	IgA	IgM
Serum	12.0	3.0	1.5	Bone marrow	55	30	15
Milk	0.1	1.5	0.4	Mammary gland	4	86	10
Parotid saliva	0.004	0.04	0.006	Parotid gland	5	87	6
Jejunal fluid <sup>c</sup>	0.005	0.05	0.002	Jejunum	3	79	18
Hepatic bile	0.09	0.07	0.02	Lacrimal gland	6	77	7
Tears	0.007	0.19	0.006				

<sup>a</sup> Data are from Brown *et al.*, 1975; Delacroix *et al.*, 1982,1985; Brandtzaeg, 1983a,b; Jonard *et al.*, 1984; Allansmith *et al.*, 1985; Kett *et al.*, 1986.

<sup>b</sup> Determined by immunofluorescence.

<sup>c</sup> The concentration is influenced by the amount of perfusate fluid added to the secretion. In some studies, IgG concentration ~IgA.

of the lower proportion of IgM-producing cells in mucosal tissue. IgM also may not be transported as well as pIgA because of a molecular weight restriction in SC-dependent transport (Schiff *et al.*, 1983). On the other hand, a compensatory increase of IgM is observed in mucosal tissue and secretions of IgA-deficient individuals (Plebani *et al.*, 1983). In some species such as rodents and rabbits, SC-dependent transport of IgM may not occur (Underdown *et al.*, 1992).

In most species, the concentration of IgG in mucosal secretions is approximately the same as or somewhat greater than that of IgM. IgG is thought to enter the mucosal secretions nonspecifically via paracellular transport or fluid phase endocytosis. A notable exception is found in the ungulates (i.e., sheep, goats, cows) which, in addition to pIgA, selectively transport the IgG1 isotype from serum into selected secretions such as colostrum, milk, and saliva (Cripps and Lascelles, 1976; Butler, 1983).

IgE has been detected in relatively low concentrations in the respiratory and gastrointestinal secretions and often is associated with allergic responses at the mucosae (Brown *et al.*, 1975; Mygind *et al.*, 1975; Jonard *et al.*, 1984). Little evidence suggests that IgE is transported specifically to mucosal secretions. Perhaps increases in permeability of mucosal tissue as a result of allergic reactions increase the concentration of IgE in mucosal secretions.

Several reports indicate that low concentrations of IgD are found in milk and saliva; this may reflect selective synthesis but not facilitated transport to the mucosal secretions (Leslie and Teramura, 1977).

### C. Species Variability with Respect to Mucosal Immunoglobulin

The information provided in Table 1 reflects data for humans. Several noteworthy differences exist among species.

*i. Serum.* In contrast to humans and nonhuman primates, the bone marrow in other mammals synthesizes negligible amounts of IgA. Instead, gastrointestinal tissue appears to be the primary source of serum IgA as well as secretory IgA

(Vaerman *et al.*, 1973). Therefore, in most mammals the level of serum IgA is approximately 10-fold less than that observed in humans and nonhuman primates. In addition, the proportion of serum IgA that is polymeric is often higher in mammals such as mice, dogs, and guinea pigs, reflecting the contribution of the gastrointestinal tissue to serum IgA as well as the degree to which the pIgR is expressed on hepatocytes (Kaartinen *et al.*, 1978; Delacroix *et al.*, 1983).

*ii. Bile.* As reviewed previously (Underdown and Schiff, 1986), only a few species such as rabbit, rat, chicken, and mouse express pIgR on hepatocytes and have a highly active transport system to remove pIgA from blood to bile. The bile of these species is a rich source of secretory IgA and free SC, with concentrations in the range of 0.5–1.5 mg/ml. IgA is predominantly polymeric (Lemaitre-Coelho *et al.*, 1977; Rose *et al.*, 1981). In contrast, other species including humans have lower concentrations of biliary IgA; the proportion of polymer to monomer is closer to unity. The mouse appears to be intermediate with respect to the level of hepatic transport of pIgA from serum. Clearly antibody-producing cells in the liver can contribute to bile IgA (Nagura *et al.*, 1983; Manning *et al.*, 1984; Jackson *et al.*, 1984; Altorfer *et al.*, 1987).

*iii. Mammary gland secretions.* The ungulates such as sheep, goats, and bovines express, in addition to pIgR, a receptor for the IgG1 isotype on mammary epithelium that transports considerable amounts of IgG1 from blood to colostrum or milk (Butler, 1983). Evidence also suggests IgG1 is transported selectively into sheep saliva (Cripps and Lascelles, 1976). The secretion of large amounts of IgG1 in these species is thought to reflect the requirement of neonates to obtain serum IgG from mother's milk early in life.

### D. Secretory Ig in Serum

Immunoassay of serum indicates that secretory IgA and secretory IgM can be detected at relatively low levels (~10 µg/ml) in serum (Iscaki *et al.*, 1979; Delacroix and Vaerman, 1981; Kvale and Brandtzaeg, 1986). These levels are elevated

in patients with liver disease. The reasons for the elevation of secretory immunoglobulin in liver disease are not entirely known, but could be (1) release of SC from damaged biliary epithelial cells, which would complex with pIg in blood, or (2) defective clearance of secretory IgA and secretory IgM, which might enter the blood after retrograde transport from mucosal tissue.

### E. Hormonal Control of Secretory Ig

Several investigators have reported hormonal control of mucosal immunoglobulin production or secretion in the reproductive tract. Estradiol in female rats regulates the mucosal immune system by controlling IgA and IgG movement from blood to tissue, as well as by influencing the number of IgA-committed cells and the expression of pIgR in the reproductive tract (McDermott *et al.*, 1980; Wira *et al.*, 1980; Sullivan and Wira, 1983; Parr and Parr, 1989). The mucosal epithelium of the male reproductive tract expresses pIgR under the influence of androgens (Parr *et al.*, 1992). Interestingly, synthesis and secretion of SC in the lacrimal gland are also under the control of androgens (Sullivan *et al.*, 1984).

## III. IgA: STRUCTURE AND ARRANGEMENT OF COMPONENT CHAINS

The function of IgA in both serum and secretions depends on the primary structure of its component chains, as well as on the conformation these chains assume in monomeric and polymeric IgA.

### A. $\alpha$ Chains

#### 1. Domain Structure of $\alpha$ Chains

Mammalian  $\alpha$  chains have three constant region domains ( $C\alpha 1$ – $C\alpha 3$ ) similar to the number of constant region domains in  $\gamma$  and  $\delta$  heavy chains whereas avian  $\alpha$  chain has four constant region domains as do  $\mu$  and  $\epsilon$  chains. Based on the similarities in structure of IgM and IgA, IgA has been proposed to have evolved after IgM but before IgG. The fact that avian  $\mu$  chains have four constant region domains would be consistent with this hypothesis (Mansikka, 1992). Evolution of the mammalian  $\alpha$  chains may have involved the loss of the avian  $C\alpha 2$  domain to yield a three-domain structure. The hinge region in IgA1 molecules has been suggested to consist of remnants of the avian  $C\alpha 2$  domain (Mansikka, 1992).

Investigators generally assume that the  $C\alpha$  domains are folded in a manner similar to the  $C\gamma$  structure that has been determined at the atomic level by X-ray crystallographic techniques. Based on this assumption, each  $\alpha$  chain domain is thought to be composed of seven  $\beta$  strands in a four–three configuration with intervening “loops” to create a  $\beta$ -barrel conformation typical of other members of the Ig superfamily (Williams, 1986; Hunkapiller and Hood, 1989). Unfortunately, the  $Fc\alpha$  structure has not been determined at the

atomic level by X-ray crystallography and the extent to which the arrangement of the  $\alpha$  chain domains in  $Fc\alpha$  mimics  $Fc\gamma$  is uncertain.

#### 2. Primary Structure of $\alpha$ Chains

Figure 1 presents the amino acid sequences of a number of  $\alpha$  heavy chain constant regions that have been obtained by amino acid or DNA sequence analysis. The variable region domains of the  $\alpha$  chains are obviously important to the antigen-binding function of IgA antibodies, but will not be discussed further.

The degree of amino acid similarity among  $\alpha$  chains of different species increases from N- to C-terminal domains; the greatest homology is observed among the  $C\alpha 3$  domains ( $C\alpha 4$  of chicken). Some of the common amino acid residues found in the  $C\alpha$  constant region domains are highly invariant in all immunoglobulin molecules and presumably are critical in maintaining the structural features common to all Ig isotypes. Typical examples that are cited often are the highly apolar intraheavy-chain disulfide bonds that are almost (but not uniformly) characteristic of the Ig fold and tryptophan residues, most of which also are buried strategically within each domain. Other residues are highly conserved among IgM and IgA molecules. The relatively high degree of homology between IgA and IgM presumably reflects their close evolutionary origin and the importance of certain residues in maintaining common structural and functional characteristics. One such structure is the characteristic 18-amino-acid extension or “tail” that, during synthesis of IgM and IgA, associates with J chain, a 15-kDa protein synthesized in plasma cells (Section III,B).

In humans, nonhuman primates, and rabbits, multiple  $\alpha$  chain isotypes have been described that define IgA subclasses (for review, see Chapter 9). Two IgA subclasses have been described in humans (reviewed by Mestecky and Russell, 1986), two in hominoid primates (gorilla, and chimpanzee; Kawamura *et al.*, 1992), and 13 in lagomorphs (see Burnett *et al.*, 1989). In all other species studied, only one IgA isotype has been observed.

Within a given species, the  $\alpha$  chains belonging to each of the subclasses are highly homologous in amino acid sequence (Figure 1). A major difference between the two human isotypes or subclasses occurs in the hinge region. IgA2 molecules lack a 13-amino-acid segment found in the hinge region of IgA1 molecules that contains five carbohydrate moieties O-linked to serine. The presence of this extended hinge region has been postulated to confer greater segmental flexibility on IgA1 molecules (Pumphrey, 1986), but renders IgA1 molecules susceptible to IgA1-specific proteases produced by bacterial pathogens at mucosal surfaces (see Chapter 12). The absence of the hinge region in IgA2 molecules makes them resistant to the IgA1-specific proteases, which presumably is advantageous to IgA2 antibody function at mucosal surfaces. Based on the criteria that IgA2 molecules do not possess the extended hinge region characteristic of IgA1 molecules and generally do not bind the lectin Jacalin (Skea *et al.*, 1988; Aucoeurier *et al.*, 1989), murine IgA appears to be similar to the IgA2 isotype of humans. In addition to the differences

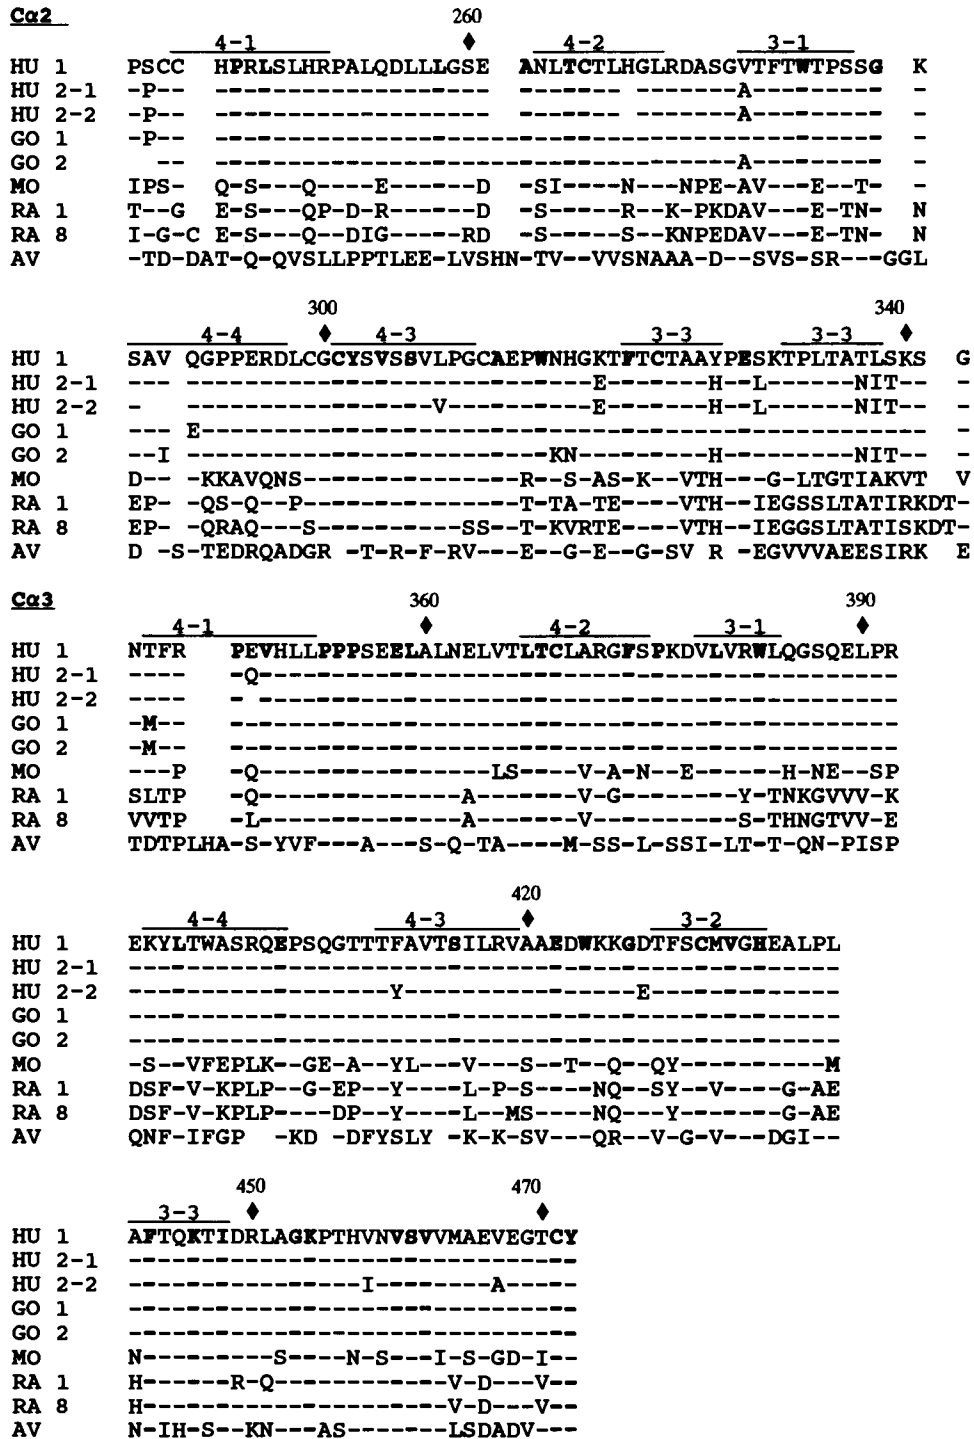

Figure 1 (Continued)

noted in the hinge region, the human IgA subclasses differ at 14 amino acid positions in the  $\alpha$  chain sequence (Figure 1).

The human IgA2 subclass exists in two allotypic forms. A major structural difference between these two allotypes concerns the arrangement of inter  $\alpha$ -L chain disulfide bridges. In IgA2 of the A2m(1) allotype, the  $\alpha$  and L chains are *not* covalently linked and therefore can be separated by exposure to dissociating agents without cleavage of disulfide bonds (Grey *et al.*, 1968). The absence of the L-H disulfide bond presumably relates to the exchange of cysteine at residue 133 for aspartic acid. Interestingly, this exchange does not prevent IgA2m(2) molecules from having the typical  $\alpha$ -L disulfide-linked configuration, presumably by linking the L chain to a cysteine residue at another location in the  $\alpha$  chain. The A2m(2) allotype differs from the A2m(1) allotype and the A1 isotype in six positions, two of which are in the C $\alpha$ 1 domain (residues 212 and 222) and four of which are located in the C $\alpha$ 3 domain (residues 411, 428, 458, and 467). Thus, the C $\alpha$ 3 domains of the A1 and A2m(1) chains are identical and the C $\alpha$ 2 domains of the A2 allotypes are identical and differ from that of A1. The A2m(1) allotype is a hybrid of A1 and A2m(2) and may have arisen by a gene conversion event (Tsuzukida *et al.*, 1979; Tucker *et al.*, 1981).

The C $\alpha$ 1 domain is the least homologous among IgA molecules but one feature, the presence of multiple "extra" intrachain disulfide loops, is common to most IgA molecules (see Figure 4). Among the 13 rabbit  $\alpha$  chain isotypes, the number of "extra" cysteine residues varies from 5 to 13 with 11 possible disulfide bond distribution patterns. These extra cysteines also may be present in the reduced (free SH) form (Burnett *et al.*, 1989).

The C $\alpha$ 2 domain of chickens is the least related domain and is thought to have been deleted in mammals (Mansikka, 1992).

The C $\alpha$ 2 domain of mammals (analogous to the C $\alpha$ 3 domain of chickens) also contains intrachain disulfide bridges not found in the other Ig isotypes (e.g., in human IgA: Cys 196-Cys 220; Cys 242-Cys 301) as well as interheavy-chain disulfide bonds that are unique to this isotype (i.e., between Cys 311 and Cys 299 on each  $\alpha$  chain). The cysteine at residue 311 within C $\alpha$ 2 is involved in a disulfide bond with SC in secretory IgA (Fallgren-Gebauer *et al.*, 1992).

The C $\alpha$ 3 domain of mammals (C $\alpha$ 4 of chickens) has fewer distinguishing features, except for the extended 18-amino-acid "tail". The penultimate residue of the  $\alpha$  chain is a cysteine that is linked covalently to J chain in IgA polymers (Garcia-Pardo *et al.*, 1981; Bastain *et al.*, 1992; Mestecky *et al.*, 1974b).

### 3. Carbohydrate Moiety of $\alpha$ Chains

Generally, carbohydrates contribute 6–7% of total molecular mass in human IgA1 and 8–10% in human IgA2 myeloma proteins (Tomana *et al.*, 1976). The higher carbohydrate content in IgA2 proteins is the result of additional N-linked oligosaccharide side chains [two in A2m(1) and three in A2m(2)]. However, the primary structures of carbohydrate side chains have been determined for very few myeloma proteins and

the considerable variability in the content, composition, and number of oligosaccharide side chains among various myeloma proteins appears quite remarkable (Wold *et al.*, 1990). The carbohydrate side chains that have been characterized on  $\alpha$  chains of both human subclasses demonstrate statistically significant differences in the amount fucose, mannose, and N-acetylglucosamine. The most striking difference is the presence of N-acetylgalactosamine in IgA1 proteins and its absence in IgA2. Differences in galactose and sialic acid are not significant (Baenziger and Kornfeld, 1974a,b; Tomana *et al.*, 1976; Torano *et al.*, 1977; Mestecky and Russell, 1986; Wold *et al.*, 1990).

The hinge region of IgA1 contains five short chains containing N-acetylgalactosamine, galactose (Baenziger and Kornfeld, 1974b), and, in some proteins, sialic acid (Field *et al.*, 1989) connected by O-glycosidic linkages to serine residues. Interestingly only a few serum proteins contain O-linked side chains. This unique property of IgA1 has been exploited in an efficient isolation of IgA1 proteins by affinity chromatography employing the lectin Jacalin (Roque-Barreira and Campos-Neto, 1985). This procedure is not absolutely specific for IgA1 proteins since a small proportion of IgA2 proteins also binds Jacalin (Aucouterier *et al.*, 1989).

The total carbohydrate content of secretory IgA is higher than that of serum IgA because of the carbohydrate-rich SC (subsequent discussion).

### B. J Chain

In the early 1970s, comparative studies of the polypeptide chain composition of polymeric Ig (secretory IgA, polymeric serum IgA, and IgM) with that of IgG revealed an additional polypeptide chain in pIg with a fast electrophoretic mobility (for review, see Inman and Mestecky, 1974; Koshland, 1985). Subsequent studies revealed that this chain was glycosylated, with a molecular mass of 15–16 kDa, and was linked by disulfide bridges to the Fc fragment of polymeric IgM or IgA of secretory and serum (myeloma) origin. Based on the given criteria (molecular mass, fast electrophoretic mobility, characteristic amino acid composition, and immunochemical cross-reactivity), the presence of J chain has been established, with varying degrees of confidence, in polymeric Ig from many vertebrate species including mammals (human, monkey, rabbit, mouse, pig, dog, goat, cat, cow, horse, rat, guinea pig, and sheep), birds (chicken and pheasant), reptiles (turtle), amphibians (frog and toad), and fishes (catfish and sharks) (Kobayashi *et al.*, 1973; Inman and Mestecky, 1974; Koshland, 1985; Mikoryak *et al.*, 1988). Most recent studies using molecular biological approaches combined with immunochemical techniques revealed that J chain also is expressed in invertebrates (earthworm, slug, clam, and silkworm) and additional vertebrate species (African clawed frog, lamprey, and newt) (Takahashi *et al.*, 1993).

Sequence analyses of mouse genomic DNA reveal that J chain-encoding information is contained in four exons of a single gene located on chromosome 5; in humans, the J chain gene is on chromosome 4.

## 1. Domain Structure of J Chain

Despite the low degree of sequence homology with H and L chains, studies of the secondary structure of J chain have been interpreted to suggest that it folds into an eight-stranded antiparallel  $\beta$  barrel (with 35%  $\beta$  sheet and the remainder in random coil; Zikan *et al.*, 1985; Pumphrey, 1986). An alternative model suggests a two-domain model in which the first domain consists of a six-stranded antiparallel  $\beta$ -barrel and the second domain (folded under the first) is a two-stranded  $\beta$  barrel (Frutiger *et al.*, 1992).

## 2. Primary Structure of J Chain

The primary structure of J chain has been determined in human, mouse, and rabbit (Figure 2). J chain consists of 137 amino acid residues and displays a high degree of sequence homology (70%) among species (Koshland, 1985; Hughes *et al.*, 1990). Incomplete sequence studies of earthworm J chain reveal a high degree of homology with both human and mouse J chains (Takahashi *et al.*, 1993). These findings, in conjunction with remarkable similarity in physicochemical properties and interspecies cross-reactivities (Kobayashi *et al.*, 1973), suggest that many of the features of J chain are conserved through evolution. J chains are rich in acidic (aspartic, glutamic) amino acid residues and low in glycine, serine, and phenylalanine; tryptophan is absent (Inman and Mestecky, 1974). Six of the eight cysteine residues form three intrachain disulfide bridges; the other two residues close to the N terminus are involved in disulfide bonds that link J chain to the penultimate cysteine residues of  $\alpha$  and  $\mu$  chains (Mestecky and McGhee, 1987; Frutiger *et al.*, 1992).

## 3. Carbohydrate of J Chain

Approximately 8% of the molecular mass of J chain is contributed by a single carbohydrate side chain linked to asparagine residue 48 by an *N*-glycosidic bond. This chain consists of fucose, mannose, galactose, glucoamine, and sialic acid (Niedermeier *et al.*, 1972; Baenziger, 1979).

## C. Secretory Component

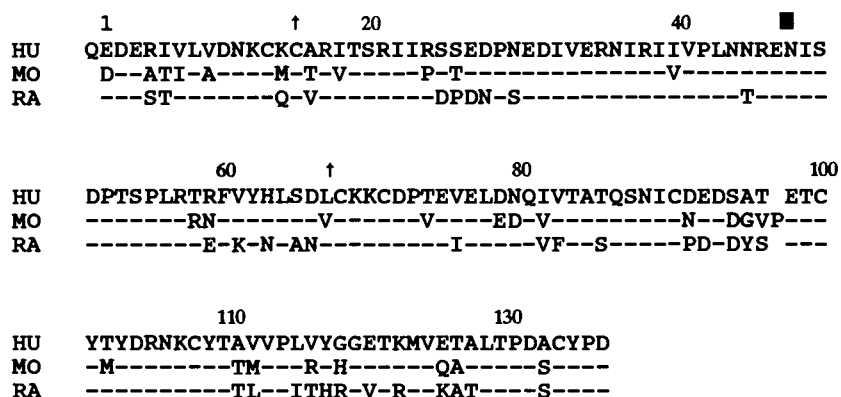

Identification of SC as part of the transport receptor for secretory IgA began with immunohistochemical studies in which specific antisera to the (secretion-specific) "secretory piece" established its presence not only within the secretory IgA molecule but as a component of mucosal epithelial cells (South *et al.*, 1966; Brandtzaeg, 1978; Crago *et al.*, 1978; Nagura *et al.*, 1979). Subsequently, SC was isolated free in mucosal secretions as well as associated with secretory IgA. The exquisite binding specificity for polymeric but not monomeric Ig was established (Mach, 1970; Radl *et al.*, 1971; Brandtzaeg, 1974; Weiker and Underdown, 1975).

### 1. SC Domain Structure

In most species, SC (molecular mass, ~70 kDa) consists of five Ig-like domains with definite but relatively low homology to the  $\lambda$  chain variable region (Mostov *et al.*, 1984). In addition to the five-domain form, rabbits synthesize a truncated three-domain form (Frutiger *et al.*, 1987). Within the basolateral membrane of mucosal epithelial cells, SC consists of five extracellular domains, a transmembrane segment, and a cytoplasmic domain. The term poly Ig receptor was proposed to differentiate between the membrane form of the transport receptor and the cleaved soluble form known as SC (Mostov *et al.*, 1984). For a more complete discussion of the pIgR, see Chapter 10.

### 2. Primary Amino Acid Sequence of SC

The amino acid sequences of pIgR have been determined completely for three species and are shown in Figure 3. In addition to the intrachain disulfide bonds that are thought to be buried within each domain, several of the domains have "extra" disulfide bonds. One of these, located in the fifth domain, is susceptible to disulfide interchange. Data from Hilschmann and colleagues (Fallgren-Gebauer *et al.*, 1992) suggest that only one cysteine residue from this labile disul-

**Figure 2** Amino acid sequence of J chain from human (HU), mouse (MO), and rabbit (RA). The two cysteine residues that join J chain to the penultimate amino acid cysteine residue in  $\alpha$  chains (Cys 471) are shown by arrows. Site of N-glycosylation is shown by filled square. Data are from Max and Kornsmeyer (1985), Frutiger *et al.* (1986), Matsuuchi *et al.* (1986), and Hughes *et al.* (1990).

fide bond (see Figures 3 and 4) is linked to one Cys 311 in the  $\text{Ca}2$  domain.

### 3. Carbohydrate of SC

Approximately 22% of the total molecular mass of SC is contributed by carbohydrates (Tomana *et al.*, 1978). The 5–7 oligosaccharide side chains contain *N*-acetylglucosamine, fucose, mannose, galactose, and sialic acid attached by *N*-glycosidic bonds (Mizoguchi *et al.*, 1982). Studies of rabbit SC indicate one common glycosylation site at the asparagine residue at position 400 and a second site in the N-terminal domain that varies among different allotypes (Frutiger *et al.*, 1988).

### D. Structure of Monomeric and Polymeric IgA

As shown schematically in Figure 5, IgA exists in both monomeric and polymeric forms. Dimers, trimers, and tetramers are found commonly, although the dimer is the predominant form in most mucosal secretions. A distinguishing feature of pIgA, as well as of IgM (which is generally pentameric), is the presence of J chain, a polypeptide synthesized by antibody-producing cells of all isotypes, which is incorporated into pIgA and IgM just prior to their secretion from plasma cells (Parkhouse and Della Corte, 1973). Chemical analysis indicated that each polymer (IgM or IgA) contains one mole of J chain (Zikan *et al.*, 1986). In native molecules of polymeric Ig, the antigenic determinants of J chain are poorly exposed; further, J chain is highly susceptible to proteolysis. These findings may explain failure to detect J chain in some polymeric Ig. Cleavage of interchain disulfide bonds usually is sufficient to release it from Ig, suggesting that only weak noncovalent interactions exist between J chain and the Fc region of polymeric Ig.

The arrangement of disulfide bonds and the manner in which J chain is linked within the polymeric structure has been a matter of debate. Two models have been presented (Figure 5). In one model, dimeric IgA consists of two monomer subunits linked end to end with J chain attaching or bonding both monomeric subunits at one cysteine residue (471) of each monomer subunit. The two remaining Cys 471 residues link directly to each other. Direct experimental data have been presented to support this hypothesis (Bastian *et al.*, 1992). A second model (Figure 5) takes into account the fact that electron micrographs present IgA dimers that appear to be shorter than would be predicted based on the expected length of each of the monomer subunits (Svehag and Bloth, 1970), as well as data that indicate that Cys 311 could be linked to Cys 471 (Underdown and Schiff, 1986). Naturally occurring as well as genetically engineered IgM, which lacks J chain, will form polymers but these are often mixtures of various oligomeric forms including hexamers, in contrast with the majority of naturally occurring IgM polymers that are primarily pentameric, suggesting that J chain may regulate the degree of polymerization of IgM and, possibly, of IgA. In so doing, J chain may be responsible for creating a conformation within pIgA and IgM that binds pIgR (Section III,E).

### E. Structure of Secretory IgA

The single most important distinguishing feature of secretory IgA with respect to serum IgA is the presence of SC. In addition to its crucial role in the transport of pIgA to mucosal secretions, SC has been shown to confer resistance to proteolysis on secretory IgA, presumably an added advantage in the gastrointestinal milieu (Brown *et al.*, 1970).

*In vitro* experiments convincingly demonstrated that SC binds only to polymeric IgA or IgM (Weiker and Underdown, 1975; Brandtzaeg, 1981). The discovery of J chain in these immunoglobulins led to the postulation that this small polypeptide is instrumental in SC binding. Brandtzaeg (1985) has maintained that SC binding by polymeric IgA and IgM is dependent on the presence of J chain: Pentameric IgM that lacks J chain did not bind SC efficiently and the ability of polymeric IgA to bind SC in solution or on the surface of SC-bearing epithelial cells was related to the J chain content. However, how the presence of J chain leads to such remarkable enhancement of SC binding is not clear. Previous structural studies of human SIgA cleaved by cyanogen bromide indicated that J chain and SC are bound to different fragments of the  $\alpha$  chain and are not connected by disulfide bridges (Mestecky *et al.*, 1974a). This result does not rule out the possibility that J chain is required to create a conformation in pIg that generates the SC binding site.

Results concerning the structure of IgA, SC, and J chain indicate that both SC and J chain display immunoglobulin domain-like folding of their polypeptide chains and belong to the immunoglobulin superfamily (Mostov *et al.*, 1984; Zikan *et al.*, 1985; Pumphrey, 1986). Therefore, the mutual interactions between the Fc portion of dimeric IgA, J chain, and SC are likely to be based on the complementarities of their domain-like structures.

Binding of pIgR to pIgA begins with a high affinity noncovalent association that is followed by the formation of disulfide bonds through which SC links to only one of the IgA monomer subunits (Underdown *et al.*, 1977; Garcia-Pardo *et al.*, 1979; Figure 5). Several groups have reported association constants on the order of  $10^8 M^{-1}$  for the noncovalent interaction, but these data in all likelihood underestimate the affinity of noncovalent binding (Schiff *et al.*, 1983). More important, however, is the fact that dissociation of the complex is much slower than the time required (30 min) for the pIgA–pIgR complex to cross the epithelial cell, during which time pIgA must stay bound to its receptor to insure that it reaches the apical face of the cell and is discharged into the lumen.

The heavy chains of pIgA and IgM, respectively, are likely to contribute to the binding site for pIgR (Geneste *et al.*, 1986). In some species, notably those that display pIgR on hepatic parenchymal cells, IgM binds homologous SC with little affinity (Underdown *et al.*, 1992). In these species, high affinity binding between IgM and pIgR has been argued to be detrimental to the host, since IgM would be lost via hepatic transport from the blood where it is known to function. Thus, the rat, rabbit, and chicken may have given up their ability to transport IgM in return for a highly active biliary transport system for pIgA. The exact nature of the binding site for pIgR on pIgA and IgM is still under study, but evidence

**Figure 3** Amino acid sequence of poly Ig receptor from human (HU), rat (RT), and rabbit (RA). The number system is after Krajči *et al.* (1991). The location of the domains (D1–D5) are according to Eiffert *et al.* (1984,1991). The location of the proposed pIg-binding site is based on the work of Frutiger *et al.* (1986), Beale (1987), and Bakos *et al.* (1991). Up arrows represent cysteine involved in linking SC to  $\text{Ca}2$  (Cys311) Down arrows indicate postulated site of cleavage that releases SC and secretory IgA from the apical face of the mucosal epithelial cell. Sequence data based on Eiffert *et al.* (1984), Mostov *et al.* (1984), Banting *et al.* (1989), and Krajči *et al.* (1992).

**Figure 4** Model of secretory IgA according to Fallgren-Gebauer and colleagues (1992). SC is bound noncovalently to the IgA dimer (model I, Figure 5) and is linked at domain five by a disulfide-bond to Cys311 in  $\text{Ca}2$  in only one monomer subunit. This figure was provided by N. Hilschmann and is based on the work of Fallgren-Gebauer *et al.* (1992).

suggests that both the heavy chains and the J chain are involved.

## IV. BIOSYNTHESIS AND ASSEMBLY OF IgA

### A. Monomeric IgA

The light and  $\alpha$  chains that become assembled intracellularly into monomeric IgA (mIgA) molecules are synthesized on separate sets of polyribosomes and are assembled into the monomeric unit through several pathways (Heremans, 1974). Depending on the cell type studied, various types of pairings of H and L chains occur early on polyribosomes, but the final core-glycosylated molecule of mIgA is assembled in the Golgi apparatus. Additional carbohydrate residues are attached during the intracellular passage of mIgA from Golgi to the cell surface and ultimate secretion into the medium.

### B. Polymeric IgA

Early investigations of the biosynthetic pathways of mouse IgA suggested that, in cells secreting polymeric IgA, a majority of intracellular IgA was present as monomers and that polymerization occurred shortly before or at the time of secretion (Parkhouse, 1971). This hypothesis is supported by subsequent comparative biochemical studies of the molecular forms of intracellular versus secreted IgA in cell lysates and tissue culture supernatants of cell derived from various human tissues, which indicated that, although small amounts of polymeric IgA were detected in some cell lysates, most intracellular IgA occurred in a monomeric form (even when the predominant form of secreted IgA was polymeric) (Buxbaum *et al.*, 1974; Moldoveanu *et al.*, 1984).

### C. Distribution of Cells Synthesizing Monomeric and Polymeric IgA

Analyses of molecular forms of IgA in perfusates and supernatants of *in vitro* cultured tissue explants as well as immu-

nohistochemical studies of mucosal tissues and glands clearly demonstrated that separate populations of pIgA- and mIgA-secreting cells exist that display a characteristic tissue distribution (for review, see Brandtzaeg, 1983a; Mestecky and McGhee, 1987; Mestecky *et al.*, 1991). Typically, the majority of IgA-producing cells in the normal human bone marrow are monomeric (they do not express J chain and do not bind SC) whereas the majority of such cells in the intestinal lamina propria produce pIgA, express J chain, and bind SC. The spleen and lymph nodes from different locations display a variable proportion of pIgA- and mIgA-secreting cells. Under pathological conditions (e.g., IgA multiple myeloma), the bone marrow may contain predominantly J chain-positive cells; concurrently, high levels of pIgA are present in blood (Mestecky *et al.*, 1980).

### D. Role of J Chain in the Polymerization of Ig

The association of J chain with pIg but not mIg in serum and secretions raised the possibility that J chain either initiated or regulated the formation of polymers intracellularly. The following observations seem consistent with this hypothesis: (1) Ig-producing cells in the submucosae of the gastrointestinal and respiratory tracts, as well as in the interstitium of mammary, salivary, and lacrimal glands, prominently display the presence of intracellular J chain and primarily secrete pIgA; (2) in contrast, IgA- or IgG-containing plasma cells from the normal bone marrow that secrete monomeric IgA are uniformly J chain negative (Brandtzaeg, 1985).

Since a small proportion of intracellular Ig is linked to J chain, this chain has been proposed to initiate polymerization by binding first to a monomeric molecule of intracellular IgA or IgM that subsequently is linked to another monomer, forming a dimeric molecule (for reviews, see Brandtzaeg, 1983a, 1985; Koshland, 1985; Mestecky and McGhee, 1987).

However, Stott (1976) observed that polymeric IgM could be detected in lysates of certain mouse cell lines in a tetrameric form lacking J chain. This polypeptide, linked to monomeric IgM, was added as a last step in the process of polymerization. Site-directed mutagenesis of cysteine residues of  $\alpha$  or  $\mu$  chains involved in J chain binding, and transfection of  $\alpha$  and L chain genes into J chain-negative cells, further disputes the necessity for J chain in polymerization (Cattaneo and Neuberger, 1987; Davis *et al.*, 1989). *In vitro* studies concerning the role of J chain in polymerization also were reported in which covalently linked IgM polymers were synthesized *in vitro* in good yield in the absence of J chain (Bouvet *et al.*, 1987).

These data suggest that J chain may not initiate polymerization but may regulate the degree and form of polymerization in pIg. In support of this hypothesis is the observation that, in the absence of J chain, polymers of Ig may form *in vitro* or *in vivo* but the preferred conformation observed under natural conditions often is not produced quantitatively. Thus, under normal conditions, J chain may act to regulate the formation of polymers which, in the case of IgA, are dimers, trimers, and tetramers and rarely become pentamers, whereas the pentamer is the preferred configuration for IgM.

**Figure 5** Schematic diagram of IgA monomer and two models of IgA dimer (I and II). The circles in the IgA1 monomer represent the O-linked carbohydrate side chains in the hinge. This region is deleted in IgA2 molecules. The squares represent N-linked carbohydrate side chains that are placed in a position consistent with their location in the Ig-domain fold. The disulfide bonds (S-S) shown in the monomer are the inter- $\alpha$ -L bond in IgA1 (also present in IgA2 m(2), inter- $\alpha$  bonds Cys241–Cys241, Cys299–Cys299, Cys311–Cys311, and Cys471–Cys471, and intra $\alpha$  bonds Cys196–Cys220 and Cys242–Cys301). In models I and II of the dimer, the inter-L bond in IgA2 m(1) is shown. In model I, the monomer subunits are joined end to end with cysteine residues from J chain linking a Cys471 from each monomer; the remaining two Cys471 residues are joined directly together (Bastian *et al.* 1992). In model II, the dimer is shown forming a more compact structure based on data presented by Svehag and Bloth (1970) and Abel and Grey (1968). The monomeric subunits are joined via two Cys311 residues from the C $\alpha$ 2 domains of one monomer subunit to two Cys471 residues from the “extended tail” of the other monomer subunit. J chain is joined within the former monomer subunit via two Cys471 residues of the “extended tail”.

### E. J-Chain Expression in B Cells Not Producing Polymeric Ig

In the bone marrow of patients with multiple myeloma, J chain frequently is detected by immunofluorescent staining of plasma cells synthesizing monomeric Ig such as IgG (Mestecky *et al.*, 1980). Similarly, J chain has been detected in IgG plasma cells from inflammatory sites and in mitogen-stimulated peripheral blood lymphocytes (Mestecky *et al.*, 1980; Brandtzaeg, 1985). The expression of J chain in cells

that are not engaged in the synthesis of polymers has been interpreted as a sign of clonal immaturity. Extensive studies of human cells from leukemic patients, established lymphoid cell lines, and Epstein–Barr virus (EBV)-transformed fetal bone marrow cells (depleted of surface Ig-positive cells) reveal that J chain may be expressed in the cytoplasm of lymphocytes from the earliest stages of their differentiation along the B-cell axis (McCune *et al.*, 1981; Hajdu *et al.*, 1983; Max and Korsmeyer, 1985; Kubagawa *et al.*, 1988). Thus, cells phenotypically characterized as null or pre-B cells contain J

chain, frequently in the absence of  $\mu$  chain. EBV-transformed fetal bone marrow cells or cells from a few patients with a clinically established diagnosis of multiple myeloma display the morphological features of plasma cells but contain no intracellular Ig; in the former, the cells exhibit a germ-line configuration or abortive VDJ rearrangement of H chain gene segments (Kubagawa *et al.*, 1988). J chain expression in B cells at early stages of differentiation is apparently different in mice in which J chain is detectable only in Ig-secreting cells but not in pre-B or B cells (Koshland, 1985).

The presence of J chain in non-pIg-producing cells is an enigma, but suggests that this protein may have an additional role in B cells that is unrelated to polymer formation. In this regard, work by Takahashi *et al.* (1993) indicates that J chain may be present in species as primitive as the earthworm.

## V. IgA METABOLISM

The metabolism of IgA has not been studied extensively. In human plasma and cerebral spinal fluid, IgG is found in concentrations that are higher than those of the other isotypes. However, the levels of individual Ig isotypes in these fluids are not reflective of their biosynthetic rates. Considering the distribution in various body fluids of the major Ig isotypes and their catabolic rates, clearly IgA is synthesized in quantities (~66 mg/kg body weight/day) that exceed by far the combined daily synthesis of all other Ig isotypes (for reviews, see Mestecky *et al.*, 1986; Conley and Delacroix, 1987).

The lower concentration of IgA than IgG in human serum is the result of the more rapid catabolism of IgA (half-life of IgA is 6 days vs 20–25 days for IgG), in conjunction with the fact that cells engaged in IgA synthesis in humans are found both in mucosal (e.g., gastrointestinal tract, salivary gland) and systemic (e.g., bone marrow and, to a lesser extent, spleen and lymph nodes) tissue.

### A. Liver as a Major Site of IgA Metabolism: SC-Dependent Clearance

The importance of the liver in IgA metabolism was established by a series of studies performed in animals and in humans with liver diseases. Experiments by Jackson *et al.* (1978) pointed out that the liver transported pIgA from blood to bile in rats. Vaerman and Delacroix (1984) proposed that, in rodents, the liver functions as an "IgA pump" that regulates serum levels of IgA by transporting circulating pIgA into the bile. By this mechanism, significant quantities of IgA are delivered into the intestinal tract of rodents. SC present on the surface of rat hepatocytes was identified as the receptor for pIgA, and is the most important receptor responsible for its selective and efficient transport into bile in several species in which pIgA is the primary form of circulating IgA (Underdown and Schiff, 1986).

Interactions between pIgA and hepatocytes are strongly species dependent. SC has been found on hepatocytes of many species (rat, rabbit, and mouse), but not on human

hepatocytes (for reviews, see Vaerman and Delacroix, 1984; Mestecky and McGhee, 1987; Brown and Kloppel, 1989). Consequently, the extent to which SC-mediated clearance of pIgA occurs is highly species dependent.

### B. Role of Other Receptors in Hepatic Clearance

IgA interactions with hepatocytes also can be mediated through hepatic receptors specific for asialoglycoproteins [asialoglycoprotein receptor (ASGP-R) or hepatic binding protein (HBP); Stockert *et al.*, 1982; Tomana *et al.*, 1988]. The presence and properties of ASGP-R have been described for hepatocytes from several species (Ashwell and Harford, 1982). ASGP-R recognizes terminal galactose residues of desialylated glycoproteins and has been proposed, in addition to SC, to play an important role in the endocytosis of IgA by hepatocytes (for reviews, see Brown and Kloppel, 1989; Mestecky *et al.*, 1991). The binding of glycoproteins, including IgA, to ASGP-R depends on  $\text{Ca}^{2+}$  and is therefore inhibitable by chelating agents. Bound IgA is internalized and the IgA-containing vesicles fuse with lysosomes, resulting in intracellular degradation.

Thus, the liver is involved in regular catabolism of immunoglobulins, including pIgA and mIgA (Moldoveanu *et al.*, 1988,1990; Tomana *et al.*, 1988). However, in humans only negligible amounts (approximately 1 mg/kg/day) of the total IgA produced in the bone marrow, spleen, and lymph nodes (approximately 20 mg/kg/day) reach the external secretions (Conley and Delacroix, 1987).

The site of catabolism of IgA was studied in animal models (Moldoveanu *et al.*, 1988,1990). Mice and monkeys (*Macaca fuscata*) were used as representatives of species with SC-positive and SC-negative hepatocytes, respectively; however, both species display ASGP-R on hepatocytes. In both species, the liver was identified as the organ with the highest uptake of mIgA and pIgA. Although both parenchymal (hepatocytes) and nonparenchymal cells were involved in the catabolism, the hepatocytes were more active. Other tissues and organs, including muscles, kidneys, skin, and spleen, also catabolized IgA, although to a much lower degree than the liver.

## VI. BIOLOGICAL SIGNIFICANCE OF THE HUMAN IgA SUBCLASSES

As described in Section III,A,2, two IgA isotypes have been described in humans (for reviews, see Mestecky and Russell, 1986; Mestecky *et al.*, 1986,1989) as well as in hominoid primates (Kawamura and Ueda, 1992; Kawamura *et al.*, 1992); 13 IgA isotypes have been reported in rabbits (Burnett *et al.*, 1989; see Chapter 9). These isotypes have been identified by sequence analysis or, in some cases, by serologic and structural studies.

Allotypic determinants specified by allelic genes have been described only in the IgA2 subclass and are now designated A2m(1) and A2m(2). The major structural difference between

these two allotypes concerns the arrangement of  $\alpha$ -L interchain disulfide bridges. In IgA2 of the A2m(1) allotype, the  $\alpha$  and L chains are *not* covalently linked and therefore can be separated by exposure to dissociating agents without cleavage of disulfide bonds (Grey *et al.*, 1968).

Population studies of the IgA2 allotypes revealed a characteristic racial and ethnic distribution. In Caucasians, the overwhelming proportion of IgA2 is of the A2m(1) allotype, whereas in Africans and in African Americans, the A2m(2) allotype dominates (Wang and Fudenberg, 1974; van Longhem and Biewenga, 1983). Interestingly, American Indians, Australian Aborigines, and Eskimos resemble Caucasians in this respect.

### A. Distribution of Human IgA Subclasses in Various Body Fluids and Tissues

Using polyclonal and monoclonal antibodies specific for human IgA1 and IgA2, several groups of investigators determined that serum IgA is represented primarily by the IgA1 subclass (~85% of total serum IgA) (for reviews see Mestecky and Russell, 1986; Conley and Delacroix, 1987). This value mirrors the proportion of IgA1- and IgA2-secreting cells in the bone marrow (Skvaril and Morell, 1974; Crago *et al.*, 1984) and, in conjunction with additional data (Alley *et al.*, 1982), indicates that almost all serum IgA originates from this source.

The proportion of IgA1 to IgA2 varies in individual secretions. Because almost all secretory IgA in humans is of local origin, this IgA1 : IgA2 ratio apparently reflects the characteristic distribution of IgA1- and IgA2-secreting cells in various tissues (Crago *et al.*, 1984; Kett *et al.*, 1986; Kutteh *et al.*, 1988). Although IgA1 cells predominate in most mucosal tissues and glands, in the large intestine and in the female genital tract the IgA2 cells equal or outnumber IgA1-positive cells. Lymph nodes contain a mixed proportion of IgA1 and IgA2 cells, depending on the source.

### B. Functional Differences between IgA Subclasses

Despite the high degree of identity between the primary structures of human IgA1 and IgA2 molecules, an understanding of the functional differences among the IgA subclasses is just beginning to emerge and is related to the structural differences between the two isotypes.

The extended hinge region in IgA1 molecules renders them highly susceptible to unique IgA1-specific proteases produced by several bacterial species, including many important human pathogens (see Chapter 12). Conversely, the absence of this region in IgA2 molecules makes them resistant to the IgA1 proteases (see Chapter 12). The extended hinge theoretically confers added segmental flexibility and increased antigen-binding ability on IgA1 molecules compared with IgA2 molecules, although this hypothesis has not been demonstrated experimentally (Pumphrey, 1986).

A second and profound structural difference between the human  $\alpha 1$  and  $\alpha 2$  chains concerns the composition and distri-

bution of the oligosaccharide side chains described in Section III,A,3. Human IgA1 and IgA2 myeloma proteins differ in the total amount and proportion of component carbohydrates, as well as in the number and distribution of oligosaccharide side chains (Niedermeier *et al.*, 1972; Tomana *et al.*, 1972, 1976, 1978; Baenziger and Kornfeld, 1974a,b; Torano *et al.*, 1977; Baenziger, 1979; Mizoguchi *et al.*, 1982; Wold *et al.*, 1990).

Differences in the carbohydrate composition of human IgA1 and IgA2 antibodies would be expected to influence a number of important properties of these molecules, some of which have been demonstrated experimentally. For example, the removal of terminal sialic acid substantially shortens the half-life of IgA molecules in the circulation because of the exposure of galactose residues that are recognized by ASGP-R on hepatocytes (Stockert *et al.*, 1982; Tomana *et al.*, 1988). Because of the availability of terminal galactose residues, IgA1 proteins bind better than IgA2 to the asialoglycoprotein receptor expressed on hepatocytes or on the human hepatoma cell line HepG2 (Tomana *et al.*, 1988).

More recent analysis indicates that some IgA myeloma proteins, especially those belonging to the IgA2 subclass (which also is represented in the mucosal secretions), display a high degree of carbohydrate heterogeneity as well as truncated oligosaccharide side chains with terminal mannose residues (Wold *et al.*, 1990). Such proteins effectively interact with gram-negative bacteria of the family Enterobacteriaceae that express type 1 fimbrial lectin. Since IgA2-producing cells predominate in the colon and vagina (Crago *et al.*, 1984; Kett *et al.*, 1986; Kutteh *et al.*, 1988), which are colonized by gram-negative bacteria expressing mannose-specific lectins, IgA2 may function in these areas independent of specific antibody activity. This type of carbohydrate-mediated interaction could form the basis for a broad antibacterial function of secretory IgA against enterobacteria, regardless of the antigenic specificity of antibody molecules, in conjunction with other immune elements.

Mildly aggregated IgA1 proteins have been demonstrated to attach to fibronectin-coated plates in greater amounts than similarly treated IgA2 proteins (Mestecky *et al.*, 1987). Although the biological significance of these *in vitro* observations is unclear at present, one may speculate that such interactions may be important in the catabolism and distribution of IgA molecules and possibly of IgA-containing immune complexes.

IgA1 and IgA2 myeloma proteins also have been compared with respect to their ability to influence biological functions of cells, such as natural killer (NK) cells or eosinophils. Secretory IgA and IgA2, but not IgA1 myeloma proteins significantly inhibit, in a concentration-dependent fashion, the NK activity of peripheral blood HNK-1<sup>+</sup> cells against K 563 target cells (Komiya *et al.*, 1986). In the eosinophil degranulation assay, IgA1 and IgA2 myeloma proteins and secretory IgA display a comparable activity (Abu-Ghazaleh *et al.*, 1989). Thus, IgA may be a principal immunoglobulin that mediates effector functions of eosinophils at mucosal surfaces in infections with parasites and in hypersensitivity diseases.

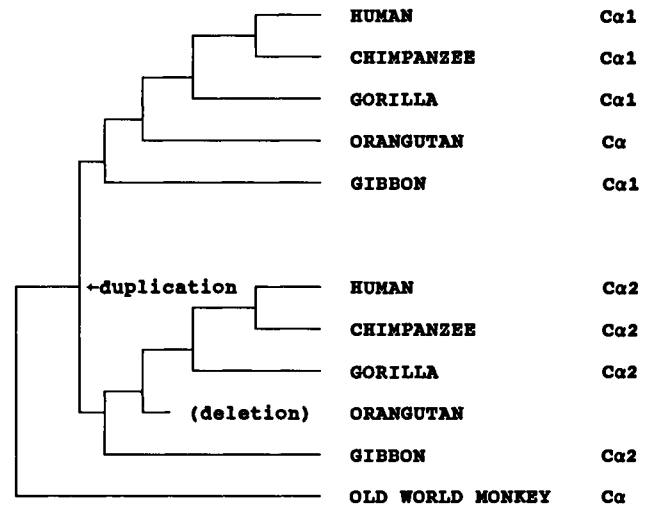

### C. Distribution of Naturally Occurring or Vaccination-Induced IgA1 and IgA2 Antibodies Specific for Various Types of Antigens

Studies of the IgA subclass association of naturally or artificially induced serum and secretory antibodies specific for different types of antigens revealed several potentially important findings. In colostrum (Ladjeva *et al.*, 1989) or saliva (Brown and Mestecky, 1985), antibodies specific for protein antigens were found predominantly in the IgA1 subclass. In contrast, antibodies to bacterial lipopolysaccharide and lipoteichoic acid in these fluids were of the IgA2 subclass. However, in serum, such antibodies were present as IgA1 (Russell *et al.*, 1986; Moldoveanu *et al.*, 1987), suggesting that they were derived from another tissue, probably bone marrow, and were induced by a different stimulatory pathway. The differences in the IgA subclass distribution of specific antibodies were even more pronounced in response to local or systemic infection or immunization. Although low levels of IgA1 and IgA2 antibodies to influenza A virus were detected before infection, IgA1 accounted for most of the rise in antihemagglutinin levels seen after infection (Brown *et al.*, 1985). However, in serum, almost all IgA antibodies were of the IgA1 subclass before and after the infection. Systemic immunization with pneumococcal polysaccharide vaccine induced a vigorous serum response in IgG and IgA isotypes. However, when analyzed by an ELISPOT assay for specific antibody-secreting cells, IgA-producing cells predominated in the peripheral blood (Lue *et al.*, 1988). Further, examination with monoclonal anti-IgA1 and anti-IgA2 reagents revealed the predominance of IgA2 cells producing specific antipolysaccharide antibodies. Comparable results were obtained in another concurrent, although independent, study (Heilman *et al.*, 1988). Subsequent immunizations of another group of young adult volunteers with tetanus toxoid or with polysaccharides from *Haemophilus influenzae* or *N. meningitidis* led to the transient appearance of antigen-specific antibody-secreting cells in the peripheral blood (Tarkowski *et al.*, 1990). Low frequencies of IgA-secreting cells, predominantly of subclass IgA1, were detected against tetanus toxoid. In contrast, the antipolysaccharide response was dominated by IgA2-producing cells.

Collectively, these results indicate that the character of an antigen greatly influences the outcome of the immune response with respect to the IgA subclass. Similar conclusions were reached in studies of the distribution of specific IgG subclass antibodies induced by systemic immunizations with protein or polysaccharide antigens (Hammerström and Smith, 1986). The mechanisms that regulate the isotype responses to various types of antigens remain speculative. Processing of different antigens and the involvement of different types of T helper cells and lymphokines (McGhee *et al.*, 1989) represent attractive avenues for future investigations.

### D. Phylogenetic Aspects of the Human IgA Subclasses

Kawamura *et al.* (1992) reported elegant work in which they obtained genomic sequences of  $\alpha$  chain genes from a

**Figure 6** Primate immunoglobulins. A phylogenetic tree tracing the origins of the IgA subclasses in hominoids and humans. The model is adapted from that of Kawamura *et al.* (1992).

series of hominoid species (Figure 6). Their data show clearly the presence of IgA1 and IgA2 molecules in some of the hominoid species, although all features (e.g., the extended hinge in IgA1) were not always present. These authors suggest that gene conversion was a major avenue to creating the IgA subclasses in humans and their immediate predecessors.

## VII. SUMMARY

Mucosal immunoglobulins represent a family of immunoglobulin isotypes that function to protect the host from molecules and microorganisms to which the mucosal surfaces are exposed continually. Transcytosis of the major isotype, IgA, is mediated by poly Ig receptor and provides mucosal secretions with a highly avid antibody.

Functional differences among the multiple IgA isotypes are just beginning to be understood. As these unfold, vaccination strategies may have to be designed to direct immune responses toward particular IgA isotypes. Preliminary findings indicate that the IgA subclass response in humans may be antigen dependent.

# Phylogenetic Aspects of Mucosal Immunoglobulins

Jean-Pierre Vaerman

## I. INTRODUCTION

The concept of a secretory immune system is based on the well-defined secretory immune systems of human, mouse, and rabbit. Essential components of these systems are a secretory immunoglobulin isotype (IgA or IgM) and a receptor-transporter system such as the polymeric IgA (or IgM) receptor (pIgR) or secretory component (SC) and J chain. This chapter summarizes the evidence for the presence of secretory IgA and SC or pIgR in various species of mammals, birds, reptiles, amphibians, and fish but does not include data on J chain, which has been well identified in cartilaginous primitive fish (Klaus *et al.*, 1971; Hagiwara *et al.*, 1985).

Unambiguous identification of an IgA molecule requires comparison of the amino acid sequence of the constant part of the heavy chain of the putative IgA with the amino acid sequences of the prototype IgA sequences of human, mouse, and rabbit. Putative IgA molecules also can be identified clearly by cross reaction with antisera specific for the prototypic  $\alpha$  chains. In the absence of such data, several other characteristics of the well-characterized IgA molecules have been used to identify putative IgA molecules, including (1) the predominant expression, relative to IgG, in exocrine secretions, (2) the differential expression of monomeric forms in serum, (3) the ability to associate in J chain-containing polymers with high affinity for SC and the formation of additional serological determinants by these associations, and (4) the abundant synthesis in mucosal plasmacytes.

The identification of putative SC components has been more difficult. IgA-bound SC is poorly immunogenic and few serological cross reactions have been reported. Further, free SC is sensitive to protease digestion and is about the same size as some immunoglobulin heavy chains.

## II. MAMMALS

IgA has been identified in all mammals examined on the basis of immunodiffusion analysis of cross reactions using mammalian or chicken antisera specific for mammalian or

chicken  $\alpha$  chains (Vaerman *et al.*, 1969; Orleans and Feinstein, 1971; Neoh *et al.*, 1973). Researchers now accept that even primitive mammals such as insectivores (mole, Orleans and Feinstein, 1971; European hedgehog, Vaerman *et al.*, 1969), monotremes (echidna), and marsupials (opossum, quokka, Bell *et al.*, 1974) possess a typical secretory IgA immune system.

As described earlier, the identification of SC or pIgR has been more difficult. However, these components have been identified in humans, dogs (Reynolds and Johnson, 1971; Delacroix *et al.*, 1983), cows (Mach *et al.*, 1969) goats and sheep (Pahud and Mach, 1970), pigs (Bourne, 1969a,b; Baumgarth *et al.*, 1990), horses (Pahud and Mach, 1972), rabbits (Cebra and Small, 1967; O'Daly and Cebra, 1971), guinea pigs (Vaerman *et al.*, 1975a), rats (Vaerman *et al.*, 1975b; Acosta-Altamirano *et al.*, 1980), and mice (Lemaître-Coelho *et al.*, 1977a; Pierre *et al.*, 1993).

## III. BIRDS

### A. Galliforms

#### 1. IgA

Lebacqz-Verheyden *et al.* (1972a,b) first reported a putative analog of mammalian IgA in chicken serum and secretions. In addition to light chain-specific common determinants, this IgA expressed antigenic determinants that were distinct from IgM and IgG (or IgY). In serum, the IgA was predominantly polymeric and represented a minor component. In contrast, the IgA was abundant in intestinal fluids, especially in gall bladder bile (Lebacqz-Verheyden *et al.*, 1974). The secretion: serum concentration ratio was also larger for IgA than for IgG and IgM in saliva, tears, and semen (Lebacqz-Verheyden *et al.*, 1974). Finally, in contrast to fluorescent anti- $\mu$  and anti- $\gamma$  antibodies, fluorescent anti-chicken  $\alpha$  chain antibodies revealed a wealth of IgA plasmacytes in duodenal, jejunal, ileal, cecal, oviduct, and bronchial lamina propria, with fewer IgA-positive cells in the spleen (Lebacqz-Verheyden *et al.*, 1974).

Bienenstock *et al.* (1972,1973a) also identified chicken IgA using antibiliary IgA antibodies that had been absorbed with IgG. These studies confirmed (Bienenstock *et al.* 1973b) the abundance of IgA in several chicken secretions and, using fluorescent-labeled antibodies, demonstrated many IgA-positive cells in the gut and other mucosae but not in the spleen. In addition, these researchers demonstrated a high level of incorporation of  $^{14}\text{C}$ -labeled amino acids into IgA, but not IgG and IgM, molecules that were secreted during short-term cultures of intestinal and other mucosae. Independently, Orleans and Rose (1972) and Rose *et al.* (1974) described a putative chicken IgA by its antigenic differences from IgM and IgG, and by higher IgA/IgG ratios in secretions than in serum. Leslie and Martin (1973) and Katz *et al.* (1974) also identified chicken IgA using similar criteria.

IgA has been identified in galliforms other than chickens by similar immunochemical, immunohistological, and biological techniques. In addition, cross reactions with anti-chicken IgA have been shown for turkey (Goudswaard *et al.*, 1977a), pheasant, Japanese quail, and guinea fowl (Parry and Aitken, 1975) but not pigeon, a member of Columbiformes in which only the former criteria were met (Goudswaard *et al.*, 1977b).

The data described were all consistent with the hypothesis of chicken IgA as a precursor of mammalian IgA. However, Hädge and Ambrosius (1983,1984,1986) used inhibition of radioimmunoassays to determine cross-reactivities and to screen for immunoglobulins resembling chicken bile IgA in concentrated serum globulins of diverse species. Since no cross-reactivities or related immunoglobulins were found, these investigators concluded that chicken bile immunoglobulin was not the precursor of mammalian IgA. These researchers termed chicken bile IgB, for dominant immunoglobulin in bile of some birds, although clearly shown in chicken serum. Based on their radioimmunoassays and immunodiffusion studies, these investigators concluded that IgY is the precursor of mammalian IgA (Hädge and Ambrosius, 1987). However, these data have not been confirmed independently, weak cross reactions in sensitive radioimmunoassays must be interpreted with caution, and some of the data presented were contradictory (outlined by Ng and Higgins, 1986).

More recent data may settle this controversial point. Manikka (1992) has obtained an amino acid sequence of the constant portion of the heavy chain that is different from IgG (or IgY) and IgM. Three nucleic acid probes including the chicken VH1 probe, a C $\mu$  probe, and a C $\gamma$  probe were used to screen 20,000 recombinant clones from a cDNA library prepared from Harderian glands, which are rich in IgA, IgM, and IgY plasmacytes. Nine clones hybridized only with VH1. One of these clones (A1) had an insert of  $\sim$ 1900 base pairs. The deduced amino acid sequence showed that it encoded a leader sequence identical to the VH1 leader followed by a V region that was 92% identical to the known germ-line VH1. Most of the differences were in the three complementary determining regions. Frameworks of A1-V and germ-line VH1 differed only by three nucleotides. After a D region, A1-J was identical to the single germ-line J sequence, followed by a C region consisting of 1329 base pairs or 443 amino acids before the stop codon. A1-C fit with four immu-

noglobulin C domains, with correctly spaced invariant cysteine-cysteine and tryptophan residues. A1 is thus a full-length H chain cDNA that is isotypically different from  $\mu$  and  $\gamma$  chains. The fowl C $\alpha$  was 37% identical to mouse C $\alpha$ ; identity to mouse C $\mu$ , C $\gamma$ 1, and C $\delta$  was much lower (29, 30, and 26%, respectively). Homology with human and rabbit  $\alpha$  chains was high. The C terminal -Cys-Tyr sequence and the C $\alpha$ 2 glucosamine binding site that are typical of mammalian  $\alpha$  chains were both present. A major difference was the presence of four C domains in chicken  $\alpha$  chain, as in chicken  $\gamma$  chain, suggesting that the fowl C $\alpha$ 2 had been deleted from the human  $\alpha$  chain during evolution.

These data clearly identify an IgA isotype in chickens and suggest that it is the precursor to mammalian IgA. Whether the amino acid sequence of H chains from fowl bile IgA will correspond to the nucleotide-derived sequence remains to be determined.

## 2. SC

Additional studies have been concerned with the association of SC with IgA and with the identification of different forms of IgA. Bienenstock *et al.* (1973b) first showed binding of radiolabeled human free SC to a chicken serum immunoglobulin that was precipitable by anti-IgA, but did not observe binding to chicken biliary IgA, suggesting the presence of SC in this chicken immunoglobulin. Rose *et al.* (1974) demonstrated that egg white contained a major 16.2S IgA that, on reduction and SDS-PAGE analysis, released a polypeptide with molecular mass of 50–70 kDa; this protein was identified tentatively as chicken SC. Antibodies that had been raised against oviduct fluid and absorbed with adult serum gave an identical reaction with egg white IgA and a soluble protein that was retained in immunoglobulin-depleted egg white and may represent SC. However, this antibody did not detect SC in chicken biliary or intestinal IgA. Leslie and Martin (1973) suggested that SC was associated with biliary IgA ( $\sim$ 350 kDa) and not with serum IgA, but this hypothesis was not demonstrated convincingly.

Katz *et al.* (1974) found no antigenic differences between IgA in sera and secretions, and concluded that the equivalent of mammalian SC does not exist in chicken. However, other investigators continued the search. Watanabe and Kobayashi (1974) compared bile and intestinal IgA from chicken. Bile IgA resembled serum IgA from chickens, was of high molecular mass (800–900 kDa), and was without SC. In contrast, intestinal IgA resembled mammalian secretory IgA, had a molecular mass of  $\sim$ 400 kDa, and was associated with SC. Subsequently, Watanabe *et al.* (1975) isolated a 70-kDa glycoprotein from gut fluid that was reactive with antibodies to intestinal but not biliary IgA. Using an antibody specific for this putative free SC, prepared by immunizing with gut SIgA and absorbing with bile IgA, these researchers determined that free gut SC was deficient compared with SC in gut SIgA. However, this finding could reflect sensitivity of the antibodies to conformational changes or to proteolysis in the gut. The anti-SC reacted with IgA in intestinal but not in other secretions; labeled free SC did not combine *in vitro* with biliary IgA or IgG. In these studies, Watanabe and Kobayashi

(1974) found the molecular mass of the IgA to be 350 kDa in gut secretions but 650–710 kDa in bile, tears, saliva, oviduct fluid, and urine. In later studies, Kobayashi and Hirai (1980) stated that chicken bile and intestinal IgA had the same size (~560 kDa) and found no evidence for SC in intestinal or bile IgA by SDS–PAGE and immunodiffusion of reduced or native proteins. The interpretation of these data is complicated by the poor immunogenicity of SC in chicken IgA and the similarity in size to the reduced  $\alpha$  chains in SDS–PAGE.

Porter and Parry (1976) isolated a putative SC with molecular mass of ~68 kDa from intestinal secretions but not from bile. Significantly, antibodies to bile IgA reacted identically with bile and intestinal IgA and partially with the 68-kDa protein. The major 15S serum IgA spurred (SC?) over the 7.5S serum IgA, as did pure bile and gut SIgA. Reduced bile IgA released a ~70-kDa protein that resembled free intestinal SC. Free SC also was identified in gut fluids from 20-day-old germ-free chicks with no IgA cells in their gut. As has been observed for mammalian SC, fluorescent labeled anti-SC antibodies stained only gut epithelium—mostly crypts in the supranuclear region, apical cytoplasm, and along basolateral membranes. However, these data seem incompatible with those of Bienenstock *et al.* (1972). Labeled human SC would not be expected to combine with polymeric chicken serum IgA bearing SC (Parry and Porter, 1978) nor with monomeric chicken serum IgA, which probably lacks J chain and thus would be unable to bind SC.

More recent experiments have concentrated on the use of functional criteria to elucidate the role of SC in galliforms. As in rats and rabbits (Lemaître-Coelho *et al.*, 1977b; Delacroix *et al.*, 1982), the levels of IgA were much higher in cannulated chicken hepatic bile than in plasma (Rose *et al.*, 1981). Again, as in rats and rabbits (Lemaître-Coelho *et al.*, 1978; Delacroix *et al.*, 1982), ligation of chicken bile ducts led to a fourfold increase in plasma IgA. Thus, the chicken liver quickly clears plasma chicken polymeric IgA by transporting it into bile. Rose *et al.* (1981) confirmed these findings by determining a high recovery in the bile of intravenously (iv) injected human labeled dimeric but not monomeric IgA, again as in rats and rabbits (Lemaître-Coelho *et al.*, 1978; Delacroix *et al.*, 1982).

Peppard *et al.* (1983) biolabeled chicken glycoproteins by iv injection of [<sup>14</sup>C]fucose in bile duct cannulated chickens, followed by iv injection of human cold dimeric IgA 30 min later. The human IgA recovered in the bile was labeled, presumably by binding to chicken SC. [<sup>14</sup>C]IgA collected from bile, when reinjected iv into a new recipient, did not reappear into the bile. Moreover, <sup>125</sup>I-labeled human milk and chicken bile IgA injected iv were not recovered in chicken bile. Thus, as has been found in rats, IgA already combined with SC is not actively cleared by the chicken liver (Vaerman and Lemaître-Coelho, 1979; Lemaître-Coelho *et al.*, 1981).

Finally, Peppard *et al.* (1986) purified human dimeric IgA by antihuman light chain immunoadsorption chromatography after its transport into chicken bile. Approximately half this IgA had increased in size by ~80 kDa, suggesting that it had bound chicken SC. After mild reduction of this immunopurified IgA, isoelectric focusing, SDS–PAGE, transfer to nitrocellulose, and reaction with rabbit antichick bile antibod-

ies, these investigators identified a protein of ~80 kDa with an isoelectric point of 4.6 that is thought to be chicken SC.

The data just discussed suggest that chicken IgA and SC have been reasonably well identified, although the case for chicken SC is less clear. Unfortunately, no serological cross reactions were reported between mammalian IgA and SC and their putative chicken equivalents. SC has not been identified in galliforms other than chickens. Since nucleic acid probes are now available for human, rabbit, and rat SC/pIgR, future identification of this elusive molecule (Peppard *et al.*, 1983) will probably rely on methods involving molecular biology as well.

### B. Anseriforms

Analogous to mammalian (or chicken) IgA have not been identified in anseriforms (Ng and Higgins, 1986; Higgins *et al.*, 1987). Ducks and geese also differ from chickens by the presence of a 5.7S Ig in the serum, as found in reptiles and lungfish. Hädge and Ambrosius (1988a,b) found no radioimmunoassay cross reactions between bile immunoglobulins of galliforms and anseriforms. None of the biliary anseriform immunoglobulins resemble mammalian IgA by radioimmunoassay cross reaction, but anseriform biliary immunoglobulins do resemble human and carp IgM by such criteria. Thus, the secretory immune system of anseriforms may be related more closely to that of reptiles, apparently relying on a predominance of IgM in secretions. In ducks, biliary IgM spurred (SC?) over serum IgM with anti-bile IgM antiserum but not with anti-serum IgM antiserum (Higgins *et al.*, 1987). However, gut secretions and immunohistological sections were not examined with antibodies specific for the spur, and no additional peptide was found in biliary IgM after reduction and SDS–PAGE. The ontogeny of IgM and IgY in bile and serum, and the kinetics of antiviral antibodies, additionally supports a secretory immune system in anseriforms (Ng and Higgins, 1986; Higgins *et al.*, 1987).

## IV. REPTILES AND AMPHIBIANS

As in ducks, three serum immunoglobulin isotypes occur in reptiles: 19S IgM and two smaller immunoglobulins, a 7.8S IgY and a 5.7S immunoglobulin. IgM predominates in the bile and gut fluids of snakes, turtles, and bullfrogs (Portis and Coe, 1975). No evidence for SC was presented in these studies. In tortoise bile and gut secretions, IgM largely predominated over the 7.8S IgY and the 5.7S immunoglobulin; fluorescent anti- $\mu$  and anti-light chain antibodies stained similar numbers of plasmacytes in intestinal mucosae (Vaerman *et al.*, 1975c), suggesting that no other major IgA-like immunoglobulin existed in the gut.

Fellah *et al.* (1992) reported that the serum of developing axolotls lacked an IgY-like immunoglobulin (11.9S dimer, Fellah and Charlemagne, 1988). However, the gut epithelium of the immature axolotls stained both with fluorescent monoclonal anti-axolotl IgY and some anti-mammalian SC antibodies. After Western blotting with anti-mammalian SC, the axo-

lotl stomach and intestinal extracts revealed 78-kDa and occasional 120 to 130-kDa bands that may represent axolotl SC and pIgR. These data require confirmation.

## V. FISH

Oral immunization of plaice with *Vibrio anguillarum* antigens resulted in higher antibody titers in gut extracts and skin mucus than in sera, whereas the serum titers were higher than those of secretions after parenteral injections (Fletcher and White, 1973). Antibodies in mucus and serum were similar to IgM in size. In sheepshead (Lobb and Clem, 1981a,b), biliary immunoglobulin was a noncovalent dimer that was antigenically identical to serum IgM. The heavy chains were smaller (~55 kDa) than those of serum  $\mu$  chains (70 kDa), but the light chains were of similar molecular mass (25 kDa). SC-like peptides were not found. Skin mucus immunoglobulins were composed of serum-like IgM and some dimers, some of which were associated covalently and, on reduction, released peptides with molecular mass of 70 kDa (H), 25 kDa (L), and 95 kDa (SC?). The only evidence for a secretory immune system in rainbow trout was the finding by St. Louis-Cormier *et al.* (1984) of serum IgM-like antibodies in mucus and immunoglobulin-containing cells in skin dermis and mucus. Local immune responses in the posterior gut of trout receiving oral human IgG were determined by immunohistology and by antibody secretion from cells of the intestine (Georgopoulou and Vernier, 1986). Oral and anal administration of *V. anguillarum* into carp (Rombout *et al.*, 1986) also suggested a local immune response, mostly in the hindgut. Oral bacteria elicited no serum antibody, whereas anal injection induced higher serum titers, with lower titers in bile and intestinal and skin mucus. Bath immunizations of catfish (Lobb, 1987) against dinitrophenyl (DNP)-albumin induced anti-DNP antibody in skin mucus of 5 of 6 fish, but induced serum antibody in only 1 of 6. The affinity-purified skin mucus antibody resembled IgM-like tetrameric serum antibody. Thus, some indication exists for a local secretory system in fish, but better characterization is required (Hart *et al.*, 1989).

## VI. CONCLUSION

The emergence of a classical primary, primarily SIgA-related, secretory humoral immune system seems to have occurred first in the galliform branch of birds, but we have adopted a mammalian viewpoint for this survey. In more primitive animal species (fish, amphibians, reptiles), whether such a viewpoint is acceptable is not clear at all. A completely different set of criteria from those used for mammals and galliforms may be required to define a mucosal immune system; the cellular components could be much more important, as could nonspecific defense factors such as complement-like proteins and mucus components. Clearly, the mucosal SIgA immune system is probably efficient, with minor variations (see, for example, the huge predominance of IgG1 in ruminant milk throughout lactation), in all mammals, as well

as in galliform birds. However, these are the limits of possible conclusions without too much risk of error.

# Developmental Aspects of Mucosal Immunoglobulin Genes: Organization and Expression of IgA Heavy-Chain, Polymeric Immunoglobulin Receptor, and J-Chain Genes

Katherine L. Knight

## I. INTRODUCTION

In Chapter 8, Vaerman described evidence for the presence of secretory IgA and a receptor-transporter (SC or pIgR) in various species of mammals, birds, reptiles, amphibians, and fish. Genes encoding these molecules are cloned principally from mammals. This chapter addresses the structure and expression of these genes.

## II. IgA HEAVY-CHAIN GENES

Genes encoding  $C\alpha$  regions are cloned from the genomes of human, mouse, cow, rabbit, and several nonhuman primates including gorilla, chimpanzee, orangutan, gibbon, and Old World monkey (Tucker *et al.*, 1981; Flanagan *et al.*, 1984; Knight *et al.*, 1988; Ueda *et al.*, 1988; Burnett *et al.*, 1989; Kawamura *et al.*, 1989,1990). With the exception of rabbits, all mammals studied have one or two IgA subclasses; correspondingly, they have one or two  $C\alpha$  genes in their germ line. As do other  $C_H$  genes, the  $C\alpha$  genes of each species studied have a separate exon that encodes each domain— $C\alpha 1$ ,  $C\alpha 2$ , and  $C\alpha 3$ —as diagrammed in Figure 1. The hinge region is not encoded as a separate exon, as it is in  $C\gamma$  and  $C\delta$  genes, but is encoded at the 5' end of the  $C\alpha 2$  exon. The hinge regions of human  $C\alpha 1$  and  $C\alpha 2$  genes contain tandem 15-bp repeat units. Kawamura *et al.* (1990) showed that the  $C\alpha 1$  and  $C\alpha 2$  genes of chimpanzee, gorilla, and gibbon have hinge structures similar to those of the human  $C\alpha 1$  and  $C\alpha 2$  genes, respectively. In contrast, the hinge region of the  $C\alpha$  gene of Old World monkeys does not contain the 15-bp repeat unit and, in general, its structure is markedly different from that of any hominoid  $C\alpha$  gene examined.

The 19-amino-acid extension found at the C-terminal end of the secreted form of  $\alpha$  heavy chains is encoded at the 3' end of the  $C\alpha 3$  exon. The transmembrane and cytoplasmic tail sequences found at the C-terminal end of the membrane form of  $\alpha$  heavy chains are encoded by one small exon,  $\alpha M$ , located approximately 2–4 kb downstream (3') of the  $C\alpha 3$ -

encoding exon (Word *et al.*, 1983; S. K. Zhai, and K. L. Knight, unpublished data). Approximately 2–6 kb upstream (5') of the  $C\alpha$  genes is the switch region that undergoes recombination in B lymphocytes during isotype switching.

### A. $C\alpha$ Genes of Mouse, Bovines, and Primates

The  $C\alpha$  gene of mouse is the 3'-most  $C_H$  gene of the H-chain gene cluster 5'- $J_H$ - $C\delta$ - $C\gamma 3$ - $C\gamma 1$ - $C\gamma 2b$ - $C\gamma 2a$ - $C\epsilon$ - $C\alpha$ -3' (Shimizu *et al.*, 1982). In humans, the  $C_H$  gene order differs slightly from that in mice, presumably because of the duplication of a cluster of two  $C\gamma$  genes, one  $C\epsilon$ , and one  $C\alpha$  gene (Figure 2). In this case, the gene order is 5'- $J_H$ - $C\mu$ - $C\delta$ - $C\gamma 3$ - $C\gamma 1$ -pseudo  $C\epsilon$ - $C\alpha 1$ -pseudo  $C\gamma$ - $C\gamma 2$ - $C\gamma 4$ - $C\epsilon$ - $C\alpha 2$ -3' (Flanagan and Rabbits, 1982; Hofker *et al.*, 1989). The bovine  $C\alpha$  gene is 3' of  $C\epsilon$ , but has not been linked by overlapping phage or cosmid clones to  $C\mu$  or  $C\gamma$  (Knight *et al.*, 1988).

### B. $C\alpha$ Genes of Rabbit and Other Lagomorphs

Rabbits are highly unusual because their germ line has 13 nonallelic  $C\alpha$  genes (Burnett *et al.*, 1989). The 13  $C\alpha$  genes span a minimum of 160 kb of DNA. Three of the  $C\alpha$  genes— $C\alpha 4$ ,  $C\alpha 5$ , and  $C\alpha 6$ —have been linked to the  $C\mu$ ,  $C\gamma$ , and  $C\epsilon$  genes by overlapping cosmid clones (Figure 3; Burnett *et al.*, 1989). The remaining 10  $C\alpha$  genes are in separate or overlapping phage or cosmid clones. Isolating phage or cosmid clones that link these 10 genes to the 5'- $J_H$ - $C\mu$ - $C\gamma$ - $C\alpha 4$ - $C\alpha 5$ - $C\alpha 6$ -3' cluster has been difficult, although multiple genomic phage and cosmid libraries were screened for clones that would link the 13  $C\alpha$  genes. Clearly, some genomic DNA segments of the  $C\alpha$  gene cluster are difficult to clone. We suggest that, because the  $C\alpha$  chromosomal region seems to have a high content of repeated elements, some DNA is deleted repeatedly during construction of the genomic libraries, making cloning the entire region difficult. Another possible reason for not being able to link the 13  $C\alpha$  genes together

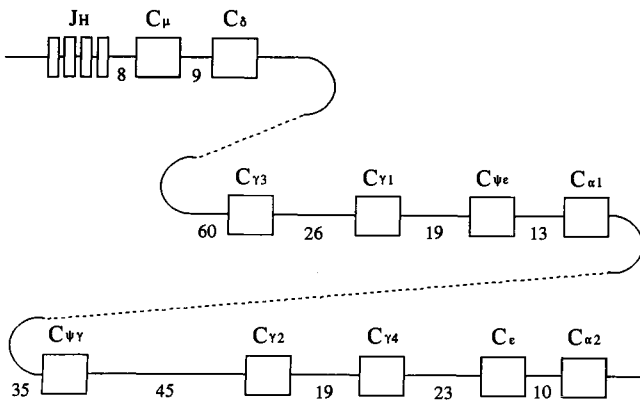

**Figure 1** Intron-exon structure of  $C\alpha$  genes. The boxes represent the exons that encode the  $C\alpha 1$  domain, the hinge (H) and  $C\alpha 2$  domain, the  $C\alpha 3$  domain and secreted tail, and the membrane/cytoplasmic domain ( $\alpha M$ ). The smaller open box represents 3'-untranslated region of the RNA.

is that some of them are not within the heavy chain chromosomal region; this possibility, however, seems unlikely.

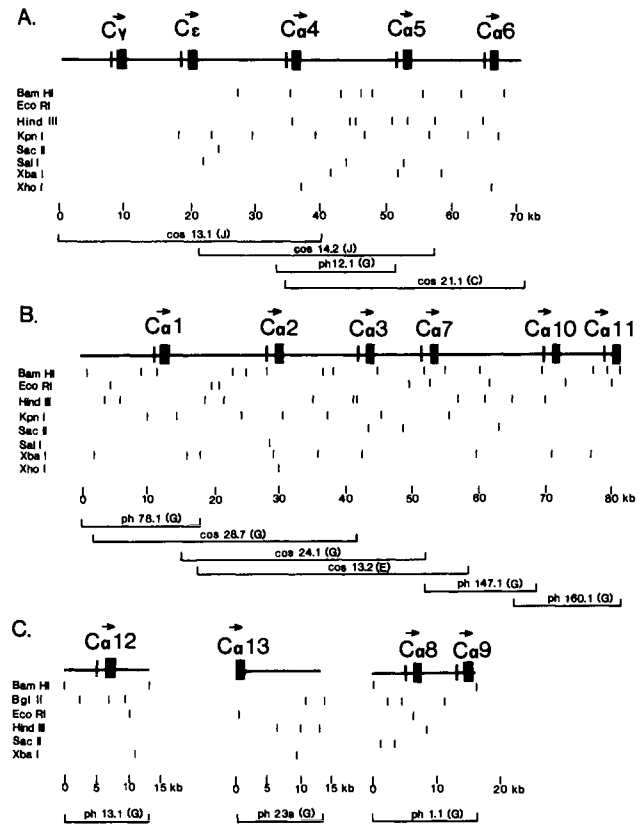

Because of the large number of  $C\alpha$  genes in rabbit compared with other mammals, Burnett *et al.* (1989) investigated whether multiple copies of  $C\alpha$  also were found in other lagomorphs. Southern blots of DNA from members of the two families of lagomorphs—Leporidae and Ochotonidae—hybridized with rabbit  $C\alpha$  probes revealed multiple hybridizing fragments in each sample of DNA (Figure 4). These data indicate that multiple  $C\alpha$  genes are found in animals throughout the order Lagomorpha and that the expansion of  $C\alpha$  genes occurred in a common ancestor. Similar attempts to identify multiple  $C\alpha$  genes in mammals that belong to an order other than Lagomorpha have been unsuccessful to date. Thus we do not yet know, in evolutionary terms, when the expansion of  $C\alpha$  occurred.

**C.  $C\alpha$  Gene of Chicken**

As described in Chapter 8, IgA-like molecules have been identified in chicken serum and secretions, but the evolutionary relationship between the heavy chains of these molecules and mammalian  $\alpha$  heavy chains is not clear. Mansikka (1992) cloned a non- $\mu$ -, non- $\gamma$ -encoding H chain cDNA from a library derived from mRNA of chicken Harderian gland, a tissue rich in plasma cells. On the basis of the deduced amino acid sequence, the constant region of the H chain encoded by the cDNA was 37% identical to murine  $C\alpha$  chains and only 29% and 30% identical to murine IgM and IgG1, respectively. The data show that chickens have a third Ig isotype that is distinct

**Figure 2** Organization of the human  $J_H$  and  $C_H$  Ig locus.

**Figure 3** Organization of 13 rabbit germline  $C\alpha$  genes.  $C\alpha$  genes are indicated by solid boxes; the vertical lines to the left of each gene indicate S regions. Arrows indicate transcriptional direction. (A) Cluster 1 obtained from overlapping cosmid and phage clones (Burnett *et al.*, 1989), showing linkage of  $C\alpha 4$ ,  $C\alpha 5$ , and  $C\alpha 6$  genes to the  $C_H$  genes,  $C\gamma$ , and  $C\epsilon$ . (B) Cluster 2 obtained from overlapping cosmid and phage clones. (C) Cluster of two  $C\alpha$  genes,  $C\alpha 8$  and  $C\alpha 9$ , and two individual clones on nonoverlapping phage clones. Reprinted with permission from Burnett *et al.* (1989).

**Figure 4** Southern analysis of lagomorph genomic DNA with the rabbit  $C\alpha$  cDNA probe. DNA samples, domestic rabbit (R), cottontail rabbit (C), jackrabbit (J), and pika (P), were restricted with *Bam* HI. Lambda *Hin* dIII size standards are indicated. Reprinted with permission from Burnett *et al.* (1989), and Oxford University Press.

from IgM and IgG, and that this isotype is most likely the homolog of mammalian IgA. Of particular interest is that these heavy chains have four  $C_H$  domains. By comparing the similarity of the sequences of each chicken  $C\alpha$  domain with mammalian  $C\alpha$  domains, Mansikka (1992) showed that the chicken  $C\alpha_2$  domain was the least similar to mammalian  $\alpha$  chains and concluded that the  $C\alpha_2$  domain was deleted in mammals during evolution.

#### D. Expression of $C\alpha$ Genes

In humans, IgA1 and IgA2 are expressed differentially in various tissues (Brandtzaeg *et al.*, 1986; Kett *et al.*, 1986; Mestecky and Russell, 1986). For example, IgA1 represents 80–95% of the IgA in serum whereas, in external secretions, it generally represents 30–50% of the IgA. The factors responsible for this differential expression are not known. In rabbits, the 13 germ-line  $C\alpha$  genes were examined for their expressibility by nucleotide sequence analysis and by transfection studies. Burnett *et al.* (1989) analyzed the nucleotide sequences and found that each of the 13  $C\alpha$  genes was expressible. Schneiderman *et al.* (1989) ligated each of the  $C\alpha$  genes to a murine VDJ gene, transfected murine L-chain-producing SP2/0 cells with each of the chimeric rabbit–mouse  $\alpha$  heavy chain gene constructs, and showed that most, if not all, of the  $C\alpha$  genes could be expressed *in vitro* in these cells. Using probes specific to each of the 13  $C\alpha$  genes, RNase protection studies of mRNA from mucosal tissues, including gut and mammary tissue, identified mRNA representing 10 of the  $C\alpha$  genes (Spieker-Polet *et al.*, 1993). These data show that rabbits express 10  $C\alpha$  genes in the mucosae. Presumably, then, 10 IgA isotypes will be found in rabbit mucosal secretions. The functional significance of multiple IgA isotypes remains to be elucidated. Serologically, only two isotypes of IgA, f and g, are well defined (Knight and Hanly, 1975). The chimeric rabbit–mouse IgA molecules generated by Schneiderman *et al.* (1989), which represent each of the IgA isotypes, can be used as immunogens to develop antibodies specific to each of the 10 isotypes. Using such antibodies, or using the RNase protection assay, the relative expression of each IgA isotype in various mucosal tissues can be determined. Considering the differential expression of the two IgA isotypes IgA1 and IgA2 in various human mucosal tissues (Brandtzaeg *et al.*, 1986; Mestecky and Russell, 1986) the 10 IgA isotypes in rabbit are likely to be expressed differentially in various mucosal tissues.

### III. CLASS SWITCHING

IgA expression results from class switching, by which in IgM–IgD-bearing B lymphocytes a  $C\alpha$  gene is rearranged to the region downstream of the rearranged VDJ gene. During isotype switching to IgA, the  $C\mu$ ,  $C\delta$ ,  $C\gamma$ , and  $C\epsilon$  genes 5' of the switched  $C\alpha$  gene and 3' of the VDJ gene are deleted from the germ line (Rabbits *et al.*, 1980; Yaoita and Honjo, 1980; Kataoka *et al.*, 1981; von Schwedler *et al.*, 1990). The isotype switch generally occurs by recombination between

the tandem direct repeat sequences, that is, switch sequences, that are found 5' of each  $C_H$  gene except  $C\delta$  (Davis *et al.*, 1980; Obata *et al.*, 1981). Switching may be regulated by the accessibility of switch regions to a recombinase that presumably is involved in the switch recombination; such recombinases are not yet identified. The induction of IgA isotype switching has been studied extensively; of particular interest are the results of Coffman and colleagues, who showed that the addition of transforming growth factor  $\beta$  (TGF $\beta$ ) to lipopolysaccharide (LPS)-stimulated cultures of murine splenic and Peyer's patch B cells resulted in an approximately 10-fold increase of IgA production (Coffman *et al.*, 1989; Lebman *et al.*, 1990a). In their experiments, TGF $\beta$  stimulated SIgA<sup>-</sup> cells to express IgA; the authors suggest that TGF $\beta$  acts as an isotype-specific factor for IgA. Stavnezer and her colleagues also studied isotype switching in a murine B-lymphoma cell line (I.29), which switches from IgM to IgA (Stavnezer *et al.*, 1985; Severinson *et al.*, 1990). These investigators found a germ-line  $C\alpha$  transcript from unrearranged  $C\alpha$  genes that spanned the  $C\alpha$  gene and a region 5' of the switch site; this sterile transcript did not have  $V_H$  or  $J_H$  gene sequences (Stavnezer *et al.*, 1988; Radcliffe *et al.*, 1990). Lebman *et al.* (1990b) cloned sterile  $C\alpha$  transcripts from TGF $\beta$ -induced LPS-stimulated B cells and also found that the transcripts contain germ-line sequences 5' to the  $\alpha$  switch site as well as  $C\alpha$  sequences. The results suggest that switching to IgA is preceded by transcription of unrearranged  $C\alpha$  genes. The function of these transcripts remains unknown, but Stavnezer *et al.* (1988) suggested that transcription may promote recombination. To date, however, we do not understand how a particular  $C_H$  gene, especially  $C\alpha$ , would be selected for transcription nor how this transcription would promote the switch recombination process.

### IV. POLYMERIC IMMUNOGLOBULIN RECEPTOR/SECRETORY COMPONENT GENES

Polymeric immunoglobulin receptor (pIgR) mediates the transport of polymeric Ig across the epithelia into secretions. Polymeric Ig binds to pIgR at the basolateral cell surface and is internalized via receptor-mediated endocytosis. The complex then is transcytosed to the apical cell surface, where the polymeric Ig is secreted with a portion of the pIgR (called SC; Brandtzaeg, 1974; Mostov and Blobel, 1982; Solari and Kraehenbuhl, 1984). Mostov *et al.* (1984) first cloned the pIgR gene from a rabbit cDNA library; subsequently, Deitcher and Mostov (1986) isolated the genomic pIgR gene from a rabbit genomic DNA library. By analyzing the deduced amino acid sequence, Deitcher and Mostov (1986) identified five extracellular domains with structural similarity to immunoglobulin domains, suggesting that pIgR is a member of the immunoglobulin superfamily (Mostov *et al.*, 1984; Hunkapiller and Hood, 1989). The sixth domain has a highly hydrophobic region and is believed to be the region that spans the cell membrane. The seventh, or cytoplasmic, domain is unusually

large, having 103 amino acids. This domain does not appear to be a member of the immunoglobulin superfamily.

Two forms of SC are found in rabbit secretions, a high molecular weight form (HMW;  $M_r \sim 81,000$ ) and a low molecular weight form (LMW;  $M_r \sim 55,000$ ) (Mostov *et al.*, 1980; Kuhn and Kraehenbuhl, 1981; Kuhn *et al.*, 1983). Deitcher and Mostov (1986) showed that these two forms probably arise from differential RNA splicing. One unusual feature of the genomic pIgR gene is that the immunoglobulin-like domains 2 and 3 are encoded by the same exon (Deitcher and Mostov, 1986). The HMW form of SC contains all seven SC domains, whereas LMW SC contains five SC domains; domains 2 and 3 are absent because of alternative splicing of the primary RNA transcript. Hanly (1992) identified repetitive sequence elements on both the 5' and the 3' side of exon 2-3, and suggests that these elements may mediate the alternative splicing event resulting in LMW SC.

The human pIgR gene also has been cloned from both a cDNA library (Krajči *et al.*, 1989) and a genomic phage library (Davidson *et al.*, 1988). Analysis of human  $\times$  mouse somatic cell hybrids localized the pIgR gene to the long arm of chromosome 1. The intron-exon organization of the human pIgR gene is similar to that of rabbit (Hanly *et al.*, 1989; Krajči *et al.*, 1992; W. C. Hanly, unpublished data), but no mRNA encoding LMW SC was found in human secretory tissues (Krajči *et al.*, 1989), indicating that the pIgR transcript is not alternatively spliced.

pIgR has been used as a model system to investigate intracellular protein traffic. The availability of the cloned pIgR gene allows systematic analysis of regions of the protein required for specific biological functions (for example, see Mostov *et al.*, 1986; Breitfeld *et al.*, 1989; Schaerer *et al.*, 1990; Apodaca *et al.*, 1991; Casanova *et al.*, 1991). Banting *et al.* (1989) cloned the rat pIgR gene as cDNA and showed that the cytoplasmic domain was conserved remarkably with the cytoplasmic domain of rabbit and human pIgR genes. Further comparison of the amino acid sequence similarities among species may help identify functionally important amino acid residues in the cytoplasmic domain.

## V. J-CHAIN GENES

J chain, a protein of 137 amino acid residues, is associated with polymeric IgA and IgM (see review by Koshland, 1985). The J-chain gene first was cloned from a murine plasmacytoma cDNA library (Mather *et al.*, 1981; Cann *et al.*, 1982) and subsequently was cloned from murine and human genomic libraries (Max and Korsmeyer, 1985; Matsuuchi *et al.*, 1986). Analysis of human  $\times$  rodent somatic cell hybrids located the human J-chain gene on the long arm of chromosome 4 (Max *et al.*, 1986); the J-chain gene in mouse is located on chromosome 5 (Yagi *et al.*, 1982). J chains are highly conserved: the sequences of these mouse and human genes are 77% identical. Analysis of the amino acid sequence and circular dichroism measurements led Zikan *et al.* (1985) to propose that the J chain may be a member of the immunoglobulin superfamily, since it has a single-domain antiparallel  $\beta$

pleated sheet bilayer structure. Previously, Cann *et al.* (1982) had proposed a two-domain structure for J chain, which was unlike that of an immunoglobulin-like fold. Although the data are more consistent with the single-domain structure for J chain, X-ray crystallographic analysis of J-chain-containing polymers will establish which model more accurately depicts the structure of J chain.

The J-chain gene consists of four exons distributed over 7.3 kb. Unlike immunoglobulin heavy- and light-chain genes, the J-chain gene does not undergo rearrangement during B cell differentiation (Yagi and Koshland, 1981; Matsuuchi *et al.*, 1986). A single primary transcript of the J-chain gene appears to be produced. Unlike  $C_H$  and pIgR gene transcripts, this transcript does not seem to undergo alternative splicing. However, like immunoglobulin light- and heavy-chain genes, the region 5' of the translational start site includes a TATA sequence as well as two tissue-specific decanucleotide and pentadecanucleotide elements that are common to human and mouse  $V_k$  genes, mouse  $V_\lambda$  genes, and heavy-chain enhancers (Mills *et al.*, 1983; Falkner and Zachau, 1984; Parslow *et al.*, 1984; Mage *et al.*, 1989). The presence of these elements in the J-chain gene suggests that its transcription may be controlled in a manner similar to that of light- and heavy-chain genes.

Expression of the J-chain gene during B-cell differentiation was studied in mouse and humans, but the results do not establish the stage in the differentiation pathway at which J-chain synthesis is initiated. In mouse, J chain was not found in  $\mu$  heavy chain producing pre-B or B lymphoma cell lines but was highly expressed in Ig-secreting B-lineage cells (Mather *et al.*, 1981; Koshland, 1985). These data indicated that J-chain expression occurred after the synthesis of  $\mu$  heavy chains. However, in human, several investigators (McCune *et al.*, 1981; Mason and Stein, 1981; Hajdu *et al.*, 1983; Max and Korsmeyer, 1985) showed that J chain was expressed in pre-B and null lymphocytic leukemias. Subsequently, Kubagawa *et al.* (1988) showed that some Epstein-Barr virus-transformed human B-cell progenitors expressed J chain in the absence of immunoglobulin gene rearrangements. These data indicate that J-chain expression precedes  $\mu$ -chain expression. The discrepancy between the J-chain expression in mouse and human B-lineage cells may reflect that most data were obtained from transformed cells (Max and Korsmeyer, 1985). Additional studies using normal untransformed cells may resolve this discrepancy.

Koshland and colleagues studied the activation of the J-chain gene in mitogen-stimulated IgM-secreting murine lymphocytes (Minie and Koshland, 1986) and in a cloned murine B-cell line (BCL<sub>1</sub>) that was stimulated by interleukin 2 (IL-2) to synthesize J-chain RNA and to secrete pentameric IgM (Blackman *et al.*, 1986). In both examples, the chromatin structure 5' to the J-chain gene was altered. Blackman *et al.* (1986) suggest that these changes make the promoter region accessible to regulatory elements that, in turn, activate transcription of the J-chain gene. The ability to activate J-chain gene transcription by stimulating BCL<sub>1</sub> cells with IL-2 provides us with a model system in which to identify and characterize regulatory elements involved in signal-induced gene activation.

## VI. CONCLUSIONS

A secretory immune system is present in most, if not all mammals, including primitive mammals such as insectivores, monotremes, and marsupials (see Chapter 8). Of nonmammalian species, a clear description of an IgA-like molecule has been given only for chicken. Most mammalian species seem to have one or two IgA isotypes expressed in secretions, but rabbits have at least 10 secretory IgA isotypes. The presence of 10 secretory IgA isotypes in rabbits is intriguing; evaluating their individual roles in secretory immunity will be important.

Genes encoding IgA heavy chains are cloned from several mammals, including humans, mice, rabbits, and bovines. These  $C\alpha$  genes are highly similar to each other and, in the future, can be used easily as probes to clone  $C\alpha$  genes of other mammals. In fact, the mammalian  $C\alpha$  probes probably can be used to identify  $C\alpha$  genes in nonmammalian species. For example, segments of  $C\alpha 3$  domains are highly conserved among mammals, and regions of the mammalian  $C\alpha 3$  domains are even highly similar to the chicken  $C\alpha$  chain. We suggest that probes derived from these conserved regions of the  $C\alpha 3$  domain-encoding region of mammalian  $C\alpha$  genes would hybridize with the  $C\alpha$  genes of nonmammalian species and aid in their cloning.

Genes encoding pIgR and J chain are cloned from rabbit and human and mouse and human, respectively. Experiments with the J-chain gene will help elucidate the role of J chain in polymeric immunoglobulins, including secretory IgA. Experiments with the pIgR gene will elucidate the means by which IgA is transcytosed across the epithelium.

# Epithelial and Hepatobiliary Transport of Polymeric Immunoglobulins

*Per Brandtzaeg · Peter Krajci · Michael E. Lamm · Charlotte S. Kaetzel*

## I. INTRODUCTION

Mucous membranes generally are protected by a physically vulnerable monolayer of epithelium that covers an enormous surface area, perhaps 300–400 m<sup>2</sup> in adult humans. Most of this area is bombarded continuously by potentially infectious agents such as bacteria, viruses, fungi, and parasites, in addition to soluble dietary and environmental substances.

The first observations suggesting that the gastrointestinal mucosa has its own humoral immune system were published at the beginning of this century (Besredka, 1919; Davies, 1922). The molecular basis for the antibody activity found in exocrine secretions was described much later when Tomasi *et al.* (1965) characterized secretory IgA (SIgA) as an IgA dimer linked to an epithelial glycoprotein of ~80 kDa. This “secretory piece” is now called the secretory component (SC) and its transmembrane counterpart (~100 kDa) often is referred to as the polymeric immunoglobulin receptor (pIgR). Both bound SC (present in SIgA) and the structurally identical free SC found in most exocrine fluids (Brandtzaeg, 1973a) are generated by cleavage from the transmembrane component (Chapter 7).

In the early 1970s, dimers and larger polymers of IgA (collectively called polymeric IgA; pIgA) first were shown to be produced mainly by plasma cells adjacent to exocrine glands, especially in the gastrointestinal mucosa (Brandtzaeg, 1973b). These cells also produce the “joining” or J chain (Brandtzaeg, 1974a, 1985), a peptide of ~15 kDa that becomes incorporated into the quaternary structure of both pIgA and pentameric IgM (Mestecky and McGhee, 1987). The J chain appears to determine the pIg structure that enables SC to complex noncovalently with pIgA and pentameric IgM, thereby being crucial to their transport through SC-expressing epithelium (Brandtzaeg and Prydz, 1984).

Thus, an interesting cooperation occurs between local plasma cells and secretory epithelia in the generation of SIgA and secretory IgM (SIgM). The gut mucosa contains most Ig-producing cells and is, therefore, quantitatively the major effector organ of humoral immunity (Chapter 21). The selectivity and capacity of the SC-mediated pIg transport mechanism are remarkable (Figure 1); more SIgA (40 mg/kg body weight) than the total daily production of IgG appears in the gut lumen every day (Conley and Delacroix, 1987).

## II. COMMON EPITHELIAL POLYMERIC Ig TRANSPORT MECHANISM

Various models have been proposed for the external translocation of IgA (Brandtzaeg, 1985). The common transport mechanism proposed in the early 1970s suggested that pIgA and pentameric IgM both are translocated through secretory epithelia by receptor-mediated endocytosis; this notion implied that SC performs this function as an integrated plasma membrane protein (Brandtzaeg 1973a,b, 1974b, 1985). The model also implied that the J chain is a key protein in this process by generating the SC binding site in the pIg structure (Brandtzaeg, 1974a,b). The obvious biological significance of the striking J-chain expression shown by immunocytes in secretory tissues (Brandtzaeg, 1985) is, therefore, that locally produced pIgA and pentameric IgM become readily available for external transport (Figure 2). This important functional goal in terms of mucosal defense is necessarily reflected by a clonal maturation stage of B cells homing to secretory sites compatible with high J-chain-expressing potency (Chapter 21).

## III. EVIDENCE THAT SECRETORY COMPONENT IS A POLYMERIC Ig RECEPTOR

### A. Epithelial Localization of SC, IgA, and IgM

Immunohistochemical staining of different human exocrine tissues has demonstrated firmly the widespread epithelial distribution of SC; no convincing documentation of primary SC deficiency is available (Brandtzaeg and Baklien, 1977a; Brandtzaeg, 1985). SC is expressed mainly by serous types of epithelial cells in gastrointestinal mucosa; salivary, lacrimal, and mammary glands; the exocrine pancreas; the renal tubules; and the fallopian tube and endocervix of the female reproductive tract. The most prominent expression is seen in crypt cells of the large bowel and in mammary glands during late pregnancy (Brandtzaeg, 1974b, 1983). Immunoelectron-microscopic studies have substantiated that not only do serous secretory cells synthesize SC, but they also clearly express SC in the basolateral plasma membrane (Brown *et al.*, 1976).

**Figure 1** Average levels of IgG (G), IgA (A), and IgM (M) in various normal human body fluids. The concentration ratios (G : A and G : M) are indicated also to show the strikingly preferential appearance of IgA and, to a lesser extent, IgM in external secretions. This selectivity is particularly remarkable for colostrum, which is obtained directly from the duct opening, thus avoiding substantial contamination of IgG from interstitial fluid by leakage through surface epithelia. Modified from Brandtzaeg (1973a).

IgA and IgM can be traced with a distribution similar to that of SC, both in the cytoplasm and in relation to the basolateral borders of serous-type secretory epithelial cells (Brandtzaeg, 1974b, 1975a; Brown *et al.*, 1976). Nevertheless, the detailed staining patterns revealed by paired immunofluorescence staining are not completely congruent; free SC is concentrated selectively in a granular pattern corresponding to the Golgi zone, whereas bound SC is seen mainly apically in the cytoplasm together with IgA and IgM (Brandtzaeg, 1974b; Poger and Lamm, 1974). Ultrastructural studies have confirmed these observations (Kraehenbuhl *et al.*, 1975; Brown *et al.*, 1976).

In the human hepatobiliary system, SC generally is found to be expressed only by the gall bladder and portal bile duct epithelia (Nagura *et al.*, 1981; Brandtzaeg, 1985; Tomana *et al.*, 1988), in contrast with the rat, rabbit, and some other species in which abundant SC expression is shown by hepatocytes (see subsequent discussion). Some reports have claimed such expression for human hepatocytes as well (Hsu and Hsu, 1980; Foss-Bowman *et al.*, 1983). Perez *et al.* (1989) reported positive staining with one of several monoclonal antibodies to SC, but in our hands this antibody reacted only with biliary duct epithelium (P. Brandtzaeg, unpublished observations).

## B. Interactions between Polymeric Ig and SC

### 1. Binding Affinity and J-Chain Dependency

The apparent association constant ( $K_a$ ) of pIg with free SC in solution is about  $10^8 M^{-1}$  (Brandtzaeg, 1985). This value is similar to that observed for a variety of antigen-antibody reactions but probably is underestimated for interactions with SC-expressing epithelial cells. In the latter case, a  $K_a$  of about  $10^9 M^{-1}$  has been suggested (Kühn and Kraehenbuhl, 1979). Both free and transmembrane SC molecules appear to depend on the presence of J chain in pIgA and pentameric IgM for the binding of these ligands (Brandtzaeg and Prydz, 1984). A crucial role of J chain in the formation of the SC binding site was, nevertheless, questioned by Schiff *et al.* (1986a), who claimed that some J chain-containing polymeric fractions of a human myeloma IgA lacked affinity for SC; however, these investigators did not formally prove the presence of J chain in the actual polymers.

Much stronger noncovalent interactions occur between pentameric IgM and SC than between pIgA (both subclasses) and SC; the  $K_a$  is several times higher for the former ligand (Brandtzaeg, 1985). Whether a "bonus effect" of a potentially higher molar J-chain content in pentameric IgM than in pIgA might explain this disparity remains to be clarified. In contrast to the notion that one J chain is found per polymer regardless of its size (Mestecky and McGhee, 1987), immunochemical quantitations have suggested the presence of two J chains in native dimeric IgA and two to four J chains in pentameric IgM (Brandtzaeg, 1985). The tendency for spontaneous dimerization shown by J chains obtained from pIgA by mild reduction could reflect that this peptide exists as a dimer in its native bound form (Brandtzaeg, 1985). Such isolated J-chain dimers show a marginal but significant affinity for free

**Figure 2** Model for the generation of human secretory IgA (SIgA) and secretory IgM (SIgM) via SC-mediated epithelial transport of J chain-containing pIgA and pentameric IgM produced by local plasma cells. (1) Synthesis and core glycosylation (—) of transmembrane SC in rough endoplasmic reticulum (RER) of secretory epithelial cell. (2) Terminal glycosylation (—●) in Golgi complex. (3) Phosphorylation (◆) at some later step. (4) Complexing of SC with J chain-containing pIg on basolateral cell membrane. (5) Endocytosis of complexed and unoccupied SC. (6) Transcytosis of vesicles. (7) Cleavage and release of SIgA, SIgM, and excess free SC. The cleavage mechanism and the fate of the cytoplasmic tail of transmembrane SC are mainly unknown. During the external translocation, covalent stabilization of the IgA-SC complexes regularly occurs (two disulfide bridges indicated in SIgA), whereas an excess of free SC in the secretion stabilizes the noncovalent IgM-SC complexes (dynamic equilibrium indicated for SIgM). Modified from Brandtzaeg (1985).

SC. Antibody to J chain blocks the binding of SC to pIgA and pentameric IgM completely (Brandtzaeg, 1985). All these observations support the idea that the J chain contributes to the SC binding site.

## 2. Molecular Topography of Interactions

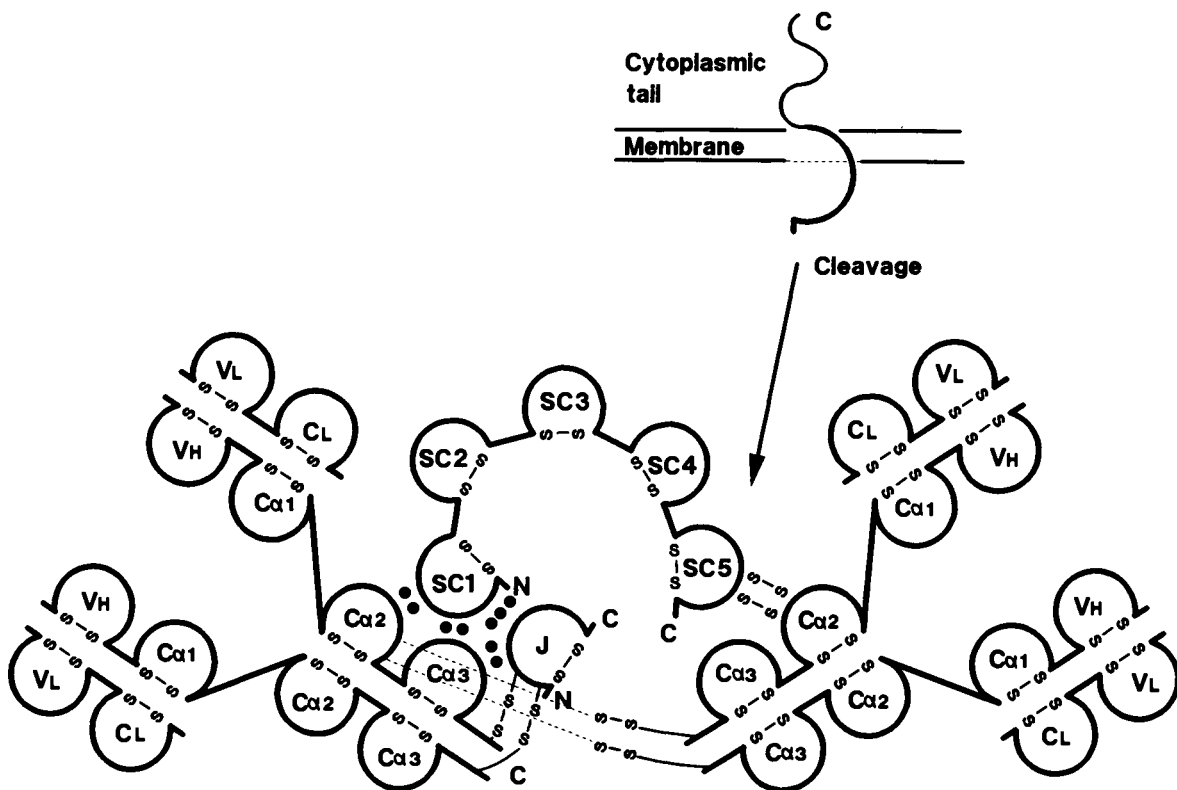

The reduction-sensitive "I determinant" region of SC (Brandtzaeg, 1971), apparently corresponding to its N-terminal or first Ig-like domain (Section IV, A), is likely to mediate the initial noncovalent interactions with pIg (Brandtzaeg, 1975b; Frutiger *et al.*, 1986; Geneste *et al.*, 1986a). The first binding step may depend on the highly conserved 15-37 amino-acid sequence that shows affinity not only for pIg but also for monomeric IgA and IgG (Bakos *et al.*, 1991). This step may be followed by further noncovalent interactions, apparently extending beyond the first domain at least in some species (Beale, 1989; Bakos *et al.*, 1991). Both the  $\text{Ca}2$  and  $\text{Ca}3$  domain of pIgA seem to take part (Geneste *et al.*, 1986b) although the exact site initially contacting the conserved SC region remains undefined. The subsequent covalent stabilization, which occurs selectively for SIgA, apparently depends on disulfide exchange reactions between one  $\text{Ca}2$  domain and the fifth domain of SC (Figure 3). However, other possibilities have not been excluded (Mestecky and McGhee, 1987). Covalent binding between pIgA and the first domain of bovine domain of bovine SC was proposed (Beale, 1989). The disul-

tion appears to occur mainly in a late transcytotic compartment, at least in rat hepatocytes (Chintalacheruvu, *et al.*, 1993).

Computer-assisted analyses of human and murine J chains suggested that they may show an Ig domain-like folding despite a low degree of amino-acid sequence homology (Zikán *et al.*, 1985). Therefore, the noncovalent binding of SC to the Fc portion of pIgA and pentameric IgM may be determined by progressive complementary interdomain interactions (Figure 3), both with the J chain and with the constant region domains of  $\alpha$  or  $\mu$  chains. With regard to pIgA, such noncovalent interactions occur also secondarily to the disulfide bonding of SC and result in a remarkable "packing" of the SIgA molecule (Brandtzaeg, 1971). This topic has been further discussed by Pumphrey (1986) and by Mestecky and McGhee (1987).

## 3. Role of Interactions in Endocytosis of Polymeric Ig

Endocytosis of pIg by epithelial cells might start with ligand-induced active clustering of the pIg-SC complexes (Brandtzaeg, 1978; Gebhart and Robenek, 1987). However, the possibility that SC becomes clustered in coated pits even without ligand complexing was suggested by immunoelectron-microscopic studies of intestinal glands from immunodeficient patients (Nagura *et al.*, 1980). An inherent tendency

**Figure 3** Putative domain interactions between J chain,  $\text{Ca}2$ ,  $\text{Ca}3$ , SC1, and SC5 in the formation of human SIgA. Noncovalent interactions (•) are shown with only one IgA subunit. Only one J chain is depicted, although this is probably an oversimplification. Also, a recent report suggests that the J chain links the two IgA monomers (Bastian *et al.*, 1992). N, amino terminus; C, carboxyl terminus; V, variable region; CL and  $\text{Ca}1-3$ , constant regions; L, light chain; H, heavy chain; SC1-5, Ig-like domains of human SC; S-S, covalent interactions.

of SC to migrate in endocytic vesicles from the basolateral plasma membrane to the apical face of glandular cells could, in fact, explain that the concentration of free SC in secretions from subjects with hypogammaglobulinemia amounts to approximately the sum of free and bound SC secreted in normal individuals (Brandtzaeg, 1973a).

In rat hepatocytes, the pIgA-SC complexes are taken up via the same clathrin-coated pits and endosomes as other imported proteins (Geuze *et al.*, 1984). The sorting for delivery to lysosomes or transport to the bile canalicular face apparently takes place in the acidic compartment of uncoupling of receptor and ligand (CURL; Geuze *et al.*, 1984; Perez *et al.*, 1988).

#### IV. MOLECULAR BIOLOGY OF SECRETORY COMPONENT

##### A. Homology among Species and Relation to the Ig Supergene Family

Sequencing of human free SC isolated from colostrum (Eiffert *et al.*, 1984) and cloning of rabbit transmembrane SC cDNA (Mostov *et al.*, 1984) showed five extracellular homologous domains with considerable similarity to Ig domains (particularly Ig V $\kappa$  and Ig V $\text{H}$  domains), each 100–115 residues long and stabilized by disulfide bridges between paired cysteines. Subsequent cloning of human transmembrane SC cDNA (Figure 4) made it possible to deduce the

complete amino-acid sequence of this receptor (Krajči *et al.*, 1989, 1991), including the peptide signal (18 residues) and 746 amino acids (the mature SC) extending 187 residues more at the C terminus than the sequence of free SC as reported by Eiffert *et al.* (1984). This extension includes the membrane-spanning segment and the cytoplasmic tail. These cloning results subsequently were confirmed by Piskurich *et al.* (1993).

The mature human SC shows an overall similarity of 56% with the 755-amino-acid-long-rabbit SC (Mostov *et al.*, 1984), 65% with the 751-amino-acid-long rat SC (Banting *et al.*, 1989), 79% with the 739-amino-acid-long bovine SC (Kulseth *et al.*, 1993), and 66% with the 753-amino-acid-long mouse SC (J. F. Piskurich, M. Hsieh, K. R. Youngman and C. S. Kaetzel, unpublished observations). As mentioned earlier (Section III,B,2), the amino-acid residues 15-37 of human SC apparently initiate its noncovalent interactions with Ig; this stretch represents a highly conserved sequence homology showing only one to five amino-acid differences among the five species; that is, the identity amounts to 78–96%, with the rat counterpart most similar to the human, followed by the mouse, bovine, and rabbit in that order. Except for this stretch, the five species show a striking increase in homology from the extracellular to the membrane-spanning and cytoplasmic parts, which is interesting in relation to the intracellular sorting of SC (Section IV,E,2).

Mostov *et al.* (1984) proposed a sixth domain in rabbit SC that includes the membrane-spanning part. However, this region shares low similarity with Ig domains and is not stabilized by a disulfide bridge. In this chapter, this region will

**Figure 4** (Top) Schematic representation of extracellular homologous human SC domains (D1–D5) with their disulfide bridges (–S–S–), segment including the membrane-spanning portion (S6), and cytoplasmic segment (S7). The serine residue known to be phosphorylated in rabbit SC is indicated (P). (Bottom) Schematic representation of the organization of exons (E1–E11) in human SC mRNA. Modified from Krajči *et al.* (1992a).

be referred to simply as the sixth segment, and the cytoplasmic tail will be called the seventh segment (Figure 4). Compared with the rabbit counterpart, the first part of the sixth segment in the other species lacks 12–15 amino acids, suggesting that this region has little functional importance. Conversely, the second half (positions 584–643) is well conserved, especially the postulated membrane-spanning part (rabbit positions 630–652) (Mostov *et al.*, 1984). This part constitutes a hydrophobic region that contains 23 uncharged residues (human positions 621–643), dividing transmembrane SC into an extracellular receptor portion and an intracytoplasmic tail.

Three putative cleavage sites have been proposed for rabbit SC, localized to Ala–Glu dipeptides that occur three times (positions 563–564, 597–598, and 605–606) in the sixth segment just upstream from the membrane-spanning portion (Kühn *et al.*, 1983; Mostov *et al.*, 1984). One of these is conserved in the rat and human sequences (Banting *et al.*, 1989; Krajčič *et al.*, 1989), but not in those of mouse and cattle.

### B. Exon–Intron Organization of the SC Gene

Cloning and characterization of the human SC gene (Figures 4 and 5) revealed its exon–intron organization in relation to the domain structure of the protein (Krajčič *et al.*, 1992a). Domains 1, 4, and 5 were shown to be confined to one exon each. Domains 2 and 3, however, were found to be encoded by exon 4, corresponding to the rabbit exon that is involved in

alternative splicing that results in the generation of a smaller transcript which, nevertheless, translates a functional receptor protein (Deitcher and Mostov, 1986). With this exception, the SC gene accords with the “one domain–one exon” rule characteristic of the Ig superfamily (Williams and Barclay, 1988). Also, within the cytoplasmic tail of human SC, encoded by the four distal exons (Krajčič *et al.*, 1992a), a striking correspondence is seen between exon boundaries and the structural determinants proposed to be responsible for the intracellular routing of SC in the rabbit (Section IV,E,2).

### C. Restriction Fragment Length Polymorphism and Chromosomal Localization of the Human SC Gene

The human SC gene exhibits a two-allelic restriction fragment length polymorphism (RFLP; Figure 6) caused by a polymorphic restriction site (for *Pvu* II) confined to its third intron (Krajčič *et al.*, 1992a). This RFLP shows an autosomal codominant expression pattern and allelic frequencies of 0.63 and 0.37 among 370 unrelated Norwegians chromosomes (Krajčič *et al.*, 1991,1992b).

*In situ* hybridization on metaphase chromosomes and discordance analysis of human–rodent somatic hybrids have assigned the human SC gene (locus *PIGR*) to region q31–q41 on chromosome 1 (Davidson *et al.*, 1988; Krajčič *et al.*, 1991). Genetic linkage was demonstrated between the SC gene and the polymorphic DNA marker *pYNZ23* (locus *DIS58*), which is linked to other markers residing in 1q32 (Krajčič *et al.*, 1992b). This linkage suggested a close relationship of *PIGR*

**Figure 5** Schematic representation of the gene encoding human transmembrane SC. to loci encoding the decay accelerating factor and the complement receptors CR1 and CR2, all involved in complement regulation.

#### D. Expression of SC mRNA

Northern blot analysis demonstrated only one human (~3.8 kb) and one rat (~3.5 kb) SC mRNA (Banting *et al.*, 1989; Krajči *et al.*, 1989, 1991), whereas rabbit was shown to express two transcripts (~3.8 kb and ~3.1 kb) that are produced by alternative splicing (Mostov *et al.*, 1984; Deitcher and Mostov, 1986), as discussed earlier.

The relative distribution of SC mRNA in human exocrine tissues (Figure 7) corresponds with earlier immunohistochemical findings (Section III, A); the highest level is seen in the gut, whereas only weak expression appears in the liver, probably reflecting inclusion of biliary duct epithelium (Krajči *et al.*, 1989). Conversely, SC mRNA is expressed by hepatocytes in rabbits and rats (Mostov *et al.*, 1984; Banting *et al.*, 1989). This remarkable disparity with respect to hepatic SC correlates with the fact that about 90% of IgA in the upper duodenal fluid is derived from bile in rats but less than 15% is so derived in humans (Conley and Delacroix, 1987).

#### E. Intracellular Routing of SC

##### 1. Transcytosis and Cleavage of the Polymeric Receptor

Cell biology studies first showed that rabbit SC is produced as a transmembrane protein 25–30 kDa larger than the secreted free or bound form (Mostov *et al.*, 1980). Subsequent experiments with the adenocarcinoma cell line HT-29 demon-

**Figure 7** Northern blot analysis of SC mRNA extracted from various human tissues as indicated. Total RNA (20  $\mu$ g) was separated by electrophoresis and hybridized with a nick-translated human transmembrane SC probe.

strated that human SC also is produced as a transmembrane precursor (~95 kDa) that, following terminal glycosylation, becomes ~20 kDa larger than the ~80-kDa secreted form (Mostov and Blobel, 1982).

After synthesis and core glycosylation in the rough endoplasmic reticulum, maturation of transmembrane SC takes place in the Golgi complex (see subsequent discussion), as shown by the acquisition of *Endo* H resistance (30–60 min). This modification probably represents the rate-limiting step

in its intracellular routing (Solari and Kraehenbuhl, 1984). SC becomes phosphorylated near or in the basolateral plasma membrane (Larkin *et al.*, 1986; Casanova *et al.*, 1990). Ligand-complexed or unoccupied SC then is endocytosed and transcytosed toward the luminal (or, in the liver, bile canalicular) plasma membrane (Brown *et al.*, 1976; Brandtzaeg, 1978; Crago *et al.*, 1978; Hoppe *et al.*, 1985). pIg-bound and free SC molecules finally are generated by cleavage from the membrane-spanning portion of the receptor and released into the secretions (Figure 2). The cleavage apparently takes place at the apical cell surface (Solari *et al.*, 1989; Schaerer *et al.*, 1990) and involves unknown enzymes that are sensitive to leupeptin (Musil and Baenziger, 1988). The fate of the membrane-spanning and cytoplasmic parts of SC is largely unknown, but an ~34-kDa fragment derived from them has been detected in the rat liver cytosol; smaller degradation products are released into rat bile (Solari *et al.*, 1989).

## 2. Signals Determining Migration and Sorting of SC

The intracellular sorting of SC is still poorly understood, but several putative determinants within its relatively long cytoplasmic tail (~15 kDa) have been identified by experiments with mutant rabbit receptor (Bomsel and Mostov, 1991). A 14-amino-acid segment (655–668) distal to the membrane-spanning segment apparently directs SC to the basolateral surface (Figure 8). Phosphorylation of serine at position 664 seems to afford the signal for sorting from basolateral early endosomes into the transcytotic pathway under the guidance of microtubules (Casanova *et al.*, 1990). Deletion of residues 670–707 causes increased degradation of receptor-bound pIg after endocytosis, whereas deletion of the C-terminal 30 amino acids (726–755) (or mutation of the tyrosine at position 668 to serine, and/or the tyrosine at position 734 to cysteine, particularly the latter) reduces the rate of internalization (Breitfeld *et al.*, 1990; Okamoto *et al.*, 1992). All these regions are highly conserved among the five species studied (Section IV, A), except that the latter tyrosine mentioned above is lacking in bovine SC. This homology suggests that the structural sorting signals possessed by the cytoplasmic tail, as well as their intracellular recognition apparatus, are quite similar. Moreover, good correspondence exists between the putative sorting determinants and the identified human exons encoding the cytoplasmic tail (Figure 8).

## V. MODULATION OF SECRETORY COMPONENT EXPRESSION

### A. Ontogenic Aspects

Human bronchial epithelium was reported to express SC at 8 weeks gestation (Ogra *et al.*, 1972), in contrast to the somewhat later expression (18–29 weeks) observed for intestinal and salivary gland epithelium (Brandtzaeg *et al.*, 1991,1992). Occasional J-chain-positive IgA immunocytes and some epithelial IgA also can be seen in parotid glands after 30 weeks gestation, suggesting that pIg transport may take place during the fetal period (Hayashi *et al.*, 1989; Thrane *et al.*, 1991). SC shows a strikingly increased expres-

**Figure 8** Schematic depiction of extracellular homologous human SC domains (D1–D5) with the membrane-spanning portion and cytoplasmic tail. The shaded areas and boxes at the bottom represent extensions of the corresponding 11 exons (Krajci *et al.*, 1992a). Exons 8–11 are lined up in relation to the different functional parts of the cytoplasmic tail recognized for rabbit SC, including the phosphorylated serine residue (P) and the C-terminal tyrosine residue (Tyr) (Bomsel and Mostov, 1991). Carbohydrate-binding sites (—●) and disulfide bridges (—S—S—) are shown also. The amino-acid residues 15–37 of D1 (●●) is likely to be involved in the initial noncovalent binding to pIg. The cysteines believed to be involved in the formation of disulfide bridges between SC and IgA are indicated by arrows (Mestecky and McGhee, 1987). A possible cleavage site for generation of free and pIg-bound SC is indicated by //.

sion in salivary gland epithelium after the second postnatal week but decreases to the perinatal level in or near the 6th month (Hayashi *et al.*, 1989; Thrane *et al.*, 1991). This temporarily raised expression, which is reflected in relatively large amounts of free SC in saliva shortly after birth (Burgio *et al.*, 1980), suggests that the secretory epithelium in the immediate postnatal period is exposed to stimulatory factors that enhance constitutive SC expression (Section V,C). This result correlates with the rapid accumulation of Ig-producing cells in exocrine tissues after birth (Chapter 21). In the intestinal crypts, adult levels of SC expression and signs of external IgA and IgM transport are seen at 1–2 weeks (Brandtzaeg *et al.*, 1991,1992).

Victims of sudden infant death syndrome (SIDS) often have been claimed to have suffered from mild upper respiratory tract infection with various viruses shortly before death. In agreement with this possibility, we found a significantly elevated number of IgA, IgM, and IgG immunocytes in salivary glands of such infants (Thrane *et al.*, 1990). Intensified local immunostimulation also was supported strongly by the fact that the salivary glands from the same SIDS victims showed significantly raised numbers of interstitial leukocytes and enhanced epithelial MHC Class II and SC expression (Brandtzaeg *et al.*, 1992).

### B. Aberrant Up-Regulation of SC in Vivo

Immunohistochemical observations in chronic gastritis demonstrated increased SC expression and enhanced uptake of IgA in fundic and antral glands surrounded by dense infiltrates of mononuclear cells (Valnes *et al.*, 1984). Similar epithelial features have been seen in celiac disease and sialadenitis (Brandtzaeg *et al.*, 1992), and most likely can be

explained by local cytokine release (Section V,C). In keeping with this suggestion, interferon- $\gamma$  (IFN $\gamma$ ) placed in the uterine cavity of rats induced raised levels of SC in uterine secretions (Wira *et al.*, 1991). Conversely, reduced expression of SC has been reported for regenerating and dysplastic colonic epithelium in inflammatory bowel disease (Brandtzaeg and Baklien, 1977; Rognum *et al.*, 1987).

Enhanced external pIg transport associated with mucosal immune responses probably explains why the serum levels of pIgA and IgM generally are increased only marginally despite the markedly expanded jejunal IgA- and IgM-producing cell populations in untreated celiac disease (Brandtzaeg, 1991). Nevertheless, the SC-dependent transport capacity may be insufficient in certain patients with an unusual intestinal IgA-producing cell proliferation, resulting in excessive amounts of pIgA in serum (Brandtzaeg and Baklien, 1977b; Colombel *et al.*, 1988).

### C. Effect of Cytokines

Recombinant IFN $\gamma$  causes a time- and concentration-dependent accumulation of SC mRNA in the human adenocarcinoma cell line HT-29, detectable 6 hr after stimulation (Krajčič *et al.*, 1993; Piskurich *et al.*, 1993). A strikingly enhanced expression of SC mRNA likewise is seen by *in situ* hybridization (Krajčič *et al.*, 1993). Cycloheximide abolishes this effect with a time course that suggests that regulatory proteins with a turnover shorter than 6 hr are required for accumulation of SC message (Krajčič *et al.*, 1993). This retarded mRNA response is in agreement with an even longer delay (6–12 hr) observed for enhancement of the intracellular pool and membrane expression of functionally active SC (Sollid *et al.*, 1987; Kvale *et al.*, 1988a,b).

Co-incubation with 5,6-dichloro-1- $\beta$ -ribofuranosyl benzimidazole (DRB), a selective inhibitor of RNA polymerase II, indicated a half-life of about 1 hr for IFN $\gamma$ -induced SC mRNA (Krajčič *et al.*, 1993). These findings, in conjunction with the identification of two consensus motifs for IFN $\gamma$ -responsive elements upstream of the first exon of the SC gene (P. Krajčič and P. Brandtzaeg, unpublished results), suggested transcriptional activation in addition to posttranscriptional stabilization of SC mRNA, as previously observed for MHC gene products (Williams, 1991).

Also, tumor necrosis factor- $\alpha$  (TNF $\alpha$ ) (Kvale *et al.*, 1988a,b) and interleukin 4 (IL-4) (Phillips *et al.*, 1990) have been found to enhance SC expression in HT-29 cells; IFN $\gamma$  and TNF $\alpha$  in combination showed an additive effect, whereas IFN $\gamma$  and IL-4 acted synergistically. IL-2, IL-3, IL-5, and IL-6 have not been found to stimulate SC (Phillips *et al.*, 1990), whereas the results for IL-1 are controversial. Kvale and Brandtzaeg (1992) observed enhancing effects of IL-1 and TNF $\alpha$  that, in combination with IFN $\gamma$ , were increased markedly in HT-29 cells differentiated by exposure to butyrate. Conversely, the effect of IL-4 alone or in combination with IFN $\gamma$  was decreased in these cells, which might be more comparable to the gut epithelium *in vivo*. In addition, transforming growth factor- $\beta$  (TGF $\beta$ ) has been reported to enhance SC expression in the IEC-6 rat intestinal cell line (McGee *et al.*, 1991).

Although SC both in humans (Section V,A) and in rats (Buts *et al.*, 1992) clearly is expressed constitutively, the above results suggest that various cytokines may be involved in its *in vivo* modulation. IFN $\gamma$ , TNF $\alpha$ , IL-1, IL-4, and TGF $\beta$  all are produced by activated mononuclear cells and, to some extent, by other cell types. The *in vivo* (Section V,B) and the *in vitro* results imply that macrophages and T cells, which most likely contribute to terminal differentiation of J-chain-positive B cells that appear at exocrine sites, also are involved in enhancing SC-dependent external transport of the local pIg product. Epithelial translocation of IgA and IgM can, in this way, be adapted to the degree of mucosal immunostimulation.

### D. Effect of Hormones

Several *in vivo* studies have demonstrated hormonal regulation of humoral immunity in the rat uterus (Sullivan and Wira, 1983; Wira and Sullivan, 1985). Estradiol and progesterone increase IgA translocation to the uterine secretions, involving enhanced serum IgA and IgG transudation as well as SC transport (Sullivan *et al.*, 1983; Wira *et al.*, 1991). However, the IgA level is suppressed by glucocorticoids such as dexamethasone, both in cervicovaginal and in salivary secretions (Sullivan *et al.*, 1983; Wira and Rossoll, 1991), although SC production by rat hepatocytes *in vivo* is increased by this steroid hormone (Wira and Colby, 1985; Buts *et al.*, 1992). Testosterone increases the external translocation of SC and IgA by lacrimal glands in rats; both proteins are found at higher levels in tears from males than in those from females (Sullivan and Allansmith, 1987). Obviously, hormonal influence on the SIgA system is complex and may vary among different secretory sites.

## VI. HEPATIC IgA TRANSPORT AND CATABOLISM

### A. Role of SC in Hepatocytes and Bile Duct Epithelium

The molecular biology of SC-dependent pIgA transport has been explored in liver cells from the rat to a great extent. This model system has contributed significantly to the understanding of intracellular protein trafficking. Translocation of serum-derived pIgA into bile was described first in this species as a rapid SC-mediated process performed by the hepatocytes (Jackson *et al.*, 1978; Fisher *et al.*, 1979; Orleans *et al.*, 1979). This transport was shown to follow a vesicular pathway to the canalicular face (Mullock *et al.*, 1979; Renston *et al.*, 1980; Takahashi *et al.*, 1982; Hoppe *et al.*, 1985; Limet *et al.*, 1985), where release into bile took place by proteolytic cleavage of transmembrane SC (Mullock *et al.*, 1980; Solari *et al.*, 1986). A similar, although less efficient, SC-dependent hepatocytic pathway has been described in mice (Jackson *et al.*, 1977; Phillips *et al.*, 1984) and rabbits (Delacroix *et al.*, 1982,1984), in contrast with the situation in humans (Section III,A; Figure 7). In fact, hepatobiliary pIgA secre-

tion appears to correlate with hepatocyte expression of SC in the species under study (Delacroix *et al.*, 1984). Transport across the biliary epithelium is likely to represent only a secondary pathway including primarily pIgA produced by plasma cells within the portal tract and gall bladder mucosa (Dooley *et al.*, 1982; Nagura *et al.*, 1983; Brandtzaeg, 1985).

Studies on hepatic transcytosis of pIgA have focused on molecular modifications of transmembrane SC during its biosynthesis and transport, as well as on the nature of the vesicular carriers. Pulse labeling of rat liver with [<sup>35</sup>S]cysteine followed by immunoprecipitation with antibodies to SC revealed that newly translated and core-glycosylated SC in the endoplasmic reticulum has an  $M_r \sim 105,000$  kDa (Sztul *et al.*, 1985; Buts *et al.*, 1992). After 15–30 min of chase with unlabeled cysteine, the  $\sim 105$ -kDa form is converted successively to two molecular species of  $\sim 115,000$  and  $\sim 120,000$  kDa, the former representing terminal glycosylation of SC in the Golgi complex (Sztul *et al.*, 1985; Solari *et al.*, 1986) and the latter representing phosphorylated mature SC (Larkin *et al.*, 1986). The fact that only terminally glycosylated SC is a target for phosphorylation is consistent with the demonstration that phosphorylation of a serine residue on its cytoplasmic tail is a critical signal for endocytosis and transcytosis (Section IV,E,2).

Evidence that hepatic transcytosis of SC–pIgA complexes is vesicular in the rat was obtained initially by quantitative electron-microscopic autoradiography (Renston *et al.*, 1980) and immunoelectron microscopy (Takahashi *et al.*, 1982; Courtoy *et al.*, 1983; Hoppe *et al.*, 1985). A distinct population of vesicular carriers from rat liver has been isolated using antibodies to the cytoplasmic tail of SC (Sztul *et al.*, 1991). These vesicles are enriched in the mature  $\sim 120$ -kDa form of SC as well as in pIgA and are depleted in elements of the secretory pathway, Golgi, sinusoidal plasma membrane, and early endosomal components. Apparently these vesicles represent a unique compartment specialized for transcytosis to the bile canaliculus. This conclusion is supported by the observation that transcytotic vesicular carriers containing mature phosphorylated SC and pIgA accumulate in the pericanalicular cytoplasm of rat hepatocytes after bile duct ligation (Larkin and Palade, 1991).

### B. Role of Other IgA Binding Activities

Although hepatobiliary transport of pIgA appears to correlate best with SC expression on the hepatocytes (Delacroix *et al.*, 1984), other cell surface receptors also may participate in the uptake of IgA by the liver parenchyma. For example, purified asialoglycoprotein receptor (ASGP-R) from rat liver was shown to bind IgA from normal human serum (Stockert *et al.*, 1982). The ASGP-R recognition site on IgA appears to be the O-linked oligosaccharides in the hinge region of the IgA1 subclass. Human monomeric IgA1 as well as SIgA1 (which cannot bind SC) was as effective as pIgA from serum in binding to ASGP-R (Tomana *et al.*, 1985). Further, binding of asialoorosomucoid by rat or mouse liver *in vivo* (Schiff *et al.*, 1984), or by plasma membrane-enriched fractions from rat, monkey, and human liver (Daniels *et al.*, 1989), was

inhibited by human IgA1 but not by rat IgA, which lacks O-linked oligosaccharides.

Hepatic uptake by ASGP-R generally results in delivery of the ligand to lysosomes for degradation. Nevertheless, Schiff *et al.* (1986b) demonstrated in rat liver that human IgA endocytosed via this receptor could dissociate within endosomes to become associated with transmembrane SC in this compartment, and thus be targeted to the transcytotic pathway for translocation as SIgA into bile. Because the expression of SC by human hepatocytes is extremely low or absent (Section III,A; Figure 7), endocytosis of IgA1 by ASGP-R may represent an important pathway for hepatic clearance of this major IgA subclass in human serum. Whereas the bulk of endocytosed IgA presumably would be catabolized in lysosomes, some of the pIgA could end up as biliary SIgA. However, experiments in nonhuman primates did not reveal any difference in hepatic clearance of intravenously injected human IgA1 and IgA2, although polymers were favored strikingly over monomers (Moldoveanu *et al.*, 1990). Thus an as yet undefined binding site for IgA is likely to exist on hepatocytes that is distinct from ASGP-R and has preferential affinity for pIgA, regardless of subclass. This binding site has been suggested previously on the basis of *in vitro* experiments with rat and human hepatocytes (Tolleshaug *et al.*, 1981; Brandtzaeg, 1985; Tomana *et al.*, 1988).

In addition, the carbohydrate moieties on human IgA have been shown to bind to galactosyltransferase enzymes, either in free form in colostrum and serum (McGuire *et al.*, 1989) or on the surface of hepatocytes and a variety of cultured cell lines (Tomana *et al.*, 1991). In the absence of UDP-galactose, cell-surface galactosyltransferase acts as a lectin and binds both IgG and IgM, as well as monomeric IgA, pIgA, and SIgA, with relatively high association constants. Because ligands bound to galactosyltransferase on cells are apparently not internalized (Tomana *et al.*, 1991), the possible role of this binding in the physiology of IgA remains unclear.

Kupffer cells and murine hepatocytes have been shown to express receptors for the Fc region of both monomeric IgA and pIgA (Sancho *et al.*, 1986). The contribution of these receptors to hepatic clearance of IgA is unclear, but nonparenchymal cells do contribute significantly to making the liver of nonhuman primates (and therefore probably humans) the major site of uptake and catabolism of circulating IgA (Moldoveanu *et al.*, 1990).

## VII. CLEARANCE OF IgA-CONTAINING IMMUNE COMPLEXES

### A. Role of the Liver

Clearance of IgA-containing immune complexes (IC) has been studied primarily with respect to systemic mechanisms relevant for circulating IC. In humans (Rifai *et al.*, 1989) and rodents (Russell *et al.*, 1981; Socken *et al.*, 1981; Harmatz *et al.*, 1982), intravenously administered IgA IC or heat-aggregated IgA are cleared primarily by the liver, presumably via the same receptors that mediate uptake of IgA (Section

VI). Thus, SC-mediated hepatobiliary transport of circulating IgA IC is probably of little or no significance in humans. Phagocytosis by Kupffer cells contributes to the clearance of IC (Rifai and Mannik, 1984); for IgA IC also containing IgG, Fc $\gamma$  and complement receptors on these cells apparently are involved (Roccatello *et al.*, 1992). Because the systemic mechanisms for clearance of IgA IC are saturable (Russell *et al.*, 1981; Rifai and Mannik, 1984), high concentrations of IgA IC in the circulation may lead to their deposition in extrahepatic tissues, as has been implicated in the pathogenesis of IgA nephropathy (Emancipator and Lamm, 1989).

### B. Role of Mucosal Epithelia

IgA antibodies are produced mainly by plasma cells in the lamina propria of mucous membranes (Chapter 21), where significant amounts of IgA IC most likely form when antigens penetrate the epithelial barrier. Thus, in addition to its role as SIgA performing immune exclusion, locally produced IgA antibodies within the mucosa may trap antigens derived from the environment, diet, and luminal microbiota or synthesized in the mucosal tissue during infections. Such IgA-mediated trapping would, by itself, be an antiinflammatory mechanism in competition with the formation of potentially harmful immune complexes containing IgM or IgG antibodies (Figure 9). Moreover, external transport of IgA IC by mucosal epithelia

could be an efficient and potentially less harmful clearance mechanism than systemic elimination of these complexes after they reach the circulation.

SC-expressing epithelial cells transport vectorially *in vitro* IC with pIgA from the basolateral surface to the apical face where release occurs (Figure 9); the antigen remains undegraded and bound to the pIgA antibody throughout transcytosis (Kaetzel *et al.*, 1991). Interestingly, monomeric IgA and IgG antibodies, when cross-linked via antigen to pIgA, also can participate in SC-mediated epithelial transcytosis (Kaetzel *et al.*, submitted). Secretory epithelium might, therefore, participate *in vivo* in the clearance of IgA IC directly at sites at which they are most likely to be formed. This antiinflammatory mechanism probably is enhanced in disease states with immunological activation as a result of cytokine-induced up-regulation of SC (Section V,C). Direct clearance of locally formed IgA IC by SC-expressing epithelia could afford an important, but hitherto unappreciated, defense function mediated by pIgA.

Evidence from *in vitro* studies also suggests that IgA IC can form within secretory epithelial cells infected with virus if these cells are simultaneously transporting specific pIgA antibody (Mazanec *et al.*, 1992). In such cases, the antibody can neutralize the virus intracellularly. Although the intracellular compartment localization and efficiency of this neutralization are currently unclear, these results could reflect still another important defense function of pIgA. On the other hand, the possibility has been suggested from similar *in vitro* experiments that SC may promote viral infection of usually resistant epithelial cells by mediating uptake of virus bound to pIgA antibody (Sixbey and Yao, 1992).

**Figure 9** It is postulated that humoral immunological homeostasis is maintained in mucous membranes through a critical balance between available immunoglobulins (for simplicity, only IgG and IgA are depicted). Secretory IgA acts in a "first line" of defense by performing antigen exclusion in the mucus layer at the epithelial surface (to the right). Antigens by-passing this barrier may meet corresponding serum-derived IgG antibodies in the lamina propria. The resulting immune complexes will activate complement, and inflammatory mediators probably are formed continuously in the mucosa. An adverse inflammatory and tissue-destructive development is most likely inhibited by blocking antibody activities exerted in the lamina propria by serum-derived monomeric IgA and locally produced monomeric or dimeric IgA. Moreover, antigens may be returned efficiently in a noninflammatory way to the lumen by the SC-mediated transport mechanism after being bound to dimeric IgA antibodies.

## VIII. CONCLUSIONS

Transmembrane SC is quantitatively the most important receptor of the immune system because it is responsible for external translocation of the major product of humoral immunity, that is, pIgA. SC also may be involved in mucosal clearance of immune complexes containing pIgA and, in rodents, in hepatic elimination of such complexes from peripheral blood. The molecular biology of SC is complicated and interesting; its function as a receptor is the best defined part of mucosal immunity and has thrown considerable light on intracellular trafficking of proteins in general. The cleavage of this receptor to release free or pIg-bound SC into the secretions is a unique process. This continuous sacrifice of large amounts of receptor protein appears biologically justified to stabilize secretory antibodies. Such stabilization is particularly successful for SIgA, in which covalent bonding takes place between SC and pIgA by disulfide exchange reaction during epithelial transcytosis; the noncovalent stabilization of SIgM apparently depends on an excess of free SC in the secretions.

# Function of Mucosal Immunoglobulins

Mogens Kilian · Michael W. Russell

## I. INTRODUCTION

### A. Immunoglobulin Isotypes at Mucosal Surfaces

Although the predominant isotype of Ig-secreting cells in most human secretory tissues is IgA, significant but variable numbers of IgM, IgG, and IgD immunocytes also occur (Brandtzaeg *et al.*, 1986b; see Chapter 21). Among the immunoglobulin isotypes present on mucosal surfaces (Table I) as a result of active secretion or of transudation, secretory IgA (SIgA) is particularly stable and well suited to function in the enzymatically hostile environment that prevails at these locations. This stability is ascribed largely to the secretory component (SC) which renders the SIgA molecule less susceptible to attack by metabolic and microbial enzymes. In contrast to SIgM, the complex of polymeric IgA (pIgA) and SC is stabilized by covalent linkages (see Chapter 7), which may contribute to its resistance to proteolytic enzymes. Moreover, SIgA has been shown to bind trypsin and chymotrypsin in an antibody-independent manner that inactivates the enzymes (Shim *et al.*, 1969).

The mucosal environment in which SIgA operates is very different from the circulation and tissues in which other Igs, including plasma IgA, operate, both physicochemically and in terms of the presence or absence of ancillary factors (notably the complement system, phagocytic or other cells, and nonspecific defense factors) and of other macromolecules. The host defense problems in the two situations are completely different: mucosal surfaces are not normally sterile but are colonized by a commensal flora that must be held in check without compromising the mucosal barrier, whereas the internal presence of a microorganism indicates a potentially life-threatening invasion. SIgA and the mucosal immune system therefore can be considered as having evolved to maintain a balance with the normal microbial flora. An important aspect of this balancing act may be the role of maternal milk SIgA antibodies in promoting the establishment of an appropriate intestinal microflora in the neonate (see Chapter 52).

### B. Protective Potential of SIgA Antibodies

Numerous studies in animal models and in humans have provided convincing evidence that protection against a variety of viral and bacterial mucosal pathogens can be obtained

by oral or intranasal immunization (see Chapter 31). Although protection generally is correlated with levels of IgA antibodies in relevant secretions, the participation of other classes of antibody or of antiviral T cells cannot be excluded, but the protective significance and superiority of SIgA antibodies has been demonstrated in several systems. Monoclonal IgA antibodies (without SC) to Sendai virus hemagglutinin–neuraminidase passively administered to the mouse respiratory tract confer significant protection against the virus (Mazanec *et al.*, 1987). Intranasal administration of affinity-purified human SIgA antibody to M protein protects mice against nasal inoculation with group A streptococci, whereas locally applied serum opsonizing antibodies are not protective (Bessen and Fischetti, 1988). In an elegant model of mucosal immunity (Winner *et al.*, 1991), pIgA antibody to *Vibrio cholerae* lipopolysaccharide (LPS), secreted into the circulation by “back-pack” tumors of mouse hybridoma cells and transported into intestinal secretions, provides serotype-specific protection against oral challenge with *V. cholerae*. In a conceptually similar model (Renegar and Small, 1991), intravenously administered monoclonal pIgA against influenza virus hemagglutinin is transported into nasal secretions of mice and protects against nasal challenge, whereas monoclonal monomeric IgA (mIgA) or IgG antibodies do not.

## II. BIOLOGICAL PROPERTIES OF IgA

As for IgG and IgM antibodies, although some biological properties of IgA antibodies may be the simple consequence of antigen binding, most depend on structures within the Fc region and, in the case of SIgA, on the attached SC and on the interactions of these structures with other molecules (Kilian *et al.*, 1988). Among the unusual structural features of human IgA is the presence of O-linked oligosaccharides in the hinge region of IgA subclass 1 (see Chapter 7). Whereas the biological significance of these sugar moieties is not fully understood, they have been implicated in carbohydrate-dependent interactions of IgA with cellular receptors (Tomana *et al.*, 1988) and may impart resistance to many proteolytic enzymes. Further, such oligosaccharides, which are found more typically in mucins, probably confer a stiff and extended conformation on the peptide chain (Jentoft, 1990), limiting the segmental flexibility of IgA1 antibodies and restricting their ability to bind to adjacent epitopes. IgA2 antibody often

**Table 1** Isotypes and Functions of Mucosal Immunoglobulins

Isotype	Occurrence	Functions
SIgA	Major form of Ig in most secretions of humans and many other mammals	Noninflammatory mucosal protection <sup>a</sup>
(S)IgM	Second most abundant Ig in most secretions; SIgM compensates for lack of SIgA in IgA deficiency	Probably similar to plasma IgM or SIgA; activates complement
IgG	Normally minor component, but relatively abundant in nasal and respiratory tract secretions; probably transudes from plasma; increased in pathological, especially inflammatory, conditions	Neutralization; potentially inflammatory; activates complement and phagocytes
IgA (plasma type)	Found in human bile and possibly other secretions; transudes from plasma, or transported by alternative secretion mechanisms	Possibly similar to SIgA; poor complement activation, or inhibitory <sup>a</sup>
IgD	Significant minor component of nasal secretions, milk	Unknown
IgE	Normally insignificant; elevated in atopic allergies and helminthic infections	Adverse hypersensitivity states (atopy); parasite expulsion

<sup>a</sup> See text for additional discussion.

is directed against polysaccharide antigens, which typically have repeating epitopes, but whether its hinge region (although shorter but with five consecutive proline residues) allows greater flexibility for divalent binding to adjacent epitopes is not known.

### A. Molecular Mechanisms of Protection by SIgA at Mucosal Surfaces

#### 1. Inhibition of Adherence: Agglutination

Concomitant with the recognition that adherence of a microorganism to a mucosal surface is a critical first step in colonization (see Chapter 6) has been the concept that inhibition of adherence by antibodies is a major protective function of mucosal immunity (Abraham and Beachey, 1985). Although the molecular nature of the adhesin–receptor interactions may not have been well defined, SIgA antibodies to microbial surfaces have been demonstrated to inhibit adherence to pharyngeal, intestinal, and genitourinary tract epithelia as well as to tooth surfaces (Williams and Gibbons, 1972; Tramont, 1977; Svanborg-Edén and Svennerholm, 1978; Hajishengallis *et al.*, 1992).

Whereas any antibody may be capable of inhibiting adherence, SIgA antibodies have advantageous properties that are

not shared by other isotypes because of the hydrophilic and negatively charged Fc · SC part of the molecule (Kilian *et al.*, 1988; see Chapter 7). In contrast IgG, with considerably fewer carbohydrate residues, is more hydrophobic and less charged in the Fc region and may substitute the specific adhesin–receptor binding with other (less specific) hydrophobic interactions. Thus, SIgA appears to surround a microbe with a hydrophilic shell that repels attachment to a mucosal surface. Presumably SIgM, which compensates for SIgA in many IgA-deficient subjects, can exert a similar effect, but specific evidence of this ability is not available. Although pIgA and SIgA antibodies are particularly adept at agglutinating microorganisms, mIgA antibodies agglutinate and precipitate poorly (Heremans, 1974), possibly because their hydrophilic Fc (or Fc<sub>2</sub> · SC) regions are less able to form Fc–Fc interactions. However, information on the composition and nature of IgA antibody–antigen complexes and precipitates involving the different molecular forms of IgA has not been obtained to test this assumption.

It is speculated that SIgA may be able to form particular associations with mucins, possibly through interactions between mucin and the mucin-like hinge region of IgA1, or even by forming disulfide bonds (Clamp, 1977). Since the binding of SIgA to bacteria renders them more “mucophilic” (Magnusson and Stjernström, 1982), this mucin affinity would help entrap the microbes within the mucus layer. High molecular weight fractions of saliva contain mucins and small amounts of SIgA, suggesting an interaction between them; binding of SIgA to the salivary mucin MG2 has been reported (Biesbrock *et al.*, 1991). An interaction between the Fc<sub>2</sub> · SC region of SIgA and mucus also is implied by the finding that spermatozoa coated with SIgA show impaired penetration of cervical mucus, but that treatment of the coated spermatozoa with IgA protease restores this ability (Bronson *et al.*, 1987).

In addition to specific antibody-mediated inhibition of adherence, human IgA and especially IgA2, which can agglutinate *Escherichia coli* through its type 1 (mannose-dependent) pili by means of mannose-rich glycan chains, also may act in this way to inhibit type 1 pilus-dependent adherence of *E. coli* to epithelial cells (Wold *et al.*, 1990).

#### 2. Virus Neutralization

A considerable body of evidence shows that SIgA antibodies to various viruses can neutralize them effectively and, although inhibition of viral binding to cellular receptors seems plausible, neutralization may occur by other mechanisms, depending on the epitope specificity, isotype, and concentration of antibody and the virus and cells involved (reviewed by Childers *et al.*, 1989). High concentrations of SIgA or IgM antibodies to influenza virus hemagglutinin inhibit cellular attachment, whereas IgG or lower concentrations of pIgA antibodies that permit attachment may inhibit internalization or intracellular replication (Armstrong and Dimmock, 1992). The isotype of antiviral antibody may be especially important because one mechanism of cellular uptake can be replaced by another. Human antibodies of any isotype to the surface gp340 of Epstein–Barr virus neutralize its infectivity for B cells (via complement receptor CR2), but pIgA antibodies

promote infection of SC-expressing HT-29 colonic carcinoma cells, thereby changing the tissue tropism of the virus (Sixbey and Yao, 1992). The general extent of this phenomenon is unknown although potentially important, particularly in connection with HIV infection in which antibodies to gp160 may inhibit CD4-mediated uptake by T cells but promote uptake by other cells with opsonic receptors.

One publication (Mazanec *et al.*, 1992) proposes a novel mechanism of viral neutralization mediated by pIgA antibodies during SC-mediated transit through epithelial cells. This mechanism was demonstrated in an elegant *in vitro* system using Sendai virus-infected Madin-Darby canine kidney (MDCK) cells expressing the transfected SC gene. The pIgA-bearing transcytotic vesicles are suggested to interact with secretory vesicles in which the replicated virus is assembled and thereby inhibit this process. Sendai virus, like other paramyxoviruses (e.g., measles, mumps, parainfluenza, and respiratory syncytial viruses), can induce membrane fusion, which may be instrumental in the interaction of the two types of vesicle. Determining the extent to which such intracellular viral neutralization occurs *in vivo* will be important since this hypothesis implies that pIgA antibody can promote recovery from viral infections of mucosae, as well as provide initial protection against them.

### 3. Neutralization of Enzymes and Toxins

Antibody-mediated inhibition of enzyme or toxin activity has been demonstrated in several systems. If this effect is simply caused by steric blocking of binding to the substrate or target molecule (or cell), or by a conformational change in the antigen molecule that affects its biological function, it may be independent of the Fc region or of antibody isotype. Specific examples of SIgA antibodies that neutralize enzymes or toxins include intestinal antibodies to cholera and related heat-labile enterotoxins (Majumdar and Ghose, 1981; Lycke *et al.*, 1987); salivary antibodies to the glucosyltransferases of *Streptococcus mutans* and *Streptococcus sobrinus*, which synthesize adherent glucans from sucrose and enable these cariogenic bacteria to adhere to tooth surfaces (Smith *et al.*, 1985); and antibodies that neutralize IgA proteases (see Section III,A).

### 4. Immune Exclusion and Inhibition of Antigen Absorption

The intestinal uptake of antigenically intact food substances (see Chapter 4) is diminished by SIgA antibodies arising from prior enteric exposure to them (Walker *et al.*, 1972). Absorption of antigen instilled into the airway is inhibited by the simultaneous administration of IgA antibody (Stokes *et al.*, 1975). The importance of immune exclusion for the protection of the host against excessive antigenic challenge from environmental macromolecules is suggested by the findings that IgA-deficient subjects show increased absorption of food antigens and formation of circulating immune complexes (Cunningham-Rundles *et al.*, 1978), as well as statistically increased susceptibility to atopic allergies or autoimmune disease.

In contrast, enteric SIgA antibodies have been suggested

to promote uptake of antigen through the M cells of Peyer's patches and, consequently, enhance the mucosal immune response to that antigen (Weltzin *et al.*, 1989). Further elaboration of the mechanism involved, especially the receptor, seems necessary to substantiate this intriguing possibility.

### 5. Interaction with Nonspecific Antibacterial Factors

The secretions of most mucosal surfaces contain an array of nonspecific defense systems that are highly effective in killing or inhibiting a broad range of bacteria and fungi (see Chapter 5). Because SIgA is able to interact with some of the protein components of these systems, ample opportunity exists for synergism in which SIgA antibodies might introduce an element of specificity. However, few such interactions have been described in molecular detail.

**a. Lactoferrin.** The bacteriostatic synergy of lactoferrin and SIgA antibodies (Stephens *et al.*, 1980) may be the result of antibody-mediated interference with alternative channels of iron uptake possessed by many mucosal organisms. Lactoferrin is a frequent contaminant of SIgA purified from secretions, but whether the implied interaction or formation of covalent complexes between lactoferrin and SIgA (Watanabe *et al.*, 1984) is important for synergy is not known.

**b. Peroxidases.** An enhancement of the inhibitory effect of lactoperoxidase-H<sub>2</sub>O<sub>2</sub>-SCN<sup>-</sup> on *S. mutans* metabolism by myeloma IgA1 and IgA2 proteins and by SIgA but not IgG or IgM has been attributed to binding of lactoperoxidase to IgA, presumably by the Fc region, and a subsequent stabilizing effect on enzyme activity (Tenovuo *et al.*, 1982).

**c. Lysozyme.** Two reports of lytic activity against *E. coli* by human or porcine colostral SIgA antibody, complement, and lysozyme have not been confirmed in other studies. Although most secretions contain lysozyme, they generally lack a functional complement system, and the ability of IgA to activate complement is controversial. Thus, the significance of this lytic system remains uncertain.

## B. Molecular Mechanisms of Protection by Circulatory IgA in Tissues

### 1. Interaction with Complement

The question of whether and how IgA activates complement is a controversial issue that has not yet been completely resolved. Early findings that IgA is incapable of binding C1q and activating the classical complement pathway (CCP) generally have been accepted; IgA molecules do not have the C1q-binding motif found in IgG. In contrast, some researchers believe that IgA activates the alternative complement pathway (ACP), but in reality the situation is more complicated. Several reports have demonstrated that artificially aggregated, chemically cross-linked, or denatured human serum polyclonal or monoclonal (myeloma) IgA or colostral SIgA can activate the ACP (Hiemstra *et al.*, 1987; for discussion, see Russell and Mansa, 1989). A chimeric human

IgA2–rat antibody produced in a mouse transfectoma cell line shows ACP activation when complexed with a haptenated protein antigen (Lucisano Valim and Lachmann, 1991). However, human monoclonal and polyclonal pIgA1 or mIgA1 antibodies, when complexed with corresponding antigen, fail to activate the ACP whereas the same antibodies, interfacially aggregated on a plastic surface or complexed with antigen after chemical cross-linking, can activate the ACP (Russell and Mansa, 1989). Naturally occurring human IgA immune complexes also fail to activate the ACP (Imai *et al.*, 1988). Note that heat-aggregated mixtures of human IgG and IgA activate the ACP in proportion to the content of IgG, and analysis of the C3b-containing complexes shows that C3b is linked to the IgG and not to the IgA component (Waldo and Cochran, 1989).

Several studies on animal (mouse, rat, rabbit) IgA antihapten antibodies have shown that, when complexed with a haptenated protein antigen, IgA antibodies activate the ACP (Pfaffenbach *et al.*, 1982; Rits *et al.*, 1988; Schneiderman *et al.*, 1990). However, certain reservations persist regarding denaturation of the IgA in purification, abnormal glycosylation of proteins produced in hybridoma or transfectoma cells, and the direct role of heavily haptenated proteins in ACP activation, all of which could materially affect the outcome. Nevertheless, human and animal IgA—which have structural differences in terms of amino acid sequence, especially in the hinge region, as well as in glycosylation (see Chapter 7) and display other important physiological differences *in vivo*—could differ also in ACP-activating properties. Additional work is necessary to clarify these issues.

In contrast, IgA antibody to the capsular polysaccharide inhibits IgG or IgM antibody-dependent complement-mediated lysis of *Neisseria meningitidis*, thereby possibly accounting for the exacerbation of meningococcal infection in certain patients (Griffiss *et al.*, 1975). Similarly, murine IgA antibodies inhibit IgG antibody-dependent complement-mediated hemolysis *in vitro* and the Arthus reaction *in vivo* (Russell-Jones *et al.*, 1980, 1981). Human monoclonal and polyclonal IgA1 antibodies inhibit IgG antibody-dependent CCP activation *in vitro*. Further, Fab fragments of IgA1 antibodies possess the same inhibitory activity as intact IgA antibodies (Russell *et al.*, 1989). Fab fragments of IgA antibodies to meningococci, which produce IgA1 protease (see Section III,A), also inhibit IgG- and complement-mediated cytotoxicity of these bacteria (Jarvis and Griffiss, 1991).

Overall, human IgA antibodies appear to have poor to no complement-activating ability by either pathway when bound physiologically to antigen, whereas the ACP-activating properties of IgA depend on some degree of denaturation or conformational change that does not ensue directly from binding to antigen, or possibly on abnormal structure. Whether such changes can occur in physiological or pathological conditions *in vivo*, or as a result of aberrant synthesis, and thereby contribute to inflammatory conditions in which IgA is implicated (for example, IgA nephropathy; see Chapter 53) remains to be elucidated. In contrast, the anti-inflammatory property of IgA antibodies with respect to CCP may be of physiological significance in controlling inflammation at or

beneath mucosal surfaces on which IgA is abundant and where maintenance of the mucosal barrier is important.

## 2. Interaction with Phagocytic Cells

Several studies indicate that IgA has a negative or inhibitory effect on phagocytosis, bactericidal activity, or chemotaxis by neutrophils and monocytes or macrophages (Kilian *et al.*, 1988). In some cases, results obtained with specific IgA antibody suggest that it competes with IgG antibody for binding to the target antigen, but in most experiments myeloma IgA proteins or colostral SIgA, regardless of antibody activity, were used. Other studies, particularly using neutrophils or monocytes derived from a mucosal environment (the gingival crevice) or cultured *in vitro* with purified myeloma IgA or colostral SIgA, reveal an opsonizing effect of IgA antibodies especially in synergy with IgG antibodies (Fanger *et al.*, 1983; Gorter *et al.*, 1987). Several instances of heat-stable (i.e., complement-independent) opsonization or antibody-dependent cell-mediated cytotoxicity by IgA antibodies (reviewed by Kerr, 1990), including the postphagocytotic respiratory burst and intracellular killing as well as degranulation of eosinophils (Abu-Ghazaleh *et al.*, 1989), have been reported to date. Generally, pIgA antibodies are more effective than mIgA; in some cases, the effect is demonstrably dependent on an intact Fc $\alpha$  region, which implies the involvement of an Fc $\alpha$  receptor (Fc $\alpha$ R) on the cells (Kerr *et al.*, 1990).

An Fc $\alpha$ R has been demonstrated on human neutrophils, monocytes/macrophages, and eosinophils (Maliszewski *et al.*, 1990; Mazengera and Kerr, 1990; Monteiro *et al.*, 1990). The  $M_r$  of the mature polypeptide chain (deduced from the cloned gene) is ~29,900, but the observed  $M_r$  of the extracted Fc $\alpha$ R (50,000–70,000; 90,000 on eosinophils) implies extensive and possibly variable patterns of glycosylation (Monteiro *et al.*, 1992). Immunoprecipitation of the deglycosylated protein with monoclonal antibody reveals two bands of  $M_r$  32,000 and 36,000 that could arise from differential mRNA splicing or mRNA processing, posttranslational modification, or even two separate, possibly allelic, genes. The neutrophil Fc $\alpha$ R has an apparent affinity for mIgA ( $\sim 5 \times 10^7 M^{-1}$ ) that is comparable with that of Fc $\gamma$ RII for IgG. This receptor binds both subclasses of IgA and SIgA equally. Approximately  $10^4$  molecules are found per cell. The Fc $\alpha$ R is expressed constitutively on neutrophils and monocytes, but culture with IgA, phorbol esters, or calcitriol enhances expression. The report that granulocyte–monocyte and granulocyte colony-stimulating factors decrease the number and increase the affinity of Fc $\alpha$ R on neutrophils (Weisbart *et al.*, 1988) awaits further explanation in molecular terms.

Despite some evidence to the contrary, human IgA can mediate phagocytosis and related processes by neutrophils and monocytes/macrophages and can induce postphagocytotic intracellular events, although the biological significance of this ability remains unclear. IgA-mediated killing of bacteria by intestinal T cells also has been described (Tagliabue *et al.*, 1986). The finding that activated murine  $\gamma\delta$  T cells express Fc $\alpha$ R (Sandor *et al.*, 1992) raises the possibility that

$\gamma\delta$  CD8<sup>+</sup> intraepithelial cells are involved. Since IgG antibodies strongly activate complement but IgA antibodies do not (and may inhibit IgG-mediated complement activation), the opsonizing effects of IgA and IgG antibodies *in vivo* in the presence of complement are probably different. At least with normal neutrophils, IgG antibodies effectively opsonize only at high concentration unless bound C3b enhances binding of the particle by engaging CR3 receptors, and IgM-mediated opsonization depends on complement activation. Moderate amounts of IgA antibodies that are insufficient to activate Fc $\alpha$ R therefore may inhibit IgG (or IgM)- and C3b-mediated phagocytosis. Similar concentration-dependent properties and interactions with other agonists have been observed in the biphasic effects of IgA on chemotaxis or chemokinesis of neutrophils exposed to other chemoattractants *in vitro* (Sibille *et al.*, 1987).

At mucosal surfaces, where SIgA is the predominant Ig, however, functionally active complement and phagocytes are not normally present. Consequently, SIgA does not have the opportunity to activate either system. Where the mucosal barrier is breached or inflammation occurs, both mucosal SIgA and submucosal pIgA secreted by resident plasma cells could have an important anti-inflammatory regulatory activity in a complex interplay of immunological effectors that may provide not only immune defense but also damage-limiting capability.

### 3. Interaction with Epithelial Cells

IgA-mediated elimination of antigen from the circulation by hepatobiliary transport (Russell *et al.*, 1981) has been demonstrated to occur notably in certain rodents and rabbits, in which rapid active transport of pIgA from the circulation to the bile occurs by means of SC expressed on the sinusoidal surface of hepatocytes (see Chapter 9). However, despite a few reports to the contrary, it is now accepted that human hepatocytes do not express SC or transport pIgA and IgA immune complexes in this manner. Nevertheless, other receptors such as the asialoglycoprotein receptor (or possibly membrane galactosyltransferase), which normally mediates the vesicular uptake of IgA and other desialylated glycoproteins for catabolism by hepatocytes (Mestecky *et al.*, 1991), may allow a proportion of the IgA that is taken up, in conjunction with any complexed antigen, to be diverted into the biliary secretory pathway instead of the lysosomal degradative pathway. Polarized monolayer cultures of SC-expressing epithelial cells also can transport pIgA and IgA-bound antigen from the basal to the luminal surface (Kaetzel *et al.*, 1991).

## III. MICROBIAL EVASION OF IgA FUNCTIONS

The importance of IgA in host-parasite relationships at mucosal membranes is revealed further by the fact that several microbial species have evolved various ways of evading its functions. The most convincing evidence in this respect involves bacterial IgA1 proteases, which have evolved inde-

pendently in several mucosal pathogens and members of the normal flora of the respiratory tract, apparently with the principal function of cleaving IgA1.

### A. Microbial Proteases

#### 1. IgA1 Proteases

Since the original detection of an IgA1 protease in the oral commensal *Streptococcus sanguis* (Plaut *et al.*, 1974), comprehensive screening of numerous species of bacteria and a few fungi, parasites, and viruses has shown that IgA1 proteases are produced by limited groups of bacteria that successfully colonize or infect mucosal membranes of humans. These pathogens include the three leading causal agents of bacterial meningitis, important respiratory tract and ear pathogens, some urogenital pathogens, and anaerobic gram-negative rods implicated in the pathogenesis of periodontal diseases (Table II). In addition, three commensals of the human oral cavity and pharynx that are responsible for initiating plaque formation on teeth produce IgA1 proteases.

All known IgA1 proteases are constitutively expressed, extracellular, postproline endopeptidases ( $M_r$  ~100,000). These enzymes attack one of the Pro-Ser (type 1 proteases) or Pro-Thr (type 2 proteases) peptide bonds within the duplicated O-glycosylated octapeptide Thr-Pro-Pro-Thr-Pro-Ser-Pro-Ser present in the hinge region of the  $\alpha$ 1 chain but absent from the  $\alpha$ 2 chain (see Chapter 7). Cleavage of IgA1 thus results in monomeric Fab fragments that retain antigen-binding properties and Fc fragments or Fc<sub>2</sub> · SC when SIgA is the substrate (for reviews, see Kilian and Reinholdt, 1986; Mulks, 1985; Plaut, 1983).

Until recently, IgA1s from humans, chimpanzee, and gorilla were the only known substrates for IgA1 proteases. However, studies by Pohlner *et al.* (1987a) revealed that, during the secretion process, the 165-kDa precursor of the IgA1 protease of *Neisseria gonorrhoeae* undergoes autoproteolysis at several sites within a sequence similar but not identical to that of the hinge region of IgA1. Synthetic decapeptides based on the sequences of two of these autoproteolytic sites (B and C) are cleaved by the *N. gonorrhoeae* type 2 protease (Wood and Burton, 1991). Homology searches identified similar sequences in the CD8 molecule of cytotoxic T lymphocytes and in granulocyte-macrophage colony-stimulating factor (Pohlner *et al.*, 1987b), but cleavage of these proteins in their natural configuration has not been demonstrated. Shoberg and Mulks (1991) showed that the type 2 IgA1 protease from *N. gonorrhoeae* cleaves several proteins in preparations of cytoplasm and outer membranes of gonococci, suggesting the possibility that IgA1 proteases may play an additional role in modulating proteins of the microorganism itself.

Some of the IgA1 proteases have been cloned in *E. coli*. The genes and their products have been fully characterized (Pohlner *et al.*, 1987a; Poulsen *et al.*, 1989; Gilbert *et al.*, 1991). The IgA1 proteases from *N. gonorrhoeae*, *N. meningitidis*, and *Haemophilus influenzae*, which show significant sequence homology, are all serine proteinases. IgA1 prote-

Table II IgA-Cleaving Activity in Microorganisms

Disease	Species	Cleavage specificity <sup>a</sup>	Fragments produced

Mucosal infections	<i>Candida albicans</i> <i>Candida tropicalis</i> <i>Torulopsis glabrata</i>	Between CH <sub>2</sub> and CH <sub>3</sub> of both IgA1 and IgA2 Same same	

<sup>a</sup> Numbers refer to the residues between which the peptide bond is cleaved (see Kilian and Reinholdt, 1986).

<sup>b</sup> See text for additional discussion.

ases from pneumococci and the oral streptococcal species are metalloproteinases and show no homology with the serine-type IgA1 proteases. Finally, the IgA1 protease of *Prevotella (Bacteroides) melaninogenica* is a cysteine proteinase (Mortensen and Kilian, 1984). Thus, bacterial IgA1 proteases with virtually identical activity have developed convergently through at least three independent evolutionary lines, thereby attesting to their biological significance.

## 2. Antigenic Polymorphism of IgA1 Proteases

Among *H. influenzae*, *N. meningitidis*, and *N. gonorrhoeae* strains, IgA1 proteases of two distinct cleavage specificities (Pro-Ser or Pro-Thr) have been observed (Kilian and Reinholdt, 1986; Mulks, 1985). Enzyme-neutralizing antibodies reveal at least 16 antigenic variants ("inhibition types") among *H. influenzae* IgA1 proteases (Kilian *et al.*, 1983), whereas antigenic variation is less pronounced among pathogenic *Neisseria* (Lomholt *et al.*, 1992) and virtually absent among oral streptococci and *Prevotella* and *Capnocytophaga* species (Frandsen *et al.*, 1987; Reinholdt *et al.*,

1990). Sequence analyses of IgA1 protease genes (*iga*) of *H. influenzae* and *N. gonorrhoeae* have disclosed that the antigenic diversity is a result of genetic exchange and recombination between and within these species (Halter *et al.*, 1989; Poulsen *et al.*, 1992). This antigenic diversity among some of the IgA1 proteases may increase their immune escape potential.

## 3. Other Microbial Proteases with IgA-Cleaving Activity

Among IgA-cleaving proteases with broader substrate specificities, one is of particular interest. Fujiyama *et al.* (1985) demonstrated an EDTA-sensitive protease in *Clostridium ramosum* that cleaves a Pro-Val peptide bond present in the  $\alpha$  chain of both IgA1 and the A2m(1) allotype of IgA2 in the transition between the C<sub>H</sub>1 domain and the hinge region. The A2m(2) allotype of IgA2 lacks the susceptible sequence. The specificity of this *Clostridium* protease may reflect the equal proportions of the two subclasses in the lower gut, which is the natural habitat of this bacterium. Although

the original IgA1/A2m(1) protease-producing strain of *C. ramosum* was isolated from a patient with ulcerative colitis, subsequent studies have not confirmed that the species plays a pathogenic role in inflammatory bowel diseases (Senda *et al.*, 1985).

Several microbial broad-spectrum proteases can degrade IgA among other proteins: strictly speaking, such enzymes should not be called IgA proteases. Their exact cleavage sites have not been determined but appear to lie outside the hinge region of IgA. Few such enzymes have been characterized; in some cases, their wide activity spectrum may be the result of several enzymes working in concert as, for example, in the case of the putative periodontal pathogen *Porphyromonas gingivalis* (*Bacteroides asaccharolyticus*), which degrades IgA1 and IgA2 as well as other immunoglobulin isotypes and many other host proteins into small fragments (Kilian, 1981). *Pseudomonas aeruginosa*, a notable opportunistic pathogen that has significant hydrolytic activity, cleaves IgA, SIgA, SC, and IgG. Among several proteases secreted by this bacterium, the elastase completely degrades the Fab fragment of IgA (Döring *et al.*, 1981; Heck *et al.*, 1990).

Of potential importance is the finding that some members of the family Enterobacteriaceae are capable of cleaving human IgA (Table II; Mehta *et al.*, 1973; Milazzo and Delisle, 1984). This activity has been detected only in fresh isolates from feces or urinary tract infections and is lost on subcultivation of the bacteria. Similar strains from culture collections have not disclosed IgA-cleaving activity, nor has restoration of lost activity been possible. Hence, nothing is known about the specificity of the enzyme(s) involved. An exception is an IgA-cleaving protease from *Proteus mirabilis*, which is stable, has a pepsin-like activity on IgA, and cleaves initially between the C<sub>H</sub>2 and C<sub>H</sub>3 domains, whereas it cleaves IgG initially on either side of the hinge region (Loomes *et al.*, 1990).

Protease activity that cleaves IgA of both subclasses between the C<sub>H</sub>2 and C<sub>H</sub>3 domains, as well as SIgA and SC, also has been demonstrated in several *Candida* species including *Candida albicans* (Table II; Reinholdt *et al.*, 1987; Rückel, 1984). Finally, trophozoites of the protozoan parasite *Entamoeba histolytica* have been noted to induce electrophoretic changes in IgA that are suggestive of proteolytic cleavage (Quezada-Cavillo and Lopez-Revillo, 1987).

#### 4. Cleavage of IgA *in Vivo*

IgA1 proteases are not inhibited by physiological protease inhibitors. Ample evidence is available for their activity *in vivo*. Characteristic fragments of IgA (Fab, Fc, Fc<sub>2</sub> · SC) have been observed in intestinal fluids, vaginal secretions of women with gonorrhoea, cerebrospinal fluid of patients with *Haemophilus meningitis*, and nasopharyngeal secretions of certain children (for review, see Kilian and Reinholdt, 1986). Further, in samples from the oral cavity including dental plaque, monomeric Fab $\alpha$  fragments have been demonstrated on the surface of bacteria (Ahl and Reinholdt, 1991). Frandsen *et al.* (1991) have provided evidence for cleavage of IgA1 in periodontitis patients by demonstrating serum antibodies specific for a neoepitope exposed on Fab $\alpha$  released from

IgA1 after cleavage by *Prevotella* or *Capnocytophaga* IgA1 proteases. IgA cleavage products similar to those obtained *in vitro* and active protease have been demonstrated in the urine of patients with *P. mirabilis* urinary tract infection (Senior *et al.*, 1991).

As are other microbial enzymes, IgA1 proteases and other IgA-cleaving proteases are subject to inhibition by specific neutralizing antibodies. Antibodies capable of inhibiting the activity of IgA1 proteases can be induced in rabbits (Kilian *et al.*, 1983). Naturally occurring neutralizing antibodies to proteases from *H. influenzae*, *N. meningitidis*, *N. gonorrhoeae*, and *Streptococcus pneumoniae* have been detected in colostral SIgA and in serum IgG and IgA (Gilbert *et al.*, 1983; Kobayashi *et al.*, 1987). High titers of neutralizing antibodies to IgA1 proteases of oral streptococci also have been detected in serum from patients with subacute endocarditis caused by the respective bacteria (Reinholdt *et al.*, 1990), whereas very low inhibitory antibody activity against *S. sanguis* IgA1 protease is present in pooled colostrum (Gilbert *et al.*, 1983). Neutralizing antibodies to the IgA1/A2m(1) protease of *C. ramosum* have not been detected, even in sera of subjects whose bowels are colonized by this bacterium (Kobayashi *et al.*, 1987).

#### 5. Biological Significance of Proteolytic IgA Degradation

Since the protective functions of IgA in its different forms depend on the integrity of the immunoglobulin molecule, any significant degradation of IgA is likely to influence its functional activity. Cleavage of IgA in the hinge region will interfere with all its Fc-dependent properties described earlier. However, the specific IgA1 and IgA1/A2m(1) proteases are uniquely adept in counteracting the effects of IgA antibodies as well as perhaps other immune effector mechanisms. Both *in vivo* and *in vitro* studies have shown that monomeric Fab fragments of antibodies, in spite of their antigen-binding activity, do not inhibit adherence and colonization of bacteria (Steele *et al.*, 1975; Reinholdt and Kilian, 1987; Ma *et al.*, 1990; Hajishengallis *et al.*, 1992). Although cross-linking and agglutination of bacteria may be a factor here, these findings indicate the importance of structures in the Fc (or Fc<sub>2</sub> · SC of SIgA) for mucosal protection. It is furthermore postulated that the binding of Fab $\alpha$  fragments to the surface of bacteria protects them from the host immune system by blocking access of intact antibodies of the same or other isotypes and of immunocompetent cells as, for example, in the inhibition of IgG and complement-mediated bacteriolysis described previously. These processes have been hypothesized to play a role in the pathogenesis of invasive infections caused by IgA1 protease-producing bacteria (Kilian and Reinholdt, 1987). Thus, IgA1 proteases appear to represent a subtle way of turning a specific immune response against a pathogen to its advantage, which may be effective no matter what other immune effector mechanisms remain intact.

Because cleavage of IgA by IgA1 proteases is not restricted to antibodies against the bacteria that secrete them, IgA1 proteases may affect host-parasite interactions involving other microorganisms. Further, cleavage of IgA1 may jeopardize

dize the immune barrier of the respiratory tract to potential allergens, as suggested by the significantly increased incidence of IgA1 cleavage in nasopharyngeal secretions of children with a history of atopic diseases (Sørensen and Kilian, 1984).

The biological consequences of cleavage of IgA by proteases that remove the C<sub>H</sub>3 domain remain unclear, partly because of our limited knowledge concerning individual Fc domains in the secondary effector functions of IgA.

## B. Other Potential Evasion Strategies

### 1. Glycosidases

IgAs, in particular SIgA, are heavily glycosylated with both N-linked and O-linked glycan chains (see Chapter 7) that may be attacked by bacterial glycosidases. As an example, *S. pneumoniae* and certain oral streptococci are capable of stripping IgA molecules of all their carbohydrate moieties (Kilian *et al.*, 1980; Reinholdt *et al.*, 1990). Studies involving IgG have disclosed dramatic effects of carbohydrate depletion (Nose and Wigzell, 1983). However, the biological consequences of such an event for IgA remain unclear, except that the ability of IgA to agglutinate *E. coli* via lectin-carbohydrate interactions (Wold *et al.*, 1990) would be lost.

### 2. IgA Binding Proteins

Some strains of pathogenic streptococci of groups A (*S. pyogenes*) and B (*S. agalactiae*) are capable of interacting with IgA of both subclasses in an antibody-independent manner. The phenomenon is the result of expression of Fc $\alpha$  binding proteins on the streptococcal surfaces (Brady and Boyle, 1990; Lindahl *et al.*, 1990). By analogy with the IgG-binding protein A on *Staphylococcus aureus*, researchers speculate that the streptococcal IgA Fc receptors serve an immune escape function at mucosal surfaces.

## IV. IgA AND HOMEOSTASIS

Despite the considerable advances that have been made in unraveling the complexities of the immune system, the biological activities and physiological functions of the major isotype of human Ig are still poorly understood. This lack of understanding is especially obvious for the circulating plasma form of IgA, which remains an enigma. The role of plasma IgA has been suggested to be that of the "discrete housekeeper," implying a background regulatory activity that is supported by a good deal of evidence. SIgA can be viewed in a similar way, except that perhaps it is the "discrete gatekeeper" whose job is to keep undesirables out. Nevertheless, clearly situations exist in which IgA function is less than discrete, since it can be involved in pathological conditions under circumstances that suggest it has a pro-inflammatory effect, for example, in IgA nephropathy and IgA immune complex-induced lung injury. Are these, however, manifestations of a derangement of normal IgA structure and function, or the exaggerated result of normal physiological IgA activ-

ity? Conversely, other mucosal diseases are associated with an apparent failure of IgA to maintain adequate anti-inflammatory control, which might be the case in inflammatory bowel disease (see Chapter 38). In this context, the balance between IgA and IgG antibodies may be the important factor (Tolo *et al.*, 1977; Lim and Rowley, 1982). An analogous situation may occur in periodontal disease, which involves chronic inflammatory destruction of the structures supporting the teeth. These situations raise the question of whether the anti-inflammatory effects of IgA can be exploited to ameliorate these conditions.

Deficiency of IgA might be expected to manifest itself in profound disturbances, but these generally do not occur. Selective IgA deficiency occurs in Western populations with a frequency as high as 1 in 400 individuals, yet the subjects usually do not suffer serious consequences, although they have statistically increased tendencies to develop upper respiratory tract and oral infections, atopy, autoimmunity, and neoplasia (Hong and Amman, 1989). However, most IgA-deficient subjects compensate by the production of secretory IgM at their mucosal surfaces, whereas noncompensators frequently suffer problems. Moreover, IgA deficiency may have much more serious consequences in populations lacking modern hygienic facilities, so the antigenic and infectious challenge to mucosal surfaces is much greater. A lower prevalence of IgA deficiency in Africa and elsewhere is consistent with this concept. Curiously, significant numbers of IgD-secreting plasma cells also occur in certain submucosae such as the nasal passages (Brandtzaeg *et al.*, 1991), but no mechanism is known for the secretion of this poorly understood isotype. Further, IgD is highly susceptible to proteolysis, thus placing it at a disadvantage in secretions in which proteases occur; apparently IgD cannot compensate for lack of IgA in IgA deficiency (Brandtzaeg *et al.*, 1986a).

IgA is a phylogenetically ancient Ig and has been found in plasma and secretions of all mammals examined. However, the concentration and relative physiological significance of this Ig vary markedly in different mammalian orders and families. Most notably in ruminants, although SIgA occurs, the dominant mucosal Ig is a subclass of IgG (IgG1) that is transported selectively into secretions by a mechanism that involves a receptor other than SC. Interestingly, ruminant IgG1 is less effective than the other IgG subclass of these animals (IgG2) in complement-mediated and opsonic effector functions, and so may share some of the noninflammatory or anti-inflammatory properties of IgA that are deemed important for mucosal protection.

# Characteristics and Functions of Mucosa-Associated Lymphoid Tissue

Kenneth Croitoru • John Bienenstock

## I. INTRODUCTION

Lymphoid tissue can be identified early in phylogeny in the gills and guts of species more advanced than cyclostomes (Good and Papermaster, 1964; Marchalonis, 1974). Evidence that this local immune system protects mucosal surfaces independent of circulating antibodies first was suggested by experiments in rabbits that were immunized orally with killed *Shigella* bacteria. These animals were resistant to experimentally induced bacillary dysentery (Besredka, 1927). In humans with dysentery, fecal antibodies can be detected before serum antibodies develop (Davies, 1922). Similar evidence exists for specific local immunity in other mucosal tissues such as the respiratory tract and the female reproductive tract (Amoss and Taylor, 1917; Byrne and Nelson, 1939; Tomasi and Bienenstock, 1968). We have come to appreciate that the lymphoid elements distributed in different mucosal tissues are part of a unique immune system that confers local immunity in a regulated fashion. This immunity protects a large and fragile epithelium, preventing the disruption of the normal physiological function of these mucosal tissues.

Technical advances in cellular and molecular biology over the last 10 years have changed our ability to probe and examine the nature and function of the mucosa-associated lymphoid tissue (MALT). New concepts have emerged and notions previously considered incorrect have been rekindled. In this chapter, we highlight some of these findings as a prelude to the chapters that follow in this section.

### A. Definitions

MALT can be separated into several components (see Table I), a few of which are described here.

#### 1. Gut-Associated Lymphoid Tissue

The gut-associated lymphoid tissue (GALT) is the most extensively studied component of MALT. This tissue consists of organized lymphoid aggregates represented by the Peyer's patches, the appendix, mesenteric lymph nodes (MLN), and solitary lymphoid nodules. In addition, the non-organized lymphoid elements in the epithelium—the intra-epithelial lymphocytes (IEL)—and in the lamina propria—the lamina propria lymphocytes (LPL)—are considered

part of GALT. Collectively, this mass of lymphoid tissue easily would challenge other lymphoid organs in size (see Figure 1).

In the chicken, an additional specialized organ can be found at the end of the intestine and is referred to as the bursa of Fabricius. This organ has been shown to be the site of primary B-cell development in the chicken (Cooper *et al.*, 1966; Perey *et al.*, 1968), a function that remains difficult to localize to any one organ in mammals.

#### 2. Bronchus-Associated Lymphoid Tissue

Burdon-Sanderson first described the lymphoid tissue in the lung in 1867 and noted that "these lymphoid follicles in the bronchial walls are therefore in every respect analogous to the lymph follicles found in other mucous membranes, e.g., tonsils, and in the intestine" (Klein, 1875). Similarities between the organized lymphoid tissue in the lung and GALT led to the term bronchus-associated lymphoid tissue (BALT; Bienenstock *et al.*, 1973a,b). As reviewed elsewhere in this book, BALT consists of lymphoid aggregates distributed in the larger passageways of the respiratory tract. As in GALT, specialized antigen sampling structures represented by lymphoid follicles with overlying follicle-associated epithelia (FAE) that contain specialized epithelial cells referred to as M cells are seen (Bienenstock and Johnson, 1976). In addition, lymphocytes are distributed in the subepithelial spaces as well as within the epithelium of the bronchi (Bienenstock, 1984). This organization suggests a functional role for BALT that is not dissimilar from that of GALT.

#### 3. Mucosa-Associated Lymphoid Tissue

The term "mucosa-associated lymphoid tissue" (MALT) arose from the realization that not only did mucosal surfaces share organizational similarities in their lymphoid elements, but also functional ones (Bienenstock *et al.*, 1978). As discussed subsequently, MALT is characterized by the predominance of local IgA production and by the finding that activated lymphocytes derived from one mucosal surface can recirculate and localize selectively to other mucosal surfaces. This connection between different mucosal surfaces permits immunity initiated at one anatomical site to protect other mucosal sites. Therefore, the tissues that are considered part of MALT include the middle ear, parts of the urogenital tract,

the mammary gland, the conjunctiva, the salivary glands, and the tonsils [as part of the nasopharyngeal lymphoid tissue (NALT); Kuper *et al.*, 1992], as well as BALT and GALT (see Figure 2).

## II. ONTOGENY

Significant species differences exist in the ontogeny of mucosal lymphoid tissues that suggest possible differences in function. In humans, lymphoid aggregates are present at birth whereas in rodents they develop after the first few weeks of life. In humans Peyer's patches develop *in utero* and increase in size and number with the exposure to gut flora, but then decrease with age (Cornes, 1965). T and B cells are found in clusters by 14 weeks gestation and increase in number thereafter; the early B cells express IgM, IgD, and CD5 (Spencer *et al.*, 1986a). Germinal centers only develop after birth (Bridges *et al.*, 1959).

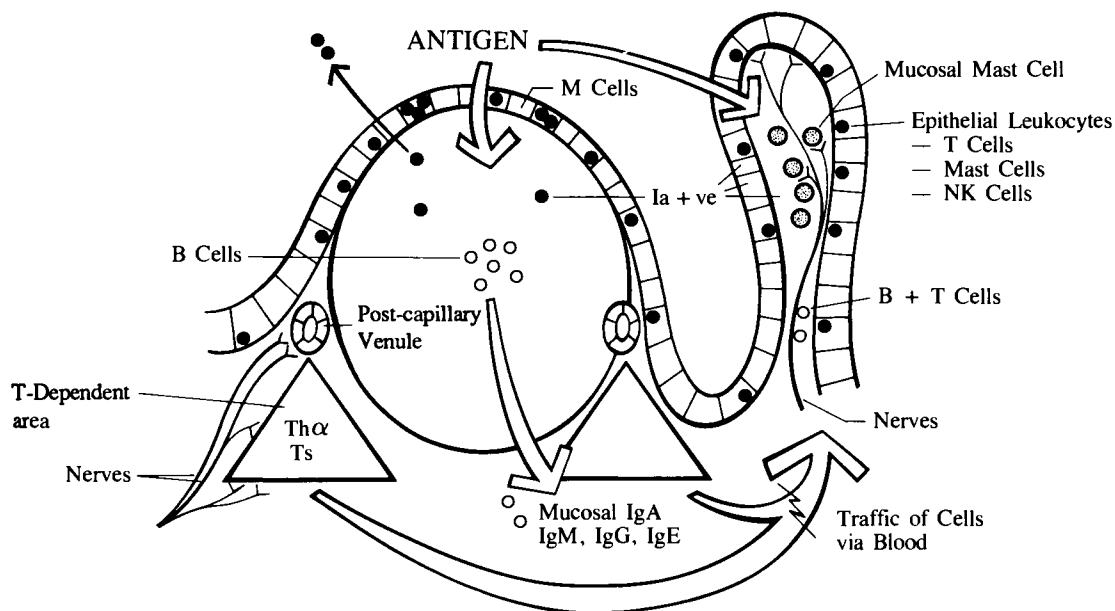

In the mouse, follicles are first identified as a cluster of reticular cells that, by day 3 after birth, become populated by lymphocytes (Joel *et al.*, 1971; Ferguson and Parrott, 1972a). Primary nodules then appear between 3 and 7 days

and germinal centers between 4 and 5 weeks of age (Ferguson and Parrott, 1972a), but not in germ-free mice (Pollard and Sharon, 1970). Interestingly, no germinal centers are seen in the Peyer's patches of the nude mouse, suggesting a T-cell dependence (Parrott, 1976). Therefore, in humans a significant degree of Peyer's patch development appears to occur independent of gut flora.

In humans, lymphoid cells including CD4<sup>+</sup> T cells appear in the lamina propria by 14 weeks gestation, whereas B cells appear by 22 weeks gestation. Plasma cells, on the other hand, only develop 12 days after birth (Perkkio and Savilahti, 1980; Spencer *et al.*, 1986a), whereas plasma cells in the lamina propria appear only after day 10 in the mouse. In humans, IELs can be identified in the fetal intestine by 11 weeks gestation (Spencer *et al.*, 1986b), whereas in mice IEL are found only by the third week of life (MacDonald and Spencer, 1990). Although this event is coincident with weaning in the mouse, it is not antigen-dependent (Ferguson and Parrott, 1972b; Ferguson, 1977). On the other hand, the gut flora does influence the number and phenotype of IELs (Ferguson and Parrott, 1972a; Leigh *et al.*, 1985). Clearly, luminal antigen has a great influence on the development of several compartments of GALT in humans and in rodents.

## III. FUNCTION OF MUCOSA-ASSOCIATED LYMPHOID TISSUE

The function of MALT can be divided into three main categories (Table II). The induction of the local immune response and the effector mechanisms of local immunity have been the focus of much of the experimental work on MALT. In addition, however, the role that MALT may play as a primary immune organ, as suggested long ago, has become the focus of more recent work.

**Figure 1** The compartmentalized anatomy of GALT and its constituent immune cells. Although differences exist between different tissues, the general organization of MALT is similar to that depicted for GALT.

**Figure 2** Lymphoid elements in GALT from the bone marrow or thymus enter the mucosa through specific high endothelial venules to occupy the different compartments. Thymic-independent mucosal T cells may arise in the fetal liver or bone marrow or develop within the intestine itself. Primary antigen exposure can occur within the Peyer's patches or possibly in the draining lymph nodes. In the Peyer's patches, B cells committed to IgA production and sensitized to foreign antigen are stimulated to proliferate. Lymphoblasts emigrate via the efferent lymphatics and mesenteric lymph nodes to the thoracic duct to recirculate via the blood stream. T lymphoblasts, detected in the thoracic duct lymph, also can recirculate. These cells can repopulate various mucosa-associated lymphoid tissues selectively undergo terminal differentiation.

### A. Primary Lymphoid Development

#### 1. Bursa of Fabricius

One of the most intriguing organs of the mucosal immune system is the bursa of Fabricius. Found in chickens, the bursa is a specialized organ that contains a major collection of lymphoid follicles in a hollow pouch-like outgrowth dorsal to the cloaca at the end of the gut. This outgrowth is attached to the cloaca by a long thin duct. The mucosal surface within this pouch is folded and contains numerous lymphoid follicles. The epithelium overlying these follicles does not lie on

**Table II** Functions of the Mucosa-Associated Lymphoid Tissue

Primary lymphoid development
Induction and amplification of the mucosal immune responses
Effector mechanisms of local immunity

a basement membrane and is part of a stratified network of stellate cells that forms the medulla of each follicle. This medulla is bounded by the basal lamina, and the cortex of the follicle lies outside this basal lamina. Lymphocytes infiltrate the medulla and epithelium overlying the follicle and may form clumps (Owen and Bhalla, 1983). This "lymphoepithelium" represents the site of primary B-cell development in the chicken (Owen and Bhalla, 1983). The bursa also can serve in antigen sampling.

#### 2. Mammalian Bursa Equivalent

In mammals, the absence of a bursa or any other clearly identifiable organ of primary B-cell development has led to a search for the "mammalian bursa equivalent." The fact that the bursa of Fabricius is part of the intestine led to speculation that mammalian GALT might serve as a site of primary lymphoid development. The features of the bursa that are characteristic of a primary lymphoid organ include a follicular structure that develops independent of antigenic stimulation, the absence of fully differentiated plasma cells; the presence of rapid cellular proliferation, thymic independence, essential nature with respect to the development of follicles in other secondary lymphoid organs, and identification as the first site of immunoglobulin synthesis (Perey, 1971). Mammalian GALT does not fulfill all these characteristics.

In 1963, Archer first suggested that the rabbit appendix might represent the bursa homolog (Archer *et al.*, 1963), an idea that was supported by others (Perey *et al.*, 1970). Several groups have shown that X irradiation and removal of the appendix, Peyer's patches, and sacculus rotundus in rabbits leads to a selective defect in antibody production (Cooper *et al.*, 1966; Perey *et al.*, 1970; Heatley *et al.*, 1982). On the other hand, the lymphoid aggregates, associated with the epithelium, such as the tonsil and Peyer's patches, do not appear to have a true lymphoepithelium in which primary B-cell development occurs (Perey, 1971). Further, Peyer's patches are found in the chicken, in which the bursa is clearly the site of B-cell development (Befus *et al.*, 1980). Therefore, the existence of a mammalian bursa equivalent in the intestine remains controversial (Archer *et al.*, 1963; Fichtelius, 1966; Meuwissen *et al.*, 1969; Perey *et al.*, 1970). More recent studies now point to the fetal yolk sac, liver, spleen, and bone marrow as sites of primary B-cell development in mammals (Owen *et al.*, 1974).

However, this issue has been re-examined in the lymphoid follicles of the proximal colon in rodents and in the Peyer's patches in sheep (Perry and Sharp, 1988; Motyka and Reynolds, 1991). In sheep Peyer's patches, for example, antigen-

independent B-cell proliferation and local apoptosis occur, and evidence suggests that immunoglobulin diversity is generated *in situ* (Griebel *et al.*, 1991; Motyka and Reynolds, 1991; Reynaud *et al.*, 1991). The CD5 or Ly1 B-cell lineage also has been shown to develop in lymphoid aggregates, referred to as milk spots, that are found in the omentum of human and mouse (Solvason and Kearney, 1992; Solvason *et al.*, 1992). Collectively, these data suggest that some degree of early differentiation of B-cell elements can occur in mammalian GALT. The advantage of the local development of the B-cell repertoire is not clear, although one could speculate that it might be involved in the generation of oral tolerance.

T-cell differentiation in the intestine also differs from that of peripheral thymus-derived T cell. Evidence is now emerging that suggests that intestinal T cells, particularly the IELs, can develop independent of thymic processing (Lefrancois *et al.*, 1990; Mosley *et al.*, 1990; Guy-Grand *et al.*, 1991; Barrett *et al.*, 1992; Croitoru and Ernst, 1992). Although the process of repertoire selection could occur in the intestinal mucosa (Bonneville *et al.*, 1990; Bandeira *et al.*, 1991; Rocha *et al.*, 1991), this event has not been demonstrated directly. The presence of a diffuse primary lymphoid organ in the intestinal epithelium, albeit for B cells, was suggested first by Fichtelius (1968). If the mucosal T-cell repertoire does indeed develop in the intestinal environment, the local antigenic milieu could influence the reactivity of these cells.

## **B. Afferent Limb of the Local Immune Response**

### **1. Peyer's Patch**

The Peyer's patches are lymphoid aggregates, first described by Johanni Conradi Peyer in 1677 in his thesis entitled "De Glandulis Intestinarum Earumque Usu et Affectionibus Cui Fubjungitur Anatomie Ventriculi Gallinacei." These clusters are found on the antemesenteric side of the distal small bowel (ileum) and colon and extend through the lamina propria and submucosa. The patches appear as mounds protruding between the intestinal villi and, on the serosal surface, as a group of small bulges. In humans, Peyer's patches increase in number and size progressively down the distal small intestine.

Peyer's patches differ from lymph nodes elsewhere in the body because they lack afferent lymphatics. This characteristic is in keeping with the notion that antigen is sampled from the lumen via the overlying epithelium. The efferent lymphatics drain to the mesenteric lymph nodes. In the normal adult, Peyer's patches contain germinal centers with B cells and internodular zones that are predominantly T cells (Faulk *et al.*, 1970; Parrott, 1976; Mayrhofer, 1984). The lymphocytes in the central areas of the follicle include IgM-, IgG-, IgA-, and IgE-producing B cells, although IgA-producing cells predominate. Interspersed are T cells, predominately CD4 helper T cells, and macrophages that function as antigen-presenting cells (APCs).

### **2. Antigen Uptake and Presentation**

The Peyer's patches are considered a major site of initiation of the local immune response in the gut, although some

researchers suggest that these clusters serve more as an amplification system in which B cells primed elsewhere are exposed to antigen (Waksman and Ozer, 1976). In this regard, investigators have suggested that the site in which priming of mucosal B-cell responses may occur is the draining lymph nodes (Craig and Cebra, 1971; Gearhart and Cebra, 1979; Cebra *et al.*, 1991). Nonetheless, in the Peyer's patches, antigen can be taken up and presented to mucosal lymphocytes. The epithelium overlying these lymphoid follicles samples and transports antigen from the lumen to the adjacent APCs and lymphoid cells (Owen and Nemanic, 1978). Referred to as the FAE, this epithelium is devoid of goblet cells and consists of specialized cuboidal cells derived from adjacent crypts (Owen and Jones, 1974; Bockman and Cooper, 1975; Bhalla and Owen, 1982). Among the FAE are further specialized cells, the M cells, that have a decreased number of small apical microvilli. The microvilli actually are replaced by microfolds, hence the name "M cell." In addition, M cells have increased numbers of cytoplasmic vesicles in which particulate antigen is transported across the cell from luminal to basement membrane surface (Owen and Jones, 1974; Owen, 1977; Smith and Peacock, 1992). Some viruses and bacteria have been shown to bind to M cells specifically (Inman and Cantey, 1971; Carter and Collins, 1974; Wolf *et al.*, 1981), making this a preferential route of entry. Given the concentration of antigen uptake at this site one should note that erosion of the FAE over the surface of Peyer's patches, (the aphthous ulcer) is the earliest lesion seen in Crohn's disease (Rickert and Carter, 1980).

The antigen transported into the Peyer's patches is then taken up by macrophages, which process and present antigen to the local T cells (MacDonald and Carter, 1982). The underlying progenitors of IgA-secreting plasma cells found in the Peyer's patches are then the first lymphocytes to be exposed to these foreign antigens (Craig and Cebra, 1975; Befus *et al.*, 1978).

### **3. Absorptive Epithelial Cells**

The absorptive epithelial cells on the luminal two-thirds of the villi of the small bowel of rat and human express the major histocompatibility complex (MHC) Class II antigen (Scott *et al.*, 1980; Mayrhofer *et al.*, 1983). The FAE overlying the Peyer's patches, on the other hand, are devoid of MHC Class II expression (Owen, 1977), suggesting that the intestinal epithelial cells may have a role in antigen presentation distinct from that of the FAE. Interestingly, the epithelial cells have been shown to stimulate the CD8 or cytotoxic/suppressor T cell preferentially (Mayer and Schlien, 1987; Bland, 1988; Bland and Kamarage, 1991). This preference may represent a mechanism that down-regulates the local immune response, preventing unwanted inflammatory responses to food antigens and normal gut flora.

## **C. Effector Arm of MALT**

### **1. Humoral Immunity—IgA**

IgA, first discovered by Heremans (Heremans *et al.*, 1959), was shown to exist in the unique form of secretory IgA (SIgA)

as the predominant immunoglobulin in external secretions (Chodirker and Tomasi, 1963; Tomasi *et al.*, 1965). In addition to IgA, IgG-, IgM- and IgE-secreting cells exist in the intestinal lamina propria, albeit at a much lower frequency. Phylogenetically, IgA is not found in some lower life forms such as cold-blooded animals. IgA deficiency in humans is associated variably with significant disease or morbidity, suggesting that IgA is not necessary for survival. However, IgA does represent a considerable advance in the adaptation of the local immune response to the rather hostile environment encountered in mucosal secretions. Certain functional properties of IgA make it ideal for protecting mucosal surfaces. First, IgA is more resistant to proteolytic degradation than IgG or monomeric IgA (Shuster, 1971; Underdown and Dorrington, 1974). Second, a specific mechanism exists for the transport of polymeric IgA (or IgM) from the lamina propria into the lumen via the epithelial cell receptor, secretory component (SC) (Brandtzaeg *et al.*, 1988). Finally, IgA does not activate complement via the classical pathway and, therefore, tends not to induce potentially damaging inflammatory reactions (Colten and Bienenstock, 1974), but functions to neutralize toxins and viruses (Ogra *et al.*, 1968; Holmgren *et al.*, 1975) and to prevent bacterial adherence to epithelial cells (Williams and Gibbons, 1972).

IgE-producing cells are found in the mucosal tissues, including Peyer's patches, as well. Durkin *et al.* (1981), in fact, showed that the numbers of IgE-bearing cells were increased in neonatal and germ-free mice and that, on conventionalization, this reverted to IgA synthesis.

The predominance of IgA in mucosal secretions is thought to be the result of the collection of IgA-selective regulatory T cells. For example, in the Peyer's patches, regulatory helper T cells are involved in switching IgM<sup>+</sup> B cells to IgA<sup>+</sup> B cells as well as in the terminal differentiation of IgA B cells (Kawanishi *et al.*, 1983a,b; Beagley *et al.*, 1989; McGhee *et al.*, 1989). As discussed subsequently, when these lymphocytes encounter antigen and become activated, they leave the Peyer's patches, since antigen specific Ig cannot be detected in Peyer's patches after oral immunization (Dolezel and Bienenstock, 1971). These lymphocytes recirculate back to the mucosa, occupying the lamina propria, where the B cell differentiates into IgA-secreting plasma cells (Befus *et al.*, 1978). Therefore, the presence of dimeric IgA has become synonymous with MALT.

## 2. Cellular Immunity

Within the epithelium, above the basement membrane, is a heterogeneous population of mononuclear cells referred to as IELs. These cells include a large population of T cells expressing T-cell receptor and CD8. The nature of these cells, their function, and their lineage relationship to thymic-dependent T cells is not clear (Croitoru and Ernst, 1992). In addition, IELs contain mast cells and their precursors, as well as antitumor and antiviral natural killer (NK) cells (Arnaud-Battandier *et al.*, 1978; Tagliabue *et al.*, 1982; Schrader *et al.*, 1983; Ernst *et al.*, 1985; Carman *et al.*, 1986). This population, therefore, has both natural cytolytic activity and classical MHC-restricted cytotoxic T cells (Ernst *et al.*, 1986). The granules of IELs contain proteases that may play a role in

influencing epithelial cell function (Guy-Grand *et al.*, 1991). In fact, a possible biological function of the IELs may be regulating the absorptive and secretory function of the epithelial cells in response to antigenic stimuli. This regulation could occur through the release of the contents of these granules or through the release of cytokines, and would be important to consider when examining the pathogenesis of inflammatory diseases of the bowel.

Within the lamina propria are lymphocytes with cytotoxic potential as well as T cells with the ability to produce cytokines. The cytotoxic T cells include cells that can be activated by stimulation of the T-cell receptor to produce tumor necrosis factor  $\alpha$  (TNF $\alpha$ ) or interferon  $\gamma$  (IFN $\gamma$ ) (Elson *et al.*, 1986; James and Strober, 1986; Deem *et al.*, 1991). These cytokines have been shown to affect epithelial cell growth and function, including the expression of MHC Class II molecules used for antigen presentation (Kvale *et al.*, 1988; Lundin *et al.*, 1990). Such interactions between elements of GALT and the structural elements of the intestine are emerging as important functions to examine in our attempt to understand the control of the physiological function of the gut.

## 3. Neural Control

The regulation of these effector functions is, in part, influenced by the local nervous tissue. The mucosal tissues, because they are highly innervated, have a major accumulation of neurotransmitters such as substance P, somatostatin, and vasointestinal polypeptide (VIP). These neurotransmitters have been shown to interact with and regulate the local immune response. Substance P, for example, can influence lymphocyte proliferation, antibody secretion, and even mucosal NK activity (Stanisz *et al.*, 1986; Croitoru *et al.*, 1990). Further, VIP has been shown to influence the selective trafficking of lymphocytes to mucosal tissues (Ottaway, 1984). These and other influences of neuropeptides and the local immune cells provide a mechanism for important interactions between the central nervous system and the local immune response (Stead *et al.*, 1987).

## 4. Lymphocyte Traffic

As discussed earlier, mucosal lymphocytes can recirculate and traffic between different mucosal tissues (see Figure 2). The MLN, for example, contains precursors for IgA plasma cells that, when adoptively transferred, will repopulate the lamina propria within 24 hr (Gowans and Knight, 1964). Thoracic duct lymphocytes also recirculate and enter the lamina propria (Gowans and Knight, 1964); this movement appears to be antigen independent (Ferguson, 1974; Halstead and Hall, 1992). Both Peyer's patch lymphocytes and BALT contain precursors for IgA-secreting plasma cells (Craig and Cebra, 1975) that could seed the intestinal lamina propria (Bienenstock *et al.*, 1978). More recent work has examined the interactions that occur between the circulating lymphocytes and the vascular endothelium in the mucosa and Peyer's patches that allow for the selective homing to mucosal tissues (Gallatin *et al.*, 1983; Navarro *et al.*, 1985; Jalkanen *et al.*, 1988).

This homing highlights the communication that exists between different mucosal sites, and allow specific antigen reac-

tivity to extend quickly over all these tissues (Bienenstock and Dolezel, 1971). Thus, the common mucosal immune system or MALT functionally behaves as one immune organ (Bienenstock *et al.*, 1978; McDermott and Bienenstock, 1979). The value of this function is exemplified by the success of oral vaccination with poliovirus, for which immunization at one mucosal site leads to protection at a second.

One of the mysteries of mucosal immunology has been the fate of the IEL population. Considered by some as terminally differentiated cells, IELs have been speculated to cross the basement membrane in both directions (Marsh, 1975). In fact, work in *Eimeria*-infected chicken has shown that IELs containing the parasite acquired in the epithelium can return to the tissues (Lawn and Rose, 1982). On the other hand, IELs have poor migratory ability (Bacq *et al.*, 1987) and turnover at quite a different rate than the adjacent epithelium (Darlington and Rogers, 1966).

Details of the molecular interactions and adhesion molecules involved in the selective trafficking of mucosal lymphocytes are discussed in other chapters.

#### IV. CONCLUSION

MALT is a complex immune organ spread over a large noncontiguous tissue that is the major barrier between the external and internal environments. This organ has evolved to protect the host without inducing potentially damaging local inflammatory responses. How this tightly regulated response is altered and how the integrity of mucosal surfaces is maintained is the key to understanding these tissues, and may be the key to the treatment of disease involving these tissues.

#### Acknowledgments

Work described in this chapter that was done by the authors was supported by the Medical Research Council of Canada and the Canadian Foundation for Ileitis and Colitis.

# Peyer's Patches as Inductive Sites for IgA Commitment

John J. Cebra · Khushroo E. Shroff

## I. ROLE OF GUT-ASSOCIATED LYMPHOID TISSUE IN THE INDUCTION OF A HUMORAL MUCOSAL IMMUNE RESPONSE

### A. Effector Arm

For decades, researchers have appreciated that specific resistance to a variety of bacterial and viral pathogens that infect via the respiratory or gastrointestinal tract was better correlated with antibody titers in local exocrine secretions than with those in serum (Francis, 1940; Smith *et al.*, 1966; Fubara and Freter, 1973). The independent findings of Hanson (1961) and Tomasi (1965) and their co-workers that secretory IgA (sIgA) was the most prevalent Ig in the exocrine secretions of most mammalian species rapidly led to the recognition of this isotype as the principal mediator of virus neutralization and blocker of bacterial adhesion at the surfaces of the wet epithelium and, hence, as the main element of the humoral mucosal immune response. The partitioning of sIgA into exocrine secretions rather than blood could be explained in part by (1) local synthesis and secretion of IgA by plasma cells in lamina propria and the interstitia of exocrine glands at sites proximal to the appearance of sIgA in secretions and (2) the selective receptor-mediated transport of IgA dimer across epithelial cell barriers and into secretions. These mechanisms for enriching sIgA in secretions raised questions concerning (1) the origins and characteristics of the precursors for IgA plasma cells, (2) the sites of their specific antigen-dependent priming and commitment to IgA expression, and (3) the trafficking of these cells to secretory tissue and their selective lodging there, relative to plasmablasts making other isotypes of Ig.

### B. Inductive Arm

Again, researchers have known for decades that a humoral mucosal immune response could be potentiated by exposure of mucosal surfaces to antigens, especially infectious replicating ones (see Smith *et al.*, 1966), although the efficacy of nonliving antigens given by this route as well as the value of parenteral priming to induce such a response have been controversial. A role for Peyer's patches, clusters of lymphoid follicles in the wall of the small intestine, in ini-

tiating this response was indicated strongly by analyses of tissues from lapine radiation chimeras (Craig and Cebra, 1971). Cells from a variety of lymphoid tissues—including spleen, peripheral blood, lymph nodes, appendix, and Peyer's patches—were adoptively transferred from donor rabbits into lethally irradiated, allogeneic recipients differing in Ig allotype (Craig and Cebra, 1971, 1975). Only cells from gut-associated lymphoid tissue (GALT), appendix, or Peyer's patches gave rise to a preponderance of donor-derived IgA plasma cells in both the spleen and the gut lamina propria of the recipients. These observations, in conjunction with similar ones on comparison of lymphoid cells from different sources after *in vitro* culture with pokeweed mitogen (Jones *et al.*, 1974), suggested that Peyer's patches were enriched sources of precursors for IgA plasma cells. Subsequently, lymphoid cells containing equivalent numbers of B cells from different tissue sources were transferred into histocompatible, congenic, sublethally irradiated murine recipients differing in Ig allotype (Cebra *et al.*, 1977; Tseng, 1981). Again, Peyer's patch cells were quantitatively most effective at transiently repopulating the intestinal lamina propria with donor-derived IgA plasma cells. However, all lymphoid cell sources tested in this histocompatible system, including peritoneal cavity cells (Kroese *et al.*, 1989), had the potential to contribute IgA plasma cells to the lamina propria of temporarily immunocompromised recipients.

The importance of Peyer's patches in the actual induction of a humoral mucosal immune response was supported by surgical construction in rabbits of pairs of externalized intestinal loops, which either had a Peyer's patch or lacked one (Robertson and Cebra, 1976). Introduction of antigens into the lumen of one loop resulted in the appearance of sIgA antibodies in both loops over a similar time course, but only if the immunized loop bore a Peyer's patch. If the immunized loop lacked a Peyer's patch, no appreciable response could be detected in the luminal secretions of either loop, irrespective of whether the nonimmunized loop contained a Peyer's patch. These observations are consistent with the importance of Peyer's patches in uptake of antigen from the gut lumen (see Chapters 2 and 3) or as a site where antigen-specific IgA-committed B cells are generated. The latter role was supported by an elegant rat model developed to analyze a humoral mucosal immune response by Pierce and Gowans (1975). Low doses (10–50  $\mu$ g) of cholera toxin, one of the

most efficacious nonreplicating mucosal immunogens known, was introduced intraduodenally twice with a fortnightly interval. Within 3–5 days of the challenge injection, a wave of cholera toxin-specific IgA plasmablasts was detected in thoracic duct lymph, followed by their accumulation in intestinal lamina propria. Using this model with extirpation of either Peyer's patches or mesenteric lymph nodes, researchers demonstrated that the presence of intact Peyer's patches but not mesenteric lymph nodes was required for the appearance of the IgA plasmablasts in thoracic duct lymph (Husband and Gowans, 1978).

## II. PHENOTYPIC AND FUNCTIONAL STATUS OF PEYER'S PATCH B CELLS: PERTURBATIONS ASSOCIATED WITH COMMITMENT TO IgA AND INDUCTION OF A HUMORAL MUCOSAL IMMUNE RESPONSE

### A. Correlation of Plasma Membrane (Surface) Phenotype of Peyer's Patch B Cells with Potential to Express Various Ig Isotypes

Adoptive transfer of subsets of Peyer's patch B cells, purified by fluorescence-activated cell sorting (FACS), to irradiated rabbit recipients indicated that the richest source of precursors for IgA plasma cells contained sIgM<sup>-</sup> sIg<sup>+</sup> B cells that bore allotype markers for IgA (Jones and Cebra, 1974; Craig and Cebra, 1975). Later, the potential of Peyer's patch B cells from mice not deliberately immunized was compared with that of B cells from other sources in a T-cell dependent antigen-dependent assay that scored individual B cells based on the output of antibody isotypes expressed by their clones (Gearhart and Cebra, 1979). Limited numbers of B cells from different sources were transferred into lethally irradiated mice that had been primed previously with a protein carrier to generate an excess of T<sub>H</sub> cells in the recipients. Within 1 day, spleens were removed and cut into fragments that were cultured with various antigenic determinants conjugated to the protein carrier. The major findings were that frequencies of B cells of certain specificities were much higher than those of B cells with other specificities and that, often, B cells with specificities in the former group gave much higher proportions of clones that solely expressed IgA when taken from Peyer's patches than when taken from other lymphoid tissues (Gearhart and Cebra, 1979; Cebra *et al.*, 1980). These IgA-committed B cells from murine Peyer's patches commonly had specificities against molecules such as phosphocholine,  $\beta$ -2-1 fructosyl-groups, and  $\beta$  galactosyl groups associated with bacterial antigens found on members of the intestinal flora (Cebra *et al.*, 1980). For this reason, it was not surprising to learn that Peyer's patches of gnotobiotic or neonatal mice lack IgA-committed B cells, but such cells appear after bacterial colonization of the gut (Cebra *et al.*, 1980, 1986; Shahin

and Cebra, 1981). Finally, separation of subsets of Peyer's patch B cells by FACS and assessment of their isotype potential by clonal analysis in splenic fragment cultures indicated that IgA-committed cells from Peyer's patches are sIgA<sup>+</sup> (Lebman *et al.*, 1987) and sIgM<sup>-</sup>sIgD<sup>-</sup> (Gearhart and Cebra, 1981). Because such sIgA<sup>+</sup> B cells appear to arise after gut mucosal stimulation with antigen but require specific T<sub>H</sub> cells and antigen to generate clones exclusively expressing the IgA isotype, we considered them operationally to represent IgA memory cells. Primary B cells, which can be isolated by FACS as sIgM<sup>+</sup>sIgD<sup>+</sup> cells, yield clones in specific fragment (Gearhart and Cebra, 1981) or single B cell clonal microcultures (Schrader *et al.*, 1990) that can express any or all Ig isotypes, including IgA (see Cebra *et al.*, 1984). Such primary B cells predominate in all lymphoid tissue and probably account for the potential of all sources to contribute IgA plasmablasts to gut lamina propria via intraclonal isotype switching to IgA, emigration of IgA blasts to exocrine tissue, and selective accumulation at these sites (see Cebra *et al.*, 1977; Tseng, 1981; Kroese *et al.*, 1989).

### B. Antigenic Stimulation of the Gut Mucosa Leads to Priming for a Subsequent Humoral Mucosal Immune Response

Much controversy existed for many years over whether or not a mucosal challenge with antigen (pathogen) could elicit a secondary mucosal IgA response—more sIgA sooner and of higher affinity than a primary sIgA response. Much of the confusion was likely the result of frequently ineffective priming for this humoral mucosal immune response. Study of the rat model for secondary responses to intraduodenal application of cholera toxin clearly showed that the challenge with cholera toxin resulted in a substantially increased number of specific IgA plasma cells in intestinal lamina propria over the number that appeared following initial gut exposure to cholera toxin (Pierce and Gowans, 1975). Acute intraduodenal or oral administration of cholera toxin, embryonated *Ascaris* eggs, or reovirus to mice resulted in 10- to 50-fold increases in antigen-specific B cells in Peyer's patches and a dominant contingent of specific IgA memory cells there (Fuhrman and Cebra, 1981; Clough and Cebra, 1983; London *et al.*, 1987). If the cholera toxin-primed mice were challenged intraduodenally *in vivo* with cholera toxin, a significant (2–5%) proportion of specific IgA plasma cells appeared in gut lamina propria (Fuhrman and Cebra, 1981). Although intraperitoneal priming with cholera toxin increased the frequency of cholera toxin-specific B cells in Peyer's patches as did intraduodenal priming with cholera toxin, it did not result in appreciable IgA-committed cells. A subsequent intraduodenal challenge with cholera toxin of intraperitoneally primed mice did not result in a significant appearance of specific IgA plasma cells in gut lamina propria. Thus, the appearance of IgA memory cells in Peyer's patches after intraduodenal priming correlates with an effective humoral mucosal immune response after gut mucosal challenge.

### **C. Generation of sIgA<sup>+</sup> Cells Within the Peyer's Patch—Is the Peyer's Patch a Source or a Sink for IgA-Committed B Cells?**

In conventionally reared (non-germ-free) mice, the greatest number of sIgA<sup>+</sup> B cells is found in Peyer's patches, compared with any other organized lymphoid tissue (Butcher *et al.*, 1982; Lebman *et al.*, 1987). At least half these sIgA<sup>+</sup> B cells are dividing, compared with about 15% of all B cells (Lebman *et al.*, 1987). Thus, sIgA<sup>+</sup> B cells are being generated in Peyer's patches. Currently, researchers question whether B cells committed to switch to IgA expression elsewhere accumulate in Peyer's patches to receive proliferative and differentiative signals (Peyer's patch is a sink) or whether uncommitted primary B cells are recruited by antigen and specific T<sub>H</sub> cells to undergo proliferation and preferential switching to IgA in the Peyer's patch microenvironment (Peyer's patch is a source)?

## **III. DO B CELLS PREFERENTIALLY ISOTYPE SWITCH TO THE EXPRESSION OF IgA IN PEYER'S PATCHES AND DO GERMINAL CENTERS PROVIDE THE MICROENVIRONMENT FOR THIS PROCESS, SERVING AS SITES FOR THE GENERATION OF IgA PREPLASMA BLASTS AND IgA MEMORY CELLS?**

### **A. Typical Characteristics of Germinal Centers and Their Putative Role in B Cell Differentiation**

Germinal centers are histologically defined, roughly spherical regions that appear transiently at the base of B-cell follicles in lymph nodes and spleen after acute, often local, stimulation by antigens (see Kroese *et al.*, 1990). These centers consist mainly of B lymphoblasts, mostly dividing or dying by apoptosis, enmeshed in a network of follicular dendritic cells that also contain tingible-body macrophages and relatively few, mostly CD4<sup>+</sup>, T cells (Rouse *et al.*, 1982; Szakal *et al.*, 1989; see Kosco, 1991). Typically, the germinal center reaction waxes and wanes over 3–4 weeks, reaching a maximum size about 10–14 days after antigenic stimulation (Coico *et al.*, 1983). However, rather large germinal centers are chronically present in all B-cell follicles of Peyer's patches in conventionally reared mammals (Butcher *et al.*, 1982; Weinstein *et al.*, 1991). The germinal center reaction appears to be dependent on CD4<sup>+</sup> T cells, does not occur in response to thymus-independent antigens in euthymic mice or to any antigen in athymic mice, and is much diminished in mice treated with anti-CD4 antibodies perinatally (Davies *et al.*, 1970; de Sousa and Pritchard, 1974; Tolaymat *et al.*, 1990). The follicular dendritic cell meshwork is particularly efficient at trapping antigen (Nossal and Ada, 1971), especially as antigen–antibody–complement complexes via FcR and com-

plement receptors on the cell surface (Klaus and Humphrey, 1977). Follicular dendritic cells may express high levels of surface major histocompatibility complex (MHC) Class II antigens, possibly containing immunogenic peptide and passively acquired from B lymphoblasts (Humphrey *et al.*, 1984; Gray *et al.*, 1991). Follicular dendritic cells and germinal center B lymphoblasts can present antigen to T cells and stimulate them (Kosco *et al.*, 1988). A mechanism has been proposed that is analogous to positive selection in the thymus, by which dividing germinal center B lymphoblasts are rescued from apoptosis via higher affinity interactions of their sIg receptors with antigens and their CD40 molecules with ligands on the surface of follicular dendritic cells (Liu *et al.*, 1989, 1991a). This hypothesis requires affinity maturation of sIg receptors on germinal center B cells and, possibly, various B-cell growth factors such as soluble CD23 provided by the follicular dendritic cells that may up-regulate expression of the *bcl-2* gene in germinal center B cells, thus somehow forestalling apoptosis (Hockenbury *et al.*, 1990, 1991; Liu *et al.*, 1991a).

Current dogma is that recirculating B cells are recruited by antigen or antigen–antibody complexes and CD4<sup>+</sup> T cells into a germinal center reaction as they pass through the corona of follicles; these B cells give rise to oligoclonal proliferation (Kroese *et al.*, 1987). Whether memory B cells rather than the more likely primary B cells can participate in germinal center reactions is still unknown (see Kroese *et al.*, 1991). Ig isotype switching appears to accompany B-cell proliferation in germinal centers; the earliest antigen-specific sIgG<sup>+</sup> cells that can be detected after antigenic stimulation bear a germinal center marker (Kraal *et al.*, 1982). The most encompassing germinal center marker for B cells of mice and several other mammalian species is the capacity to bind relatively high levels of the lectin peanut agglutinin (PNA<sup>high</sup>) (Rose *et al.*, 1980). Regretably, this property is shared with other cell types such as cortical thymocytes and goblet cells, and often must be defined quantitatively rather than qualitatively by analysis using FACS.

In addition to Ig isotype switching, another molecular genetic process peculiarly associated with memory B cells has been detected among germinal center B lymphoblasts: point mutations in the productive VDJ and VJ segments encoding the variable regions of their H and L chains, respectively (Apel and Berek, 1990; Jacob *et al.*, 1991). Using either hybridomas formed by splenic PNA<sup>high</sup> partners (Apel and Berek, 1990) or polymerase chain reaction products from small numbers of cells dissected from sections of splenic germinal centers (Jacob *et al.*, 1991), sequencing of gene segments for variable regions has indicated that point mutations arise with high frequency during B-cell division in germinal centers. Although hybridomas expressing variants of germ-line V-region genes that no longer bind the putative provoking antigen have been detected (Apel and Berek, 1990), variants expressing the sequences commonly associated with higher affinity antigen-specific memory cells have not yet been recovered (Jacob *et al.*, 1991).

Generally, germinal center B cells do not secrete detectable amounts of antibody, but immunohistochemical methods

have revealed cytoplasmic specific antibody (Szakal and Tew, 1991; Terashima *et al.*, 1991). Nevertheless, a considerable variety of circumstantial and direct evidence indicates that preplasmablasts are generated in germinal centers and that some of these emigrate to secrete antibody elsewhere (see subsequent discussion). Certainly, adoptive transfer of germinal center B cells, enriched by binding to PNA, results in specific antibody responses in recipients (Coico *et al.*, 1983; Kraal *et al.*, 1988). However, requisite criteria for the transferred response being mediated by memory B cells—antigen and specific Th-cell dependence for restimulation—were not satisfied. Nevertheless, detection of point mutations in variable region genes from germinal center cells, especially their greater prevalence in complementarity determining regions, suggesting antigen selection (Apel and Berek, 1990), establishes the occurrence of a process in germinal centers that is required for the generation of memory B cells. Functional evidence for the development of memory B cells in germinal centers is awaited (see Cebra *et al.*, 1991).

**B. Preferential Switching to IgA Expression by Peyer's Patch Germinal Center B Cells and Antigen-Specific Precursors of Antibody-Secreting Cells Is Likely the Result of the Intrinsic Influence of Their Microenvironment**

Our previous working hypothesis was that the physiological status of the chronically present Peyer's patch germinal centers differed from the state of the transient centers in lymph nodes and that this discrepancy could account for the apparent differences in isotype preference exhibited by B cells responding at the two sites to a new local antigenic stimulus (Cebra *et al.*, 1977). In other words, a novel antigenic stimulus of Peyer's patches would be superimposed on various prior environmental stimuli and would, perhaps, benefit from an unusual level or pattern of cytokines not ordinarily present in the lymph node germinal center microenvironment. One simple benefit might be an increased number of divisions—greater clonal burst size—without maturation to plasma cells by B cells in Peyer's patch germinal centers (Cebra *et al.*, 1977). Larger burst sizes stochastically might lead eventually, through consecutive isotype switching, to VDJ recombination to the  $C\alpha$  gene, the most 3' of the murine  $C_H$  gene cluster (Shimizu *et al.*, 1982). Alternatively, Peyer's patch germinal centers may differ intrinsically from those of lymph nodes in their content of particular kinds of antigen-presenting cells, stromal cells, or regulatory T cells and, hence, in the particular kinds of cytokines or switch factors available. To test these different hypotheses to explain IgA isotype preference in Peyer's patches, we sought to initiate acute germinal center reactions *de novo* in both Peyer's patches and lymph nodes, to analyze Ig isotype expression in germinal centers as well as the functional potential of B cells from the two types of sites to produce antibody of various isotypes within similar time intervals after local antigenic stimulation. Our approach (Weinstein and Cebra, 1991) was to initiate acute *de novo* germinal center reactions in Peyer's patches of germ-free mice by orally infecting with

reovirus serotype 1 (see London *et al.*, 1987) or in lymph nodes of conventionally reared mice by footpad injection of the infectious virus. If the formerly germ-free mice infected orally with reovirus are kept in isolators under otherwise germ-free conditions, the germinal center reactions in Peyer's patches wax and wane while the intestinal virus infection is resolved completely. The germinal center reactions and antibody expression by B cells from Peyer's patches of these mice were compared with those from lymph nodes of mice injected in footpads with infectious virus. Initially, prior to, and for 3 days after oral infection, the Peyer's patch B-cell follicles of germ-free mice contain no germinal centers, unlike those of conventionally reared mice (see Figure 1). The development of germinal centers in either Peyer's patches or lymph nodes was followed after local infection using both FACS analysis for PNA<sup>high</sup> B cells and immunohistochemical staining of tissue sections. Typically, germinal center B cells appeared first at day 6, reached maximum numbers by days 10–12, and declined during the period of days 14–21 after infection at both Peyer's patch and lymph node sites. The earliest and most persistent germinal center cells displayed the phenotype PNA<sup>high</sup>sK<sup>high</sup> at both sites, whereas cells with the PNA<sup>high</sup>sK<sup>low</sup> phenotype were only prevalent around the time of maximal germinal center reaction (Weinstein and Cebra, 1991). These two phenotypes of germinal center B cells have been equated with centrocytes and centroblasts, respectively (Raedler *et al.*, 1981). Whereas the time courses of the acute reactions were similar at the two sites, the two types of reactions differed conspicuously in several respects: (1) B lymphoblasts appeared with the phenotype sIgA<sup>+</sup> by day 6 and persisted through day 19 in Peyer's patches but not in lymph nodes, and most of these were PNA<sup>high</sup>sIgA<sup>+</sup> and occurred in germinal centers. A very small component of sIgG1<sup>+</sup> cells was detected in lymph nodes but not in Peyer's patches. (2) On secondary local reinfection with reovirus, the germinal center reactions in Peyer's patches and lymph nodes again exhibited similar time courses, but in the lymph nodes they were exaggerated whereas in the Peyer's patches they were attenuated compared with the primary reactions. (3) More sIgA<sup>+</sup> cells that were PNA<sup>low</sup> appeared in Peyer's patches and many more sIgG1<sup>+</sup> cells, both PNA<sup>high</sup> and PNA<sup>low</sup>, appeared in lymph nodes after reinfection, but not vice versa.

To assess the functional significance of these perturbations in subsets of Peyer's patch and lymph node B cells detected by surface phenotyping, lymphoid tissue fragment cultures (Logan *et al.*, 1991) were initiated *in vitro* using Peyer's patch or lymph node samples taken at different times during the course of the germinal center reactions after acute *in vivo* local infection with reovirus. Supernatants from the cultures were analyzed for both reovirus-specific antibody and total Ig of each isotype secreted during 7–10 days of culture. We found that acute local infection of mice with reovirus resulted in Peyer's patch fragment cultures that secreted exclusively IgA and IgM *in vitro* or in lymph node cultures that secreted IgM, IgG1, and IgG2 antibodies. Cultures initiated 3 days after infection from either source of tissue secreted only IgM, but by day 6 cultures could be initiated that progressed to the expression of non-IgM isotypes of antibody (Weinstein

**Figure 1** Consecutive sections of B-lymphocyte follicles in Peyer's patches from formerly germ-free mice after oral infection with type 1 reovirus 3 or 11 days previously. The sections were analyzed immunohistochemically using biotinylated peanut agglutinin (PNA) or biotinylated anti-IgM, -IgD, or -IgA, followed by avidin/peroxidase and its substrate (see Weinstein and Cebra, 1991, for experimental details). The sections taken at day 3 after infection are similar to those from noninfected germ-free mice.

and Cebra, 1991). In general, fragment cultures initiated after secondary local reinfections quantitatively and qualitatively reflected the secondary germinal center reactions: Peyer's patch fragment cultures produced less antibody but mostly IgA, whereas lymph node fragment cultures produced more antibody and mostly IgG1, compared with cultures initiated after primary *in vivo* local infection. The prompt switching to the expression of different non-IgM/IgD isotypes in Peyer's patches rather than lymph nodes during acute *de novo* germinal center reactions at the two types of sites suggests differences in their microenvironments as the basis for isotype preference rather than differences in the physiological states that commonly prevail in conventionally reared animals. A possible molecular basis for the observed preference for IgA expression by B cells stimulated in Peyer's patches may be the prevalence of direct IgM-to-IgA isotype switching there, compared with a perhaps more typical consecutive or sequential isotype switching in lymph nodes, eventually leading to some IgA-committed cells. Such a distinction remains to be

supported, perhaps by seeking evidence for switch- $\gamma$  (S $\gamma$ ) footprints within the recombined S regions of IgA-expressing cells developed from or at different lymphoid sites (see Yoshida *et al.*, 1990).

### ***C. Molecular Genetic Features and Functional Potential of Germinal Center B Cells from Peyer's Patches Also Reflect the Preference for Ig Isotype Switching to IgA in GALT***

Evaluating the functional potential of germinal center B cells, including those from Peyer's patches, by *in vivo* or *in vitro* methods has proven difficult. Essential frequency analyses for specificity and isotype potential of germinal center B cells *in vitro* have been unsuccessful to date—germinal center cells usually die rapidly in culture—and assessment of their functional potential by adoptive transfer has been confounded both by the lack of homing receptors on most

germinal center B cells and by the difficulty of establishing a germinal center precursor-Ig-secreting progeny relationship in the host (Reichert *et al.*, 1983; Lebman *et al.*, 1987). For instance, adoptive transfer of PNA<sup>high</sup> B cells from Peyer's patches yields no clonal precursors in the splenic fragment assay, whereas all IgA memory cells that give IgA-only secreting clones are found in the PNA<sup>low</sup> fraction of Peyer's patch cells (IgA memory cells) (Lebman *et al.*, 1987). Thus, we sought to assess the possible functional potential of germinal center B cells from Peyer's patches by *in situ* hybridization for mRNA encoding the various isotypes of Ig heavy chains using riboprobes (Weinstein *et al.*, 1991). We have identified a novel phenotype characteristic of germinal center B cells from the Peyer's patches of conventionally reared mice undergoing natural chronic intestinal stimulation by environmental antigens. The major subset of germinal center cells that is PNA<sup>high</sup>sK<sup>low</sup> contains levels of cytoplasmic mRNA $\alpha$  or mRNA $\mu$  that are easily detectable by *in situ* hybridization at levels that are intermediate between those of plasma cells and small resting B lymphocytes. About 40% of this germinal center subset has easily detectable mRNA $\alpha$  and about 50% contains mRNA $\mu$ . Enrichment of sIgA<sup>+</sup> and sIgA<sup>-</sup> cells by FACS led to the recovery of essentially all the cells with moderate levels of mRNA $\alpha$  in the sIgA<sup>+</sup> fraction of cells (48% positive). The sizes of the cytoplasmic mRNAs, determinable by Northern analysis, were similar to those encoding the membrane and secretory forms of the  $\mu$  and  $\alpha$  chains. Thus, much of the mRNA for Ig heavy chains in germinal center cells is likely to be mature, potentially productive message.

To determine whether most Peyer's patch germinal center B cells that were sIgA<sup>+</sup> and expressed mRNA $\alpha$  had undergone switch recombination of the VDJ gene segment to C $\alpha$  gene, we determined their relative content of C $\mu$ , C $\gamma$ 1, and C $\alpha$  genes. Restriction enzyme digestion and Southern analysis of genomic DNA from the PNA<sup>high</sup>sK<sup>low</sup> and the sIgA<sup>+</sup> cells prepared by FACS indicated that these subsets had lost about 25% and 80% of their C $\mu$  and C $\gamma$ 1 genes relative to C $\alpha$  genes, respectively (Weinstein *et al.*, 1991). Thus, irreversible isotype switching, with deletion of intervening C<sub>H</sub> genes, occurs in germinal centers. Most Peyer's patch germinal center cells are not expressing sIgA or mRNA $\alpha$  via processing of polycistronic mRNA or transplicing of mRNAs while in some intermediate, possibly reversible, stage of the switching process.

We have developed a single B cell clonal microculturing technique, using alloreactive cloned Th cells and dendritic cells, that is supportive of IgA expression (Schrader *et al.*, 1990). These cultures permit IgA expression by clones from IgA memory cells and from sIgM<sup>+</sup>sIgD<sup>+</sup> primary B cells after intracлонаl isotype switching (Schrader *et al.*, 1990; George and Cebra, 1991). However, although effective T, B, and dendritic cell interactions presumably do not require B cells to have competent homing receptors, germinal center B cells did not develop into secretory plasma cells in microculture, despite their extensive proliferation. Because proliferation and differentiation often have been observed to be seemingly antagonistic processes (see Bishop and Haughton, 1987), we assessed the effect of blocking division on Ig secretion by germinal center B cells from Peyer's patches (George and

Cebra, 1991). If division of germinal center B cells is blocked by either X irradiation (1600 rad) or aphidicolin, a specific inhibitor of DNA polymerases, a high proportion of the Ig-positive microcultures (60–70%) exclusively would express IgA. About 30–40% of the division-blocked germinal center B cells responded with Ig secretion; both dendritic cells and Th cells were required for such expression. We propose that our microculture assay of germinal center B cells from Peyer's patches reveals a subset of cells, preplasmablasts, that are committed to secretion. Such cultures indicate that, although many germinal center B cells die *in situ* by apoptosis, death need not be their immediate fate if their division is blocked and they are provided with necessary supportive cells and cytokines. These cultures also emphasize the extraordinary preference for the expression of IgA by the preplasmablasts in the germinal centers of Peyer's patches.

#### **D. Does Switch Recombination to C $\alpha$ Gene Commence and Proceed in the Germinal Centers of Peyer's Patches?**

The expression of transcripts initiated 5' of S $\alpha$  of the C $\alpha$  gene in germ-line context has been found to precede and be predictive of subsequent recombination of an active VDJ gene segment with the C $\alpha$  gene in sIgM<sup>+</sup> cell lines cultured *in vitro* to give rise to IgA-secreting progeny (Stavnezer *et al.*, 1988). Using the p5'S $\alpha$  probe developed for these studies, we analyzed total cytoplasmic RNA from unfractionated, PNA<sup>high</sup>, and PNA<sup>low</sup> Peyer's patch cells collected at various times after acute oral infection of germ-free mice with reovirus (Weinstein and Cebra, 1991). Dot-blotting and Northern analyses showed that C $\alpha$  germ-line transcripts could be detected by day 3 and persisted through at least day 12 after infection. Transcripts of 1.7 and 6.0 kb predominated that were detected readily only in the RNA from unfractionated and PNA<sup>high</sup> Peyer's patch cells as early as 2–3 days before sIgA expression was observed on germinal center B cells. No germ-line C $\alpha$  transcripts could be detected in cells from lymph nodes undergoing germinal center reactions. Thus, our observations on normal B cells developing *in vivo* in Peyer's patch germinal centers indicate that the switch recombination process to C $\alpha$  gene proceeds at that site and likely begins there. However, we cannot formally exclude the selective accumulation of precursors already biased toward expression of C $\alpha$  germ-line transcripts in the germinal centers of Peyer's patches.

#### **E. Are Germinal Centers in Peyer's Patches a Source of IgA Memory Cells?**

Analogous to the earliest appearance of sIgG<sup>+</sup> cells in the germinal centers of locally stimulated lymph nodes (Kraal *et al.*, 1982), sIgA<sup>+</sup> B cells are detected first in the developing germinal centers of Peyer's patches from orally infected germ-free mice (Weinstein and Cebra, 1991). B cells with the phenotype of IgA memory cells—PNA<sup>low</sup>sIgA<sup>+</sup>—appear later in the Peyer's patches of these formerly germ-free mice after acute gut mucosal infection. However, a precur-

sor-product cell relationship still has not been established between germinal center B cells and functional memory B cells from any lymphoid source (see Cebra *et al.*, 1991), although distinct pathways leading to either preplasmablasts or memory B cells have been hypothesized for germinal center cells (Liu *et al.*, 1991a). V $\lambda$  genes from B cells isolated from perinatal ovine ileal Peyer's patches have been analyzed for variants of germ-line genes (Reynaud *et al.*, 1991). Molecular genetic analysis has indicated that variation of a sort consistent with the occurrence of point mutations begins before birth in ileal Peyer's patches but becomes extremely prevalent after birth, when clustering of changes in nucleotide sequence in the complementarity determining regions, indicating antigen selection, may be occurring. Thus, as do splenic germinal centers (Apel and Berek, 1990), ovine ileal Peyer's patch germinal centers exhibit a genetic process of change that is required for the affinity maturation of Ig receptors that characteristically has occurred in typical memory B cells.

### Acknowledgments

The authors wish to thank Ethel Cebra for assistance in the production of this manuscript and Arthur Anderson for the immunohistochemical analyses shown in the figure.

# Regulation of IgA B Cell Development

Warren Strober • Rolf O. Ehrhardt

## I. INTRODUCTION

In this chapter, we consider the process that governs the emergence of IgA B cells in mucosal follicles and thus determines why IgA antibodies dominate the mucosal humoral immune response. This process, known as IgA switch differentiation, is the most used of the possible pathways that B cells follow as they transform into cells producing the various Ig isotypes, yet in some ways it is the most poorly understood: in contrast to the switch differentiation resulting in the various IgG isotypes and IgE, IgA switch differentiation has not been reproduced *in vitro* satisfactorily to date and the various cell–cell interactions or cytokines involved have not yet been identified clearly. IgA switch differentiation is also the most unique and seemingly the most vulnerable of the switch processes, unique because it is the only form of B-cell switching that clearly is tied to a specific site, the mucosal lymphoid environment, and vulnerable because in various congenital and acquired immunodeficiencies it is often the form that is most affected by the disease.

In summarizing the very considerable body of research that relates to IgA switch differentiation, we hope to clarify some of the advances that have informed this field and to focus on the problems that remain to be solved. Our approach is to consider first B-cell switch differentiation in general, drawing attention to the ways in which IgA switching is one example of a process that characterizes all B cells. We then turn to IgA switch differentiation in particular, dwelling on the phenomena that set this form of switching apart from other forms. In this discussion, we highlight the information that is solid and unassailable in this area, as well as the information that is uncertain and requires further support. Finally, we abstract from the studies already presented the information necessary to create as complete a picture of IgA switch differentiation as currently possible.

## II. MOLECULAR FEATURES OF Ig CLASS SWITCHING

### A. Switch Differentiation—S Regions

B cells undergo a complex developmental process that can be divided roughly into antigen-dependent and antigen-

dependent phases (reviewed by Kishimoto and Hirano, 1989). The task of the first phase is the selection and assembly of the genes encoding the variable region of the Ig molecule, a process that allows the B cell to gain its definitive specificity. Such selection and assembly occur as a result of a random recombination process by which selected V, D, and J gene segments come together to form a single VDJ gene complex. At this point, the Ig gene has all the elements in place for VDJ–C $\mu$  transcription: 5' promoter, rearranged VDJ gene segment, VDJ–C $\mu$  intron containing various enhancer sites, and, finally, the C $\mu$  gene. A very similar series of molecular events now can take place with respect to the various segments of one of the light chain genes. The task of the second phase of B-cell development is either terminal differentiation into IgM-producing plasma cells or switch differentiation into B cells producing another Ig isotype, followed again by terminal differentiation. Switch differentiation involves a second recombination event, this time leading to replacement of the C $\mu$  gene with a downstream (3') C $H$  gene. In this way, the downstream C $H$  gene assumes the position formerly occupied by the C $\mu$  gene and the new VDJ–C $H$  gene complex formed can be transcribed.

The process of switch differentiation, in its simplest form, involves a recombination between specialized DNA segments known as switch regions (S regions) that lie ~2 kb upstream (5') of their respective C $H$  genes. These S regions are structurally similar DNA segments composed of tandem repeats of short (5-bp) units organized into 20- to 80-bp larger units, depending on the C $H$  gene with which they are associated. Despite this organization, rearrangement does not occur at conserved recombination splice sites (as in the case of VDJ recombination) and, thus, is not likely to involve Ig class-specific recombinases capable of recognizing particular S-region target sequences. However, the repetitive structure of the switch region implies that the recombination machinery involved in switching relies on an array of generic splice sites and end-region joining interactions.

The recombination process, involving the joining of the upstream and downstream S-region sites, would be expected to generate a loop of DNA that is excised when the S-region segments are joined. That this actually occurs was inferred initially from the molecular analysis of the S-region splice sites in clonal B cells that have undergone switching and from the fact that C $H$  gene order is usually, if not always, preserved, indicating that recombination is intra (not inter)-

chromosomal. However, recombination via looping-out of intervening DNA has been shown directly by the fact that switch recombination is accompanied by the elaboration of circular DNA excision products that contain the 3' segment of the upstream S region and the 5' segment of the downstream S region (Iwasato *et al.*, 1990; Matsuoka *et al.*, 1990; Yoshida *et al.*, 1990).

One of several insights to emerge from the study of such DNA circles is that they can contain 3' S $\gamma$  rather than 3' S $\mu$  linked to a more downstream 5' S-region segment. For example, in the case of cells undergoing IgE switch differentiation, DNA circles containing S $\gamma$ 1–S $\epsilon$  and S $\mu$ –S $\epsilon$  fragments are found, indicating that IgE switch rearrangement is accompanied by intermediate rearrangements between S $\mu$  and S $\gamma$ 1 and S $\epsilon$ . Similarly, in the case of switching to IgA, circles containing S $\gamma$ –S $\alpha$  as well as S $\mu$ –S $\alpha$  fragments are found, showing that switching to IgA is accompanied by intermediate rearrangement between S $\mu$  and S $\gamma$  or S $\gamma$  and S $\alpha$  (Matsuoka *et al.*, 1990; Iwasato *et al.*, 1992). Although these data indicate that the switch process may proceed by steps, they do not invalidate the concept that switch differentiation always involves the differentiation of an sIgM<sup>+</sup> B cell into a B cell expressing a single downstream isotype. Stated differently, the data do not necessarily imply that cells bearing a downstream isotype, such as one of the IgG subclasses, switch to an even more downstream isotype, such as IgE or IgA. Thus, although dual-positive B cells bearing two isotypes such as sIgM and sIgG may appear transiently during switch differentiation, no evidence exists that the dual-positive B cells actually have undergone a recombination event. As discussed subsequently, they may be producing two isotypes simultaneously as the result of a process known as transsplicing. Thus, at the moment, regarding intermediate S–S recombination as a transient intracellular phenomenon that accompanies B cell switching and acknowledging that sequential switching at the molecular level is not reflected by stepwise switching at the cellular level is best.

### **B. Influence of Cytokines on Switch Differentiation**

A considerable body of data has now accumulated that indicates that the molecular processes just described that underlie switch differentiation are not random or "stochastic" events, but are processes that are induced by influences acting from outside the cell. This external control first became apparent when researchers discovered that, whereas lipopolysaccharide (LPS)-stimulated mouse B cells produce mainly IgG3 and IgG2b (Yuan and Vitetta, 1983; Lutzker *et al.*, 1988; Rothman *et al.*, 1990), the same cells cultured in the presence of interleukin 4 (IL-4) produced large amounts of IgG1 and decreased amounts of IgG3 and IgG2b (Isakson *et al.*, 1982). In later studies, IL-4 was shown to (1) induce purified sIgM<sup>+</sup> B cells to produce IgG1, (2) increase the precursor frequency of IgG1-secreting B cells in limiting dilution studies, and (3) induce molecular events involving the C $\gamma$ 1 gene segment that precede the onset of B-cell proliferation (see below) (Vitetta *et al.*, 1985; Coffman *et al.*, 1986; Berton *et al.*, 1989; Esser and Radbruch, 1989). These studies rule

out the possibility that IL-4 merely promotes the selective proliferation of B cells that already had switched to IgG1 expression, and focus attention on the ability of this lymphokine to induce IgG1 switch differentiation. Finally, note that IL-4 (at high concentrations) also induces IgE switch differentiation (Coffman and Carty, 1986; Coffman *et al.*, 1986; Leberman and Coffman, 1988). Although this effect is quantitatively small in comparison to the IgG1 effect, it is critical to IgE production since mice treated with anti-IL-4 have greatly reduced or even absent IgE responses when challenged with an IgE antibody-inducing stimulus.

In other studies, interferon  $\gamma$  (IFN $\gamma$ ) and transforming growth factor  $\beta$  (TGF $\beta$ ) also were shown to act as switch factors. IFN $\gamma$  induces mouse B cells to switch to IgG3 and IgG2a, the former when anti-IgD (coupled to dextran) is the proliferative stimulus, the latter when LPS is the proliferative stimulus (Snapper and Paul, 1987; Snapper *et al.*, 1992). Of interest is that these IFN $\gamma$  effects are inhibited by IL-4 and, in turn, IL-4 effects are inhibited by IFN $\gamma$ ; thus, IL-4 and IFN $\gamma$  appear to be two lymphokines that have opposing functions with respect to induction of switch differentiation. TGF $\beta$ , on the other hand, induces LPS-stimulated B cells to switch to IgA (Coffman *et al.*, 1989; Sonoda *et al.*, 1989). In this case, studies parallel to those conducted with IL-4 showed that TGF $\beta$  acts on purified sIgM<sup>+</sup> B cells and induces IgA-specific molecular events prior to B-cell proliferation; thus, TGF $\beta$  is promoting a true switching event rather than inducing selective IgA B-cell proliferation.

The effects of lymphokines and cytokines on switch differentiation also could be appreciated at the molecular level, since treatment of B cells with LPS plus IL-4 could be shown to enhance the occurrence of DNA circles containing S $\mu$ –S $\gamma$ 1 fragments and, correspondingly, suppress the occurrence of S $\mu$ –S $\gamma$ 3 and S $\mu$ –S $\gamma$ 2b fragments (Iwasato *et al.*, 1990, 1992; Matsuoka *et al.*, 1990; Yoshida *et al.*, 1990). Similarly, treatment of cells with LPS plus TGF $\beta$  favored the occurrence of DNA circles containing S $\mu$ –S $\alpha$  (or S $\gamma$ –S $\alpha$ ) fragments (Matsuoka *et al.*, 1990; Iwasato *et al.*, 1992). Therefore, these data provide direct molecular evidence that cytokines induce certain types of isotype switching.

### **C. Role of B-Cell Activation in Switch Differentiation**

The capacities of lymphokines and cytokines to act as inducers of B-cell switch differentiation, as just described, usually are demonstrated in activated B cells. Researchers generally have assumed that cell activation is a necessary (if not sufficient) condition for B-cell switch differentiation. Thus, although early molecular events of switch differentiation can be initiated by lymphokines and cytokines in resting B cells (see subsequent discussion), no evidence exists that these substances can cause resting B cells to complete the switch process, that is, undergo switch recombination in the absence of a proliferative stimulus. Also, the type of proliferative stimulus causing B-cell activation may influence certain kinds of switching, either directly or indirectly via induction of cytokine production by B cells. LPS, for instance, induces

sIgM<sup>+</sup> B cells to switch to IgG3- and IgG2b-producing B cells in the absence of T cells (Yuan *et al.*, 1983; Lutzker *et al.*, 1988; Rothman *et al.*, 1990). However, whereas the switch to IgG3-producing B cells seems to be induced by the proliferative stimulus alone, the switch to IgG2b-producing cells actually is mediated via TGF $\beta$  production by the LPS-stimulated B cells (Snapper and Mond, 1993). Similarly, anti-IgD (coupled with dextran) supports IFN $\gamma$ -induced switching to IgG2a and TGF $\beta$ -induced switching to IgA, but does not support IL-4-induced switching to B cells producing IgE (Snapper *et al.*, 1991). Finally, several observations show that IFN $\gamma$  or TGF $\beta$  effects on B-cell differentiation vary with the type of B-cell stimulus used. For instance, IFN $\gamma$  inhibits IgG3 secretion in LPS-stimulated sIgM<sup>+</sup> B-cell cultures but enhances IgG3 secretion in anti-IgD and T cell-stimulated sIgM<sup>+</sup> B-cell cultures (Snapper *et al.*, 1992); in a similar vein, TGF $\beta$  enhances IgA secretion only in LPS-stimulated sIgM<sup>+</sup> B-cell cultures, not in T cell-stimulated cultures (Ehrhardt *et al.*, 1992). Note, however, that the characteristic measured in these cases was immunoglobulin secretion rather than the number of B cells bearing the downstream isotype, so the different effects seen could relate to terminal differentiation rather than to switch differentiation. This latter point actually was proven in the TGF $\beta$  example, in which both LPS and T-cell stimulation were found to induce a similar amount of sIgA<sup>+</sup> B cells but very different amounts of IgA secretion (Ehrhardt *et al.*, 1992).

An even better case for the role of B-cell activation in switch differentiation has emerged from studies of B-cell activation via cell–cell interaction. That B cells can be activated via the latter mechanism was shown initially by the fact that activated T-cell clones or cell membranes derived from such clones induce resting B cells to proliferate and to differentiate (Kupfer *et al.*, 1986; Sanders *et al.*, 1986; Swain and Dutton, 1987; Vitetta *et al.*, 1987; Whalen *et al.*, 1988; Hodgkin *et al.*, 1990; Noelle *et al.*, 1992). Later, such proliferation and differentiation was shown to involve the binding of CD40 ligand on the T cell to the CD40 molecule on the B cell; the latter was shown to be the major signaling pathway through which T cells stimulate B cells during cognate/non-cognate cell interactions (Banchereau *et al.*, 1991).

In the same studies, of more direct interest to this discussion, the activation signal delivered by the CD40 ligand was shown to be quite different from that delivered by more conventional proliferative signals. Thus, in studies of human cells, stimulation of B cells with anti-CD40 antibodies was found to lead to stimulation of B cells in such a way that they are maintained in culture for weeks rather than days. Further, it was shown whereas *Staphylococcus aureus* Cowen I (SAC) induces B cells to produce only negligible amounts of IgM, this stimulus in conjunction with anti-CD40 induces B cells to produce large amounts of IgM as well as considerable amounts of IgG and IgA; in addition, whereas SAC or anti-IgM plus TGF $\beta$  and IL-10 produces very little IgA, these stimuli given with anti-CD40 give rise to large amounts of IgA (Rousset *et al.*, 1991; Defrance *et al.*, 1992). Thus, the CD40 proliferative signal may prepare the cell for switch and/or terminal differentiation much better than anti-IgM or SAC can. This last conclusion is punctuated by the

finding that patients with the hyper-IgM syndrome, whose B cells synthesize IgM but not IgG or IgA, appear to have a defective or absent CD40 ligand on their T cells, suggesting that B-cell signaling via CD40 is a necessary precondition for switch and/or terminal differentiation (Aruffo *et al.*, 1993; Cutler Allen *et al.*, 1993).

To complete the discussion of the role of proliferation signals on B-cell differentiation we mention that, in the studies with anti-CD40, mere cross-linking of CD40 was not sufficient to stimulate the B cell; the anti-CD40 had to be presented by an antigen-presenting cell (a mouse L cell transfected with a human Fc receptor gene) (Banchereau *et al.*, 1991; Rousset *et al.*, 1991), suggesting that the CD40 signal is “incomplete” without certain as yet undefined accessory signals. In this context, note that CD45 cross-linking has been shown to regulate LPS-induced IgG3 switching and that LyB-2 (CD72) cross-linking has been shown to regulate LPS plus IL-4-induced IgG1 switching (Ogimoto *et al.*, 1992). These studies provide tangible evidence that the cell–cell interactions necessary for switch differentiation involve a complex series of signals that may modify the switch and also terminal differentiation.

#### **D. Molecular Events Accompanying Cytokine Induction of Switch Differentiation**

The ability of various proliferation signals, cell–cell interactions, and cytokines to influence switch differentiation raised the immediate question of how such stimuli function at the molecular level. If we assume at this point that switch differentiation is indeed a directed event, as the data on the effect of cytokines in B-cell switch differentiation strongly imply, then two broad molecular mechanisms can be suggested to explain such direction. The first is that the factors directing switch differentiation induce C<sub>H</sub>-specific recombinases that act only on particular C<sub>H</sub> gene segments to bring about switch rearrangement. Evidence in favor of this view derives from the analysis of DNA circles generated during switch recombination (Iwasato *et al.*, 1990; Matsuoka *et al.*, 1990; Yoshida *et al.*, 1990). Such analyses show that S $\mu$ –S $\gamma$ 1 breakpoints are dispersed in both the S $\mu$  and S $\gamma$ 1 regions, whereas S $\mu$ –S $\alpha$  breakpoints occur in the 3' half of S $\mu$  and the 5' half of S $\alpha$ ; thus, one might postulate that the recombinases mediating C $\mu$ →C $\gamma$ 1 switches and C $\mu$ →C $\alpha$  switches are different because the former is promiscuous in its selection of donor and acceptor S-region splice sites whereas the latter is fastidious. However, these data also can be explained by assuming that S-region accessibility to a common recombinase is more or less complete in C $\mu$ →C $\gamma$ 1 switching whereas it is limited in C $\mu$ →C $\alpha$  switching.

Evidence against the view that Ig-specific recombinases are induced by particular cytokines comes from data obtained by Marcu and his associates, showing that the presence of recombinases does not insure that recombination will occur (Ott *et al.*, 1987). In the relevant studies, these authors have demonstrated that, when Abelson virus-transformed pre-B cells are transfected with a retroviral vector containing S $\mu$  and S $\gamma$ 2b inserts separated by a selectable marker that is lost

on  $S\mu$ - $S\gamma 2b$  recombination (thereby allowing isolation and study of cells containing recombined vector segments), authentic  $S\mu$ - $S\gamma 2b$  recombination occurs in cells that have not rearranged their endogenous  $C_H$  genes. Thus, the presence of a recombinase is necessary but not sufficient for recombination; further, recombinases exist in cells (pre-B cells) prior to induction by cytokines and, by implication, the latter do not act by inducing recombinase synthesis or activation.

A second possible molecular mechanism that has been proposed to explain directed switch differentiation is that directing factors acting on B cells render particular  $C_H$  gene segments accessible to recombinases (and other necessary proteins) that secondarily mediate the switch process. The earliest evidence in favor of this view was the observation that certain B-cell lines were capable of elaborating transcripts originating from a  $C_H$  gene to which the cell eventually would switch. For example, Yancopoulos *et al.* (1986) showed that, in Abelson murine leukemia virus-transformed pre-B cell lines switching to cells expressing  $\gamma 2b$ , the switch was preceded by transcription of an mRNA originating 2 kb upstream of the  $S\gamma 2b$  region and terminating at the 3' end of the  $C\gamma 2b$  gene segment. Additional work showed that this "germ-line" or "sterile" transcript has an exon located 2 kb upstream of the  $C\gamma 2b$  gene segment which, during transcription, is spliced to the  $C_H 1$  domain of the  $C\gamma 2b$  gene segment. At about the same time, Stavnezer and co-workers showed that similar germ-line transcripts occur in I.29 B-cell lymphoma cells that switch under the influence of LPS to cells expressing IgA or, to a far lesser extent, IgG2a or IgE (Stavnezer *et al.*, 1985; Shockett and Stavnezer, 1991). Again, germ-line transcripts relating to each of the expressed Ig genes were found; in addition, the genes in question were shown to be hypomethylated (an indication that they were available to mRNA polymerase) and displayed DNA hypersensitivity (an indication that they were associated with exposed chromatin).

With the demonstration that transcriptional activity of downstream genes preceded class switching, a series of studies quickly followed that showed that the very factors that induce class switching at the cellular level induce germ-line transcription at the molecular level. Thus, in a series of studies involving pre-B cells (Abelson virus-transformed B-cell lines), B-cell lymphomas, and normal B cells, Lutzker *et al.* (1988) showed that various switch factors induce the production of germ-line transcripts corresponding to the Ig genes to which the cells switch. IL-4, for instance, induces IgG1 germ-line transcripts and  $C\epsilon$  germ-line transcripts in lymphoma or normal B cells; such induction is inhibited by IFN $\gamma$ . Similarly, IFN $\gamma$  induces  $C\gamma 3$  germ-line transcripts in association with anti-IgD cell stimulation and  $C\gamma 2b$  germ-line transcripts in association with LPS stimulation (Lutzker *et al.*, 1988; Gerondakis, 1990). Finally, Stavnezer and colleagues showed that TGF $\beta$  induces increased  $C\alpha$  germ-line transcripts in I.29 lymphoma B cells in an amount roughly equivalent to the increase in cells induced to express IgA. Additionally, in this case, the effect of the cytokine increase was shown by nuclear run-on analysis to be the result of increased mRNA transcription rather than decreased mRNA turnover (Shockett and Stavnezer, 1991). Note that, in I.29

B cells and CH12.LX B cells, that is, cell lines that spontaneously undergo IgA switch differentiation, IL-4 also induces increased IgA switching, albeit to a lesser extent than TGF $\beta$ , and that such switching also is accompanied by increased  $C\alpha$  germ-line transcription that is inhibited by IFN $\gamma$  (Stavnezer *et al.*, 1985; Kunimoto *et al.*, 1988).

A common associated finding in the studies of cytokine-induced germ-line transcription just cited is that the latter temporarily precedes switch differentiation. This fact, along with the fact that germ-line transcription can be considered a marker of upstream  $C_H$  gene accessibility, strongly implies that the mechanism of cytokine-induced switch differentiation relates, at least in part, to the ability of cytokines to change the ability of recombination machinery to gain access to 5' regulatory regions of  $C_H$  genes. Stated another way, these data strongly support the accessibility theory of directed switch differentiation.

### E. Dual-Positive B Cells Occurring during Switch Differentiation

Another important advance in the understanding of Ig class switching, one that interrelates with the expanding knowledge of germ-line transcription, concerns the fact that B cells undergoing switch differentiation pass through a stage in which they can express surface IgM as well as one of the downstream Ig isotypes. This phenomenon was noted first by Perlmutter and Gilbert (1984), who reported that normal mouse spleen contains sIgM<sup>+</sup> sIgG1<sup>+</sup> dual-positive B cells that contain nuclear mRNA transcripts for both these Ig classes. Later, Snapper and Paul found that B cells stimulated by LPS and IL-4 develop (at a reasonably high frequency) into cells expressing sIgM and sIgG1 or into cells expressing surface IgM and IgE (Snapper *et al.*, 1988). Similarly, Yaoita *et al.* (1982) showed that mice stimulated with *Nippostrongylus braziliensis* (a potent inducer of T cells producing IL-4) develop cells that bear both sIgM and sIgE. These dual-positive B cells could, of course, be transient cells that are dual-isotype expressing because of the persistence of mRNA message characteristic of an earlier stage of development. This idea, however, is not supported by the finding that the downstream gene in the dual-positive cells studied by both Perlmutter and Gilbert (1984) and Yaoita *et al.* (1982) had not undergone rearrangement.

Similar and complementary results were obtained in the study of dual-positive cell lines. Chen *et al.* (1986) showed that, in a sIgM<sup>+</sup> sIgG1<sup>+</sup> dual-positive variant of the BCL1 murine B-cell line, both the IgM and IgG1 produced by the cell had the same idiotype and utilized a single  $J_H$  gene segment; in addition, extensive analysis of the entire Ig gene in this cell showed no evidence of  $C_H$  rearrangement. Similar findings were obtained in sIgM<sup>+</sup> sIgG<sup>+</sup> and sIgM<sup>+</sup> sIgE<sup>+</sup> dual-positive Epstein-Barr virus (EBV)-transformed B-cell lines. Finally, Kunimoto and Strober showed that the lymphoma cell line CH12.LX, a line that spontaneously switches from sIgM cells to sIgA cells at a low frequency and increases such switching when cultured with IL-4 and/or TGF $\beta$ , gives rise to a sIgM<sup>+</sup> sIgA<sup>+</sup> dual-positive cell during the switch

process (Kunimoto *et al.*, 1988). These authors also analyzed a stable dual-positive clone of this line and showed rather unequivocally that both  $C\mu$  and  $C\alpha$  mRNA were utilizing the same VDJ segment, and that the  $C\alpha$  gene in both alleles was not juxtaposed to the rearranged VDJ segment, that is, the  $\mu$  mRNA and  $\alpha$  mRNA were arising from a single Ig gene on a single chromosome. These studies thus established that dual-positive unrearranged B cells are a regular occurrence during switch differentiation. Whether they are an obligate pathway of such differentiation remains to be seen.

The molecular mechanism explaining the occurrence of dual-positive but unrearranged B cells is not yet resolved. As mentioned earlier, Perlmutter and Gilbert (1984) showed that dual-positive cells contain nuclear mRNA for both Ig species. These authors postulated that the mRNAs may arise from alternative splicing of long mRNA transcripts that span multiple Ig genes. This view, however, seems unlikely in view of the instability of such transcripts and of the fact that certain cell lines seem precommitted to a particular isotype. Another explanation is that VDJ mRNA may be "transpliced" to  $C_H$  gene mRNA, the latter presumably arising from germ-line transcripts, as discussed previously. That transplicing does, in fact, occur is supported by several observations. First, in earlier studies rabbits were shown to be heterologous for  $V_H$  and  $C_H$  allotype Ig markers, although the  $V_H$  markers and  $C_H$  genes are encoded by different chromosomes. Second, Shimizu has shown that, in B cells of transgenic mice carrying a human  $C\mu$  transgene, a hybrid message may occur containing transgene VDJ mRNA spliced to endogenous  $C_H$  gene mRNA (Shimizu *et al.*, 1989). Since, in these studies, the transgene was *not* located in the  $J_H$  and  $C_H$  gene regions, the splice was presumed to be a transsplice. One possible alternative explanation of this finding is that the trans-mRNA occurred via S-S recombination, that is, intrachromosomal splicing. Indeed, Gerstein *et al.* (1990) have presented evidence that, in hybridoma B-cell lines containing a mouse VDJ- $C_H$  transgene on one chromosome, the transgene can give rise to mRNA that is linked to mRNA derived from endogenous  $C\alpha$  gene. In this case, the authors provide good evidence that this mixed product is generated by transgene isotype switching and that actual joining of VDJ of the transgene with  $C\alpha$  occurred at the DNA rather than at the mRNA level. Despite these findings, intrachromosomal splicing and S-S recombination do not seem to explain the trans-mRNA in the transgenic model of Shimizu *et al.*, (1989, 1991), these authors have provided evidence that in, a lymphoma B cell derived from the transgenic mouse and containing the transgene, no evidence was found of S-S rearrangement.

Additional support for transplicing also comes from the studies of Nolan-Willard and colleagues (1992), who have shown, using the double-isotype expressing BCL1 lymphoma B cells mentioned previously, that the cells produce a pre-RNA in their nuclei that contains  $\mu$  and  $\gamma 1$  linked sequences. The pre-RNA is about 15 kb long, rather than 150 kb as one might expect from a long transcript; thus, in these double-isotype producing cells, the synthesis of the linked mRNA must have occurred by a transplicing mechanism or, as the authors suggest, by "discontinuous transcription."

## F. Induction and Function of Germ-line Transcripts

As discussed earlier, various cytokines induce germ-line transcription in the process of bringing about switch differentiation (Stavnezer-Nordgren and Sirlin, 1986; Lutzker *et al.*, 1988; Stavnezer *et al.*, 1988). The question therefore arises about the molecular mechanism involved in such induction. To begin to answer this question, Stavnezer and colleagues have analyzed the regulatory regions 5' to the  $I\alpha$  gene segment in the I.29 B-cell line, that is, the start site of  $C\alpha$  germ-line transcript in this cell (Lin and Stavnezer, 1992). These studies have shown that, although this site contains neither a TATA box nor an Sp1 element near the possible mRNA initiation sites, it does contain DNA sequences with homology to a variety of known target sites of DNA binding proteins that are involved in regulation of transcription of mRNA, for example, AP-2, NF-III, and ATF/CRE sites. Further, in a series of studies in which the 5'  $I\alpha$  sequences were fused to a reporter gene and the resulting constructs transfected into permissive B-cell lymphomas, the ATF/CRE sequence was shown to be important for constitutive expression of the germ-line transcript. On the other hand, TGF $\beta$  induction of transcription depended on the presence of sequences present at position -128 to -106 and position -41 to -30 relative to the upstream-most mRNA initiation site. This region, subsequently termed the TGF-RE, contains tandem repeats of the 5' CACAG(G) and CCAGAC 3' motifs. Stavnezer and colleagues suggest that up-regulation of  $C\alpha$  germ-line transcripts may occur as a result of TGF $\beta$  induction of a DNA binding factor that competes with suppressor factors for occupation of the TGF-RE (Lin and Stavnezer, 1992).

The ATF/CRE just mentioned binds a family of transcription factors that is involved in the induction of many different mRNAs, including the major histocompatibility complex (MHC) Class II A( $\alpha$ ) mRNA. The TGF-RE, on the other hand, is homologous with sequences in the promoters of the mouse and human TGF $\beta 1$  genes and in the  $\beta$ -actin gene. Thus, the various regulatory sequences mediating TGF $\beta$  effects are not specific for  $C\alpha$  germ-line transcription. Indeed, these elements have been found upstream of several of the  $C_H$  genes, a fact that correlates with the discovery that TGF $\beta$  induces IgG2a switch differentiation in LPS-stimulated murine B cells (McIntyre *et al.*, 1993).

Assuming that the regulation of  $C\alpha$  germ-line transcripts in I.29 cells by TGF $\beta$ , as just described, can be considered a model for regulation of germ-line transcripts generally, the data just presented suggest that lymphokines and cytokines influence germ-line transcription via the induction of regulatory DNA binding factors. In this context, that different lymphokines and cytokines have different effects (induce different types of switch differentiation) seems reasonable because they induce different DNA binding factors. Indeed, even in cases in which two different cytokines induce the same germ-line transcript, for example, IL-4 and TGF $\beta$  induction of  $C\alpha$  germ-line transcripts, the molecular mechanism underlying induction is likely to involve a distinct array of DNA binding factors, since these cytokines have been shown to induce  $C\alpha$  germ-line transcripts at different rates and magnitudes.

Finally, whether induction of DNA binding factors also accounts for lymphokine and cytokine effects on the earliest steps of switch differentiation, such as accessibility itself, and whether such induction is the same as germ-line transcript induction, is still unknown.

The emerging data relative to the regulation of germ-line transcription beg the question of the function of the germ-line transcripts. One possibility is that they have no function and occur merely because of the accessibility of the region 5' to the  $C_H$  genes to transcriptional factors and enzymes. This possibility is unlikely, however, because the germ-line transcripts have specific start sites in the I region as well as specific splice sites and, thus, seem too highly structured to be random (opportunistic) transcriptional products. Another possibility is that germ-line transcripts play a necessary role in switch recombination, either directly via the function of the germ-line transcript itself or indirectly via a translation product of the transcript. Wakatsuki and Strober addressed this possibility by transfecting plasmids producing antisense oligonucleotides specific for sequences in the  $I\alpha$  region into CH12.LX B cells in an attempt to down-regulate  $C\alpha$  germ-line transcription in such cells. These investigators found that such transfection did, in fact, down-regulate  $C\alpha$  germ-line transcription and, in doing so, led to a decrease in the appearance of dual-positive (sIgM<sup>+</sup>sIgA<sup>+</sup>) B cells and IgA synthesis (Wakatsuki and Strober, 1993). From this result, germ-line transcripts appear to be a necessary if not a sufficient condition for switch differentiation.

### G. Molecular Mechanisms Related to Human Switch Differentiation

To this point in our discussion, we have been concerned mostly with studies relating to mouse Ig switch differentiation. We now turn our attention to what is known about switch differentiation in human cells.

The human Ig heavy-chain gene is far more complex than the murine Ig gene because it is composed of two separate units, one containing an initial group of  $C_H$  genes— $C\gamma3$ – $C\gamma1$ – $\psi C\epsilon$ – $C\alpha1$ —followed by a second group of  $C_H$  genes— $\psi C_H$ – $c\gamma2$ – $C\gamma4$ – $C\epsilon$ – $C\alpha2$ —that are presumed to have arisen as a result of gene duplication events. Despite this increased complexity, the fine structure of human  $C_H$  genes is remarkably similar to that of mouse  $C_H$  genes with respect to S regions and regions upstream of the S regions extending into the I regions. This similarity includes an evolutionarily conserved region 5' to and overlapping the human  $I\gamma4$  and  $I\epsilon$  gene segments and the mouse  $I\gamma2b$  gene segments that includes the regulatory regions of these human and mouse I region gene segments (Flanagan and Rabbitts, 1982; Hofker *et al.*, 1989).

This structural homology is reflected in important functional similarities relating to molecular events occurring during human and murine switch differentiation. In particular, human B cells that are about to undergo switch differentiation first produce germ-line transcripts initiating 5' to the  $C_H$  gene to which the cell is switching. That these transcripts are under the transcriptional control of cytokines was shown in relation to IgE switch differentiation, for which IL-4-treated B cells,

in the absence of other stimuli, were found to produce  $I\epsilon$  germ-line transcripts, and in relation to IgA switch differentiation, for which TGF $\beta$  was shown to induce  $I\alpha$  germ-line transcripts (Berton *et al.*, 1989; Lebman *et al.*, 1990). The need for proliferative stimuli in such induction was studied in relation to  $I\epsilon$  germ-line transcription. No such stimuli were found to be necessary, although T cells or other stimuli such as anti-CD40 antibody were necessary for IgE secretion (i.e.,  $C\epsilon$  switch differentiation). Whether TGF $\beta$  alone can induce  $I\alpha$  germ-line transcripts (in the absence of other stimuli) is less clear; however, we know that not every proliferative stimulus acts in conjunction with TGF $\beta$  to bring about IgA secretion: anti-CD40 antibody and certain antigens have this ability but anti-Ig cross-linking antibodies do not (Defrance *et al.*, 1992).

With respect to IgG subclass germ-line transcripts, studies have shown that germ-line transcripts associated with  $C\gamma$  genes in the first duplication unit ( $C\gamma3$  and  $C\gamma1$ ) require proliferative stimuli for induction, for example, SAC or SAC plus IL-2 (alone or in combination with other cytokines), whereas the germ-line transcripts associated with the  $C\gamma$  genes in the second duplication unit ( $C\gamma2$  and  $C\gamma4$ ) can be induced by cytokines alone (IFN $\gamma$  and IL-4, respectively; Kitani and Strober, 1993, in press). Other effects of proliferation stimuli and cytokines on  $I\gamma$  germ-line transcript expression were that, whereas  $I\gamma1$  germ-line transcripts were induced by SAC alone and such induction was not enhanced by cytokines,  $I\gamma3$  germ-line transcripts required both SAC and IL-4. In addition, whereas  $I\gamma2$  germ-line transcript was induced by a proliferation stimulus or by IFN $\gamma$  alone,  $I\gamma4$  germ-line transcript was not induced by a proliferation stimulus and only by IL-4 alone. Thus, the germ-line transcripts associated with each of the  $C\gamma$  genes are unique in their regulatory requirements. Finally, IFN $\gamma$  and IL-4, as in murine systems, have opposing actions because IFN $\gamma$  down-regulates both  $I\gamma1$  and  $I\gamma4$  germ-line transcripts induced by IL-4.

The new data concerning  $I\gamma$  germ-line transcript regulation have certain implications regarding the two duplication units in the Ig gene region. First, the regulation of  $I\gamma$  germ-line transcripts arising from the first and second duplication units appears to be governed by somewhat different mechanisms, since transcription of germ-line transcripts from  $C_H$  genes in the first unit requires a proliferation signal whereas transcription from those in the second does not (Kitani and Strober, 1993). This functional difference appears to be imbedded in a structural difference since, in human B-cell malignancies, *c-myc* translocation has been found mainly in the S regions of the first duplication unit (Hamlyn and Rabbitts, 1983; Care *et al.*, 1986).

Second, based on the capacity of  $C\gamma$  genes to respond to IL-4 and IFN $\gamma$  induction, evolutionary relationships between human  $C\gamma2/C\gamma4$  and murine  $C\gamma3/C\gamma1$  can be assigned, suggesting that these gene pairs define a unit that underwent duplication or deletion during evolution. For instance, duplication of a pair of primordial  $C\gamma$  genes could have led to the  $C_H$  gene format present in the mouse, whereas duplication of the entire  $C_H$  array (including the  $C\epsilon$  and  $C\alpha$  genes) led to the  $C_H$  gene format in humans (Flanagan and Rabbitts, 1982; Hofker *et al.*, 1989).

Third, these studies lead to the possibility that human B cells are separable into two lineages that express either of the genes in the  $C\gamma 3/C\gamma 1$  gene pair of the  $C\gamma 2/C\gamma 4$  gene pair. This concept is based on the fact that human B-cell leukemia lymphoma cell lines can express simultaneously  $C\gamma 1$  and  $C\gamma 3$  germ-line transcripts originating from the first duplication unit exclusively (Sideras *et al.*, 1992). In addition, several groups have described switchable IgM-producing human B-cell lines that constitutively produce  $C\gamma 1$  and  $C\gamma 3$  germ-line transcripts and switch to IgG1 and IgG3 B cells, respectively (Sideras *et al.*, 1992; Kuze *et al.*, 1991; Mizuta *et al.*, 1991). These cells are thus similar to normal B cells that switch to IgG1 and IgG3 B cells when stimulated by SAC and IL-4 or SAC alone. The fact that these cells do not produce  $C\gamma 1$  and  $C\gamma 3$  germ-line transcripts when stimulated with IFN $\gamma$  or IL-4 alone suggests that they represent a lineage only capable of differentiating into B cells expressing the isotypes corresponding to the  $C_H$  genes in the first duplication unit.

Fourth, and finally, the fact that lymphoma B cells can express simultaneously  $C\gamma 1$  and  $C\gamma 3$  germ-line transcripts from the first duplication unit leads to the further suggestion that Ig genes in a given unit are under the control of factors that affect all Ig genes in that unit. This possibility could explain the observation that human B-cell lines differ from mouse B-cell lines by the fact that the gene rearrangement of the Ig gene on the unexpressed allele frequently does not correspond to that of the Ig gene on the expressed allele. This observation now can be explained on the assumption that, in humans, the entire duplication unit rather than the specific Ig gene becomes accessible after the cell is subject to a particular induction signal. Thus, directed switch differentiation only requires that the unexpressed  $C_H$  allele be in the same duplication unit as the expressed allele.

Molecular analyses of regulatory sequences 5' to the I gene segments in humans are only now becoming available. As in murine systems, initiation sites at I gene segments are heterogeneous and lack classic 5' promoters. Structural studies initiated to date reveal enhancer and repressor regions in the region 5' to the  $I\gamma 3$  gene segment, as well as binding sites for known transcription factors. However, much additional work will be necessary to gain even a skeletal picture of the molecular regulation of these human I gene segments.

### III. CELLULAR BASIS OF IgA B-CELL DIFFERENTIATION

#### A. Peyer's Patches, Loci of IgA B-Cell Development

Studies of the cellular basis of IgA B-cell differentiation can be said to begin with the landmark experiments of Craig and Cebra (1981), who showed that adoptively transferred Peyer's patch cell populations could repopulate the intestinal lamina propria and spleen of X irradiated rabbits with IgA B cells far more efficiently than could lymph node cell populations. Earlier, Rudzik and his colleagues (1975) extended these findings by showing in a very similar system that adop-

tively transferred bronchial lymph node cells were also very efficient in repopulating intestinal lamina propria. These findings, eventually verified in a syngeneic cell transfer system in mice, were the first to show that Peyer's patches are a major site of IgA B-cell development (Tseng, 1981). In addition, these studies presaged a great number of studies that established that IgA B cells developing in Peyer's patches and bronchial lymph nodes migrate through the draining mesenteric lymph node and also through the spleen on their way to the lamina propria of the various mucosal surfaces.

These studies establishing the origin of IgA B cells in Peyer's patches correlate with those focused on the cellular architecture of the Peyer's patches. Peyer's patches contain germinal centers characterized by a high proportion of sIgA<sup>+</sup> B cells (75–80%), whereas germinal centers in peripheral lymph nodes contain very low numbers of such cells (Butcher *et al.*, 1982). The sIgA<sup>+</sup> germinal center B cells are rapidly dividing cells that, for the most part, die by apoptosis before leaving the center. However, when their proliferation is inhibited chemically or physically or they are cultured with competent T cells, these cells develop into IgA-secreting cells (see subsequent discussion). A related finding is that Peyer's patches contain memory IgA B cells, a B-cell population specific for a particular antigen and expanding rapidly when restimulated with that antigen. The precise localization of such B cells in the patch is unknown, but suggesting that they are part of the recycling B-cell population in the germinal centers is tempting. Finally, note that memory B cells, whatever their location, should be distinguished from terminally differentiated IgA plasma cells. The latter are only rarely found in Peyer's patches and develop from the subpopulation of sIgA<sup>+</sup> B cells that escape from the Peyer's patch germinal centers and migrate to other sites such as the bone marrow or the lamina propria. The factors that allow sIgA B cells to migrate out of germinal centers, and thus to pursue a terminal differentiation pathway, are still poorly understood.

Whereas IgA B-cell development is one of the predominant features of Peyer's patches of rodents (and humans), IgM B-cell development may characterize this lymphoid site in other species. Thus, as shown by Reynolds and his colleagues, neonatal sheep contain ileal Peyer's patches that contain a rapidly proliferating sIgM<sup>+</sup> B-cell population and differ from more conventional sIgA<sup>+</sup> B cell-containing Peyer's patches in jejunal areas (Pabst and Reynolds, 1986; Reynolds, 1986; Reynolds and Kirk, 1989). These ileal patches involute as the sheep matures and contain cells that, for the most part, undergo cell death in the patch rather than migrate to other lymphoid tissues; thus, these regions may be a kind of "bursal equivalent," that is, a generation of pro-B, pre-B, and immature B cells.

Other cells found in the Peyer's patches are T cells, which are numerous in both the follicular and interfollicular areas. The follicular T cells are almost all CD4<sup>+</sup> T cells, whereas the interfollicular T cells are CD4<sup>+</sup> T cells interspersed with small numbers of CD8<sup>+</sup> T cells. A unique feature of the Peyer's patch CD4<sup>+</sup> T-cell population is that it contains a subset of Th1<sup>-</sup> cells (about 15% of the total) located mainly, if not exclusively, in the follicles (Harriman *et al.*, 1990). The latter rarely are found in other lymphoid organs (~5%) and

when they are, they are  $\text{Thy}^{\text{dull}}$  rather than  $\text{Thy1}^-$ . Various *in vitro* studies reveal that this population arises from  $\text{Thy1}^+$  T cells as a result of cell activation; thus, their presence in Peyer's patches is an indication of a high state of T-cell activation in this lymphoid site.

Finally, Peyer's patches contain various types of dendritic cells, including interdigitating dendritic cells that are highly efficient antigen-presenting cells capable of addressing T cells, as well as follicular dendritic cells capable of addressing B cells (Spalding *et al.*, 1983; Tew *et al.*, 1990). The precise localization of these cells within the Peyer's patch is unknown although, on the basis of information from other lymphoid organs, interdigitating dendritic cells are in the interfollicular areas whereas follicular dendritic cells are in germinal centers. As we shall see, evidence is emerging that interdigitating dendritic cells may play an important role in the T-cell activation processes occurring in Peyer's patches and, secondarily, in the IgA switch differentiation process. What role, if any, follicular dendritic cells have in IgA switch differentiation is unknown.

### **B. B Cell- and T Cell-Centered Theories of IgA Switch Differentiation**

The identification of the Peyer's patches and bronchial lymph nodes as major sites of B-cell development and IgA switch differentiation focused attention on conditions at those sites that make such development possible there but not at other lymphoid sites. Historically, two competing hypotheses describing these conditions have been proposed. In one hypothesis, IgA switch differentiation is visualized as a B cell-centered process that occurs when B cells are subjected to intense antigen-driven stimulation. In this view, although T cell interaction with B cells is assumed to occur in the usual antigen-mediated (cognate) fashion, the T cells themselves (or, indeed, other accessory cells) play no role in B-cell development other than the facilitation of B-cell activation and terminal differentiation. This theory, originally put forward by Cebra and his colleagues, took advantage of the fact that B cells entering the Peyer's patches (presumably  $\text{sIgM}^+$  B cells) encounter an environment in which cells are more exposed to all sorts of antigens (and mitogens). Assuming that the latter would subject the B cells to a unique inductive influence that results in progressive switch differentiation was reasonable. In addition, the theory took advantage of the fact that, in mice, the  $\text{C}\alpha$  gene is the most 3' of the  $\text{C}_H$  genes. Thus, any process that favored progressive switch differentiation would lead inevitably to the emergence of IgA B cells.

Several facts, both theoretical and experimental, now have led to the abandonment of this theory, at least in its simplest form. First, the theory does not explain the fact that direct stimulation of B cells with any of a variety of T cell-independent mitogens or antigens does not lead to significant IgA switch differentiation and IgA secretion. Second, the theory would predict that, under active stimulation leading to more 3' switch differentiation, the  $\text{C}\gamma 2a$  and  $\text{C}\epsilon$  genes, the penultimate  $\text{C}_H$  genes (and the equivalent genes in humans),

also would be overexpressed in Peyer's patches; However, no evidence exists that this is true. Third, the theory presupposes intermediate switching from the various  $\text{C}\gamma$  genes (or  $\text{C}\epsilon$  gene) to the  $\text{C}\alpha$  gene. Although we have seen evidence that this can occur at the molecular level and, indeed, dual-positive cells appear that can switch to more downstream isotypes, no evidence exists that stable  $\text{sIgG}^+$  or  $\text{sIgE}^+$  B cells are switchable to more downstream isotypes such as IgA. Moreover, even progressive switching at the molecular level occurs under the influence of cytokines, that is, not as a result of stimulation of B cells in the absence of T cells or other cells.

The latter point introduces the fourth and main problem with the B cell-centered theory of IgA switch differentiation, the fact that it is "out of synch" with the entire thrust of current concepts of isotype differentiation, which consistently relate a particular form of switch differentiation to a particular cytokine influence. In this regard, we have little reason to believe that  $\text{sIgA}^+$  B cells are different from B cells expressing other isotypes in being the end result of an external inductive influence. Interestingly, Cebra and his colleagues have, themselves, provided a persuasive argument against B cell-centered IgA switch differentiation. These authors have shown that *de novo* induction of a germinal center reaction in Peyer's patches by infection of germ-free mice with reovirus is sufficient to induce high numbers of Peyer's patch B cells expressing  $\text{sIgA}$  (Weinstein and Cebra, 1991). This study shows that, even in a Peyer's patch containing B cells not chronically exposed to a multitude of the antigens present in the normal gut, IgA switch differentiation in Peyer's patches is favored.

Whereas the B cell-centered theory of IgA switch differentiation clearly is untenable as originally proposed, it may contain a germ of truth. IgA switch differentiation in Peyer's patches may be B cell-centered in the sense that the B cells undergoing this process have been committed to it partially before they enter the patch and thus do not require a specific inductive influence to complete their differentiation program. One might speculate that the partially committed cells are either  $\text{sIgM}^+$  B cells or dual-positive  $\text{sIgM}^+\text{sIgA}^+$  B cells that are producing  $\text{C}\alpha$  germ-line transcripts and thus have an accessible region 5' to the  $\text{C}\alpha$  gene segment. One might speculate further that such cells arise via random (stochastic) switch differentiation at some site of early B-cell development and then migrate to Peyer's patches via a patch-specific homing mechanism.

Several scraps of data can be marshaled to support this theory. First, the idea that some  $\text{sIgM}^+$  B cells present in Peyer's patches are precommitted to IgA switch differentiation is supported by the knowledge that such B cells do, in fact, exist in the form of lymphoma B-cell lines such as CH12.LX B cells and I.29. Such cells may be present normally in a more transient form at certain lymphoid sites and migrate from the latter to the Peyer's patches. Worth mentioning in this context is that CH12.LX B cells arose in animals subjected to systemic immunization and thus did not necessarily arise in mucosal tissues. Second, this idea is favored by the knowledge that, at least in humans, a considerable number of IgA-producing B cells develops in a lymphoid organ other

than the Peyer's patch—the bone marrow. Although such bone marrow IgA B cells may have originated in Peyer's patches and are merely undergoing terminal differentiation in the bone marrow, the reverse also may be true: the bone marrow may be the site of initiation of IgA B-cell development and the Peyer's patches the site where such development is completed. Third, putative partially committed IgA<sup>+</sup> B cells, dual-positive sIgM<sup>+</sup>sIgA<sup>+</sup> B cells (5–7%) are found in Peyer's patches in substantial numbers (R. Ehrhardt, Gregory R. Harriman, John K. Inman, and W. Strober, unpublished observations). Although such cells usually are thought to arise secondary to a process inductive of IgA switch differentiation, this need not be the case; these cells may be the starting point of Peyer's patch IgA B-cell development rather than the intermediate point. Finally, some data show that certain B cells bear surface receptors that allow interaction with high endothelial venules in Peyer's patches and thus would facilitate selective entry of B cells into this lymphoid site (as opposed to peripheral lymph nodes); thus, some support is available for the possibility that cells precommitted to IgA switch differentiation preferentially accumulate in Peyer's patches.

The data in favor of a resurrected B cell-centered theory of IgA B-cell differentiation cannot be considered sufficient to establish its validity. Additional evidence, such as the demonstration that at least some B cells entering Peyer's patches are, in fact, partially committed to IgA switch differentiation at the molecular level (i.e., are synthesizing  $\alpha$  germ-line transcripts), will be necessary. Further, demonstrating that such partially committed B cells do not require specific inductive signals at their site of origin or in the patch will be essential; otherwise, the B-cell centeredness is more apparent than real since, in this case, only the nature or location of the external signal is changed, not its existence. Finally, why and how a cell undergoing IgA switch differentiation on a random basis also acquires a cell surface protein that enables specific homing to the Peyer's patch must be explained. These additional requirements for proof of the theory emphasize the distance that must be traveled before it is accepted; nevertheless, the theory must be kept in mind, since at least some elements ultimately may prove to be true (see further discussion).

A second hypothesis concerning IgA switch differentiation and one that, as mentioned, is more consonant with processes that govern differentiation of B cells of other Ig isotypes, is that such differentiation is a directed process in which B cells in the Peyer's patch are induced to undergo IgA switch differentiation by Ig class-specific inductive cells or factors derived from such cells. Early evidence in support of an essential role of T cells in IgA B-cell differentiation was the observation that thymectomized rabbits have decreased IgA antibody responses and normal IgM and IgG responses; similarly, nude mice manifest a selective IgA deficiency (Clough *et al.*, 1971; Pritchard *et al.*, 1973). These observations in studies of whole animals eventually were related to Peyer's patch T-cell function by Elson and Strober who showed that, whereas antigen-activated T cells derived from Peyer's patches enhance LPS-driven IgA synthesis, they suppress LPS-driven IgM and IgG synthesis; on the other hand, spleen

T-cell populations activated in the same way suppress LPS-driven responses of any isotype (Elson *et al.*, 1970). Since in titration studies in which increasing numbers of spleen T cells were cultured with a fixed number of Peyer's patch B cells, IgM, IgG, and IgA responses were equally susceptible to the suppressive influence of concanavalin A (Con A) activated spleen T cells, the enhancing effect of Peyer's patch T cells could not be the result of an inherent inability of Peyer's patch IgA B cells to respond to a suppressive influence. In parallel studies, Mongini *et al.* (1983) studied isotype switching of B cells using a splenic focus technique in which isotype switching in clonal B-cell populations of adoptively transferred, irradiated mice was evaluated. In this study, the addition of T cells to the inoculum of cells used to replete "indicator" mice was shown to enhance the frequency of IgA-expressing clones and such clones usually did not co-express the various IgG subclasses. Collectively, these initial studies of IgA B-cell differentiation established the point that such differentiation is regulated by T cells in a manner that, at least in part, is distinct from that governing IgG B-cell differentiation.

From the data gathered by Elson *et al.* (1979), whether the regulatory effect of Peyer's patch T cells was operating at the level of switch differentiation or terminal differentiation could not be determined since the Peyer's patch B cells under study contained, at least in part, sIgA<sup>+</sup> B cells that already had undergone isotype switching. To address this question, Kawanishi *et al.* (1983) prepared cloned Thy1<sup>+</sup> T-cell populations from the spleen and Peyer's patches and found that LPS-stimulated sIgM<sup>+</sup> B cells cocultured with Peyer's patch T-cell clones either remained as sIgM<sup>+</sup> B cells (~36%) or differentiated into sIgA<sup>+</sup> B cells (~40–45%); very few (~3%) differentiated into sIgG<sup>+</sup> B cells. This result was in striking contrast with LPS-stimulated sIgM<sup>+</sup> B cells cultured alone or with spleen T-cell clones. In this case, the resulting cells were either sIgM<sup>+</sup> or sIgG<sup>+</sup> B cells and very few of the cells were sIgA<sup>+</sup> B cells (0.3–0.4%). Other findings emerged from these studies: (1) The Peyer's patch-derived T-cell clones did not induce LPS-stimulated sIgG<sup>+</sup> B cells to become sIgA<sup>+</sup> B cells, indicating that they were not inducing progressive and stepwise switching. (2) The Peyer's patch-derived cloned cells did not augment B-cell proliferation in general, or IgA B-cell proliferation in particular, over that induced by LPS, so their effect cannot be attributed to preferential proliferation of preformed sIgA<sup>+</sup> B cells. (3) Neither Peyer's patch-derived nor spleen-derived T-cell clones induced significant numbers of plasma cells capable of producing either IgG or IgA. In fact, both types of clones greatly decreased the occurrence of IgM or IgG plasma cells, and only the Peyer's patch-derived clone caused an increase in IgA plasma cells compared with B cells stimulated by LPS alone. This result suggested that the processes of switch differentiation and terminal differentiation are separate phenomena. Finally, sIgA<sup>+</sup> B cells (or, indeed, sIgG<sup>+</sup> B cells), once having switched, could be induced to undergo terminal differentiation into Ig-secreting plasma cells if they were cocultured with appropriate helper T cells (i.e., T cells producing cytokines that induce terminal B-cell differentiation). Collectively, the results of these studies suggested that IgA B-cell

switch differentiation was indeed a Peyer's patch T cell-directed process and therefore provided an explanation why IgA switch differentiation occurs predominantly in Peyer's patches.

The general concept that switch T cells of the type described by Kawanishi and colleagues do, in fact, exist was supported by subsequent studies by Mayer and his colleagues (1985, 1986) relating to a human lymphoma T-cell line derived from a patient with the Sézary syndrome. These authors showed first that the lymphoma T cells, when cocultured with normal B cells (non-T cells) and pokeweed mitogen, induced IgG and IgA secretion but little or no IgM secretion, and induced normal sIgM<sup>+</sup> tonsillar B cells to produce IgG and IgA. They then showed that this T-cell line induced cells from patients with hyper-IgM syndrome, that is, patients with an immune defect in which only IgM is secreted (in increased amounts), to produce IgG and IgA. On the basis of these data, the investigators concluded that the lymphoma cell line was composed of "switch" T cells that induced, in this case, both IgG and IgA switching; in addition, they postulated that the patients with hyper-IgM syndrome had a defect in their switch T cells. As already mentioned, this latter hypothesis has received support from the finding that the hyper-IgM syndrome is caused by a CD40-ligand defect.

Yet other evidence for the existence of switch T cells was obtained by Benson and colleagues, who derived Con A-induced T-cell clones from gastrointestinal tissues and showed that these lines had a far greater propensity to induce IgA secretion than similar lines obtained from peripheral blood (Benson and Strober, 1988). More precisely, these researchers showed that several of these lines had a greater capacity to increase IgA production in sIgM<sup>+</sup> sIgA<sup>-</sup> B cells rather than in sIgM<sup>-</sup> sIgA<sup>+</sup> B cells, suggesting that some of the lines were acting as switch T cells.

These studies in support of the concept that switch T cells present in Peyer's patches account for IgA switch differentiation (and perhaps other types of switching, as well) must be considered in light of subsequent studies that are, at best, highly equivocal in their support of this concept. Phillips-Quagliata and colleagues showed, in several studies, that T cells from various organs were equally efficient in inducing IgA responses (Al Maghazachi and Phillips-Quagliata, 1988a,b; Arny *et al.*, 1984). In one study, for example, antigen-primed peripheral lymph node T cells induced as good an IgA response as antigen-primed Peyer's patch T cells in *in vitro* cultures of hapten-primed B cells containing the T-cell priming antigen (Arny *et al.*, 1984). Similarly, in another study, this group of investigators found that (KLH)-specific T-cell clones were capable of inducing IgA responses regardless of their tissue of origin, that is, KLH-induced T cell clones derived from peripheral lymph nodes, spleen, and Peyer's patches all helped (TNP-KLH) primed B cells to produce IgA anti-TNP antibody when the latter were cultured with T-cell clones from these sources and TNP-KLH (Al Maghazachi and Phillips-Quagliata, 1988b). These data, tending to undermine the concept that IgA-specific switch T cells exist in Peyer's patches, are mitigated by the fact that the study design used makes it difficult to distinguish the effects

of T cells on switch differentiation from the effects on terminal differentiation: plaque-forming cell responses were measured and the starting B-cell population contained B cells that already had expressed IgG. Further, a larger fraction of Peyer's patch T-cell clones was found to support high IgA responses than clones from other tissues, and representative Peyer's patch T-cell clones were shown to support IgA but not IgG responses when B cells were stimulated with low doses of antigen. Overall, these attempts to demonstrate IgA-specific switch T cells in Peyer's patches in an antigen-specific system were not fully convincing.

### C. Role of Dendritic Cells in IgA B-Cell Differentiation

At the same time, Kawanishi and colleagues were pursuing the idea that T cells were the key cell in the Peyer's patch necessary for IgA switching, other investigators were pursuing the possibility that the Peyer's patch cell necessary for IgA-specific switching is a dendritic cell. In initial studies of the latter cell type, Spalding and co-workers (1984) showed that mixtures of periodate-activated T cells and dendritic cells (T cell-dendritic cell clusters) derived from Peyer's patches induced either whole spleen or Peyer's patch B-cell populations to produce IgA in amounts that were equal or even greater than that of IgM. In contrast, whereas T cell-dendritic cell clusters from spleen had an equal capacity to induce IgM, they induced 10 to 100-fold less IgA. These data could be explained by the ability of Peyer's patch T cell-dendritic cell clusters to induce terminal B-cell differentiation, since the B-cell population induced did not consist of purified sIgM<sup>+</sup> B cells and may have contained substantial numbers of sIgA<sup>+</sup> B cells. However, Spalding *et al.* (1986) followed these studies with ones in which the capacity of a T cell-dendritic cell clusters to induce a pre-B cell line to switch to IgA was determined. These researchers showed that T cell-dendritic cell clusters obtained from Peyer's patches induced pre-B cells to produce mainly IgA (plus small amounts of IgM and IgG), whereas clusters obtained from the spleen induced the pre-B cells to produce IgM and little or no IgG and IgA. Surprisingly, in these experiments the source of the T cells seemed less important than the source of the dendritic cells: mixtures of Peyer's patch dendritic cells with either Peyer's patch T cells or spleen cells resulted in substantial amounts of IgA secretion (and lesser amounts of IgG or IgM secretion), whereas mixtures of spleen dendritic cells and either Peyer's patch or spleen T cells, resulted in mainly IgM secretion. Thus, Spalding and co-workers suggested that either the dendritic cell rather than the T cell was the cell in Peyer's patches critical for IgA switch differentiation or the Peyer's patch dendritic cell was necessary for the activation of T cells in a manner that endows the latter with IgA switch capability.

Additional studies on the role of dendritic cells in IgA B-cell switch differentiation were performed by Cebra and colleagues. In these studies, Peyer's patch B-cell populations

were primed with an antigen, enriched for cells responding to the antigen, and cultured at limiting dilution in the presence of priming antigen, dendritic cells, and conalbumin-activated T cells of the clonal T-cell line D10, a T<sub>H</sub>2-type T cell responsive to conalbumin (George and Cebra, 1991). These investigators found that, whereas B cells cultured with T cells alone gave rise to a small number of clones that produce only IgM antibodies, B cells cultured with T cells plus dendritic cells gave rise to clones that produced IgG and IgA antibody as well as IgM antibody (including clones producing only IgA or only IgG antibody). Moreover, additional studies showed that dendritic cell–T cell mixtures could induce purified sIgD<sup>+</sup> B cells to give rise (again under limiting dilution conditions) to clones producing mixtures of immunoglobulins, including IgA. Although these studies appear to show that dendritic cell–T cell mixtures do indeed induce isotype switching (IgA as well as IgG), the magnitude of the switch is unclear since the measurement was of the percentage of clones giving rise to IgA secretion and not the percentage of sIgA<sup>+</sup> B cells. Under these conditions, low levels of IgA switch differentiation would be considered a positive indicator for switching.

One key difference between the study by Cebra and colleagues and the earlier work by Spalding and colleagues is that, in the Cebra studies, the dendritic cell–T cell clusters inducing IgAB-cell differentiation could be derived from either the Peyer's patch or the spleen whereas, in the Spalding studies, they could be derived only from the Peyer's patch. Cebra and colleagues reasoned that this critical difference is explained by the assumption that, in the Spalding studies, the dendritic cells taken from Peyer's patches had been activated by environmental antigens (prior to isolation) and therefore were able to induce T-cell activation, whereas dendritic cells from spleen were not so activated and did not induce T-cell activation. On the other hand, in the Cebra system, antigen was added to the cultures so both spleen and Peyer's patch dendritic cells were equally stimulatory. Note, however, that this explanation of the Spalding observation fails to give an explanation for why IgA switch differentiation does not occur in the spleen during the course of an infection.

#### **D. Role of TGFβ and Other Switch Factors in IgA B-Cell Differentiation**

One question that might be raised in relation to the role of either T cells and dendritic cells in IgA B-cell differentiation is whether either of these cell types acts via a switching factor. In the earlier studies of Kawanishi *et al.* (1983), a factor inducing IgA B-cell differentiation was not found in supernatants of cloned Peyer's patch T cells, nor was IgA switch factor found in T cell–dendritic cell cluster supernatants by Spalding *et al.* or Cebra *et al.* On one hand, Spalding and colleagues emphasized that T cell–dendritic cell clusters required direct contact with B cells to achieve their effects and on the other hand, Phillips-Quagliata *et al.* did obtain evidence for the presence of an IgA switch factor (Al Maghazachi and Phillips-Quagliata, 1988a). Phillips-Quagliata and

co-workers identified at least one Con A-stimulated clonal T-cell population that produced a factor that helped IgG and IgA responses but not IgM responses (Al Maghazachi and Phillips-Quagliata, 1988a). Curiously, although this clone induces B-cell differentiation, it fails to induce B cell proliferation. This observation raises an interesting question regarding the relationship of switch differentiation to B-cell proliferation.

Far more solid evidence for the presence of an IgA switch factor came with the demonstration by two groups that TGFβ could induce LPS-activated mouse splenocytes to switch from IgM to IgA production (Coffman *et al.*, 1989; Sonada *et al.*, 1989). In the relevant studies, these investigators showed that TGFβ augmented LPS-induced IgA production 10-fold or more, particularly in cultures also containing terminal differentiation factors such as IL-5 and IL-2. Thus, while IgA constitutes only 0.1% of the total Ig produced by LPS-stimulated B cells cultures in the absence of TGFβ, the percentage increases to 15–25% in LPS-stimulated cultures containing TGFβ plus IL-2. This striking finding in murine B-cell systems was confirmed by others (Kim and Kagnoff, 1990; Lebman *et al.*, 1990a,b; Ehrhardt *et al.*, 1992) and, in addition, was extended to human B-cell systems (Islam *et al.*, 1991; Nilsson *et al.*, 1991; Defrance *et al.*, 1992; van Vlasselaer *et al.*, 1992), in which B cells were stimulated with pokeweed mitogen in the presence of CD4<sup>+</sup> T cells.

From the outset, strong evidence was presented that this TGFβ effect is manifest at the level of isotype switch differentiation rather than terminal differentiation. First were the findings that TGFβ acts on sIgA<sup>-</sup> B cells rather than sIgA<sup>+</sup> B cells and that TGFβ increases the frequency of B-cell clones secreting IgA rather than the number of IgA B cells per clone. Second came evidence that TGFβ induces the production of Cα germ-line transcripts which, as noted earlier, is an early molecular step in the IgA switch process. Third, and finally, was the observation that TGFβ has no selective effect on B-cell viability and produces its maximal effect on IgA production if added early in the culture period and then removed isotype; and, in fact, TGFβ inhibits IgA production by already switched IgA<sup>+</sup> B cells (Kim and Kagnoff, 1990; Ehrhardt *et al.*, 1992). Collectively, these data establish beyond question that, under *in vitro* conditions, TGFβ does act as an IgA switch factor. The data fall short, however, of providing a clear picture of the role of this cytokine in overall IgA B-cell differentiation as it occurs *in vivo*. To approach this more fundamental question, such issues as the precise stage of B-cell differentiation at which TGFβ acts, its class and, tissue specificity, the magnitude of its effect, and, finally, its collateral properties must be explored more completely.

With respect to data on the stage of B-cell development at which TGFβ acts, the fact that this cytokine induces Cα germ-line transcripts in sIgM<sup>+</sup> B cells localizes the effect to an early stage of IgA switch differentiation. This early action does not necessarily imply, however, that TGFβ initiates IgA switch differentiation since, as discussed at some length previously, the first step of isotype differentiation involves the processes that lead to an increase in the accessibility to

transcriptional enzymes of the regions 5' to  $C_H$  genes rather than to germ-line transcription, the latter being viewed as a secondary event. Data on whether  $TGF\beta$  can induce  $C\alpha$  accessibility (as well as  $C\alpha$  germ-line transcription) is equivocal at best (Lebman *et al.*, 1990a,b; Islam *et al.*, 1991; Nilsson *et al.*, 1991; Lin and Stavnezer, 1992). In murine systems, studies of  $TGF\beta$  switch effects on normal B cells always have been conducted in the presence of a B-cell stimulant such as LPS, leaving open the possibility that the B-cell stimulant induces  $C\alpha$  accessibility (albeit at a low level) and that the action of  $TGF\beta$  is limited to its effect on  $C\alpha$  germ-line transcription occurring after induction of  $C\alpha$  accessibility. In this context, the accessibility induced by the B-cell stimulant is assumed to be nonspecific with respect to Ig class and, indeed, may relate to all Ig classes; thus, the fact that  $TGF\beta$  seems to have a specific effect on IgA switching could arise from the fact that it has an Ig-specific effect on  $C\alpha$  germ-line transcription. Also relevant to the discussion of whether  $TGF\beta$  induces  $C\alpha$  accessibility in murine B-cell systems is the fact that  $TGF\beta$  does not induce CH1 B cells, a murine lymphoma sIgM<sup>+</sup> B-cell line that is not demethylated at the  $C\alpha$  locus (i.e., does not have an accessible  $C\alpha$  locus), to produce  $C\alpha$  germ-line transcripts or to secrete IgA (Whitmore *et al.*, 1990). However, CH1 B cells may be inherently unswitchable, as are most immortal B-cell lines.

Data on human B cells are similar to those on murine B cells. Again, the effect of  $TGF\beta$  effects on  $C\alpha$  germ-line transcription were evaluated on resting sIgA<sup>-</sup> B cells with a sensitive reverse transcriptase-polymerase chain reaction (RT-PCR) assay; researchers found that, whereas induction of  $C\alpha 1$  germ-line transcription required  $TGF\beta$  plus mitogen, induction of  $C\alpha 2$  transcription required only  $TGF\beta$  (Islam *et al.*, 1991). Thus, in this instance  $TGF\beta$  may act as a factor inducing both accessibility and germ-line transcription.

A final possibility relative to  $TGF\beta$  effects on early molecular events of IgA switch differentiation is that, although  $TGF\beta$  induces some level of  $C\alpha$  accessibility, this effect is marginal and, in any case, subordinate to its effect on  $C\alpha$  germ-line transcription. Indirect evidence for this hypothesis comes from studies of CH12.LX B cells, a sIgM<sup>+</sup> lymphoma B-cell line mentioned earlier that is demethylated in the  $C\alpha$  locus (i.e., has an accessible  $C\alpha$  gene segment) and undergoes spontaneous switching to sIgA<sup>+</sup> B cells at low frequency (Arnold *et al.*, 1988; Kunimoto *et al.*, 1988). Presumably, such cells are "preswitched" B cells, meaning they have received an initial switch signal that set them on a pathway of IgA B-cell differentiation before they were immortalized. In studies of the effects of cytokines on these B cells, Strober and colleagues have shown that a particular subclone of these cells that switches only to IgA can be induced by LPS and IL-4, LPS and  $TGF\beta$ , or LPS and IL-4/ $TGF\beta$  to increase greatly  $C\alpha$  germ-line transcription and the frequency of switching to IgA (Kunimoto *et al.*, 1988). In this case, whereas the spontaneous switching to IgA B cells is 2%, in the presence of IL-4/ $TGF\beta$  the frequency of switching is 50–70%. These data in addition to data obtained with another preswitched lymphoma B-cell line (I.29), indicate that, although  $TGF\beta$  induction of IgA switch differentiation in normal B cells is modest (see subsequent discussion), this cyto-

kine has a profound effect on already switched B cells, suggesting that the true stage at which this cytokine acts is after the initial switch event (Shockett and Stavnezer, 1991).

Additional studies relative to this point were done by Whitmore *et al.* (1990), who showed that CH12.LX B cell subclones capable of switching to a number of Ig isotypes, but mainly IgA (i.e., clones that differ to some extent from those studied by Kawanishi *et al.*, 1983, which switch only to IgA), are induced by  $TGF\beta$  to switch to various Ig isotypes as well as to IgA and that, in general,  $TGF\beta$  does not affect the relative frequency of IgA switching, only the absolute frequency. Thus,  $TGF\beta$  appears not to have an isotype-specific effect on preswitched B cells and appears to facilitate switching to all isotypes in such cells. This result, in turn, implies that  $TGF\beta$  is a general or non-isotype-specific inducer of germ-line transcription and that its IgA-specific effects on normal B cells are the result of selective antiproliferative activity on non-IgA B cells, as discussed previously. This view is supported by molecular findings that show that  $TGF\beta$ -responsive elements are found in several Ig regulatory regions, not only in the IgA regulatory region, again suggesting that the primary effect of  $TGF\beta$  is on regulation of germ-line transcription rather than on accessibility (Lin and Stavnezer, 1992).

A second consideration relevant to the role of  $TGF\beta$  in isotype switching, one that complements the discussion on the locus of the  $TGF\beta$  effect, relates to the magnitude of this effect. In the earliest studies by Lebman and colleagues relating to the ability of  $TGF\beta$  to affect IgA switching,  $TGF\beta$  was shown to induce only a small fraction of LPS-stimulated sIgM<sup>+</sup> B cells to switch to sIgA<sup>+</sup> B cells (3.2%). From these data one might conclude that, although  $TGF\beta$  does indeed induce IgA switching, it does so only at a minor and nonphysiological rate that is in no way comparable to the rate observed at *in vivo* IgA induction sites, at which the frequency of Ig switching is at the 70–85% level (Butcher *et al.*, 1982). However, LPS is not a physiological B-cell stimulant so one can argue that, when B cells are stimulated in other ways, a more significant  $TGF\beta$ -mediated IgA induction can be seen. To examine this question, Ehrhardt *et al.* (1992) stimulated highly purified sIgM<sup>+</sup>sIgD<sup>+</sup> B cells (containing <0.2% sIgA<sup>+</sup> B cells) in a T cell-independent fashion, that is, with LPS or with anti-IgD-dextran (T cell-independent B cell mitogens), and in a T cell-dependent fashion, that is, with T cells in a cognate interaction (using a T-cell clone that recognized rabbit Ig determinants and B cells treated with IgG rabbit anti-IgM) or in a noncognate interaction (using irradiated anti-CD3-activated T-cell clones in the absence of additional mitogens or antigens), all in the presence and absence of  $TGF\beta$ . These investigators found that, regardless of the method of B-cell stimulation,  $TGF\beta$  induced only a small fraction of B cells (1–3%) to undergo IgA switch differentiation. Note that this low frequency of  $TGF\beta$ -induced switching to IgA contrasts with the high frequency of IL-4-induced switching to IgG (Snapper and Paul, 1987) or, as mentioned, with the high frequency of switching to IgA observed in the germinal centers of Peyer's patches (Butcher *et al.*, 1982). Therefore, we must conclude that  $TGF\beta$  is either a weak, that is, nonphysiological IgA switch signal or, alternatively,

that TGF $\beta$  is a secondary signal that only operates effectively in the context of a more primary signal that prepares cells to respond to TGF $\beta$  with C $\alpha$  germ-line transcripts and switch signals. Of these two views, the latter seems more reasonable in light of the observation already mentioned that high levels of IgA switching (20–70%) can be obtained in cultures of CH12.LX B cells, that is, B cells that are precommitted to IgA switching. However, more physiological methods of inducing high level IgA switch differentiation in normal B cells must be found before this question can be answered definitively.

Note that the magnitude of IgA switch differentiation induced by TGF $\beta$ , as assessed by the appearance of sIgA<sup>+</sup> B cells (2–3%), seems too low to account for the amount of IgA secreted after 7–10 days (20% of total Ig secreted). The reason for this paradox became apparent in studies also conducted by R. Ehrhardt, G. R. Harriman, Y. K. Inman, and W. Strober, (unpublished observations), who stimulated purified sIgA<sup>+</sup> B cells (>95% pure) in a highly efficient fashion to undergo terminal differentiation into IgA-secreting plasma cells by incubating the B cells with T cells in a cognate or noncognate fashion. In this case, an excess of  $2 \times 10^5$  ng IgA were produced per  $10^5$  B cells, indicating that the 2000–6000 ng IgA produced in LPS-stimulated sIgM<sup>+</sup> B-cell cultures containing TGF $\beta$  really does represent the differentiation of only 2–3% of the B cells present. In view of these findings, the TGF $\beta$ -induced switching is quantitatively minor, even if the amount of IgA secreted is considered. In retrospect, this amount was only impressive when TGF $\beta$ -induced IgA secretion was compared with IgA secretion in the absence of this lymphokine.

A third consideration concerning the role of TGF $\beta$  in IgA switch differentiation concerns its overall role in physiological IgA switching as opposed to switching that occurs *in vitro*. More specifically, we must reconcile the fact that IgA B-cell development is site specific, that is, a characteristic of Peyer's patch lymphoid follicles, with the fact that TGF $\beta$  production is widespread and occurs in many, if not all, lymphoid tissues. Thus, although the data indicates that all kinds of lymphoid cells are important producers of this cytokine, no evidence suggests that such production itself creates a situation in which TGF $\beta$  plays a unique role in B-cell development in lymphoid tissues in general or in Peyer's patches in particular. Overall, the most likely conclusion to be drawn from the fact that TGF $\beta$  secretion is widespread, and probably sufficient in many tissues to support IgA switching, is that TGF $\beta$  is best viewed as a cofactor that acts on B cells that already have received signals to commit to IgA switch differentiation.

A final consideration relating to the physiological role of TGF $\beta$  in IgA switch differentiation relates to the inhibitory effect of this cytokine on lymphoid cells. Even before the effect of TGF $\beta$  on IgA switching was known, TGF $\beta$  had been shown to have a profound negative effect on both B- and T-cell proliferation, including LPS-induced B-cell proliferation (Kehrl *et al.*, 1986, 1987, 1991; Wahl *et al.*, 1988; Moses *et al.*, 1990). This suppressive effect was most evident for IgG and IgM secretion, but was seen also for IgA secretion. We have shown that, although TGF $\beta$  clearly enhances LPS-

induced IgA synthesis, such enhancement is obtained most clearly by addition of anti-TGF $\beta$  to the culture 1–2 days after the start of the culture, suggesting that the positive effect of TGF $\beta$  on IgA B-cell switch differentiation can be mitigated subsequently by the negative effect of TGF $\beta$  on B-cell terminal differentiation (Ehrhardt *et al.*, 1992). In addition, in cells activated by other more physiological signals such as cognate or noncognate T-cell interactions, TGF $\beta$  either has no effect on overall IgA secretion or actually inhibits IgA secretion unless anti-TGF $\beta$  is added to the 48-hr cultures. Finally, B cells in cultures containing low doses of TGF $\beta$  (0.1 ng/ml) secrete more than 15 times the amount of IgA than do B cells in cultures containing high doses of TGF $\beta$  (1.0 ng/ml), despite an increase in sIgA<sup>+</sup> B cells in the high-dose TGF $\beta$  cultures. These data, plus the fact that the inhibitory effect of TGF $\beta$  is much more evident in the T-cell activation systems than in the LPS activation system, strongly suggest that IgA secretion is not a sensitive indicator of IgA switch differentiation, especially when B-cell stimulation by a factor other than LPS is used. In general, the presence of TGF $\beta$  in a lymphoid milieu is a double-edged sword. We are prompted to postulate that, if TGF $\beta$  plays a physiological role in IgA B-cell differentiation, that role requires the B cell to receive the TGF $\beta$  signal at a particular induction site (the mucosal follicle) and then to migrate rapidly to another site (the lamina propria) where TGF $\beta$  effects are, attenuated. Finally, note that the capacity of TGF $\beta$  to exert an antiproliferative effect on B cells may be one of the ways in which this cytokine influences IgA switching. The concept applicable here is that TGF $\beta$ , by preventing cells from entering the G<sub>1</sub> phase of the cell cycle while favoring cell–cell interaction via induction of MHC Class II determinant expression (Moses *et al.*, 1990), increases the interval of time that an isotype-nonspecific differentiation signal can be applied without leading to cell division and terminal differentiation. Thus, a greater chance exists that C $\alpha$  accessibility will occur and that other, more IgA-specific differentiation effects can supervene and move the system in favor of IgA B-cell differentiation.

Evidence has appeared that another B-cell differentiation factor, IL-10, also plays a role in IgA B-cell differentiation. In the relevant studies conducted by Banchereau and colleagues, human B cells stimulated with anti-IgM plus anti-CD40 antibody in the presence of TGF $\beta$  and IL-10 were shown to produce impressive amounts of IgA (Defrance *et al.*, 1992). Since, in these studies, IgA secretion rather than the frequency of sIgA<sup>+</sup> B cells was measured, the question remains whether IL-10 is acting as a terminal differentiation factor in this case.

#### IV. OVERVIEW OF IgA B CELL SWITCH DIFFERENTIATION

Having discussed at some length the molecular and cellular factors involved in B-cell isotype differentiation generally, as well as the cellular and humoral factors involved in IgA B-cell switch differentiation particularly, we can draw together various pieces of evidence to create a more-or-less coherent

outline of the processes that govern the emergence of IgA B cells in mucosal tissues.

IgA B-cell differentiation probably can be said to begin when inductive T cells interact with sIgM<sup>+</sup> B cells and initiate the molecular processes that lead to IgA switch differentiation. What are the characteristics of these "switch" T cells? In the first place, these cells are likely to be activated T cells that have gained the ability to bring about IgA switching after antigen-specific interaction with Peyer's patch antigen-presenting cells, (i.e., interdigitating dendritic cells). The working hypothesis here is that the dendritic cells in Peyer's patches unique in their capacity to induce IgA "switch" T cells by some as yet undefined cell-cell interaction or cytokine effect. However, we cannot rule out the possibility that the stimulatory interaction is not unique and that T cells in Peyer's patches are not intrinsically different from cells at other sites.

The bases for saying that a T cell and not a dendritic cell provides the key switch signal to B cells undergoing IgA switch differentiation are several. First, T cells alone seem able to induce isotype switch differentiation under appropriate conditions, whereas dendritic cells alone have not been shown to have this ability (Kawanishi *et al.*, 1983; Mayer *et al.*, 1986). Evidence to the contrary, such as that of Spalding *et al.*, showing that the ability of T cell-dendritic cell clusters to induce IgA switching seemed to be associated with the dendritic cell rather than the T cell, can be explained by assuming that (1) T cells from any tissue can act as IgA-specific switch cells, provided they are activated in an appropriate way, and (2) such activation is brought about by Peyer's patch dendritic cells rather than by spleen dendritic cells, because the former develop in a characteristic way in the mucosal environment. Indeed, in the studies by Cebra and colleagues, Peyer's patch and spleen dendritic cells were able to support IgA switch differentiation to an equal extent, presumably because external stimulation of dendritic cells was provided in this case (Schrader *et al.*, 1990; George and Cebra, 1991).

A second and perhaps more cogent reason to posit the primacy of a T-cell signal in IgA switch differentiation comes from work showing that B-cell switch differentiation, regardless of isotype specificity, occurs more readily during T cell-B cell interactions. Thus, as reviewed earlier, purified sIgM<sup>+</sup>sIgD<sup>+</sup> B cells stimulated with conventional B-cell mitogens such as anti-IgM or SAC (in the presence of TGFβ) have been shown to produce little IgA, whereas the same cells stimulated by one of these mitogens plus anti-CD40 antibody (again in the presence of TGFβ) produce large amounts of IgA (Defrance *et al.*, 1992). These data suggest that T-cell signaling via CD40 is necessary for IgA switch differentiation and that high levels of CD40 ligand expression may, in fact, be one of the defining features of an IgA-specific switch T cell.

Although the CD40 ligand-CD40 interaction may be necessary for IgA switch differentiation, it is almost certainly not sufficient, since little evidence suggests that this interaction does anything more than prepare the cell for "generic" switch differentiation. As reviewed in the discussion on the role of cytokines in switch differentiation, a cytokine with a now

well-described ability to induce IgA switch differentiation under a variety of B-cell activation conditions (Coffman *et al.*, 1989; Sonada *et al.*, 1989; Kim and Kagnoff, 1990; Leberman *et al.*, 1990a,b; Islam *et al.*, 1991; Ehrhardt *et al.*, 1992). However, in suggesting TGFβ as the directing cytokine in IgA B-cell switch differentiation, at least two caveats must be remembered. First, the magnitude of IgA switch differentiation induced by TGFβ, including that induced in B cells activated by T cells via a CD40 ligand-CD40 interaction, is quite modest (≤3%). Second, TGFβ is secreted in many tissues in addition to the Peyer's patches, so this cytokine hardly can account for the unique relationship between Peyer's patches and IgA B-cell development. Based on these caveats, TGFβ is best looked on as a cofactor in IgA switch differentiation that acts opportunistically on sIgM<sup>+</sup> B cells in Peyer's patches while the latter are receiving additional IgA-specific switch signals. The concept that TGFβ plays only a limited role in IgA switch differentiation leaves us with the necessity of considering other possible switch T-cell influences that account for the large-scale IgA switch differentiation actually observed in Peyer's patches. Such other influences could involve as yet undefined cell-cell interactions that are accessory to the CD40 ligand-CD40 interaction or to other cytokines.

Another point to consider in relation to other possible IgA switch differentiation signals is that these signals may consist of an inhibitory signal that negatively regulates switching to more 3' C<sub>H</sub> genes, rather than an enhancing signal that positively regulates C<sub>α</sub> switching. At the moment, support for this inhibition mechanism of IgA switching is scant. One piece of evidence is that the switch T-cell clones identified by Kawanishi *et al.* (1983), despite being capable of inducing high frequency IgA switch differentiation, fail to induce IgA secretion. Similarly, although TGFβ suppresses IgA secretion (as well as IgA and IgM secretion), at the same time it induces IgM B cells to undergo switch differentiation to IgA (Ehrhardt *et al.*, 1992).

So far in this discussion, we have assumed that the B cell acted on initially by switch T cells is a completely unswitched sIgM<sup>+</sup> B cell that does not have accessible regions 5' to the C<sub>α</sub> gene and does not produce C<sub>α</sub> germ-line transcripts. At this point, however, we also should consider the possibility that the B cells acted are, in reality, B cells that are partially committed to IgA switch differentiation (i.e., partially switched B cells) and, thus, are capable of responding to "switch" signals with high-frequency IgA switching. One fact in favor of this concept is that partially switched B cells already exist in the form of several B-cell lymphoma lines such as CH12.LX B cells and I.29 B cells (Arnold *et al.*, 1988; Kunitomo *et al.*, 1988; Shockett and Stavnezer, 1991). As described earlier, these B cells are largely sIgM<sup>+</sup> B cells that spontaneously switch to sIgA<sup>+</sup> B cells at a low rate. In keeping with this fact, they have accessible regulatory regions 5' to the C<sub>α</sub> gene segment and continually are synthesizing C<sub>α</sub> germ-line transcripts. Other properties of these CH12.LX cells that are germane to this discussion are that (1) in undergoing isotype switch, they appear to become dual-positive sIgM<sup>+</sup>sIgA<sup>+</sup> B cells that have not yet rearranged their productive C<sub>H</sub> genes (and thus still retain the C<sub>μ</sub> gene segment),

and (2) CH12.LX B cells, in contrast to normal sIgM<sup>+</sup> B cells, respond to TGFβ (and, to a lesser extent, to IL-4) with high-frequency switch to sIgA<sup>+</sup> B cells. Thus, as indicated earlier, such precommitted cells are much more responsive to the switch impetus of TGFβ than are normal sIgM<sup>+</sup> B cells.

If we consider these partially switched B-cell lines models of B cells in Peyer's patches that are capable of responding to IgA-specific switch signals, we can postulate that partially switched B cells of this kind initially develop in bone marrow during the course of VDJ gene arrangement, possibly as a result of intracellular conditions occurring during this process. These cells, although still expressing surface IgM or perhaps expressing sIgM and sIgA, then migrate to Peyer's patches as a result of as yet poorly understood cell homing patterns. Alternatively, they migrate to many or most lymphoid organs, but only receive a secondary switch signal in Peyer's patches. The main evidence for this hypothesis, already alluded to previously, is that the partially switched B cells (of the CH12.LX type) respond with greater alacrity to TGFβ than do normal sIgM<sup>+</sup> B cells. Another kind of evidence relates to the fact that, to date, demonstrating high-frequency IgA switch differentiation *in vitro* has been difficult, possibly because, in the studies conducted to date, the subpopulation in Peyer's patch B cells that is susceptible to switching has not been identified. Relevant here is the fact that the switch T-cell clone studies by Kawanishi and colleagues caused 3–4 times more switching of Peyer's patch B cells than of spleen B cells, suggesting that B cells in the patches may be more "switchable" than B cells in the spleen (Kawanishi *et al.*, 1982,1983). Finally, the idea that IgA switch differentiation is initiated in the bone marrow is favored by the fact that mature IgA B cells are unusually plentiful in human and mouse bone marrow. More study of Peyer's patch B-cell populations for evidence of the presence of an "immature" partially switched B-cell population is necessary to bring this theory to more serious consideration.

In summary, this discussion has emphasized that, although we can be reasonably sure that IgA switch differentiation requires the influence of a T cell as well as the probable influence of one or more isotype-directing cytokines, much is still unknown about this differentiation process. In particular, whether the B-cell target is an uncommitted B cell or a B cell partially committed to IgA switch differentiation and whether additional as yet undefined cytokines or cell–cell interactions are necessary for either of these targets to become fully differentiated IgA B cells is still unknown. Further studies using newer *in vitro* culture techniques and cells from different lymphoid sites are necessary to decide these issues.

# Diversity and Function of Antigen-Presenting Cells in Mucosal Tissues

Asit Panja · Lloyd Mayer

## I. OVERVIEW OF ANTIGEN PRESENTATION

The most important feature of the immune system is its ability to distinguish between self and nonself. The network of defense against nonself is maintained by an intricate communication system between specialized cells that are stationed throughout the body. These cells, T and B lymphocytes, interact to fight off foreign pathogens that gain access to the host. T cells and B cells possess specialized receptor molecules on their surfaces that are capable of recognizing and responding to foreign antigens, B cells by their surface immunoglobulin and T cells by their antigen receptor. Surface immunoglobulin (sIg) is capable of binding to antigen (Ag) in solution. However, unlike B cells, T cells can interact only with antigen that is cell bound and presented in association with products of the major histocompatibility complex (MHC) on an antigen-presenting cell (APC) (Ziegler and Unanue, 1981). One group of MHC glycoproteins, known as Class I molecules, arms the immune system to help eradicate cells that have been altered secondary to infection or malignant degeneration. These molecules are expressed on virtually all nucleated cells in the body. The other group of MHC glycoproteins, known as Class II molecules, binds processed peptides that had been taken up exogenously by APCs and presents them to helper T cells. In peripheral blood, lymph nodes, and spleen, helper T cells ( $CD4^+$ ) recognize antigen bound to MHC Class II molecules on macrophages and B cells. Cytotoxic T cells ( $CD8^+$ ), on the other hand, are restricted to recognizing antigen bound to MHC Class I molecules.

Given the general characteristics of this system, we must realize that regulation of immune responses depends on the nature of antigen handling by the APCs through appropriate cellular and molecular mechanisms.

### A. Types of Antigen-Presenting Cells

Several distinct cell types have been documented to function as APCs for T-cell activation (Rosenthal and Shevach, 1973; Nussenzweig and Steinman, 1980; Ziegler and Unanue, 1981; Pober *et al.*, 1983; Geppert and Lipsky, 1985). Although most of our knowledge is limited to *in vitro* systems, clearly differences exist among various APCs relating to their mecha-

nism(s) of antigen presentation as well as to other accessory functions. Monocytes and macrophages are the principal APCs located in blood, lymph nodes, spleen, and interstitium. These cells are large, with active lysosomes, endosomes, and hydrolytic enzymes. These phagocytes are not only vital for the initiation of immune responses, but also play a crucial role in T-cell activation through their ability to produce potent accessory cytokines. B cells, apart from their major function as antibody-producing cells, also possess phagocytic capacity, most effectively via interaction of specific Ag with sIg receptors. When antigen is encountered by sIg on the B cell, the antigen is internalized in an endocytic vacuole and subsequently processed and presented, complexed to MHC Class II determinants, to the helper T cell. This activated T cell in turn secretes the necessary cytokines required for B cells to become antibody-producing plasma cells. Steinman and Cohn (1973) described a novel cell isolated from the mouse spleen that appears to be one of the most potent APCs—the dendritic cell. Distinct from the macrophages and B cells, dendritic cells are irregularly shaped cells with abundant Class II antigens but no Fc receptors (Steinman and Nussenzweig, 1980). These cells are potent stimulators in a mixed lymphocyte reaction and, on a cell per cell basis, are probably the most effective APCs described to date. Dendritic cells are not phagocytic and therefore require accessory cells to process proteins into peptides that can complex with MHC molecules. These cells are ubiquitous, however, and are found within lymph nodes, spleen, thymus, and the gastrointestinal tract. Depending on location, dendritic cells are part of a family of APCs that promote local immune responses. In the skin, these are the classical Langerhans cells; in the gut, they are represented by the “veiled cells” in the Peyer’s patch (see subsequent discussion).

These three cell types (B cells, monocytes, dendritic cells) constitute the group termed the “professional APCs,” since they express Class II molecules, typically process and present Ag to T cells, and, as will be described, provide the conventional accessory signals required for T-cell activation. However, several investigators have described other cells capable of expressing Class II molecules (when activated) and presenting peptides to T cells. However, the results of T-cell interactions with these “nonprofessional APCs” are quite distinct from the interactions described previously. Ac-

tivated human T cells are such a cell type that can express Class II molecules (Lanzavecchia *et al.*, 1988; Siliciano *et al.*, 1988). These cells are capable of taking up, processing, and presenting human immunodeficiency virus (HIV) gp120 protein to other T cells and presenting mouse monoclonal antibodies (mAbs) against the T-cell receptor (TcR), CD3, CD4, and CD8 molecules that bind to the T cell surface. However, in contrast to professional APCs, activated T cells are unable to present soluble antigen (e.g., tetanus toxoid) (Lanzavecchia *et al.*, 1988) and generally result in the induction of anergy (La Salle *et al.*, 1992). Class II Ag expression has been induced on fibroblasts, endothelial cells, and a variety of epithelial cells and, although the Class II molecules can be recognized by the T-cell receptors, these cells are either poorly stimulatory or evoke a unique type of immune response. The neoexpression of Class II molecules on epithelial cells in the thyroid or the pancreatic islets has been invoked to explain the induction of autoimmunity (Botazzo *et al.*, 1983; Piccinini *et al.*, 1987), with the presentation of self peptides to previously tolerized self-reactive T cells. Clearly this area of research is growing rapidly, and our knowledge base relating to the regulation of immune responses using such cells is expanding. One such cell, the intestinal epithelial cell, is described in greater detail in a subsequent section.

## II. MECHANISMS OF ANTIGEN UPTAKE

For foreign antigen to be placed into a form that can be recognized by the T-cell Ag receptor, it must be taken up and processed within intracytoplasmic organelles. Mechanisms of antigen uptake include those that are nonspecific, random, and therefore less efficient and those mediated by receptor interactions, which have higher efficiency. First we discuss receptor-mediated uptake, which is different for various APCs.

### A. sIg-Mediated Uptake of Antigen

Antigen uptake by B cells was reported first by Chesnut and Grey (1981). In this study, these investigators demonstrated the capacity of rabbit IgG-specific B cells to present processed rabbit IgG to T cells. Clearly this way of generating a specific immune response is extremely effective. If antigen-specific B cells are presenting to antigen-specific T cells, help for clonal growth or differentiation (specific or nonspecific) can be focused on these activated B cells. In such an antigen-driven system, the requirement for high concentrations of antigens needed to activate T cells would be less. Studies by Rock and colleagues (1984) have demonstrated that hapten-specific B lymphocytes are extremely efficient at presenting hapten to T cells via hapten binding to surface Ig molecules. In contrast to the nonspecific antigen uptake by B cells, maximal stimulation of responding T lymphocytes can be achieved with a minimum of antigen (Chesnut *et al.*, 1982). Thus, within a lymph node, antigen carried to the primary

follicles may interact with sIg on B cells and be presented as peptides to parafollicular T cells.

### B. Fc Receptor-Mediated Antigen Uptake

With the exception of dendritic cells, which are nonphagocytic, all professional APCs express Fc receptors (FcR). These receptors are specific for distinct Ig isotypes and vary in their ability to bind immune complexes. FcR appears to play a major role in the immune response by facilitating antigen uptake after binding to an immune complex. In this respect, initial evidence was provided by Cohen and co-workers (1973), who showed that cytophilic antibodies in the serum of immune animals could enhance the antigen-presenting capacity of naive macrophages. Further, a similar phenomenon was demonstrated by Celis and Chang (1984), documenting that the presence of FcR<sup>+</sup> APCs could reduce 10- to 100-fold the concentration requirement of hepatitis B virus surface antigen (HBsAg) to trigger an HBsAg-specific T-cell clone. This phenomenon was supported further by studies by Kehry and Yamashita (1990), in which they described that presentation of trinitrophenol (TNP) carrier conjugates by mouse B cells could be enhanced 100- to 1000-fold if TNP-specific IgE is bound to FcεRII on mouse B cells.

### C. Uptake by Complement Components

Complement is the clearest example of the incorporation of the innate (nonspecific) immune system with adaptive (specific) immunity. Bacterial products can trigger the alternative pathway of complement activation, resulting in the generation of C3b fragments. C3b fragments coat bacteria, rendering them accessible to complement receptors on B cells and monocytes. Thus, in the absence of an adaptive immune response (i.e., antibody), bacteria can be opsonized by macrophages, processed, and presented to T cells, initiating a specific immune response.

Immune complexes also can bind complement (IgG and IgM), and therefore be susceptible to uptake through C3b receptors. Studies by Daha and van Es (1984) demonstrated, in a guinea pig model, that receptors for C3b are present on red blood cells, which seem to bind complement-coated immune complexes and deliver them to the Kupffer cells in the liver. Arvieux and colleagues (1988) showed that triggering of tetanus toxoid antigen-specific T cells by Epstein-Barr virus (EBV)-transformed B cells can be enhanced by binding C3b or C4b components to the antigen. Thus, through a number of interactions, complement can play an important role in Ag uptake.

### D. Antigen Uptake by Phagocytosis

To this point we have discussed specific mechanisms for antigen uptake, yet a very important mechanism is the one that occurs before any immune response has been generated—nonspecific phagocytosis. As the term suggests, B cells and monocytes can sample their environment by engulfing macromolecules through pinocytosis or by uptake of molecules in clathrin-coated pits. By either mechanism, the

process is relatively inefficient; only a small fraction of the antigen is taken up. However, by any of these processes, Ag is incorporated into the endosomal compartment, where processing begins in an effort to generate a specific response.

### III. MECHANISMS OF ANTIGEN PROCESSING

As mentioned in the introduction, antigens must be processed before they are presented to and recognized by T cells. Conventionally, APCs (monocytes, B cells) internalize exogenous antigens through phagocytosis (a phenomenon first described by Metchnikoff in 1884) as described earlier. Within the endosome, limited proteolysis results in the generation of fragments that subsequently are expressed on the cell surface in combination with MHC Class II molecules (Germain, 1986). Endogenous Ags (viral proteins) utilize a distinct pathway described subsequently and typically associate with Class I molecules.

The numerous steps and mechanisms of these cytosolic phenomena (processing) are not completely understood. The endosomal compartment develops an acidic pH that facilitates proteolytic enzyme activity that digests pinocytosed material (Braciale *et al.*, 1987). After digestion in the endosome, the antigen fragments have one of two fates: they can bind to Class II molecules in multivesicular bodies and be recycled back to the membrane as a complex or the endosome can fuse with a lysosome, resulting in further proteolysis and loss of immunogenicity or potential recycling to the surface. The signals that direct the choice of one pathway or the other are unknown. However, Class II molecules produced in the Golgi are associated with a third chain, the invariant chain (Cresswell, 1992). This chain stabilizes the Class II molecule so it can exit the Golgi, but will dissociate in an acidic compartment allowing peptide to bind to the MHC molecule. Once dissociated, the Class II molecule is targeted to the surface. Fusion of multiple endosomes or Golgi vesicles with endosomes forms multivesicular bodies that may be important in signaling recycling.

Peptides generated by processing associate with the antigen-binding groove in the MHC. Typically, for macrophage- and B cell-derived peptides, these peptides between 8 and 14 amino acids in length (Sette and Grey, 1992). Thus, potential differences in processing machinery may alter the types of immune response generated. Association of peptides with MHC Class I molecules is different than association with Class II. Class I molecules formed in the endoplasmic reticulum (ER) associate with cytoplasmic peptides that are carried to the ER by peptide transporters (Monaco, 1992). Peptides of shorter length (compared with Class II MHC) are generally the rule (8 to 10-mers) (Braciale, 1992). Class I-peptide complexes traffic to the membrane, where they can be recognized by TcRs on CD8<sup>+</sup> T cells. One additional intracytoplasmic transporter has been identified that may be relevant in the gastrointestinal tract. The family of heat-shock proteins bind peptides and can transfer these peptides to Class I (and maybe Class II) molecules within the cell (Vanbuskirk *et al.*, 1989).

### IV. ANTIGEN-PRESENTING CELLS PRESENT IN THE MUCOSAL TISSUES

Because of differences in the antigenic microenvironments of the different organs, the responsibilities of the local immune systems also must be different. To coordinate these diverse responsibilities, the mechanisms of antigen handling also must be diverse. Among the mucosal tissues, the intestinal mucosa is the largest and is exposed continuously to food antigens, viruses, bacteria, parasites, or the by-products of these organisms. For this reason, it is appropriate that antigen presentation, interactions between immunocompetent T cells and APCs, and other immunological phenomena also are very specialized.

Although other mucosal sites (lung, bladder) also are exposed chronically to Ag, the volume of antigens is much less. Therefore, let us first discuss mechanisms of antigen entry into the gastrointestinal mucosa. Early reports suggested that specialized epithelial cells, M cells, were responsible for antigen handling in the gut. M cells are believed to derive from epithelial cells and reside over Peyer's patches (Shimizu and Andrew, 1967; Wolf and Bye, 1984). Some variability has been seen in the reports that these cells express Class II molecules on their surface (Bjerke and Brandtzaeg, 1988; Bland and Kambarage, 1991). Large particulate Ags seem particularly well suited for uptake by M cells (Owen, 1977) and some viruses bind to M cells via a specific receptor (e.g., poliovirus, reovirus III) (Wolf *et al.*, 1981; Sicinski *et al.*, 1990). However, the number of M cells in the intestine is limited when compared to the vast array of immunogenic substances encountered in the lumen. M cells appear to transport antigen by transcytosis without any processing of the antigen (Owen *et al.*, 1986), so the immune response relies on macrophages lying below the M cells. Major evidence for this concept has been provided by the studies of Owen and Jones (1974) documenting that these cells lack lysosomes, an important source of proteolytic enzymes in their cytoplasm.

The transport of large macromolecules has been demonstrated clearly by many researchers. Although controversy exists over whether M cells express Class II molecules (Hirata *et al.*, 1986; Bjerke and Brandtzaeg, 1990), the general feeling is that these cells do not interact with T cells in the lamina propria. Instead, antigens pass through in pinocytotic vesicles untouched or unprocessed. One group of investigators has documented the presence of acidic vesicles (lysosomes?) in these cells, but formal proof is still required (Allen *et al.*, 1992). M cells predominate in the small bowel, where Ag entry is greatest, but also exist in the colon and rectum. In fact, some investigators have suggested that these cells may be the site of entry for HIV (Lehner *et al.*, 1991).

The next obvious question is what happens to Ag after passage through the M cell. This question raises the issue of the role of macrophages in the gastrointestinal tract. Macrophages are quite heterogeneous, and subpopulations localize to distinct areas in the gastrointestinal tract, where they express different functional properties. Much of the information regarding intestinal macrophages comes from immunohistochemical studies, unfortunately with some degree of dispar-

ity. However, the disparate findings can be explained. Most studies come to a general consensus on location and functional properties. Researchers generally agree on the location of intestinal macrophages: the villous core of the small bowel, the subepithelial space in the crypt, under the dome (M cell) epithelium overlying Peyer's patches, and in the patch itself (Golder and Doe, 1983; Selby *et al.*, 1983; Winter *et al.*, 1983; Berken *et al.*, 1987; Harvey and Jones, 1991). Most groups report that macrophages are greater in number in the small bowel, underscoring a role in Ag sampling, detoxification via release of chemical mediators (superoxides, etc.), and scavenging of potentially harmful substances (with possible release into the lumen). This latter point has been suggested by the finding of large amounts of carbon particles in carbon-fed mice within subepithelial macrophages, and little free carbon elsewhere (including the patch) (Joel *et al.*, 1978). Several types of material have been found within macrophages, including DNA from damaged cells (Sawicki *et al.*, 1977). Colonic macrophages may be increased because of the numbers of enteric Ags that pass through or between the epithelium.

With respect to M cell transport of Ag, subepithelial macrophages take up the transported Ag and presumably "carry" it to the Peyer's patch. The actual transfer of Ag has not been elucidated, especially since the number of macrophages within the patch is limited and Ag transfer has never been visualized. Within the villous core, the observations have been more clear. Macrophages reside near plasma cells in the subepithelial layer. Non-M cell-transported Ag may be processed and presented by the macrophage, although formal proof of this behavior is required. Macrophages in the small and large bowel have been reported to be suppressive, secreting prostaglandin E<sub>2</sub> (PGE<sub>2</sub>), and inhibiting immune responses (Pavli *et al.*, 1990) in a manner similar to alveolar macrophages (in a mixed lymphocyte reaction). These cells do express nonspecific esterase and acid phosphatase, consistent with conventional APCs, but the level of expression is lower than that of peripheral monocytes in some studies (Mahida *et al.*, 1989). These enzymes, however, render the cells functional as APCs.

Functionally, gut macrophages are also quite heterogeneous. Generally, they are poorly adherent to plastic although this characteristic may relate to isolation by Ficoll-hypaque (Verspaget and Beeken, 1985). These cells do adhere to fibronectin-coated plates, however, and can be enriched by this method. Gut macrophages express FcR and take up immune complexes (coated red blood cells, toxin-antitoxin complexes). Phagocytosis can stimulate the respiratory burst, which is less active than that of peripheral monocytes but present nonetheless. Finally, these cells produce complement components C3 and C4 and express complement receptors. However, as stated earlier, they may be suppressive in mixed lymphocyte reactions; macrophages within the patch are poorly stimulatory (Le Fevre *et al.*, 1979). This latter point is important because, with the potential for a large antigen load in the patch, priming but not active immune response is consistent with the histology of the patch, which differs from a reactive lymph node. Thus, in summary, much is still unknown about intestinal macrophages. Our knowl-

edge has been limited by the lack of good reproducible methods for purification of large populations of these cells, coupled with the marked heterogeneity evident within the gut.

If the macrophages do not play a key role in immune responses in the gut, what cell fills this role? As discussed earlier, the most potent APC described to date is the dendritic cell. For these cells too, we are hampered by heterogeneity—interdigitating cells in the lymph node, Langerhans cells in the skin, and so on all fall into this category. Two populations of dendritic cells have been described in the gut. The classical dendritic cell is esterase negative, acid phosphatase negative, FcR negative, fibronectin nonadherent, and strongly DR positive with dendritic extensions that are actively involved in T-cell interactions (Sminia and Jeunssen, 1986; Nahida *et al.*, 1988; Marsetyawan *et al.*, 1990; Bland and Kamarage, 1991). This type of dendritic cell, also called the "veiled cell" in the gut, is found in the lamina propria throughout the small bowel, predominantly in subepithelial tissue. Functionally, these cells are potent stimulators of the mixed lymphocyte reaction (MLR; Mahida *et al.*, 1988). A second type of dendritic cell is the interdigitating cell found in Peyer's patches. These cells, isolated by several groups, are effective APCs but, interestingly, in one study appear to promote IgA-specific responses [possibly related to transforming growth factor  $\beta$  (TGF $\beta$ ) production] (Spalding and Griffith, 1986; Spalding *et al.*, 1984). These cells likely prime the Ag-specific response in the patch and generate IgA-specific responses. However, these cells fail to explain the dichotomy of immune responses in the gastrointestinal tract (active immunity vs. tolerance).

We are, therefore, left with one cell (B cells have not been studied carefully for their APC function in the gut) that has been proposed as a major player in antigen presentation in the gut—the intestinal epithelial cell (IEC). Several groups studying different model systems have documented that intestinal epithelium, especially in the small bowel, constitutively expresses Class II molecules (Wiman *et al.*, 1978; Mason *et al.*, 1981; Selby *et al.*, 1981; Kaiserlian *et al.*, 1990; Mayer *et al.*, 1990). Further, subsequent studies revealed that these cells could function as APCs, processing and presenting Ag to primed T cells (Bland and Warren, 1986a,b; Mayer and Shlien, 1987; Kaiserlian *et al.*, 1989). However, the unique feature is that these cells appear to activate CD8<sup>+</sup> suppressor T cells selectively by direct activation (Bland and Warren, 1986a,b; Mayer and Shlien, 1987) or by suppression by soluble factors (PGE<sub>2</sub>) (Santos *et al.*, 1990). Such findings concur with the phenomenon of oral tolerance, in which the mechanisms of suppressor cell activation were previously unclear. However, epithelial cells are capable of stimulating CD4<sup>+</sup> T cells as well (Kaiserlian *et al.*, 1989; Mayer and Eisenhardt, 1990) via classical Class II-mediated pathways. Under most circumstances, suppression would predominate whereas in other situations (e.g., inflammatory states), helper T cell activation could occur.

The expression of Class II molecules by IECs has been somewhat controversial. Although researchers generally agree that small bowel IECs constitutively express Class II molecules, identification of these molecules on colonocytes has been more variable. With sensitive techniques, Class II

molecules can be detected with expression that may be patchy. Expression appears to relate to the presence of intraepithelial lymphocytes (IELs) (Cerf-Bensussan *et al.*, 1984) and is enhanced in states in which interferon  $\gamma$  is produced or passively administered (Quyang *et al.*, 1988; Steiniger *et al.*, 1989; Masson and Perdue, 1990; Zhang and Michael, 1990). The distribution of Class II molecules on the IECs is also of interest. Presumably because of the overlapping membranes on the microvillous border, Class II molecules are highly expressed on the luminal side. Intuitively, this situation makes little sense since cell interactions (i.e., T cell-IEC) do not occur in the lumen. However, Bland (1990) has suggested that the Class II molecules may serve as "peptide receptors" for predigested (or preprocessed) peptides that result from proteolysis within the stomach and upper small bowel. Peptides bound to Class II molecules then would be internalized and presented to lamina propria T cells (via fenestrations in the basement membrane) or even potentially to IELs.

Several unresolved issues remain. The first relates to the ability of IECs to take up and process large macromolecules into a form recognized by the TcR. Small di- and tripeptides (predigested) are taken up by IECs, but little evidence exists for larger macromolecular transport. However, some data suggest that at least malignant epithelial cell lines take up large proteins (tetanus toxoid, transferrin) and incorporate them into multivesicular bodies (L. P. So, K. Pelton, G. Small, and L. Mayer, unpublished observations). Bland and colleagues have shown that rat IECs take up ovalbumin, but processing is limited; fixed conventional APCs fail to present IEC-processed Ags (suggesting that distinct peptides are generated; Bland and Whiting, 1989). Further, the I-E molecules expressed on murine IECs may be altered, potentially reducing the potency of these molecules as restriction elements.

A second major issue is the fact that a Class II molecule-bearing cell stimulates CD8<sup>+</sup> T cells, especially if one assumes that IECs are stimulating IELs (typically CD8<sup>+</sup>). The data on this topic are only now becoming available; some suggest a non-class II-CD8 interaction between IECs and T cells (Mayer *et al.*, 1990), and potentially a nonclassical Class I molecule such as CD1d or TL, demonstrated to be present on human and murine IECs (Bleicher *et al.*, 1990; Hershberg *et al.*, 1990; Blumberg *et al.*, 1991). The interaction of a Class I-like molecule with CD8<sup>+</sup> T cells may overshadow the "typical" interaction of Class II with CD4. These speculations are just that and, although IECs are tempting cells to evoke in normal antigen presentation in the gut, no *in vivo* model has been generated and no clear evidence exists that these cells function as APCs in a physiological system.

## V. SUMMARY

Given the nature of the gastrointestinal tract and its continuous Ag exposure, obviously unique systems of Ag handling must be developed. Clearly typical APCs do not function typically in the gastrointestinal tract and atypical (nonprofessional) APCs may play a more dominant role. However, a clear understanding of this entire process awaits the develop-

ment of physiological model systems in which these hypotheses can be tested.

# Oral Tolerance and Regulation of Immunity to Dietary Antigens

Allan Mcl. Mowat

## I. INTRODUCTION

The diet of all animals consists of a complex mixture of animal and vegetable products, most of which are nonself in immunological terms and, hence, are potentially antigenic. As other chapters in this volume describe, the gut-associated lymphoid tissues (GALT) are the largest in the body and contain a wide array of different effector mechanisms to counter continual bombardment by potential pathogens. Mobilization of this powerful battery of responses against food antigens would be undesirable, partly because it would limit their uptake and metabolic usefulness but more importantly because hypersensitivity to foods can produce intestinal pathology, as typified by celiac disease and other food sensitive enteropathies (FSE).

These conditions are rare, not because intestinal digestion destroys all immunologically relevant food antigens, but because the intestinal immune system can discriminate actively between food antigens and those of pathogenic importance. Contrary to the widespread belief among immunologists, a substantial proportion of ingested protein is absorbed intact in an immunologically relevant form. Thus, each meal results in the absorption of significant amounts of intact protein that certainly are within the range capable of stimulating immune responses if administered by other routes (Swarbrick *et al.*, 1979; Kilshaw and Cant, 1984; Husby *et al.*, 1987; Harmatz *et al.*, 1989). The purpose of this chapter is to review the immunoregulatory mechanisms that prevent the induction of hypersensitivity by this formidable antigenic challenge.

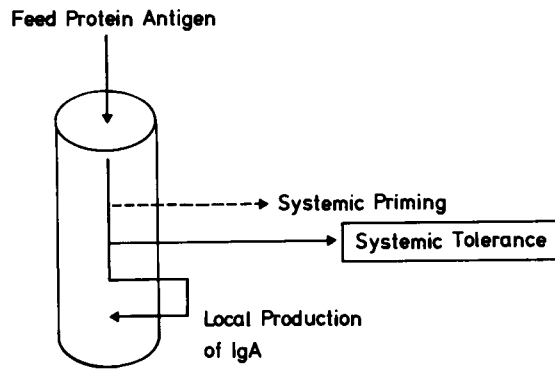

## II. IMMUNE RESPONSES TO DIETARY ANTIGENS

The immune system can react in three principal ways when a novel antigen is present in food (Figure 1). First, a local secretory IgA antibody response may occur in the intestine; second, the systemic immune system may be primed, with evidence of serum antibodies and cell mediated immunity (CMI); finally, a state of systemic immunological tolerance may develop, preventing the induction of active immunity when the offending antigen is encountered on subsequent occasions.

Experimental evidence suggests that the production of local IgA antibodies to food antigens may mediate a specific immune exclusion mechanism that, thereafter, prevents the uptake of the appropriate antigen (Swarbrick *et al.*, 1979; Challacombe and Tomasi, 1980). That this mechanism is one means of preventing clinical food hypersensitivity is consistent with the higher frequency of antibodies and hypersensitivity to food proteins that occur in individuals with selective IgA deficiency (Crabbé and Heremans, 1967; Walker, 1987). Nevertheless, most patients with this extremely common form of immune deficiency are entirely normal and have no evidence of food sensitivity. The relative importance of intestinal IgA in the prevention of food sensitivity is challenged further by the fact that stimulating IgA antibodies by immunizing normal animals orally with conventional protein antigens is difficult (Elson and Ealding, 1984; Lycke and Holmgren, 1986; Wilson *et al.*, 1989; van der Heijden *et al.*, 1991; McGhee *et al.*, 1992; Mowat *et al.*, 1993). Further, normal humans have little or no intestinal IgA antibody against food antigens (O'Mahony *et al.*, 1991). Thus, production of secretory IgA antibodies alone is unlikely to account for the absence of hypersensitivity reactions to food antigens, although this mechanism seems likely to provide a useful back-up to other, more potent immunoregulatory mechanisms.

## III. ORAL TOLERANCE

Tolerance is a state of specific immunological unresponsiveness to antigens that, under other circumstances, are capable of inducing an active immune response. One of the most reliable means of inducing immunological tolerance in experimental animals is presenting the antigen by the oral route. Tolerance is the usual result of administering a novel antigen to a naive animal by this route. Oral tolerance has been described best in laboratory rodents, but its presence has been implied in many other species including humans (Korenblatt *et al.*, 1968; Lowney, 1968; Walker, 1987), pigs (Miller *et al.*, 1984; Stokes *et al.*, 1987), dogs (Cantor and Dumont, 1967), guinea pigs (Heppell and Kilshaw, 1982), and rabbits (Bhagal *et al.*, 1986). Species differences do occur, however. Inducing oral tolerance in rabbits or guinea pigs (Peri and Rothberg, 1981; Heppell and Kilshaw, 1982) is

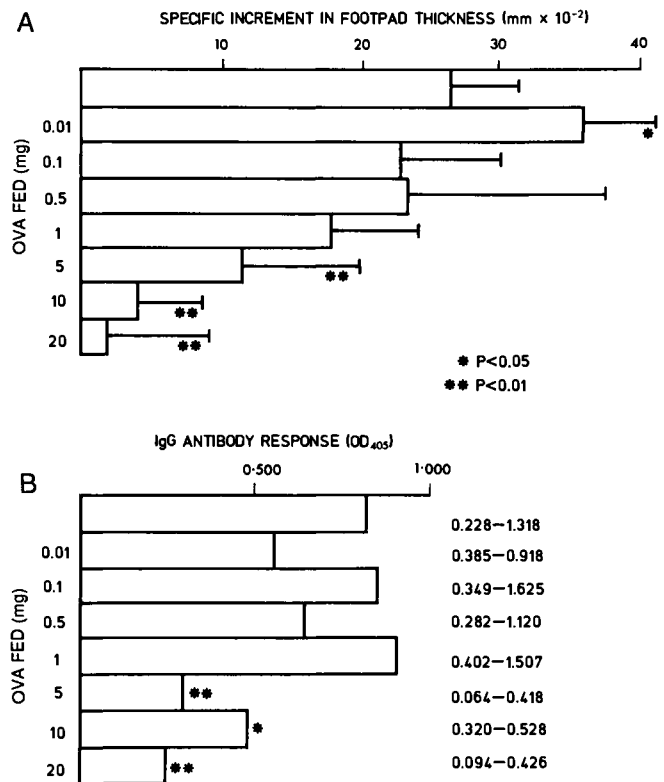

**Figure 1** The immunological consequences of feeding antigen. Depending on the antigen, the animal model, and the circumstances involved, oral administration of antigen may stimulate production of secretory IgA antibodies in the intestine, may induce a primary systemic immune response, or may result in systemic unresponsiveness to subsequent challenge with the antigen. In practice, this systemic tolerance is the usual result of feeding a novel protein antigen to a naive mature animal.

relatively difficult, whereas ruminants may not develop significant tolerance to dietary materials at all (Stokes, 1984).

The phenomenon is illustrated readily by feeding mice a single dose of a few milligrams of a protein such as ovalbumin (OVA) some time before immunizing the animals with the antigen in adjuvant via an immunogenic route. In most experiments of this type, antigen-fed animals have almost complete suppression of their immune response to the challenge immunization (Figure 2). In this discussion, we focus on oral tolerance to protein antigens and address the hypothesis that this mechanism is the principal means of preventing food hypersensitivity.

### A. Background

The possibility that ingestion of antigen might have immunological consequences different from those associated with systemic immunization was raised first in an anecdotal report by Dakin (1829), who described how South American Indians ate poison ivy in an attempt to prevent what we now understand as contact hypersensitivity to the plant (Dakin, 1829). Subsequently, the author and scientist H. G. Wells conducted a large series of experiments that showed that anaphylactic reactions to OVA and other proteins in guinea pigs could be inhibited by prior feeding of the appropriate material (Wells and Osborne, 1911). The immunological nature of the phenomenon first was established by the much later experiments of Chase (1946), using contact sensitizing agents. Exploiting the knowledge that was emerging at that time on cellular immunity and on the induction of tolerance in other systems, Chase's work demonstrated the antigen specificity of oral tolerance and recognized how readily the immune system could be down-regulated by what came to be known as the Sulzberger-Chase phenomenon. Since then, the protocols of inducing oral tolerance and the mechanisms involved have attracted considerable attention, not only from mucosal immunologists but also from individuals interested in using this

**Figure 2** Induction of tolerance by feeding the protein antigen ovalbumin (OVA) to normal adult mice. A dose-dependent suppression of systemic delayed type hypersensitivity (DTH) (A) and IgG antibody (B) responses to subcutaneous challenge with OVA in adjuvant in mice fed OVA. Systemic T cell responses (DTH) are more sensitive to the effects of antigen feeding and also show evidence of priming when the lowest doses of OVA are used.

system as a model of immunoregulation or as a means of artificially inhibiting immune responses to antigens of immunopathological importance.

### B. Scope

The induction of systemic tolerance by feeding antigen has been demonstrated with a wide range of nonreplicating antigens. In addition to the many proteins that have been studied, these antigens include contact sensitizing agents (Galister, 1973; Asherson *et al.*, 1977, 1979; Newby *et al.*, 1980; Gautam and Battisto, 1985), heterologous red blood cells (Kagnoff, 1978a, 1980; Mattingly and Waksman, 1980; Kiyono *et al.*, 1982; MacDonald, 1983), allogeneic leukocytes (Sayegh *et al.*, 1992), and inactivated viruses or bacteria (Stokes *et al.*, 1979; Challacombe and Tomasi, 1980; Rubin *et al.*, 1981). Although the majority of immunological studies have concentrated traditionally on familiar model antigens such as sheep red blood cells (SRBC) and OVA, more recent work also has used proteins of immunopathological importance, including myelin basic protein (MBP), uveal S antigen, and collagen (Nagler-Anderson *et al.*, 1986; Higgins and Weiner, 1988; Lider *et al.*, 1989; Nussenblatt *et al.*, 1990;

Zhang *et al.*, 1990; see Thompson and Staines, 1990, for review). The results obtained using different protein antigens are often similar, indicating the reproducibility of the phenomenon. However, the exact dose required for optimal induction of tolerance may differ, perhaps reflecting size- or charge-related differences in uptake by the intestine as well as inherent differences in immunogenicity.

Virtually all proteins examined have been found to induce oral tolerance, although some controversy exists over whether this also applies to proteins with unusual abilities to bind to and be absorbed by the intestinal mucosa, for example, cholera toxin. Cholera toxin has an almost unique ability to stimulate primary secretory IgA antibody responses after feeding and also has been shown to stimulate systemic antibody and CMI responses by the oral route (Elson and Ealding, 1984; Lycke and Holmgren, 1986; Wilson *et al.*, 1991; McGhee *et al.*, 1992). In addition, cholera toxin acts as an adjuvant for other orally administered proteins, allowing them to provoke both systemic and local immunity rather than the tolerance found after feeding the protein alone. These results suggest that cholera toxin overcomes the immunoregulatory mechanisms that normally produce oral tolerance, but whether this characteristic reflects its ability to bind specifically to enterocytes or its pharmacological effects on cell activation is not clear.

In contrast to the similarities between different proteins, the oral tolerance induced by antigens such as SRBC and contact sensitizing agents may be regulated in quite distinct ways (see subsequent discussion). In the case of SRBCs, this difference may reflect, in part, their particulate nature and the fact that these antigens have a thymus-independent component.

### C. Immunological Consequences of Oral Tolerance

All aspects of the immune response can be rendered tolerant by feeding antigen. A single feed of protein antigen will tolerize subsequent systemic IgM, IgG, and IgE antibody responses (Vaz *et al.*, 1977; Ngan and Kind, 1978; Richman *et al.*, 1978; Swarbrick *et al.*, 1979; Challacombe and Tomasi, 1980; Titus and Chiller, 1981; Mowat *et al.*, 1982; Thompson and Staines, 1990), as well as CMI responses measured by lymphocyte proliferation (Challacombe and Tomasi, 1980; Titus and Chiller, 1981; Higgins and Weiner, 1988; Lider *et al.*, 1989), cytokine production (Whitacre *et al.*, 1991), and delayed-type hypersensitivity (DTH) or contact sensitivity *in vivo* (Asherson *et al.*, 1977, 1979; Miller and Hanson, 1979; Newby *et al.*, 1980; Titus and Chiller, 1981; Mowat *et al.*, 1982; Gautam and Battisto, 1985; Kay and Ferguson, 1989a,b). CMI responses are much easier to tolerize than are humoral immune responses, requiring less antigen and persisting much longer after feeding (Figure 2; Heppell and Kilshaw, 1982; Mowat *et al.*, 1982; Mowat *et al.*, 1986; Strobel and Ferguson, 1987; Kay and Ferguson, 1989a,b). This finding extends to primed animals, in whom DTH responses can be suppressed fairly readily by feeding OVA after systemic immunization whereas serum antibody responses re-

main relatively unaffected (Lamont *et al.*, 1988a; Peng *et al.*, 1989a). In parallel, oral tolerance to proteins exhibits classical carrier specificity (Hanson *et al.*, 1977; Richman *et al.*, 1978; Titus and Chiller, 1981; Cowdrey and Johlin, 1984) and tolerance of antibody production *in vivo* can be broken if the defective helper T cells are bypassed using an unrelated carrier or are stimulated with lipopolysaccharide (LPS) (Titus and Chiller, 1981; Mowat *et al.*, 1986). When B cells are tolerized by feeding antigen, they recover much more quickly than T cells (Vives *et al.*, 1980).

One exception to the general rule that antibody responses are relatively difficult to tolerize is IgE production, which is remarkably sensitive to inhibition by feeding antigen before or after parenteral immunization (Ngan and Kind, 1978; Jarrett and Hall, 1984; Saklayen *et al.*, 1984). Interestingly, similar findings have been made in the experimental tolerance that can be induced by exposing animals to aerosols of protein antigen (Holt *et al.*, 1981). In conjunction with the fact that IgE and DTH responses are the mechanisms most frequently associated with pathological food hypersensitivity (Mowat, 1993), these results suggest that prevention of food-specific IgE and DTH responses may be the most important biological role of oral tolerance.

The status of mucosal immune responses in orally tolerized animals is less clear. Initial reports suggested that the degree of tolerance of systemic immunity induced by feeding antigen correlated directly with the concomitant development of secretory IgA antibody responses and IgA-mediated immune exclusion (Swarbrick *et al.*, 1979; Challacombe and Tomasi, 1980). In addition, mice fed antigen were reported to have concomitant induction of Peyer's patch T cells that suppressed IgG production but helped the synthesis of IgA antibodies (Richman *et al.*, 1981). However, strain differences in immune exclusion among protein-fed mice do not correlate with their susceptibility to oral tolerance (Stokes *et al.*, 1983a). In addition, several investigators using both protein and nonprotein antigens have shown that intestinal IgA production is tolerized by feeding antigen (Kiyono *et al.*, 1982; MacDonald, 1983). These latter findings are consistent with the apparent absence of IgA antibodies against food antigens in normal individuals and indicate that local IgA production probably is regulated in the same way as systemic immunity in orally tolerant animals.

### D. Time Course and Duration of Oral Tolerance

Systemic tolerance can be demonstrated very soon after a single feed of protein. Significantly suppressed responses to systemic challenge with OVA are observed within 2 days of feeding the antigen (Challacombe and Tomasi, 1980). The maximum degree of unresponsiveness then occurs during the first weeks after feeding; in most experimental protocols, a 1- to 2-week gap between feeding and challenge has been found to be the most appropriate. The resulting tolerance is then remarkably persistent, although its exact duration depends on the nature of the systemic immune response under study. Work with OVA has shown that, although tolerance of serum IgG antibody responses had almost disappeared by 6 months

after a single feed of OVA, the DTH tolerance remains essentially intact up to at least 18 months (Strobel and Ferguson, 1987). In view of the fact that the average life-span of a laboratory mouse is little more than 2 years, these findings highlight the potency and stability of this immunoregulatory phenomenon. In addition, these data are further evidence that systemic T-cell responses are affected more readily by feeding antigen than is humoral immunity.

Tolerance induced by feeding other antigens such as heterologous red cells may not develop so rapidly, since multiple feeds of SRBCs over a period of >2 weeks often are required for unresponsiveness to be demonstrable. This result may reflect the fact that SRBCs may induce a primary immune response when given orally and that this priming first must be overcome before tolerance ensues (Kagnoff, 1978a,b; David, 1979; Mattingly and Waksman, 1980).

#### IV. FACTORS THAT INFLUENCE THE INDUCTION AND MAINTENANCE OF ORAL TOLERANCE

##### A. Nature of Antigen

As we have discussed, a wide range of antigens is capable of inducing oral tolerance. Although differences in dose response, time course, and the exact mechanisms involved may exist, the eventual effects on the systemic immune response are generally similar, irrespective of the antigen. However, certain types of antigen are more likely to provoke active immunity rather than tolerance by the oral route, particularly viable organisms such as viruses and bacteria (Stokes *et al.*, 1979; Rubin *et al.*, 1981). This difference in response is not dependent on the nature of the antigens involved, since the same organisms will induce oral tolerance if killed or inactivated (Rubin *et al.*, 1981). In addition, soluble proteins expressed as gene products in live bacteria are immunogenic when given orally (Dahlgren *et al.*, 1991).

Inducing tolerance by feeding thymus-independent antigens also is generally impossible (Stokes *et al.*, 1979; Titus and Chiller, 1981), even if these are administered in association with a thymus-dependent antigen. Thus, mice fed killed *Escherichia coli* develop tolerance to the thymus-dependent K antigen but acquire local and systemic immunity to the thymus-independent O antigen on the same organism (Stokes *et al.*, 1979). Particulate antigens are also less able than soluble antigens to induce oral tolerance, since OVA coated onto polyglycoside microspheres stimulates active immunity by the oral route (McGhee *et al.*, 1992).

These findings may help explain the ability of the intestinal immune system to discriminate between dietary and pathogenic antigens, since many potentially invasive bacteria will present a large amount of thymus-independent antigen (e.g., LPS) in particulate form and, of course, a large proportion of this material will be viable. How the intestinal immune system can distinguish between immunogenic and tolerogenic materials is not known, but may relate to the ability of viable

organisms to provide a persistent stimulus to the immune system or to invade lymphoid tissues beyond the intestinal mucosa. Particulate antigens also may be taken up and processed by the intestine more efficiently, perhaps because such antigens may target M cells in Peyer's patches (Owen, 1977; Pappo and Ermak, 1989), whereas soluble materials may enter diffusely across the villus epithelium.

##### B. Antigen Dose

A wide range of antigen doses will induce significant oral tolerance; a single feed of a few milligrams of protein is sufficient in mice (Figure 2; Hanson *et al.*, 1977; Mowat *et al.*, 1986). The exact dose required for the optimal effect depends on the protein under study. The different limbs of the systemic immune response are differentially susceptible. Maximal immune suppression after feeding OVA occurs with doses ranging from 1 to 20 mg protein, but DTH responses can be tolerized reproducibly by doses of as little as 100  $\mu$ g OVA, whereas at least 5–10 mg are necessary to inhibit humoral immunity (Figure 2).

At doses immediately below those that induce tolerance, feeding antigen has no effect on systemic immunity, whereas even lower amounts actually may prime the immune response (Figure 2; Lamont *et al.*, 1989). In mice, systemic priming occurs during doses of 1–50  $\mu$ g protein and affects T-cell responses more than humoral immunity. A similar phenomenon has been noted in piglets, in which large amounts of weaning diet produce tolerance and low amounts prime the animals to develop food sensitivity (Miller *et al.*, 1984). Interestingly, initial exposure to low amounts of food antigens also has been suggested to predispose to eczema in children (Jarrett, 1984).

##### C. Genetic Background of Host

Since celiac disease is linked closely to the HLA-DQw2 locus of the human major histocompatibility complex (MHC; Howell *et al.*, 1986), determining how genetic factors influence the regulation of immune responses to fed protein antigens under experimental conditions is important. Several early studies noted strain differences in the susceptibility of mouse strains to the induction of oral tolerance by feeding OVA, although these differences were not investigated systematically and their basis was not addressed (Lafont *et al.*, 1982; Stokes *et al.*, 1983a; Tomasi *et al.*, 1983). Similar differences have been observed in the induction of oral tolerance in primed animals (Lafont *et al.*, 1982). In a more detailed analysis of oral tolerance to OVA, we found that the majority of mouse strains was tolerized readily by feeding this antigen (Lamont *et al.*, 1988b). Few consistent genetic influences could be identified, including those encoding the idiotypic regions of immunoglobulins. Interestingly, the susceptibility to induction of oral tolerance did not correlate with differences in tolerance induced by the intravenous route, underscoring the possibility that tolerance to fed antigens involves

mechanisms distinct from those that control immunity to parenterally administered antigen (see subsequent text).

One important aspect to emerge from this work was that mice carrying the H-2<sup>d</sup> MHC haplotype were particularly susceptible to the induction of tolerance, whereas the H-2<sup>b</sup> haplotype frequently was associated with less profound tolerance. Of particular note, BALB/B mice were much more difficult to tolerate than the congenic BALB/c strain (Figure 3; Mowat *et al.*, 1987; Lamont *et al.*, 1988b). Since these mice differ only at the MHC, these data support a possible role for MHC genes in regulating oral tolerance to protein antigens. These strain differences did not reflect differences in the processing of protein in the intestine, but were the result of the inability of the BALB/B immune system to be regulated by tolerogenic protein coming from the intestine (Mowat *et al.*, 1987). The immunological basis of this MHC-linked effect remains to be established. Note that other non-MHC-linked genes have been implicated in oral tolerance, both to OVA and to human  $\gamma$  globulin (Tomasi *et al.*, 1983). These background genes do not appear to operate via the immune exclusion function of secretory IgA antibody, but resistance to tolerance induction correlated with unusually rapid clearance of absorbed antigen from the circulation (Stokes *et al.*, 1983a). Thus, oral tolerance induction may be under the control of several genes that may influence both specific immune responsiveness and nonspecific factors such as protein clearance and catabolism.

One additional level of genetic control that has been noted is that strains of mice with genetically determined systemic lupus erythematosus (SLE)-like autoimmune disease are unusually resistant to the induction of tolerance by feeding certain protein antigens (Cowdrey *et al.*, 1982; Miller *et al.*, 1983; Carr *et al.*, 1985). These well-established experimental models could provide useful means of investigating the immunological basis of antigen-specific regulation of immunity to fed proteins.

**Figure 3** Genetic differences in oral tolerance. BALB/B (H-2<sup>b</sup>) mice are resistant to the induction of tolerance by feeding doses of ovalbumin (OVA) that suppress delayed type hypersensitivity (DTH) and antibody responses in congenic BALB/c (H-2<sup>d</sup>) mice.

#### D. Influence of Host Age on Susceptibility to Oral Tolerance

Food hypersensitivities are most common in infants, particularly at or near the time of weaning. Note, therefore, that neonatal and weaning mice exhibit defects in the induction of tolerance by feeding protein antigens. Mice fed OVA on the first day or two of life do not develop the tolerance of systemic immunity found in adults fed the same weight-related dose. Indeed, OVA-fed infant mice show evidence of systemic priming when challenged parenterally as adults, particularly with respect to systemic DTH responses (Hanson, 1981; Strobel and Ferguson, 1984). Similar findings have been reported in neonatal mice exposed early in lactation to gluten present in the milk of mothers fed a gluten-containing diet (Troncone and Ferguson, 1988). In addition, the ability to sensitize calves or piglets by feeding antigen during the preweaning period further supports an age-related defect in oral tolerance at this time (Miller *et al.*, 1984; Stokes, 1984; Barratt *et al.*, 1987; Stokes *et al.*, 1987).

This defect in tolerance does not correlate with differences in the amount of protein absorbed by the neonatal intestine and can be corrected by transfer of mature lymphocytes (Hanson, 1981; Peng *et al.*, 1989a). Thus, the infant response may reflect an inability of the immature immune system to respond appropriately to intestinally derived tolerogen. The adult pattern of susceptibility to tolerance develops after 4 days of age and is established fully around 7 days. However, an additional transient defect in tolerance induction occurs in the days around weaning (Hanson, 1981; Strobel and Ferguson, 1984). This latter phenomenon is not related to the age of the animal, but is influenced by the process of weaning itself and is likely to be determined by the alterations in intestinal microenvironment or in systemic hormone levels associated with weaning.

At the other end of the age spectrum, aging mice have been reported to become increasingly resistant to the induction of oral tolerance by feeding OVA (S. J. Challacombe, personal communication). Since this observation seems unusual in view of the apparent preservation of the intestinal immune system in aged animals, its significance is unclear.

#### E. Influence of Intestinal Flora

Evidence from both human and veterinary work suggests that clinical food sensitive enteropathy may develop subsequent to intestinal infection. As we have noted, the changes in gut flora at the time of weaning may be associated with a period of defective oral tolerance. One of several possible explanations for these findings is that bacterial products may influence the regulation of immune responses to dietary antigens.

The immunomodulatory effects of LPS and other bacterial products are well known. Substantial evidence suggests that germ-free mice have defective systemic immune competence (MacDonald and Carter, 1979; Collins and Carter, 1980). That these effects may extend to mucosal immunoregulation was suggested by the fact that germ-free mice cannot be tolerized

by feeding SRBC (Wannemuehler *et al.*, 1982b). In addition, inducing tolerance by feeding SRBC to C3H/HeJ mice that have a genetically determined inability to respond to LPS is impossible (Kiyono *et al.*, 1982; Michalek *et al.*, 1982; Mowat *et al.*, 1986; Kitamura *et al.*, 1987). Unlike normal congenic C3H mice, LPS-unresponsive animals are primed by feeding SRBC and develop systemic antibody and DTH responses as well as local IgA antibodies. These effects were associated with a defect in the induction of suppressor T cells ( $T_s$ ) and a parallel appearance of contrasuppressor T cells (Suzuki *et al.*, 1986a,b; Kitamura *et al.*, 1987; Fujihashi *et al.*, 1989).

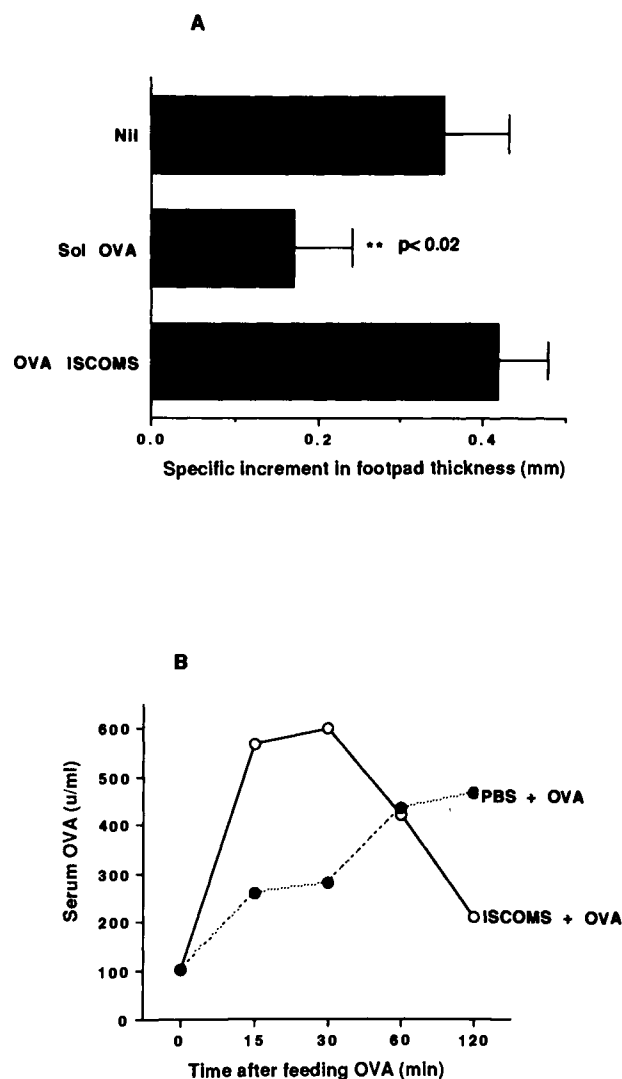

Although these results support an important role for LPS in mucosal immunoregulation, subsequent work by ourselves and others has shown that LPS has no influence on immune responses to fed protein antigens. Oral tolerance to proteins is entirely normal in LPS-unresponsive C3H/HeJ mice, and exogenous LPS has no effect on T-cell tolerance in normal mice fed OVA (Saklayen *et al.*, 1983; Mowat *et al.*, 1986). Thus, bacterial LPS seems unlikely to play an important role in the regulation of immunity to the majority of dietary antigens, which are protein in nature. However, the possibility that other bacterial products may influence these responses cannot be excluded. Clearly, LPS may influence responsiveness to certain antigens, particularly those with a strong thymus-independent component such as SRBCs.

#### F. Role of Intestinal Absorption and Antigen Uptake

As we shall discuss, oral tolerance to protein antigens reflects the manner in which the protein is processed in the intestine (see subsequent text). Thus, we might predict that any factor that alters either the amount or the chemical nature of the antigen absorbed from the intestine also will influence the immunological consequences of this material. This idea is supported by the high levels of food-specific antibodies that occur in individuals with disorders that cause increased intestinal permeability to macromolecules, for example, Crohn's disease and celiac disease (Cunningham-Rundles, 1987; Walker, 1987). Although increased permeability to antigen may explain in part the absence of tolerance in mice fed OVA incorporated in lipophilic immune stimulating complexes (ISCOM) containing the detergent saponin (Quil A; Figure 4), a firm correlation between antigen uptake and tolerance or priming remains to be established.

#### G. Nutritional Influences on Oral Tolerance

The function of the immune system is highly dependent on the nutritional status of the host. Several reports have been made that protein-calorie malnutrition compromises the ability of animals to make mucosal immune responses (Chandra *et al.*, 1987). Nutritional deficiencies are most likely to occur in the early neonatal period, when the risk of disordered regulation of immunity to fed antigens is also at its highest. However, little is known of the influence of nutrition on oral tolerance, partly because distinguishing between the effects of malnutrition itself and those that are the result of secondary

**Figure 4** Incorporation in immune stimulating complexes (ISCOMS) prevents the induction of oral tolerance. (A) Mice fed a dose of ovalbumin (OVA), which in soluble form induces tolerance of systemic delayed type hypersensitivity (DTH) responses, are not tolerized if OVA is incorporated into ISCOMS. (B) Feeding ISCOMS increases the speed and amount of OVA uptake into serum after a test feed.

complications, such as intestinal abnormalities or infection, is frequently difficult. One carefully controlled study has shown that mice on an isocaloric low-protein diet have defective induction of tolerance after feeding OVA and that this defect is related to a primary effect of malnutrition on the immune system (Lamont *et al.*, 1987). If this finding extends to other forms of malnutrition, particularly in developing animals, poor nutritional status could predispose to food hypersensitivity in infancy.

#### H. Immunological Status of the Host

For many years, researchers have known that inducing systemic tolerance in animals that previously have been primed to the antigen is difficult or impossible. Although

initial work suggested that a similar effect of priming extended to oral tolerance (Hanson *et al.*, 1979a), several investigators have since shown that oral tolerance can be induced in parenterally primed mice (Lafont *et al.*, 1982; Higgins and Weiner 1988; Lamont *et al.*, 1988b; Lider *et al.*, 1989; Peng *et al.*, 1989b; Thompson and Staines, 1990). Larger doses of fed antigen or more frequent feeds may be required to obtain degrees of tolerance equivalent to those found in naive animals; also, only a short time window after systemic priming may exist during which oral tolerance is inducible. These findings may help explain why multiple feeds of relatively large amounts of antigen are required to induce tolerance to SRBCs, since these contain antigens to which mice frequently are primed via cross-reacting intestinal flora; a primary immune response can be detected before tolerance ensues (see preceding discussion). As is seen in naive hosts, tolerance to protein antigens in primed animals affects T-cell responses more than humoral immunity (Lamont *et al.*, 1988b; Peng *et al.*, 1989b) and exhibits clear strain differences. However, whether similar immunoregulatory mechanisms govern the tolerance in the two types of host is not clear (see subsequent discussion). Interestingly, studies have shown that feeding specific antigen also can be used to inhibit established autoimmune diseases such as experimental autoimmune encephalomyelitis and collagen-induced arthritis (Higgins and Weiner, 1988; Lider *et al.*, 1989; Thompson and Staines 1990). Thus, the oral route may be potentially useful for immunotherapeutic intervention in antigen-specific immunopathology. The relatively good ability of oral tolerance to overcome systemic priming also may explain the fact that several clinical food sensitivities, including cow milk protein intolerance and eczema, are transient in nature; affected patients apparently acquire specific tolerance.

## V. MECHANISMS OF ORAL TOLERANCE

### A. Introduction

Most mechanistic studies in oral tolerance were performed during the late 1970s and early 1980s, at a time when the immune system was not understood at the molecular or cellular level. Several different mechanisms were suggested to be responsible for the ability of fed antigen to inhibit immune responsiveness but, as with many other immunoregulatory phenomena, this result usually was seen as a manifestation of  $T_s$  activity. Considerable efforts were made to establish the nature and origin of these cells and to understand how fed antigen could induce their activation preferentially. However,  $T_s$  have proved resistant to the major advances in molecular and cell biology that have elucidated the basis of most other T cell functions. As a result, researchers now consider  $T_s$  unlikely to exist as a discrete population of lymphocytes. The basis of immunoregulation has undergone a period of reexamination. Before reviewing the evidence for  $T_s$  and other immunoregulatory mechanisms in oral tolerance, we first discuss briefly how current views have altered our understanding of other forms of tolerance (Table I).

**Table I** Current Concepts in Systemic Tolerance<sup>a</sup>

### B. Mechanisms of Peripheral Tolerance and Immunoregulation

Clonal deletion and anergy of antigen-reactive T cells now are believed to be the principal mechanisms responsible for most forms of tolerance induced by parenteral routes (Schwartz, 1989; Holan *et al.*, 1991). Clonal deletion occurs predominantly in the thymus of developing animals, where immature T cells undergo apoptosis after encountering self-antigens on medullary antigen-presenting cells (APC). Clonal deletion also may occur during tolerance induction in the periphery of mature animals, but this event probably reflects a state of specific cellular hyporesponsiveness at the level of antigen-specific T cells. This “anergy” occurs when the molecular signaling events that normally produce T-cell activation after presentation of antigen on APCs are altered and further stimulation by antigen is prevented (Mueller *et al.*, 1989).

Several conditions favor the induction of anergy rather than immune activation, including the amount and nature of the antigen. In addition, growing evidence suggests that clonal anergy is particularly likely when antigen is presented on “nonprofessional” APC which, although expressing appropriate MHC antigens, do not produce the co-stimulatory mediators necessary for T-cell activation (Mueller *et al.*, 1989). APC of this type include a variety of MHC Class II-expressing epithelial cells, indicating the possible importance of this mechanism in regulating immunity in a tissue such as the intestine, where epithelial expression of MHC Class II antigens is a normal event.

Our current understanding of immunoregulation has been increased further in recent years by the discovery that the immune response is controlled by a series of interacting cytokines. Of particular note is the proposal that the outcome of immunization is dependent on the activation of discrete populations of CD4<sup>+</sup> helper T cells ( $T_H$ ), which can be discriminated on the basis of their pattern of cytokine production.  $T_H1$  cells produce interleukin 2 (IL-2), interferon  $\gamma$  (IFN $\gamma$ ), and tumor necrosis factor  $\beta$  (TNF $\beta$ ; lymphotoxin), and are responsible for DTH responses and cytotoxicity, whereas  $T_H2$  cells produce interleukins 4, 5, 6, 9, and 10 and are classical helper cells for antibody production (Mossmann and Coffman, 1989). The induction of these T-cell subsets

by antigen appears to depend on the nature of the APC involved. In addition to playing quite distinct effector roles in the immune system, each of these T-cell subsets can inhibit the functions of the other. The nature of the immune response that eventually occurs reflects the outcome of the interactions between competing cytokines. That production of individual cytokines also can influence whether administration of antigen produces tolerance or immunity is suggested by the findings that antibodies to IFN $\gamma$  can prevent the induction of tolerance to intravenously administered OVA (Hayglass and Stefura, 1991) as well as the induction of antigen-specific T-cell anergy *in vitro* (Liu and Janeway, 1990). Analogous studies have implicated similar roles for IL4 and transforming growth factor  $\beta$  (TGF $\beta$ ) in parenterally induced tolerance (Schurmans *et al.*, 1990; Karpus and Swanborg, 1991).

Collectively, these studies indicate that the regulation of immune responses is determined by the way in which antigen is presented to the immune system and that the nature of the eventual response may reflect production of individual cytokines. Ascertaining the relevance of these recent developments to the existing knowledge on oral tolerance discussed in the following sections will be important.

### C. Suppressor T Cells and Oral Tolerance

T<sub>s</sub> have been implicated in virtually all models of oral tolerance in experimental animals. Early studies in guinea pigs fed contact sensitizing agents noted the presence of an active suppressor mechanism *in vivo* (Chase and Battisto, 1955), and the ability of T cells to transfer tolerance first was reported in 1976 in rats fed bovine serum albumin (BSA; Thomas and Parrott, 1974). Support for a role for T<sub>s</sub> came from two approaches. First, the induction of oral tolerance by feeding OVA, cholera toxin, or contact sensitizing agents could be prevented by treating mice with drugs that were believed to be specifically toxic to T<sub>s</sub>, for example, cyclophosphamide and 2'-deoxyguanosine (Mowat *et al.*, 1982; Kay and Ferguson, 1989b; Mowat, 1986). By abrogating oral tolerance, cyclophosphamide also allows the development of immune complex glomerulonephritis in mice fed multiple doses of bovine gamma globulin (BGG; Gesualdo *et al.*, 1990). Second, transferable T<sub>s</sub> were found after feeding a wide range of experimental antigens, including proteins, contact sensitizing agents, and SRBC as well as several antigens of pathological importance (Ngan and Kind, 1978; Kagnoff, 1978a; Miller and Hanson, 1979; Kiyono *et al.*, 1982; MacDonald, 1983; Gautam and Battisto, 1985; Mowat, 1985, 1986; Lider *et al.*, 1989; Nussenblatt *et al.*, 1990; Thompson and Staines, 1990). Interestingly, most evidence showed that T<sub>s</sub> could inhibit only systemic T-cell responses in antigen-fed animals, whereas humoral immune responses remained unaffected by T<sub>s</sub> activity.

In virtually all cases examined, these suppressor cells were CD8<sup>+</sup> T cells that acted in the afferent phase of the immune response. In addition, reports were made of networks in which a number of T<sub>s</sub> interacted to produce inhibition of the response (Mattingly and Waksman, 1980; MacDonald, 1982;

Gautam and Battisto 1985). As in many other systems, the nature of the T-cell receptor (TcR) expressed on the T<sub>s</sub> during oral tolerance has never been elucidated. Nevertheless, one study has proposed that the T<sub>s</sub> induced by aerosol exposure of mice to OVA carry the unusual  $\gamma\delta$  form of the TcR (McMenamin *et al.*, 1991). In view of the fact that  $\gamma\delta$ <sup>+</sup> T cells may accumulate in the gut, examining whether these findings extend to oral tolerance would be of interest.

The effector T<sub>s</sub> found in antigen-fed animals were believed to originate in the Peyer's patches soon after feeding antigen, before migrating to the mesenteric lymph nodes and then to systemic lymphoid tissues (Asherson *et al.*, 1977, 1979; Ngan and Kind, 1978; Mattingly and Waksman, 1978; MacDonald, 1982). This behavior was not shown directly and the site of the interaction between antigen and T<sub>s</sub> was never determined. Subsequent studies proposed that the induction of T<sub>s</sub> required presentation of fed antigen by specialized APC that differed from conventional APC in their expression of molecules thought to be encoded by "I-J" genes found within the MHC Class II locus. *In vivo* treatment with antibodies against I-J molecules prevented the induction of tolerance in mice fed OVA, whereas similar treatment with antibodies against classical MHC Class II antigens had no effect (Mowat *et al.*, 1988). Since the T<sub>s</sub> induced by feeding OVA did not themselves express I-J markers, these experiments were interpreted to show that fed antigen associated preferentially with I-J<sup>+</sup> APCs that then stimulated T<sub>s</sub>. This hypothesis was entirely compatible with contemporary studies in which a network of "I-J-restricted" APCs and T<sub>s</sub> appeared to be responsible for a number of other models of tolerance (Green *et al.*, 1983; Granstein and Green, 1985). However, the significance of these findings is now unknown, since the biochemical and genetic nature of the I-J molecule has not been elucidated and its very existence is controversial. Elucidating the molecular basis of the interactions between APCs and regulatory T cells in antigen-fed animals is a major challenge to mucosal immunologists.

An additional layer of complexity in the groups of regulatory T cells found in antigen-fed animals comes from suggestions that, under certain circumstances, a population of "contrasuppressor T cells" (T<sub>cs</sub>) may counteract the effects of T<sub>s</sub> (Suzuki *et al.*, 1986a,b; Kitamura *et al.*, 1987). These T<sub>cs</sub> first were described as responsible for the lack of oral tolerance in LPS-unresponsive mice fed SRBC and appeared to act by interfering with the ability of T<sub>s</sub> to inhibit specific antibody production. Evidence also was presented that the T<sub>cs</sub> had selective effects on IgA production. More recently, T<sub>cs</sub> function has been reported to be associated with a small population of spleen and intestinal intraepithelial T lymphocytes (IEL) that express the  $\gamma\delta$  TcR (Fujihashi *et al.*, 1989, 1990). Although these findings raise many intriguing issues concerning the possible role of mucosal lymphocytes in regulating immunity to dietary antigens, note that the reports of T<sub>cs</sub> in antigen-fed animals have been made only with SRBC and in an extremely limited number of mouse strains. Further, the existence of these cells is now considered even more unlikely than that of T<sub>s</sub> themselves.

## D. Other Immunoregulatory Mechanisms

### 1. Clonal Anergy and Deletion of T Lymphocytes

No studies of clonal deletion or anergy in oral tolerance have been published. However, several workers have reported that T-cell tolerance in antigen-fed mice does not necessarily correlate with the presence of  $T_s$  (Titus and Chiller, 1981; Hanson and Miller, 1982; Tomasi *et al.*, 1983). Further, as we have noted, humoral immunity in antigen-fed animals may not be regulated by  $T_s$ . Studies using limiting dilution analysis have suggested that individual antigen-specific effector T cells from mice fed MBP are anergic in the absence of  $T_s$  (Whitacre *et al.*, 1991). In addition, one report in abstract form has presented evidence for specific absence of T cells expressing the V $\beta$ 8.2 TcR in SJL mice fed MBP (Whitacre *et al.*, 1990). Since the immune response to MBP in this strain is dominated by V $\beta$ 8.2<sup>+</sup> T cells, these results support the possibility that clonal deletion of antigen-specific T cells may occur during oral tolerance. Confirming and extending these findings, perhaps using the superantigen-based approaches that have proved successful in other models of tolerance, is now important.

### 2. Role of Cytokines

As we have noted, increasing evidence suggests that preferential induction of individual cytokines may be of critical importance in a number of forms of immunoregulation. That this mechanism may be involved in oral tolerance is suggested by the differential effects of antigen feeding on systemic cellular and humoral immunity, as well as by the possibility that local IgA responses are relatively preserved during oral tolerance. One report has suggested that " $T_s$ " from rats fed MBP can inhibit responses of primed T cells to a third party antigen, a phenomenon that has been ascribed to the involvement of nonspecific soluble mediators released by the  $T_s$  after contact with the antigen (Miller *et al.*, 1991a). The cytokines involved have yet to be identified with certainty, but administration of IFN $\gamma$  interferes with the induction of oral tolerance in mice (Zhang and Michael, 1990), and preliminary studies indicate that *in vivo* depletion of TGF $\beta$  (Miller *et al.*, 1991b) or IL-4 (Figure 5) can substantially prevent tolerance in mice fed OVA. These findings indicate the need for more extensive studies of the relationship between cytokine production and oral tolerance.

### 3. Role of B Lymphocytes and Antibody

Although oral tolerance has been ascribed most frequently to the induction of  $T_s$ , several other regulatory mechanisms have been reported. Suppressor B cells have been found in mice fed contact sensitizing agents (Asherson *et al.*, 1977, 1979), and oral tolerance to these antigens can be enhanced by administration of polyclonal B cell activators (Newby *et al.*, 1980).

Transferring tolerance using serum-derived material from protein-fed animals is not possible (Hanson *et al.*, 1979b). However, isolated reports suggest that tolerance to SRBCs

**Figure 5** A role for interleukin 4 in oral tolerance. Mice treated with anti-IL4 antibody 1 day before feeding ovalbumin (OVA) do not have the significant tolerance of systemic delayed type hypersensitivity (DTH) responses seen in untreated OVA-fed controls.

and certain contact sensitizing agents can be transferred using serum from antigen-fed mice (André *et al.*, 1975; Kagnoff, 1978b; Chalon *et al.*, 1979; Bhogal *et al.*, 1986). The material responsible appears to be IgG and is likely to be an anti-idiotypic antibody rather than an antibody directed at the antigen itself. Regulation of immunity by anti-idiotypic antibody also has been described in mice tolerized by portal vein inoculation of allogeneic lymphocytes (Sato *et al.*, 1988). Although the significance of these findings for more usual forms of oral tolerance has not been established, note that milk from mice tolerized orally or parenterally during pregnancy can induce tolerance in the neonate by transfer of anti-idiotypic antibody (Wannemuehler *et al.*, 1982a; Jarrett and Hall, 1984). Thus, the possibility remains that this mechanism provides a means of conferring tolerance on the neonate at a time when susceptibility to food sensitivity is high.

### E. Role of Intestinal Processing in Oral Tolerance

The ability of orally administered antigen to modulate systemic immune responses requires the absorption of small amounts of immunologically intact material from the intestine. Substantial evidence exists that intestinal processing events are critical for oral tolerance to proteins. Serum removed from mice fed OVA 1 hr beforehand induces systemic tolerance when transferred intraperitoneally to naive syngeneic recipients. The tolerance selectively inhibits systemic DTH responses in the recipients and is related to the activation of cyclophosphamide-sensitive  $T_s$  by OVA-fed serum (Strobel *et al.*, 1983; Bruce and Ferguson, 1986a,b). Similar findings have been made with other protein antigens (Kay and Ferguson, 1989b; S. Strobel, unpublished observations). The processing event necessary for the generation of the serum tolerogen appears to occur in the intestine itself, since

serum taken from mice given equivalent doses of protein by other parenteral routes is never able to reproduce appropriate tolerance in naive recipients (Bruce and Ferguson 1986a). However, the site of this processing is unknown and the relative roles of the intestinal epithelium or local lymphoid cells have not been ascertained. The precise nature of the tolerogen present in OVA-fed serum is also unclear. The tolerogenic material appears in serum within 20–30 min of feeding and therefore is unlikely to involve any immunologically active molecule (Peng *et al.*, 1990). In addition, this result argues against a need for proteolytic digestion. This idea is supported by the fact that the tolerogen reacts with antibodies directed at native OVA (Bruce and Ferguson, 1986b) and elutes on gel filtration columns or high performance liquid chromatography (HPLC) with the native molecule (Bruce and Ferguson, 1986b; H. J. Peng and S. Strobel, personal communication). These findings suggest that a simple filtration mechanism in the intestine may produce deaggregated monomers of protein that are known to be tolerogenic in other systems. However, since the ability of serum to transfer tolerance is not related directly to the absolute amount of protein present (Peng *et al.*, 1990), intestinal processing may cause subtle changes in the charge or conformation of the antigen that influence its immunogenicity.

Proteolytic digestion is unlikely to generate selected peptide fragments containing “suppressor determinants” that can prevent responsiveness to the intact antigen, as suggested in other models (Kölsch, 1984). Feeding artificial peptides usually induces the same degree of tolerance as that found after feeding the intact antigen (Higgins and Weiner, 1988). Rectal administration of proteins also induces tolerance, and *in vivo* inhibition of pancreatic enzyme activity has no effect on induction of oral tolerance (Strobel, 1984). Thus, proteins do not need to undergo proteolysis to induce tolerance by the oral route.

Collectively, these findings support the view that tolerogenic moieties of proteins produced during intestinal processing are responsible for the induction of systemic tolerance, at least for T-cell responses. Since this material has little or no effect on humoral immune responses, however, additional mechanisms must influence the hyporesponsiveness of antibody responses in protein-fed mice.

**F. Role of Antigen Presentation in Oral Tolerance**

Virtually all immune responses require the activation of T cells by short peptides bound in the surface groove of MHC molecules. Complex nonviable antigens, such as those that induce oral tolerance, first must be taken up by accessory cells in the immune system, processed intracellularly within endosomes, and presented as a complex with MHC Class II antigens. As we have discussed, evidence shows that these APC functions not only control the specificity and level of the resulting immune response but also determine whether active immunity or tolerance occurs after administration of antigen (Mueller *et al.*, 1989).

Therefore, that APC activity appears to be critical in regulating the immunological consequences of feeding antigens

is not surprising. This ability first was suggested by the finding that feeding one antigen to naive mice causes transient activation of the reticuloendothelial system (RES) and interferes with the induction of tolerance by feeding a second antigen (Stokes *et al.*, 1983b). Oral tolerance in mice fed OVA also can be prevented by *in vivo* administration of a number of agents that activate the accessory cell functions of the RES, including estrogen, muramyl dipeptide (MDP), and a graft-versus-host reaction (GvHR; Mowat and Parrott, 1983; Strobel *et al.*, 1985; Strobel and Ferguson, 1986). Once again, tolerance of DTH responses was more susceptible to modulation by activating the RES. Further work showed that, although these agents affected many functions of the RES, their effects on oral tolerance correlated specifically with enhanced APC activity in the spleen (Figure 6). In contrast, bacterial LPS, which did not influence DTH tolerance (see preceding discussion), had no ability to enhance antigen presentation. More recently, *in vivo* administration of IFN $\gamma$  has been shown to prevent the induction of oral tolerance in mice, reinforcing the possible role of agents with the capacity to activate APC (Zhang and Michael, 1990).

The basis of these effects remains to be established, but could include increased expression of MHC Class II antigens, enhanced production of co-stimulatory factors, or alterations in the intracellular processing pathways themselves. The resulting effect may be to alter the balance between distinct populations of APCs so that a larger proportion of fed antigen is presented by APCs with a conventional ability to stimulate T cells, rather than by the putative T<sub>s</sub>-activating “I-J+”

	Prevention of tolerance	Carbon clearance	APC activity	Mucosal DTH
Estradiol	Yes	↑↑	↑	Yes
MDP	Yes	→	↑	Yes
GvHR	Yes	→	↑	Yes (?)
LPS	No	→	↑	(?)

**Figure 6** Role of antigen presenting cells in oral tolerance. Treatment of mice with estradiol, muramyl dipeptide (MDP), or a graft versus host reaction (GvHR) prevents the induction of oral tolerance by feeding ovalbumin (OVA) and enhances the ability of splenic adherent cells to present OVA to primed T cells. Bacterial LPS has no effect on oral tolerance to OVA and does not enhance antigen-presenting all (APC) activity *in vivo*.

APCs discussed earlier. Although this hypothesis has yet to be tested in oral tolerance, a differential effect on APC populations of this type may explain the ability of UV light to modulate immune responses *in vivo* (Green *et al.*, 1983).

The influence of the RES on oral tolerance may be of particular relevance in explaining the high incidence of clinical food sensitivity during the period of weaning. As we have discussed, feeding one novel antigen may interfere with tolerance to those encountered subsequently. In addition, a number of products from intestinal flora must have the potential to activate APCs. Thus, modulation of APC function by the rapid exposure to new food antigens and bacterial flora at weaning may help predispose the infant to potentially harmful defects in oral tolerance.

### G. Role of the Liver in Oral Tolerance

A large proportion of the antigens absorbed from the intestine will travel directly to the liver via the portal venous system. The liver is the largest tissue of the RES, raising the possibility that this organ may be a major site of the antigen processing events that determine the immunological consequences of antigen feeding.

For many years, researchers have known that administration of antigen directly into the portal system induces a state of tolerance that has many similarities to oral tolerance (Qian *et al.*, 1985; Fujiwara *et al.*, 1986; Sato *et al.*, 1988). An early study in rats indicated that oral tolerance was unaffected when the liver was bypassed by a porto-caval shunt (Thomas *et al.*, 1976), but the many side effects of this surgical maneuver make interpretation of the results difficult. The inability of intravenously injected protein to generate the serum tolerogen found after antigen feeding (Strobel *et al.*, 1983; Bruce and Ferguson, 1986a) also argues against a critical involvement of the liver in oral tolerance, since we might anticipate that intravenously injected antigen also will accumulate rapidly in this organ. Nevertheless, intestinally derived material entering by the portal tracts may be processed by accessory cells distinct from those in contact with the systemic circulation. Thus, a role for the liver in oral tolerance cannot be excluded entirely.

### H. Conclusions

Based on the foregoing discussion, clearly multiple mechanisms may be responsible for the induction and maintenance of tolerance to orally administered antigens, presumably reflecting the importance of regulating immune responses to dietary antigens. The role played by individual mechanisms depends on the antigen, the nature of the host animal, and the aspect of the systemic immune response that is under investigation. We have emphasized the view that oral tolerance may be the result of intestinally derived moieties that are presented by specialized APCs to  $T_s$ . However, most of the evidence for this mechanism has come from studies of tolerance to protein antigens, and its effects are exerted mainly on systemic cellular immunity. In addition, many of these phenomena have yet to be examined in light of the more

recent developments in cellular and molecular immunology. Considerable work remains to be done if the mechanisms regulating immunity to the full range of dietary antigens are to be elucidated.

## VI. CLINICAL AND PRACTICAL RELEVANCE OF ORAL TOLERANCE

### A. Consequences of Breakdown in Oral Tolerance

We already have discussed the concept that the strength and persistence of oral tolerance indicate its importance in preventing hypersensitivity to food proteins. This idea is based both on the relative infrequency of naturally occurring immunological responsiveness to dietary antigens and on a substantial amount of experimental evidence (Table II).

As we have seen, oral tolerance to proteins in normal mice can be prevented by depleting  $T_s$  *in vivo* and by activating APCs. In addition, tolerance does not occur after feeding very low doses of antigen or in animals during the immediate neonatal or weaning periods. In all these cases, subsequent oral challenge of the mice with antigen results in the development of mucosal pathology in the jejunum consisting of crypt hyperplasia, crypt hypertrophy, and increased infiltration of the epithelium by lymphocytes (Mowat and Ferguson, 1981; Mowat and Parrott, 1983; Mowat, 1986; Strobel and Ferguson, 1986; Stokes *et al.*, 1987; Lamont *et al.*, 1988). These features are accompanied by a local cell-mediated immune response in the draining mesenteric lymph nodes (Mowat and Ferguson, 1982; Mowat and Parrott, 1983) and are identical to the early stages of mucosal immunopathology found in other experimental forms of intestinal cell-mediated immunity, including GvHR and allograft rejection (Mowat and Felstein, 1990). Since the intestinal damage in these conditions is caused by the production of T cell-dependent cytokines, a breakdown in oral tolerance is likely to allow the priming of local cytokine-producing T cells that have the capacity to

produce pathology on re-exposure to antigen. Note that the ability of an immunomodulatory agent to allow mucosal DTH is predicted by its effects on tolerance of systemic DTH responses, rather than humoral immunity, thus underlining the importance of preventing T-cell responses to food antigens.

The features of the mucosal immunopathology induced experimentally in the absence of oral tolerance are also qualitatively similar to those found in naturally occurring FSE (Mowat, 1984; Ferguson, 1987). That a defect in oral tolerance may account for the development of FSE under natural conditions is suggested by studies in weaning piglets that have shown that the development of postweaning diarrhea is influenced markedly by the age of introduction of novel antigens and can be prevented by artificially inducing oral tolerance to the antigens to be fed at weaning (Miller *et al.*, 1984; Stokes *et al.*, 1987). Neonatal calves exhibit a similar susceptibility to developing systemic hypersensitivity and enteropathy in response to dietary proteins such as soy protein (Barratt *et al.*, 1987). The mechanisms underlying the naturally occurring conditions have yet to be established, but experimental studies suggest that these may be genetically or maturationally dependent alterations in APCs, intestinal processing, and immunoregulatory T cells.

### B. Oral Tolerance and Immunotherapy

The oral route offers a convenient and highly acceptable means of administering therapeutic agents. In recent years, interest has developed in the possibility of exploiting oral tolerance to modulate antigen-specific immunopathology (Table III; see Thompson and Staines, 1990, for review). Several experimental immunological diseases can be prevented by prior feeding of appropriate protein antigens, including experimental autoimmune encephalomyelitis (Higgins and Weiner, 1988; Lider *et al.*, 1989; Nussenblatt *et al.*, 1990), collagen-induced arthritis, adjuvant arthritis (Zhang *et al.*, 1990), experimental autoimmune uveoretinitis (Nussenblatt *et al.*, 1990), and immune complex-mediated glomerulonephritis (Devey and Bleasdale, 1984; Gesualdo *et al.*, 1990).

Oral tolerance in these pathological systems shows many phenomenological and mechanistic similarities to that using model protein antigens, affecting T-cell responses predominantly and involving populations of T<sub>s</sub>. Encouragingly, in some cases, suppressing established disease by feeding antigen has also proved possible, indicating the possible usefulness of this approach in clinical practice. Although as yet no published reports are available of oral tolerance being exploited for treating clinical disease, a trial of feeding brain-derived material as a means of inhibiting multiple sclerosis is currently underway in the United States (Marx, 1991). Given the increasingly successful identification and purification of autoantigens, similar trials soon could be considered for a variety of organ-specific autoimmune diseases. In addition, feeding allogeneic leukocytes has been reported to suppress specifically the subsequent rejection of cardiac allografts (Sayegh *et al.*, 1992). The possibility of using the oral route to induce specific tolerance to alloantigens in prospec-

tive transplant recipients is therefore an attractive, if long-term, proposition. These and other clinical applications of oral tolerance may be helped dramatically by the development of transgenic cattle, whose milk may provide a source of large quantities of specific antigens in an ideal form for oral administration in bulk (Gershon, 1991).

### C. Development of Oral Vaccines

A major goal of current vaccine research is the construction of orally active vaccines that contain recombinant proteins or peptides as the immunogen. Such vaccines clearly will be unsuccessful unless the induction of oral tolerance can be overcome. An understanding of the principles involved will assist the design of appropriate vectors. From the foregoing discussion, we can predict that a successful vaccine should be particulate in nature (viable or not) and should contain adjuvant moieties capable of modulating either the uptake of the associated proteins by the intestine or their presentation by APCs within the immune system.

Several approaches that fulfill these conditions have been developed, including attenuated mutant strains of *Salmonella* as vectors for foreign genes and the use of cholera toxin as a mucosal adjuvant (McGhee *et al.*, 1992). Although these vectors have been successful, there are several reasons having nonantigenic vectors that do not themselves induce active immune responses (which could limit the use of multiple immunization). Coating proteins onto polyglycoside microspheres is one possible answer to this problem (McGhee *et al.*, 1992), but these agents have no adjuvant properties. We have shown that incorporation of proteins into ISCOMs containing Quil A (saponin) overcomes the induction of oral tolerance and allows the development of primary immune responses both in the intestine and the systemic immune system (Mowat and Donachie, 1991; Mowat *et al.*, 1991; Mowat, *et al.* 1993). The effectiveness of these small particles (30–40 nm) partly reflects increased uptake of antigen from the intestine, possibly because of the relative stability of ISCOMs in the harsh environment of the gut or because the detergent properties of Quil A potentiate transfer of protein

across the epithelium. In addition, Quil A itself is an orally active adjuvant (Chavali and Campbell, 1987) that may enhance APC activity. The success of ISCOMs encourages the belief that continued study of oral tolerance will allow the development of other orally active vaccines.

# Functional Aspects of the Peptidergic Circuit in Mucosal Immunity

David W. Pascual • Andrzej M. Stanisiz • Kenneth L. Bost

## I. INTRODUCTION

When considering the processes of immune protection, we distinguish between those events that govern antigen recognition by lymphoid cells and those that govern nonspecific elimination by macrophages and polymorphonuclear cells. These defense mechanisms are mediated by a cascade of events requiring cell–cell interactions and subsequent release of their soluble products, for example, cytokines, antibodies, and receptor molecules, to regulate these responses. How the nervous system can intervene in such processes, particularly at mucosal sites or mucosa-associated lymphoid tissue (MALT) where these neural mediators have been shown to concentrate, is addressed in this chapter. The contribution of the sensory neurons is examined, particularly the contents of the peripheral nerve fibers (peptidergic fibers) containing the neuropeptides (stored in secretory vesicles) substance P, vasoactive intestinal peptide, somatostatin, gastrin-releasing polypeptide, and calcitonin gene-related peptide.

When considering such cross-communication between the nervous and immune systems, we must examine the intrinsic properties of their mediators. Neuropeptides will, most likely, affect a localized area rather than induce a systemic effect. This property complements the inherent mobility of leukocytes and enhances the opportunity for neural–immune interactions, suggesting that leukocytes may be innervated transiently, especially in light of the ultrastructural studies with rat spleens demonstrating synaptic-like contacts between sympathetic nerve fibers and lymphocytes (Felten and Olschowka, 1987). Further, the close approximation between lymphoid sites and nerve fibers (Felten *et al.*, 1985; Ottaway *et al.*, 1987; Stead *et al.*, 1987b), in particular in mucosal sites of the gut, poses the unique question of whether mediators of one system can induce functional alterations of another system. One manifestation of such neuroimmune communication by which the central nervous system (CNS) can alter the immune system was evident when lesions in the hypothalamus decreased the levels of thymocytes and splenocytes (Roszman *et al.*, 1985). Conversely, an example of immune modification of neural elements is illustrated in the study in which the stimulation of cultured neonatal rat superior cervical ganglion (SCG) with interleukin 1 $\beta$  (IL-1 $\beta$ ) resulted in an increase in preprotachykinin (PPT) message with subsequent increase in substance P (SP) production (Jonakait and Schot-

land, 1990; Hart *et al.*, 1991). Interferon  $\gamma$  (IFN $\gamma$ ) and prostaglandin synthesis inhibitors could reduce both PPT message and SP production induced by IL-1 $\beta$  stimulation. In a similar fashion, when rat SCG were cultured with unstimulated splenocytes (Barbany *et al.*, 1991), tyrosine hydroxylase mRNA diminished by 50% but 400% enhancement of PPT mRNA and 50% enhancement of neuropeptide Y (NPY) were observed. In the presence of concanavalin A (Con A), mitogen-stimulated splenocytes decreased tyrosine hydroxylase mRNA and NPY mRNA expression by 75% and 70%, respectively. PPT mRNA was unaffected by this stimulation. Collectively, these studies suggest that elements from the immune and nervous systems are shared, that is, neurotransmitters, neuropeptides, and neuroendocrine hormones can affect lymphoid function and, conversely, cytokines can affect neural function. Obviously, to grant biological significance to these studies, a mode of uptake of such neuroimmune modifiers by the cells in question must be demonstrated. In this regard, an intriguing aspect of this neuroimmune network is the expression of neuropeptide and neuroendocrine hormone receptors on leukocytes. Over 20 such neuropeptide and neuroendocrine hormone receptors (Bost, 1988) have been identified on normal mononuclear and polymorphonuclear leukocytes and on tumor cell lines (Table I). The expression and regulation of these receptors by leukocytes is energy demanding; therefore, we must assume that their expression is important and not the result of indiscriminate mRNA transcription, that is, these events are regulated. The expression of these receptors by various subpopulations of leukocytes on their cell surfaces provides the means to receive neuronal signals that can alter immune function. Thus, the focus of this chapter is to describe the attributes of the nervous system that contribute to governing the immune surveillance of MALT.

## II. MUCOSA-ASSOCIATED LYMPHOID TISSUE NEUROPEPTIDES

### A. Substance P and Tachykinins

The CNS-derived 11-amino-acid neuropeptide substance P (SP; Chang and Leeman, 1971) is a product of the sensory

ganglion cells, and is transported to peripheral sites where it is stored and released on noxious stimulation (Pernow, 1983). Classically, SP is recognized for its ability to contract ileum smooth muscle cells and to act as a pain signal neurotransmitter (Pernow, 1983). The SP amino acid sequence (Table II) is conserved among mammals (bovine, human, and rat sequences) and belongs to a family of related peptides called tachykinins (Erspamer, 1981), each of which bears a common C-terminal amino acid sequence (Phe-X-Gly-Leu-Met-NH<sub>2</sub>, where X is a branched aliphatic or aromatic amino acid). An additional feature intrinsic to many of the enteric neuropeptides is the amidation of its C-terminal residue. The two mammalian tachykinin genes encode preprotachykinin A (PPT-A), which generates SP and substance K (SK; neurokinin A), and preprotachykinin B (PPT-B), which produces neurokinin B (neuromedin K). Alternate RNA splicing of the PPT-A gene produces three SP-encoding mRNAs (Nawa *et al.*, 1984; Krause *et al.*, 1987): the  $\alpha$  transcript encodes SP only; the  $\beta$  transcript encodes SP, SK, SK(3-10), and neuropeptide K (SK-containing peptide); and the  $\gamma$  transcript encodes SP, SK, SK(3-10), and neuro-

peptide  $\gamma$  (variant of neuropeptide K). Expression of the different PPT-A mRNAs is both species and tissue dependent (Helke *et al.*, 1990). For instance, in bovine tissues,  $\alpha$ -PPT mRNA is predominant in the brain whereas  $\beta$ -PPT mRNA is predominant in the intestine, in contrast to the rat, in which  $\gamma$ - >  $\beta$ - >  $\alpha$ -PPT mRNA in all tissues.

Outside the brain, SP is found in greatest concentrations (nanomolar and subnanomolar levels) in the gut (Pernow, 1983). The SP-containing nerve fibers are a major component of the enteric nervous system. Neurons containing SP also innervate lymphoid tissues, that is, spleen and lymph nodes (Felten *et al.*, 1985; Popper *et al.*, 1988; Lorton *et al.*, 1991). Consequently, the presence of SP at nanomolar concentrations is suggestive of an SP contribution to the regulation of immune function in gut-associated lymphoid tissues (GALT). Anatomical data have provided direct evidence for interactions between gut mast cells and nerve fibers containing SP (Stead *et al.*, 1987b). In the Peyer's patches, some evidence suggests that SP-containing nerve fibers infiltrate T-cell zones and associate with macrophages, a result that contrasts with what is observed in the lamina propria. Here, IgA plasma

Table II Sensory Neuropeptide Sequences

Gene	Translated products	Amino acid sequences
Preprotachykinin A	Substance P (SP)	Arg-Pro-Lys-Pro-Gln-Gln-Phe-Phe-Gly-Leu-Met-NH <sub>2</sub>
	Substance K (SK)	His-Lys-Thr-Asp-Ser-Phe-Val-Gly-Leu-Met-NH <sub>2</sub>
Preprotachykinin B	Neurokinin B (NKB)	Asp-Met-His-Asp-Phe-Phe-Val-Gly-Leu-Met-NH <sub>2</sub>
Vasoactive intestinal polypeptide	Vasoactive intestinal peptide (VIP)	His-Ser-Asp-Ala-Val-Phe-Thr-Asp-Asn-Tyr-Thr-Arg-Leu-Arg-Lys-Gln-Met-Ala-Val-Lys-Lys-Tyr-Leu-Asn-Ser-Ile-Leu-Asn-NH <sub>2</sub>
	Peptide histidine isoleucine amide (PHI)	His-Ala-Asp-Gly-Val-Phe-Thr-Ser-Asp-Phe-Ser-Arg-Leu-Leu-Gly-Gln-Leu-Ser-Ala-Lys-Lys-Tyr-Leu-Glu-Ser-Leu-Ile-NH <sub>2</sub>
	Peptide histidine methionine (PMI)	Positions 1-27 identical with PHI -----Ser-Leu-Met-NH <sub>2</sub>
Somatostatin	Somatostatin	Ala-Gly-Cys-Lys-Asn-Phe-Phe-Trp-Lys-Thr-Phe-Thr-Ser-Cys
Gastrin-releasing polypeptide (humans)	Gastrin-releasing polypeptide (GRP)	Val-Pro-Leu-Pro-Ala-Gly-Gly-Gly-Thr-Val-Leu-Thr-Lys-Met-Tyr-Pro-Arg-Gly-Asn-His-Trp-Ala-Val-Gly-His-Leu-Met-NH <sub>2</sub>
Bombesin (frog)	Bombesin	Pyr-Gln-Arg-Leu-Gly-Asn-Gln-Trp-Ala-Val-Gly-His-Leu-Met-NH <sub>2</sub>
Calcitonin	Calcitonin	Cys-Gly-Asn-Leu-Ser-Thr-Cys-Met-Leu-Gly-Thr-Tyr-Thr-Gln-Asp-Leu-Asn-Lys-Phe-His-Thr-Phe-Pro-Gln-Thr-Ser-Ile-Gly-Val-Gly-Ala-Pro-NH <sub>2</sub>
	Calcitonin gene-related peptide $\alpha$ (CGRP- $\alpha$ )	Ser-Cys-Asn-Thr-Ala-Thr-Cys-Val-Thr-His-Arg-Leu-Ala-Gly-Leu-Leu-Ser-Gly-Gly-Val-Val-Lys-Asp-Asn-Phe-Val-Pro-Thr-Asn-Val-Gly-Ser-Glu-Ala-Phe-NH <sub>2</sub>
Calcitonin gene-related peptide $\beta$	Calcitonin gene-related peptide $\beta$ (CGRP- $\beta$ )	Positions 1-34 identical with CGRP- $\alpha$ -----Lys-Ala-Phe-NH <sub>2</sub>

cells can be found in densely innervated areas, suggesting that these cells may be more likely to be influenced by neuropeptides (Stead *et al.*, 1987a).

Although limited evidence exists demonstrating peptidergic fibers coming into close association with B-cell follicles in mammalian lymphoid tissues, the chicken is potentially the best experimental model to delineate the linkage between the nervous system and B-cell differentiation. The extent of infiltration by peptidergic fibers into the bursa of Fabricius was examined (Zentel and Weihe, 1991). SP, in addition to other enteric neuropeptides—vasoactive intestinal peptide (VIP), calcitonin gene-related peptide (CGRP), and galanin—was found distributed throughout the bursa of Fabricius and bordering B cells in the follicle cortex in three distinct fiber subpopulations: SP-containing, SP + CGRP-containing, and VIP + galanin-containing fibers. VIP-containing fibers were the only such peptidergic fibers that came in contact with some macrophages. However, this association between peptidergic nerve fibers and B cells was not evident with human tonsillar B cells as it was with those B cells in the bursa of Fabricius. SP-containing fibers in human tonsil were seen primarily in the perivascular plexus with low level expression in the interfollicular areas and adjacent to T cells and macrophages (Weihe and Krekel, 1991). In the mesenteric lymph nodes, SP innervation was sparse and was found associated with 5–10% of the arterioles and venules in the medulla adjoining the T-cell region, as well as in the capsule (Popper *et al.*, 1988). In the same study, SP receptor binding sites were examined by quantitative receptor autoradiography. Between 25 and 35% of the germinal centers expressed SP binding sites, whereas limited binding sites were

found on arterioles and venules in the T-cell region and internodular region near the capsule. SP-containing fibers also are found in the bronchus-associated lymphoid tissue (BALT). In the rat BALT, SP-containing fibers were localized to the subepithelial zone (Inoue *et al.*, 1990).

To endow biological significance for the expression of SP receptors (SP-R) on lymphocytes and other accessory cells (Bost, 1988; Bost and Pascual, 1992), SP-R expression has been shown by radiolabeled ligand binding studies. Such studies have demonstrated the presence of SP-R on surfaces of B cells and T cells isolated from the spleen and Peyer's patches that have binding characteristics similar to SP-R in neural tissues (Nakata *et al.*, 1988). Evidence to this effect is based on the following observations: (1) similar dissociation constant; (2) similar rank-order displacement by related tachykinins; and (3) identification of 58-kDa protein that binds SP, and (4) the expression of brain SP-R mRNA sequence by CD4<sup>+</sup> T lymphocytes isolated from *Schistosomiasis mansoni*-induced granulomas (Elliott *et al.*, 1993). SP-R initially was shown to be expressed by the human B lymphoblastic cell line IM-9 (Payan *et al.*, 1984a); much of our current understanding of the physical characterization of SP-R has been derived from extensive studies of this cell line (Payan *et al.*, 1986). By radiolabel binding studies, these cells have been demonstrated to bind SP with a dissociation constant of 0.65 nM and to exhibit a single class of SP-R. IM-9 lymphoblasts preferentially bound SP over other tachykinins via the C terminus since SP fragment (1–4) failed to inhibit radiolabeled SP binding competitively whereas SP fragment (4–11) could compete effectively. Using radiolabeled SP in cross-linking studies (Payan *et al.*, 1986), the SP-R was deter-

mined to be a 53,000–58,000 dalton protein. Antireceptor antibodies (Pascual *et al.*, 1989; van Ginkel *et al.*, 1993) have confirmed this finding, which fully supports studies with SP-R in neural tissues. The binding domain for SP-R appears to involve the putative first and third extracellular regions since antibodies directed to peptide sequences to these domains inhibited radiolabeled SP binding to SP-R (van Ginkel *et al.*, 1993). The advent of cloning the rat brain SP-R (Hershey and Krause, 1990) and bovine brain SK-R (Masu *et al.*, 1987) has demonstrated that these receptors belong to G-protein coupled receptor family with seven putative transmembrane spanning regions. This same SP-R exists on lymphocytes as well based on the confirmations by two independent laboratories. Each have shown that murine mononuclear cells express authentic SP-R. A portion of the murine macrophage SP-R was cloned using reverse transcriptase polymerase chain reaction (RT-PCR), and demonstrated complete homology with murine brain SP-R (Bost, 1993). Applying similar strategy, the cDNA for authentic SP-R was cloned and sequenced from liver granulomas isolated from *Schistosomiasis mansoni*-infected mice, and no mRNA for SK-R or neurokinin B could be detected (Elliott *et al.*, 1993). These findings confirm the presence of SP-R on lymphocytes and macrophages, and that the lymphoid SP-R is identical to brain SP-R as opposed to being a separate SP-R isoform.

Functional attributes of SP have been studied best with B lymphocytes and macrophages (Bost and Pascual, 1992; Pascual *et al.*, 1992). Early studies had suggested that SP behaves as a B-cell differentiation factor. When mononuclear fractions from the murine spleen, mesenteric lymph nodes, and Peyer's patches were co-stimulated with 1.0  $\mu\text{g/ml}$  Con A and 10 nM SP, IgA production increased by 70, 40, and 300%, respectively (Stanisz *et al.*, 1986). To a lesser extent, IgM levels were altered significantly by 20–40%. Using these culture conditions, no significant increases in IgG secretion by mononuclear cells isolated from these tissues were observed. Consequently, this study does suggest that SP may stimulate IgA secretion preferentially or, alternatively, may indicate that SP is an IgA switching factor (Xu-Amanu *et al.*, 1993). The ramifications of such possibilities are intriguing in light of the abundance of SP-containing neurons in the gut (Hokfelt *et al.*, 1980). Alternatively, SP may stimulate selectively the proliferation of one surface Ig phenotype as opposed to another. Examination of the proliferative effects of SP on these mixed cultures revealed that SP induced 60% increase in the amount of [ $^3\text{H}$ ]thymidine incorporated versus cultures treated in the absence of neuropeptide. Although substantial enhancement in IgA production was observed, which mononuclear cell subpopulation or combination was affected most greatly by SP was unclear from this study since each cell subpopulation is known to exhibit SP receptors. Thus, to evaluate SP effects on lymphoid function effectively, SP function had to be assessed with purified lymphoid cell subpopulations.

In an attempt to delineate the mechanisms of how SP behaves as a B-cell differentiation factor (Pascual *et al.*, 1991b, 1992; Bost and Pascual, 1992), the direct effect of SP on CD5<sup>+</sup> B-lymphoma cell lines CH12.LX.C4.4F10 (an IgA producer) and CH12.LX.C4.5F5 (an IgM producer) was as-

sessed. From radiolabel binding experiments, these CH12LX subclones were shown to bear SP receptors (between 500 and 600 receptors/cell) similar to those levels found on normal B lymphocytes, with binding affinities ( $K_d \sim 0.69\text{nM}$ ) similar to those found on normal B lymphocytes (Stanisz *et al.*, 1987) and IM-9 B lymphoblasts (Payan *et al.*, 1984a) as well. On direct SP stimulation of CH12.LX.C4.4F10 cells, IgA production could be enhanced by 35% at subnanomolar concentrations whereas a similar stimulation on CH12.LX.C4.5F5 cells resulted in no significant change in the amount of IgM produced. SP had no effect on cell proliferation when ascertained by [ $^3\text{H}$ ]thymidine uptake. The biological significance for the expression of SP-R on B lymphocytes was enhanced by the observation that SP, in the presence of a secondary signal, could augment immunoglobulin synthesis. The addition of a suboptimal dose of lipopolysaccharide (LPS; 50 ng/ml) with varying concentrations of SP to CH12.LX.C4.5F5 cells resulted in a 172% increase in IgM production at 0.1 nM and 1.0 nM SP doses.  $\mu$  Chain message was enhanced only moderately (50–60%) by this mode of stimulation. Modest increases in IgM production also were observed with picomolar concentrations of SP. High doses of SP (100 nM) were not as effective in enhancing IgM production as were subnanomolar concentrations of SP suggesting SP-R desensitization at these higher SP concentrations. Moderate increases in IgA production were observed for CH12.LX.C4.4F10 cells stimulated in a similar fashion, as for the IgM-producing CH12 clone. In the presence of suboptimal dose of LPS, again subnanomolar concentrations of SP were most effective in enhancing IgA production by 50%; no differences in  $\alpha$  chain message were observed. Further evidence to support that these events are receptor mediated was provided when duplicate cultures were performed in the presence of 1000-fold excess SP antagonist (D-Pro<sup>2</sup>-D-Phe<sup>7</sup>-D-Trp<sup>9</sup>-SP), resulting in the specific inhibition of SP-induced IgM and IgA enhancement and no effect on the enhancement induced by LPS alone. Similar effects mediated by SP also could be shown with purified B cells isolated from the spleen. In one study (Pascual *et al.*, 1991a), >99% sIg<sup>+</sup> B lymphocytes isolated from mouse spleens cultured with varying concentrations of SP (0.1 pM–100 nM) had no effect on Ig production. Again, the presence of a co-stimulating triggering mechanism was required, similar to those required for IL-4 and IL-5 co-stimulation assays. The addition of 10  $\mu\text{g/ml}$  LPS to optimal doses of SP resulted in substantial enhancement of IgM and IgG3 production, as much as 500 and 1000% increase, respectively (Pascual *et al.*, 1991a). Even picomolar concentrations of SP could increase IgM levels significantly. IgA production was enhanced significantly, but only moderately. The significance of this study is twofold. First, SP could stimulate B cells directly in the absence of accessory cells. Second, physiologically relevant concentrations of SP could enhance Ig synthesis by purified B cells. This observation is in agreement with previous reports (Stanisz *et al.*, 1986) about the ability of SP to modify Ig synthesis, although optimal stimulatory concentrations of SP differed. At doses optimal for Ig production, SP in the presence of LPS was antiproliferative for purified B cells, and more inhibitory at higher SP concentrations (Pascual *et al.*, 1991a). An antiproliferative effect of SP also

was observed with isolated splenic mononuclear cells treated simultaneously with LPS and SP (Krco *et al.*, 1986); however, the extent of inhibition or the dose effect was not observed. The enhanced antibody production induced by SP in B cells could be explained by the possibility that selected B-cell subpopulations are responsive to SP stimulation. Using the ELISPOT assay, purified splenic B cells subjected to LPS/SP co-stimulation were determined to show increased numbers of spot-forming cells. From these studies analyzing the modulation of Ig synthesis by B cells, we conclude that, despite the differences in the experimental conditions, in each case SP requires a coactivation signal to achieve an augmentation in Ig production. Normal Peyer's patch B lymphocytes are also sensitive to SP stimulation (Pascual *et al.*, 1993). As with splenic B cells, Peyer's patch B cells required a coactivation signal, and in this case, suboptimal dose of recombinant IL-6 was used. Nanomolar concentrations of SP induced 150% increase in IgA, 175% increase in IgG, and 25% increase in IgM. Clearly, these studies suggest differential expression of SP-R on B lymphocyte subpopulations.

Although we have discussed the potential significance of SP as a neuroimmune modulator in various *in vitro* studies, some intriguing aspects to SP *in vivo* function exist. One of the first *in vivo* studies that suggested a possible correlation between SP and Ig production was performed by Helme *et al.* (1987). The premise for this study takes advantage of the selective action of the neurotoxin capsaicin, which destroys unmyelinated sensory neurons present in peripheral tissues when rats are treated neonatally (Buck and Burks, 1986). As a consequence of such treatment, neuropeptides such as SP are depleted from peripheral sites (Nagy *et al.*, 1981, 1983; Buck and Burks, 1986). Neonatally capsaicin-treated rats were allowed to mature and were subjected to sheep red blood cells challenge. This treatment resulted in greater than 80% reduction in IgM and IgG plaque-forming cell response by popliteal lymph nodes compared with plaque-forming cell response in SRBC-challenged rats. Clearly, these results denote the significance of neuronal input, particularly the presence of neuropeptides, for the development of antibody responses. This lack of antigen responsiveness or suppression exhibited by capsaicin-pretreated rats was determined to be reversible on coadministration of SP with SRBC. In a subsequent study (Eglezos *et al.*, 1990), a similar magnitude of inhibition in antibody responses was obtained in rats treated with the SP antagonist Spantide during antigen priming. Whereas these studies examined the contribution of SP depletion to antigen challenge, the direct *in vivo* significance of SP for immune function was examined in a study in which the administration of SP via miniosmotic pump for 7 days was examined (Scicchitano *et al.*, 1988a). After a 1-week infusion, lymphocytes from the Peyer's patches were cultured for 7 days in the presence of Con A, and subsequently assessed for Ig production by isotype-specific plaque-forming cell response. A preferential enhancement of IgA-secreting cells (260% increase) in contrast to no significant changes for IgM- and IgG-secreting cells could be demonstrated. When similar analysis was performed with lymphocytes isolated from the spleen, IgA-producing cells were the predominant cell type expressed (~380% increase) although enhancement

of IgM-secreting cells also was noted (~190% increase). Enhanced cell-proliferative responses by Peyer's patch and splenic lymphocytes also were observed as a consequence of this *in vivo* SP administration. Similarly, in an antigen-specific system, mice were infused with SP for 1 week via miniosmotic pumps and simultaneously immunized with UV-inactivated rotavirus (Ijaz *et al.*, 1990). Increased levels of antirotavirus antibody in the milk of lactating females as well as in the serum were shown. Using Western blot analysis, increased levels of antibodies to rotaviral antigens VP4, VP6, and VP7 were observed. In summary, *in vivo* infusion of SP stimulates the development of Ig-producing cells whereas *in vivo* SP depletion reduces the number of Ig-producing cells.

In addition to B cells, macrophages have been shown to express receptors for SP and be influenced in their function by SP. Hartung *et al.* (1986) demonstrated the expression of a single class SP-R on guinea pig macrophages with a dissociation constant of 19 nM. This binding was mediated via the C terminus. Both human monocytes and guinea pig peritoneal macrophages stimulated with SP at nanomolar concentrations evoked increased chemotaxis (Wiedermann *et al.*, 1989). Further, SP stimulation of monocytes and macrophages enhances the release of cytokines. SP, as well as related tachykinins, induced the release of IL-1-like activity from the mouse macrophage cell line P388D1 in a dose-dependent fashion (Kimball *et al.*, 1988). Human peripheral blood monocytes also could be stimulated by SP to release IL-1, IL-6, and tumor necrosis factor  $\alpha$  (TNF $\alpha$ ; Lotz *et al.*, 1988). The mode of action in both studies was similar because stimulation was via the SP C terminus, since SP(4-11), SK, and neurokinin A each could induce cytokine release. Whereas these studies show that macrophages are responsive to SP, other studies have found macrophages to be a mobile source of SP, which can be produced by peritoneal macrophages (Pascual and Bost, 1990a) as well as by P388D1 cells (Pascual and Bost, 1990b). Macrophage-derived SP regulates thymocyte proliferation activity, presumably that mediated by IL-1 and IL-6, in an autocrine/paracrine fashion. By culturing P388D1 cells in the presence of a monoclonal anti-SP (N terminus specific) antibody, 40-50% reduction of mouse thymocyte proliferation activity was noted. Peritoneal macrophage-derived SP and its related SP mRNA were later shown to be upregulated by LPS (Bost *et al.*, 1992). An intriguing observation of the relationship between SP and macrophages is that SP can regulate the production and release of cytokines, particularly those responsible either directly or indirectly for IgA production by Peyer's patch lymphocyte cultures. IL-1 (Cowdery *et al.*, 1988) and IL-6 (Beagley *et al.*, 1989) have been shown to promote IgA responses; both of these cytokines are inducible by SP stimulation. In conjunction with anatomical evidence of its vasodilatory properties and histamine releasing abilities, SP at mucosal sites such as gut (Furness and Costa, 1980; Felten *et al.*, 1987; Makhlof, 1990) and lung (Lundberg and Saria, 1987; Wiederman *et al.*, 1987) represents an additional factor, particularly at localized sites, that can regulate immune function and contribute to inflammation (Payan, 1989). As a result of its association with inflammation and macrophages, SP can be referred to as a pro-inflammatory peptide. Clinical

manifestations of SP as a pro-inflammatory peptide are supported by its increased presence at concentrations up to 3 ng/ml in inflammatory exudates (Tissot *et al.*, 1988; Schiogolev *et al.*, 1989). Its presence in synovial fluids isolated from human arthritic patients (Marshall *et al.*, 1990; Argo *et al.*, 1992). Examination of SP-R function from rheumatoid arthritis patients indicates an apparent SP-R desensitization by systemic and synovial fluid lymphocytes. This was evident by the lack in change in SP-mediated lymphocyte proliferation and an associated increase in GM-CSF production (Argo and Stanisz, 1992). With experimental animals, studies (Levine *et al.*, 1984; O'Byrne *et al.*, 1992) suggests that SP contributes to the exacerbation of arthritis. Increased SP and SP receptor expression also has been demonstrated in patients with Crohn's disease and colitis (Koch *et al.*, 1987; Mantyh *et al.*, 1988). In other models of intestinal inflammation, *Trichinella*-infected rats exhibit increased levels of SP in inflamed jejunum (Swain *et al.*, 1992), and treatment with anti-SP antibodies result in reduced gastrointestinal inflammation and restored SP-induced cell proliferation by Con A-stimulated lymphocytes (Argo and Stanisz, 1993).

Limited reports are available of SP modulation of T-cell function. In the one report previously described (Stanisz *et al.*, 1986), Con A stimulation of splenic mononuclear cells suggests that SP may be co-stimulating T cells to release B-cell differentiating cytokines. We have been able to demonstrate that SP promotes Th2-type cytokine production. The addition of SP to Con A-stimulated murine splenic and Peyer's patch CD4<sup>+</sup> T cells result in enhanced number of IL-5 producing cells, whereby three- to five-fold increases were noted, while the number of IFN- $\gamma$  producing cells remain unchanged (D. W. Pascual, submitted). In contrast, SP promotes Th1-type response in murine schistosomiasis (Elliott *et al.*, 1993), where increased IFN- $\gamma$  levels were shown, and no change in IL-5 levels were observed. Obviously, these represent different experimental paradigms, but suggest the influence of SP in T cell-dependent immune responses (Figure 1). In one of the first reports (Payan *et al.*, 1983) describing SP stimulation of lymphocytes, researchers demonstrated that SP behaved as a cell proliferation factor for T cells, yet this proliferation-enhancing ability was not observed with B cells (Pascual *et al.*, 1991a,b). SP co-stimulation of Con A-treated lamina propria lymphocytes (LPL; 64% CD3<sup>+</sup> and 11% CD19<sup>+</sup>) derived from human colon specimens diminished [<sup>3</sup>H]thymidine incorporation over 50% in a dose-dependent fashion, with maximal effect at nanomolar concentrations (Elitsur and Luk, 1990). Natural killer (NK) activity by murine intestinal intraepithelial leukocytes (IELs) was shown to be enhanced by SP in *in vitro* assays from normal mice as well as in mice infused with SP (Croitoru *et al.*, 1990). As much as a 10-fold increase in NK activity by Thy1<sup>-</sup> cells was observed when 10 nM SP was incubated with IEL effector cells and Yac-1 target cells.

### B. Vasoactive Intestinal Peptide

First identified for its potent vasodilatory properties (Said and Mutt, 1970), VIP is a 28-amino-acid peptide with C-

**Figure 1** SP participates in the promotion of IgA responses either directly on IgA producing B cells or indirectly on Th2-type cells or macrophages. SP acts as a co-stimulatory signal for B cells activated by antigen or cytokines to elicit an enhanced IgA response, or SP can also provide a co-stimulatory signal to Th2 cells to produce IL-5, an IgA-promoting cytokine. To activated macrophages, SP can induce the production of IL-6, an additional late-acting differentiating factor for IgA and IgG responses. Interestingly, activated macrophages also produce SP, and in an autocrine/paracrine fashion can regulate constitutive IL-1/IL-6 production. Thus, macrophage-produced SP may be important for localized regulation of cytokine-induced inflammation. In addition, SP can also stimulate Th1 cells to produce IFN- $\gamma$ ; however, evidence to this effect has only been shown for schistosomiasis-induced granulomas since no change in the number of IFN- $\gamma$ -producing cells was observed when normal CD4<sup>+</sup> T cells are stimulated with SP and mitogen. Thus, these observations most likely represent separate models of SP induction.

terminal amidated asparagine (Table II). No deviation among bovine, rat, human, canine, and porcine sequences was evident, but variations were seen in guinea pig and chicken sequences (McDonald, 1991). VIP is cotranslated from a 1.8- to 2.1-kb mature mRNA that encodes another C-terminal amidated peptide designated PHI (peptide histidine isoleucine amide) and, in humans, PHM (peptide histidine methionine amide) (Gozes *et al.*, 1987; Linder *et al.*, 1987) as the VIP-PHI/PHM preprohormone 170 amino acids in length. The preprohormone is processed into a prohormone of 18 kDa. Further processing generates both VIP and PHI/PHM. Known for its ability to induce vasodilation and act as a potent mediator of smooth muscle relaxation (Said, 1984), VIP is found in the central nervous system as well as in peripheral nerves (Larsson *et al.*, 1976), particularly in the peptidergic nerves (Schultzberg *et al.*, 1980; Ekblad *et al.*, 1987; Makhlof, 1990). These types of nerve fiber are found abundant in mucosal tissues: gastrointestinal tract, male and female genital tract, upper respiratory and nasal mucosa, and salivary glands (Larsson *et al.*, 1976; Polak and Bloom, 1982). In the gastrointestinal tract, nerve fibers containing VIP are present in both the small and large intestine, with extensive innervation in all layers (Ekblad *et al.*, 1987, 1988). VIP also can be found coexisting with SP in similar enteric neurons of the myenteric plexus and submucosal plexus (Makhlof, 1990). VIP-containing nerve fibers also have been found in

lymphoid tissues including the thymus, spleen, and Peyer's patches (Felten *et al.*, 1985; Ottaway *et al.*, 1987).

The presence of VIP receptors (VIP-R) on leukocytes has been determined by radiolabel binding studies (Table I). From these studies and cross-linking experiments, VIP-R has been shown on human MOLT-4b T lymphoblasts (Beed *et al.*, 1983). These cells express a single class VIP-R with an apparent size of 47,000 daltons (Wood and O'Dorisio, 1985), which correlates closely with VIP-R found on liver (Couvineau *et al.*, 1986) and pancreatic acinar cells (McArthur *et al.*, 1987). The VIP-R on the MOLT-4b T cells appears to activate cAMP via a stimulatory guanine nucleotide binding protein (O'Dorisio *et al.*, 1985). Maximum effect was obtained with nonphysiological doses of VIP, but increased cAMP production still was observed at nanomolar concentrations and could synergize with forskolin. The human myeloma cell line U266 also expresses a single class receptor with a  $K_d$  of 7.6 nM (Finch *et al.*, 1989), similar to what has been observed with MOLT-4b lymphocytes ( $K_d = 7.3$  nM). Normal mouse lymphocytes also have been shown to express VIP-R. These receptors were found primarily on T cells (Ottaway and Greenberg, 1984). VIP-R density was greatest, in descending order, on lymphocytes isolated from subcutaneous lymph nodes, mesenteric lymph nodes, spleen, and Peyer's patches. In one report (Sreedharan *et al.*, 1991), the authors suggested that they have cloned the human VIP-R gene with libraries derived from the pre-B Nalm 6 cell line, which shares >90% nucleic acid and amino acid sequence homology with the G-protein coupled canine orphan receptor previously cloned by a separate group of investigators (Libert *et al.*, 1989, 1990). The deduced sequence of 362 amino acids exhibits a hydrophathy profile common to G-protein coupled, seven transmembrane-region type receptors. Cos-6 cells transfected with the cDNA clone for human VIP-R bound radioiodinated VIP with a dissociation constant of 2.5 nM.

The first evidence for VIP mediation of immune function was the finding that polymorphonuclear leukocytes produce VIP (O'Dorisio *et al.*, 1980), but the functional significance of this finding remains to be elucidated. Subsequent studies have shown VIP to inhibit mitogenic-induced proliferation of murine lymphocytes reversibly (Ottaway and Greenberg, 1984; Krco *et al.*, 1986; Stanisiz *et al.*, 1986) as a consequence of decreased IL-2 production, but not to affect T suppressor cell activity (Ottaway, 1987; Boudard and Bastide, 1991). Maximum inhibition of mitogen-induced cell proliferation by VIP occurred within the first 24 hr of neuropeptide exposure, and did not appear to be cAMP-dependent (Boudard and Bastide, 1991). Prepro-VIP, synthesized from the preprohormone sequence that encodes three neuropeptides [VIP, PHM (27-mer), and peptide histidine valine (PHV; 42-mer)], also inhibited the proliferation of Con A-stimulated murine lymphoid cells from Peyer's patches, spleen, and mesenteric lymph nodes (Yiangou *et al.*, 1990). Human peripheral blood lymphocytes and human jejunal IEL proliferation responses to Con A were not affected by VIP (Roberts *et al.*, 1991), but LPL proliferation from human colonic specimens was inhibited by nanomolar concentrations of VIP (Elitsur and Luk, 1990).

Short-term (24-hr) Con A stimulation of mesenteric lymphnode cells reduced the number of VIP binding sites (Ottaway, 1987), an indication that VIP receptors on lymphocytes can be regulated. Depletion of L3T4<sup>+</sup>, but not Lyt2<sup>+</sup>, mesenteric lymph node cells resulted in diminished radiolabeled VIP binding (Ottaway, 1987), suggesting the preferential expression of VIP receptors on T helper cells. Interestingly, VIP was shown to enhance IgM production (+70%) while preferentially diminishing IgA production (-70%) by Con A-stimulated Peyer's patch mononuclear cells (Stainsz *et al.*, 1986). However, in this study, ascertaining whether VIP was acting directly on VIP-R on B cells (Finch *et al.*, 1989; O'Dorisio *et al.*, 1989) or mediating its effects via VIP-R on T cells and macrophages (Ottaway, 1984; Segura *et al.*, 1991), which in turn stimulated the secretion of cytokines promoting B-cell differentiation, was difficult. VIP-containing neurons have been demonstrated to extend into the T-cell regions of the Peyer's patches (Ottaway *et al.*, 1987), most likely to affect the CD4<sup>+</sup> T cells. This population of T cells bears VIP receptors whereas CD8<sup>+</sup> cells do not (Ottaway, 1987). Thus, stimulation of CD4<sup>+</sup> T cells can modulate Ig synthesis. In this regard, finding that, in the presence of Th2 cells and derived cytokines, VIP could affect B-cell differentiation would not be unexpected. In addition to these activities, VIP has been found to reduce NK cell cytotoxic activity (Rola-Pleszczynski *et al.*, 1985) and to have mast cell secretagogue activity (Piotrowski and Foreman, 1985). VIP can affect lymphocyte migration, since VIP-treated lymphocytes tend to migrate less into mesenteric lymph nodes and Peyer's patches than into spleen, lung, or peripheral blood (Ottaway, 1984). Inhibition of lymphocyte migration out of sheep popliteal lymph nodes also was observed (Moore, 1984). Again, using the murine schistosomiasis model, eosinophils in the induced granulomas were found to produce VIP (Mathew *et al.*, 1992), which induces granuloma T cells to generate IL-5. It was also observed that the IL-5-producing T cells were not reactive with soluble ova antigen. Thus, this study suggests that eosinophil-derived VIP can invoke IL-5 release by a T-cell receptor-independent mechanism. In an attempt to understand the endocrine and neuronal contribution to immune protection of the eye, one study (Kelleher *et al.*, 1991) assessed the contribution of various endocrine hormones and neuropeptides to lacrimal secretory component (SC) levels. VIP concentrations of 1.0  $\mu$ M, but not peptide concentrations from 1.0 nM to 100 nM, were effective in stimulating rat lacrimal gland acinar cells to release SC. This increase in SC output was time dependent, requiring the presence of VIP for 4-7 days, whereas short-term exposure (<24 hr) had no effect.

### C. Somatostatin

Widely distributed in the central and peripheral nervous system, the 14-amino-acid peptide somatostatin (growth hormone release-inhibiting hormone; Table II) is present throughout the gastrointestinal tract in nerve cells of the myenteric plexus and submucous plexus (Schultzberg *et al.*,

1980) as well as in endocrine cells (Elde and Hokfelt, 1979; Hokfelt *et al.*, 1980). Its mRNA encodes a prohormone of 12,800 daltons; after posttranslational processing, somatostatin 14 is generated (Funckes *et al.*, 1983).

The first evidence of lymphocytes expressing somatostatin receptors (Table I) was reported by Bhatena *et al.*, (1981). Somatostatin binding sites were evident on lymphocytes and monocytes, as determined by radiolabel binding studies. Two classes of somatostatin receptors later were identified on human T-cell lines and on an Epstein-Barr virus-transformed B-cell line: high-affinity receptors displayed dissociation constants with picomolar values and low-affinity receptors showed dissociation constants in the nanomolar range (Nakamura *et al.*, 1987). Likewise, examination of the Jurkat human leukemic T-cell line and U266 human IgE myeloma cell line by radiolabel binding studies for the expression of somatostatin receptors showed that these cells exhibited biphasic binding characteristics with high-affinity receptors and  $K_d$  values of 3 pM (~150 receptors/cell) and 5 pM (~1150 receptors/cell), respectively (Sreedharan *et al.*, 1989a). Low-affinity receptors expressed by the Jurkat T cells and U266 myeloma cells displayed binding constants of 66 nM and 100 nM, respectively. In contrast, only a single class binding receptor for somatostatin was found on the mouse IgA myeloma cells MOPC 315 (Scicchitano *et al.*, 1988b). A dissociation constant of 1.6 nM with ~40,000 receptors/cell was obtained. When compared with human lymphoid somatostatin receptors, this evidence suggests that the  $K_d$  for this murine somatostatin receptor resembles the low-affinity receptor.

Somatostatin inhibits the release of a variety of hormones including growth hormone, insulin, and VIP (Reichlin, 1986). Similar inhibitory action also is observed in the immune system. Somatostatin at picomolar concentrations inhibited the proliferation of phytohemagglutinin (PHA)-stimulated T lymphocytes and the MOLT-4 T lymphoblasts at the DNA and protein levels (Payan *et al.*, 1984b); nanomolar concentrations were inhibitory for the proliferation of human colonic LPL (Elitsur and Luk, 1990). To obtain similar inhibitory effects, nanomolar (Stanisz *et al.*, 1986) and micromolar (Argo *et al.*, 1991) concentrations of somatostatin were required to inhibit Con A-stimulated murine Peyer's patch and splenic mononuclear cells. However, the *in vivo* administration of somatostatin via miniosmotic pump for constant delivery for 7 days resulted in enhanced suppressive effect with Peyer's patch mononuclear cells were assayed subsequently *in vitro*. A 70% reduction of mitogen-induced cell proliferation was observed with splenocytes from *in vivo*-treated mice, but the addition of somatostatin to these same *in vitro* cultures resulted in greater inhibition, exceeding 90% of cell proliferation. Further examination of the ability of somatostatin to modulate lymphoid function revealed that this neuropeptide exerted an inhibitory effect on IgA (20–50% reduction) and, to lesser degree, on IgM (10–30% reduction) production by murine mononuclear cells from the spleen and Peyer's patches (Stanisz *et al.*, 1986). Similarly, IgA production by MOPC 315 cells was inhibited at nanomolar concentrations of somatostatin by as much as 60% (Scicchitano *et al.*, 1988b). However, at  $10^{-12}M$  somatostatin, as much as a 40% increase

in IgA production was observed. Further investigation is required to understand the significance of this latter observation.

### D. Gastrin-Releasing Polypeptide and Bombesin

The term bombesin refers to a family of peptides that share a conserved 7-amino-acid C terminus (Trp-Ala-Val-Gly-His-Leu-Met-NH<sub>2</sub>) that is the minimal fragment required for bombesin-like activity. This tetradecapeptide (Table II) was identified first in frog skin extracts (Anastasi *et al.*, 1971); subsequently, mammalian and avian 27-mer counterparts were identified from gastrointestinal extracts and referred to as gastrin-releasing polypeptide (GRP) (Spindel, 1986). In mammalian gut, GRP is restricted solely to the neurons (Moghimzadeh *et al.*, 1983) and found predominantly in those neurons of the large intestine, whereas fewer neurons are found in the small intestine (Moghimzadeh *et al.*, 1983; Ekblad *et al.*, 1987, 1988). Bombesin/GRP can elicit gastric acid and pancreatic enzyme secretion as well as induce gall bladder and intestinal smooth muscle contraction (Fave *et al.*, 1985; Spindel, 1986). The human GRP gene is 10 kb in length and gives rise to three different mRNA species as a result of alternate splicing. However, the full-sized form is the predominant species (Spindel *et al.*, 1987). The human prohormone is a 148-amino-acid polypeptide that undergoes posttranslational processing to produce GRP.

Limited reports have been made examining the effects of bombesin/GRP on lymphoid cells. In one study, the proliferative ability of bombesin was assessed and shown to have little or no effect on Con A- or LPS-induced lymphoid cell proliferation (Krcso *et al.*, 1986), but was antiproliferative for human colonic LPL (Elitsur and Luk, 1990). However, as an IgA releasing factor, bombesin was shown to enhance effectively the *in situ* release of antigen-specific IgA and IgG antibodies from perfused rat intestine (Jin *et al.*, 1989). The rapid release of these antibodies may be, in part, the result of the evocation of cholecystokinin and gastrin (Freier *et al.*, 1987), which also have been shown to induce the release of IgA and IgG antibodies from the intestine.

### E. Calcitonin Gene-Related Peptide

The spontaneous switch in a rat medullary thyroid carcinoma that resulted in diminished calcitonin production led to the discovery of a novel mRNA product that was larger than the calcitonin mRNA (Amara *et al.*, 1982). This new mRNA was shown to result from alternate RNA processing. After posttranslational processing of the 16-kDa prohormone, a novel peptide was generated. This neuropeptide, which was called calcitonin gene-related peptide (CGRP), shared little homology with calcitonin. The alternative gene processing of the calcitonin gene for the production of calcitonin and CGRP appeared to be tissue specific (Rosenfeld *et al.*, 1983). CGRP is a 37-amino-acid peptide (Table II) and shares similar C-terminal amidation with the other sensory neuropeptides. This peptide has the additional feature of a disulfide linkage between cysteine residues at positions 2 and 7. A

second CGRP was discovered from a separate gene (Amara *et al.*, 1985) and referred to as  $\beta$ -CGRP, differing from  $\alpha$ -CGRP by a conservative amino acid substitution at position 35 (lysine for glutamic acid). CGRP exhibits both potent vasodilatory (Brain *et al.*, 1985) and intestinal smooth muscle relaxant (Barthó *et al.*, 1987) properties. Similar to SP, CGRP is disseminated throughout the central and peripheral nervous systems (Clague *et al.*, 1985; Hanko *et al.*, 1985; Tschopp *et al.*, 1985). During capsaicin treatment, CGRP is co-depleted with SP from unmyelinated sensory neurons (Nagy *et al.*, 1981; Sternini *et al.*, 1987). Immunoreactive nerve fibers containing CGRP have been localized in the medulla and T-cell zone in the mesenteric lymph nodes (Popper *et al.*, 1988). Nerve fibers containing immunoreactive CGRP were detected in arterioles and venules with extensions entering the parenchyma of the mesenteric lymph nodes. By quantitative receptor autoradiography, distinct sites of CGRP binding were determined to be distributed throughout the mesenteric lymph nodes, with the greatest concentration of CGRP binding in ~25% of the germinal centers. Binding sites also were observed on 50% of the arterioles and venules in the medulla, T-cell region, and internodular region.

Mouse splenocytes have been shown to express binding sites (Table II) for CGRP. Half-maximal inhibition of radioiodinated CGRP binding to splenocytes was achieved with 0.4 nM unlabeled CGRP (Umeda *et al.*, 1988). Subsequent analysis (Umeda and Arisawa, 1989) performed on T cell-enriched fractions (nylon wool nonadherent cells) revealed a biphasic binding curve with a high-affinity binding site ( $K_d$  of 0.35 nM; 265 sites/cell) and a low-affinity binding site ( $K_d$  of 48 nM; 13,000 sites/cell). Binding of radiolabeled ligand was unaffected by salmon or human calcitonin. Radioiodinated CGRP binding to T-cell lymphocyte membranes could be dissociated in part by the nucleotide analog Gpp(NH)p, suggesting that the mouse T lymphocyte CGRP receptor may be coupled to the stimulatory guanine nucleotide regulatory binding protein. In contrast to murine lymphocytes, rat lymphocytes (McGillis *et al.*, 1991) demonstrated a single class of high-affinity receptors for radioiodinated CGRP with a dissociation constant of 0.81–0.87 nM for splenocytes (970 receptors/cell) and enriched T cells (750 receptors/cell). B cells displayed a similar  $K_d$  of 0.39 nM and similar numbers of receptors as T cells. Affinity labeling studies cross-linking lymphocytes with radioiodinated CGRP produced three bands when analyzed on SDS-PAGE, all of which could be inhibited specifically with unlabeled CGRP: a high molecular weight form, a 220-kDa protein, and a 75-kDa protein. Macrophages also express CGRP receptors. Plasma membranes prepared from the P388D1 murine macrophage cell line were found to exhibit, minimally, a high-affinity receptor for radiolabeled CGRP with a dissociation constant of 1.8 nM (Abello *et al.*, 1991). This CGRP was coupled to adenylate cyclase since nanomolar concentrations of CGRP were effective in stimulating P388D1 adenylate cyclase activity in a dose-dependent fashion.

CGRP inhibited both Con A- and PHA-induced but not LPS-induced proliferation of mouse splenocytes in a dose-dependent fashion, with maximal inhibition seen at a concentration of  $10^{-8}$  M (Umeda *et al.*, 1988) within the first 24 hr

(Boudard and Bastide, 1991). In contrast to VIP, CGRP had no effect on IL-2 production by Con A-stimulated splenocytes (Boudard and Bastide, 1991), but CGRP increased cAMP levels in enriched murine T cells (Umeda *et al.*, 1988; Boudard and Bastide, 1991). As had been shown with murine T cells, rat lymphocytes stimulated with CGRP also could elicit maximal cAMP production at concentrations near the  $K_d$  for the CGRP receptor (McGillis *et al.*, 1991). CGRP also could inhibit macrophage function. Using an ovalbumin-specific T-cell line, CGRP-stimulated peritoneal macrophages inhibited antigen presentation when measured by the decrease in cell proliferation by these T cells (Nong *et al.*, 1989). In the same study, human monocytes pretreated and not co-stimulated with CGRP at nanomolar concentrations could inhibit IFN $\gamma$ -induced H<sub>2</sub>O<sub>2</sub> production effectively. Although the studies examining the immunomodulatory of CGRP are still limited, learning the development of CGRP functional attributes and assessing whether this neuropeptide will enhance or antagonize SP immunostimulatory effects will be interesting since these neuropeptides coexist in peptidergic nerve fibers in lymphoid tissues.

### III. PEPTIDERGIC-IMMUNE CIRCUIT

We have provided here the experimental evidence for the existence of the communication system between the nervous and immune systems. Having determined that various neuropeptides do play a role in the modulation of the function of various arms of the cellular and humoral immune network, determining the intracellular mechanisms involved becomes increasingly significant. Further, the shared expression of neuropeptide and cytokine receptors by elements of the immune and nervous systems, as well as the ability to respond to these diametric molecules, supports the existence of such a neural-immune circuit. In view of these observations, efforts were put forth to investigate the possibility that neuropeptides were generated by cells other than those of neuronal origin. Consequently, leukocytes were shown to synthesize SP (Pascual and Bost, 1990b), VIP (Matthew *et al.*, 1992), and somatostatin (Sreedharan *et al.*, 1989b). These findings led some researchers to speculate that the neural-immune network is functionally bidirectional (Spector and Goetzl, 1989). If the neural-immune network is bidirectional as proposed, leukocyte-derived neuropeptides could act at neuronal or endocrine sites, even those at distant sites, in a systemic fashion. However, no *in vivo* evidence exists to support this hypothesis. In fact, even if leukocyte-derived neuropeptides could reach their respective neuronal receptors, the concentrations of leukocyte-derived neuropeptides generally have been found to be 1000-fold less than neuronal concentrations. Thus, at these concentrations, leukocyte-derived neuropeptides seem unlikely to compete effectively with neuronal production and release.

One aspect of the studies addressing leukocyte-derived neuropeptides that has failed to gather consideration is why these neuropeptides are produced by leukocytes. Whereas intricate studies have shown the production of neuropeptides

by leukocytes, studies of the purpose of such production have been minimal. One possibility for their production is that low level production of neuropeptides may represent a mechanism for maintaining the expression of their respective receptors on the leukocyte cell surface. In the case of macrophage-derived SP (Pascual and Bost, 1990b), investigators suggested that macrophages produced SP in a paracrine/autocrine fashion to regulate cytokine production. Likewise, eosinophil-derived VIP may be important for nonspecific activation of T cells during schistosomiasis. Thus, if leukocyte-synthesized neuropeptides can affect their own function, we must consider them functionally similar to cytokines. It may be important for them not to function at neuronal or endocrine sites; they may, instead, exhibit properties not previously considered. Consequently, leukocyte-derived neuropeptides introduce a novel regulatory circuit to immune regulation. Such an additional regulatory pathway also may have its own mode of neuropeptide release. Previous studies have shown the sensitivity of neural elements to cytokine stimulation to induce the release of neuropeptides (Jonakait and Schotland, 1990; Hart *et al.*, 1991), but these same cytokines may not affect leukocyte-derived neuropeptide release.

Much must still be learned about the mechanisms used by the peptidergic circuit to regulate immune function in MALT. We are beginning to learn about the ability of lymphocytes and macrophages to respond to neuropeptides. Subsequent studies should provide insight into the modulation of neuropeptide receptors on leukocytes, particularly understanding the regulatory mechanisms and events responsible for the expression of neuropeptide receptors. This expression can be especially significant in mucosal tissues, where the presence of neuropeptides is associated greatly with leukocytes. The consequence of understanding the relationship between the nervous system and the immune system will provide a basis for future treatment of mucosal inflammatory diseases, Crohn's disease and colitis, autoimmune diseases, arthritis, and multiple sclerosis (myelin basic protein), as well as for the development of new vaccines to mucosal pathogens. In general, this new field offers additional therapeutic strategies in the manipulation of immunity in various pathological states. Assessing the neuronal component will become more prevalent when addressing immune regulation in MALT. Thus, with the development of cDNA probes and monoclonal antibodies to neuropeptide receptors, the regulation of these receptors on lymphoid cells and macrophages can be addressed readily, providing a functional understanding of the neural-immune network.

# The Role of B-1 Cells in Mucosal Immune Responses

Frans G. M. Kroese • Aaron B. Kantor • Leonore A. Herzenberg

## I. INTRODUCTION

The intestinal lamina propria of the gut contains numerous plasma cells that characteristically secrete IgA. This IgA is transported across the epithelium into the gut lumen to prevent invasion of microorganisms. The high level of IgA in mucosal secretions testifies to its importance as part of the first line of defense of an animal. In fact, approximately 15 million IgA-secreting cells are found in the intestine of the mouse, which is 10 times more than the total number of IgM-secreting cells in lymphoid tissues (Van der Heijden *et al.*, 1987). Given the estimated half-life of 5 days for the vast majority of intestinal IgA plasma cells (Mattioli and Tomasi, 1973), many IgA plasma cells must develop daily from B cells to guarantee a continuous supply of cells. According to the prevailing paradigm, intestinal IgA plasma cells are derived from conventional B cells located mainly in the Peyer's patches of the small intestine (for review, see Phillips-Quagliata and Lamm, 1988; Tseng, 1988).

In this chapter, we review analyses of irradiated and nonirradiated B-cell lineage chimeras and  $\mu, \kappa$  transgenic mice from our laboratories that indicate that many intestinal IgA plasma cells arise from Ly-1 B cells that predominate in the peritoneal cavity (Ly-1 B cells are now designated B-1 cells; Kantor *et al.*, 1991). Data from several other laboratories that support this finding are also discussed. Finally, the mucosal IgA plasma cells are considered in the context of the layered immune system (Herzenberg and Herzenberg, 1989).

## II. CURRENT VIEW ON THE ORIGIN OF INTESTINAL IgA PLASMA CELLS

Peyer's patches (and appendix) are well known to contain enriched numbers of precursor cells for intestinal IgA plasma cells (Craig and Cebra, 1971, 1975; Rudzik *et al.*, 1975; Tseng, 1981, 1984). This conclusion was reached mainly after short-term (up to 2 weeks) transfer experiments with various cell populations to X-irradiated animals, and was initiated in the early 1970s by the classic rabbit experiments by Craig and Cebra (1971, 1975). Collectively, these (and other) repopulation studies led to the following working model (for reviews, see Phillips-Quagliata and Lamm, 1988; Tseng, 1988). Antigen probably enters the Peyer's patches through specialized epithelial cells (M cells) with short microvilli and an intracel-

lular vesicular transport system, located in the epithelium covering each follicle (Owen, 1977). In the Peyer's patches, antigen is processed by macrophages and presented to T helper cells, leading to the activation of B cells. Committed B cells leave the Peyer's patches, migrate to the mesenteric lymph nodes, and enter the blood circulation by way of the thoracic duct. These cells may expand and differentiate further in the spleen and, after some time, migrate into the gut lamina propria, where they mature to IgA-producing plasma cells. This differentiation process from Peyer's patch precursor B cell to mature IgA-secreting plasma cell in the intestinal lamina propria takes approximately 1 week.

Analysis of the phenotype of the IgA precursor cells located in the murine Peyer's patch shows that the majority of them express sIgM, sIgD, and complement (C3) receptor (Tseng, 1984). Tissue-section staining indicates that these cells are located in the lymphocyte corona of the lymphoid follicle (Butcher *et al.*, 1982). A second but minor population of IgA plasma cell precursors consists of surface/cytoplasmic IgA<sup>+</sup> blastoid cells that are likely to be derived from the IgM<sup>+</sup>IgD<sup>+</sup> cells, and are found in the Peyer's patches and, in higher numbers, in the mesenteric lymph nodes and thoracic duct lymph (Guy-Grand *et al.*, 1974; McWilliams *et al.*, 1975; Pierce and Gowans, 1975; Roux *et al.*, 1981). In repopulation studies, this last population of IgA precursors homes immediately after transfer to the gut lamina propria (<24 hr). In Peyer's patches, sIgA<sup>+</sup> cells are located almost exclusively in the germinal centers of the lymphoid follicles (Butcher *et al.*, 1982). In the germinal centers, antigen-triggered B cells expand, undergo isotype switching, introduce somatic mutations in their V<sub>H</sub> genes, and differentiate into memory cells (for review, see Kroese *et al.*, 1990). Therefore, the (conventional) IgA plasma cell precursors in the Peyer's patches may acquire somatic mutations in their V<sub>H</sub> genes, resulting in high affinity antibodies with a narrow specificity.

## III. B-1 CELL LINEAGE

B-1 cells (Ly-1 B cells) constitute a small but functionally very important subset of murine B cells that produces much serum immunoglobulin, including autoreactive and antibacterial antibodies. B-1 cells are distinguished from conventional B cells by phenotype, development, anatomical localization,

and function (for reviews, see Hardy and Hayakawa, 1986; Herzenberg *et al.*, 1986; Hayakawa and Hardy, 1988; Kipps, 1989; Kantor and Herzenberg, 1993). B-1 cells are virtually absent from lymph nodes and Peyer's patches and are present at low frequency in spleen; however, they constitute a major fraction of the B cells in the peritoneal and pleural cavities. B-1 cells express high levels of sIgM but low levels of sIgD and B220 (RA3-6b2; Coffman and Weissman, 1981). Figure 1 shows the predominance of B-1 cells in the BALB/c peritoneal cavity and the absence of these cells in the Peyer's patches. Conventional B cells, which are dull for IgM and bright for IgD, predominate in Peyer's patches and other secondary lymphoid organs. In the peritoneal and pleural cavities, B-1 cells also express CD11b (Mac-1). B-1 cells can be divided into two independently self-replenishing populations: B-1a cells, which express detectable levels of CD5, and B-1b (formerly called "sister" cells), which do not. Both populations are present in the peritoneal and pleural cavities.

Extensive adoptive transfer studies have shown that B-1 cells and conventional B cells have different developmental pathways and have distinct progenitor cells that develop independently of each other. In essence, B-1 cells arise early during ontogeny from progenitor cells located in the fetal omentum (Solvason *et al.*, 1991) and fetal liver (Solvason *et*

*al.*, 1991; Hardy and Hayakawa, 1992; Kantor *et al.*, 1992). After weaning, B-1 cells maintain themselves by self-replenishment and are independent of the bone marrow. Conventional B cells, in contrast, arise later in ontogeny and are replenished by *de novo* production from adult bone marrow.

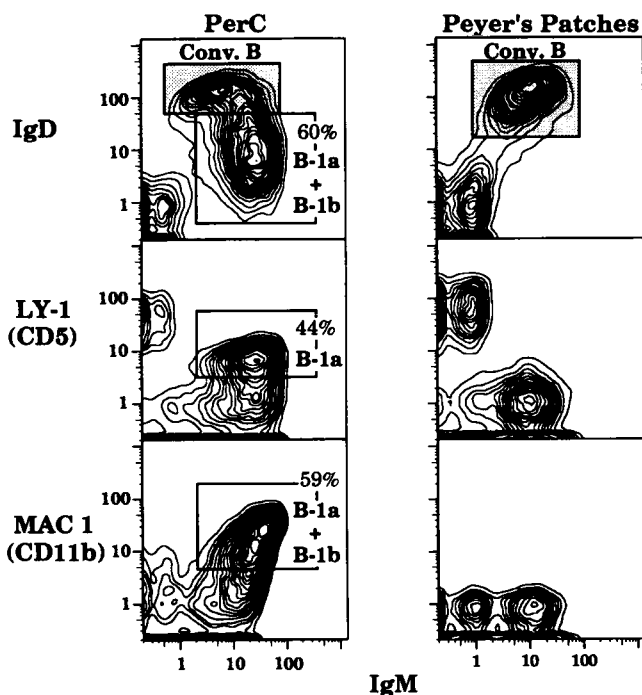

Although their overall numbers are low (<5% of the peripheral B cells), B-1 cells produce much of the serum Ig, including half the IgM and IgA in radiation chimeras (Kroese *et al.*, 1989); however, they express a limited repertoire (Förster *et al.*, 1988a; Pennel *et al.*, 1988; Tarlinton *et al.*, 1988) including near exclusive use of V<sub>H</sub>11 and V<sub>H</sub>12, which are specific for phosphatidylcholine (PtC; Hardy *et al.*, 1989; Pennel *et al.*, 1989; Carmack *et al.*, 1990). B-1 cells produce autoantibodies to Fc $\gamma$  (rheumatoid factor; Casali *et al.*, 1987; Hardy *et al.*, 1987; Burastero *et al.*, 1988) and thymocytes (Hayakawa *et al.*, 1990), and antibodies that react with microorganismal coat antigen such as  $\alpha$ 1-3 dextran (Förster and Rajewsky, 1987), PtC, and undefined determinants on *Escherichia coli* (Pennel *et al.*, 1985; Mercolino *et al.*, 1986). These B-1 cell antibodies tend to have low affinity and broad specificity (Lalor and Morahan, 1990). In contrast, B-1 cells respond poorly to commonly used exogenous antigen such as sheep erythrocytes and TNP-KLH; Hayakawa *et al.*, 1984). The majority of B-1 cell antihapten antibodies does not show the high affinity binding or fine specificity of conventional B cells (Lalor and Morahan, 1990). Thus, an apparent dichotomy exists in the expressed repertoire of conventional and B-1 cells. Little is known about the subdivision between B-1a and B-1b cells.

Although mature B-1 cells are only a minor population of B cells, their functional properties suggest that these cells play a crucial role in the first line of protection of the animal against common microorganisms, including those that are ubiquitous in the gut. This hypothesis raises the question of whether B-1 cells could be involved in mucosal IgA immune responses.

#### IV. PERITONEAL RESERVOIR OF PRECURSORS FOR GUT IgA PLASMA CELLS

We examined the possible role of B-1 cells in the mucosal immune response by using stable long-term B lineage chimeras (Kroese *et al.*, 1989, 1992). These chimeras exploit the self-replenishing properties of B-1 cells and their poor repopulation by adult bone marrow, especially in the presence of mature B-1 cells. Lethally irradiated mice are reconstituted with syngeneic bone marrow (BM) and peritoneal washout cells (PerC) from immunoglobulin (Ig) allotype (Igh-C) congenic donors (Figure 2). In these mice, B cells, plasma cells, and serum immunoglobulins derived from either donor population can be distinguished on the basis of the allotype they express.

Multiparameter flow cytometry (fluorescence-activated cell sorting; FACS) analysis of these chimeras (>2 months after transfer) demonstrates that essentially all B cells in Peyer's patch (Figure 3), spleen, and lymph node are conventional B cells derived from the bone marrow donor (b allo-

**Figure 1** Comparison of Peyer's patch (*right*) and peritoneal cavity (*left*) B cells. Representative plots are shown for untreated Balb/c mice. The FACS phenotype of conventional B, B-1a, and B-1b cells are indicated. Reagents: fluorescein conjugated anti-IgM (DS1); allophycocyanin-conjugated anti-CD5 (53-7); and anti CD11b (M1/70); and biotin-conjugated anti-IgD (AMS9.1) followed by Texas Red-Avidin. The percentages of cells within the boxed populations are given per total number of live lymphocytes after gating on forward and side scatter and propidium iodide. All the plots presented have 5% probability contours.

**B-1 cells express PerC-donor allotype (a)  
Conventional B cells express BM-donor allotype (b)**

**Figure 2** Preparation of radiation chimeras. Recipients [here, b allotype BAB/25 (Igh-C<sup>b</sup>)] mice are X-irradiated and reconstituted with peritoneal cells from an allotype Balbc/Hz and syngeneic (BAB) bone marrow.

type). B cells derived from the PerC donor (a allotype) belong exclusively to the B-1 cell lineage. PerC-derived B-1a and B-1b cells are abundant again in the peritoneal (Figure 3) and pleural cavities of the recipient mouse and are found only at low frequencies in peripheral lymphoid tissues.

Immunohistological analysis of lymphoid organs confirms the FACS data. Specifically, in Peyer's patches only rare surface IgM-, IgD-, or IgA-positive cells of PerC donor allotype are detected in the lymphocyte corona of the lymphoid follicle. However, despite the low overall numbers of PerC-derived B cells in these PerC/BM chimeras, approximately 40% of the IgA plasma cells in the gut lamina propria and half the IgM plasma cells in the spleen are derived from PerC donor cells, even up to 1 year after transfer. Consistently, half the IgA and IgM in the serum are of the PerC donor allotype (Kroese *et al.*, 1989).

Similar data are obtained with nonirradiation B lineage chimeras (Kroese *et al.*, 1989). For example, neonatal chimeras were prepared by transfer of PerC into Igh-C congenic neonatal homozygotes treated from birth with anti-IgM allotype-specific antibodies (Lalor *et al.*, 1989b). This procedure depletes host B cells but does not affect the injected donor B cells. After stopping the antibody treatment, development of host B-1 cells is suppressed permanently, although host conventional B cells return to normal levels. In these chimeras, B-1 cells are derived exclusively from the PerC donor, and many IgA plasma cells in the gut express the PerC donor Ig allotype (Kroese *et al.*, 1989).

The production of IgA plasma cells from B-1 cells in the nonirradiated chimeras indicates that the repopulation of the lamina propria by PerC-derived cells in the irradiation chimeras is not likely to be the result of nonspecific and immediate homing of cells. Such an aberrant migration pattern could, for example, be induced by the X-irradiation procedure, which may lead to short-term inflammation of the intestine.

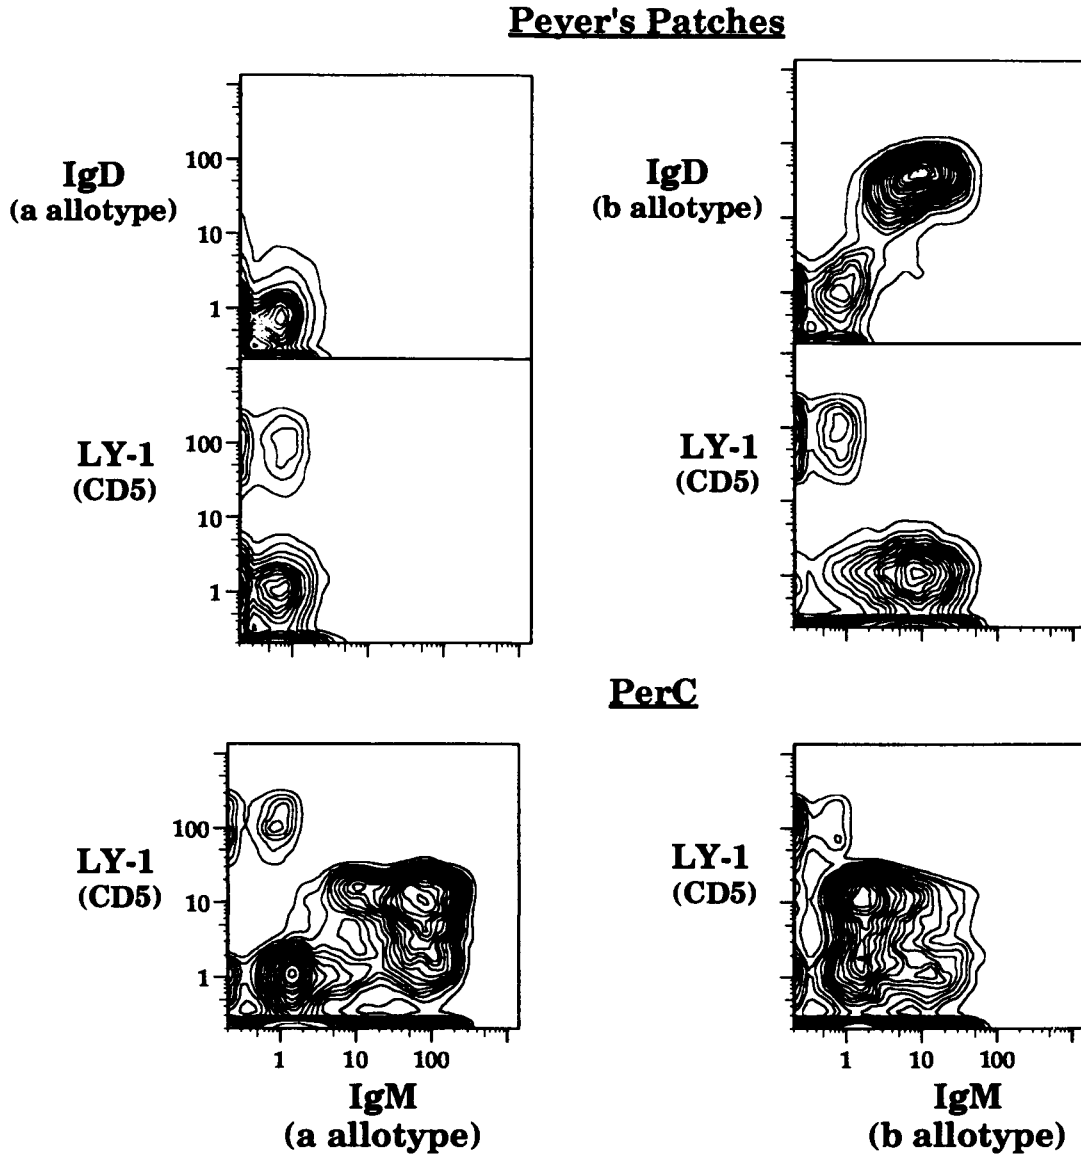

Immediate nonspecific homing is also unlikely, since PerC-derived IgA plasma cells appear in the intestinal lamina propria of the recipients at least 1–2 weeks after transfer (Kroese *et al.*, 1989).

These findings challenge the prevailing view that the vast majority of IgA plasma cells in the intestinal lamina propria originates from (conventional) B cells located in the Peyer's patches. Instead, the data demonstrate that the murine peritoneal cavity may serve as a huge reservoir of B cells that are capable of differentiating into IgA-secreting plasma cells. Further, given the observation that, even up to 1 year after transfer, PerC-derived IgA plasma cells are seen in the intestinal lamina propria, these PerC-derived plasma cells must be either extremely long-lived (which is rather unlikely; Mattioli and Tomasi, 1973) or derived from self-replenishing precursor cells. Since FACS analysis shows that all PerC-derived sIgM<sup>+</sup> cells in these long-term stable chimeras are self-replenishing B-1 cells, the data strongly indicate that B-1 cells present in the peritoneal cavity are responsible for high numbers of intestinal IgA plasma cells.

## V. IgA PLASMA CELLS IN $\mu,\kappa$ TRANSGENIC MICE BELONG TO THE B-1 CELL LINEAGE

In a second distinct approach, we examined the lineage origin of intestinal IgA plasma cells in IgM transgenic mice. The introduction of a functionally rearranged immunoglobulin  $\mu$  heavy-chain transgene interferes with the normal development of the B-cell pool and antibody repertoire (Herzenberg *et al.*, 1987; Herzenberg and Stall, 1989; Müller *et al.*, 1989; Forni, 1990; Grandien *et al.*, 1990; Iacomini *et al.*, 1991). These transgenic mice have severely reduced numbers of B cells. As expected by the principle of allelic exclusion, the rearranged transgene inhibits further endogenous immunoglobulin heavy-chain gene rearrangements and subsequent expression. This inhibition, however, does not occur in all cells. Some B cells express endogenous IgM molecules, often concomitant with the transgenic IgM. FACS analysis and transfer studies with the transgenic mouse lines M54 and M95 have shown that the transgene selectively affects the two B cell lineages: only conventional B cells are depleted in these mice and expression of endogenous immunoglobulins is restricted totally to the B-1 cell lineage (Herzenberg *et al.*, 1987; Herzenberg and Stall, 1989). Endogenous immunoglobulin and transgenic IgM can be distinguished from each other by Igh-C allotype. Despite the loss of endogenous conventional B cells, these mice have almost normal levels of endogenous serum immunoglobulin. Most significantly, serum IgA is near normal in these animals (Grandien *et al.*, 1990).

Similar to the findings with the M54 mice, we have shown that the majority of B cells in the peripheral lymphoid organs of B6-SP6 ( $\mu,\kappa$  transgenic) mice expresses only transgenic IgM, whereas many peritoneal B cells express endogenous IgM (either alone or in combination with transgenic IgM; Kroese *et al.*, 1992). These endogenous IgM<sup>+</sup> peritoneal B cells nearly all belong to the B-1 cell lineage as determined by FACS phenotype. Furthermore, transgenic BM poorly

**Figure 3** FACS analysis of radiation chimeras. BAB recipients of Balb/c PerC and BAB bone marrow were analyzed 10 wk after transfer. PerC-derived (a allotype) B-1a and B-1b cells are found in the recipient peritoneal cavity (PerC) but not Peyer's patches. Bone marrow-derived (b allotype) conventional B cells predominate in the Peyer's patches and other secondary lymphoid organs. Allotype specific reagents: fluorescein conjugated anti-Igh-6a (IgM of the a allotype, DS1); fluorescein conjugated anti-Igh-6b (IgM of the b allotype, AF6-78); biotin-conjugated anti-Ig5a (IgD of the a allotype, AMS9.1); and biotin-conjugated anti-Ig5b (IgD of the b allotype, AF6-122) (b allotype Mab).

reconstitutes endogenous IgM<sup>+</sup> B cells, just as adult BM from normal mice poorly reconstitutes B-1 cells. Most significantly, IgA plasma cells are found in the intestinal lamina propria of these B6-Sp6 mice and approximately 25% of them also contain transgenic IgM in their cytoplasm. Since the constant part of this IgA can be derived only from endogenous heavy-chain genes in these mice and the majority of IgA positive cells do not express the transgenic idiotype, these IgA plasma cells must be the result of an isotype switch from an endogenous IgM-expressing cell. Endogenous IgM is expressed almost exclusively by B-1 cells in these transgenics, suggesting that essentially all IgA plasma cells

in the gut lamina propria of these mice belong to the B-1 cell lineage.

## VI. ROLE FOR B-1 CELLS IN MUCOSAL IMMUNITY

The two different sets of experiments described earlier (i.e., B lineage chimeras and  $\mu,\kappa$  transgenic mice) strongly indicate that B-1 cells generate many IgA plasma cells in the lamina propria. Several other lines of evidence also support

our notion that B-1 cells contribute significantly to the gut IgA response. (1) Elegant experiments by Solvason *et al.* (1991) have shown that grafts of fetal omentum into adult severe combined immunodeficiency (SCID) mice reconstitute B-1 cells (both B-1a and B-1b) but not conventional B cells. These grafts also lead to the appearance of IgA plasma cells in the gut and IgM plasma cells in the spleen. (2) Several B-1 cell lymphomas (CH12.LX, CH27, and I.29) preferentially switch *in vitro* from IgM expression to IgA expression (Stavnezer *et al.*, 1985; Arnold *et al.*, 1988; Whitmore *et al.*, 1991). (3) Virtually all B cells in autoimmune viable motheaten mice are B-1 cells; the serum of these mice contains extremely high levels of IgM, IgG3, and IgA (Sidman *et al.*, 1986). (4) CBA/N Xid mice almost completely lack B-1 cells (Herzenberg *et al.*, 1986) and have a defective immune response to certain antigens such as phosphorylcholine and *Salmonella typhimurium* (Mond *et al.*, 1977; O'Brien *et al.*, 1979). However, CBA/N Xid mice populated with B-1 cells from the peritoneum of responsive CBA/CA mice have strong serum and mucosal IgA responses after oral immunization with *S. typhimurium* (Pecquet *et al.*, 1992).

Collectively, these findings are reconciled most easily with the hypothesis that B-1 cells play a significant role in the generation of IgA plasma cells in the intestinal lamina propria. This view is also consistent with the finding that intraperitoneal priming of animals is the most effective route to enhancing mucosal IgA immune responses (Pierce and Gowans, 1975; Pierce and Koster, 1980). In addition, this hypothesis also may explain how surgical removal of Peyer's patches and prolonged thoracic duct cannulation (to deplete Peyer's patch-derived cells) fail to result in a significant drop in numbers IgA plasma cells in the gut lamina propria (Mayrhofer and Fisher, 1979; Heatley *et al.*, 1981; Enders *et al.*, 1988).

Formal proof of a role of B-1 cells in the mucosal immune response requires further study. Rare sIgA<sup>+</sup> memory cells in the PerC may be responsible for the repopulation of gut IgA plasma cells after transfer (Kroese *et al.*, 1989). Transfer experiments with sorted B-cell populations into allotype congenic hosts could clarify this point, as well as distinguish the relative roles of B-1a and B-1b cells.

## VII. MUCOSAL IgA RESPONSES AND THE LAYERED IMMUNE SYSTEM

The developmental pattern of the B and T cell lineages can be considered in the context of an evolutionarily layered immune system (Herzenberg and Herzenberg, 1989; Herzenberg *et al.*, 1992; Kantor *et al.*, 1992). In this view, the lymphocyte lineages that develop at different overlapping times during ontogeny of mammals reflect the progressive emergence of layers of hematopoietic progenitor cells during evolution. B-1 cells and some  $\gamma\delta$  T cells that arise earliest in ontogeny (Havran and Allison, 1988; Ito *et al.*, 1989) would represent the evolutionarily most primitive layer of the vertebrate immune system. This view is supported by evidence showing that some  $\gamma\delta$  T cells (Tonegawa, 1989) and B-1 cells share many characteristics, such as predominant localization

outside lymphoid tissues including the mucosal epithelium and restricted repertoires. Conventional B cells and  $\alpha\beta$  T cells arise later in ontogeny and are considered more recent evolutionary developments.

Functional considerations indicate that B-1 cells and early  $\gamma\delta$  T cells, by nature of their repertoire and anatomical location, may create a first line of defense against invading pathogens. B-1 cells tend to produce a restricted set of low-affinity broad-specificity germ-line antibodies that react with common antigens on ubiquitous microorganisms. In contrast, conventional B cells produce a larger more diverse set of antibodies capable of specific high-affinity interactions with particular pathogens.

The B-1 cell repertoire is established shortly after birth, in part by positive selection, at a time when the animal encounters common exogenous (microorganismal) antigens for the first time. Feedback inhibition from mature B-1 cells (Lalor *et al.*, 1989a,b) and decreased progenitor activity (Hayakawa *et al.*, 1985; Kantor *et al.*, 1992) restrict changes in the B-1 cell antibody repertoire, beginning near adolescence. Thus, the B-1 cell antibody repertoire provides an efficient and early first line of defense against many common bacteria that challenge the animal at birth and throughout life.

Conventional B cells produce a larger more diverse set of antibodies because of continuous generation from stem cells in bone marrow throughout life. These antibodies are capable of specific high-affinity interactions with particular pathogens. The conventional B cell repertoire thus is potentially able to combat any microorganisms, including those that are less common, that escape through the barrier created by the B-1 cell antibodies.

The mucosae are attacked continuously by numerous microorganisms and require a sophisticated immune system that benefits from both layers of the immune system. The importance of a mucosal immune system is indicated by the extremely high numbers of IgA plasma cells in the lamina propria and by the fact that the mucosal immune system is evolutionarily old (Phillips-Quagliata and Lamm, 1988). The layered immune system is clearly evident in the mucosae, as reflected by differentiation into IgA plasma cells from both B-1 cells located in the peritoneal cavity and conventional B cells located in the Peyer's patches. Antigen can be processed by macrophages and presented to T helper cells; the T cells, with antigen, activate the conventional Peyer's patch B cells. These cells leave the patches by way of the mesenteric lymph nodes and thoracic duct into the circulation to migrate back to the gut lamina propria for their final differentiation to IgA-producing plasma cells.

As we have shown in this chapter, some of the gut IgA plasma cells belong to the B-1 cell lineage. B-1 cells reside primarily within the peritoneal and pleural cavities and have not been demonstrated in sizable numbers in the intestinal lamina propria (F. G. M. Kroese, A. B. Kantor, and A. M. Stall, unpublished observations). Where and how these cells receive their initial antigenic stimulus, where these cells switch from IgM expression to IgA expression, and where these cells expand is virtually unknown. Cell kinetics data demonstrate that B-1 cells within the peritoneal cavity do

not divide extensively and turn over only approximately 1% per day (Förster *et al.*, 1988b; Deenen and Kroese, 1993). Thus, proliferation of antigen-triggered B-1 cells must take place outside the peritoneal cavity before they differentiate into IgA-secreting cells to give rise to the large number of IgA plasma cells required every day. Perhaps B-1 cells leave the peritoneal cavity through draining lymph nodes or the pleural cavity into the circulation (Kroese *et al.*, 1992).

The relative contribution of the two lineages to the IgA response in normal animals is not known, nor do we know whether both B-1a and B-1b cells could be involved in the production of IgA plasma cells. Importantly, whether the two types of IgA-producing plasma cells exert different functions and have different antibody repertoires remains to be determined. For example, the IgA plasma cells from the B-1 cell lineage might produce low-affinity multireactive IgA to commensal microorganisms and give the animal a baseline level of protection by these antibodies. This IgA might play a role in the maintenance of the gut flora. IgA produced by plasma cells derived from the Peyer's patch, in contrast, could be responsible for producing specific high-affinity antibodies with somatic mutations that are essential to combatting more pathogenic bacteria in the gut. An advanced and layered humoral immune system such as this would be highly practical because it would combine the effective components common to more primitive vertebrates, which are provided by B-1 cells, with the more recently evolved and sophisticated components that are provided by conventional B cells.

# Lymphocyte Homing to Mucosal Effector Sites

Julia M. Phillips-Quagliata · Michael E. Lamm

## I. INTRODUCTION

Protection of the mucosae of the gastrointestinal, respiratory, and urogenital tracts, which interface with the environment, is a major preoccupation of the mammalian immune system. The total surface area of these tracts is much greater than that of the skin, and their moist nutrient-rich secretions provide an ideal milieu for the proliferation of many potentially pathogenic microorganisms. The mucosae would continually be infected by viruses, bacteria, and other parasites were they not protected by a variety of competent T cells and natural killer (NK) cells as well as by secretory immunoglobulin (Ig) capable of preventing microbial adhesion. The Ig of major importance in protecting the mucosae is secretory IgA.

## II. DISTRIBUTION OF EFFECTOR CELLS IN THE MUCOSA

### A. IgA-Producing Plasma Cells

In the gastrointestinal and upper respiratory tracts, nose, middle ear, gall bladder, uterine mucosa, and biliary tree, as well as in the salivary, lactating mammary, prostate, and lacrimal glands, IgA is produced locally (reviewed by Scicchitano *et al.*, 1988). In all these locations, the numbers of plasma cells producing IgA greatly exceed those producing other isotypes, emphasizing the importance of IgA in their defense and, indeed, in the defense of the whole body. Calculations from data of Brandtzaeg *et al.* (1989) indicate that  $\sim 5 \times 10^{10}$  IgA-producing immunocytes populate the adult human small bowel alone, compared with a total of approximately  $2.5 \times 10^{10}$  immunocytes producing Ig of all isotypes in the bone marrow, spleen, and lymph nodes. If estimates of the numbers of IgA plasma cells in other mucosal sites are added, approximately 75% of all Ig-producing immunocytes in the body make IgA.

Humans have two subclasses of IgA: IgA1 and IgA2; cells producing these subclasses show regional differences in distribution. For example, IgA1 cells predominate over IgA2 in the spleen, peripheral and mesenteric lymph nodes, tonsils, stomach, and duodenum; the numbers of cells producing the two subclasses are more nearly equivalent in the lacrimal and salivary glands, and IgA2-containing cells predominate

inate in the large intestine (Crago *et al.*, 1984; Kett *et al.*, 1986).

### B. T Cells

Although secretory immunoglobulins provide a major protective element, the presence of unique populations of T cells in mucosae such as that of the small intestine strongly suggests that they, too, play an important role in local protection. The two major populations of T cells in the small intestine are intraepithelial T (IEL) and lamina propria T (LPL) lymphocytes.

In mice, IEL consist of a mixed population. About 45% are conventional thymus-processed Thy1<sup>+</sup>T lymphocytes that express T-cell receptor (TCR) $\alpha\beta$ . About 10% of these bear CD4 whereas 90% bear classical CD8 molecules, that is, these cells are mostly of the suppressor/cytotoxic phenotype. The other 55% are thymus-independent T cells that arise from bone marrow progenitors migrating directly to the gut. Many of these cells express little or no Thy 1 and bear either TCR $\alpha\beta$  or TCR $\gamma\delta$  and CD8 molecules made only of homodimeric  $\alpha$  chains rather than the usual  $\alpha$  and  $\beta$  (Lyt 2 and Lyt 3) chains (Parrott *et al.*, 1983; Klein, 1986; Bonneville *et al.*, 1988, 1990; Goodman and Lefrancois, 1988, 1989; Takagaki *et al.*, 1989; De Geus *et al.*, 1990; Guy-Grand *et al.*, 1991a,b; Rocha *et al.*, 1991). These T cells are present in nude and germ-free mice (Guy-Grand *et al.*, 1991a) and do not undergo negative selection against superantigens such as Mls in mouse strains expressing them (Rocha *et al.*, 1991). In all species examined, including humans (Cerf-Bensussan *et al.*, 1985), mice (Guy-Grand *et al.*, 1978), rats (Mayrhofer 1980), and rabbits (Rudzik and Bienenstock, 1974), a high percentage of the IELs contain intracytoplasmic granules with sulfated proteoglycans like those of mucosal mast cells and also contain perforin and the granzymes usually present in cytotoxic T cells. IEL have been shown to be highly cytotoxic in "redirected" cytotoxicity assays involving the TCR-CD3 complex, designed to circumvent the problem of their unknown specificity (Guy-Grand *et al.*, 1991b). The fact that these cells are already cytotoxic, in contrast to peripheral CD8<sup>+</sup> T cells which must be activated before they will differentiate into cytotoxic cells, implies that inductive stimuli (presumably including bacterial antigens and lymphokines) available in the intestinal microenvironment keep them in a constant state of readiness to kill potential targets. This idea is supported

by the finding of Lefrancois and Goodman (1989) that IELs from germ-free mice are not cytolytic but become cytolytic when the mice are adapted to nonsterile conditions. In mice (Wu *et al.*, 1991) and humans (Balk *et al.*, 1991), unusual nonpolymorphic major histocompatibility complex (MHC) Class I antigens QA, TL, and CD1 are present on enterocytes. Evidence suggests that at least some cytotoxic IELs might be restricted by these antigens rather than by conventional Class I antigens. Natural cytotoxicity against classical NK targets also is expressed by intraepithelial cells that contain large granules (Tagliabue *et al.*, 1981, 1982), but whether the cells responsible are genuine NK cells, lacking the TCR, or are members of one of the IEL populations described earlier is controversial. Monoclonal antibodies (MAb) that recognize human (Cerf-Bensussan *et al.*, 1987), mouse (Kilshaw and Murant, 1990), and rat (Cerf-Bensussan *et al.*, 1986) IELs are available. These MAbs stain virtually all IELs and a fraction of LPLs in the appropriate species, but whether the epitopes recognized are involved in migration of the T cells to the intraepithelial site or are induced by some factor(s) produced by or in the vicinity of the intestinal epithelial cells is not clear. Indirect evidence (Kilshaw and Murant, 1990) favors the latter hypothesis, since the determinant recognized on murine IELs is up-regulated by culturing them in the presence of transforming growth factor  $\beta$  (TGF $\beta$ ). Messenger RNA for TGF $\beta$  is known to be present in intestinal epithelial cells, suggesting that they produce this cytokine (Barnard *et al.*, 1989).

T cells and mucosal mast cells, which differ from mast cells in other tissue locations by their lack of serotonin (Enerbäck, 1966), are scattered among the IgA plasma cells in the lamina propria (Guy-Grand *et al.*, 1978). In humans, 95% of LPLs express TCR $\alpha\beta$ ; approximately 50% are of the helper/inducer phenotype, expressing CD4, and 35% are of the suppressor/cytotoxic phenotype, expressing CD8. Many appear to be memory T cells since they are CD45RO positive (Zeitz *et al.*, 1991). In mice, more than 50% of CD3<sup>+</sup> LPLs are CD4<sup>+</sup> (Mega *et al.*, 1991). Clear evidence has been presented that human (Kanof *et al.*, 1988) and mouse (Mega *et al.*, 1991) LPLs provide helper function to B cells.

### III. IMMUNIZATION OF THE MUCOSA-ASSOCIATED LYMPHOID TISSUES

Because the mucosae interface with the environment and are moist, they are constantly exposed to antigens of microbial origin. In addition, the intestinal mucosa is exposed to antigens derived from food and the respiratory mucosa is exposed to inhaled antigens. During the evolution of the mammalian mucosal immune system, the mucosal lymphoid tissues have become adapted to fulfill several functions necessary for immunological protection: they have developed means of sampling antigens in the environment and of preventing induction of harmful allergic immune responses; they have developed means of optimizing production of protective IgA antibody against pathogens and of passing it into the secretions, where it can act to prevent penetration of mucosae

by the pathogens; and they have developed means of distributing effector T and B cells to local and distant mucosal sites.

#### A. Uptake of Antigen: Role of Epithelial and Dendritic Cells

The apical surfaces of the columnar absorptive cells of the intestinal villus epithelium are bathed in antigen and express MHC Class II antigens. These cells might be expected to be capable of taking up antigen and presenting it to local T cells and, indeed, they have been shown, at least *in vitro*, to act as antigen-presenting cells for both murine (Kaiserlian *et al.*, 1989) and human T cells (Mayer and Shlien, 1987). Presentation of antigens by these cells generally, however, leads to the induction of suppressor T cells rather than the T helper cells required for IgA immune responses (Mayer and Shlien, 1987). *In vivo*, these cells may participate in the induction of suppression that often is seen when antigens are delivered by the enteric route (Ngan and Kind, 1978; Richman *et al.*, 1978, 1981). Presumably the adaptive advantage of these suppressor mechanisms is to prevent induction of allergy to food proteins and commensal bacteria living within the lumen of the intestine. That immune responses to potential pathogens be actively induced is essential however, to the protection of the mucosae and this induction requires penetration of the mucosae by antigen in a form in which it can stimulate the immune system.

To induce IgA immune responses in the intestinal mucosae, the work of several investigators (Robertson and Cebra, 1976; Cebra *et al.*, 1977; Husband and Gowans, 1978), who have inoculated antigen into sections of small intestine (Thirty-Vella loops) containing or not containing Peyer's patches, demonstrates that antigen must enter the nodular lymphoid tissue of the gut-associated lymphoid tissue (GALT) at some stage of the immunization process. Under physiological conditions, antigen enters these nodules from the lumen of the intestine by way of the specialized epithelium that covers them.

The nodular tissues of GALT and their analogs in bronchus-associated lymphoid tissue (BALT) consist of lymphoid follicles (Figure 1), found singly in the oral mucosa (Nair and Schroeder, 1986), intestine (Burbige and Sobky, 1977; Keren *et al.*, 1978), and bronchi (Racz *et al.*, 1977); van der Brugge-Gamelkoorn *et al.*, 1985) or in clusters in the nose-associated lymphoid tissue of mice and rats (Belal *et al.*, 1977; Spit *et al.*, 1989) and in the tonsils, adenoids, Peyer's patches, and appendix (Bockman and Cooper, 1973; Waksman and Ozer, 1976; Owen and Nemanic, 1978). The follicle-associated epithelium (FAE) is usually quite distinct from the surrounding glandular epithelium and appears to have little glandular or secretory activity (Bockman and Cooper, 1973; Bockman *et al.*, 1983; Owen and Jones, 1974; Owen, 1977), with few goblet cells and few columnar absorptive cells. Within the FAE are cells with short irregular microvilli and many tubules, vesicles, and vacuoles in the cytoplasm; these cells are commonly called M cells. In the small intestine, M cells appear to develop from the same crypt epithelial cell precursors as the villus epithelial cells (Schmidt *et al.*,

**Figure 1** Diagram of MALT nodule with adjacent villi. The numbers of circles representing IgA, IgM, and IgG plasma cells reflect the approximate proportions of these cells in the lamina propria of the small intestine.

1985) but mature more rapidly (Roy, 1987) and bear unique surface antigens (Roy *et al.*, 1987). M cells have been shown to take up and transport various macromolecules intact from the lumen of the intestine (Bockman and Cooper, 1973; Owen and Jones, 1974; Owen, 1977) or bronchi (Richardson *et al.*, 1976; van der Brugge-Gamelkoorn *et al.*, 1985) to the lymphoid cells lying within the “domes” of the nodules immediately beneath them. M cells in the GALT can also transport larger particles such as bacteria (Shimizu and Andrew, 1967; Carter and Collins, 1974) and carbon and latex particles (LeFevre *et al.*, 1978; Owen and Nemanic, 1978), but those in the BALT apparently do not (Bienenstock *et al.*, 1973a,b). GALT M cells also take up and transport immune complexes, using a novel Ig receptor capable of binding either IgA or IgG (Weltzin *et al.*, 1989). A major feature distinguishing molecules capable of inducing strong mucosal immune responses from those that do not is likely to be the presence of an element that promotes binding to GM1 and GM2 gangliosides on the surface of intestinal epithelial cells (Pierce and Koster, 1980; Pierce *et al.*, 1982; Aizpurua and Russell-Jones, 1991), but no clear evidence exists that such gangliosides are restricted to FAE.

Relatively large numbers of CD4<sup>+</sup>T cells lie in clusters within and immediately beneath the FAE (Bjerke *et al.*, 1988), but that much antigen is presented directly to them by M cells, which are mostly MHC Class II (HLA-DR)-negative, seems unlikely (Hirata *et al.*, 1986; Bjerke *et al.*, 1988). However, many subepithelial DR-positive dendritic cells exist (Brandtzaeg, 1985). Dendritic cells reaching the thoracic duct lymph of mesenteric lymphadenectomized rats have been shown to bear antigens injected into the lumen of the intestine and to present them to primed T cells (Liu and Macpherson, 1991). Presumably such dendritic cells participate in presenting intestinal antigen to GALT T cells, but precisely where presentation takes place is unknown. This event probably occurs within the domes, which contain both B and T cells (Tseng, 1988), and the regional lymph nodes. Dendritic cells have been shown to be extremely supportive of IgA responses in clonal microcultures of primed Peyer’s patch B cells and cloned T cells (Schrader *et al.*, 1990). Whether the dendritic cells, macrophages, or even B cells carry antigen down to the B cells in the corona and germinal center is unknown. In GALT nodules, the germinal centers are said to contain macrophages but they lack reticular dendritic cells, which

are present in germinal centers in peripheral lymph nodes and spleen (Waksman *et al.*, 1973). Antigen localization in splenic follicles has been shown to be complement dependent (Papamichail *et al.*, 1975; Klaus and Humphrey, 1977), and may require lymphocytes bearing complement receptors (Gray *et al.*, 1984).

### B. Lymphatic Drainage

The nodules lack afferent lymphatics. Fluid capable of carrying dissolved antigen and of flushing out unattached cells including dendritic cells and lymphocytes percolates via interstitial spaces across the domes and through the follicle away from the lumen of the mucosal organ. Experiments with dye (Carter and Collins, 1974) have shown that some slight lateral movement of fluid and, presumably, of cells into the lamina propria immediately surrounding the follicle can occur, but is minimized by the pattern of lymphatic drainage of the lymphoid nodules. Most of the fluid is collected into discrete efferent lymph channels that form basket-like structures around the bases of the follicles. From these it passes into the lymphatic network in the wall of the mucosal organ. In this network, the fluid coming from the nodule is mixed with lymph from the surrounding mucosa and drains into the afferent lymphatics of a regional lymph node. In the case of the respiratory mucosae, the regional lymph nodes are the mediastinal (bronchial) lymph nodes; in the case of the small intestine, these are the mesenteric lymph nodes. Lymphocytes in the fluid pass into the regional lymph node where they mature and subsequently are dispersed throughout the body in the blood.

### C. Structure–Function Relationships in MALT Nodules

The domes of GALT follicles contain both T lymphocytes and medium-to-large IgM<sup>+</sup>IgD<sup>+</sup>B lymphocytes and may be equivalent to the marginal zone of the spleen (Nieuwenhuis *et al.*, 1974), whereas the coronas contain mainly small IgM<sup>+</sup>IgD<sup>+</sup>B lymphocytes and may be equivalent to the mantle zone of the follicles in spleen and lymph nodes (Tseng, 1988). Between the follicles are thymus-dependent areas with many small T cells and conventional high endothelial venules (HEV) through which circulating lymphocytes gain access to the lymphoid nodule.

In the base of the follicle in conventionally reared mammals is always a germinal center containing large DNA-synthesizing B cells that, because they bear on their surface plentiful terminal galactosyl residues, can be stained strongly with fluorescent conjugates of the lectin peanut agglutinin. About 60% of the germinal center cells in GALT express surface IgA (Butcher *et al.*, 1982; Lebman *et al.*, 1987), in contrast to germinal center cells in peripheral lymph nodes, which bear mainly IgM during a primary immune response or IgG during a secondary response (Kraal *et al.*, 1982). Germinal centers in peripheral lymphoid tissue have long been thought to be sites at which B-cell memory and secondary IgG and IgA plasma cell responses are generated (Thorbecke *et al.*,

1974; Klaus and Kunkl, 1981; Nieuwenhuis *et al.*, 1981; Tsiagbe and Thorbecke, 1991); researchers commonly suppose that, in conventional mammals, GALT and BALT germinal centers are maintained by enteric and inhaled antigens respectively. Cebra *et al.* (1991) have discussed the possibility that the precursors of Peyer's patch germinal center cells switch to IgA under the influence of local stimuli, but cannot formally exclude the possibility of selective accumulation of precursors already committed to IgA expression in the germinal centers of Peyer's patches. Studying this problem is difficult because germinal center cells tend to die rapidly in culture and lack "homing" receptors (Reichert *et al.*, 1983), so they cannot reliably be examined by adoptive transfer *in vivo*. The relationship, if any, between the B cells in the domes and the B cells in the coronas and germinal centers of the nodules is unknown. Even with regard to the peripheral lymphoid system, whether primary and memory B cells have the same precursors is still a matter of debate. Some investigators have hypothesized that, when virgin splenic B cells are stimulated with antigen and appropriate T-cell help, they undergo unequal division giving rise both to antibody-forming cells and to secondary or "memory" B cells (Williamson *et al.*, 1976). Work with B cells separated on the basis of their expression of an epitope recognized by the J11d MAb (Bruce *et al.*, 1981) has, instead, indicated that the B cells that give rise to secondary responses may have different precursors from those responsible for primary responses (Linton *et al.*, 1989). Tseng (1988) suggests that the small IgM<sup>+</sup>IgD<sup>+</sup>B cells in the corona of the Peyer's patch might be virgin B cells that, after encountering their specific antigen, eventually would give rise to IgA plasma cells in the lamina propria at mucosal sites. The B cells in the domes, which are larger than those in the corona and bear the LECAM-1 (MEL 14) antigen (Tseng, 1988) that permits them to migrate through peripheral lymph node HEV (Gallatin *et al.*, 1983), might be memory B cells originally generated in germinal centers and now capable of responding rapidly to a second encounter with specific antigen. However, although MALT nodules clearly are involved in the development of mucosal IgA responses, researchers have not firmly established that this is where priming takes place. In fact, that B cells can be efficiently primed here seems unlikely since very little help (Arny *et al.*, 1984; Dunkley and Husband, 1986) and a great deal of suppression (Ngan and Kind, 1978; Richman *et al.*, 1978, 1981) and systemic tolerance induction (Thomas and Parrott, 1974; Hanson *et al.*, 1977; Vaz *et al.*, 1977; Arny *et al.*, 1984; Challacombe and Tomasi, 1987) are the usual responses of Peyer's patch T cells when mice and rats are primed enterically with soluble antigens, although some T-cell help is induced in Peyer's patches by particulate antigens such as sheep erythrocytes (Arny *et al.*, 1984). Inducing an immune response in the mucosa by administering antigen solely via the enteric route is generally difficult, except when viruses (Orgra *et al.*, 1968), cholera toxin (Elson and Ealding, 1984; Lebman *et al.*, 1988; Liang *et al.*, 1988; Chen and Strober, 1990), invasive microorganisms (Carter and Collins, 1974), or repeatedly administered particulate antigens (Crabbé *et al.*, 1969; André *et al.*, 1978; Weisz-Carrington *et al.*, 1979) are used. Immediately after enteric priming,

antigen-specific B (Kagnoff, 1977) and T (Kagnoff and Campbell, 1974; Issekutz, 1984) cells usually disappear from the Peyer's patches. Their numbers are then expanded in the regional mesenteric lymph node, suggesting that they actively emigrate, perhaps in association with antigen-coated dendritic cells. Inducing an immune response in the mucosa by first priming via the intraperitoneal route and then boosting with the same antigen via the enteric route is relatively easy (Pierce and Gowans, 1975), that is, the follicles of Peyer's patches may function more as sites of secondary expansion of B cells primed in other lymphoid organs than as sites at which priming occurs. Some antigen injected via the intraperitoneal route might penetrate Peyer's patches from its serosal surface (Dunkley and Husband, 1986), but most of it probably passes into the mediastinal (Carter and Collins, 1974) and perhaps mesenteric lymph nodes, conceivably in conjunction with B cells that are members of the population resident in the peritoneal cavity, as described in a subsequent section. Under natural conditions, T and B cells are likely to be primed in mesenteric lymph nodes by intestinal antigen carried there by macrophages or dendritic cells in the lymph coming from the Peyer's patches. Once primed, the T and B cells can migrate to Peyer's patches and mount secondary responses to antigen retained at that site. Substances such as cholera toxin that act as mucosal adjuvants may not only promote induction of help rather than suppression, but may facilitate penetration of antigen past the Peyer's patch to the mesenteric lymph nodes.

#### IV. COMMITMENT TO IgA AND MATURATION OF B LYMPHOCYTES IN THE MUCOSAL IMMUNE SYSTEM

##### A. Factors Affecting Commitment to IgA Production

The mucosal nodules in conventional mammals must have some special characteristic that accounts for the fact that many B cells maturing within them eventually produce IgA. The nature of the special nodular influence is still unclear, although a great deal is now known about cytokines that can influence IgA production. Over the years, most work has been based on the hypothesis that factors available or produced in the mucosal nodules cause preferential switching of immunoglobulin genes downstream from  $C\mu$  to  $C\alpha$  or proliferation and eventual differentiation of those B cells that do switch to IgA. The prime mover in producing the relevant factors has generally been supposed to be the nodular T cell. Some evidence suggests that T cells derived from Peyer's patches and activated with concanavalin A produce factors that promote greater IgA responses by splenic B cells than do factors produced by similarly activated splenic T cells (Elson *et al.*, 1979; Kawanishi *et al.*, 1982, 1983; Arny *et al.*, 1984). Evidence also exists that IgA Fc receptors up-regulated on the surface of T helper cells derived from Peyer's patches may help these cells focus on B cells bearing surface IgA (Kiyono *et al.*, 1982, 1984). No good evidence exists,

however, that recently primed Peyer's patch-derived T cells capable of interacting in a cognate manner with hapten-primed B cells are more likely to contain T-cell clonal precursors capable of helping IgA responses than are similarly primed T cells derived from peripheral lymphoid tissue (Teale, 1983; Arny *et al.*, 1984; Phillips-Quagliata and Al Maghazachi, 1987; Al Maghazachi and Phillips-Quagliata, 1988). In mucosal nodules, cytokines produced by local bystander T cells activated by repeated encounters with environmental antigens or, perhaps, bacterial superantigens (Herman *et al.*, 1991) are likely to help drive B cells toward an almost exclusive commitment to IgA. In agreement with this idea is the observation that interleukin 4 (IL-4) and IL-5, which are of great significance in helping IgA responses, are produced by Th2 rather than Th1 cells (Mosmann *et al.*, 1986) and multiple contacts with antigen are known to be required for generation of Th2 cells (Swain *et al.*, 1988). Peyer's patch and, to a lesser extent, mesenteric lymph node T-cell populations are known to produce much higher ratios of IL-4 to IL-2 than spleen and peripheral lymph node populations (Daynes *et al.*, 1990). Cytokines known to be of importance in promoting IgA responses *in vitro* include TGF $\beta$  (Coffman *et al.*, 1989; Sonoda *et al.*, 1989; Kim and Kagnoff, 1990; Lebman *et al.*, 1990a; Kunimoto, 1991), which may promote switching by inducing transcription of the germ-line  $C\alpha$  gene (Lebman *et al.*, 1990b; Lin *et al.*, 1991); IL-4 and IL-5 (Coffman *et al.*, 1987; Murray *et al.*, 1987; Beagley *et al.*, 1988; Harriman *et al.*, 1988), which respectively promote activation of B cells potentially able to make IgA as well as differentiation of those that have already switched from surface IgA expression to the secretory state; and IL-6, which promotes high level secretion of IgA (Beagley *et al.*, 1989; Kunimoto *et al.*, 1989). Although these cytokines promote IgA responses, they are not produced solely by mucosal T cells. TGF $\beta$  is made by many ubiquitous cell types, so the problem of the uniqueness of mucosal nodules with respect to commitment to IgA production is not solved. Stromal cells unique to the mucosal nodules could be producing crucial factors or the population of B cells on which the factors act could be preselected in some way, so switching to IgA is more likely to occur. The B cells in mucosal nodules are, indeed, selected by virtue of the fact that, to arrive in the mucosal nodule, their precursors must at some time have expressed a surface molecule (Holzmann and Weissman, 1989; Holzmann *et al.*, 1989) necessary for binding to a receptor on the nodular HEV (Streeter *et al.*, 1988). Expression of this molecule may be in some way coupled to the tendency to switch to IgA: For example, the same nuclear factors might be involved.

##### B. Commitment of Cells to Migration within the Mucosal Immune System

The origins of the effector lymphocytes in the mucosae and the mechanisms by which they arrive there and acquire the properties that distinguish them from cells of the same general type in other locations are under intense investigation. The T-cell pool that contributes to the IELs contains both "conventional" and "unconventional" precursors.

Conventional T-cell precursors include thymus-processed T cells with TCR  $\alpha\beta$  and either CD4 or classical CD8 molecules. These cells are derived from cells that encounter antigen in the Peyer's patches and migrate by way of the thoracic duct and blood to colonize the intestinal mucosa (Guy-Grand *et al.*, 1978). Unconventional T cells comprise the cells with TCR  $\alpha\beta$  or  $\gamma\delta$  that, in mice, lack Thy1 and have homodimeric CD8. Without prior antigenic stimulation, these cells migrate directly from bone marrow to the gut epithelium which, for them, may in some way resemble the thymic epithelium (Guy-Grand *et al.*, 1991a). Conventional and unconventional T cells are likely to use different trafficking signals.

The B-cell pool that contributes to the IgA plasma cells similarly may contain conventional and unconventional B cells. For many years, researchers have known that the lymphoid follicles of both BALT and GALT in mice (Tseng, 1981, 1984a) and rabbits (Craig and Cebra, 1971, 1975; Rudzik *et al.*, 1975a,b) are highly enriched in precursor B cells that, on intravenous transfer, are capable of replacing the mucosal IgA plasma cell population of recipients after depletion by irradiation. The cells responsible seem to be conventional B cell precursors, now provisionally called B-2 cells (Kantor, 1991a,b). These cells are fetal liver or bone marrow derived, and mature through stages at which they express high levels of surface IgD (Tseng, 1988). Work by Kroese *et al.* (1989) shows, however, that in chimeric mice constructed by reconstituting lethally irradiated mice with mixtures of peritoneal cells and bone marrow cells from congenic pairs of mice differing in immunoglobulin allotype, 30–40% of the IgA plasma cells appearing in the intestinal lamina propria after about 12 days bear the allotype of the peritoneal cell donor, that is, they appear to be derived from the recycling populations of unconventional B cells, now sometimes called coelomic or B-1 cells (Kantor, 1991a,b), that predominate in the peritoneal and pleural cavities (Hayakawa *et al.*, 1983, 1986; Herzenberg *et al.*, 1986) and apparently descend from precursors in the fetal liver and omentum rather than the bone marrow (Solvason *et al.*, 1991). These unconventional B cells express only low levels of IgD and may or may not bear CD5 (Hardy and Hayakawa, 1986; Herzenberg *et al.*, 1986). Very few of the B cells in the Peyer's patches of the recipients of the mixed populations express the allotype of the peritoneal cell donor; these cells seem to be derived mostly from B-2 cells (Kroese *et al.*, 1989). Interpreting the numbers of intestinal IgA plasma cells derived from B-1 rather than B-2 cell populations in the experiments of Kroese *et al.* (1989) is somewhat difficult because when mixed populations of B-1 and B-2 cells are injected into immunodeficient mice, B-1 cells actually seem to suppress the Ig secretory activity of B-2 cells (Riggs *et al.*, 1990). Further, whether the peritoneal precursors of the IgA plasma cells appearing in the lamina propria were unprimed (virgin) cells at the time of transfer, which seems likely from the fact that they take 12 days to appear in lamina propria, or were memory B cells, already primed to intestinal antigens but present for some unknown reason in the peritoneal cavity at the time of transfer, is not certain. In addition, whether the peritoneal IgA plasma cell precursors were or were not contained in the approximately 1% of cells in the population already bearing surface IgA at

the time of transfer is unclear. Despite these caveats, the finding is of tremendous interest and potential importance because many B-1 cells make germ-line "natural" antibodies that react both with autoantigens and with common microbial epitopes. Such antibodies are thought to constitute a first line of defense against infection, and a contribution to local immunity in the lamina propria makes good evolutionary sense.

### C. Routes of Migration of IgA B Cells

In broad outline, the pattern of immunization, isotype-switching, maturation, and migration of the B cells in the mucosal immune system has, until recently, been thought to be fairly well understood, but the information currently available may be applicable only to conventional B-2 cells. The overall scheme may have to be modified in light of the possibility that the coelomic B-1 cell population contributing to the lamina propria IgA plasma cell population may not pass through MALT nodular lymphoid tissue or lymph nodes.

B-cell proliferation and commitment to IgA production both appear to take place in the lymphoid nodules of BALT and GALT (Jones and Cebra, 1974; Jones *et al.*, 1974; Cebra *et al.*, 1977, 1983; Roux *et al.*, 1981; Tseng, 1981, 1984a). The cells then leave the lymphoid nodules and pass into the regional lymph nodes, that is, the mesenteric lymph nodes in the case of GALT (Griscelli *et al.*, 1969; Guy-Grand *et al.*, 1974; McWilliams *et al.*, 1975, 1977) and the mediastinal lymph nodes in the case of BALT (McDermott and Bienenstock, 1979). In the regional lymph nodes, IgA-committed and mucosa-committed B cells continue to proliferate and mature into blast cells capable of migration. At this stage, they leave the lymph node in its efferent lymph and are transported to the thoracic duct (Gowans and Knight, 1964; Griscelli *et al.*, 1969; Hall *et al.*, 1972; Guy-Grand *et al.*, 1974; Pierce and Gowans, 1975). From the thoracic duct, these cells pass into the blood, which carries them to the lamina propria of various mucosal organs.

In irradiated rabbits, most IgA plasma cells appearing in the spleen 7 days after transfer of Peyer's patch cell populations have been shown to develop from a  $\mu$  chain-negative population (Jones *et al.*, 1974) that contains  $\alpha$  chain-bearing cells (Jones and Cebra, 1974), but no direct evidence exists that the  $\alpha$  chain-bearing cells are the precursors. In mice, Peyer's patch cell populations clearly contain two sets of intestinal IgA plasma cell precursors: resting  $\text{IgM}^+ \text{IgD}^+$  double-bearing, complement receptor-positive cells that give rise to IgA plasma cells in the intestines of irradiated recipients about 12 days after intravenous transfer of normal or lymphoblast-depleted Peyer's patch cell populations (Tseng, 1984a) and DNA-synthesizing surface IgA-bearing B cells that, in double transfer studies done in unirradiated mice, take about 3 days to mature into intestinal IgA plasma cells (Tseng, 1981). The data suggest that the  $\text{IgM}^+ \text{IgD}^+$  population may represent the corona B cells whereas the DNA-synthesizing IgA-bearing cells may come from germinal centers, but this idea is difficult to prove because germinal center B cells lack surface molecules that would permit them to

migrate to lymphoid tissues, and tend to be removed from the circulation in the lungs and liver (Reichert *et al.*, 1983).

Very few cells in radiolabeled Peyer's patch populations have the ability to migrate to lamina propria within 24 hr of intravenous transfer, in contrast to the plentiful numbers of lymphoblasts in mesenteric lymph nodes (Griscelli *et al.*, 1969; Guy-Grand *et al.*, 1974; McWilliams *et al.*, 1975, 1977) and thoracic duct lymph (Gowans and Knight, 1964; Hall *et al.*, 1972; Guy-Grand *et al.*, 1974; Pierce and Gowans, 1975; McDermott and Bienenstock, 1979) that do so with alacrity. The Peyer's patch cells that survive intravenous injection seem to require time to mature and develop the surface molecules necessary to allow them to migrate before they can settle in lamina propria. After intravenous injection, these cells generally do so in a nonphysiological site, the spleen (Tseng, 1981); normally, cells leaving the Peyer's patch would be transported by lymph into the regional mesenteric lymph node. After intravenous injection, some radiolabeled DNA-synthesizing Peyer's patch cells can, in fact, cross the walls of blood vessels in the small intestine, reach the intestinal lymph, and be carried into the marginal sinus of the mesenteric node (Roux *et al.*, 1981). Whether they leave from blood vessels in the Peyer's patch or the lamina propria is not known. To study the question, the distribution of IgA-containing radiolabeled Peyer's patch and mesenteric lymph node blasts 30 min after intravenous injection into syngeneic recipients was examined by autoradiography and immunofluorescence in transverse sections of small intestine cut through the center of Peyer's patches (Phillips-Quagliata *et al.*, 1983). More than 90% of the IgA-containing Peyer's patch-derived blasts in each section were located in the Peyer's patch portion of the section, although it only occupied about half the area. The other 10% was found in the lamina propria of the intestine, like the majority of mesenteric lymph node-derived lymphoblasts. The data suggest that Peyer's patch blasts that are sufficiently mature to be capable of migrating to GALT after intravenous injection tend to do so through the HEV of the patch rather than through the walls of vessels in the lamina propria. The ability of mesenteric node versus Peyer's patch IgA-committed blasts to discriminate between the lamina propria and the Peyer's patch strongly suggests that the recognition signals used by B lymphoblasts in these two locations are not the same, although small T lymphocytes may recognize lamina propria vessels by the same molecule used on Peyer's patch HEV (Streeter *et al.*, 1987). Lamina propria IgA-containing B-cell populations have been isolated and shown to be capable of returning to lamina propria after intravenous injection (Tseng, 1984b). The nature of the population with this ability to go back to lamina propria is unclear, but these cells could represent recently arrived mesenteric lymph node blasts that, left undisturbed, would settle down and become plasma cells. Alternatively, these cells could represent a population that actually recirculates through lamina propria. Such a population might be related to the peritoneal B-1 cell population.

Under physiological conditions, maturation of IgA B cells derived from GALT and BALT nodules into blast cells capable of migrating into lamina propria clearly takes place in the draining mesenteric and mediastinal nodes, respectively.

Suggested but not proven is the idea that the lymph nodes of the head and neck similarly serve as maturation sites for cells derived from the lymphoid follicles in the lymphoid tissue of the oropharynx (Nair and Schroeder, 1986) and nose (Belal *et al.*, 1977; Spit *et al.*, 1989). By the time they are ready to migrate, the cells are actively synthesizing DNA (Gowans and Knight, 1964; Griscelli *et al.*, 1969; Hall *et al.*, 1972; Guy-Grand *et al.*, 1974; McWilliams *et al.*, 1975, 1977; Pierce and Gowans, 1975; McDermott and Bienenstock, 1979), bear surface IgA (Guy-Grand *et al.*, 1974; McWilliams *et al.*, 1975, 1977), and lack complement receptors (McWilliams *et al.*, 1975) known to be present on their IgM<sup>+</sup>IgD<sup>+</sup> precursors in the Peyer's patch (Tseng, 1984a). Populations of GALT-derived T (Guy-Grand *et al.*, 1974, 1978; Parrott and Ferguson, 1974; Rose *et al.*, 1976; Sprent, 1976) and IgG-committed B (McDermott and Bienenstock, 1979) lymphoblasts also follow the same path.

The route by which GALT-derived IgA-committed B cells return to the lamina propria of the gut has been termed the IgA cell cycle (Lamm, 1976). A similarly circular route is apparently followed by BALT-derived IgA-committed B lymphoblasts to the lamina propria in the respiratory tract. Both GALT and BALT nodules, however, contain the precursors of cells eventually capable of migrating to the lamina propria of either the intestine or the respiratory tract (Rudzik *et al.*, 1975a,b). Indeed, the migratory cells derived from GALT and BALT can evidently recognize and settle in both local and distant mucosal sites, leading to the inference that there is a common mucosal immune system with shared endothelial cell markers or chemotactic signals, permitting emigration of the lymphoblasts from the vasculature at several locations. Populations of IgA-committed B lymphoblasts, expanded as a result of immunization in GALT or BALT, are known to be able to settle not only in the intestinal (Guy-Grand *et al.*, 1974; McWilliams *et al.*, 1975, 1977; McDermott and Bienenstock, 1979) and bronchial (McDermott and Bienenstock, 1979) lamina propria but also at sites such as the lactating mammary gland (Roux *et al.*, 1977; McDermott and Bienenstock, 1979), uterine cervix (McDermott and Bienenstock, 1979), and salivary and lacrimal glands (Montgomery *et al.*, 1983). However, a certain regional preference exists, since mesenteric lymph node cells localize much better in the small intestine than in the lungs and the reverse is true of cells from the mediastinal lymph nodes (McDermott and Bienenstock, 1979). Further, intravenously injected labeled cells, taken from the thoracic duct after intraduodenal immunization, lodge preferentially in the jejunum whereas those taken after intracolonic immunization lodge preferentially in the colon (Pierce and Cray, 1982). Cells immunized at proximal rather than distal sites within the small intestine, however, show no preference for localizing at the site of immunization (Husband and Dunkley, 1985). The extent of localization depends on regional blood flow and so can be increased in regions of local inflammation (Rose *et al.*, 1976; Ottaway *et al.*, 1983), but localization is initially independent of local specific antigen, that is, the lymphoblasts are not migrating toward their specific antigen sequestered in lamina propria (Guy-Grand *et al.*, 1974; Parrott and Ferguson, 1974; Hall *et al.*, 1977; Husband, 1982).

The presence of antigen within the lamina propria does, however, influence the outcome of migration: without it, IgA plasma cell precursors that initially localize to lamina propria disappear; with it, they remain (Husband, 1982; Husband and Dunkley, 1985) and proliferate (Husband, 1982; Mayrhofer and Fisher, 1979). The presence of immune T cells is also necessary for optimal localization of these cells (Dunkley and Husband, 1991).

## V. MECHANISMS OF MUCOSAL MIGRATION

Compared with our understanding of the pathways of migration of the lymphocyte precursors of mucosal IgA plasma cells, little is known about the underlying mechanisms. For leukocytes in general, including lymphocytes, interactions between reciprocal sets of homing receptors on the circulating cells and so-called vascular addressins on endothelial cells are believed to be critical (Butcher, 1991; Chin *et al.*, 1991; Picker and Butcher, 1992). Some of these sets are expressed constitutively whereas others are induced by local activating signals such as cytokines acting on both circulating and endothelial cells. No individual set by itself is likely to account for a particular regional mode of lymphocyte homing, but the net effect of the expression of multiple interacting sets that individually vary in their binding affinity probably determines the preferential anatomic localization of a particular class of leukocytes.

The best studied vascular addressin relevant to MALT is a receptor on the endothelium of HEV of Peyer's patches and mesenteric lymph nodes and, much less prominently, on the flat-walled venules of mucosal lamina propria (Streeter *et al.*, 1988; Jalkanen *et al.*, 1989; Picker and Butcher, 1992). This addressin, for which a corresponding lymphocyte homing receptor has not yet been identified, is likely to be particularly relevant to the circulation of small lymphocytes through the Peyer's patch and mesenteric lymph node HEV, and possibly through the venules of mucosal lamina propria. Evidence for its role in the highly efficient, directed migration to the lamina propria of the lymphoblasts that are the immediate precursors of mucosal plasma cells is less compelling. For example, the degree of expression of the mucosal addressin is inversely proportional to the homing tendency of mesenteric lymph node-derived IgA plasmablasts, that is, this addressin is expressed much less in lamina propria, to which IgA plasmablasts efficiently home, and much more in Peyer's patches, to which mesenteric node-derived IgA plasmablasts show no directed movement.

In addition to the putative lymphocyte receptor for the mucosal addressin, several other lymphocyte surface moieties have been suggested for accessory roles in homing to MALT, including CD44, integrins, and the high endothelial binding factor for Peyer's patches (Picker and Butcher, 1992). In addition to components of endothelium, local chemoattractants, perhaps including products of the differentiated mucosal epithelium, may play an important role in lymphocyte homing to lamina propria (Czinn and Lamm, 1986). Such a possibility would fit nicely into current multifactorial con-

cepts of cell homing. In turn multifactorial regulation of homing, including local factors, could explain the final localization of B and T lymphoblasts, which segregate themselves after entry into lamina propria. B lymphoblasts initially accumulate around the crypts before distributing themselves in the villi; T lymphoblasts go directly to the lamina propria high in the villi or to the villus epithelium (McDermott *et al.*, 1986). Expression of lymphoblast homing signals is constitutive in the lamina propria of the small intestine, but under hormonal control in the female genital tract (McDermott *et al.*, 1980) and lactating mammary gland (Weisz-Carrington *et al.*, 1978).

We hypothesize (Figure 2) that commitment of the majority of the B cells in MALT both to IgA production and to seeking lamina propria at the plasmablast stage is most likely the end result of antigen- and T cell-driven expansion of B-cell populations initially selected for their ability to cross the endothelium in the MALT nodule or the lamina propria. This ability probably is controlled by different moieties that may or may not, on a stochastic basis, be expressed on cells of the same lineage. Cells that can gain access to the mucosal lymph by extravasating from blood in either the MALT nodule or the lamina propria will eventually arrive via the afferent lymphatics and marginal sinus in the regional lymph node, where they may be primed and expanded in number. Whereas those initially extravasating in the MALT nodule may or may not eventually express lamina propria-seeking tendencies, those extravasating in lamina propria presumably continue to be able to do so after priming and differentiation. After priming and maturation, the cells leave the lymph node in efferent lymph and are carried through the thoracic duct to the blood. Primed B cells that are destined to become plasma cells and fail to express molecules permitting them to cross the endothelium in lamina propria may end up in the spleen or bone marrow. Those cells that express a moiety allowing them to penetrate lamina propria do so and settle there, providing, after the first exposure to a mucosal antigen, an IgM plasma cell response in lamina propria. Primed B memory cell precursors that express the moiety that allows them to cross the HEV of MALT nodules can migrate to these nodules, where they come under the influence of nodular cytokines that drive them toward expansion and the switch to IgA production. Their progeny mature within the draining lymph node into IgA-producing plasmablasts capable of populating the lamina propria. Primed B memory cells derived from lamina propria-seeking precursors that express peripheral lymph node rather than MALT nodule HEV binding moieties may (especially in situations of artificial immunization) encounter their antigen and T-cell help in nonmucosal lymph nodes. If they do, they may give rise to lamina propria IgG rather than IgA plasma cells because only the mucosal nodules contain the T-cell and accessory-cell populations that drive preferential switching to IgA.

Coelomic B-1 cells, which seem not to recirculate through lymph nodes via HEV, may recirculate through lamina propria, reaching regional lymph nodes in the afferent lymph via the marginal sinus. If these cells do not encounter their antigen, they may simply pass through the lymph nodes via their medullary sinuses and return in the efferent lymph to the blood through the thoracic duct. Conceivably, vessels in the peritoneal cavity may share an addressin with lamina

**Figure 2** Hypothetical model for the migration of B cells in the mucosal immune system. Open vessels in the MALT nodule and adjacent villi represent lymphatics; solid vessels represent the venous system. (1) Antigen crosses the epithelium of the MALT nodule through the M cells and makes contact with dendritic cells, B cells, and T cells that have entered the nodule through its HEV. Cytokines available in the nodule promote switching to IgA by B cells in the germinal center. (2) A mixed population of cells coming from both the nodule and the lamina propria is carried with antigen in the lymph to the regional mucosa-associated lymph node. (3) In the mucosa-associated lymph node, unprimed B cells are primed and memory B cells are boosted. Some primed B cells mature into IgM-bearing plasmablasts capable of seeding the lamina propria, some into memory B cells capable of recirculating through HEV. B cells derived from memory cells that were boosted by antigen in the MALT nodule mature into IgA plasmablasts. (4) Mature plasmablasts and memory cells leave in efferent lymph and are carried by the blood to the mucosa and exocrine glands as well as to other lymph nodes. (5) Plasmablasts capable of extravasating in lamina propria at mucosal sites and in exocrine glands do so and settle down to become plasma cells, which are mostly IgA producers. Blood-borne unprimed B cells that are capable of extravasating in lamina propria do so; eventually, these cells are transported by lymph to the draining mucosa-associated lymph node, are primed, and so enter the cycle. (6) Memory cells with appropriate HEV-binding receptors enter the MALT nodule or lymph nodes. If they enter the MALT nodule or the mucosa-associated lymph nodes, they encounter their specific antigen again and the population is expanded. Nodular influences that promote IgA production drive the population toward a major commitment to this isotype. If the memory cells enter the peripheral lymph nodes and do not reencounter their antigen, their numbers are not increased. If they do encounter their antigen in peripheral lymph nodes, their numbers are increased but, in the absence of nodular influences that promote IgA responses, they mature into IgG rather than IgA plasma cells.

propria, although not necessarily the same one used by B-2 cell-derived lamina propria plasma cell precursors.

This hypothetical model for the expansion and control of migration of mucosa-seeking B cells admits the possibility of small populations of B-cell precursors with specific ability to seek the lamina propria at sites such as the lactating mammary gland or the proestrous uterus, while avoiding the lamina propria of the intestinal or respiratory tracts. The mammary gland and uterus do not have a nodular lymphoid tissue associated with them and are not generally under intense antigenic bombardment, so these populations generally would not be much expanded. Precursor B cells extravasating from blood in these locations presumably could be immunized by antigens draining into the regional peripheral lymph nodes

after experimental immunization, but would be unlikely to become heavily committed to IgA production. Nevertheless, B cells primed in these locations might include a contingent capable of being boosted in BALT or GALT nodules and, subsequently, of populating the mucosae in which they originally extravasated with specific IgA plasma cells, while leaving the respiratory or intestinal tract relatively free of specific IgA plasma cells.

As discussed in more depth elsewhere (Phillips-Quagliata and Lamm, 1988), the evolution of the migratory patterns of IgA B cells in the mucosal immune system probably has a very long history. In modern mammals, the ability of effector cells immunized against pathogens present in the gastrointestinal and respiratory tracts to migrate to other mucosal sites

enables them to protect these sites against microbial contamination from the excreta. The delivery of IgA-producing plasmablasts to the lactating mammary gland is of particular significance because it results in transmission in milk of secretory IgA specific for maternal enteric microorganisms to the gastrointestinal tract of the immunologically immature infant. The infant is thus protected against the very microorganisms it is most likely to receive from its mother. The subtle interplay between the cytokines that determine the isotype of the immune response, the homing receptors on the lymphocytes, and the vascular addressins with which they interact, as well as the sex hormones that control expression of the molecules necessary for migration to the lactating mammary gland, is finely tuned and undoubtedly has contributed to the success of mammals in colonizing the earth.

# Cytokines in the Mucosal Immune System

Deborah A. Lebman • Robert L. Coffman

## I. INTRODUCTION

The expression of specific isotypes is regulated by cytokines that act either to mediate heavy-chain class switching or to stimulate the maturation of B cells expressing particular isotypes. The mucosal immune system is distinguished from other secondary lymphoid organs by the predominance of IgA in mucosal secretions. In considering the potential relevance of cytokines in the generation of an IgA response *in vivo*, we must realize that the processes of isotype switching to IgA and maturation of membrane IgA-expressing cells to IgA-secreting cells take place in different anatomical locations. The precursors of IgA-secreting cells are generated primarily in the Peyer's patches (Craig and Cebara, 1971). However, IgA-secreting plasma cells are found in the lamina propria of exocrine tissues (Tomasi, 1983).

Although the actual basis for the preferential generation of an IgA response in mucosal tissues remains unclear, the identification of cytokines that specifically stimulate IgA expression *in vitro* raises the possibility that local production of specific cytokines within mucosal tissues is involved in the establishment of a microenvironment conducive to the generation of a secretory IgA response. Although several cytokines that affect IgA secretion have been described, we must realize that little evidence exists that these cytokines act analogously on IgA secretion *in vivo* and *in vitro*. However, precedence does exist for cytokines that regulate isotype secretion *in vitro* acting similarly *in vivo* (Finkelman *et al.*, 1989). Specifically, interleukin 4 (IL-4), which was shown to mediate isotype switching to IgE *in vitro*, appears to have a similar function *in vivo*. The following sections describe the mechanism of action of different cytokines that influence IgA expression and discuss production of cytokines in mucosal tissues.

## II. CYTOKINES THAT INFLUENCE MATURATION OF IgA-EXPRESSING CELLS TO IgA-SECRETING CELLS

### A. Interleukin 5

The initial description of a factor in T-cell supernatants that enhanced IgA secretion (IgA-enhancing factor or IL-5) was followed by a series of papers describing its mechanism

of action (Coffman *et al.*, 1987; Murray *et al.*, 1987). IL-5 is a dimeric polypeptide with a molecular mass of 45–60 kDa (Bond *et al.*, 1987). The initial reports demonstrated that IL-5 alone caused a four to fivefold enhancement in IgA secretion in cultures of B cells stimulated with the mitogen lipopolysaccharide (LPS). The increase in IgA secretion was augmented further by the addition of a second cytokine, IL-4, which by itself has little effect on IgA secretion. Both cytokines characteristically are produced by a subset of helper T cells—Th2 cells (Mosmann and Coffman, 1989).

The most commonly used culture systems for investigating the effects of cytokines on isotype expression are LPS-stimulated B-cell cultures. The addition of IL-5 to LPS-stimulated cultures of either splenic or Peyer's patch B cells resulted in a comparable three-to-fivefold increase in IgA secretion (Lebman and Coffman, 1988b). To elucidate the mechanism of action of IL-5, Peyer's patches were separated into mIgA<sup>+</sup> and mIgA<sup>-</sup> populations, which then were stimulated separately with LPS in the presence or absence of IL-5. Interestingly, the results obtained in different laboratories were disparate. Some investigators observed that the majority of IgA was derived from the mIgA<sup>+</sup> population and suggested that IL-5 acted to stimulate the maturation of mIgA-expressing cells to IgA-secreting cells (Harriman *et al.*, 1988). However, others observed that the majority of secreted IgA in these cultures was derived from the mIgA<sup>-</sup> population (Lebman and Coffman, 1988b). One drawback in using LPS-stimulated cultures to study the effects of cytokines on Peyer's patch populations is the nature of the LPS-responsive population itself. The majority of mIgA<sup>+</sup> cells in the Peyer's patch are derived from germinal center cells, which can be distinguished by their ability to bind relatively higher levels of peanut agglutinin (PNA) than non-germinal center cells (Butcher *et al.*, 1982). Peyer's patch cells were separated into PNA<sup>high</sup> and PNA<sup>low</sup> populations and stimulated with LPS alone or with IL-5. Not only was the majority of secreted IgA derived from the PNA<sup>low</sup> population, but the PNA<sup>high</sup> population was essentially nonresponsive (Lebman and Coffman, 1988b). Thus, a large proportion of mIgA<sup>+</sup> cells cannot respond in these cultures.

The mechanism for IL-5-induced enhancement of IgA secretion was resolved using a different culture system. Instead of polyclonally activating B cells with the mitogen LPS, B cells were stimulated with an autoreactive T helper cell (Lebman and Coffman, 1988b), a Th1 cell that secreted neither IL-4 nor IL-5 and, by itself, stimulated substantial prolifer-

eration but very little immunoglobulin secretion. In T cell-stimulated cultures, Peyer's patch B cells secreted considerably more IgA than splenic B cells. Further, the majority of secreted IgA in these cultures was derived from the mIgA<sup>+</sup> population, suggesting that IL-5 stimulates maturation of IgA-committed precursors and not heavy-chain class switching to IgA.

The previously described studies investigated the effects of IL-5 on B cells that were activated *in vitro*. One of the characteristics of gut-associated lymphoid tissue (GALT) is the presence of chronically active germinal centers in the Peyer's patches. As a consequence, a significant proportion of Peyer's patch mIgA<sup>+</sup> cells that are located in the germinal centers are also in cycle, that is, they are activated *in vivo* (Butcher *et al.*, 1982; Leberman *et al.*, 1987). IL-5 induces this *in vivo* activated mIgA<sup>+</sup> population to high rate IgA secretion (Beagley *et al.*, 1988). Although the Peyer's patches are the source of precursors of IgA-secreting cells, maturation does not occur within them (Craig and Cebra, 1971; Tomasi, 1983). Thus, if IL-5 acts *in vivo* to stimulate maturation of IgA-expressing cells to IgA-secreting cells, it does not act within the microenvironment of the Peyer's patch. However, evidence suggests that IL-5 can influence IgA secretion *in vivo*. Transgenic mice carrying the IL-5 gene have both elevated levels of serum IL-5 and elevated levels of IgA and IgM (Tominaga *et al.*, 1991).

### B. Interleukin 2

In the course of the early studies investigating the IgA-enhancing effects of recombinant cytokines, IL-1, IL-3, granulocyte-macrophage colony stimulating factor (GM-CSF), and interferon  $\gamma$  (IFN $\gamma$ ) were observed not to alter IgA secretion in cultures of LPS-stimulated blasts. However, IL-2 caused a two- to threefold enhancement in IgA secretion in these cultures (Coffman *et al.*, 1987). Additional studies demonstrated that, analogous to IL-5, IL-2 induced a higher level of IgA secretion in T cell-stimulated cultures of Peyer's patch B cells than in similar cultures of splenic B cells (D. A. Leberman and R. L. Coffman, unpublished results). The secreted IgA in these cultures was derived from the mIgA<sup>+</sup> population, suggesting that IL-2 can act to cause maturation to IgA secretion (Table I). IL-2 is less effective than the combination of IL-4 and IL-5 in stimulating IgA secretion. However, these data indicate that cytokines characteristic of both Th1 and Th2 cells (cf. Section V; Chapter 20) are capable of playing a role in the terminal differentiation of mIgA-expressing cells.

### C. Interleukin 6

IL-6 has a broad range of activities in both lymphoid and nonlymphoid tissues (reviewed by Van Snick, 1990). Historically, the molecule that ultimately was identified as IL-6 was associated with growth and differentiation of B-lineage cells. Accessory cells, particularly macrophages, are a primary source of IL-6 in freshly isolated lymphoid cell cultures (Van Snick, 1990). Consequently, the effect of IL-6 on isotype

**Table I** IgA Secretion in Th-Stimulated Cultures<sup>a</sup>

<sup>b</sup> T-depleted Peyer's patches (PP) were separated into mIgA<sup>+</sup> and mIgA<sup>-</sup> populations using flow cytometry.

production in murine lymphocytes was investigated in cultures of purified Peyer's patch B cells in the absence of mitogen (Beagley *et al.*, 1989; Kunimoto *et al.*, 1989). In unfractionated Peyer's patch B cells, IL-6 induced a higher level of IgA secretion than IL-5 (Beagley *et al.*, 1989). Other investigators observed that either IL-5 or IL-6 alone induced a modest increase in IgA secretion in cultures of T cell-depleted Peyer's patch cells, but the combination of the two cytokines greatly increased the level of IgA secretion (Kunimoto *et al.*, 1989). The combination of IL-5 and IL-6 was particularly effective in enhancing IgA secretion. Although IL-6 induced mIgA<sup>+</sup> cells that were activated *in vivo* to secrete IgA, it did not increase IgM or IgG secretion in cultures of Peyer's patch B cells. Further, IL-6 did not cause mIgA<sup>-</sup> cells to secrete IgA, suggesting that the effect of IL-6 was not stimulation of isotype switching to IgA. Thus, to date, three cytokines—IL-2, IL-5, and IL-6—have been shown to play a role in promoting the maturation of murine mIgA-expressing cells into IgA-secreting cells. However, evidence only exists to substantiate a role *in vivo* for IL-5.

## III. CYTOKINES THAT INDUCE ISOTYPE SWITCHING TO IgA

Transforming growth factor  $\beta$  (TGF $\beta$ ) is a ubiquitous 25-kDa peptide (Sporn *et al.*, 1986) that is pleiotropic in action. TGF $\beta$  was characterized initially on the basis of its ability to stimulate anchorage-independent growth of fibroblasts (Assoian *et al.*, 1983). In early studies on its effects on lymphoid populations, TGF $\beta$  was shown to inhibit both human T-cell proliferation and immunoglobulin secretion (Kehrl *et al.*, 1986, 1987) and to prevent the maturation of murine pre-B cells to mature B cells (Lee *et al.*, 1987). As a result of these studies, TGF $\beta$  was regarded to be immunosuppressive. Since many recombinant cytokines were derived from supernatants of Cos-7 cells, a fibroblast cell line

that secretes TGF $\beta$ , investigating the effects of TGF $\beta$  in B-cell cultures became important. Although Beagley and colleagues did not see any effect of TGF $\beta$  on IgA production by unstimulated Peyer's patch B cells (Beagley *et al.*, 1989), Coffman and colleagues (1989a) observed that the addition of TGF $\beta$  to LPS-stimulated splenic B cells induced a 5- to 10-fold increase in IgA secretion concomitant with a similar decrease in IgM secretion. Further, the addition of both IL-2 and TGF $\beta$  to LPS-stimulated cultures induced an enhancement in IgA secretion that was greater than the combined effects of either cytokine alone, suggesting that IL-2 could synergize with TGF $\beta$  in generating an IgA response. The basic finding of this study was confirmed by several other groups of investigators (Sonoda *et al.*, 1989; Chen and Li, 1990; Kim and Kagnoff, 1990a). IL-5 also was observed to synergize with TGF $\beta$  to enhance IgA secretion (Sonoda *et al.*, 1989). Interestingly, some variation exists in the ability of TGF $\beta$  alone to stimulate IgA secretion. Some investigators have found it necessary to add both TGF $\beta$  and IL-2 to cultures to obtain significant enhancement in IgA secretion (Kim and Kagnoff, 1990a).

Studies at the cellular level of the effect of TGF $\beta$  on IgA secretion have provided evidence that TGF $\beta$  acts to stimulate isotype switching to IgA. In the initial reports on the IgA-enhancing ability of TGF $\beta$ , an interesting dichotomy was observed (Coffman *et al.*, 1989a). Although TGF $\beta$  enhanced IgA secretion by mIgA<sup>-</sup> cells, it inhibited IgA secretion by mIgA<sup>+</sup> cells. Nonetheless, TGF $\beta$  induced an increase in the proportion of mIgA<sup>+</sup> cells (Lebman *et al.*, 1990a). The addition of IL-2 to cultures containing LPS and TGF $\beta$  neither caused a further increase in the proportion of mIgA<sup>+</sup> cells nor overcame TGF $\beta$ -induced inhibition of proliferation, yet the addition of IL-2 to TGF $\beta$ -containing cultures caused an additional 10- to 20-fold increase in IgA secretion. The observation that only a small proportion of splenic B cells was induced to express mIgA by TGF $\beta$  raised the possibility that expressing mIgA was not necessary to develop into an IgA-secreting cell. To address this issue, splenic B cells were stimulated with LPS in the presence of both TGF $\beta$  and IL-2 for 4 days. Subsequently, the mIgA<sup>+</sup> and mIgA<sup>-</sup> cells were isolated and cultured for an additional 3 days. Virtually all the secreted IgA was derived from cells that were induced to express mIgA. Thus, the combination of TGF $\beta$  and IL-2 caused a transition from mIgA<sup>-</sup> to mIgA<sup>+</sup> to IgA-secreting cells (Lebman *et al.*, 1990a). Additional evidence for the roles of TGF $\beta$  and IL-2 in IgA responses was derived from limiting dilution analysis (Kim and Kagnoff, 1990b). TGF $\beta$ , but not IL-2, caused approximately a 20-fold increase in the frequency of IgA-secreting cells. Further, the addition of IL-2 to TGF $\beta$ -containing cultures increased IgA secretion without increasing the frequency of IgA-secreting cells. Collectively, these studies indicate that TGF $\beta$  induces isotype switching to IgA and IL-2 acts to induce terminal differentiation of mIgA-expressing cells.

Molecular analysis of the effects of cytokines on IgA production has provided additional insights into both the role of cytokines and the specific T helper cell populations in the generation of IgA responses at mucosal sites. Heavy-chain class switching requires a recombination between switch (S)

regions located immediately 5' to each heavy-chain locus (C<sub>H</sub>). This recombination juxtaposes a specific variable region (V<sub>H</sub>) with a new C<sub>H</sub> (Davis *et al.*, 1980). A large body of evidence in normal cells and cell lines demonstrated that this recombination is preceded by the appearance of transcripts containing germ line sequences (Stavnezer *et al.*, 1985, 1988; Lutzker and Alt, 1988; Berton *et al.*, 1989; Esser and Radbruch, 1989; Radcliffe *et al.*, 1990). These germ-line transcripts initiate 5' to the particular S region to which recombination is targeted and proceed downstream through the constant region. The association of germline transcripts with IgA expression initially was described in the I.29 cell line (Stavnezer *et al.*, 1988). On stimulation with LPS, I.29 cells switch preferentially to either IgA or IgE. However, prior to stimulation, these cells contain germline transcripts consisting of a pseudo-exon 5' to S $\alpha$  (I $\alpha$ ) spliced to C $\alpha$  (Radcliffe *et al.*, 1990). The addition of TGF $\beta$  to LPS-stimulated B-cell cultures results in the appearance of similar transcripts (Figure 1; Lebman *et al.*, 1990).

Secreted IgA from cultures stimulated with a Th2 specific for rabbit immunoglobulin is antigen dependent. Further, the secreted IgA in these cultures is derived from mIgA<sup>+</sup> cells (D. A. Lebman, unpublished results). In contrast to TGF $\beta$ -containing LPS-stimulated cultures, the induction of IgA secretion in Th2 cell-stimulated, antigen-dependent cultures is not accompanied by the appearance of germline  $\alpha$  mRNA transcripts (Figure 2). The model proposing that isotype switching is preceded by the appearance of germline transcripts is supported further by the observation that the CH12 lymphoma, which preferentially undergoes isotype switching to IgA, contains germline  $\alpha$  mRNA transcripts (Figure 2).

**Figure 1** Transforming growth factor  $\beta$  (TGF- $\beta$ ) induces germline  $\alpha$  mRNA transcripts. Poly (A)<sup>+</sup> RNA was isolated from splenic B cells stimulated for 3 days as indicated. Total mRNA was isolated from the IgA-secreting myeloma MOPC 315. (A) Northern blot was hybridized with a probe specific for germline transcripts (I $\alpha$ ). (B) The same northern blot was hybridized with a constant region probe that would detect both productive and germline  $\alpha$  mRNA (C $\alpha$ ). Reprinted with permission from Lebman *et al.* (1990b).

**Figure 2** Stimulation with Th2 cells does not induce isotype switching. Peyer's patch B cells were stimulated with a T helper cell specific for rabbit immunoglobulin and rabbit anti-mouse IgA alone or in the presence of cytokines or anti-cytokines, as indicated. (A) Northern blot was hybridized with a C $\alpha$  probe. (B) Northern blot was hybridized with a probe specific for germline  $\alpha$  mRNA (5'S $\alpha$ ).

Thus, studies on the molecular mechanism of isotype switching confirm the functions of TGF $\beta$  and Th2 cytokines in isotype switching and maturation of mIgA-expressing cells to IgA-secreting cells, respectively.

#### IV. CYTOKINES INVOLVED IN IgA EXPRESSION BY HUMAN B CELLS

Several cytokines that act to enhance the maturation of mIgA<sup>+</sup> murine B cells to IgA-secreting cells or to induce isotype switching to IgA have been described (Table II). However, the effects of cytokines on isotype secretion by human B cells are not as well documented. The problem in studying the action of cytokines in the human B-cell system appears to stem, in part, from a difficulty in finding methods to stimulate growth and differentiation of human B cells in a way analogous to murine B cell stimulation. However, several groups have approached this problem using different protocols to stimulate B cells. As the results emerge, similarities

and differences appear in the response patterns of human and murine B cells. In comparing the results obtained with human B cells to those obtained with murine B cells, note that not only are the stimuli not comparable but the source of cells is also different. The information on murine cells has been gained largely by studying the response of Peyer's patch or splenic B cells whereas, in human studies, the B cells frequently are derived from the tonsils.

Virtually all human B cells can be induced to proliferate by stimulating them for 3 days in the presence of phorbol dibutyrate and ionomycin (Flores-Romo *et al.*, 1990). The addition of either IL-2 or IFN $\alpha$  to these cultures caused enhanced secretion of IgA. In contrast, IL-5 had no effect on IgA secretion in these cultures. A second protocol for inducing human B-cell proliferation is triggering them by cross-linking CD40 antigen (Rousset *et al.*, 1991). To do this, anti-CD40 is presented to B cells on fibroblast cells that stably express Fc $\gamma$ RII/CDw32. Since this method of stimulation induces B-cell proliferation in a factor-independent way, it provides a good model system for investigating the effects of cytokines on isotype expression (Rousset *et al.*, 1991). In these cultures, no individual cytokine effectively induces IgA secretion. However, in the presence of IL-4, both IL-2 and IFN $\gamma$  induce substantial levels of IgA secretion. The combination of IL-4 and IL-5 also increases IgA secretion, albeit not as effectively as the combination of IL-4 and IL-2. The effects of either IL-2 or IFN $\gamma$  in combination with IL-4 are not limited to IgA. The combination of IL-2 and IL-4 also causes a substantial increase in IgM secretion, whereas IFN $\gamma$  and IL-4 increase IgG secretion. In contrast, the effect of IL-5 appears to be limited to IgA secretion. No studies are available to indicate whether the increases in isotype expression result from inducing heavy-chain class switching or preferential stimulation of isotype-committed precursors.

On a molecular level, the response of murine and human

**Table II** Cytokines that Enhance IgA Secretion by Murine B Cells<sup>a</sup>

Isotype switching	Maturation
TGF- $\beta$	IL-2 IL-5 IL-6

<sup>a</sup> Cytokines are characterized as stimulating heavy chain class switching by mIgA<sup>+</sup> cells (isotype switching) or as enhancing secretion by mIgA<sup>+</sup> cells (maturation).

B cells to TGF $\beta$  is similar. The addition of TGF $\beta$  to human splenic B cells stimulated with *Branhamella catarrhalis* results in the induction of germline transcript for both classes of IgA (Islam *et al.*, 1991). The structure of the human germline  $\alpha$  mRNA transcripts is analogous to that of the murine transcripts (Nilsson *et al.*, 1991). The genomic sequence of the germline exons for the two human IgA subclasses, as well as the region 5' to the germline exons, is highly conserved. Further, putative regulatory regions 5' to the germline exons are conserved between mice and humans. Unfortunately, the signals, if any, that are required to induce these germline  $\alpha$  mRNA-producing human B cells to mature to IgA-secreting cells are not established. However, if the molecular mechanisms for isotype switching in human and mouse are similar, TGF $\beta$  is likely to induce isotype switching to IgA in both species.

## V. CYTOKINE PRODUCTION BY T HELPER SUBSETS

T helper cell subsets have been divided into two distinct classes, Th1 and Th2, on the basis of the pattern of cytokines secreted (Table III; reviewed by Mosmann and Coffman, 1989). Characteristically, Th1 cells secrete IL-2, IFN $\gamma$ , and lymphotoxin; Th2 cells secrete IL-4, IL-5, and IL-10. Although subsets of Th cells that secrete other patterns of cytokines exist, functionally the Th1 and Th2 subsets are best characterized (Mosmann and Moore, 1991). The relative roles and potential interactions of these subsets in the generation of specific types of immune response can be related to the cytokines they produce. Further, evidence suggests that these subsets play important roles *in vivo* in mice and humans.

Both Th1 and Th2 cells can stimulate B cells to proliferate, undergo clonal expansion, and secrete immunoglobulin (Coffman *et al.*, 1988). B cells can respond to the different helper subsets regardless of their state of activation. However, the Th1 subset of helper cells is less efficient than the Th2 subset in stimulating antibody production by resting B cells. Although growth and maturation per se appear to be relatively independent of the stimulating helper cell, the pattern of isotypes secreted is dependent on the phenotype of the stimulating Th cell (Table IV). Th1 cells are relatively more efficient in stimulating IgG2a responses, whereas Th2 cells are

**Table IV** Patterns of Immunoglobulin Isotype Expression in Th1- and Th2-Stimulated B Cell Cultures<sup>a</sup>

Isotype	Supernatant levels (day 7) <sup>b</sup> (% total response)	
	Th1	Th2
IgA	0.5–1	0.25–1
IgM	50–90	55–90
IgG1	5–20	5–40
IgE	<.01	0.05–2
IgG2a	1–20	0.4–1
IgG2b	0.3–2	0.2–1
IgG3	0.2–1	0.2–0

<sup>a</sup> Cultures of T-depleted spleen cells were stimulated for 7 days with either a Th1 or a Th2 helper cell clone. Th1-stimulated cultures also received anti-IFN $\gamma$  and IL-2.

<sup>b</sup> Supernatant levels are recorded as percentages of total immunoglobulin secreted.

relatively more efficient in stimulating IgE responses. The difference in isotype display potentially is related to the difference in cytokine secretion pattern. Th1 cells secrete IFN $\gamma$ , which has been shown to be involved in isotype switching to IgG2a (Snapper *et al.*, 1988). On the other hand IL-4, which is a product of Th2 cells, stimulates isotype switching to IgE (Lebman and Coffman, 1988a). Note that the ability of the two helper subsets to stimulate IgA secretion relative to total immunoglobulin secretion is comparable (Table IV).

Th2 cytokines play a significant role in the mediation of allergic responses. IL-4, which stimulates isotype switching to IgE, also has mast cell stimulating activity (Lee *et al.*, 1986). In addition IL-5, whose role in IgA production was discussed in another section (Section II.A), has been shown to enhance eosinophil growth and differentiation both *in vitro* and *in vivo* (Sanderson *et al.*, 1986; Coffman *et al.*, 1989b). IgA can bind to eosinophils and stimulate their degranulation (Abu-Ghazaleh *et al.*, 1989), suggesting a role for IL-5 production in inflammatory bowel disease.

A dichotomy of function between the two predominant helper subsets has been suggested. Th1 cells are associated with delayed-type hypersensitivity whereas Th2 cells are associated with antibody responses (reviewed by Mosmann and Moore, 1991). These two types of response also have been suggested to be mutually exclusive (Parish, 1972). Cytokines produced by the different Th subsets appear to be involved in regulation of the balance of helper subsets. For example, IFN $\gamma$  inhibits the growth of Th2 cells whereas IL-4 preferentially stimulates their growth (Fernandez-Botran *et al.*, 1988). On the other hand IL-10, which is produced by Th2 cells, inhibits cytokine production by Th1 cells. The interplay of Th cells and cytokines potentially is involved in maintaining the integrity of the mucosal immune system.

**Table III** Cytokine Production by T Helper Subsets<sup>a</sup>

Th1	Th2
IL-2	IL-4
IFN $\gamma$	IL-5
Lymphotoxin	IL-6
	IL-10

<sup>a</sup> For each subset the cytokines that are produced uniquely are shown. Data were derived from Mosmann and Moore (1991).

## VI. CYTOKINE PRODUCTION IN MUCOSAL SITES

The basis for the preferential generation of precursors of IgA-secreting cells in the Peyer's patches remains unclear. Before the cloning of cytokines and the elucidation of their role in regulating isotype expression, investigators had begun to accumulate evidence suggesting that specific T helper populations in the Peyer's patches were involved in the generation of a secretory IgA response (Kawanishi *et al.*, 1983a, b; Kiyono *et al.*, 1984). The discovery that IL-5 enhanced IgA production and was secreted by a specific subset of T helper cells, Th2 cells, provided new impetus for the study of T cells in GALT with an emphasis on cytokine production in mucosal sites. In trying to understand the role of cytokines in the preferential generation of an IgA response in mucosal sites, we must consider the separation of mucosal sites into IgA-inductive and IgA-effector sites. Although the precursors of IgA-secreting cells are generated preferentially in the Peyer's patches, an IgA-inductive site, maturation of these cells to IgA secretion occurs in the lamina propria, an IgA-effector site (Craig and Cebra, 1971; Tomasi, 1983).

Considering the role of IL-5 in IgA secretion, investigators began to look for evidence that IL-5-secreting cells were present in the Peyer's patches (Schoenbeck *et al.*, 1989). Freshly isolated Peyer's patch T cells were separated on the basis of their adherence to *Vicia villosa* agglutinin. On *in vitro* stimulation with a combination of the T-cell mitogen concanavalin A and IL-1, the lectin adherent population secretes IL-5 whereas the lectin nonadherent population secretes IL-2. Interestingly, the supernatants from the adherent but not the nonadherent population supported IgA secretion in cultures of LPS-stimulated splenic B cells. This study provided evidence that Th subsets with both Th1 and Th2 phenotypes were present in an IgA-inductive site.

The ability to assess the actual number of T cells secreting specific cytokines provided a tool for comparing the ratio of Th1 and Th2 subsets in different mucosal sites (Taguchi *et al.*, 1990). Th1 cells were enumerated on the basis of IFN- $\gamma$  secretion whereas IL-5 secretion was used to define Th2 cells. Although relatively few cytokine-producing cells are found in either freshly isolated spleens or Peyer's patches, the patches contain more cytokine-producing cells, which could reflect the fact that Peyer's patches are a site of chronic antigenic stimulation. On *in vitro* activation, both spleen and Peyer's patch were shown to have relatively equal numbers of IL-5- and IFN- $\gamma$ -secreting cells. Similarly, relatively equal numbers of IL-5- and IFN- $\gamma$ -secreting cell are found among intraepithelial lymphocytes (IELs) although, compared with Peyer's patches, IELs have two- to threefold more cytokine-secreting cells. The only mucosal tissue that was enriched for IL-5-secreting cells was the lamina propria, which had a 3 : 1 ratio of IL-5- to IFN- $\gamma$ -secreting cell (Taguchi *et al.*, 1990). Thus, IgA-effector but not IgA-inductive sites are enriched for Th2 cells. These studies correlate with previous observations (Table III) that both Th1 and Th2 can provide T-cell help for the generation of IgA-producing B cells. Further, they demonstrate that a site that is enriched for IgA-secreting cells, the lamina propria, also is enriched for IL-5-secreting

cells, suggesting an *in vivo* role for Th2 cells in the generation of a secretory IgA response.

A great deal of effort has been put forth to correlate CD4<sup>+</sup> Th subsets and cytokine production with mucosal immunity, yet freshly isolated IELs also produce cytokines associated with T helper function (Taguchi *et al.*, 1991). However, a major proportion of IELs expresses CD8, and most of these CD8<sup>+</sup> cells use  $\gamma\delta$  T-cell receptors (TcR; Goodman and LeFrancois, 1988). A considerable proportion of this population expresses both IFN- $\gamma$  and IL-5 (Taguchi *et al.*, 1991). In fact, in terms of cytokine production, CD8<sup>+</sup>  $\gamma\delta$  TcR- using cells contain subsets similar to those described for CD4<sup>+</sup> Th cells (Taguchi *et al.*, 1991). Although the role of this population is not established, their cytokine production potential raises the possibility that they function at mucosal barriers to regulate immune responses (Taguchi *et al.*, 1990).

## VII. CONCLUSIONS

The cloning of cytokines has made it possible to analyze their effects on isotype secretion and to speculate on their role at mucosal surfaces. Although no cytokine appears to be expressed uniquely in a mucosal tissue, the balance of cytokine-expressing cells at mucosal sites may be critical to maintaining the integrity of the mucosal immune system. Thus, the dichotomy of function of Th cells and the role of cytokines in regulating Th balance that has been applied to the study of systemic immunity is equally relevant to mucosal immunity. Although many questions have been answered concerning the *in vitro* actions of cytokines in the regulation of IgA expression, little is known about how these cytokines act *in vivo*.

# Distribution and Characteristics of Mucosal Immunoglobulin-Producing Cells

Per Brandtzaeg

## I. INTRODUCTION

More than two decades ago, the major immunoglobulin (Ig) present in exocrine secretions was shown to be a dimeric IgA covalently bound to an epithelial glycoprotein of about 80 kDa (Tomasi *et al.*, 1965), now called the secretory component (SC). Pentameric IgM likewise is actively enriched in most secretions and is associated with SC, although not in a covalently stabilized complex (Brandtzaeg, 1975). This difference largely explains that secretory IgA (SIgA) survives better than secretory IgM (SIgM) in intestinal fluid (Richman and Brown, 1977). However, a striking heterogeneity exists in SIgA with respect to proteolytic resistance, depending on whether the subclass IgA1 or IgA2 constitutes the Ig moiety (Mestecky and McGhee, 1987).

The secretory immune system is the best defined aspect of mucosal immunity. This adaptive humoral defense mechanism depends on a fascinating cooperation between the local B-cell system and the secretory epithelia. Terminally differentiated B cells, appearing as Ig-producing blasts and plasma cells (collectively called immunocytes) in histologically normal secretory tissues, produce mainly dimers and larger polymers of IgA (Brandtzaeg, 1985). Such polymeric IgA (pIgA) contains a 15-kDa polypeptide called the "joining" or J chain (Mestecky and McGhee, 1987) and therefore can become bound to SC expressed basolaterally on the secretory epithelial cells as a pIg receptor (pIgR; Chapter 10). Pentameric IgM also contains J chain and, hence, can be transported externally by the SC-mediated endocytic mechanism (Brandtzaeg, 1985).

## II. NORMAL MUCOSAL STATE

### A. Immunoregulatory Mechanisms

Regulation of mucosal immunity is believed to be exerted primarily in organized lymphoepithelial structures such as gut-associated lymphoid tissue (GALT), which includes the Peyer's patches and solitary lymphoid follicles. Additional immune regulation mediating terminal B-cell differentiation, and probably also peripheral tolerance or hyporesponsiveness to nonmicrobial antigens, may involve various cells

both in the lamina propria and in the epithelial compartment (Chapters 12, 13 and 16).

B cells that have received their "first signals" of stimulation in GALT migrate with primed T cells through mesenteric lymph nodes to peripheral blood. Both types of memory cells finally are seeded by extravasation into distant gut mucosa and, to some extent, other more remote secretory tissues (Mestecky, 1987; Mestecky and McGhee, 1987; Brandtzaeg and Bjerke, 1990). "Second signals," modulated by various tissue elements expressing HLA Class II determinants and by regulatory T lymphocytes, cause terminal maturation of B cells to Ig-producing immunocytes. Most of these cells apparently belong to clones of an early differentiation stage compatible with gene activation promoting J-chain expression, regardless of concomitant Ig class production (Brandtzaeg, 1974a, 1985; Brandtzaeg and Korsrud, 1984; Bjerke and Brandtzaeg, 1990a). The obvious functional goal of this immunoregulatory development is generation of SC-binding pIg locally, where external transport through SC-positive epithelium can take place readily to generate SIgA and SIgM antibodies (Chapter 10).

This brief account of mucosal immune regulation does not give full justice to all the research work that has been performed, mainly in experimental animals. However, how the local inductive and suppressive immunoregulatory mechanisms are achieved is admittedly still obscure (Brandtzaeg *et al.*, 1989). The Peyer's patches have, for the last two decades, been considered the major precursor source of B cells giving rise to the predominant mucosal IgA immunocyte populations (Chapter 13). Particular "switch cells," acting by poorly defined mechanisms on the Ig heavy-chain constant region ( $C_H$ ) genes to drive the phenotypic expression from IgM directly to IgA, have been postulated in murine Peyer's patches (Kawanishi *et al.*, 1985). Similar cells have been cloned more recently from the human appendix (Benson and Strober, 1988).

The IgA-promoting role of various T cell-derived lymphokines or interleukins (IL) in the mucosal B-cell differentiation process is being subjected to extensive investigation, including studies on IL-2 through IL-12 as well as transforming growth factor  $\beta$  (TGF $\beta$ ) (Chapter 14). IL-2, IL-5, and perhaps IL-6 are, moreover, involved in the up-regulation of J-chain expression, whereas IL-4 may have an opposing role (Tigges *et al.*, 1989; Takayasu and Brooks, 1991; Randall *et al.*, 1992).

Interestingly, intestinal lamina propria T cells may show particularly high capacity to secrete IL-2 and IL-5 (James, 1991). Further, evidence suggests that J-chain expression can take place independently of Ig production, but the secretion of this peptide depends on its intracellular association with pIgA or pentameric IgM (Brandtzaeg and Berdal, 1975; Kubagawa *et al.*, 1988; Mestecky *et al.*, 1990), perhaps because accessible thiol groups of free J chain prevent its transport from the endoplasmic reticulum (Alberini *et al.*, 1990).

## B. Distribution of Ig-Producing Immunocytes in Human Exocrine Tissues

### 1. Immunohistochemical Methodology for Immunocyte Recording

Specimens of exocrine tissues can be prepared for immunohistochemistry in principally three different ways: as fresh-frozen tissue for cryosections; by a precipitating or coagulative fixative (e.g., ethanol) followed by paraffin wax embedding; or by a cross-linking fixative (e.g., formaldehyde) followed by embedding. Cryosections usually are best suited for membrane-anchored glycoproteins, whereas formaldehyde-fixed tissue is preferred for easily diffusible components of low molecular weight. However, masking of antigenic determinants is a problem in immunohistochemical studies of glycoproteins that have been subjected to cross-linking fixatives, although partial unmasking by enzyme digestion of the tissue sections usually can be achieved, especially when polyclonal antibody reagents are applied (Brandtzaeg, 1982).

For reliable demonstration of interstitial and epithelial Ig distribution, ethanol fixation is undoubtedly the method of choice (Brandtzaeg, 1982). Modification of this approach by including a prefixation tissue washing period is often necessary for visualization of Ig-producing and Ig-bearing cells against a fairly unstained background (Brandtzaeg, 1974b). The antigenic determinants of certain molecules, such as IgA-associated J chain, are masked even in such ethanol-fixed tissue; denaturation of tissue sections in acid urea is therefore necessary for reliable detection of J chain-producing immunocytes of this class (Brandtzaeg, 1983a).

In addition to these important precautions, appropriate morphometric methods must be applied for the quantification of Ig-producing cells to produce meaningful data that can be compared among various laboratories. Immunocyte densities preferably are reported as number of cells/mm<sup>2</sup> of section area or defined tissue compartment. However, in most secretory tissues, the immunocyte density is strikingly heterogeneous so the selection of fields to be evaluated must be performed in a well-defined manner (Korsrud and Brandtzaeg, 1980). Paired staining of two or three Ig isotypes in the same tissue section is always preferable to obtain reliable phenotype ratios (Brandtzaeg 1974b, 1982). In the gut lamina propria, reporting the number of immunocytes per length unit of the gut (Figure 1), including the full height of the mucosa (Brandtzaeg and Baklien, 1976), is most representative.

**Figure 1** Schematic representation of normal (*top*) and diseased (*bottom*) "tissue unit" defined in a 6- $\mu$ m thick tissue section (small intestine illustrated). The lamina propria area included varies among different specimens depending on the height of the tissue unit: The total number of Ig-producing immunocytes per unit is determined by this variable as well as by the cell density. The distribution of dots indicates heterogeneity in cell density. The highest density of Ig-producing immunocytes normally is found around the base of the villi in the normal small intestine or close to the lumen in "flat" lesions or normal colonic mucosa. The definition of the corresponding 200- $\mu$ m zones, which may be used for quantitative comparisons within or between units, is shown by vertical lines. Modified from Brandtzaeg and Baklien (1976).

### 2. Normal Adult Secretory Tissues

**a. Class distribution of Ig-producing cells.** Secretory tissues of adults normally contain a remarkable preponderance of IgA-producing immunocytes, including plasma cells and blasts (Figure 2), particularly the intestinal mucosa, as first reported by Crabbé *et al.* (1965) and Rubin *et al.* (1965). We have estimated that almost  $10^{10}$  such cells occur per meter of adult bowel (Brandtzaeg and Baklien, 1976), with a predominance proximally and distally (Figure 3). Absolute figures are difficult to obtain for other secretory tissues in which the cells are distributed much more heterogeneously throughout the stroma than they are in the gastrointestinal lamina propria; however, on the basis of our quantitative data (Figure 4), most gland-associated IgA cells are located in the gut (Brandtzaeg, 1983b). Moreover, the size of this cell population is impressive in view of the comparable figure ( $2.5 \times 10^{10}$ ) estimated for bone marrow, spleen, and lymph nodes together (Turesson, 1976). Therefore, at least 80% of all Ig-producing immunocytes of the body are located in the gut (Brandtzaeg *et al.*, 1989). A similar estimate has been reported for mice (van der Heijden *et al.*, 1987). Aging does not reduce the remarkable Ig-producing capacity of the intestinal mucosa (Penn *et al.*, 1991).

The large output of IgA in colostrum might imply that lactating mammary glands either harbor a remarkably active secretory immune system or, alternatively, drain pIgA from serum selectively. In fact, human colostrum contains about

**Figure 2** Immunofluorescence staining for IgA (rhodamine) and IgG (fluorescein). (a) Double exposure showing both isotopes. (b) Selective filtration for IgG staining in same field from nasal mucosa. Note relatively few IgG-producing cells (arrows) among densely packed IgA immunocytes adjacent to acini (A), which show selective uptake of IgA.  $\times 190$ .

300 times more SIgA than stimulated parotid secretion and about 60 times more than normal unstimulated whole saliva (Brandtzaeg, 1983b). However, the density of IgA-producing cells is similar in human salivary and lactating mammary glands, but six to seven times less than in lacrimal glands and colonic mucosa (Figure 4). The daily output of IgA/gm wet weight is, moreover, similar for salivary and lactating mammary glands. Thus a large capacity for storage of IgA in the mammary gland epithelium and the duct system appears to explain the striking output of IgA during feeding. No evidence exists for a selective extracellular accumulation of serum-derived or locally produced pIgA in the glandular stroma (Brandtzaeg, 1983b).

IgM-producing cells normally constitute a substantial but variable fraction of the immunocyte populations in secretory tissues of adults (Figure 5). The reason for the relatively high proportion of this class in the proximal small intestine is unknown (Figure 3). IgG-producing cells constitute 3–5% of the immunocytes in normal intestinal mucosa, but a considerably larger percentage is found in nasal and gastric mucosa (Figure 5). Only occasional IgD and IgE immunocytes are encountered in the gastrointestinal tract, whereas IgD-producing cells constitute a significant fraction (2–10%) of the glandular immunocytes in the upper respiratory tract, including nasal mucosa and salivary and lacrimal glands (Brandtzaeg *et al.*, 1979; Korsrud and Brandtzaeg, 1980; Brandtzaeg, 1984).

We have interpreted this regional difference to suggest that partial sequential downstream switching according to the location of the  $C_H$  genes on chromosome 14 ( $\mu$ - $\delta$ - $\gamma 3$ - $\gamma 1$ - $\alpha 1$ - $\gamma 2$ - $\gamma 4$ - $\epsilon$ - $\alpha 2$ ) might be a preferential B-cell differentiation pathway in the upper digestive and respiratory tracts, whereas more extensive sequential switching—perhaps combined with direct switching from  $C_H\mu$  (IgM) to  $C_H\alpha 2$  (IgA2)—might be prominent in the distal gut (Brandtzaeg *et al.*, 1986). This notion has been supported by findings in subjects with selective IgA deficiency: The absent IgA immunocytes are replaced largely by the IgM class in gut mucosa but often by J chain-expressing IgD immunocytes in the upper digestive and respiratory tracts (see subsequent discussion).

**b. Subclass distribution of Ig-producing cells.** Immunohistochemical studies with monoclonal antibodies (MAbs) against the two IgA subclasses have supported further the idea of regional immunoregulatory differences (Kett *et al.*, 1986). Again we found a remarkable disparity between the upper digestive and respiratory tracts compared with the distal gut: IgA1 immunocytes predominated (80–93%) in the former secretory tissues whereas IgA2 immunocytes were usually most frequent (~60%) in the normal large bowel mucosa (Figure 6).

Similar studies with MAbs against the four human IgG subclasses have been difficult to perform because IgG-producing cells are so few in normal gut mucosa. However,

**Figure 3** Median numbers (and observed ranges) of Ig-producing immunocytes (IC) per mucosal tissue unit in the normal proximal jejunum, ileum, and large bowel. The median percentage class distributions of the immunocyte populations are given also. All tissue units are  $500 \mu\text{m}$  wide (vertical axis); the median height (horizontal axis) for each specimen category is indicated ( $n$  = number of subjects). Data adapted from various immunohistochemical studies reported by the author's laboratory.

we have obtained immunohistochemical results in the large bowel (Nilssen *et al.*, 1991) that, on a relative basis, agree remarkably well with the spontaneous secretion of IgG subclasses observed in cultures of lamina propria lymphoid cells (Scott *et al.*, 1986). Our immunohistochemical studies of IgG-producing cells in upper respiratory tract mucosa (Brandtzaeg *et al.*, 1987), as well as in normal ileal (Bjerke and Brandtzaeg, 1990b) and colonic (Nilssen *et al.*, 1991) mucosa, have shown that IgG1 is the predominating subclass ( $>55\%$ ), which is also the case in normal serum. However, IgG2 cells are generally more frequent (20–35%) than IgG3 cells (4–6%) in the distal intestinal mucosa (Bjerke and Brandtzaeg, 1990b; Nilssen *et al.*, 1991), whereas the reverse is often true in the upper respiratory mucosa (Brandtzaeg *et al.*, 1987).

This IgG subclass disparity also supports the idea that the B-cell switching pathways differ in various regions of the mucosal immune system, as discussed earlier. Although particular T cells or lymphokines that fully explain Ig isotype selection have not been identified, serum IgG subclass responses are well documented to be influenced by the nature of the stimulatory antigen. Many carbohydrate and bacterial

antigens preferentially induce an IgG2 response, whereas proteins (which are clearly T cell-dependent antigens) primarily generate a coordinate IgG1 and IgG3 response (Papadea and Check, 1989). Regional environmental factors thus may contribute to the different proportions of IgG subclass-producing cells seen in the upper respiratory and distal gut mucosa. Such environmental influence is likely to explain the disparity observed for the IgA subclass-producing cells as well because proteins stimulate mainly IgA1 whereas carbohydrate antigens, particularly *Escherichia coli* lipopolysaccharide, tend to favor IgA2 responses (Brown and Mestecky, 1985; Mestecky and Russell, 1986; Tarkowski *et al.*, 1990).

The upper respiratory tract microbiota might contribute significantly to B-cell regulation in that region and perhaps explain the prominent local IgD response seen in many IgA-deficient patients (Brandtzaeg *et al.*, 1979, 1987; Korsrud and Brandtzaeg, 1980; Brandtzaeg and Korsrud, 1984). Most strains of *Haemophilus influenzae* and *Moraxella (Branhamella) catarrhalis*, which are frequent colonizers of the upper respiratory tract, produce an IgD-binding factor (protein D) and therefore may exert great impact on local B-cell activation by cross-linking surface IgD and HLA Class I determinants (Ruan *et al.*, 1990; Janson *et al.*, 1991). B lymphocytes of the follicular mantle zones in the tonsils are usually strongly positive for both these molecules (Brandtzaeg, 1987), and could be stimulated by protein D to proliferate and differentiate in a polyclonal (antigen-independent) manner. This type of stimulation also might contribute to the fact that, normally, particularly many IgD and IgA1-producing cells exist in the upper digestive and respiratory tracts (Figures 5 and 6). One may speculate that cross-linking of surface IgD favors a sequential differentiation pathway, mainly terminating with IgA1 production, whereas direct switching from IgM to IgA2 predominates in GALT in which lipopolysaccha-

**Figure 4** Densities (numbers/ $\text{mm}^2$ ) of immunoglobulin-producing cells of different classes, as indicated, in sections of various normal human secretory tissues. Data adapted from various immunohistochemical studies reported by the author's laboratory.

**Figure 5** Percentage distribution of IgA-, IgM-, IgG-, and IgD-producing immunocytes in various normal human secretory tissues. Data adapted from various immunohistochemical studies reported by the author's laboratory.

rides could tend to suppress IgD expression (Parkhouse and Cooper, 1977). Perhaps the IgA1 protease-producing bacteria of the upper respiratory tract are equipped with protein D to favor the development of a local secretory immune response that they can evade.

**c. J-chain production.** Almost 90% of the IgA1 and virtually 100% of the IgA2 immunocytes in normal gut mucosa produce pIgA with associated J chain (Crago *et al.*, 1984; Kett *et al.*, 1988; Bjerke and Brandtzaeg, 1990a). The same is true in other exocrine tissues (Brandtzaeg and Korsrud, 1984). Most of the mucosal IgM immunocytes also produce J chain, which

in both classes becomes incorporated into the pIg structure intracellularly (Brandtzaeg, 1983a,1985). However, J-chain incorporation appears not to be necessary for assembly of the polymers and their secretion from the immunocytes (Cattaneo and Neuberger, 1987; Davis and Shulman, 1989), a fact that further attests to the role of this peptide in the generation of the SC binding site of pIgA and pentameric IgM (Brandtzaeg, 1985; Bouvet *et al.*, 1987).

Direct evidence that J chain-positive mucosal IgA immunocytes indeed synthesize a high level of pIgA was obtained first by an SC binding test performed on tissue sections; a striking heterogeneity in the proportion of monomers-to-

**Figure 6** Percentage subclass distribution of IgA-producing immunocytes in various human lymphoid and normal secretory tissues. Based on data from Kett *et al.* (1986).

polymers produced by such immunocytes in lymphoid tissue outside exocrine sites was also suggested (Brandtzaeg, 1973; 1974a) and later confirmed by a spot-ELISA method (Tarkowski *et al.*, 1991). Furthermore, the cytoplasmic affinity for SC shown *in vitro*, as well as the immunohistochemical requirement for unmasking of cytoplasmic J chain (Brandtzaeg, 1983a), support the idea that substantial intracellular polymerization of IgA normally takes place in the J chain-positive immunocytes (Brandtzaeg, 1985). This appears to be different in malignant B-cell lines (Brandtzaeg, 1983a; Moldoveanu *et al.*, 1984), but available methods do not allow accurate determination at the single cell level of the proportion of monomers-to-polymers produced by IgA immunocytes (Tarkowski *et al.*, 1991). Immunoelectron-microscopical localization of J chain in normal intestinal IgA immunocytes suggests that the polymerization process begins in the rough endoplasmic reticulum (Nagura *et al.*, 1979); this notion has been supported by similar studies performed on transformed normal B cells (Moro *et al.*, 1990).

Interestingly, almost 80% of the intestinal IgG-producing cells also normally express cytoplasmic J chain (Brandtzaeg and Korsrud, 1984; Bjerke and Brandtzaeg, 1990a), although this peptide does not become associated with IgG but is degraded intracellularly (Mosmann *et al.*, 1978). Moreover, the J chain is produced by a considerable fraction of IgG cells and most IgD cells in normal nasal mucosa and in salivary, lacrimal, and mammary glands (Brandtzaeg, 1974a; Brandtzaeg *et al.*, 1979; Korsrud and Brandtzaeg, 1980; Brandtzaeg and Korsrud, 1984). When positive for J chain, these mucosal immunocyte classes might be considered terminally differentiated "spin-offs" from early memory clones which, through sequential C<sub>H</sub> switching, are on their maturation pathway to pIgA production (Brandtzaeg, 1985).

## C. Ontogeny of Mucosal Immunocytes

### 1. Perinatal Period

Scattered B and T lymphocytes are seen in the human fetal gut lamina propria from 14 weeks gestation (Spencer *et al.*, 1986). A few IgM- and IgG-producing plasma cells have been reported to appear somewhat later and remain in small numbers until birth, whereas IgA immunocytes are either absent or extremely rare (Brandtzaeg *et al.*, 1991). In contrast, human fetal salivary glands sometimes contain additional IgA-producing cells, especially after 30 weeks gestation (Hayashi *et al.*, 1989); most of these immunocytes (~90%) are of the IgA1 subclass and virtually all express J chain (Thrane *et al.*, 1991). This apparent difference in immunological activation between salivary glands and gut mucosa is intriguing (Brandtzaeg *et al.*, 1991). However, fetal GALT is certainly immunocompetent, at least during the final trimester; numerous plasma cells can appear in the intestinal mucosa in response to intrauterine infection (Silverstein and Lukes, 1962).

The postnatal numbers of IgA- and IgM-producing immunocytes in the intestinal lamina propria (including the appendix) and salivary glands start to rise rapidly after 2-4 weeks, the IgA class becoming predominant after 1-2 months (Figure

**Figure 7** Numeric development of IgA-, IgM-, IgG-, and IgD-producing immunocytes in human parotid glands relative to age in weeks. Based on data from Thrane *et al.* (1991).

7). For the first 6 months, moreover, a striking admixture of IgD-producing cells is often seen in the salivary glands (Thrane *et al.*, 1991), which is interesting in relation to terminal B-cell differentiation for this region (see earlier). Also, a considerable proportion (about 50%) of infants has detectable amounts of IgD in whole saliva during the same time period (Gleeson *et al.*, 1987a). This IgD most likely reaches the secretion by passive diffusion from the local immunocytes because of increased postnatal epithelial permeability.

During the first 3 months after birth, the IgA1:IgA2 immunocyte ratio observed in salivary glands approaches the normal adult value of approximately 65:35 (Kett *et al.*, 1986), which might reflect an increasing postnatal influx of IgA precursor cells from GALT where the IgA2 isotype normally predominates (Bjerke and Brandtzaeg, 1990b). At the same time, the high level of J-chain expression (94-97%) is maintained for both subclasses (Thrane *et al.*, 1991).

### 2. Childhood Development

**a. Normal state.** At an average age of 15 months (Figure 7), the number of IgA immunocytes has approached the lower normal adult range in salivary glands (Korsrud and Brandtzaeg, 1980); the subsequent increase throughout early childhood seems to be small (Hayashi *et al.*, 1989). Blanco *et al.*, (1976) also observed no significant increase of intestinal IgA-producing cells after 1 year, but IgM-producing cells decreased. A similar trend of decreasing intestinal IgM immunocytes with age has been reported by others, although associated with a continuing increase of IgA immunocytes (Savilahti, 1972), even after 2 years (Maffei *et al.*, 1979). In the human appendix, however, no such increase was seen after 5 months (Gebbers and Laissue, 1990).

Cripps *et al.* (1989) reported that almost one-third of infants under 2.5 years of age have only monomeric IgA in saliva, but this finding subsequently was refuted (Smith *et al.*, 1989). The expression of J chain by virtually all salivary IgA immunocytes, both before and after birth (Thrane *et al.*, 1991), strongly suggests that local humoral immunity depends on activation of the secretory immune system in infancy also.

The progressive cellular shift from IgA1 to IgA2 production (Thrane *et al.*, 1991) is reflected in the respective salivary subclass levels (Smith *et al.*, 1989; Müller *et al.*, 1991).

Remarkably, the IgG-producing cell population in the appendix lamina propria becomes substantial after a few months (Gebbers and Laissue, 1990), a feature that can be ascribed to the fact that the 0.1-mm zone adjacent to the numerous lymphoid follicles, and including the domes, contains almost 50% immunocytes of the IgG class (Bjerke *et al.*, 1986). We have suggested that this accumulation reflects local terminal differentiation of B cells belonging to relatively mature memory clones. Generation of such clones in lymphoepithelial structures might reflect the magnitude of topical immunological stimulation and seems to take place increasingly in the order of Peyer's patches (Bjerke and Brandtzaeg, 1986), appendix (Bjerke *et al.*, 1986), and tonsils (Brandtzaeg, 1987). Conversely, dissemination of IgA cell precursors with activated J-chain genes most likely depends on the continuous generation of early memory clones (Brandtzaeg, 1985; Brandtzaeg and Bjerke, 1990). The potency of a lymphoid tissue to function as precursor source for the secretory immune system thus may be related inversely to the local IgG response, in harmony with the major role suggested for Peyer's patches in mucosal IgA responses.

**b. Effect of antigenic load.** The topical antigenic and mitogenic load seems to be decisive for the postnatal development of mucosal immunity. The indigenous microbial flora is probably of utmost importance, as suggested by the fact that the intestinal IgA system of germ-free or specific pathogen-free mice is normalized after about 4 weeks of conventionalization (Crabbé *et al.*, 1970; Horsfall *et al.*, 1978). *Bacteroides* and *E. coli* strains seem to be particularly stimulative for the development of intestinal IgA immunocytes (Moreau *et al.*, 1978). Artificial colonization of infants with a nonenteropathogenic strain of *E. coli* likewise has resulted in enhanced formation of IgA in the gut (Lodinova *et al.*, 1973). Antigenic constituents of food probably exert an additional stimulatory effect, as suggested in mice fed hydrolyzed milk proteins (Sagie *et al.*, 1974) and in parenterally fed babies (Knox, 1986). In the latter case, however, a deleterious effect of malnutrition or retarded bacterial colonization cannot be excluded.

Reduced amounts of microbial and dietary antigens apparently explain why the colonic numbers of IgA- and IgM-producing cells are decreased by about 50% after 2–11 months in children who had been subjected to defunctioning colostomies (Wijesinha and Steer, 1982). Postnatal and prolonged observations on defunctioned ileal segments in lambs have revealed even more strikingly a scarcity of immunocytes in the lamina propria. This result was explained by reduced local accumulation of B-cell blasts and might have involved both hampered migration of such precursors into the mucosa and subsequently their decreased local proliferation and differentiation (Reynolds and Morris, 1984).

Geographical variations have a striking impact on the mucosal immune system. In contrast to infants in Sweden, infants in a developing country that are exposed to poliovirus often show substantial levels of salivary SIgA antibodies to

poliovirus as early as 1 month after birth and generally approach adult antibody levels by the age of 6 months (Carlsson *et al.*, 1985). Infants heavily exposed to *E. coli* from birth on increase their salivary SIgA antibody levels significantly by 2–3 weeks of age and reach adult levels rapidly (Mellander *et al.*, 1985). In less-exposed infants, such levels are not attained until about 1 year of age, both for total SIgA and for SIgA antibodies to *E. coli* O antigens (Mellander *et al.*, 1984). However, Swedish infants show an indication of enhanced attainment of increased salivary SIgA antibody levels in relation to hospitalization compared with home care, which also often involves more regular breast feeding (Mellander *et al.*, 1984). A striking increase of salivary SIgA in Australian children starting school also has been ascribed to environmental impact, particularly of repeated respiratory tract infections (Gleeson *et al.*, 1987b).

**c. Alterations associated with SIDS.** The incidence of sudden infant death syndrome (SIDS) is correlated significantly with respiratory viral isolation in the general pediatric population and appears to be increased in cold weather (Milner and Ruggins, 1989). The finding of raised concentrations of IgM and IgA in bronchial lavage fluid, and an increased number of the three major immunocyte classes in interstitial lung tissue, therefore might reflect an intensified local immune response (Forsyth *et al.*, 1989). In keeping with this suggestion, we found significantly elevated numbers of all three major immunocyte classes in the parotid glands on an absolute basis in the order IgA>IgM>IgG (Thrane *et al.*, 1990). The idea of intensified local immunostimulation also was supported strongly by the fact that the parotid glands from the same SIDS victims showed significantly raised numbers of interstitial leukocytes and enhanced epithelial HLA Class II and SC expression (Thrane *et al.*, 1993).

### III. MUCOSAL PATHOLOGICAL STATES

Published data on the major Ig-producing immunocyte classes in diseased intestinal mucosae show striking discrepancies (Brandtzaeg and Baklien, 1976; Brandtzaeg *et al.*, 1992; Scott *et al.*, 1992). In addition to general methodological difficulties, as briefly discussed earlier, the selection of tissue samples poses a great problem in inflammatory bowel disease, which may show highly varying histopathological features even in the same specimen. Our immunohistochemical results have demonstrated a dramatic and predominant numerical increase of IgG immunocytes, both in ulcerative colitis and in Crohn's disease (Brandtzaeg *et al.*, 1992). Moreover, although the IgA-producing cells remain the overall dominating immunocyte class in the lesion, they are aberrant by showing an increased IgA1 subclass proportion (Kett and Brandtzaeg, 1987) and decreased J-chain expression (Brandtzaeg and Korsrud, 1984; Kett *et al.*, 1988). A significant difference between the mucosal immune response seen in Crohn's disease and ulcerative colitis is the relatively more prominent IgG1 production in the latter disorder (Scott *et al.*, 1986; Kett *et al.*, 1987).

Although much less dramatic, a disproportionate local overproduction of IgG is also a feature of other mucosal

inflammatory diseases such as chronic gastritis (Valnes *et al.*, 1986), celiac disease (Scott *et al.*, 1992), chronic rhinitis (Brandtzaeg, 1984), and chronic sialadenitis (Brandtzaeg, 1989). Local defense thus tends to be shifted from immune exclusion mediated by SIgA (and SIgM) to immune elimination through inflammatory and phagocytotic amplification mechanisms induced by IgG antibodies. This shift obviously may be of immunopathological importance for disease activity and persistence (Brandtzaeg *et al.*, 1989,1992).

#### IV. SELECTIVE IgA DEFICIENCY

##### A. "Compensatory" Terminal B-Cell Differentiation

The principal finding in gastrointestinal mucosa of subjects with markedly decreased or absent serum IgA is that the IgA-producing immunocytes are reduced in number or completely lacking, whereas IgG- and especially IgM-producing cells are increased substantially (Brandtzaeg *et al.*, 1968,1979; Savilahti, 1973). IgD- and IgE-producing cells are found rarely so the mucosal immunocyte population usually consists of 20–35% IgG and 65–75% IgM (Brandtzaeg *et al.*, 1979; Kanoh *et al.*, 1987; Nilssen *et al.*, 1992). However, the activity of the secretory immune system in IgA deficiency may be quite unpredictable on the basis of the serum level of IgA, although decreased intestinal IgA- to IgM-cell ratio appears to be a good indicator of a significant IgA deficiency after infancy. Thus, the intestinal IgA cell population is commonly intact when serum IgA concentrations are above 18% of the normal average whereas, at values between 18% and 5%, the number of jejunal IgA cells usually is decreased but that of IgM cells is increased (Savilahti, 1974).

Nevertheless, even patients presenting with a truly selective IgA deficiency (serum IgA < 0.05 g/liter) often have a few scattered IgA-producing cells in their intestinal mucosa (McClelland *et al.*, 1976; Scotta *et al.*, 1982); rare cases have indeed been reported to have fairly normal numbers of such immunocytes (Brandtzaeg *et al.*, 1981; Hong and Ammann, 1989; Savilahti and Pelkonen, 1979; Swanson *et al.*, 1968). However, in their jejunal mucosa, the IgM cell population always seems to be expanded aberrantly whereas such expansion is not necessarily seen in their large bowel mucosa (Brandtzaeg *et al.*, 1981; Savilahti and Pelkonen, 1979). IgA immunocytes (and apparently normal secretory immunity) in the gut also has been observed in a patient with severe combined immunodeficiency despite lack of lacrimal, salivary, and serum IgA (Rubinstein *et al.*, 1973). The persistent antigenic and mitogenic load on the intestinal mucosa probably explains these differences. Thus, terminal differentiation to IgA-producing cells takes place when peripheral blood lymphocytes from IgA-deficient patients are infected with Epstein-Barr virus (French and Dawkins, 1990) and sometimes also after mitogen treatment *in vitro* (Conley and Cooper, 1981; Hanson *et al.*, 1983).

As discussed earlier, a striking disparity exists between various exocrine sites in terms of IgD- and IgM-producing

cells (Figure 5). These differences are amplified remarkably in IgA-deficient subjects whose glandular tissues from the upper respiratory tract often (but not always) contain an abundance of IgD-producing cells (25–80%) whereas such immunocytes only occasionally amount to 5%, and usually remain below 1%, in the gastrointestinal mucosa (Brandtzaeg *et al.*, 1979,1987; Korsrud and Brandtzaeg, 1980; Kanoh *et al.*, 1987). The compensatory nasal immunocyte population in addition consists of 10–70% IgG cells but only 7–25% IgM cells (Brandtzaeg *et al.*, 1979;1987), whereas the latter immunocytes amount to 65–75% in the gastrointestinal mucosa of IgA-deficient subjects (Brandtzaeg *et al.*, 1979; Kanoh *et al.*, 1987; Nilssen *et al.*, 1992). Notably, compensation with IgD rather than IgM production in respiratory mucosa appears to be associated with reduced resistance to infections (Brandtzaeg *et al.*, 1987).

The IgG1 fraction of the compensatory IgG cell population generally is increased, particularly in the jejunal mucosa where, on average, it represents almost 90% (Nilssen *et al.*, 1992). Interesting in this context is the fact that IgA-deficient subjects often have increased serum levels of IgG1, including casein antibodies belonging to this subclass (Out *et al.*, 1986). In contrast to the normally preferential IgG2 antibody response to polysaccharides, moreover, adults with selective IgA deficiency often show enhanced IgG1 (and IgG3) responses to such antigens, apparently reflecting an immunological maturation delay similar to that seen in early childhood (Robertson *et al.*, 1989).

##### B. Replacement of J Chain-Positive Immunocytes

When IgA-producing cells appear at secretory sites in IgA deficiency, they show normal or excessive J-chain expression (Brandtzaeg *et al.*, 1979, 1981; Brandtzaeg and Korsrud, 1984). Interestingly, the expanded IgD cell population of the upper respiratory tract also retains its high level (95–100%) of J-chain positivity (Brandtzaeg *et al.*, 1979; Brandtzaeg and Korsrud, 1984), whereas this expression in IgG immunocytes of nasal (~50%) and jejunal (~70%) mucosa is often somewhat reduced compared with normal levels (Brandtzaeg and Korsrud, 1984; Nilssen *et al.*, 1992), perhaps as an effect of inflammatory changes. However, J-chain expression has been reported to be quite high (~90%) for IgG cells in normal rectal mucosa from IgA-deficient subjects (Kanoh *et al.*, 1987).

The total number of Ig-producing immunocytes per defined jejunal mucosal tissue unit (Figure 1) in subjects who completely lacked IgA cells was distributed within a range (40–227) that overlapped with values found for the total immunocyte numbers in normal controls (observed range 86–199) and in adults with treated celiac disease (observed range 144–335) (Brandtzaeg *et al.*, 1979; Nilssen *et al.*, 1992). Also, the total number of Ig-producing cells/mm<sup>2</sup> 6- $\mu$ m thick normal parotid tissue section from an IgA-deficient subject was within the range for normal parotid immunocyte populations (29 compared with 26–98). The immunocyte density (cell number/mm<sup>2</sup>) in the lacrimal gland of another IgA-deficient patient likewise was well within the normal range

(432 compared with 307–789). We did not attempt to obtain absolute figures for the nasal immunocyte populations because of the heterogeneous cell distribution within the nasal glands in individual cases, but the impression was that the total number of Ig-producing cells was fairly high in the IgA-deficient specimens compared with normal controls (Brandtzaeg *et al.*, 1987).

These results show that the migration of B cells to secretory sites and their compensatory terminal differentiation are fairly well maintained in IgA deficiency. The prominent J chain-expressing capacity exhibited by the local immunocytes, regardless of the concomitant Ig class produced, probably reflects the fact that these B cells belong to early memory clones whose terminal differentiation pathway to pIgA production has been blocked.

## V. SUMMARY

Exocrine tissues contain more than 80% of all Ig-producing cells. The major product of these gland-associated or mucosal immunocytes is pIgA with high affinity for SC expressed by secretory epithelial cells. The SC binding site of poly-IgA and pentameric IgM depends on incorporation of J chain into the polymer structure. The obvious biological significance of the striking J-chain expression shown by immunocytes in secretory tissues is that the locally produced Ig polymers become readily available for external transport through nearby SC-positive epithelium. This important functional goal in terms of clonal differentiation might be sufficient justification for the J chain to be expressed by B cells terminating locally with IgD or IgG production. These immunocytes are probably “spin-offs” from the differentiation process on its way to pIgA production, thus representing a B-cell maturation stage compatible with homing to exocrine tissues. Observations in IgA-deficient individuals suggest that the magnitude of this homing is fairly well maintained, even when the differentiation pathway to pIgA is blocked. Little is known about the immunoregulation underlying the striking disparity of both the class (IgD/IgM) and the subclass (IgA1/IgA2 and IgG2/IgG3) expression patterns shown by gland-associated immunocytes in various regions of the body, but the local microbiota might have a great impact. Whether an inherent disparity exists in immigrating B cells derived from different mucosal precursor sources such as the Peyer’s patches and tonsils remains to be shown.

# T Helper Cells for Mucosal Immune Responses

Hiroshi Kiyono · Jerry R. McGhee

## I. INTRODUCTION

The mucosal surfaces in humans are collectively larger than the size of a basketball court and, as such, require an enormous contribution from our immune system for their protection. The humoral immunity for mucosal sites is mediated largely by secretory IgA (SIgA) antibodies, which represent >80% of total Ig in external secretions and are produced as polymeric (usually dimeric) IgA by plasma cells in mucosal effector tissues (see Chapters 7, 11, 21). Most mucosal IgA is produced in the lamina propria of the gastrointestinal tract, where estimates of populations numbering  $\sim 1 \times 10^{10}$  plasma cells/m human intestine have been made (Brandtzaeg, 1989). In addition, the bone marrow is a major site for plasma cells that produce monomeric IgA found in serum IgA; these cells constitute the second most dominant isotype in the human circulation. In fact, estimates suggest that approximately two-thirds of the total Ig made in mammals are of the IgA isotype (Solomon, 1980; Conley and Delacroix, 1987). Important questions that arise from these data are: (1) how do we regulate the production of this enormous amount of IgA and (2) why is IgA preferentially produced in mucosal effector sites? As will become clear in this chapter, T cells are of central importance in regulating mucosal immunity, including IgA responses, and T helper (Th) cells constitute the largest cellular component of the mucosal immune system.

We have known for two decades that IgA responses are highly T cell dependent. This knowledge emerged from three separate lines of early work. The first line came from studies of athymic nude mice that were shown to have deficient levels of serum IgA as well as IgG1, IgG2a, and IgG2b whereas IgM levels were normal or even elevated (Crewther and Warner, 1972; Pritchard *et al.*, 1973). Thymic grafting of nude mice restored serum Ig, including IgA, to normal levels (Pritchard *et al.*, 1973). A subsequent study focusing on the serum and plasma cell IgA isotype clearly showed that serum IgA and intestinal IgA plasma cells were deficient in nude mice (Guy-Grand *et al.*, 1975). However, a second study disagreed somewhat with this result and suggested that depressed numbers of IgA plasma cells were found in the lung, parotid, and lactating mammary glands but normal levels were noted in the small intestine (Weisz-Carrington *et al.*, 1979). This discrepancy is most likely explained by age and environmental antigens that impinge on mucosal tissues since aged nude mice showed increases in IgG subclasses and IgA, correlating

with increased IgA and IgG plasma cell numbers in bone marrow (Piquet, 1980). Of interest was the finding that deficient numbers of IgA plasma cells also were seen in mucosal tissues of older nude mice, as in younger ones; this study was the first to show that serum IgA originates from bone marrow and not from mucosal sites (Piquet, 1980). These results also suggest that mucosal IgA responses are regulated more tightly by thymus-derived cells than are IgA responses in the bone marrow. A second line of work has shown that neonatal thymectomy results in depressed levels of IgA in serum and external secretions, as well as in diminished SIgA responses (Ebersole *et al.*, 1979; Clough *et al.*, 1971). The final line of evidence stems from studies of patients with immunodeficiencies. For example, patients with ataxia telangiectasia showed complex B and T cell abnormalities with resulting IgA deficiency (Waldmann *et al.*, 1983). Studies also have shown that T-cell abnormalities occur in IgA-deficient subjects (Waldmann *et al.*, 1976); however, this result has not been a universal finding and a deficiency in Th cells alone does not explain IgA deficiency.

To facilitate our discussion of Th cells in IgA responses, we reemphasize that the mucosal immune system can be divided into two separate but interconnected compartments. Mucosal inductive sites include the gut-associated and bronchus-associated lymphoreticular tissues (GALT and BALT) which are placed strategically in the gastrointestinal tract and the upper respiratory tract where they encounter environmental antigens. Several studies have shown that stimulation of Th and IgA precursor B cells in GALT with orally administered antigens leads to the dissemination of B and Th cells to mucosal effector tissues, such as the lamina propria of the gastrointestinal and upper respiratory tracts, and to secretory glands for subsequent antigen-specific SIgA responses (reviewed by McGhee *et al.*, 1989). These mucosal effector tissues have two broad characteristics: (1) they contain Th cells and B cells with enriched numbers of IgA plasma cells, and (2) they are covered by epithelial cells that produce the polymeric Ig receptor (SC) that transports pIgA into the external secretions. The induction of immune B and Th cells in GALT, followed by their exodus to effector sites for the development of mucosal immune responses, is often termed the common mucosal immune system (McGhee *et al.*, 1989; see also Chapters 12, 13, 19, 21, 35, 43). We place a major emphasis on the characteristics of Th cells in GALT and on their function in IgA plasma cell responses in mucosal ef-

factor tissues. However, T cells also have been shown to induce B cells to switch from IgM to IgA (and to IgG); this function also receives some attention in this chapter.

## II. Th CELLS IN MUCOSAL INDUCTIVE TISSUES

Reviewing certain basic features of Th cell activation and function before discussing Th cell studies in mucosal immune responses may be helpful to the reader. Activation of Th cells by antigen requires processing of the antigen and subsequent reexpression of specific peptide by antigen-presenting cells (APC) in GALT. The APCs in GALT include macrophages, B cells, and dendritic cells that are closely related to the Langerhans cells of skin (reviewed by McGhee *et al.*, 1989). The APCs in GALT process the antigen in endocytic compartments into peptide epitopes that become associated with major histocompatibility complex (MHC) Class II molecules. Th cells are CD3<sup>+</sup>  $\alpha\beta$  T-cell receptor (TcR)<sup>+</sup>, and most (but not all) are CD4<sup>+</sup>; the latter of these cells respond to peptide epitopes associated with MHC Class II in the membrane of the APCs (Marrack and Kappler, 1986; Bierer *et al.*, 1989). Th-APC contact occurs between the  $\alpha\beta$  TcR and the presented MHC Class II peptide epitope, forming a ternary complex that is reinforced by reaction of the CD4 molecule with a conserved Class II determinant (Bierer *et al.*, 1989). Other recognition systems also reinforce the Th-APC interaction (Kupfer and Singer, 1989) and contribute to Th-cell activation via the CD3 peptides (Clevers *et al.*, 1988).

Activated Th cells and their derived cytokines are sufficient to induce B cells to enter G<sub>1</sub> phase for completion of the cell cycle and division, as well as for induction of B cells to differentiate terminally into plasma cells. Interestingly, interleukin 4 (IL-4), IL-5, and IL-6, which are tandem products of Th2 cells (see subsequent text), are adept at inducing these three major steps. Nevertheless, the exact requirements for induction of B-cell entry into the cell cycle and subsequent division are not known; however, some studies

suggest that Th-B-cell contact is required (Owens, 1988), whereas others suggest that Th cell-derived cytokines (Leclercq *et al.*, 1986) such as IL-2, IL-4, IL-5, and IL-6 are sufficient to stimulate resting B cells and lead to plasma cell induction. As we will see in the discussion that follows, interactions of B cells with Th cells also induce activation of Th cells with subsequent cytokine production and cytokine receptor expression, especially in anamnestic responses in which Th cells have re-entered the quiescent stage (G<sub>0</sub> and G<sub>1</sub>) and memory B cells act as APCs for induction of Th cell re-entry into G<sub>1</sub>. The subsequent division of and cytokine production by these Th cells may trigger B cells to divide and differentiate into a clonal population of plasma cells. Speculating that the initial induction of Th cells by APCs occurs in GALT, for example, in the Peyer's patches, is tempting; however, memory B cells and Th cells (in G<sub>0</sub>) in mucosal effector sites such as the lamina propria of the small intestine may represent the major locale for Th-B-cell interactions resulting in the IgA response.

GALT consists of Peyer's patches, the appendix, and solitary lymphoid nodules, yet most studies, especially in mice, have been done with Peyer's patches (McGhee *et al.*, 1989). The parafollicular regions of Peyer's patches are enriched for T cells and are immediately adjacent to the follicles, or B-cell zones, containing the germinal centers. These T-cell areas possess high endothelial venules (HEV) that are the entry sites for lymphocytes to populate the Peyer's patches continuously. Further, the T-cell zones contain dendritic cells, an important type of APC in GALT for induction of Th cells (Spalding *et al.*, 1983, 1984). In GALT, 35–40% of mononuclear cells are CD3<sup>+</sup> T cells with a CD4:CD8 ratio of ~2:1 (Table I). The first definitive evidence for functional Th cells in murine Peyer's patches was provided by experiments in which the addition of Peyer's patch T cells to B-cell cultures (from nude mouse Peyer's patches) restored *in vitro* IgM antibody responses to a T cell-dependent antigen (Kagnoff and Campbell, 1974). Further, mice orally primed with heterologous erythrocytes were shown to contain Th cells that supported *in vitro* IgM responses to hapten erythrocyte carrier (Kagnoff, 1975).

**Table I** Characteristics of Murine T Cell Subsets in Mucosal Inductive and Effector Tissues

Mucosal tissues	Frequency of CD3 <sup>+</sup> T cells (%)	TcR expression (%)		Frequency of CD4 <sup>+</sup> T cells (%) <sup>a</sup>	Ratio of Th1:Th2	Ratio of CD4:CD8
		$\alpha\beta$	$\gamma\delta$			
<b>Inductive sites</b>						
Peyer's patches	25–35	>90	1–5	60–65	1:1	2:1
<b>Effector sites</b>						
Lamina propria (GI)	40–60	>95	1–5	55–60	1:2–3	2:1
Intraepithelium	80–90	35–45	45–65	5–10	1:1 <sup>b</sup>	1:7–8
Salivary glands	40–55	85–95	5–15	40–45	1:2	1:1

<sup>a</sup> Frequency of CD4<sup>+</sup> T cells in CD3<sup>+</sup> T cell fraction.

<sup>b</sup> In IELs, CD8<sup>+</sup> T cells were separated into IFN $\gamma$ -producing and IL-5-secreting T cells.

Direct evidence for T-cell regulation of IgA production came from a seminal comparative study with mitogen-activated T cells from Peyer's patches and spleen of mice. Concanavalin A (Con A)-stimulated Peyer's patch T cells selectively induced IgA synthesis in lipopolysaccharide (LPS)-triggered Peyer's patch or spleen B-cell cultures whereas identically treated spleen T cells suppressed IgA, IgG, and IgM production in these cultures (Elson *et al.*, 1979). This work implies that IgA isotype-specific T cells were present in higher frequencies in Peyer's patches and could explain why IgA responses are induced selectively in mucosal tissues. Additional support for this hypothesis was provided in antigen-specific systems in which oral administration of T cell-dependent antigens such as sheep erythrocytes (SRBC), whole bacteria, and soluble proteins induced Th-cell responses in Peyer's patches with resultant IgA responses in spleen and mucosal effector regions (Richman *et al.*, 1981; Kiyono *et al.*, 1983).

A major advance in this area has been the development of an enzymatic dissociation procedure that allows recovery of all lymphoreticular cell subsets from the Peyer's patches (Kiyono *et al.*, 1982b). Cultures from normal mice supported *in vitro* IgM anti-SRBC responses, whereas cells from Peyer's patches of orally immunized mice supported IgA anti-SRBC responses (Kiyono *et al.*, 1982b). Peyer's patch Th cells from the mice given SRBC by the oral route were shown to support IgM and IgA anti-SRBC responses when added to normal B-cell cultures (Kiyono *et al.*, 1982b). Note that this enzyme procedure allows recovery of MHC Class II<sup>+</sup> macrophages and dendritic cells (Spalding *et al.*, 1983; Kiyono *et al.*, 1982b) and that Peyer's patch dendritic cells could be induced to form large clusters with CD4<sup>+</sup> T cells in the presence of the oxidative mitogen sodium periodate (Spalding *et al.*, 1984). These Peyer's patch dendritic cell-CD4<sup>+</sup> T-cell clusters preferentially supported IgA synthesis in either Peyer's patch or spleen B-cell cultures (Spalding *et al.*, 1984).

### III. T CELL INDUCTION OF CLASS SWITCHING AND IgA PRODUCTION

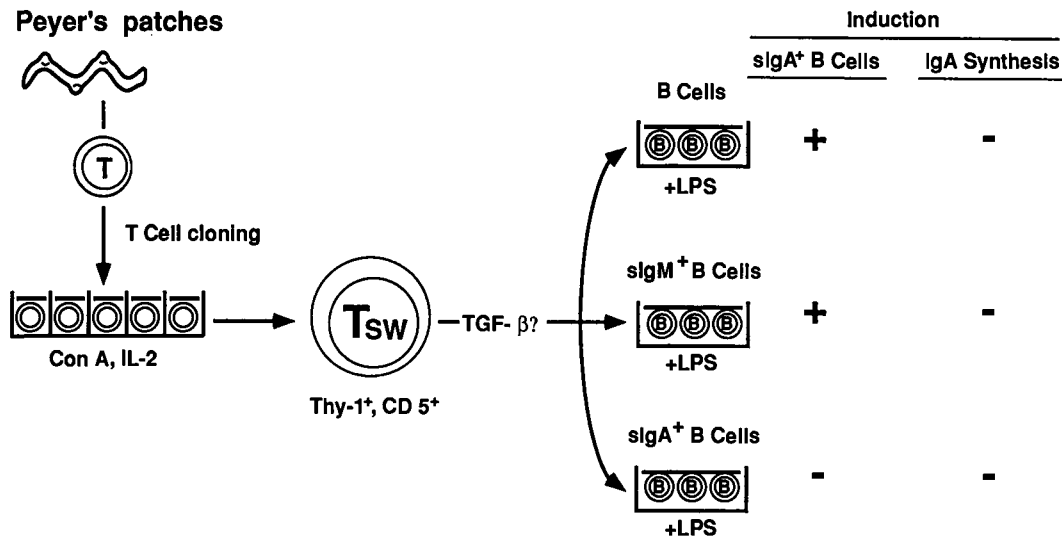

Two related developments have helped elucidate how Th cells function to induce and to direct B cells to develop into plasma cells, including those of the IgA isotype. The first was the development of procedures that allow cloning of antigen-specific Th cells and, more recently, analysis of subsets of Th cells that mediate different effector functions (see subsequent discussion). The second was the cloning of cytokines, including IL-1 through IL-13, interferon  $\gamma$  (IFN $\gamma$ ), tumor necrosis factor  $\alpha$  and  $\beta$  (TNF $\alpha$  and  $\beta$ ), transforming growth factor  $\beta$  (TGF $\beta$ ), and others, which has allowed us to determine their roles in the immune response. We will minimize our discussion of cytokines (see Chapter 20 for more details) and mention them only as necessary to understand the function of Th cells in IgA responses.

Two major types of CD4<sup>+</sup> T cells have been isolated and cloned from murine Peyer's patches and are separable based on the target B cell affected. These two types of T cells

should not be confused with the two Th cell subsets, Th1 and Th2, which are described in more detail in Section IV. One type of T-cell clone induced surface IgM positive (sIgM<sup>+</sup>) B cells to switch to sIgA expression (Kawanishi *et al.*, 1983a, 1985) whereas the second Th cell type preferentially supported antigen-specific IgA responses (Kiyono *et al.*, 1982a, 1984, 1985). The initial studies with T switch (T<sub>sw</sub>) cells used T-cell clones derived by mitogen stimulation and IL-2-supported outgrowth that, when added to sIgM<sup>+</sup>sIgA<sup>-</sup> B-cell cultures, resulted in marked increases in sIgA<sup>+</sup> cells (Kawanishi *et al.*, 1983a; Figure 1). Peyer's patch T<sub>sw</sub> cells did not induce IgA secretion, even when incubated with sIgA<sup>+</sup> B-cell enriched cultures; however, addition of B-cell growth and differentiation factors readily induced the latter cultures to secrete IgA (Kawanishi *et al.*, 1983b). Specificity studies indicated that T<sub>sw</sub> cells were autoreactive (Kawanishi *et al.*, 1985), suggesting that the microenvironment of the Peyer's patch was conducive to their induction.

Another population of isotype-specific Th-cell clones derived from Peyer's patches induced the proliferation and differentiation of sIgA<sup>+</sup> B cells into IgA-producing plasma cells (Kiyono *et al.*, 1982a, 1984; Figure 2). These Peyer's patch Th-cell clones were derived from Peyer's patches of mice fed SRBC (Kiyono *et al.*, 1982a); clones generally were divisible into two groups. One group supported IgM, low IgG, and IgA anti-SRBC responses whereas a second group preferentially supported IgA responses (Kiyono *et al.*, 1982a, 1984). These Peyer's patch Th-cell clones expressed Fc receptors for IgA (Fc $\alpha$ R; Kiyono *et al.*, 1982a). Hybridomas derived from them secreted IgA binding factors (Kiyono *et al.*, 1985), which helped explain their preferential induction of IgA responses. Further, another study has provided interesting new evidence that the expression of Fc $\alpha$ R is always associated with Th2 cells but not Th1 cells (see discussion of Th1 and Th2 cells; Sandor *et al.*, 1990). In this study, large numbers of Th1 and Th2 cell clones were examined for Fc $\alpha$ R expression. This receptor was expressed only on Th2 cell clones on stimulation via the TcR-CD3 complex (Sandor *et al.*, 1990). Finally, other investigators also have isolated Th cell clones specific for keyhole limpet hemocyanin (KLH) from mouse Peyer's patches; one of four clones supported antigen-specific IgA responses (Al Maghazachi and Phillips-Quagliata, 1988). Unfortunately, cytokine profiles of T<sub>sw</sub> cells or cloned Peyer's patch Th cells were not done, so no conclusions could be drawn about the role of cytokines in  $\mu \rightarrow \alpha$  switches or in preferential IgA responses. However, in conjunction with current knowledge of Th1 and Th2 cells, as well as their derived cytokines (see Section IV), one could postulate that T cells that are involved in isotype switching might be TGF $\beta$ -producing cells whereas Fc $\alpha$ R<sup>+</sup> Peyer's patch Th cells could be Th2 type cells that preferentially produce IL-5 and IL-6 on antigen stimulation (Figures 1 and 2).

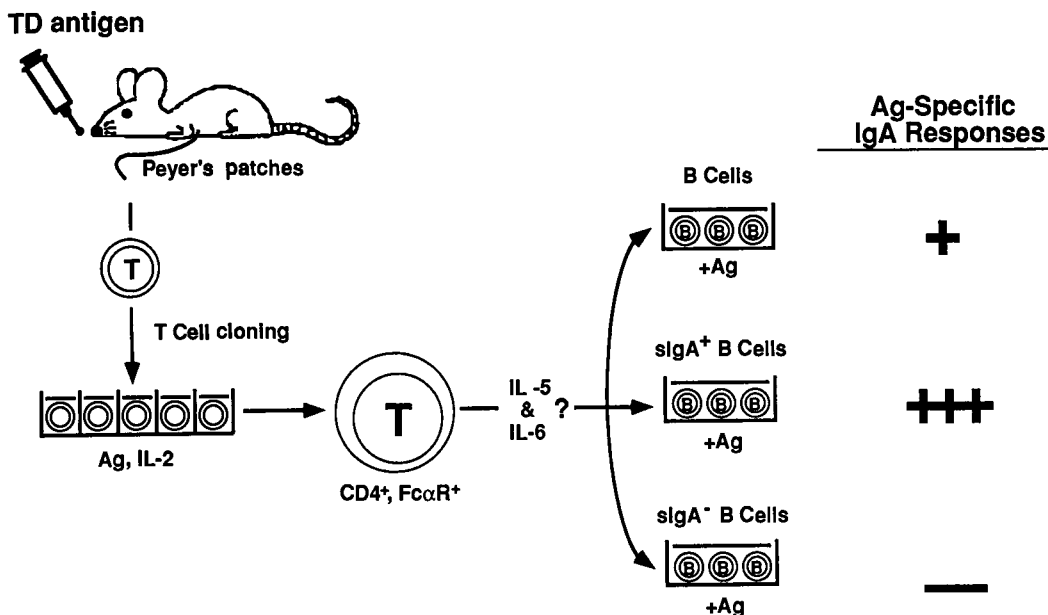

Evidence for T<sub>sw</sub> cells in human IgA responses also has been presented. Malignant T cells from a patient who suffered from a mycosis fungoides/Sézary-like syndrome (T<sub>Rac</sub> cells) induced tonsillar sIgM<sup>+</sup> B cells to switch to and secrete IgG and IgA (Mayer *et al.*, 1985). Further, T<sub>Rac</sub> cells, when added to B-cell cultures obtained from patients with hyper-IgM

**Figure 1** IgA inductive tissue (Peyer's patch) contains switch T cells that induce sIgM<sup>+</sup> B cells to become sIgA<sup>+</sup> B cells.

immunodeficiency, induced eight of nine cultures to secrete IgG and three of nine to produce IgA (Mayer *et al.*, 1986). T-cell clones also have been obtained from human appendix. These clones, or their derived culture supernatants, provided preferential help for IgA synthesis (Benson and Strober, 1988). Direct evidence was provided that CD3<sup>+</sup>CD4<sup>+</sup>CD8<sup>-</sup> T-cell clones induced  $\mu \rightarrow \alpha$  B-cell switches as well as the terminal differentiation of sIgA<sup>+</sup> B cells to IgA-producing plasma cells (Benson and Strober, 1988). Additional studies are needed to determine the mechanism(s) for the observed class switch and the possible contribution of cytokines to this process (see Chapter 20).

The dendritic cells in Peyer's patches, in association with T cells, also have been tested for their potential to induce B-cell and pre-B cell class switching (Spalding and Griffin, 1986). For example, dendritic cell-T cell mixtures from Peyer's patches were shown to induce pre-B cells to undergo  $\mu \rightarrow \alpha$  and some  $\mu \rightarrow \gamma$  class switches, and to develop into Ig-producing cells of IgA and, to a lesser extent, IgM and IgG isotypes (Spalding and Griffin, 1986). On the other hand, dendritic cell-T cell mixtures from spleen induced pre-B cells to mature and secrete IgM. Further support of a role for dendritic cells and T cells in switching and differentiation comes from experiments that showed that an IL-3-dependent

**Figure 2** The initial proof for IgA isotype-specific T helper cells that selectively interact with sIgA<sup>+</sup> B cells and support IgA responses.

pre-B cell line (LyD9) also could be induced to undergo class switching and maturation (Kinashi *et al.*, 1988). Coculture of LyD9 cells with bone marrow stromal cells or with dendritic cell-T cell mixtures induced *in vitro* maturation and secretion of IgM and IgG (Kinashi *et al.*, 1988). The dendritic cell-T cell mixtures were derived from spleen in this latter study, which may explain the non-IgA isotype profile seen (Kinashi *et al.*, 1988).

#### IV. ROLE OF Th1 AND Th2 CELLS IN MUCOSAL IMMUNE RESPONSES

A concept of two distinct Th subsets was generated initially based on functional criteria, using uncloned murine Th-cell populations. Th cells were divided into Th1 and Th2 cells according to the difference in their delivery of helper signals to B cells (Tada *et al.*, 1978; Swierkosz *et al.*, 1979; Melchers *et al.*, 1982). The classical Th cells were thought to require cognate interactions between T and B cells to provide helper effects for B cells, in which the former cells responded to carrier antigenic determinants while the latter cells recognized the hapten molecule. This type of Th cell was designated Th1 (Tada *et al.*, 1978; Swierkosz *et al.*, 1979; Melchers *et al.*, 1982; Kim *et al.*, 1985). In contrast to Th1 cells, the other subset of Th cells, known as Th2, did not require a cognate interaction for their helper function, but provided an enhancing signal in a noncognate fashion (Tada *et al.*, 1978; Swierkosz *et al.*, 1979; Melchers *et al.*, 1982; Kim *et al.*, 1985). Th2 type cells also were suggested not to require MHC restriction for their helper activity. Most investigators now agree that Th cells, the majority of which are CD4<sup>+</sup>, recognize antigen peptide presented by MHC Class II, which is sufficient to induce their activation. Thus, the Th1 and Th2 distinction based on the cognate interaction is less apparent. Further, using the Th1 and Th2 designations in the context described here is more useful.

In early 1986, a completely new concept for Th1 and Th2 cell function was introduced by the analysis of a wide variety of murine Th-cell clones for their profiles of cytokine synthesis (Mosmann *et al.*, 1986). In the original study, a total of 22 different murine Th-cell clones was examined for IL-2, IFN $\gamma$ , and IL-4 production; approximately half the Th-cell clones produced only IL-2 and IFN $\gamma$  whereas the other half preferentially secreted IL-4 (Mosmann *et al.*, 1986). Using additional cytokine-specific bioassay and mRNA analysis, a distinct pattern of cytokine production by murine Th1 and Th2 cells was established (Coffman *et al.*, 1988; Mosmann and Coffman, 1989; Mosmann and Moore, 1991; Street and Mosmann, 1991). Th1 cells were capable of producing IL-2, IFN $\gamma$ , and TNF $\beta$  (lymphotoxin) whereas Th2 cells did not produce these cytokines (Table II). On the contrary, Th2 cells exclusively secreted IL-4, IL-5, and IL-6 (and, as later shown IL-10) on antigen or mitogen stimulation (Table II). To date, no specific cell surface molecules that differentiate between Th1 and Th2 cells have been identified. Note that Th1 and Th2 cells can cross-regulate each other via these respective cytokines (Mosmann and Coffman, 1989; Mos-

**Table II** Th1 and Th2 Cells for the Regulation of IgA Responses

Th subsets	Cytokine produced	Key effect on IgA responses
Th1	IL-2	Augments IgA synthesis; synergizes with IL-5 and TGF- $\beta$ for enhanced IgA synthesis
	IFN $\gamma$	Down-regulate Th1 cells
	TNF $\beta$ (LT)	None (? Needs investigation)
	TGF $\beta$ (?)	Induces IgA isotype switching
Th2	IL-4	May be involved IgA isotype switching; may augment IL-5 induced IgA synthesis
	IL-5	Induce differentiation of sIgA <sup>+</sup> B cells to plasma cells; synergizes with TGF- $\beta$ to enhance IgA production
	IL-6	Induces maximum IgA synthesis; acts on sIgA <sup>+</sup> B cells and induces IgA secreting plasma cells
	IL-10	Down-regulates Th1 cells

mann and Moore, 1991; Street and Mosmann, 1991). IL-2 and IL-4 produced by Th1 and Th2 cells, respectively, are important cytokines for the growth of both types of T cells. IFN $\gamma$ , a product of Th1 cells, down-regulates Th2 cell function whereas IL-10, secreted by Th2 cells, inhibits Th1 cells (Mosmann and Moore, 1991; Street and Mosmann, 1991).

The function of Th1 and Th2 cells for B-cell responses has been studied in some detail. Although helper activity can be provided to B cells by both Th-cell subsets, Th2 cells seem to be much more effective (Coffman *et al.*, 1988; Mosmann and Coffman, 1989). This difference could be the result of the profile of cytokines secreted by Th1 and Th2 cells. For example, high doses of IFN $\gamma$  are immunosuppressive and cause inhibition of B-cell responses (Reynolds *et al.*, 1987; Mosmann and Coffman, 1989). Further, Th1 cells have been shown to kill B cells, directly, probably by production of lymphotoxin and IFN $\gamma$  (Janeway *et al.*, 1988). Since these two molecules are powerful cytokines for the elimination of intracellularly infected host cells via activation of macrophages and direct cytolytic activity, Th1 cells are perhaps better capable of helping host defenses against intracellular parasites (Mosmann and Coffman, 1989; Mosmann and Moore, 1991; Street and Mosmann, 1991). In addition, Th1 cells have been shown to be involved in the regulation of a Jones-Mote type delayed-type hypersensitivity (DTH) reaction, since co-injection of a Th1 clone and antigen into the footpads of virgin mice led to the induction of antigen-specific and MHC-restricted inflammation (Cher and Mosmann, 1987) whereas Th2 cells did not cause development of any inflammation.

In contrast to Th1 cells and their derived cytokines, cytokines produced by Th2 cells, including IL-4, IL-5, and IL-6, are potent soluble factors for the activation, proliferation, growth, and differentiation of B cells (see more details in Chapter 20). In this regard, Th2-cell clones have been shown to induce growth and differentiation of the majority of B cells

in limiting dilution cultures (Lebman and Coffman, 1988). Th2 cells and their secreted cytokines can regulate both resting and large (activated) B-cell populations. In the most cases, resting B cells require direct cell contact with Th2 cells for their activation, growth, and differentiation (Rasmussen *et al.*, 1988). On the other hand, large B cells can proliferate and differentiate in response to culture supernatants from Th2 cells without any physical Th-B-cell linkage (Herron *et al.*, 1988).

Another unique feature of Th1 and Th2 cells is that individual subsets of Th cells can potentiate certain isotypes of B-cell responses because of their secreted cytokines. For example, Th1 cells preferentially support IgG2a synthesis in B-cell cultures (Coffman *et al.*, 1988; Mosmann and Coffman, 1989). IFN $\gamma$ , a product of Th1 cells, has been shown to be involved in IgG2a isotype switching and to enhance IgG2a synthesis in LPS-stimulated B-cell cultures (Coffman *et al.*, 1988; Snapper *et al.*, 1988). Since IgG2a is a complement-fixing cytotoxic antibody and possesses a high-affinity Fc $\gamma$ R on macrophages, this interaction further supports the view that Th1 cells and their secreted cytokines (e.g., IFN $\gamma$ ) are important in host defense against intracellularly infected cells and in DTH responses. Th2 cells, in contrast, support more IgG1, IgE, and IgA responses than Th1 cells (Coffman *et al.*, 1988; Mosmann and Coffman, 1989). Th2-derived IL-4 enhances IgG1 secretion in LPS-triggered B-cell culture via an increase in isotype switching of sIgG<sup>-</sup> B cells to sIgG1<sup>+</sup> B cells (reviewed by Paul, 1987). However, Th1 cells also can support IgG1 responses (Coffman *et al.*, 1988). Thus, the IgG1 response can be induced in an IL-4-independent manner as well. Several lines of evidence, both *in vivo* and *in vitro*, strongly demonstrated that IL-4 produced by Th2 cells is important for the induction of IgE synthesis (Paul, 1987; Lebman and Coffman, 1988; Finkelman *et al.*, 1990). IL-4 acts directly on sIgM<sup>+</sup> B cells and induces them to switch to sIgE<sup>+</sup> B cells (Paul, 1987; Lebman and Coffman, 1988). Interestingly, anti-IL-4 or IFN $\gamma$  treatment shuts down IgE responses both *in vivo* and *in vitro* (Coffman and Carty, 1986; Finkelman *et al.*, 1990). Thus, one can suggest that cross-regulation of Th1 and Th2 cells is important in isotype-specific responses in which IgE responses are Th2 and IL-4 dependent whereas IFN $\gamma$  produced by Th1 cells down-regulates IL-4-induced IgE responses. Although Ig genes encoding  $\epsilon$  and  $\alpha$  chains are clustered closely in the 3' region, IgE responses rarely are seen at normal mucosa. Since relatively high numbers of cytokine-producing Th1 and Th2 cells can be isolated from both IgA inductive and effector sites (Taguchi *et al.*, 1990; Mega *et al.*, 1992), IFN $\gamma$  produced by Th1 cells may suppress IL-4 production by Th2 cells specifically, whereas the production of other Th2 cytokines (e.g., IL-5 and IL-6) that are essential for IgA synthesis may be maintained.

For IgA responses, clearly Th2 cells regulate the terminal differentiation of sIgA<sup>+</sup> B cells to IgA-secreting plasma cells, since the addition of IL-5 or IL-6 to cultures containing either LPS-stimulated splenic B cells or freshly isolated Peyer's patch B cells resulted in the preferential induction of IgA synthesis (see Chapter 20). Th2-like autoreactive Th-cell clones generated from murine Peyer's patches originally were

reported to enhance IgA synthesis in LPS-triggered B-cell cultures (Murray *et al.*, 1987). Also, culture supernatants from Th2-cell clones independently were shown to augment IgA production under similar B-cell culture conditions (Coffman *et al.*, 1987). However, when culture supernatants from Th1 clones were tested for IgA-enhancing factor, none of the Th1-cell clone-derived culture supernatants supported IgA responses in LPS-treated B-cell cultures. These findings led to the purification of IgA-enhancing factor; a partial sequence containing 21 amino acids from this factor exactly matched murine IL-5 (Bond *et al.*, 1987). In addition, numerous studies have examined further the molecular aspects of Th2-cell involvement in IgA responses. Researchers now generally accept that Th2-derived IL-5 and IL-6 are essential cytokines for the development of IgA plasma cells (see Chapter 20). However, concluding that only Th2 cells and their secreted IL-5 and IL-6 are important in the regulation of sIgA<sup>+</sup> B cell responses would be too simplistic since IL-2, a product of stimulated Th1 cells, has been shown to enhance IgA synthesis in LPS-stimulated B-cell cultures (Coffman *et al.*, 1987). However, the magnitude of IgA enhancement by IL-2 was lower than that of Th2-cell derived cytokines (Coffman *et al.*, 1987). Further, IL-2 synergistically augmented IgA synthesis in TGF $\beta$ -treated B-cell cultures in the presence of LPS (Lebman *et al.*, 1990). Therefore, one must emphasize that, although Th2 cells tend to play a major role in the differentiation of sIgA<sup>+</sup> B cells to IgA plasma cells, Th1 cells and their cytokines certainly can influence IgA B-cell responses. Thus, an optimal relationship between Th1 and Th2 cells via their respective cytokines is probably essential for the maintenance of appropriate IgA responses in mucosal associated tissues.

To date, most Th1 and Th2 cell studies have been done with cloned T cells. Their natural existence *in vivo* has not been demonstrated directly. However, studies using IFN $\gamma$ - and IL-5-specific ELISPOT assays and mRNA analysis have revealed that these Th1 and Th2 cells exist *in situ* in both IgA inductive and effector sites (Taguchi *et al.*, 1990; Mega *et al.*, 1992). When freshly isolated CD3<sup>+</sup>CD4<sup>+</sup>CD8<sup>-</sup> T cells from Peyer's patches and lamina propria of intestine were examined for IFN $\gamma$ -producing Th1 and IL-5-secreting Th2 cells, a distinct pattern of Th1 and Th2 cell distribution was seen (Taguchi *et al.*, 1990). Higher numbers of CD4<sup>+</sup> T cells, which were producing IFN $\gamma$  or IL-5 spontaneously, were always noted in IgA effector tissues compared with IgA inductive sites. In the case of the latter tissue, approximately equal frequencies of IFN $\gamma$  (Th1)- and IL-5 (Th2)-producing cells were found (Taguchi *et al.*, 1990). Upon T-cell stimulation via the TcR-CD3 complex or lectin receptor, increased numbers of cytokine-producing T cells were evident in both Th1 (IFN $\gamma$ ) and Th2 (IL-5) cell subsets (Taguchi *et al.*, 1990; Xu-Amano *et al.*, 1992). Therefore, an equal appearance of Th1 and Th2 cells in Peyer's patches may represent an appropriate cross-regulation of these two subsets of Th cells that may contribute to the suppression of the sIgA<sup>+</sup> B-cell differentiation step. Although Peyer's patches contain significant numbers of sIgA<sup>+</sup> B cells, very few IgA plasma cells actually occur in this tissue. In a separate study, using IL-2 and IL-4 as indicators of Th1 and Th2 cells, respectively, Peyer's

patches and mesenteric lymph nodes that receive draining lymphocytes from Peyer's patches were suggested to possess both Th1 and Th2 cells (Daynes *et al.*, 1990). Note that cultivation of Peyer's patch T cells with anti-CD3 antibody resulted in the predominant production of IL-4, suggesting that a preferential induction of Th2 cells occurs in IgA inductive sites on stimulation. Collectively, these findings indicated that CD4<sup>+</sup> Th cells, which have the potential to become either Th1 or Th2 cells, reside in the IgA inductive sites.

For the induction of Th1 and Th2 responses to antigen-specific IgA responses, one study has provided an important finding that oral administration of T cell-dependent antigen (e.g., SRBC) induced a higher frequency of Th2 (IL-5) cells than of Th1 (IFN $\gamma$ ) cells in T-cell cultures prepared from Peyer's patches and spleen (Xu-Amano *et al.*, 1992). Further, high levels of IL-5-specific mRNA was noted in CD4<sup>+</sup> T cells from Peyer's patch T-cell cultures of orally immunized mice. Thus, oral administration of T cell-dependent antigen preferentially induces antigen-specific Th2 cells in IgA inductive sites (Xu-Amano *et al.*, 1992). These antigen-stimulated Th2 cells may leave Peyer's patches and migrate into the IgA effector sites, such as lamina propria of intestine and exocrine glandular tissues, where these cells can provide the necessary cytokines (e.g., IL-5 and IL-6) for sIgA<sup>+</sup> B cells to become IgA-secreting plasma cells. In this regard, a higher frequency of Th2 (IL-5) cells than IFN $\gamma$ -producing Th1 cells was seen in IgA effector sites (Taguchi *et al.*, 1990; Mega *et al.*, 1992; see Section V).

Several studies have provided strong evidence that human Th cells also can be separated into Th1 and Th2 cells according to their cytokine profile (reviewed by Romagnani, 1991). *Mycobacterium tuberculosis*-specific CD4<sup>+</sup> Th-cell clones generated from healthy donors were categorized as Th1 type cells, since these clones produced IFN $\gamma$  and IL-2 (Del Prete *et al.*, 1991). On the other hand, *Toxocara canis*-specific CD4<sup>+</sup> Th-cell clones secreted Th2 cytokines, including IL-4 and IL-5. In addition, allergen-specific CD4<sup>+</sup> Th-cell clones from atopic disease patients were preferentially grouped as Th2 cells (Parronchi *et al.*, 1991). Therefore, clearly Th1 and Th2 cells exist in both murine and human systems. The cross-regulation of Th1 and Th2 cells via respective cytokines thus can influence the outcome of isotype-specific responses. Further, the nature of antigen and its

presentation to Th cells will affect the induction of Th1 and Th2 cells. Since both IgA inductive and effector sites possess several immunologically unique features and are exposed continuously to a wide variety of environmental antigens, considering CD4<sup>+</sup> Th cells in mucosal associated tissues to have novel interaction pathways between Th1 and Th2 cells to regulate mucosal IgA immune responses is logical (Figure 3).

## V. Th CELLS IN MUCOSAL EFFECTOR TISSUES

Antigen uptake via M cells or follicle-associated epithelial (FAE) cells into mucosal associated lymphoreticular tissues (including GALT and BALT) results in antigen stimulation of B and T lymphocytes that leave IgA inductive tissues via the efferent lymphatics. These lymphocytes then home to the effector sites, including the lamina propria of the upper respiratory and gastrointestinal tracts, the reproductive tract, and exocrine glandular tissues through the common mucosal immune pathway.

The lamina propria of the gastrointestinal tract has been characterized as an example of a major mucosal effector site (reviewed by Brandtzaeg, 1984; Brandtzaeg *et al.*, 1985). Note that, in contrast to IgA inductive sites, major studies for the characterization of lamina propria T cells have been done in the human system. The intestinal lamina propria contains primarily B cells (including plasma cells), T cells, and macrophages. In addition, mucosal inflammatory cells such as eosinophils and mast cells are also present in lamina propria. Among B-lineage cells, which represent 20–40% of lamina propria cells, approximately 80% of the plasma cells in the small intestine produce antibodies of the IgA isotype (Brandtzaeg, 1984; Brandtzaeg *et al.*, 1985), as reflected by an abundant production of IgA in external secretions of mucosal effector tissues. Substantial numbers of T cells are also present in this tissue; approximately 50% of lamina propria lymphocytes are CD3<sup>+</sup> T cells (Brandtzaeg, 1984; Brandtzaeg *et al.*, 1985; Mega *et al.*, 1992; Table 1). The majority of CD3<sup>+</sup> T cells is CD4<sup>+</sup>CD8<sup>-</sup> (~40–60% of CD3<sup>+</sup> T cells) and the ratio of CD4 to CD8 is ~2–3:1 (Brandtzaeg, 1984;

**Figure 3** Current concepts for T cell and cytokine regulation of IgA responses in IgA inductive (*left*) and effector (*right*) sites.

Brandtzaeg *et al.*, 1985; Mega *et al.*, 1992). These CD4<sup>+</sup> T cells have been shown to exert helper effects on Ig secretion, including the IgA isotype in B-cell cultures prepared from the lamina propria and the peripheral blood (Clancy *et al.*, 1984; Elson *et al.*, 1985). In addition, when CD4<sup>+</sup> T cells isolated from human mesenteric lymph nodes, a population of T lymphocytes that is presumably on its way to lamina propria regions, were cultured with B cells, elevated IgA secretion compared with IgG and IgM was noted (Pang *et al.*, 1986). This helper function for the IgA isotype was higher with mesenteric lymph node CD4<sup>+</sup> T cells than with peripheral blood CD4<sup>+</sup> T cells. These findings provide evidence that CD4<sup>+</sup> T cells in IgA effector tissues such as intestinal lamina propria can provide helper functions for IgA B cell responses.

The CD4<sup>+</sup> Th cells in intestinal lamina propria can be separated further into helper-inducer (Leu 8<sup>-</sup> and 2H4<sup>-</sup>) and suppressor-inducer (Leu 8<sup>+</sup> and 2H4<sup>+</sup>) phenotypes based on their immunological function as well as Leu 8 and 2H4 expression (James *et al.*, 1986; Kanof *et al.*, 1988). Lamina propria CD4<sup>+</sup> Th cells possessed higher numbers of cells with a phenotype associated with helper-inducers and a corresponding decrease in the proportion of suppressor-inducer type CD4<sup>+</sup> T cells compared with their systemic counterparts (e.g., peripheral blood; James *et al.*, 1986). CD4<sup>+</sup> T cells that coexpress Leu 8 suppress Ig synthesis. On the other hand, Leu 8<sup>-</sup> and CD4<sup>+</sup> T cells isolated from lamina propria support both IgA and IgG synthesis in pokeweed mitogen (PWM)-stimulated peripheral blood B-cell cultures (Kanof *et al.*, 1988). In another study, the possible existence of preactivated IgA isotype-specific Th cells in normal human lamina propria was suggested (Smart *et al.*, 1988). When the T cell-enriched fraction from the human colonic mucosa, which contained a 3:1 ratio of CD4:CD8, was tested for enhancing function, maximum enhancing activity was seen for the IgA isotype with increasing numbers of T cells. Further, cocultivation with PWM in this system had no significant effect on IgA synthesis, suggesting that lamina propria Th cells were activated *in situ* (Smart *et al.*, 1988). Further, normal lamina propria T cells were shown to possess higher gene expression associated with cell activation compared with T cells in systemic tissues (Zeitz *et al.*, 1988). CD4<sup>+</sup> T cells isolated from normal nonhuman primates had high percentages of IL-2 receptor (IL-2R)-positive cells that contained increased mRNA levels for this receptor. Collectively, these findings indicate that intestinal lamina propria contains significant numbers of activated CD4<sup>+</sup> Th cells that are capable of providing helper signals for the enhancement of IgA responses.

Since the concomitant appearance of activated CD4<sup>+</sup> Th cells and high numbers of IgA plasma cells are always seen in IgA effector sites such as the intestinal lamina propria, an interesting possibility was raised that Th2 cells may occur in high frequency in these tissues (Taguchi *et al.*, 1990). When CD4<sup>+</sup> T cells were isolated from normal murine lamina propria and tested for IFN $\gamma$ -producing Th1 and IL-5-secreting Th2 cells by respective cytokine-specific ELISPOT assays, although significant numbers of Th1 cells were seen in lamina propria, the frequency of Th2 cells was always higher (Th1:Th2 = 1:3). Thus, greater numbers of IL-5-producing

Th2 cells were present in IgA effector sites at which Th cells were activated *in vivo* in response to environmental antigens (Taguchi *et al.*, 1990). Further, Northern blot analysis of mRNA from lamina propria T cells of normal nonhuman primates revealed that higher message levels for IL-4 and IL-5 were seen compared with T-cell fractions from systemic tissues, including peripheral lymph nodes and spleen (James *et al.*, 1990). In addition to the Th2 cytokines, mRNA levels for IL-2 and IFN $\gamma$  (Th1 cytokines) also were increased in lamina propria T cells (James *et al.*, 1990). Based on these observations, one can envision that higher numbers of Th2 cells than Th1 cells reside in lamina propria; however, both subsets of CD4<sup>+</sup> Th cells are activated and are producing their respective cytokines for the regulation of the IgA response.

The occurrence of activated CD4<sup>+</sup> Th cells with a higher frequency of Th2 cells at IgA effector sites seems to provide an appropriate environment for IgA B-cell responses. However, one must always remember that Th2 cells also play an important role in classical allergic responses in which IgE synthesis and the numbers of eosinophils and mast cells are increased. The intestinal mucosa has a significant number of mast cell precursors that is higher than elsewhere in the body (Crapper and Schrader, 1983). Thus, IL-3 produced by both Th1 and Th2 cells in intestinal lamina propria could induce these precursors to become mature mast cells. CD4<sup>+</sup> T cells isolated from mesenteric lymph nodes of *Nippostrongylus brasiliensis*-infected rats were shown to produce IL-3, which can induce mucosal mast cells from bone marrow cultures (McMenamin *et al.*, 1985). In other studies, CD4<sup>+</sup> Th cells from the thoracic duct of *Trichinella spiralis*-infected rats were separated into two subsets according to OX22 expression (Wang *et al.*, 1990). When OX22<sup>+</sup> CD4<sup>+</sup> Th cells were transferred adoptively to naive rats and then challenged with *T. spiralis*, this subset of CD4<sup>+</sup> Th cells substantially enhanced the number of mucosal mast cells. In contrast, OX22<sup>-</sup>CD4<sup>+</sup> Th cells increased the number of resident eosinophils in the intestine (Wang *et al.*, 1990). Further, this latter CD4<sup>+</sup> Th-cell subset provided helper activity for B cells and conferred protection against *T. spiralis*. Thus, the models of mucosal regulation by CD4<sup>+</sup> Th1 and Th2 cells are complex. One must always envision the importance of CD4<sup>+</sup> Th cells in regulation of mucosal associated responses other than the IgA B-cell responses.

In addition to lamina propria T cells, large numbers of T cells also are found in the intraepithelial compartment of the intestine. Intraepithelial lymphocytes (IELs) possess several unique features in terms of their TcR expression, T-cell subsets, and immunological functions (see Chapter 24). One of the novel characteristics of murine IELs is that IEL preparations contain CD8<sup>+</sup> T cells that produce Th1 and Th2 cytokines spontaneously (Taguchi *et al.*, 1990, 1991). Approximately equal numbers of IFN $\gamma$ - and IL-5-secreting CD8<sup>+</sup> T cells that express either TcR  $\alpha\beta$  or TcR  $\gamma\delta$  were seen in isolated IELs (Taguchi *et al.*, 1991). The immunological role of these cytokine-producing TcR  $\alpha\beta$ <sup>+</sup> and TcR  $\gamma\delta$ <sup>+</sup> CD8<sup>+</sup> T-cell subsets in mucosal immune responses remains to be elucidated. In addition to their cytokine production capability, most studies have provided evidence that a distinct subset

of IEL T cells can provide an immunoregulatory function for IgA responses (Fujihashi *et al.*, 1990,1992). When TcR  $\gamma\delta^+$  T cells from IELs of mice orally immunized with T cell-dependent antigen were transferred adoptively to mice orally tolerized with the same antigen, the oral tolerance was converted to antigen-specific immune responses including those of the IgA isotype (Fujihashi *et al.*, 1990,1992). On the other hand, TcR  $\alpha\beta^+$  T cells from IELs of the same mice provided helper function for IgA responses (Fujihashi *et al.*, 1992). Thus, subsets of IEL T cells also could be important in regulating the IgA response, that is, TcR  $\gamma\delta^+$  Th cells could provide protection or augmentation of TcR  $\alpha\beta^+$  Th cells in the presence of oral tolerance to maintain appropriate IgA responses at the mucosal barrier.

In addition to the lamina propria regions of the gastrointestinal tract, another important IgA effector site is represented by exocrine glandular tissues. In this regard, saliva has been extensively used as a convenient secretion to analyze induction of antigen-specific sIgA responses. Further, salivary glands contain high numbers of IgA-producing cells (Mega *et al.*, 1992; see Chapter 15). The lymphocytes from murine submandibular glands contain approximately 40–55% CD3<sup>+</sup> T cells with a CD4:CD8 ratio of 1.0 (Mega *et al.*, 1992) (Table I). A similar finding also was observed in rats, in which the lymphocytes were shown to contain approximately 60% W3/13<sup>+</sup> T cells with a CD4:CD8 ratio of 1.3 (Pappo *et al.*, 1988). When the frequency of Th1 and Th2 cells was examined in CD4<sup>+</sup> T cells isolated from murine salivary glands, IL-5-producing Th2 cells were always more abundant than IFN $\gamma$ -secreting Th1 cells (Mega *et al.*, 1992). This finding was in complete agreement with other studies in which the intestinal lamina propria region was shown to contain cytokine-producing CD4<sup>+</sup> Th cells with a preference for Th2 cells (Taguchi *et al.*, 1990).

## VI. SUMMARY: OVERVIEW OF Th CELL REGULATION OF MUCOSAL IMMUNE RESPONSES

IgA inductive tissues (e.g., GALT or Peyer's patches) and IgA effector sites such as intestinal lamina propria and salivary glands contain several distinct T-cell subsets that possess unique biological characteristics for the induction and regulation of IgA immune responses. In GALT, two major subsets of T cells are present that are capable of regulating IgA isotype switching and terminal differentiation of post-switched sIgA<sup>+</sup> B cells to become IgA plasma cells (Figures 1 and 2). The T<sub>sw</sub> cells act on sIgM<sup>+</sup> B cells in Peyer's patches and induce them to switch sIgA<sup>+</sup> B cells. Whether T<sub>sw</sub> cells produce TGF $\beta$  for the induction of IgA isotype switching still is not known. Further, testing whether T<sub>sw</sub> cells can be categorized into a family of Th1 or Th2 cells is important. The other subset of T cells is composed of helper T cells that possess the capability to interact preferentially with sIgA<sup>+</sup> B cells and induce them to become IgA-secreting plasma cells. This type of Th cell tends to fall in the category of Th2 cells, which can produce IL-5 and IL-6 for the differentiation

of sIgA<sup>+</sup> B cells to high IgA-secreting plasma cells (Figures 2 and 3). The exact immunological mechanism for this selective interaction between Th2 cells and sIgA<sup>+</sup> B cells remains to be elucidated.

GALT has been shown to contain CD4<sup>+</sup> Th cells that can become either Th1 or Th2 cells. Both Th1 and Th2 cells are essential for the regulation of IgA B-cell responses since IL-2 and IL-5 and IL-6 (and perhaps others) produced by Th1 and Th2 cells, respectively, are important cytokines for the enhancement of IgA responses. Oral administration of T cell-dependent antigens induces antigen-specific Th1 and Th2 cells, with preferential induction of IL-5-producing Th2 cells. Thus, stimulation of Th cells and IgA precursor B cells in GALT via the oral route is an important consideration for the induction of appropriate antigen-specific IgA responses in distant mucosal effector sites.

In IgA effector sites, CD4<sup>+</sup> Th cells that can augment IgA B-cell responses are present in intestinal lamina propria. As one might expect, because of the unique immunological and physiological characteristics of the gut in which lymphocytes are exposed continuously to environmental antigens, CD4<sup>+</sup> Th cells are activated *in situ* and produce immunoregulatory cytokines. IFN $\gamma$ - and IL-2-producing Th1 and IL-5- and IL-6-secreting Th2 CD4<sup>+</sup> Th cells are found in this tissue. The ratio of Th1 to Th2 cells is approximately 1:2–3, which provides an appropriate environment for sIgA<sup>+</sup> B cells to become IgA plasma cells since Th2 cells secrete essential cytokines (IL-5 and IL-6) for these B cells. A similar situation also occurs in other IgA effector tissues such as the salivary glands, a major IgA source for the oral cavity. The salivary glands contain cytokine-producing CD4<sup>+</sup> Th cells with a high frequency of Th2 cells. Note that Th1 and Th2 cells are important in the induction and regulation of IgA responses because of cross-regulation of Th1 and Th2 cells via respective cytokines. Further, cytokines (e.g., IL-2, IL-5, and IL-6) produced by these two subsets of CD4<sup>+</sup> T cells are essential for mucosal IgA immune responses. In addition to these CD4<sup>+</sup> Th cells that reside in IgA effector tissue (e.g., intestinal lamina propria), T cells reside in the epithelium itself (IELs) and also can be important regulatory cells for mucosal IgA responses.

Clearly T cells, especially CD4<sup>+</sup> Th cells, are an essential element in the induction and maintenance of appropriate IgA responses in mucosal associated tissues. This view has been demonstrated convincingly *in vivo*. Chronic treatment of mice with monoclonal anti-CD4 antibody dramatically reduced the numbers of IgA plasma cells in intestinal lamina propria (Mega *et al.*, 1991). In addition to IgA effector sites, IgA inductive sites such as the Peyer's patches also are affected by chronic CD4<sup>+</sup> Th cell deficiency. The size of Peyer's patches, especially the germinal centers where induction of IgA precursor B cells occurs, was reduced significantly (Mega *et al.*, 1991). A subset of T cells, V $\beta$ 1<sup>+</sup> T cells elegantly were shown to be essential to the IgA response in chickens (Cihak *et al.*, 1991). Multiple injections of anti-TcR2 (V $\beta$ 1-specific antibody) in embryonic life followed by thymectomy after hatching deleted V $\beta$ 1<sup>+</sup> T cells in young birds. In these birds, IgA antibody production was impaired completely, whereas other types of antibody production were maintained

(Cihak *et al.*, 1991). Further, antigen-specific secretory IgA antibodies were not induced in response to mucosal immunization with tetanus vaccine. These *in vivo* studies further emphasize that IgA responses are CD4<sup>+</sup> Th cell dependent. The last study provided additional evidence that a subset of CD4<sup>+</sup> Th cells plays an important role in the induction and regulation of mucosal IgA responses. The concept of IgA-specific Th cells remains an important and essential part of our understanding of the precise regulatory mechanisms of the mucosal IgA response.

# Human Gastrointestinal Mucosal T Cells

Stephen P. James • Martin Zeitz

## I. INTRODUCTION

T cells in the gastrointestinal (GI) tract are thought to play a central role in GI host defense and in regulation of GI function. Cells present in organized lymphoid sites such as the Peyer's patches, mesenteric lymph nodes, and appendix are thought to carry out specialized tasks necessary for initiating responses to antigens present in the intestinal lumen. After activation, cells leave these sites and recirculate in the systemic circulation, from which they enter the diffuse lamina propria compartment of the mucosa. The intestinal lamina propria and epithelium constitute the largest single T-cell site in humans. Peyer's patches are much less prominent in humans than in rodents. In addition, the lamina propria of the colon of humans normally contains large numbers of lymphocytes, whereas that of rodents contains few lymphocytes. Substantial evidence suggests that T lymphocytes associated with the human GI tract have unique characteristics that reflect their specialized roles in host defense in the mucosa (Table I). In this chapter, the phenotypic and functional characteristics of human and nonhuman primate GI T cells are reviewed. By necessity, the ability to manipulate mucosal T cells in humans experimentally is, for the most part, limited to *in vitro* studies of isolated cells or tissue explants. Despite these limitations, considerable information is available concerning the function of human GI T cells. Further, this information serves as the foundation for the study of diseases of the human GI tract.

## II. PHENOTYPIC CHARACTERISTICS

### A. Lymphocyte Subpopulations

Many of the characteristics of mucosal lymphocytes are probably the result of prior activation in response to antigens and mitogens present in the GI lumen. Lymphocytes in the intestinal mucosa first interact with antigens in the organized lymphoid tissues (Peyer's patches and lymphoid follicles in the colon) and further differentiate and mature in the germinal centers of the lymphoid follicles. Thereafter, they rapidly leave the mucosa and migrate through the mesenteric lymph nodes and the thoracic duct to reach the systemic circulation. From the blood, these antigen-activated lymphocytes migrate back to the mucosa and extravasate preferentially into the

lamina propria, becoming lamina propria lymphocytes (LPL), and the intraepithelial compartment above the basement membrane, becoming intraepithelial lymphocytes (IEL). Thus, most of the lymphocytes that enter the diffuse compartments of the GI tract (LPL, IEL) are likely to have had prior antigen activation and are likely to be memory cells.

Memory T cells are, by definition, cells that already have been in contact with antigens; they are adapted to their new tasks by the expression of various surface antigens that are absent from or expressed to a lesser degree on naive cells, by an altered pattern of lymphokine secretion, by different functional capacities, and by changes in their proliferative responses to different stimuli (Sanders *et al.*, 1988b). Previously, *in vitro* activation of CD45RA-positive, CD29-negative peripheral blood T lymphocytes by antigen has been shown to lead to a transition to CD45RA-negative, CD29-positive T cells (Akbar *et al.*, 1988; Clement *et al.*, 1988). This finding and functional studies have led to the conclusion that naive (or virgin) T cells can be distinguished from memory T cells by their expression of different antigen specificities of the CD45 cell-surface glycoprotein complex or CD29, the  $\beta 1$  chain of the integrin family (Sanders *et al.*, 1988a). The transition from naive to memory T-cell function is accompanied by a shift from the 205/220-kDa determinant (recognized by 2H4 monoclonal antibody) to the 180-kDa form (recognized by UCHL1 monoclonal antibody) of the CD45 cell-surface glycoprotein complex. These different molecules represent cell-type specific alternative splicing from a common precursor gene (Streuli *et al.*, 1987; Akbar *et al.*, 1988). Other markers have been described that are coexpressed with CD45 or CD29 after the transition from naive to memory T cells (Sanders *et al.*, 1988a). Naive T cells can be characterized as CD45RA-high, LFA-3-low, CD2-low, LFA-1-low, CD45R0-low, and CD29-low; memory T cells represent the reciprocal subset.

CD4- and CD8-positive T cells are present in the lamina propria in similar proportions compared with the peripheral blood (Selby *et al.*, 1983; James *et al.*, 1986; Schieferdecker *et al.*, 1990). Thus, regarding the major T-cell subpopulations, peripheral blood T cells and lamina propria T cells do not appear to be different. However, further investigations showed that only few lamina propria lymphocytes express CD45RA (recognized by 2H4) and the vast majority of cells are CD45R0 positive (recognized by UCHL1) (Schieferdecker *et al.*, 1990; Figure 1). In contrast, in peripheral blood, approximately 30% of T cells are CD45RA positive and

<sup>b</sup> N.D., Not determined.

30-50% are CD45R0 positive. Thus, the CD45 phenotype of LPLs resembles that of memory T cells. However, expression of another marker of memory T cells, CD29 ( $\beta$ 1 integrin), is not increased in the lamina propria compared with peripheral blood. The phenotype of lamina propria T lymphocytes therefore only partially corresponds to that of memory T cells as defined by *in vitro* studies with peripheral blood lymphocytes. These phenotypic studies are an indication that T cells in the human intestinal lamina propria are a specialized memory T-cell subset.

### B. Receptors Controlling Lymphocyte Migration

Naive and memory T cells are likely to have specific migration pathways throughout the body that enable antigen-specific immune responses to be concentrated at specific sites. Directed migration into normal or inflamed tissues probably is controlled by expression of a distinct pattern of specific adhesion molecules on the cell surface. The best studied "homing" receptor is the L-Selectin (LAM-1, LECAM-1, Leu-8, MEL 14) molecule. The L-Selectin antigen is ex-

pressed on neutrophils and monocytes and on subpopulations of T and B cells (Gatenby *et al.*, 1982; Kansas *et al.*, 1985a,b), but is not expressed on platelets. On circulating cells, 60-70% of T cells are L-Selectin positive, including both CD4<sup>+</sup> and CD8<sup>+</sup> cells. Although most L-Selectin-positive T cells are CD45RA positive, L-Selectin-positive T cells are found in both the naive (CD45RA-positive) and memory (CD29-positive) T-cell subsets. The latter observation is substantiated by the finding that some L-Selectin positive lymphocytes can respond to recall antigens (Bookman *et al.*, 1986). About half the circulating B cells are L-Selectin positive; evidence is presented in this chapter that these subpopulations differ in function. L-Selectin is expressed weakly on natural killer (NK) cells. Although L-Selectin expression is modulated rapidly by activation (Kanof and James, 1988), it is expressed stably in high levels on some T-cell lines (Bookman *et al.*, 1986) and clones and on some B-cell lines.

Few lymphocytes in the human or primate intestinal lamina propria are L-Selectin positive, whereas the majority of cells in mesenteric lymph nodes, which presumably drain the Peyer's patches, are L-Selectin positive (James *et al.*, 1986, 1987a; Figure 2). Several explanations for this observation are apparent. One explanation is based on the observation that substantial activation of lymphocytes occurs in the intestinal lamina propria (Zeitz *et al.*, 1988a; see subsequent dis-

**Figure 1** Expression of CD45RA and CD45R0 on human peripheral blood (PBL; left) and intestinal lamina propria lymphocytes (LPL; right). PBL and LPL were isolated from macroscopically normal small intestine and were stained with monoclonal antibodies 2H4 (CD45RA) or UCHL-1 (CD45R0) and analyzed by flow cytometry. LPL are nearly devoid of CD45RA-positive cells and express a high percentage of CD45R0-positive cells.

**Figure 2** Expression of Leu-8/MEL14 lymph node homing receptor on intestinal lymphocytes. Peripheral blood (*left*) and intestinal lamina propria (*right*) lymphocytes from a normal nonhuman primate were stained with anti-CD45RA FITC and anti-Leu-8-PE and analyzed by dual fluorescence flow cytometry. Few lymphocytes in the lamina propria express the peripheral lymph node homing receptor or CD45RA.

cussion). Therefore, cells in the lamina propria might not express L-Selectin because they are in an activated state associated with low L-Selectin expression. However, this explanation is unlikely to be complete. First, when lamina propria lymphocytes are isolated and cultured in the absence of any stimulus, they do not re-express L-Selectin (Berg *et al.*, 1991). Further, intestinal lamina propria lymphocytes have little if any mRNA for L-Selectin following activation with potent inducers of L-Selectin mRNA, such as phorbol 12-myristate 13-acetate (PMA), these cells continue to lack L-Selectin mRNA (Berg *et al.*, 1991). Finally, only a proportion of L-Selectin-negative cells in the intestinal lamina propria actually are activated and express interleukin 2 (IL-2) receptors. L-Selectin-negative lymphocytes in the intestinal lamina propria share some characteristics with L-Selectin-negative lymphocytes in the circulation. The latter do not have evidence of activation, do not express L-Selectin mRNA and are not able to express L-Selectin after induction with PMA. Further, L-Selectin-negative cells isolated from the intestinal lamina propria and circulating L-Selectin-negative lymphocytes both have a similar high level of helper activity in pokeweed mitogen (PWM)-stimulated cultures. Based on these findings, L-Selectin-negative cells in the circulation are actually likely to arise from L-Selectin-positive precursors by a process of differentiation that remains to be defined. Further, these data suggest that L-Selectin-negative cells preferentially enter the intestinal lamina propria. The mechanism by which this occurs is as yet unknown, but may involve increased expression of other adhesion molecules that are known to be present on memory lymphocytes (Sanders *et al.*, 1988a) or other as yet undefined adhesion molecules. Finally, lymphocytes that enter the lamina propria are likely to acquire additional characteristics that may be unique to their microenvironment, for example, expression of HML-1 (see subsequent discussion).

Since lymphoid cells in the intestinal lamina propria have the phenotypic and functional characteristics of "memory"

lymphocytes, including low expression of CD45RA (James *et al.*, 1986, 1987a) and high expression of CD45R0 (Schieferdecker *et al.*, 1991), glycoproteins expressed on memory lymphocytes may be important in localization of cells to the intestinal lamina propria. In addition to increased expression of the CD45R0 glycoprotein, circulating memory lymphocytes have been shown to have increased expression of a number of molecules that have been implicated in cell adhesion and cellular interactions, including CD2, LFA-1, LFA-3, CD29, and CD44 (Sanders *et al.*, 1988a). As indicated earlier, both CD29 ( $\beta$  chain ( $\beta_1$  chain of integrins) and CD44 may play a role in localization of lymphoid cells to mucosal endothelium; therefore CD29 and CD44 may be important in intestinal homing.

Although lymphocytes in the intestinal lamina propria have almost exclusively the surface glycoprotein characteristics of memory lymphocytes, this alone does not account for mucosal lymphocyte localization for several reasons. First, cells with the memory phenotype are heterogeneous for the L-Selectin phenotype, that is, CD45RA-negative lymphocytes can be L-Selectin positive or negative. In addition, both L-Selectin positive and L-Selectin-negative CD4<sup>+</sup> T cells are able to respond to the recall antigen purified protein derivative (PPD) (Takada *et al.*, 1989), indicating that the presence or absence of the L-Selectin antigen is not a marker of immunological memory. Similarly, long-term memory B cells have been shown to be L-Selectin positive (Kraal *et al.*, 1988). Finally, although human intestinal lamina propria lymphocytes do not bind to peripheral lymph nodes, they do bind to human appendix or murine Peyer's patch lymph nodes; however, they have no increased binding to mucosal tissue in comparison with peripheral blood lymphocytes (Jalkanen *et al.*, 1989). In contrast, lamina propria lymphoblasts have greatly increased binding to mucosal tissues. Therefore, the exclusive localization of L-Selectin-negative lymphocytes to the lamina propria is not solely the result of the presence of memory cells in this subset. These observations suggest that newly expressed molecules or a change in density of surface molecules such as CD44 on activated lymphocytes (Willerford *et al.*, 1989) may be a critical determinant of localization of lymphocytes in the intestinal mucosa.

### C. Mucosal T-Cell Specific Antigens

Monoclonal antibodies have been developed for rats (RGL1; Cerf-Bensussan *et al.*, 1986), mice (M290; Kilshaw and Murant, 1990) and humans (HML-; Cerf-Bensussan, 1987; Ber-Act8; Kruschwitz *et al.*, 1991) that recognize lymphocyte surface antigens that are expressed nearly exclusively in the mucosal immune system. By immunohistology and flow cytometry, approximately 40% of lamina propria lymphocytes and nearly all IELs in humans were shown to express the surface antigen recognized by HML-1 (Cerf-Bensussan *et al.*, 1987; Schieferdecker *et al.*, 1990; Ullrich *et al.*, 1990a). Reactivity also is seen in a few cells in the extrafollicular areas of lymph nodes and tonsils, as well as in splenic red pulp (Kruschwitz *et al.*, 1991).

Immunoprecipitation and polyacrylamide gel electrophoresis (PAGE) have shown that the HML-1 antigen is a hetero-

dimer comprising a 150-kDa  $\alpha$  chain and a 120-kDa  $\beta$  chain (Cerf-Bensussan *et al.*, 1992). Using monoclonal antibody Ber-Act8, which recognizes a different epitope of the same antigen, a trimeric structure also has been described (150; 125; and 105-kDa subunits; Kruschwitz *et al.*, 1991). Both the  $\alpha$  and the  $\beta$  chain of HML-1 are glycosylated. Pulse-chase experiments indicate that precursor forms exist for both subunits; the larger  $\alpha$  chain precursor (160 kDa) is reduced in size by posttranslational cleavage of a 10-kDa peptide and the smaller  $\beta$  chain precursor is increased in size by modification of the *N*-glycans (Cerf-Bensussan *et al.*, 1992).

Dual color cytofluorometry has shown that HML-1 is expressed preferentially on CD8<sup>+</sup> T cells; however, a significant proportion of CD4<sup>+</sup> lamina propria T cells also expresses HML-1 (Schieferdecker *et al.*, 1990; Figure 3). The low number of CD45RA-positive cells in the human intestinal lamina propria is almost exclusively HML-1 negative. Therefore, HML-1 has been hypothesized to be a tissue-specific memory T-cell marker exclusively expressed in the environment of the gut (Schieferdecker *et al.*, 1991). However, only a partial overlap in expression of CD29 and HML-1 is seen. In one study, the differential expression of homing-associated adhesion molecules on human peripheral blood T cells was investigated (Pricker *et al.*, 1990). The small proportion of circulating human T cells expressing the mucosal lymphocyte-associated antigen recognized by the monoclonal antibody Ber-Act8 (identifying the same antigen as HML-1) was shown also to have the CD29-low phenotype. These results are in agreement with the finding of an intermediate expression of CD29 on lamina propria T cells and further

support the hypothesis of a tissue-specific modulation of memory or homing-associated T-cell surface antigens.

Expression of HML-1 is induced on HML-1-negative peripheral blood lymphocytes by *in vitro* activation using various stimuli (Schieferdecker *et al.*, 1990). However, certain differences are seen in the kinetics of expression of HML-1 when compared with the established T-cell activation antigen CD25. CD25 can be detected very early after mitogenic stimulation (within the first 24 hr), maximal expression is on day 1 or 2, and the number of positive cells decreases rapidly during the following days. In contrast, HML-1 is expressed later, maximal expression is on day 5–7, and only a slight decrease occurs up to day 10. In addition, whereas nearly 100% of activated T cells become CD25 positive, HML-1 expression in mitogen-stimulated cultures does not exceed 50% (Schieferdecker *et al.*, 1990). HML-1 therefore can be defined as an activation marker with characteristics shared by T-cell differentiation antigens used for the definition of memory T cells, that is expressed *in vivo* only in the environment of the intestine.

The function of the antigen recognized by HML-1 is not completely understood. The phenotypic data mentioned earlier and the kinetics of expression after activation are indications that this antigen may define a subset of memory T cells located in the intestinal immune system. In one study, tryptic peptides cleaved from purified  $\beta$  chain of HML-1 were sequenced and the amino acid sequence was compared with a protein data bank, revealing strong homology with the integrin  $\beta$  chains (Cerf-Bensussan *et al.*, 1992). Although the primary structure of the  $\alpha$  chain of HML-1 has not been determined, these data indicate that HML-1 may be a novel human integrin. Integrins mediate cell-cell adhesion and binding to extracellular matrix components and, therefore, play important roles in lymphocyte homing, differentiation, and activation. Preliminary evidence suggests that triggering HML-1 with monoclonal antibody was co-stimulatory activity on human intestinal and peripheral T cells (Sarnacki *et al.*, 1991; H. Schieferdecker and M. Zeitz, unpublished results). Although the natural ligand of HML-1 is not known, HML-1 might be an important surface molecule in the regulation of the local immune response in the intestine.

#### D. T-Cell Receptor Expression in the Intestinal Mucosa

More than 95% of the normal intestinal lamina propria T cells express the  $\alpha\beta$  T-cell receptor (TcR) heterodimer (Ullrich *et al.*, 1990a). Although T cells are found in the human epithelium (IEL) as in the mouse, in humans only about 10% of small bowel IELs (range: 5–20%) express this receptor. In the colon, a much higher proportion of IELs expresses  $\gamma\delta$  receptors (Deusch *et al.*, 1991; Porcelli *et al.*, 1991). Thus, in humans the majority of T cells in the mucosa express the  $\alpha\beta$  TcR that predominates in the periphery. Using polymerase chain reaction (PCR) amplification for different specific *V $\beta$*  families, only a few *V $\beta$*  families have been shown to predominate in human IELs (Balk *et al.*, 1991; VanKerckhove *et al.*, 1992). Further, sequences of VDJC showed evidence of oligoclonality of T-cell clones from human IELs.

**Figure 3** HML-1 antigen is expressed on both CD4 and CD8 positive lamina propria lymphocytes. Dual color flow cytometry analysis of human peripheral blood (*left*) and intestinal lamina propria (*right*) lymphocytes that were stained with anti-CD4 PE or anti-CD8 PE and HML-1 plus FITC anti-mouse IgG. HML-1 is nearly absent on peripheral blood lymphocytes. More CD8 than CD4 lamina propria lymphocytes express HML-1.

Results for lamina propria T lymphocytes also showed skewing toward particular families, however, the level of heterogeneity was intermediate between peripheral blood and IELs. These interesting results suggest that factors may exist in the intestinal epithelium, for example, exogenous antigens or superantigens perhaps in combination with unique major histocompatibility complex (MHC) determinants expressed in the epithelium, that drive selective expansion of specific families of T cells.

### III. ACTIVATION OF LAMINA PROPRIA T CELLS

T-cell activation is followed by an early expression of the IL-2 receptor on the cell surface. The interaction of the IL-2 receptor with IL-2 is a critical event in T-cell proliferation, differentiation, and function (Greene *et al.*, 1986). Intestinal T cells are in close proximity to a large number of antigens and substances with mitogenic properties. Therefore, the question arises whether lamina propria T cells differ in their state of activation from T cells in other sites of the immune system. Using Northern blot analysis in nonhuman primates to study the transcription of the gene for the IL-2 receptor  $\alpha$  chain (CD25), mRNA for the IL-2 receptor  $\alpha$  chain has been shown to be clearly detectable in freshly isolated lymphocytes from the intestinal lamina propria whereas, in the other populations from the spleen, mesenteric lymph nodes, or the peripheral blood, IL-2 receptor mRNA is found only after activation *in vitro* (Zeitz *et al.*, 1988a; Figure 4).

**Figure 4** IL-2 receptor alpha chain mRNA is present in freshly isolated lamina propria lymphocytes. RNA was isolated from HUT 102 cell line (positive control), resting peripheral blood lymphocytes (PBL), mesenteric lymph nodes (MLN), or lamina propria lymphocytes (LPL) of a normal nonhuman primate. RNA was also isolated from lymphocytes that were activated with concanavalin A (Con A) *in vitro*. Northern blot of total cellular RNA was hybridized with probe specific for IL-2 receptor alpha chain. 10 $\mu$ g of RNA was loaded per lane.

Correspondingly, by flow cytometry, 15% (range; 6–29%) of freshly isolated intestinal lamina propria lymphocytes have been shown to be CD25 positive, but less than 3% of the other lymphocyte populations have that phenotype. CD4<sup>+</sup> and CD8<sup>+</sup> T cells express CD25 to a similar extent. The increased CD25 expression of lamina propria lymphocytes is correlated with a high proliferative response to low doses of IL-2, indicating that the IL-2 receptors are able to transduce the signal after IL-2 binding. In agreement with an increased state of activation of lamina propria T cells, these cells are able to synthesize high amounts of IL-2 after activation (Zeitz *et al.*, 1988a). Lamina propria lymphocytes also express MHC Class II antigens (Zeitz *et al.*, 1988a) and other T-cell activation markers (Peters *et al.*, 1986). Expression of CD25 in the lamina propria has been confirmed in humans by immunohistology of frozen tissue sections (Ullrich *et al.*, 1990b) and flow cytometry (Schieferdecker *et al.*, 1990). The finding that the mucosal T-cell associated antigen recognized by HML-1 is an antigen that can be induced by activation further supports the concept of an increased activation of lamina propria T cells. The increased state of activation of lamina propria T cells may be the result of the continuous exposure to antigens and mitogens from the gut lumen. The increased state of activation of lamina propria T cells and their unique phenotype are accompanied by characteristic functional changes after stimulation with antigens in comparison with cells from other compartments of the immune system.

### IV. LYMPHOKINE PRODUCTION AND UTILIZATION BY INTESTINAL T CELLS

Many of the functions carried out by T cells in the GI immune system are thought to be mediated, at least in part, by their secreted lymphokines. Therefore, a detailed understanding of the lymphokines produced by mucosal T cells is necessary to understand their function. Further, alterations in the patterns of cytokines produced by mucosal cells may be important in the pathogenesis of intestinal disease. Experiments have been carried out to determine whether differences exist in the steady-state levels of lymphokine mRNA after activation of lymphocytes isolated from different sites of normal nonhuman primates (James *et al.*, 1990). Using conventional Northern blots, no specific hybridization with different lymphokine probes was detected in unactivated lymphocytes obtained from any site. When lymphocytes from different sites were activated with a combination of ionomycin and PMA, both mesenteric lymph node and lamina propria T cells were found to express high levels of mRNA for IL-4 and IL-5, in comparison with cells from peripheral blood, spleen, or peripheral lymph nodes (Figure 5). Lamina propria lymphocytes also had the highest levels of IL-2 mRNA, whereas mesenteric lymph node IL-2 mRNA was lower. In contrast, interferon  $\gamma$  (IFN $\gamma$ ) mRNA was low in mesenteric lymph nodes compared with all other sites. Thus, intestinal lamina propria lymphocytes have high capacity to express IL-2, IFN $\gamma$ , IL-4, and IL-5 mRNA whereas mesen-

**Figure 5** Northern blot for lymphokine mRNA in intestinal lymphocytes. Lymphocytes were obtained from different sites in a normal nonhuman primate (1, peripheral blood; 2, spleen; 3, peripheral node; 4, mesenteric node; 5, lamina propria) and were activated with ionomycin and PMA. Total cellular RNA was hybridized with probes for IL-2, IFN gamma, IL-4, IL-5, and actin. Activated intestinal lymphocytes have high expression of IL-4 and IL-5 mRNA.

teric lymph node cells have much lower capacity to express IL-2 and IFN $\gamma$  but have a high capacity to express IL-4 and IL-5 mRNA after activation. The higher potential for expression of IL-2 was confirmed at the level of secreted proteins in studies of isolated primate lamina propria lymphocytes, in which activated intestinal T cells were demonstrated to have high production of IL-2 bioactivity (Zeitz *et al.*, 1988a). These studies indicate that mucosal T cells may be substantially different from T cells in other sites with respect to their potential for modulating immune responses; additional evidence that this is the case is described subsequently.

The ability of human IELs to produce lymphokines also has been examined. IELs isolated from surgically resected specimens have an ability similar to that of peripheral blood lymphocytes to produce IL-2 and IFN $\gamma$  in response to stimulation with phytohemagglutinin (PHA; Ebert, 1990). Previously human IELs were shown to proliferate poorly in response to mitogens, but the addition of sheep erythrocytes or anti-CD2 monoclonal antibodies greatly enhances their proliferative responses. Similarly, addition of sheep erythrocytes greatly enhances lymphokine production by human IELs. These preliminary results indicate that human IELs, like murine IELs, have substantial potential for production of lymphokines. However, the extent to which lymphokines are produced *in vivo* and their physiological effects in the human GI epithelium are unclear.

Studies also have been carried out to examine the capacity of intestinal T-cell populations to use IL-2 or IL-4 as a growth factor. The proliferative responses of T cells isolated from either mesenteric lymph node or lamina propria were compared with those of T cells from peripheral blood or spleen of

normal nonhuman primates (James *et al.*, 1990). Background proliferative responses and responses induced by concanavalin A (Con A) were not significantly different among the different cell populations. Human recombinant IL-2 induced dose-dependent proliferative responses of nonhuman primate T cells that were highest in T cells isolated from the intestinal lamina propria. In contrast, when T cells were cultured with recombinant human IL-4 alone, significant dose-dependent proliferative responses were not observed in T cells isolated from any site. When T cells from peripheral blood, spleen, or mesenteric lymph node were cultured with IL-4 and PMA, dose-dependent proliferative responses were observed; responses were highest in T cells isolated from the mesenteric lymph node. In contrast, T cells from the lamina propria did not exhibit a significant proliferative response to IL-4 + PMA at any dose, although these cells showed a high response to Con A and had the highest responses to IL-2 alone. These findings suggest that T cells in inductive and effector compartments of the mucosal immune system may differ in important ways in their responses to lymphokines. In particular, IL-4 may be an important autocrine factor in the mesenteric lymph nodes for T-cell growth and differentiation, whereas IL-2 may be the critical autocrine factor for growth and differentiation of T cells in the lamina propria.

## V. IMMUNOREGULATORY FUNCTION OF INTESTINAL T CELLS

As indicated in the introduction the GI immune system is confronted with the necessity of responding to or being tolerant of various pathogens and antigens in the GI tract. One of the ways in which this response is accomplished is through regulation of immune responses by T cells. T cells exert their regulatory influence (help, suppression) on immunoglobulin synthesis, which is the major focus of this section, but also exert regulatory influences on other lymphoid and non-lymphoid cells. These regulatory influences probably are mediated in part by the secreted products of T cells and, as discussed earlier, evidence suggests that mucosal T cells may be characterized by the high potential for production of certain cytokines after activation.

In earlier studies, isolated human lamina propria cells were found to be similar to peripheral blood cells in the capacity to regulate PWM-stimulated immunoglobulin synthesis (James *et al.*, 1985). Lamina propria T cells had a similar capacity to provide help, and did not appear to have any increased suppressor function in comparison to peripheral blood lymphocytes. When lamina propria CD4<sup>+</sup> T cells were discovered to differ phenotypically from peripheral blood T cells (see previous discussion), the helper function of lamina propria T cells was re-examined in several ways. For some time, researchers have known that immunoglobulin synthesis is suppressed in PWM-stimulated cultures at high CD4/B cell ratios. This phenomenon is caused by the fact that the CD4<sup>+</sup> population is heterogeneous, that is, that the CD4<sup>+</sup>LAM-1<sup>-</sup> population has high helper activity and the CD4<sup>+</sup>LAM-1<sup>+</sup> subpopulation, which represents about 60% of CD4<sup>+</sup> T cells,

suppresses immunoglobulin synthesis (Kanof *et al.*, 1987). The *in vitro* variation of the inhibitory function of CD4<sup>+</sup>LAM-1<sup>+</sup> T cells with changes in the T cell/B cell ratio may be caused by the requirement of the inhibitory effect of these cells for direct contact between T and B cells. Further, the LAM-1 molecule may be involved in the function of these cells since, when the CD4<sup>+</sup>LAM-1<sup>+</sup> subpopulation is treated with anti-LAM-1 under conditions that cross-link the monoclonal antibody, the suppressor function of these cells is enhanced. When CD4<sup>+</sup> T cells from the lamina propria were studied using similar methods, lamina propria CD4<sup>+</sup> cells did not suppress immunoglobulin synthesis at high T cell/B cell ratios. The ability of these cells to inhibit immunoglobulin synthesis was not enhanced by treatment with anti-LAM-1 (Kanof *et al.*, 1988; Figure 6). The helper and suppressor capacity of the CD4<sup>+</sup>LAM-1<sup>-</sup> and the CD4<sup>+</sup>LAM-1<sup>+</sup> subpopulations does not appear to be inherently different in the lamina propria, since highly purified preparations of these two cell types have identical function, whether isolated from the lamina propria or peripheral blood (Kanof *et al.*, 1988b). Thus, these studies confirm the fact that the predominance of CD4<sup>+</sup>LAM-1<sup>-</sup> cells in the intestinal lamina propria indicates that their net functional capacity is shifted significantly toward helper function in comparison with T cells in the peripheral blood.

The suppressor function of CD8<sup>+</sup> lamina propria T cells has been studied also. The proportion of CD8<sup>+</sup> cells in the lamina propria is similar to that in peripheral blood. In PWM-stimulated cultures, these cells have a similar ability to inhibit immunoglobulin synthesis (James *et al.*, 1985). However,

**Figure 6** Regulatory function of intestinal lamina propria CD4 T cells. CD4 T cells from human peripheral blood (□, ◆) or intestinal lamina propria (◼, ◇) were cultured with non-T cells and pokeweed mitogen (PWM) for 10 days in presence (◆, ◇) or absence (□, ◼) of anti-Leu-8 monoclonal antibody. IgG in culture supernatants was determined by ELISA. Lamina propria CD4 T cells do not inhibit IgG synthesis at high T/B ratios.

only modest suppressor activity is found unless the cells are activated by exposure to a mitogen such as Con A. Currently, whether the suppressor function of lamina propria T cells differs from that of peripheral blood cells is unclear; however, as noted earlier, an increased proportion of CD8<sup>+</sup> cells from the intestinal lamina propria expresses IL-2 receptors, indicating that these cells are in a more activated state. The function of lamina propria CD8<sup>+</sup> cells also may differ from that of peripheral blood but, as for the studies of CD4<sup>+</sup> cells, these differences may not become apparent until new and more specific methods are identified to study subpopulations of suppressor lymphocytes.

In the studies described in this section using human lamina propria CD4<sup>+</sup> T cells, no IgA isotype specificity was observed, that is, no evidence was found that lamina propria T cells preferentially augment IgA synthesis rather than IgG or IgM (James *et al.*, 1985). This result might seem surprising in view of the evidence presented earlier that mucosal T cells have high potential for expression of lymphokines such as IL-5 that enhance IgA B-cell differentiation (Murray *et al.*, 1987; Yokota *et al.*, 1987; Harriman *et al.*, 1988). However, the evidence suggests that, within the intestinal lamina propria, the great preponderance of IgA-secreting cells is not determined by preferential production of IgA-specific helper factors but that the B cells that enter and undergo differentiation in the lamina propria already are committed to IgA production.

Since the studies discussed already indicated significant differences in the production and utilization of lymphokines by mesenteric lymph node and lamina propria T cells, studies were carried out to determine whether these differences might result in differences in the regulatory function of these T-cell populations (James *et al.*, 1990). First, to evaluate this question, the effect of exogenous (recombinant, r) lymphokines on the capacity of PWM stimulated human lymphocytes to produce immunoglobulin was determined. Both rIL-2 and rIFN $\gamma$  enhanced immunoglobulin synthesis in a dose-dependent fashion. In related studies, IL-2 was demonstrated to enhance the helper activity of mucosal T cells for immunoglobulin synthesis (James and Graeff, 1987). In contrast, as previously described (Jelinek and Lipsky, 1988), recombinant human IL-4 caused a dose-dependent inhibition of immunoglobulin synthesis. This inhibitory effect was reversed by addition of recombinant human IFN $\gamma$ . The reversal of the IL-4 inhibitory effect by IFN $\gamma$  was observed only at low doses of IL-4, and was not observed at high doses of IL-4 (1000 U/ml).

These results suggested that lamina propria T cells, which express higher levels of IL-2 and IFN $\gamma$  mRNA, would have greater helper function for immunoglobulin synthesis than mesenteric lymph node T cells. In other studies, nonhuman primate mesenteric lymph node and lamina propria T cells were cultured with autologous spleen B cells, alone or in the presence of increasing doses of recombinant human IL-4. Significantly more immunoglobulin was produced in cultures containing lamina propria T cells than mesenteric lymph node T cells, and the helper effect of lamina propria T cells was less inhibitable by exogenous IL-4 (James *et al.*, 1990). In summary, these studies of the immunoregulatory potential

of lamina propria T cells *in vitro* indicate that such cells have high potential for helper activity, consistent with their phenotypic characteristics and potential for lymphokine gene expression discussed previously.

## VI. T CELL ANTIGEN-RECEPTOR TRIGGERED FUNCTION OF INTESTINAL LYMPHOCYTES

Many of the functional studies described so far have relied on the activation of lymphoid cells using mitogens to study their function. This approach to the study of lymphocytes might not necessarily be representative of the outcome of exposure of lamina propria lymphocytes to specific antigens or pathogens. Therefore an animal model was established to examine this question in more detail. The function of lymphocytes isolated from the intestinal lamina propria of nonhuman primates with rectal infection with *Chlamydia trachomatis* (Serovar L2; lymphogranuloma venereum) was studied (James *et al.*, 1987b; Zeitz *et al.*, 1988b). This infectious model is of particular interest because the histopathological features of lymphogranuloma venereum bear a striking resemblance to those of Crohn's disease of the colon. As expected, T cells from peripheral blood, spleen, mesenteric lymph nodes, and particularly draining lymph nodes had a significant proliferative response when exposed to *C. trachomatis* antigens. However, T cells isolated from either the involved rectum or distant sites in the lamina propria did not exhibit a proliferative response when challenged with chlamydial antigens, although they did proliferate in response to mitogens such as Con A (Figure 7). This failure of lamina propria T cells to exhibit antigen-specific proliferative responses in lymphogranuloma venereum is not because of the absence of functional antigen-presenting cells or the presence of suppressor cells. Further, this finding may be a more general aspect of T-cell function in the lamina propria, since similar results were obtained in studies of animals rectally immunized with *Bacillus Calmette-Guérin* (BCG). Other lines of evidence also indicate that TcR-triggered activation of lamina propria lymphocytes may differ from that of circulating T cells. Anti-CD3-mediated activation of lamina propria lymphocytes is markedly lower than that of peripheral blood lymphocytes, but activation through the CD2 alternative pathway is normal in lamina propria lymphocytes (Qiao *et al.*, 1991). The most interesting aspect of these studies was that, although T cells from the lamina propria were unable to proliferate in response to antigens, antigen-specific T cells are present in this site, as was shown by experiments in which lamina propria T cells exposed to specific antigens could provide help for immunoglobulin synthesis (Figure 7). Thus, antigen-specific T cells are present in the intestinal lamina propria but, at least in certain circumstances, they have lost the capacity for proliferation while retaining the capacity to mediate helper function on antigen stimulation. An important implication of this study is that T-cell proliferation may not be a suitable test for the presence of antigen-

**Figure 7** Antigen-specific proliferation of intestinal lamina propria lymphocytes (LPL) and antigen-induced production of helper factors by lamina propria T cells. Lymphocytes from the peripheral blood (PBL), the spleen, mesenteric lymph nodes (MLN), or the intestinal lamina propria (LPL) were isolated from nonhuman primates infected with *Chlamydia trachomatis*. Cell populations were stimulated with chlamydial antigens *in vitro*, and proliferation was measured by [<sup>3</sup>H]thymidine incorporation (delta cpm; *left*). Spleen B cells from infected animals were cocultured with T cells from uninfected animals (control) or infected animals (LGV-inf) and cultures were stimulated either with pokeweed mitogen (PWM) or with chlamydial antigens (LGV). IgG production was measured in culture supernatants (*right*). Lamina propria T cells from immune animals do not proliferate but do provide help for Ig synthesis in the presence of chlamydial antigens.

specific T cells in sites of active mucosal inflammation, and tests of T-cell function may be required to demonstrate the presence of antigen-specific T cells.

## VII. CYTOTOXIC FUNCTION OF INTESTINAL LYMPHOCYTES

Cytotoxic lymphocytes might play an important role in the function of the intestinal immune system and in the pathogenesis of intestinal disease in several different ways (James and Strober, 1986). First, cytolytic cells might play a role in injuring, either directly or indirectly via a bystander effect, any of the following cells: infectious organisms, neoplastic cells, infected cells, normal epithelial cells, altered epithelial cells, or stromal cells of the intestine. Second, the absence or inhibition of function of cytolytic cells might have a negative role in a disease state, because absence or a deficiency

of activity might cause a local immunodeficiency state. Third, cytolytic cells might have indirect effects through their interactions with other cells of the GI immune system. Several different lymphocyte-mediated cytotoxic mechanisms might be active in the intestine, including NK cell cytotoxicity, antibody-dependent cellular cytotoxicity, T-cell mediated cytotoxicity, and, finally, lymphokine activated killer cell cytotoxicity. Both phenotypic and functional studies are consistent with the conclusion that the effector cells of NK and antibody-dependent all cytotoxicity activity are infrequent in the intestinal lamina propria (James and Graeff, 1985). On the other hand, evidence suggests that T-cell cytotoxicity plays an important role in immune function in the intestine. T-cell cytotoxicity is typified by the classical cytotoxic T lymphocyte (CTL) assay, in which the cytolytic effector cell specifically recognizes specific antigen in the context of HLA Class I determinants. Based on discussion of lymphocyte phenotypes in the intestine, clearly T cells are present with the typical markers of cytolytic T cells. However, showing experimentally that functional cytolytic T cells are present in this site has been much more problematic. To demonstrate this function, one must not only obtain functional mucosal lymphocytes, but also have an assay system that utilizes a target cell with the appropriate antigenic and HLA determinants, a requirement that is usually not possible in human experiments. In animal models, demonstrating the presence of antigen-specific cytolytic T cells during viral infection (Issekutz *et al.*, 1984) and in animals immunized with alloantigens (Klein and Kagnoff, 1987) has been possible. To date, however, no convincing demonstration has been made of antigen-specific cytolytic T-cell function in humans. However, progress in our understanding of cytolytic T-cell function may allow for the study of these cells without actually knowing the antigen or MHC specificity of the effector cell. When cytolytic T cells are exposed to monoclonal anti-CD3 antibodies and target cells that are capable of binding the monoclonal antibody via Fc receptors, the effector cell is triggered to lyse the target cell without a requirement for MHC or antigenic specificity (Phillips and Lanier, 1986). Similarly, lectins such as PHA can trigger the same process, although this triggering is not limited to that of cytolytic T cells. Thus, the previous demonstration that the intestinal mucosa contains cells capable of mediating lectin-dependent cytotoxicity is indirect evidence that the intestinal mucosa contains cytolytic T cells (MacDermott *et al.*, 1980). These observations have been extended further by the demonstration of anti-CD3-triggered cytotoxicity mediated by intestinal lymphocytes (Shanahan *et al.*, 1988). Interestingly, peripheral blood CD8<sup>+</sup> lymphocytes that mediate CD3- or lectin-triggered cytotoxicity are primarily Leu-7 positive, whereas this phenotypic marker is infrequent on intestinal lymphocytes, suggesting that the frequency of this cytolytic T-cell type is very low in the lamina propria or, more likely, that in the intestine cytolytic T cells may not express this antigen. The physiological significance of these findings is uncertain at present, since the *in vitro* experiments only indicate that cells with potential for cytolytic function are present in the intestine. Whether these cells are triggered normally or during

disease processes remains to be shown. Speculating that this form of non-antigen-specific killing may be important is interesting; for example, bacterial products might trigger killing of innocent bystander cells under certain conditions.

## VIII. SUMMARY

The findings presented in this chapter provide substantial evidence that lymphocytes in the intestinal lamina propria differ from lymphocyte populations in the circulation or in other tissue sites in a number of ways. First, lamina propria lymphocytes are phenotypically distinct because few of these cells normally express the LAM-1 or CD45RA antigens. The presence of these molecules on CD4<sup>+</sup> T cells correlates with suppressor and suppressor-inducer function. Therefore the majority of CD4<sup>+</sup> T cells in the intestinal lamina propria has the phenotype associated with high helper activity. A substantial proportion of lamina propria lymphocytes also shows evidence of activation, based on expression of the IL-2 receptor  $\alpha$  chain and HLA-DR molecules. Lymphocytes in the intestinal lamina propria are different in their potential for expression of lymphokine gene products, since activated cells from the lamina propria have high expression of mRNA for IL-2, IL-4, IL-5, and IFN  $\gamma$  in comparison with circulating lymphocytes. Mesenteric lymph node T cells also differ from circulating lymphocytes in their high expression of IL-4 and IL-5 mRNA. An additional difference between mesenteric lymph node and lamina propria T cells is that the former are capable of proliferating in response to IL-4, whereas the latter are not. These phenotypic and mRNA differences of lamina propria lymphocytes also correlate well with their high helper activity for immunoglobulin synthesis *in vitro* in the PWM system. T cells with the potential for cytolytic activity are present in the intestinal lamina propria, although as yet no definitive evidence exists that they are cytolytically active under physiological or pathological conditions. Finally, in a model system of intestinal inflammation (lymphogranuloma venereum in nonhuman primates), lamina propria T cells at the site of inflammation were unable to respond to specific antigens with proliferation but did respond with high helper activity. These observations are all consistent with the conclusion that T cells in the lamina propria are pleomorphic, but are highly enriched for subpopulations of activated memory cells that are geared for effector functions such as helper and cytolytic functions. These functions are likely to be critical in maintaining normal host defense in the mucosal environment.

# Basic Aspects of Intraepithelial Lymphocyte Immunobiology

Leo Lefrancois

## I. INTRODUCTION

Intraepithelial lymphocytes (IELs) constitute the first immune cell line of defense in the intestine, that is, IgA in the intestinal lumen is likely to represent the first immunological defense encountered by an intestinal pathogen, followed by the anti-invasive glycocalyx of the intestinal mucosa. Any organism that was able to traverse these barriers could encounter IELs, which are interspersed between the columnar epithelial cells of the villi in the small and large intestine (Figure 1). Thus, infection of the epithelium with the subsequent expression of peptidic foreign antigen associated with major histocompatibility complex (MHC) molecules could result in IELs mounting an immune response. Alternatively, IELs could respond directly to foreign antigens such as intact bacteria. However, the precise *in vivo* function of IELs remains elusive. This chapter highlights the most recent findings in this area and presents the current questions being addressed in IEL research.

## II. PHENOTYPE OF INTRAEPITHELIAL LYMPHOCYTES

### A. T-Cell Receptor Expression

As can other T cells, IELs can be subdivided into two classes based on T-cell receptor (TcR) type: those expressing  $\alpha\beta$  TcRs and those expressing  $\gamma\delta$  TcRs. However, mouse small intestinal IELs (Bonneville *et al.*, 1988; Goodman and Lefrancois, 1988) and human large intestinal IELs (Deusch *et al.*, 1991) contain much higher percentages of  $\gamma\delta$  T cells than do other lymphoid sites. Mouse IEL populations can contain 20–80%  $\gamma\delta$  T cells and human large intestinal IEL isolates contain, on average, 37% (range: 13–87%)  $\gamma\delta$  T cells. Human small intestinal IELs are composed of ~10%  $\gamma\delta$  T cells (mean 13% of 28 samples; Jarry *et al.*, 1990), but this percentage is considerably higher than that observed in lamina propria (<1–5%), indicating that  $\gamma\delta$  T cells exhibit a predilection for the intestinal mucosa, regardless of their location along the intestinal tract. Although a monoclonal antibody (MAb) specific for the rat  $\gamma\delta$  TcR has not yet been described, studies using anti-CD3 and anti- $\alpha\beta$  TcR MAbs

suggest that  $\gamma\delta$  T cells constitute 10–50% of rat small intestinal IELs (Viney *et al.*, 1989/1990; Vaage *et al.*, 1990; Fangmann *et al.*, 1991). In addition,  $\gamma\delta$  T cells constitute a large percentage of IELs in the chicken (Bucy *et al.*, 1988) and in ruminants (Hein and MacKay, 1991). The factors controlling IEL subset ratios in the various species are not known. The demonstration that human large intestine contains significantly higher percentages of  $\gamma\delta$  T cells than human small intestine (although these values were not obtained from the same donors) suggests species-specific as well as organ-specific factor involvement in the control of IEL subpopulations.

### B. CD4 and CD8 Expression

An interesting characteristic of IELs is their predominant expression of CD8. In the mouse >90% of IELs are CD8<sup>+</sup>, irrespective of TcR expression (Parrot *et al.*, 1983; Goodman and Lefrancois, 1989). Human TcR  $\alpha\beta$  IELs are primarily CD8<sup>+</sup> but CD4<sup>+</sup>CD8<sup>-</sup> and CD4<sup>-</sup>CD8<sup>-</sup> TcR  $\gamma\delta$  IELs can be detected. Human peripheral blood  $\gamma\delta$  T cells are ~25% CD8<sup>+</sup> whereas human  $\gamma\delta$  IELs are 50–80% CD8<sup>+</sup> (Trejdosiewicz *et al.*, 1989; Jarry *et al.*, 1990; Deusch *et al.*, 1991). Predominant CD8 expression implies that IELs will react with antigen in a class I MHC-restricted fashion, which has been demonstrated for some  $\alpha\beta$  IELs but not for  $\gamma\delta$  IELs (see subsequent discussion).

Although most IELs are CD8<sup>+</sup>, a significant percentage expresses CD4 and CD8 (double positives, DPs). DPs have been noted for mouse (Mosley *et al.*, 1990a; Lefrancois, 1991) and rat IELs (Fangmann *et al.*, 1991). In the latter, 30% of the IELs are CD4<sup>+</sup>CD8<sup>+</sup>. In the mouse, ~10% of  $\alpha\beta$  IELs are CD4<sup>+</sup>CD8<sup>+</sup>, but in some experiments >80% of  $\alpha\beta$  IELs are CD4<sup>+</sup>CD8<sup>+</sup> (Lefrancois, 1991a; Table I). Outside the thymus, the gut is the only site in which substantial numbers of CD4<sup>+</sup>CD8<sup>+</sup> T cells can be found. In contrast to the majority of thymic DPs, intestinal DPs express high levels of TcR. Moreover, intestinal DPs lack the CD8  $\beta$  chain (Ly3), which further distinguishes them from their thymic CD8 $\beta$ <sup>+</sup> counterparts (Lefrancois, 1991a). Double-positive IELs are constitutively cytolytic but do not proliferate in response to anti-TcR MAb stimulation (Gramzinski *et al.*, 1993). Thus, CD4<sup>+</sup>CD8<sup>+</sup> IELs appear functionally mature in some respects. Determining whether intestinal DPs serve as develop-

**Figure 1** Localization of  $\gamma\delta$  intraepithelial lymphocytes (IELs). Frozen sections of mouse small intestine were reacted with the GL3 MAb followed by incubation with a peroxidase-labeled anti-hamster Ig reagent and development with DAB. Arrows indicate IELs. LP, lamina propria.

mental intermediates during IEL differentiation is an area of current study.

### C. T-Cell Differentiation Antigens; A Partial List

#### 1. Thy1

In contrast to the vast majority of other mouse peripheral T cells, a substantial proportion of IELs lacks Thy1 (Parrot *et al.*, 1983). Roughly 20% of  $\alpha\beta$  IELs and 70% of  $\gamma\delta$  IELs are Thy1<sup>-</sup> (Table I). Freshly isolated IELs are constitutively cytolytic, as measured by a redirected lysis assay (Goodman and Lefrancois, 1989). The majority of such cytolytic activity is confined to the Thy1<sup>+</sup> subset of either  $\gamma\delta$  or  $\alpha\beta$  IELs, although some controversy exists over this point (Viney *et al.*, 1989/1990; Guy-Grand *et al.*, 1991a). In our hands, Thy1<sup>+</sup>

IELs exhibit at least 100-fold greater cytolytic activity than Thy1<sup>-</sup> IELs. The IEL population of germ-free mice is composed primarily of  $\gamma\delta$  T cells that are Thy1<sup>-</sup> and weakly or non-cytolytic. After introduction of these animals into non-germ-free conditions, IELs begin to express Thy1 and, simultaneously, become cytolytically active (Lefrancois and Goodman, 1989). Additionally, substantial numbers of  $\alpha\beta$  IELs infiltrate the epithelium and the number of  $\gamma\delta$  IELs increases (Bandeira *et al.*, 1990b; T. Goodman and L. Lefrancois, unpublished results). These results suggest that Thy1 expression and cytolytic activity of IELs are inducible by environmental antigens, likely to be derived from bacteria colonizing the gut. Moreover, gut colonization results in the expansion or the recruitment of  $\alpha\beta$  IELs. Whether these effects are the result of direct activation of IELs via antigen-TcR interactions remains to be demonstrated.

**Table I** Relative Frequencies of Intraepithelial Lymphocyte Subpopulations<sup>a</sup>

TcR $\gamma\delta$ IEL subset	(%)	TcR $\alpha\beta$ IEL subset	(%)
Thy1 <sup>+</sup> CD4 <sup>-</sup> 8 <sup>+</sup> Ly3 <sup>-</sup> CD5 <sup>-</sup>	26 ± 5	Thy1 <sup>+</sup> CD4 <sup>-</sup> 8 <sup>+</sup> Ly3 <sup>+</sup> CD5 <sup>+</sup>	50 ± 17
Thy1 <sup>-</sup> CD4 <sup>-</sup> 8 <sup>+</sup> Ly3 <sup>-</sup> CD5 <sup>-</sup>	74 ± 5	Thy1 <sup>+</sup> CD4 <sup>-</sup> 8 <sup>+</sup> Ly3 <sup>-</sup> CD5 <sup>-</sup>	33 ± 19
		Thy1 <sup>-</sup> CD4 <sup>-</sup> 8 <sup>+</sup> Ly3 <sup>-</sup> CD5 <sup>-</sup>	14 ± 3
		Thy1 <sup>-</sup> CD4 <sup>-</sup> 8 <sup>+</sup> Ly3 <sup>+</sup> CD5 <sup>-</sup>	4 ± 3
		Thy1 <sup>+</sup> CD4 <sup>+</sup> 8 <sup>+</sup> Ly3 <sup>-</sup> CD5 <sup>+</sup>	9 ± 8

<sup>a</sup> IELs from a minimum of eight experiments using at least three mouse strains were analyzed for the expression of the indicated determinants by two- and three-color fluorescence flow cytometry.

We have attempted to duplicate this differentiation scheme *in vitro*. Thy1<sup>-</sup> IELs were purified by fluorescence activated cell sorting (FACS) and stimulated *in vitro* with anti-TcR MAb. In response to anti-CD3 stimulation in the presence of interleukin 2 (IL-2), Thy1<sup>-</sup> noncytolytic IELs proliferated, acquired cytolytic activity, and began to express Thy1 (Figure 2; Gramzinski *et al.*, 1993). However, CD5 and CD8 $\beta$  were not induced by activation. The *in vitro* differentiated population therefore phenotypically resembled the Thy1<sup>+</sup> CD8 $\beta$ <sup>-</sup> CD5<sup>-</sup> IEL subset expressing either TcR subtype (Table I). *In vivo* reconstitution experiments using highly purified IEL subsets will be required to determine whether these results represent an *in vitro* correlate to IEL differentiation *in vivo*.

## 2. CD8 $\beta$

The absence of CD8 $\beta$  (Ly3) on subsets of IELs has been known for some time (Parrot *et al.*, 1983). Multicolor fluorescence analysis has been employed to demonstrate that all  $\gamma\delta$  IELs and ~50% of  $\alpha\beta$  IELs are CD8 $\beta$ <sup>-</sup> (Table I; Lefrançois, 1991a). Human CD8<sup>+</sup>  $\gamma\delta$  IELs are also predominantly CD8 $\beta$ <sup>-</sup> (Jarry *et al.*, 1990). Interestingly, those CD4<sup>-</sup>CD8<sup>-</sup>  $\gamma\delta$  T cells from thymus or spleen that are induced to express CD8 are also CD8 $\beta$ <sup>-</sup>, suggesting that  $\gamma\delta$  T cells in general are unable to synthesize or express CD8 $\beta$  (Cron *et al.*, 1989; MacDonald *et al.*, 1990a).

CD8 exists as a cell-surface complex, usually dimers, of  $\beta$  chains associated with  $\alpha$  or  $\alpha'$  chains (Ledbetter and Seaman, 1982). The  $\alpha'$  chain lacks a portion of the cytoplasmic tail that the  $\alpha$  chain contains, but is otherwise identical to the  $\alpha$  chain. The  $\alpha$  but not the  $\alpha'$  chain is sufficient to allow signal transduction via CD8 (Zamoyska *et al.*, 1989). Since many IELs are CD8 $\beta$ <sup>-</sup>, we determined which  $\alpha$  chain type was expressed by these cells. IELs expressed CD8 $\alpha$  but little CD8 $\alpha'$  compared with thymocytes, which expressed roughly equivalent quantities of  $\alpha$  and  $\alpha'$  (Figure 3; CD8 $\beta$  is difficult to label). These results are worth considering in light of the finding that anti-CD8 MAbs greatly inhibit anti-TcR MAb-triggered CD8<sup>+</sup> lymph node T-cell proliferation, but only

**Figure 2** *In vitro* differentiation of Thy1<sup>-</sup> intraepithelial lymphocytes (IELs). Thy1<sup>-</sup> IELs were purified by removal of Thy1<sup>+</sup> cells by fluorescence-activated cell sorting. Thy1<sup>-</sup> IELs were stimulated *in vitro* with immobilized anti-CD3 in the presence of IL-2 for 5 days. The cells were analyzed for the indicated determinants before and after culture.

marginally inhibit Thy1<sup>-</sup> IELs and do not inhibit Thy1<sup>+</sup> IEL proliferation (see subsequent discussion). This apparent lack of signal transduction does not appear to be the result of the predominant use of  $\alpha'$  chains by IELs or the lack of association of IEL CD8 with the *src*-like kinase p56<sup>lck</sup> that is involved in TcR-CD8 signal transduction (Gramzinski and Lefrançois, unpublished observations).

## 3. CD5

Whereas virtually all peripheral T cells and thymocytes express CD5 to some degree, certain IEL subsets do not. Mouse (Lefrançois, 1991a) and human  $\gamma\delta$  IELs lack CD5 (Trejdosiewicz *et al.*, 1989; Jarry *et al.*, 1990), in contrast to peripheral  $\gamma\delta$  T cells. Further, approximately 50% of mouse, rat (Fangmann *et al.*, 1991), and human  $\alpha\beta$  IELs are CD5<sup>-</sup> (Table I). CD5 expression does not appear to correlate with Thy1 or CD8 $\beta$  expression. The functional significance of the absence of CD5 is unknown. However, a ligand for CD5 has been identified as the CD72/Lyb-2 B-cell surface protein (Van de Velde *et al.*, 1991). Perhaps the lack of IEL CD5 expression reflects the lack of a necessity for IEL-B cell interactions. Alternatively, other IEL-specific interaction molecules may be present but remain unidentified.

## 4. CD45

The CD45 antigens are a family of high molecular weight glycoproteins (170–260 kDa) that are expressed exclusively

**Figure 3** Biochemical analysis of intraepithelial lymphocyte (IEL) CD8. CD8 was immunoprecipitated from surface-labeled thymocytes (lane 2) or IELs (lane 3) and analyzed by SDS-PAGE.

by hematopoietic cells. The intracytoplasmic domain of CD45 is a tyrosine phosphatase thought to play a role in a signal transduction cascade involving CD4/CD8, p56<sup>lck</sup>, and TcR (Clark and Ledbetter, 1989). The function of the CD45 extracellular domain is not known, but the B lymphocyte adhesion molecule CD22 has been shown to interact with T-cell CD45 (Stamenkovic *et al.*, 1991). Eight CD45 isoforms are possible that are generated by alternative mRNA splicing of three exons (4, 5, and 6) near the 5' end of the CD45 gene (Thomas and Lefrancois, 1988). Antigenic determinants encoded by these exons or expressed on subsets of CD45 molecules (e.g., carbohydrate antigens) are termed CD45-restricted determinants (CD45R). Distinct CD45 isoforms are expressed in a developmentally regulated fashion during T-cell differentiation. CD8<sup>+</sup> peripheral T cells can be distinguished from CD4<sup>+</sup> T cells by CD45 isoform type; the CD4<sup>+</sup> subset can be subdivided further by CD45 isoform expression (Lefrancois and Goodman, 1987; Bottomly *et al.*, 1989). In addition to isoforms generated via mRNA splicing, other modifications of CD45 occur that can be detected by MAbs or biochemical analysis. Examples of these modifications are the CT1 and M371 determinants, which are carbohydrate-dependent CD45 epitopes (Lefrancois, 1987; Kilshaw and Baker, 1989). CT1 is expressed by early fetal thymocytes and by activated CD8<sup>+</sup> cytotoxic T lymphocyte (CTL) clones *in vitro*. Interestingly, CT1 is expressed at high levels by a subset of Thy1<sup>-</sup> IELs of either TcR type (Goodman and Lefrancois, 1989). Thus, the only *in vivo* sites of CT1 expression are the fetal thymus and the gut. One could speculate that a functional link exists between CT1 expression in these sites, since T-cell differentiation occurs in the fetal thymus and is likely to occur in the intestinal mucosa (see subsequent discussion).

CD45 isoform expression by human and mouse IELs has been analyzed using MAbs and molecular techniques. Mouse IELs express a 260-kDa isoform that is not generated by mRNA splicing but appears to be the result of hyperglycosylation of the molecule (Goodman *et al.*, 1990). This form is not present in significant quantities on other T cells. The polymerase chain reaction (PCR) and restriction mapping of the resulting products were used to analyze mouse IEL CD45 alternative exon usage. Three mRNA isoforms were detected: one utilizing a single variable exon (exon 5) and two containing two variable exons (exons 4 and 5 or exons 5 and 6). In addition, MAbs specific for exon 4-encoded determinants (generally B-cell specific) react with a subset of IELs.

Human IELs have been shown to express CD45 determinants that generally are associated with activated T cells. The majority of human IELs are CD45RO<sup>-</sup> and CD45RA<sup>-</sup>, in contrast to peripheral T cells which are ~50% CD45RO<sup>+</sup> and ~50% CD45RA<sup>+</sup> (Halstensen *et al.*, 1990). CD45RA<sup>+</sup> T cells are thought to be naive whereas CD45RO cells are memory or activated cells. These results agree with those demonstrating that fresh mouse IELs are constitutively cytolytic, implying that they are activated *in situ*. The antigens involved in this activation process have not been identified.

### 5. IEL-Specific Integrin Expression

The MAb M290 stains ~90% of mouse IELs and ~20% of CD8<sup>+</sup> lymph node T cells, although to a much lower intensity than that obtained with IELs (Kilshaw and Murant, 1990). M290 does not react with significant numbers of CD4<sup>+</sup> lymph node T cells or with B cells. M290 immunoprecipitates from IELs a complex of 3–4 proteins with apparent molecular weights similar to those of previously described integrins. N-Terminal sequences of the mouse M290 120-kDa  $\beta$  subunit and the  $\beta_7$  integrin chain have been shown to be identical (Yuan *et al.*, 1991). However,  $\beta_7$  mRNA expression does not correlate with M290 expression, since B cells and spleen cells have high levels of  $\beta_7$  mRNA. The  $\beta_7$  subunit is likely to be utilized by lymphocytes other than IELs and the M290 MAb is likely to react with the  $\alpha$  subunit of the IEL integrin (Yuan *et al.*, 1991).

Human and rat IELs appear to express a molecular complex similar or identical to that recognized by the M290 MAb. In the human, the HML-1 antigen is expressed by ~90% of IELs but also is found on ~40% of lamina propria T cells, primarily of the CD8<sup>+</sup> subset (Cerf-Bensussan *et al.*, 1987). Outside the intestine, HML-1 is expressed on few lymphoid cells. However, HML-1 is inducible on peripheral blood T cells by mitogen or antigen activation (Schieferdecker *et al.*, 1990). HML-1 has been shown to recognize an antigen identical to that recognized by the MAbs B-ly7, Ber-Act8, and LF61. B-ly7 was generated against a hairy cell leukemia cell line (HCL); all these MAbs react with the majority of HCL lines (Kruschwitz *et al.*, 1991). The MAbs immunoprecipitate a trimeric 150/125/105-kDa complex similar to that immunoprecipitated by M290 from mouse IELs, although M290 also precipitated several proteins of lower  $M_r$ . In the rat, the cellular distribution and biochemical characteristics of the antigens recognized by the RGL-1 MAb are similar to those

of the HML-1 and M290 antigens (Cerf-Bensussan *et al.*, 1986). Interestingly, RGL-1 reacted with a high percentage of rapidly dividing cells in the mesenteric lymph node and the thoracic duct. These cells are thought to be immediate precursors of IELs (probably of the  $\alpha\beta$  TcR type) and other intestinal T cells. Overall, the results indicate that IELs are likely to use adhesion structures that share common subunits with other lymphocyte integrins but also contain subunits restricted in expression to IELs and their precursors. These complexes may be involved in homing of IELs to the gut mucosa or may play a role in IEL adherence to the basement membrane during residence in the gut. Since IELs turn over much less rapidly than the villous epithelial cells that are sloughed into the intestinal lumen every few days, IELs require a specific mechanism to remain in the villi as the epithelium migrates "over" them. Histological analysis generally shows IELs to be closely apposed to the basement membrane, where they may interact specifically with components of that structure.

### III. MATURATION AND SELECTION OF INTRAEPITHELIAL LYMPHOCYTES

#### A. $\gamma\delta$ T Cells

##### 1. Origin

Studies using nude mice and thymectomized bone marrow or fetal liver irradiation chimeras have demonstrated that a significant proportion of mouse  $\gamma\delta$  IELs is extrathymically derived (Bonneville *et al.*, 1990; DeGeus *et al.*, 1990; Lefrancois *et al.*, 1990; Mosley *et al.*, 1990b; Bandeira *et al.*, 1990a; Guy-Grand *et al.*, 1990a). In our hands, Thy1<sup>+</sup> and Thy1<sup>-</sup>  $\gamma\delta$  IELs are generated in ATXBM mice. Thy1<sup>+</sup>  $\gamma\delta$  IELs can be found in some but not all nude mice. These results indicate that Thy1 expression is not necessarily linked to thymic derivation. Prior to T cell colonization of the thymus at 11 days of mouse fetal ontogeny, V $\gamma$ 5 rearrangements (the predominant V $\gamma$  region utilized by IELs) can be detected in fetal gut and liver, indicating that extrathymic  $\gamma$  TcR rearrangement can occur (Carding *et al.*, 1990). In addition, the recombination activating gene 1 is expressed by IELs (subset analysis was not performed), albeit at much lower levels than in thymocytes (Guy-Grand *et al.*, 1991b). Thus, significant extrathymic maturation of  $\gamma\delta$  IELs occurs in the mouse intestine. Studies of rat IELs have demonstrated that the majority are thymus-derived and express the  $\alpha\beta$  TcR (Viney *et al.*, 1989/1990; Vaage *et al.*, 1990; Fangmann *et al.*, 1991). However, a thorough analysis of  $\gamma\delta$  IEL maturation in the rat has not been performed, in part because of the lack of an anti- $\gamma\delta$  TcR MAb. Whether  $\gamma\delta$  IELs mature before or after arrival in the intestine and what other cell types are involved in the maturation (e.g., intestinal epithelial cells) is currently being studied.

##### 2. TcR V Region Expression

Mouse  $\gamma\delta$  IELs express a restricted set of V $\gamma$  and V $\delta$  regions. V $\gamma$ 5 is expressed by 50–80% of  $\gamma\delta$  IELs as detected

by MAb binding. The MAb GL5 is V $\gamma$ 5 specific and reacts with IELs from all mouse strains except four that contain a polymorphism in the V $\gamma$ 5 region that results in a single amino acid change (Goodman *et al.*, 1992). A small percentage of IELs, ~5%, expresses V $\gamma$ 2 whereas V $\gamma$ 3 expression cannot be detected by a V $\gamma$ 3-specific MAb. PCR analysis and DNA sequencing revealed that significant numbers of in-frame V $\gamma$ 4 mRNAs were present in IELs (Asarnow *et al.*, 1989; Takagaki *et al.*, 1989). For the most part, other V $\gamma$  regions do not appear to be utilized by IELs.

The expression of V $\delta$  regions is somewhat more extensive than that of V $\gamma$  regions. Using the MAb GL2, which is V $\delta$ 4-specific, we have shown that V $\delta$ 4 is expressed by 15–60% of  $\gamma\delta$  IELs, depending on the mouse strain (see subsequent discussion). Two-color analysis using the GL5 and GL2 MAbs indicates that virtually all the V $\delta$ 4<sup>+</sup> subset is contained in the V $\gamma$ 5<sup>+</sup> population, whereas significant numbers of V $\gamma$ 5<sup>+</sup>/V $\delta$ 4<sup>-</sup> IELs are observed (L. Lefrancois and T. Goodman, unpublished results). Other V $\delta$ -specific MAbs are not available at this time. However, Northern blot and PCR analysis reveals that V $\delta$ 6 is used frequently whereas V $\delta$ 5 and V $\delta$ 7 are utilized at lower frequencies. V $\delta$ 1, 2, and 3 are not expressed in significant quantities.

Unlike the  $\gamma\delta$  TcRs expressed by dendritic epidermal cells of the skin and the reproductive tract, IEL TcR sequences contain significant junctional diversity. Non-germ-line encoded (NGE) nucleotides and shortened V and J ends are present in the rearranged  $\gamma$  gene sequences, resulting in a great deal of junctional diversity (Asarnow *et al.*, 1989; Takagaki *et al.*, 1989). The various mechanisms for generating junctional diversity are used extensively in  $\delta$  gene rearrangements, including use of multiple D and different J segments, insertion of NGE nucleotides, and imprecise joining. Thus,  $\gamma\delta$  IELs have the potential to react with a large array of antigens, which may be required to respond to the bacteriological load of the intestine.

The genetics of human  $\gamma\delta$  IELs has not been extensively studied. One report claimed that the relative percentages of V $\gamma$ 9<sup>+</sup> and V $\gamma$ 2<sup>+</sup> (these chains preferentially associate) IELs from the small intestine are similar to those present in peripheral blood  $\gamma\delta$  cells (Jarry *et al.*, 1990). Also,  $\gamma\delta$  IELs utilize primarily the non-disulfide-linked form of the TcR, in contrast to peripheral  $\gamma\delta$  cells which use the disulfide-linked form (Spencer *et al.*, 1989). In the colon, an average of 70% of  $\gamma\delta$  IELs uses the V $\delta$ 1 gene segment, compared with 40% of  $\gamma\delta$  peripheral blood T cells (Deusch *et al.*, 1991). Moreover, whereas ~60% of  $\gamma\delta$  peripheral blood T cells uses V $\gamma$ 9 and V $\delta$ 2, only ~20% of colonic IELs expresses these V regions. The J region usage of the V $\delta$ 2<sup>+</sup> IELs was also distinct from that of peripheral  $\gamma\delta$  T cells; the J $\delta$ 1 segment was used much less frequently by IELs than by peripheral  $\gamma\delta$  T cells. The junctional diversity of colonic  $\gamma\delta$  TcRs has not been analyzed.

In sum,  $\gamma\delta$  IELs utilize a restricted subset of V regions and, on rearrangement, significant junctional diversity is generated. Further diversity is produced by differing combinations (e.g., V $\delta$ 4-V $\gamma$ 5; V $\delta$ 6-V $\gamma$ 5). The results from the genetic analysis of human and mouse  $\gamma\delta$  IELs further strengthen the likelihood that a distinct  $\gamma\delta$  lineage exists that preferentially localizes to the intestinal mucosa.

### 3. $\gamma\delta$ TcR Selection

Although the preferential use of V regions suggests an ongoing selection process, such a mechanism has not been demonstrated. However, in the case of  $V\delta 4^+$  mouse IELs, extrathymic positive or negative selection can occur (Lefrancois *et al.*, 1990). Using recombinant inbred and congenic mouse strains we demonstrated that positive selection of  $V\delta 4^+$  IELs is dependent on the presence of Class II MHC I-E molecules, particularly I-E<sup>k</sup>.  $V\delta 4^+$  IELs increase from ~30% in I-E strains to ~60% of total  $\gamma\delta$  IELs in I-E<sup>k</sup> strains. However, IELs from AKR/J mice (also I-E<sup>k</sup>) are of the  $V\delta 4^{\text{low}}$  phenotype. We have shown that this phenotype is the result of an active negative selection of  $V\delta 4^+$  IELs in this strain (L. Lefrancois, unpublished results). Non-MHC antigens appear to be involved in  $V\delta 4^+$  IEL selection, but these antigens have not been identified. Many instances of I-E-dependent selection of T cells expressing various  $V\beta$  regions have been reported; in many cases, retroviral superantigens derived from mouse mammary tumor virus are responsible for the selection (reviewed by Acha-Orbea and Palmer, 1991). Perhaps viral or bacterial superantigens are involved in  $\gamma\delta$  IEL selection as well.

An interesting aspect of  $V\delta 4^+$  IEL selection is the fact that the selection requires Class II MHC expression but the selected IELs are  $CD8^+$ . Although  $CD8^+$  IELs might be expected to be Class I MHC restricted, selection by MIs (i.e., viral superantigens) also has been shown for peripheral  $CD8^+$   $\alpha\beta$  T cells to be Class II I-E dependent (MacDonald *et al.*, 1990b). Thus, superantigen selection appears to bypass the normal accessory molecule restriction of a particular T cell subset, yet data obtained from mice lacking Class I MHC because of disruption of the  $\beta$ -2 microglobulin gene also should be considered. IELs from these animals contain apparently normal numbers of  $CD8^+$   $\gamma\delta$  T cells, whereas  $CD8^+$   $\alpha\beta$  IELs are essentially absent (Raulet *et al.*, 1991). Moreover, IELs from these mice express their normal complement of TcR V regions. Thus, Class I MHC does not appear to be involved in the generation of  $\gamma\delta$  IELs, but this finding does not preclude the possibility that  $\gamma\delta$  IELs react with antigens in the context of Class I MHC. Since these cells do not mature in the thymus where most Class I MHC-based selection occurs, alternative selection mechanisms are likely to be in place for  $\gamma\delta$  IELs.

The latter possibility is strengthened by studies of IELs in mice expressing an alloantigen-specific transgenic  $\gamma\delta$  TcR (Barrett *et al.*, 1992). In mice expressing this transgene and the selecting alloantigen,  $\gamma\delta$  T cells are deleted in the thymus and spleen. However, IELs with normal receptor levels are present in these animals that are unresponsive to activation. As the mice age, these anergic self-reactive IELs gradually diminish in number. Thus, selection of  $\gamma\delta$  T cells in epithelial tissue appears to be dependent on induction of clonal anergy with eventual deletion.

#### B. $\alpha\beta$ T Cells

##### 1. Origin

In contrast to  $\gamma\delta$  IELs, most  $\alpha\beta$  IELs require the thymus for maturation. However, some variable extrathymic produc-

tion of  $\alpha\beta$  IELs appears to occur. In thymectomized irradiated bone marrow chimeras, significant numbers of donor-derived  $\alpha\beta$  IELs were detected in some animals but not in others. In nude mice,  $\alpha\beta$  IELs are found rarely (Bandeira *et al.*, 1990b; Bonneville *et al.*, 1990; DeGeus *et al.*, 1990) although an occasional preparation can contain large numbers of these cells (L. Lefrancois, unpublished results).

A putative "thymoindependent"  $\alpha\beta$  population has been proposed to exist in the gut (Murosaki *et al.*, 1991; Rocha *et al.*, 1991). This contention is based on the finding that certain  $V\beta$  regions that are not found on peripheral T cells are expressed by a subset of IELs (reviewed by Lefrancois, 1991c). Lack of deletion in the IEL compartment was considered evidence that these cells do not mature in the thymus. The forbidden V regions are expressed by  $CD8\beta^-$  IELs but not by  $CD8\beta^+$  IELs supporting the concept that the  $CD8\beta^-$   $\alpha\beta$  TcR subset is derived extrathymically. However, the data from nude mice and thymectomized chimeras must be considered. Since few  $\alpha\beta$  T cells generally are found in nude mice, the  $CD8\beta^-$  subset may be more likely to require some thymic influence, perhaps via interaction with thymus-derived  $CD8\beta^+$   $\alpha\beta$  IELs or other T cells. Alternatively, these forbidden clones could traffic through the thymus and escape deletion only to be tolerized in the periphery. In this regard, whether IELs expressing forbidden V regions are functional has not been shown. Further studies of this intriguing subset are required to understand their origin and function.

##### 2. $\alpha\beta$ TcR Selection

As just discussed,  $V\beta$  selection in the gut does not necessarily occur as predicted by the selection patterns of other peripheral T cells. To understand in more detail the relationship between  $CD8\beta$  expression and V region selection, we analyzed  $CD4^+CD8^+$  IELs that are  $CD8\beta^-$ . Table II shows the results of analysis of  $V\beta 6$  and  $V\beta 14$  expression in  $CD4^-CD8^+$  and  $CD4^+CD8^+$  IELs compared with lymph node T cells. The interesting result is that, although  $V\beta 6$  was expressed in  $CD4^-CD8^+$  IELs, it was deleted from lymph node T cells as well as from  $CD4^+CD8^+$  IELs. Most  $V\beta 6^+$  IELs were found in the  $CD8\beta^-$  subset (data not shown).  $V\beta 14$  was expressed in all lymph node and IEL subsets. These results indicate that  $CD8\beta$  expression (or lack of it) is not sufficient to explain the expression of forbidden V regions. A thorough analysis of several  $V\beta$  regions in various mouse strains confirmed these findings and also demonstrated other nonpredicted selection patterns (Badiner *et al.*, 1993).

Data from studies of human  $\alpha\beta$  IELs indicate that a restricted subset of V regions is expressed by IELs compared with peripheral blood T cells (Balk *et al.*, 1991; Van Kerckhove *et al.*, 1991). In two independent studies, V region analysis demonstrated that IELs were oligoclonal, expressing predominant V regions, some of which were shared among IELs of different individuals. In one study, an oligoclonal T-cell line and a clone expressing a dominant V region were shown to react with CD1, a nonpolymorphic Class I-like molecule (see subsequent discussion). Oligoclonal expansion was proposed to occur in response to a restricted set of antigens, some of which may be nonpolymorphic.

**Table II** TcR V $\beta$  Expression in Intraepithelial Lymphocytes and Lymph Node Subsets<sup>a</sup>

V $\beta$	% Positive			
	Lymph node subset		IEL subset	
	CD4	CD8	CD4 <sup>-</sup> 8 <sup>+</sup>	CD4 <sup>+</sup> 8 <sup>+</sup>
6	0.5 $\pm$ 0.4	0.5 $\pm$ 0.2	4.7 $\pm$ 2.5	0.5 $\pm$ 0.4
14	9.5 $\pm$ 0.4	18.6 $\pm$ 4.9	10.6 $\pm$ 5.7	6.9 $\pm$ 2.5

<sup>a</sup> AKR/J IELs were isolated and expression of the indicated antigens was tested by three-color fluorescence flow cytometry.

### C. Epithelial Cell Involvement

Since most  $\gamma\delta$  IELs and perhaps a subset of  $\alpha\beta$  IELs (at least in the mouse) mature outside the thymus, several investigators have proposed the involvement of the intestinal epithelium in IEL differentiation. Thymic and gut epithelium are endoderm derivatives and have several similar characteristics. Villous epithelium constitutively expresses MHC Class II molecules; this expression can be up-regulated by lymphokines such as interferon  $\gamma$  (IFN $\gamma$ ; reviewed by Bland, 1988). Intestinal epithelial cells are able to process and present antigen to Class II-restricted T cells, although whether IELs respond to epithelium-presented antigen is not known.

Several studies have suggested that  $\gamma\delta$  T cells in general may react with nonpolymorphic antigens such as heat-shock proteins or Class I-like molecules such as CD1 or TLA. The demonstration that TLA in the mouse and CD1 in the mouse and the human are expressed prominently by intestinal epithelial cells supports this theory (Bleicher *et al.*, 1990; Hershberg *et al.*, 1990). TLA also is expressed by ~50% of  $\alpha\beta$  IELs and ~25% of  $\gamma\delta$  IELs and is predominantly expressed by the Thy1<sup>-</sup> subset (Hershberg *et al.*, 1990). TLA and CD1 exhibit restricted expression patterns, with predominant expression in the intestine, suggesting an important role for these molecules in intestinal immunity. Although  $\alpha\beta$  IEL reactivity to CD1 has been demonstrated, as discussed earlier,  $\gamma\delta$  IEL reactivity to nonclassical MHC molecules has not been reported.

## IV. FUNCTIONAL PROPERTIES

### A. Cytolytic Activity

Freshly isolated CD8<sup>+</sup> mouse IELs are constitutively cytolytic but do not possess natural killer activity. This activity is confined largely to the Thy1<sup>+</sup> subset;  $\gamma\delta$  and  $\alpha\beta$  IELs are cytolytic. The cytolytic activity is measured using a redirected lysis assay in which IELs are reacted with an anti-TcR MAb followed by incubation with a radiolabeled target cell that expresses an Ig Fc receptor. In this way, a measure of total cytolytic capability is obtained irrespective of the specificity of the effector cell. Since CD8<sup>+</sup> lymph node T

cells are negative in this assay, IELs are assumed to be activated *in situ* by the supposed constant antigenic bombardment of the intestinal mucosa. This theory is supported by the finding that colonization of the gut induces Thy1 expression and cytolytic activity in IELs. However, a specific target cell for IEL cytolytic activity has not been found. IELs did not lyse a panel of tumor target cells and also did not lyse antigen-presenting cells (not derived from gut) that were preincubated with bacterial lysates (T. Goodman and L. Lefrancois, unpublished results). Thus, either the correct antigenic moiety has not been tested or the antigen-presenting cell employed was lacking in a necessary component. "Preactivated" IELs may recognize antigen only as presented by intestinal epithelium. Purified CD8<sup>+</sup> IELs do not exhibit natural killer activity.

TcR  $\alpha\beta$  IELs can be primed against alloantigen or viral antigen (Ernst *et al.*, 1986; London *et al.*, 1989; Offit and Dudzik, 1989; Lefrancois, 1991b). Reovirus infection results in the generation of MHC-restricted virus-specific cytolytic Thy1<sup>+</sup> TcR  $\alpha\beta$  IELs. TcR  $\gamma\delta$  IELs do not respond to reovirus antigens. However, whether resident  $\alpha\beta$  IELs respond to viral challenge or whether other T cells infiltrate the mucosa after infection is not clear. A cytolytic CD1-specific human IEL line has been produced by stimulation of jejunal IELs with phytohemagglutinin (PHA), lymphokines, and allogeneic peripheral blood lymphocytes (Balk *et al.*, 1991). Thus, at least some  $\alpha\beta$  IELs have characteristics of classical cytotoxic T lymphocytes. The specificity of  $\gamma\delta$  IELs remains unknown.

### B. Proliferative Capacity

Several reports indicate that IELs respond poorly or not at all to proliferative signals including mitogens, phorbol esters, or anti-TcR MAb (Ebert, 1989; Mowat *et al.*, 1989; Mosley *et al.*, 1991). However, we routinely maintain IELs in culture for several weeks after stimulation with anti-TcR MAb. In our hands, culture of Thy1<sup>+</sup> IELs with immobilized anti-CD3 or anti- $\gamma\delta/\alpha\beta$  MAb results in significant proliferation (Gramzinski *et al.*, 1993). Proliferation is the result of an IL-2-IL-2 receptor autocrine pathway, yet the maximum proliferation of IELs is 10–20% of that obtained with CD8<sup>+</sup> lymph node cells (Figure 4). Thy1<sup>-</sup> IELs proliferated significantly less than Thy1<sup>+</sup> IELs in response to anti-TcR stimulation, but proliferation was enhanced by the addition of IL-2 to the cultures (Figure 4). Interestingly, the addition of anti-CD8 MAbs to the cultures strongly inhibits CD8<sup>+</sup> lymph node T-cell proliferation but only marginally affects IEL proliferation (Gramzinski *et al.*, 1993). This result suggests that IEL CD8 is functionally distinct or that the IEL CD8 signal transduction pathway differs from that of peripheral T cell CD8. Overall, the results indicate that IELs are able to respond to proliferative signals but to a reduced level compared with lymph node T cells. This phenomenon could be the result of down-regulation of proliferative pathways by continuous antigenic stimulation or the result of our lack of knowledge of the growth requirements of IELs.

**Figure 4** Proliferative capacity of intraepithelial lymphocytes (IELs). Thy1<sup>+</sup> (top) or Thy1<sup>-</sup> (middle) CD4<sup>+</sup>CD8<sup>+</sup> IELs or CD4<sup>-</sup>CD8<sup>+</sup> lymph node (bottom) T cells were stimulated *in vitro* for 3 days with immobilized anti-CD3, anti- $\alpha\beta$  TcR (H57), or anti- $\gamma\delta$  TcR (GL4) MAb in the absence (solid bars) or presence (hatched bars) of recombinant IL-2. Cells were pulsed with [<sup>3</sup>H]thymidine for the final 24 hr of culture followed by harvesting and scintillation counting. n.d., Not done.

### C. Lymphokine Production

IELs produce an array of lymphokines similar to those produced by other CD8<sup>+</sup> T cells. *In situ* analysis demonstrates that IELs produce IFN $\gamma$  and IL-5 (Taguchi *et al.*, 1990). Analysis of culture supernatants from anti-TcR MAb-activated  $\gamma\delta$  or  $\alpha\beta$  IELs indicates that both subsets produce IL-2, IFN $\gamma$  and transforming growth factor  $\beta$  (TGF $\beta$ ) but do not produce IL-4 (Barrett *et al.*, 1990). The role of IEL lymphokine production in intestinal immune responses remains to be elucidated.

### D. Regulatory Role for $\gamma\delta$ IEL?

Some intriguing data have been reported suggesting that  $\gamma\delta$  T cells, including IELs, may function as regulatory cells (Fujihashi *et al.*, 1989, 1990). Using a system of oral tolerance to sheep red blood cells (SRBC), these authors demonstrated that transfer of antigen-primed CD4<sup>-</sup>CD8<sup>-</sup> splenic  $\gamma\delta$  T cells from nude mice or  $\gamma\delta$  IELs from normal mice can reverse oral tolerance. This function was attributed to Thy1<sup>-</sup>  $\gamma\delta$  IELs of either CD4<sup>-</sup>CD8<sup>+</sup> or CD4<sup>-</sup>CD8<sup>-</sup> phenotype. This phenomenon has not been reported for other antigens, and whether the antigen-primed  $\gamma\delta$  T cells can respond to SRBCs has not been shown. Significant efforts should be applied to determining whether this function is generalized and to analyzing the specificity of such regulatory cells.

## V. SUMMARY

The complexity of the IEL compartment rivals that found in the thymus. Indeed, mounting evidence suggests that the intestine may be a lymphocyte generative organ analogous in some ways to the thymus. In the case of  $\gamma\delta$  IELs, clearly extrathymic maturation occurs. Although this pathway has not been proven to exist in humans, it seems likely based on the phenotypic similarities between mouse and human  $\gamma\delta$  IELs that distinguish them from peripheral  $\gamma\delta$  T cells. Restricted V gene usage by IELs suggests that their surveillance capabilities are skewed toward a discrete set of antigens that is likely to be tissue specific. The TcRs expressed appear to be polyclonal, based on junctional sequences.

TcR  $\alpha\beta$  IELs also appear to express a restricted set of V regions preferentially. However, skewing toward particular V region usage appears to be the result of oligoclonal expansion of certain IEL clones, perhaps in response to a limited array of antigens. For a subset of  $\alpha\beta$  IELs that expresses forbidden V regions, the TcR selection process is distinct from that of conventional CD8<sup>+</sup> T cells, including other IELs. Whereas most  $\alpha\beta$  IELs are thymus derived, the role of the thymus in the production of forbidden  $\alpha\beta$  IEL clones is unclear.

Although much progress has been made in the areas of IEL phenotypic characterization, *in vitro* functional assays, and TcR expression, the specificity and function of IELs *in vivo* remains obscure. At least some  $\alpha\beta$  IELs can respond to antigens such as viral proteins in a conventional MHC-restricted cytotoxic T-lymphocyte response. The function of the  $\alpha\beta$  T-cell subsets that are unique to the IEL compartment, for example, the CD4<sup>+</sup>CD8<sup>+</sup> IELs, remains to be determined. With respect to  $\gamma\delta$  IELs, no defined "conventional" responses for  $\gamma\delta$  T cells are known. We are hard-pressed to define specific functions at this time. Except for assumptions concerning function made based on phenotype and anatomical location, little substantive progress has been made. The development of novel *in vivo* and *in vitro* assays may be required before a breakthrough is realized in the area of IEL function.

### Acknowledgments

I would like to thank Gloria Badiner, Tom Goodman, Rozenne LeCorre, and Robert Gramzinski for their perseverance in generating much of the data presented from our laboratory. I also thank Earl Adams for his expert assistance with flow cytometry.

# IgE-Mediated Responses in the Mucosal Immune System

*Kimishige Ishizaka*

## I. INTRODUCTION

IgE is the least component of immunoglobulins. The concentration of IgE in the serum of normal individuals is on the order of 100–300 ng/ml. However, IgE antibodies have unique biological activities. The antibodies sensitize mast cells and basophilic granulocytes of homologous species; the reaction of antigen to cell-bound IgE antibodies induces the release of various mediators that cause allergic reactions. Under normal circumstances, allergic diseases are induced by exposure to extrinsic antigens such as allergens. Therefore, IgE-mediated allergic diseases are induced most frequently in the respiratory tract, gastrointestinal tract, and skin. Since the IgE antibody response also is induced by allergens, conceivably IgE antibodies formed in mucosal lymphoid tissues may play important roles in allergic diseases. Indeed, IgE-producing cells are detected more frequently in mucosal lymphoid tissues than in the major lymphoid organs such as spleen and peripheral lymph nodes (Tada and Ishizaka, 1970). High frequency of IgE-producing cells in mucosal lymphoid tissues appears to be the result of local immune response to extrinsic antigens. Different from IgA, IgE in secretions does not contain secretory component (SC) and has the same physicochemical properties as IgE present in the serum (Newcomb and Ishizaka, 1970). To date, mechanisms of the IgE antibody response and IgE-mediated hypersensitivity reactions have been studied in experimental models using splenic lymphocytes, peritoneal or bone marrow-derived mast cells, and peripheral blood basophilic granulocytes. In this chapter, the fundamental mechanisms of IgE-mediated responses, which were elucidated using these systems, are summarized briefly with some attention to mucosal immune systems.

## II. BASIC MECHANISMS INVOLVED IN THE IgE ANTIBODY RESPONSE

### A. Dissociation between the IgE and IgG Antibody Response

In atopic patients, IgE antibody levels in serum do not show much fluctuation. Considering that the half-life of IgE

in normal individuals is 2–3 days, formation of IgE antibodies appears to be persistent in these patients. Although the quantity of allergen inhaled by the patients during a pollen season is on the order of micrograms, the IgE and IgG antibody levels in their serum increase after the season and the antibody levels are well maintained during the remainder of the year (Ishizaka, 1976). Another unique characteristic of atopic patients is a relatively high concentration of IgE antibodies among various isotypes. Unless the patients receive immunotherapy, the concentration of IgE antibodies against allergen in their serum is comparable to that of IgG antibodies and usually higher than that of IgA antibodies. Considering that the concentration of total serum IgE is less than 1/10,000 of the concentration of total IgG, the immune response of atopic patients to allergens includes some conditions favorable for the IgE isotype.

A series of experiments in inbred strains of mice revealed that persistent IgE antibody formation was obtained only when genetically high responder strains were immunized with a minute dose of a potent immunogen and an appropriate adjuvant (Ishizaka, 1976). An increase in the dose of the immunogen resulted in an increase in the magnitude of IgG antibody response, but made the IgE antibody response transient and caused dissociation of the IgE antibody response and IgG antibody response.

As expected, the IgE antibody response appears to be controlled by immune response (Ir) genes that are linked to the major histocompatibility complex (MHC). However, an entirely different type of genetic control was found in the mouse that uniquely controls the IgE isotype. For example, SJL and AKR mice showed a poor IgE antibody response to various protein antigens despite a substantial IgG antibody response to the same antigen (Levine, 1971). This genetic control provides another restriction for the persistent IgE antibody formation and causes dissociation of IgE antibody response and IgG antibody response.

### B. Role of IL-4 in IgE Synthesis

The IgE antibody response is highly T cell dependent, suggesting that T cell-derived lymphokines are involved in the differentiation of B cells to IgE-forming cells. Indeed, results of experiments by several groups of investigators revealed that interleukin 4 (IL-4) from helper T cells is essential

to IgE production. That stimulation of mouse B cells with lipopolysaccharide (LPS) results in the differentiation of B cells and the formation of a variety of Ig isotypes except IgE is well known. However, culture of the same B cells with LPS and 300–1000 units/ml recombinant IL-4 results in the formation of IgE and selective enhancement of IgG1 formation, accompanied by decreases in IgG2b and IgG3 formation (Coffman *et al.*, 1986). The concentration of IL-4 required for switching of B cells for IgE synthesis was much higher than the physiological concentration. However, addition of IL-5 with IL-4 diminished the minimum concentration of IL-4 required for IgE synthesis to 5–10 units/ml.

The effect of IL-4 on IgE synthesis also was demonstrated in *in vitro* immunoglobulin formation by human peripheral blood mononuclear cells (PBMC) (Pene *et al.*, 1988). Culture of normal human PBMCs with 100 units/ml human IL-4 resulted in the formation of IgE. IL-4 also induced IgG4 synthesis. For the formation of IgE by normal human B cells, however, both T cells and monocytes are required (Pene *et al.*, 1988). Additional studies have shown that interaction of B cells with T cells is required for IL-4-induced IgE synthesis by normal B cells (Vercelli *et al.*, 1989; Parronchi *et al.*, 1990).

The major effect of IL-4 on IgE synthesis is switching of resting B cells to the precursors of IgE-forming cells that bear surface IgE. Culture of pure murine B cells with LPS and IL-4 resulted in the appearance of IgE-bearing B cells and IgG1-bearing B cells; depletion of sIgE<sup>+</sup> B cells developed in the culture abolished IgE formation in the system (Snapper *et al.*, 1988). The mechanism for isotype switching is the deletion of immunoglobulin gene segments. Yoshida *et al.*, (1990) characterized immunoglobulin switch circular DNA present in lymph nodes of mice infected with the nematode *Nippostrongylus brasiliensis* and in normal splenic lymphocytes cultured with LPS and IL-4, and identified two kinds of circular DNA as excision products of switch recombination of immunoglobulin heavy-chain constant region genes. One of them was a recombinant between C $\mu$  and C $\gamma$ 1, and the other was a recombinant between C $\gamma$ 1 and C $\epsilon$  (Figure 1). Such circular DNA was not detected when spleen cells were cultured with LPS alone. Further, no  $\epsilon$  circles were identified for the switch from C $\mu$  to C $\epsilon$ . Thus, in the IL-4-mediated class switch, switch recombination appears to occur in a successive manner, first from C $\mu$  to C $\gamma$ 1 and then from C $\gamma$ 1 to C $\epsilon$ . Detection of switch circular DNAs supports the notion that IL-4 triggers the switch recombination rather than selects the preswitched cells for  $\epsilon$ . Indeed, IL-4 induces germ-line  $\epsilon$  chain transcription in normal B cells (Geronclakis, 1990); however, IL-4 alone is not sufficient for the formation of switch circular DNA. More recently, similar findings were obtained in human lymphocyte systems. Induction of  $\epsilon$  switching occurs through a recombination deletion event. In the human system, however, switching might occur in successive steps from IgM to IgG4 and IgG4 to IgE (Gascan *et al.*, 1991). Not only IL-4 but also T cell–B cell interaction is required for switching (Vercelli *et al.*, 1987). The relative contributions of IL-4 and CD4<sup>+</sup> T cells to the switching remain to be determined. However, direct T cell–B cell interactions were reported to provide the first signal, which is

**Figure 1** Successive switch recombination from  $\mu$  to  $\gamma$ 1 (a), and then from  $\gamma$ 1 to  $\epsilon$  (b or c). Two kinds of switch circular DNAs are detected; one is from the recombination between C $\mu$  and C $\gamma$ 1; the other is between C $\gamma$ 1 and C $\epsilon$ . In some  $\epsilon$  switch circles (b), S $\mu$  sequence is inserted between S $\epsilon$  and S $\gamma$ 1, indicating that the S $\mu$  sequences in the  $\gamma$ 1 gene were used for recombination with S $\epsilon$ . In the other  $\epsilon$  circle, no S $\mu$  sequence was retained on the excision product (c). Reprinted with permission from Yoshida *et al.* (1990).

required for initiating B cells to respond to IL-4, and IL-4 was reported to direct switching to IgG4 and IgE (Vercelli *et al.*, 1989).

### C. Suppression of IgE Synthesis by Antagonists to IL-4

The effect of IL-4 on B cells has been shown to be counteracted by interferon  $\gamma$  (IFN $\gamma$ ). This cytokine inhibits not only the IL-4-induced increase in Ia expression and Fc $\epsilon$ R2 expression on resting B cells, but also the formation of IgE and IgG1 by B cells stimulated with LPS plus IL-4 (Coffman and Carty, 1986). The IL-4-induced formation of IgE by human PBMC also was inhibited by IFN $\gamma$  or IFN $\alpha$  (Pene *et al.*, 1988). These findings suggest that the proportion among various cytokines in the environment of B cells may affect the distribution of antibodies among various isotypes.

As expected, *in vitro* IgE synthesis by murine B cells stimulated by IL-4 and LPS could be inhibited by monoclonal anti-IL-4. Suppressive effects of the monoclonal antibody or IFN $\gamma$  suggested the possibility that anti-IL-4 or IFN $\gamma$  might be effective in suppressing *in vivo* IgE synthesis. Indeed, an intraperitoneal injection of 20 mg monoclonal anti-IL-4 into BALB/c mice resulted in suppression of IgE synthesis in-

duced by infection of *Nippostrongylus brasiliensis* (Finkelman *et al.*, 1986). Similarly, an intravenous iv injection of anti-IL-4 suppressed the secondary IgE antibody response of mice to a protein antigen as well as the on-going IgE antibody formation. The results support the concept that IL-4 is required for the IgE antibody response. However, that an injection of 1–2 mg anti-IL-4 into mice failed to affect the IgE synthesis is rather surprising. Results of an attempt to suppress *in vivo* IgE synthesis with IFN $\gamma$  were also discouraging. In the experiment carried out by Finkelman *et al.* (1988), enhanced IgE and IgG1 formation was induced by injecting goat antimouse IgD antibodies; the anti-IgD-treated mice received intraperitoneal injections of 12,500–50,000 u IFN $\gamma$  twice daily for 3 days. The results showed that the treatment with 25,000 u or more of IFN $\gamma$  per injection reduced both IgE and IgG1 levels to one-fifth to one-tenth; however, 6250 u of IFN $\gamma$  per injection did not have a significant effect on IgE and IgG1 synthesis. The quantities of IFN $\gamma$  required to regulate the IgE synthesis appear to be too much for clinical purposes. Indeed, clinical application of IFN $\gamma$  for the treatment of hay fever was unsuccessful. Li *et al.* (1990) injected up to 0.2 mg recombinant IFN $\gamma$  3 times a week to rhinitis patients who were allergic to ragweed. After 4 weeks of treatment, however, no effect was observed in weekly symptom score or serum IgE antibody titer. Another course of the same treatment was given to the same patients prior to ragweed season; however, the treatment gave no significant effect on the IgE antibody titer and failed to suppress the secondary IgE antibody response observed after the ragweed season.

#### D. Requirement of IL-4-Producing Helper T cells for IgE Synthesis

As described earlier, the persistent IgE antibody response is obtained only when high responder mice were immunized with a minute dose of a potent immunogen. Since this dose of antigen with antigen-presenting cells is not sufficient to stimulate helper T cells for IL-4 or IL-2 production, one may speculate that differentiation of B cells to IgE-forming plasma cells is triggered by cognate interaction between antigen-specific helper T cells and B cells rather than by bystander effects of IL-4. If cognate interaction is the mechanism, anti-IL-4 or IFN $\gamma$  has much less chance of preventing the effect of helper T cells.

Mosmann *et al.* (1986) described that mouse helper T-cell clones can be classified into two subtypes, Th1 and Th2, that produce different interleukins on antigenic stimulation. Both subtypes express Lyt 1 and L3T4; however, Th1 produces IL-2, IFN $\gamma$ , and lymphotoxin whereas Th2 produces IL-4 and IL-5. Coffman *et al.* (1988) found that both Th1 and Th2 clones can provide help to B cells under appropriate conditions; however, important differences are seen in the Ig isotypes produced by B cells in response to the different T-cell subsets. These investigators employed rabbit IgG-specific helper T-cell clones, and induced polyclonal activation of normal B cells by coculture of the B cells and the Th clone with rabbit antimouse Ig antibodies. As shown in Table

**Table I** Isotype Distribution of Polyclonal Response of Normal B Cells to RGG-Specific Helper T Cell Clones<sup>a</sup>

Isotype	Th2 (ng/ml)	Th1 (ng/ml)	Th1 + IL-2 + anti-IFN $\gamma$ (ng/ml)
IgM	98,000	248	65,000
IgE	187	<1	<1
IgA	487	<1	825
IgG <sub>1</sub>	21,600	<8	5280
IgG <sub>2a</sub>	39	14	2760
IgG <sub>2b</sub>	189	<8	135
IgG <sub>3</sub>	354	<8	474

<sup>a</sup> Reprinted with permission from Coffman *et al.* (1988).

I, these researchers found that the Th2 clone gave much better help than the Th1 clone for the production of Ig. The major Ig produced by the B cells with the Th2 clone were IgM and IgG1, but a substantial quantity of IgE also was produced in the culture. In contrast, the same B cells failed to form IgE when they were cultured with the Th1 clone. Since IFN $\gamma$  suppresses Ig formation, these investigators added anti-IFN $\gamma$  antibody and supplemented the Th1 system with IL-2. Under these conditions, substantial amounts of IgM, IgG1, and IgG2a were produced, but IgE was not detected in the culture supernatant (c.f. Table I). However, the addition of IL-4 to the Th1 system resulted in the formation of IgE. These results show that Th2 cells, which form IL-4, are essential for IgE synthesis. Accumulated evidence suggests that the Th1 and Th2 subsets do not represent distinct lineages, and a single helper T cell can develop into either Th1 or Th2 (Swain *et al.*, 1990). For example, Gajewski *et al.* (1989) have shown that Th1 clones developed when antigen-primed lymph node cells were activated by antigen and then propagated in the presence of IFN $\gamma$ , whereas propagation of the same antigen-activated lymph node cells by recombinant IL-2 alone resulted in preferential development of Th2 clones. Also, the presence of IL-4 during the propagation of antigen-activated cells facilitated the development of Th2 clones (Fernandez-Botran *et al.*, 1988).

In contrast to the murine system, human helper T-cell clones cannot be classified into Th1 and Th2 subtypes (Paliard *et al.*, 1988). Some helper cell clones form IL-2, IL-4, and IFN $\gamma$ . Romagnani *et al.* (1989) reported that the frequency of IL-4-producing Th clones is higher in atopic patients than in nonatopic individuals. More recently, however, the same investigators found that the frequency of IL-4-producing Th clones also depends on the immunogen (Parronchi *et al.*, 1991). These investigators have isolated Th clones specific for allergen, and those specific for the other immunogens such as tetanus toxoid or purified protein derivative (PPD) of tubercle bacilli, from peripheral blood of the same atopic patients and have examined profiles of interleukin production by each clone. The researchers found that the majority of Th clones specific for allergen produced IL-4 alone or IL-4 with a limited amount of IFN $\gamma$ , whereas essentially all T-cell

clones specific for bacterial antigen produced both IL-4 and IFN $\gamma$ . When the T-cell clones were cultured with autologous B cells and respective antigen, IgE synthesis was observed only with Th clones that can produce IL-4 alone or IL-4 with a limited amount of IFN $\gamma$ . The reasons for the differences in the profiles of interleukin production among allergen-specific Th cells and bacterial antigen-specific Th cells are not known. However, the results indicate that repeated natural exposures to an allergen provide favorable conditions for the development of Th2-like helper cells or that mucosal tissues provide a favorable environment for the development of IL-4-producing helper T cells (see Chapters 19 and 20).

### III. IgE-MEDIATED ALLERGIC REACTIONS

#### A. Structural Basis of Sensitization of Mast Cells with IgE Antibodies

The most important immunological property of IgE antibody is the ability to sensitize homologous tissues for reaginic hypersensitivity reactions. This ability is a common property for IgE for all mammalian species in which this immunoglobulin isotype has been described. Sensitization of homologous tissues with IgE is the result of its binding to mast cells and basophils. Indeed, IgE binds to normal basophils and mast cells with high affinity. As shown in Table II, the number of receptors (Fc $\epsilon$ RI) per mast cell and basophil granulocyte is  $2\text{--}3 \times 10^5$  per cell. The forward rate constant ( $k_1$ ) and dissociation constant ( $k_{-1}$ ) for the binding of IgE to the receptors are on the order of  $1\text{--}2 \times 10^5 M^{-1} \text{sec}^{-1}$  and  $2\text{--}10 \times 10^{-5} \text{sec}^{-1}$ , respectively. Thus, the equilibrium constant ( $K_A$ ) between IgE and the receptors is on the order of  $10^9$  to  $10^{10} M^{-1}$  (Ishizaka, 1985). As shown in Table II, these values are comparable for human and rodent IgE. It is well known that an optimal latent period for skin sensitization by IgE antibodies is 1 to 3 days and that the sensitization with IgE antibodies persists for a long period of time. High affinity of IgE for Fc $\epsilon$ RI and a low dissociation constant between IgE and the receptors on mast cells explains why a minute

dose of IgE antibodies can sensitize homologous tissues and why the sensitization with the antibodies is so persistent.

IgE binds to mast cells and basophils through the Fc portion of the molecule. The affinity of the Fc fragments of E myeloma protein for Fc $\epsilon$ RI was comparable to that of native IgE molecules. Application of recombinant gene technology led to cloning of the human  $\epsilon$  chain gene. Recombinant Fc $\epsilon$  chain fragments blocked passive sensitization of human skin to Prausnitz-Küstner reactions and could sensitize cultured human basophils for anti-IgE-induced histamine release (Ishizaka *et al.*, 1986). Indeed, recombinant Fc $\epsilon$  peptide, in the dimeric form, and native IgE had comparable affinity for Fc $\epsilon$ RI on human basophils.

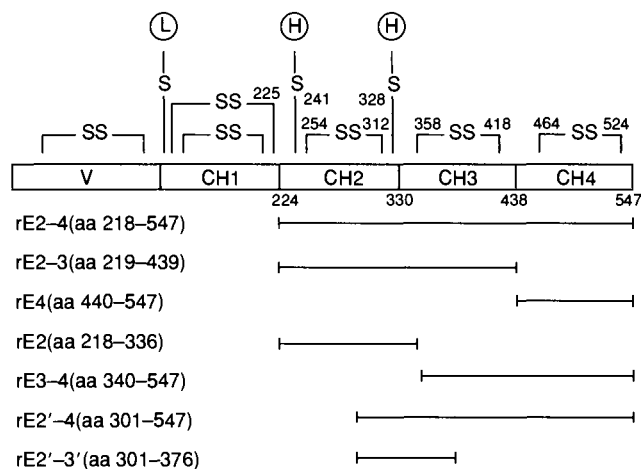

Helm *et al.* (1988,1989) prepared a series of overlapping recombinant Fc $\epsilon$  gene products that represent smaller fragments of Fc $\epsilon$  and found that the peptide representing amino acid sequence 301–376 in the  $\epsilon$  chain could block the *in vivo* passive sensitization of human skin mast cells and the *in vitro* sensitization of human basophils with human IgE antibodies (c.f. Figure 2). However, approximately 10-fold higher molar concentrations of the recombinant peptide than E myeloma protein were required for 50% inhibition of Prausnitz-Küstner reaction or histamine release (Helm *et al.*, 1989). Thus, the recombinant peptides that represent the C-terminal 30 amino acids of C $\epsilon$ 2 and the N-terminal half (46 amino acids) of the C $\epsilon$ 3 domain appear to contain the structures involved in the binding of IgE to Fc $\epsilon$ RI.

The precise regions involved in the binding of Fc $\epsilon$ RI were identified by expressing chimeric  $\epsilon$  heavy-chain genes composed of a mouse Vh domain and human C $\epsilon$  in which various domains were replaced by their murine counterparts. This approach was based on the fact that human IgE binds to Fc $\epsilon$ RI on human mast cells but not to Fc $\epsilon$ RI on mouse mast cells, whereas mouse IgE can bind to Fc $\epsilon$ RI on mast cells from both species (Conrad *et al.*, 1983). Nissin *et al.* (1991) found that all the chimeric IgE molecules that contain the murine C $\epsilon$ 3 domain bound equally to both the rodent and the human Fc $\epsilon$ RI, whereas replacement of the mouse second constant region domain (C $\epsilon$ 2) with human C $\epsilon$ 2 did not affect the binding capacity of the mutated IgE to murine mast cells nor its ability to mediate degranulation. These findings show

**Table II** Affinity of IgE for IgE Receptors on Mast Cells and Basophils of Homologous Species

Cells	Number of receptors/cells ( $\times 10^{-5}$ )	$k_1$ ( $\times 10^{-5} M^{-1} \text{sec}^{-1}$ )	$k_{-1}$ ( $\times 10^5 \text{sec}^{-1}$ )	$K_A$ ( $\times 10^{-9} M^{-1}$ )
Rat basophilic leukemia cells	$3.55 \pm 0.67$	$149 \pm 0.19$	$1.85 \pm 0.07$	7.84
Normal rat mast cells	$3.08 \pm 0.49$	$1.65 \pm 0.42$	$2.05 \pm 0.21$	8.05
Normal mouse mast cells <sup>a</sup>	$2.30 \pm 0.59$ ( $3.21 \pm 0.73$ )	$1.94 \pm 0.16$ (2.23)	$11.07 \pm 0.23$ (6.24)	1.75 (3.57)
Cultured human basophils	$3.06 \pm 0.28$	$1.88 \pm 0.32$	$9.94 \pm 0.36$	2.75

<sup>a</sup> Peritoneal mast cells from BALB/c mice; numbers in parentheses are obtained with mast cells from CBA mice.

**Figure 2**  $\epsilon$  chain fragments having affinity for  $Fc\epsilon RI$ . (Top) Covalent structure of the human  $\epsilon$  chain, indicating the positions of the intra-chain disulfide bonds (SS), the interheavy (S-H) and heavy-light (S-L) chain disulfide bonds, and the boundaries of the five structural domains, that is, variable (v) and constant (c) regions. (Bottom) Peptides synthesized by *E. coli* expression of gene fragments encoding the indicated protein sequences. Among the peptides rE 2-4, rE 2-3, rE 2'-4, and rE 2'-3' could block passive sensitization of human skin with IgE antibodies. Reprinted with permission from Helm *et al.* (1988).

that the  $C\epsilon 3$  domain is involved in the binding of  $Fc\epsilon RI$ . The C-terminal half of the  $C\epsilon 2$  domain, which is essential for peptide 301–376 to bind to  $Fc\epsilon RI$ , appears to play an important role in the stabilization of the conformation of the binding site.

The  $Fc\epsilon RI$  on rodent mast cells consist of three different polypeptide chains that is,  $\alpha$ ,  $\beta$ , and  $\gamma$ ; the gene encoding each polypeptide chain was cloned (Kinet *et al.*, 1987,1988; Blank *et al.*, 1989). The binding site for IgE is known to be present on the  $\alpha$  chain; however, precise structures involved in the high affinity binding are not known.

### B. Immunological and Biochemical Mechanisms for Mediator Release

Mast cells and basophils are triggered for mediator release when cell-bound IgE antibody molecules are cross-linked by multivalent antigen. Experiments have shown that direct cross-linking of  $Fc\epsilon RI$  by divalent antireceptor antibodies resulted in the release of mediators and degranulation (Ishizaka and Ishizaka, 1978). In this artificial system, IgE is not involved in triggering mediator release. Under physiological conditions, however, IgE antibodies are anchored to  $Fc\epsilon RI$ . Thus, cross-linking of IgE by multivalent antigen mediates the bridging of receptor molecules, which in turn triggers activation of mast cells.  $Fc\epsilon RI$  is suspected to be one of the few membrane components through which mediator release can be triggered. Since no immunoglobulin other than IgE will bind to  $Fc\epsilon RI$  with high affinity, triggering of mediator release through  $Fc\epsilon RI$  can be mediated only by IgE antibodies.

Cross-linking of cell-bound IgE on  $Fc\epsilon RI$  on mast cells results in activation of various membrane-associated enzymes, which leads to the release of vasoactive amines such as histamine and derivatives of arachidonic acid (c.f. Figure 3). The major biochemical pathway for mediator release is not known. However, researchers generally believe that the activation of phospholipase C (PLC) may play a key role in the early stage of the biochemical process for mediator release. The activation of this enzyme results in the cleavage of phosphatidylinositol 4,5-diphosphate to form inositol 1,4,5-triphosphate ( $IP_3$ ) and diacylglycerol (DAG).  $IP_3$  in turn induces intracellular mobilization of  $Ca^{2+}$  from endoplasmic reticulum, whereas DAG activates protein kinase C. An increase in intracellular  $Ca^{2+}$  in mast cells is well known to result in histamine release.

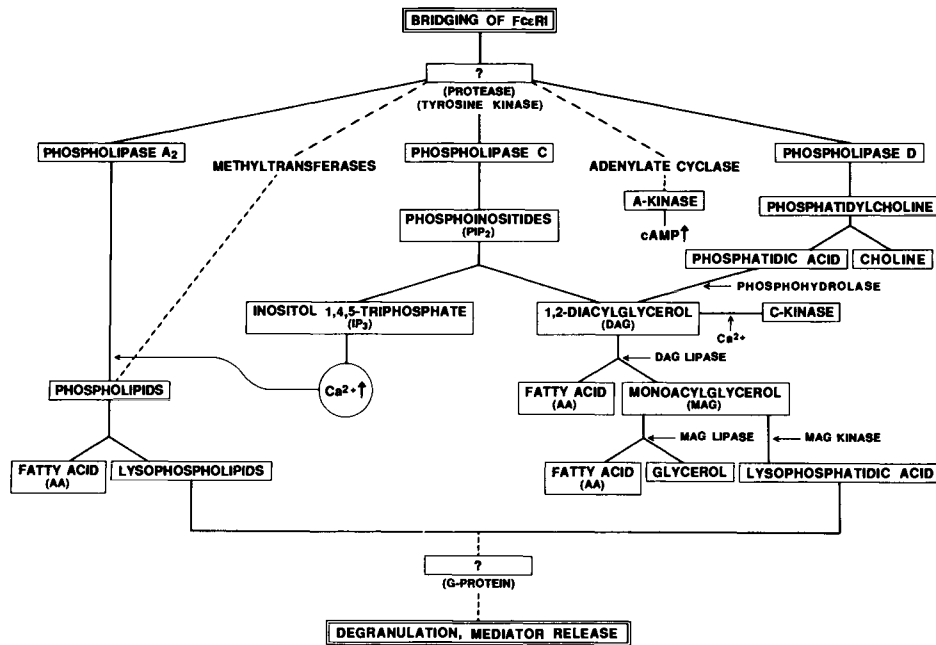

Phospholipase  $A_2$  in mast cells is activated by cross-linking of  $Fc\epsilon RI$ . This enzyme is involved in the release of both histamine and arachidonate (Nakamura *et al.*, 1991). Particularly, this enzyme appears to be important for the formation of arachidonic acid, which would be the source of prostaglandins and leukotrienes. Arachidonic acid could be formed by hydrolysis of DAG by DAG lipase and of monoacylglycerol by MAG lipase (c.f. Figure 3). However, experiments on bone marrow-derived murine mast cells indicated that the major pathway for the formation of arachidonate is hydrolysis of phospholipids by phospholipase  $A_2$  ( $PLA_2$ ) (Nakamura *et al.*, 1991).

Arachidonic acid is converted to prostaglandins through cyclooxygenase pathways and to leukotrienes through lipoxygenase pathways (Holgate *et al.*, 1988).  $PLA_2$  also may be involved in the formation of platelet activating factor (PAF). These derivatives appear to be involved in causing immediate allergic reactions and participate in inducing allergic inflammation.

In addition to histamine and vasoactive amines described earlier, mast cells release several chemotactic factors and granule-associated proteolytic enzymes. Further, studies indicate that cross-linking of cell-bound IgE on mouse mast cells by multivalent antigen induces synthesis and release of various interleukins such as IL-1, IL-3, IL-4, IL-6, granulocyte-macrophage colony stimulating factor (GM-CSF), and tumor necrosis factor ( $TNF\alpha$ ) (Burd *et al.*, 1989; Gurish *et al.*, 1991). IgE-dependent stimulation of IL-3-dependent mouse mast cell lines resulted in the formation of IL-3, IL-4, IL-5, and IL-6 (Plaut *et al.*, 1989). These findings suggest that the cytokines may be involved in causing allergic inflammation. Several lines of evidence have been accumulated that  $TNF\alpha$  from mast cells recruits leukocytes and contributes to IgE-dependent inflammation. An important question that remains to be answered is whether cross-linking of  $Fc\epsilon RI$  on human mast cells may induce the formation of such cytokines. If this is the case, cytokines such as  $TNF\alpha$  from lung mast cells may contribute to late phase reactions expressed in human lung.

### C. Role of IgE Antibodies in Allergic Disease and Mucosal Immunity

Allergic rhinitis or pollinosis is well established to be caused by IgE antibodies to which the patients are sensitive.

**Figure 3** Schematic model of biochemical events in mast cells induced by cross-linking of cell-bound IgE antibodies by multivalent antigen. How triggering signals from Fc $\epsilon$ RI are transmitted to enzymes such as phospholipase C and phospholipase A<sub>2</sub> is not known but possible participation of protein tyrosine kinase or GTP-binding protein is predicted. An increase in intracellular Ca<sup>2+</sup> is sufficient to induce mediator release. Under physiological conditions, both mobilization of intracellular Ca<sup>2+</sup> and Ca<sup>2+</sup> influx contribute to the increase in intracellular Ca<sup>2+</sup>.

In allergic patients who have not received immunotherapy, a statistical correlation is seen between the concentration of IgE antibodies in the serum and their symptom score during the season (Lichtenstein *et al.*, 1973). Many of their symptoms can be explained by the release of vasoactive amines from mast cells, which cause an increase in vascular permeability and contraction of smooth muscles. On the other hand, asthma represents an inflammatory disease of the bronchi and has not been considered an IgE-mediated allergic disease. However, in extrinsic asthma, inhaling allergen can induce both immediate (20 min) and late phase (4–12 hr) increase in airway resistance. Inhaling allergen also can produce a prolonged increase in nonspecific bronchial reactivity, one of the characteristic symptoms in asthma. The immediate response is caused by IgE-dependent mediator release from mast cells whereas late phase response is caused by inflammation. Dolovich *et al.* (1973) demonstrated that allergic inflammation in human skin can be induced by anti-IgE, suggesting that the inflammation was the consequence of mediator release from mast cells that was induced by allergen–IgE antibody reactions at the early stage. Proving a casual relationship between chronic (not seasonal) exposure to an allergen such as dermatophagoides and a chronic disease such as asthma is very difficult. However, evidence has been presented that IgE antibodies to dust mite, cat, and cockroach allergens are each significantly correlated with asthma (Pollart *et al.*, 1989). Thus, epidemiological studies indicate that IgE antibodies against allergens play an essential role not only in hay fever but also in chronic asthma.

Accumulated evidence indicates that IgE antibodies play an important role in immunity against some parasites (Capron *et al.*, 1987). Another possible role of IgE antibodies would be increasing vascular permeability, resulting in an increase in local concentration of antibodies of the other isotypes (Steinberg *et al.*, 1974). Since IgE-mediated reaction occurs immediately after antigen exposure, IgG antibodies accumulated into the site effectively participate in immunity. Mucosal tissues are rich in mast cells, which should have been sensitized with IgE antibodies formed in mucosal lymphoid tissues. One may expect that the role IgE antibodies play as “gate keepers” may be important in local immunity in mucosal tissues.

# Inflammation: Mast Cells

A. D. Befus

## I. INTRODUCTION

One hallmark of the virtually ubiquitous mast cell is that it bears thousands of high affinity receptors for IgE. When IgE antibodies occupying these receptors are cross-linked by specific antigens, the cell is activated and releases, in an explosive or more slowly timed manner, a myriad of stored or newly synthesized inflammatory mediators. Such allergic reactions which may have both immediate and late phases are prominent at mucosal surfaces presumably because of the pronounced antigenic exposures at these sites and the positive, but poorly understood, relationship between IgE production and mucosal surfaces. In addition, the presence and abundance of mast cells at mucosal surfaces, at times in the epithelium but normally in the underlying lamina propria and associated musculature, contributes to hypersensitivity reactions at these sites.

However, not only the clinical significance of mast cells in mucosal allergic responses such as extrinsic asthma (see Chapter 44) and food allergies (see Chapter 40), but evidence that these cells are willing participants in normal physiological events and in many, if not most, non-IgE-mediated inflammatory reactions throughout the body has spawned extensive investigations. Moreover, in rodents and in humans, abundant evidence suggests that mast cell populations at mucosal surfaces can be distinguished by the high proportion of cells with a characteristic "mucosal" phenotype.

Although some of the information is sparse and often restricted to studies in only a single species or with *in vitro* approximations of *in vivo* populations, cells of this "mucosal" phenotype are distinct from mast cells elsewhere. They differ in their protein composition and arsenal of mediators, their discriminating responsiveness to certain secretagogues that activate mast cells from other, largely connective tissue sites, and their restricted responsiveness to the fleet of anti-allergic and anti-inflammatory drugs (see Befus, 1989).

This chapter provides a summary of the general properties of mast cells; their ontogeny, mediator repertoire, responsiveness to activating, and regulatory stimuli; and their spectrum of functions. However, a primary focus is on the distinctive qualities of mast cells at mucosal surfaces that may uncover functions specific to these locations. Given the breadth of this volume and the limitations that it poses on each chapter, readers who seek more extensive information are referred to several reviews of mast cells and their hetero-

geneity and function (Bienenstock, 1988; Befus, 1989; Benyon *et al.*, 1989; Galli, 1990; Gordon *et al.*, 1990; Schwartz, 1990; Miller, 1992).

## II. STRATEGIES TO EXPLORE MAST CELL HETEROGENEITY AND FUNCTION

In 1966, Enerback clarified some confusing literature and established that mast cell populations in the gastrointestinal tract of the rat were morphologically, histochemically, and functionally distinct from more widely studied mast cells in the peritoneal cavity and connective tissues (see Enerback, 1987; Galli, 1990). These two cell populations have become known as intestinal mucosal mast cells (IMMC) and connective tissue mast cells (CTMC), of which the peritoneal mast cell (PMC) has been studied most widely because of the ease of its isolation and purification. Numerous reviews are available of the details of the distinctions between these two mast cell types, so this information will not be repeated in a comprehensive manner. However, a brief description of the evolution of the field may help the reader place specific information in the appropriate context.

In mice, the dramatic increase in the numbers of IMMCs that follows intestinal helminth infection is dependent on an intact thymus. In contrast, in many situations increases in the numbers of CTMCs are not thymus dependent. This thymus dependency of intestinal mastocytosis is based on the requirement for interleukin 3 (IL-3); repetitive administration of IL-3 reconstitutes the ability of athymic mice to express hyperplasia of IMMCs (Abe and Nawa, 1988). However, this explanation may be an oversimplification since other T cell-derived cytokines, including IL-4 (see Galli, 1990) and IL-10 (Thompson-Snipes *et al.*, 1991), are also cofactors for mast cell development.

To characterize IMMCs more fully and compare them with CTMCs, structural, histochemical, and immunohistochemical analyses have been conducted on the cells *in situ*. For example, characteristics of their proteoglycan content and expression of certain serine proteases have been evaluated with such approaches. In addition, procedures were developed to disperse mast cells from the intestine and other tissues enzymatically and mechanically. Mast cell-specific components were studied in such cell mixtures and strategies were developed to enrich and purify the cells or some of their components for further analyses.

In the rat, purifying PMCs and IMMCs from their respective sources is possible but, in the mouse, although PMCs can be purified, the isolation and purification of IMMCs has been an insurmountable challenge. Similarly, mast cells from the human intestine have been impossible to purify, although dispersed mixtures of intestinal cells containing up to 30% mast cells have been studied (Befus *et al.*, 1987). These dispersed cell populations from the human intestine, and from lung as well (Schulman, 1990), contain two distinct populations of mast cells, histochemically analogous to PMCs and IMMCs of rats. These and other histochemical studies of mast cells from human tissues (e.g., Enerback, 1987) have established that these two histochemically distinct populations are found in virtually all sites investigated to date, although their relative abundance varies. Whether these populations are functionally distinct as in the rat remains to be confirmed. Schwartz and colleagues provided compelling evidence that the cell populations differ in protease content; the cell type histochemically analogous to the PMC expresses both chymase and tryptase (MC<sup>TC</sup>) in considerable abundance, whereas the IMMC-like mast cell expresses only tryptase (MC<sup>T</sup>) in abundance (Irani *et al.*, 1986).

*In vitro* culture also has been a powerful tool with which to investigate mast cells and their phenotypic heterogeneity. Since the original observations by several investigators of mast cell development and persistence in IL-3-containing cultures of murine bone marrow or lymphoid tissues, such systems have been employed to investigate mast cell ontogeny and phenotype. Much has been learned from these cultures. The development of clonal populations or populations "frozen" in a particular phenotype by viral transformation (Reynolds *et al.*, 1988) has aided greatly in dissecting very complicated issues of phenotypic diversity. Galli (1990) identified the benefits of these approaches and appropriately expressed caution about the relationship of these cultured cells to *in vivo* populations or to their development.

The bases for mast cell heterogeneity are complex (e.g., Befus, 1989; Kitamura, 1989) and have been expressed thoughtfully by Galli (1990). Although two easily distinguished populations (CTMC and IMMC) can be identified in rodents, whether or not these are the only two populations distinct in so many ways is unclear. Other equally distinct populations may exist in different tissues or in other species, or perhaps only minor variations of these two themes exist. As new information has been uncovered, mast cell populations from various sources have been shown to differ in a number of characteristics. However, the information is not of sufficient quantity or clarity to allow useful definition of cell subsets beyond their location, perhaps because the bases for heterogeneity are diverse and may include distinct mast cell lineages (irreversible commitment to a particular phenotype at some phase in development), processes of cell maturation and differentiation in response to selected microenvironmental stimuli, renewal after activation and mediator depletion or synthesis, and acquisition of components produced by other cell types (Galli, 1990).

In recent years, a powerful tool with which to study mast cell heterogeneity and function has been the use of mice of the W/W<sup>v</sup> or SI/SI<sup>d</sup> genotypes. Although both these strains

of mice are congenitally mast cell deficient, the natures of their deficiencies are distinct. W/W<sup>v</sup> mice are deficient in the stem cells of the mast cell lineage. Their mast cell deficiency can be reconstituted with normal bone marrow, and they are capable of producing mast cell growth factors. SI/SI<sup>d</sup> mice have a deficit in the tissue microenvironment that induces mast cell development, but possess mast cell precursors. Kitamura and colleagues (Kitamura, 1989) used these mice to explore the defects and the ontogeny and function of mast cells. Alone and in collaboration with Kitamura, Galli and co-workers have defined these experimental approaches carefully and presented an algorithm for their use (Galli, 1990).

### III. ONTOGENY

Mast cells can be detected in many tissues before birth, but their numbers are generally low (Watkins *et al.*, 1976). In sites such as the peritoneal cavity and intestine, mast cells do not approach normal adult levels until 2–3 months of age (Watkins *et al.*, 1976; Woodbury *et al.*, 1978). As indicated earlier, mastocytosis in selected tissues such as the intestine can occur in response to certain stimuli; in some cases, as in the intestinal mucosa in response to helminthic infection, this activation is thymus dependent, but in other cases it is not.

Mast cell precursors are derived from pleuripotent hemopoietic stem cells; in humans, these cells express CD34 (Kirshenbaum *et al.*, 1991). During their development, and under the influence of IL-3 and IgE, mast cell precursors become committed to the mast cell lineage that, in some tissues such as mesenteric lymph nodes of helminth-infected mice, can be identified as a mast cell committed precursor (MCCP) line by the ability to develop into granulated mast cells in fibroblast-conditioned medium and in the absence of exogenous IL-3 (perhaps an autocrine pathway of IL-3 production; Ashman *et al.*, 1991; Figure 1). This fibroblast-conditioned medium is a rich source of stem cell factor (SCF, *c-kit* ligand; Williams *et al.*, 1990), a multipotent growth factor with mast cell growth activity. W/W<sup>v</sup> mice are deficient in MCCP but produce SCF, whereas SI/SI<sup>d</sup> mice generate MCCP but are deficient in SCF (Jarboe and Huff, 1989).

Several environmental factors have the potential to impinge on this stem cell and committed precursor to facilitate differentiation and subsequent maturation. These factors include SCF (*c-kit* ligand; Tsai *et al.*, 1991), CD45 ligand (Brommeyer *et al.*, 1991), IL-3 (Ashman *et al.*, 1991), IL-4 (Hamaguchi *et al.*, 1987), IL-10 (Thompson-Snipes *et al.*, 1991), and nerve growth factor (NGF; Matsuda *et al.*, 1991; Figure 1). Both IL-4 and NGF appear to facilitate development of CTMC-like MCs (Hamaguchi *et al.*, 1987; Matsuda *et al.*, 1991). To date, no information is available on the microenvironmental factors that selectively induce or enhance the development of IMMC-like MCs. Granulocyte-macrophage colony stimulating factor (GM-CSF) (Bressler *et al.*, 1989), interferon  $\gamma$  (IFN $\gamma$ ; Nafziger *et al.*, 1990), transforming growth factor  $\beta$  (TGF $\beta$ ; Broide *et al.*, 1989), and even hista-

**Figure 1** Factors that regulate the ontogeny of mast cells during the course of their development from stem cells to mature tissue-dwelling subpopulations (abbreviations in text).

mine (Schneider *et al.*, 1990) may down-regulate these developmental processes (Figure 1).

The commitment to CTMC or IMMC characteristics appears not to be irreversible, that is, the cells of one or the other phenotype are capable of changing into cells of the other phenotype, a process referred to by Kitamura and colleagues as transdifferentiation. The experimental approaches employed and evidence for this phenomenon have been reviewed by Kitamura (1989) and Galli (1990), although the extent to which transdifferentiation might occur *in vivo* and the signaling systems involved have not been explored.

#### IV. REPERTOIRE OF MEDIATORS

Mast cells throughout the body have the potential to produce a spectrum of powerful mediators (Table I), many of which are pro-inflammatory, especially when large quantities are released in an explosive manner. Some of the best known mediators are produced in advance, for example, histamine, proteases, and other enzymes, and are stored in cytoplasmic granules in association with the proteoglycan matrix. When the cell is activated, exocytosis of granule contents occurs, in turn initiating a complex of cascading events with short-term or more prolonged time courses. In addition, activation induces the synthesis of lipid and other mediators that are released immediately into the local milieu, including prostaglandins, leukotrienes, platelet activating factor-acether (PAF-acether), and nitric oxide (Table I).

Considerable excitement has surrounded observations that mast cells constitutively express certain cytokines (Table I) and, when activated, rapidly produce mRNA for an impressive array of cytokines. However, much of this information on cytokines has been established with cell lines, and some studies have been restricted to measuring mRNA rather than the protein products. Thus, the extent to which mast cells are an important source of cytokines *in vivo* requires considerable investigation. That rodent and human mast cells are a prominent source of the multifunctional mediator tumor necrosis factor  $\alpha$  (TNF $\alpha$ ; Bissonnette and Befus, 1990; Gor-

<sup>a</sup> Abbreviations: ECF/NCF, eosinophil/neutrophil chemotactic factors; RMCP, rat mast cell protease; PAF, platelet activating factor-acether; PGD<sub>2</sub>, prostaglandin D<sub>2</sub>; LT, leukotriene; TNF, tumor necrosis factor; IL, interleukin; IFN $\gamma$ , gamma interferon.

<sup>b</sup> The evaluation of mediator distribution in human mast cells is based on the most abundant mast cell type in the named tissue, recognizing that histochemically and protease content-distinct populations are mixed in all tissues.

don and Galli, 1991; Benyon *et al.*, 1991a) and that important effects emanate from its release from mast cells (Klein *et al.*, 1989; Gordon and Galli, 1991) has been well established. However, factors other than IgE that dictate whether or not mast cells, macrophages, or other cells are the immediate source of TNF $\alpha$  in an inflammatory event remain to be clarified.

Unfortunately, given the heterogeneity of mast cells, the mosaic of information that one draws on to present a summary of their mediators (Table I) comes from studies with mast cells from different species and collected from different tissue sites by a profusion of techniques. Thus, one must be cautious when making generalizations and be careful to establish that the mediator repertoire of mast cells in a particular site does or does not follow closely the pattern of the "generalized" mast cell. Equal caution must be taken when discussing the functions of these mediators; some may have functions that can be generalized easily in different species or tissues, for example, well-known actions of histamine on the vasculature or the substrate specificities of selected enzymes. However, other mediators may express site-specific functions dictated by conditions in the local microenvironment. For example, the overall actions of histamine in a tissue may vary from those in another tissue or at another time in the same tissue. Such distinct responses could depend on the abundance and competence of selected cell populations designated to respond to this mediator, because of their expression of H1, H2, or H3 histamine receptors or because of alterations in the catabolism or activity of the mediator itself.

Finally, although in our efforts to understand cascading networks of biological responses we use reductionist approaches, mast cells release a spectrum of mediators at one time and no mediator can be viewed in isolation. Moreover, depending on the stimulus applied, mast cells may release mediators in a differential fashion. For example, histamine can be released in preference to 5-hydroxytryptamine (5HT) and vice versa by murine skin mast cells (e.g., Meade *et al.*, 1988). For human skin mast cells, although the magnitude of histamine release is similar with both secretagogues, an IgE-dependent stimulus releases 10- to 20-fold more prostaglandin D<sub>2</sub> (PGD<sub>2</sub>) and leukotriene C<sub>4</sub> (LTC<sub>4</sub>) than the neuropeptide

substance P (see Benyon *et al.*, 1989). Few of these types of issues have been analyzed with the care needed to provide more than a "generalized" view of mast cells.

## V. MODULATION OF MAST CELL FUNCTION

### A. Activation

Until recently, studies of the factors that stimulate mast cells have focused largely on secretagogues for histamine or other mediators such as 5HT, arachidonic acid metabolites, proteases, or lysosomal enzymes. The list of such secretagogues is long (Figure 2), yet unlikely to be complete. For example, although rodent IMMCs are unique in many ways and one might speculate that they are responsive to signals specific for the intestinal or other mucosal environments, no secretagogues have been identified that stimulate IMMCs but fail to stimulate CTMCs. In contrast, numerous secretagogues such as certain neuropeptides and endorphins activate CTMCs but not IMMCs (e.g., Bienenstock, 1988).

In addition to the classical antigen-specific IgE-dependent sensitization of mast cells, antigen-specific sensitization has been attributed also to a T cell-derived factor not cross-reactive with IgE (e.g., Meade *et al.*, 1988). However, progress in the characterization of this factor has been slow and its potential relevance for mast cells other than in murine skin requires additional study. Other mast cell activating factors are not known to be linked to antigen in a specific manner, although after antigen challenge the cascade of events may lead to continued mast cell activation, perhaps in a mediator-specific fashion, insuring the continued participation of these cells in the ongoing immune and inflammatory responses.

For example, complement-derived anaphylatoxins, certain neuropeptides, endogenous opiates, rat mast cell protease I (RMCP I), or relatively poorly known factors from a variety of cell types collectively called HRFs (histamine releasing factors) may be important in different pathological states. HRFs include connective tissue activating peptide II (CTAP

**Figure 2** Factors that activate, prime or inhibit mast cell functions (abbreviations in text).

II), the closely related cleavage product, neutrophil-activating peptide (NAP 2) (Baeza *et al.*, 1990), or, in the hands of some authors, neutrophil activating peptide 1 (NAP 1) (Dahinden *et al.*, 1989), now recognized as IL-8. In addition to these HRFs, at least one other HRF activity with an apparent molecular mass of 40–41 kDa remains to be fully characterized (Baeza *et al.*, 1990). The elucidation of the different uses of and cascades of responses to these pathways of mast cell activation will contribute much to our understanding of the functions of these cells.

Perhaps more complex than the cytokine network in modulating mast cell function is the interaction between mast cells and the nervous system. The close anatomical association of mast cells and nerves in the mucosa (Stead *et al.*, 1987), the role of substance P and mast cell activation in wheal and flare reactions (see Stead *et al.*, 1990), the differential activation of mast cell subpopulations by neuropeptides and endorphins (e.g., Shanahan *et al.*, 1985), and even the classical Pavlovian conditioning of mast cell secretion (MacQueen *et al.*, 1989) disclose the breadth of the spectrum of nervous control of mast cell function. Moreover, this interaction is bidirectional; mast cell activation, in turn, regulates nervous system function through mediators such as PDG<sub>2</sub> (e.g., Udem and Weinreich, 1989). Given the elaborate, partially autonomous enteric nervous system, in studies of the physiology of the intestinal mucosa or other mucosal sites an understanding of normal mast cell–nerve interactions and of their alterations in inflammatory states clearly will be beneficial.

The intestinal mucosa may be a rich source of other factors that stimulate mast cell secretion, such as hitherto poorly studied endogenous components or exogenous factors derived from infectious agents or foodstuffs. For example, several studies have established that members of the defensin/corticostatin family of polypeptides derived from neutrophils and other cell types (Lehrer *et al.*, 1991) are potent stimulators of histamine secretion from mast cells (A. Bateman, C. Mowat, D. Befus, and S. Solomon, unpublished results). One member of this family, cryptdin, appears to be derived from Paneth cells in the intestinal crypt as well as from other intestinal leukocytes (e.g., Ouellette and Lualdi, 1990). Determining whether or not this member of the family has specificity for the activation of IMMCs or for differential mediator release, as opposed to other members of the family that might activate CTMCs, will be interesting.

A similar specificity of activation, differential mediator release, or inhibition may exist for other endogenous intestinal components or for toxins or other metabolic products of the intestinal flora. Lipophilic but not hydrophilic bile acids have been shown to induce cytotoxic release of histamine from CTMCs as well as from cultured mast cells with some properties of IMMCs (Quist *et al.*, 1991). Clearly evidence exists for activation (Konig *et al.*, 1989) and inhibition (Nakagomi *et al.*, 1990) of CTMCs by bacterial products, but to date no studies of differential activation, mediator secretion, or inhibition of IMMCs have been conducted. As such investigations are done in the near future, exploring markers of mast cell function other than simply histamine secretion will be important. For example, cytokine production, protein bio-

synthesis, and other metabolic activities associated with growth, differentiation, and maturation must become more widely used in assaying mast cell involvement in these and other physiological and pathophysiological pathways.

## B. Inhibition

Although much effort has been invested in the search for drugs that inhibit the activation of mast cells (Figure 2) or antagonize selected mediators such as histamine or arachidonic acid metabolites, no fully satisfactory or specific drugs have been discovered. For a review of many drugs that inhibit the actions of mast cells, including corticosteroids, disodium cromoglycate, sulfasalazine, cyclosporin A, and antihistamines, see Benyon *et al.*, (1991b). Certain drugs appear to affect mast cells in multiple sites (e.g., corticosteroids), whereas others inhibit CTMCs but appear to be without effect on IMMCs in rodents (e.g., disodium cromoglycate). The actions of these drugs may be diverse, in part depending on site and duration of use. For example, the observations that dexamethasone appears to induce ingestion of IMMCs by macrophages (Soda *et al.*, 1991) requires careful investigation.

Unfortunately, the information from human mast cells is confusing because all populations of human mast cells are mixed (as discussed earlier). Whether or not a partial response to the drug (e.g., 30–70% inhibition) reflects a limited responsiveness by all cells in the mixed population or a marked response by some cells and no response by others is unclear.

In the future, more emphasis will be placed on studies of endogenous inhibitors of mast cell activation (Figure 2) and development. This area of research has been neglected to date, yet many pathways for the regulation of mast cell function must exist *in vivo*. For example, we have established that interferons inhibit histamine and TNF $\alpha$  release from CTMCs and IMMCs in rats (Bissonnette and Befus, 1990). We have shown that, after preincubation of rat CTMCs with TGF $\beta$ , the release of TNF $\alpha$  and histamine is inhibited (E.Y. Bissonnette and A. D. Befus, unpublished observations). Others have shown that IL-8 (Grant *et al.*, 1991) and lactoferrin (Theobald *et al.*, 1987) inhibit histamine secretion.

## VI. PLETHORA OF FUNCTIONS

Given the tremendous spectrum of mediators stored and secreted by mast cells, or newly synthesized and released when the cell is activated, concisely listing the specific functions of the mast cell is difficult. In a broad biological sense, mast cells have been shown to be involved in responses ranging from elicitation of cardiopulmonary responses in anaphylaxis (Takeishi *et al.*, 1991), experimental allergic encephalomyelitis (Dietsch and Hinrichs, 1989), and host defenses (Matsuda *et al.*, 1987; Abe and Nawa, 1988) to immune complex- (Ramos *et al.*, 1990) and substance P-induced inflammation (Yano *et al.*, 1989). Accordingly, in this chapter a

more generalized conceptualization of mast cell function will be outlined (Figure 3).

The targets of mediators secreted by mast cells may include almost any cell in the body: connective tissue cells, endothelium, epithelium, cells of the immune system, and cells of the nervous system, as well as smooth muscle. These targets may respond to interaction with mast cell mediators in a number of ways, including alterations in their survival; short term secretory, contractile, migratory, or other functional responses; competency, proliferation, differentiation, or maturation; and overall tissue or organ physiology or pathophysiology. Many of these responses are associated with inflammation, its associated tissue damage, and subsequent repair processes.

In addition to the knowledge of mast cell mediators that have been studied for many years, for example, histamine and certain arachidonic acid metabolites, priorities for investigation in the next few years will lie in evaluating the production and roles of mast cell-derived cytokines in inflammatory conditions of differing etiology. For example, when are mast cells a prominent source of TNF $\alpha$  (e.g., Gordon and Galli, 1991) in comparison with other cell sources of this potent cytokine? Another emphasis will be on elucidating the *in vivo* substrates and functional activities of the multiple serine and other proteases in the mast cell (Schwartz, 1990). For example, the catalytic site of mast cell tryptase appears to be critical in tryptase augmentation of histamine-induced smooth muscle contraction in dog bronchi (see Caughey, 1990), tryptase mitogenic activity for fibroblasts (Ruoss *et al.*, 1991), and degradation of bronchodilatory neuropeptides such as VIP (vasoactive intestinal polypeptide) and PHM (peptide histidine-methionine) (Caughey, 1990). Understanding the orchestration of release of proteases and their activities in inflammatory sites promises to clarify many aspects of mast cell function *in vivo*.

Postulating that this variety of functions of proteases and other mast cell-derived mediators is not restricted to pronounced inflammatory reactions, but is ongoing during the course of normal physiological homeostasis, albeit in subtle unobtrusive ways, is reasonable. Such subtle and ongoing mast cell function, perhaps driven by both the endocrine

(Befus, 1990) and the nervous (Stead *et al.*, 1990) system, is likely to be difficult to measure, given our emphasis to date on assay systems in which explosive degranulation events have been evaluated. Innovative approaches are required to begin to address this hypothesis and to address specifically its implications in the context of the homeostasis of mucosal function in health and disease.

# Cytokines in the Liver and Gastrointestinal Tract

*Fernando Anaya-Velazquez • Graham D. F. Jackson • Peter B. Ernst •  
Brian J. Underdown • Jack Gauldie*

## I. INTRODUCTION

Although immunological interactions between the liver and the intestine have been described for years, the liver often is perceived to function primarily as a "scavenger" within the reticuloendothelial system. The broader contributions of the liver can be appreciated if one considers that this organ can function in lymphopoiesis (particularly in neonates), clearance of immune complexes, antigen presentation, acute inflammation, IgA transport, local synthesis of immunoglobulin, cell-mediated cytotoxicity, and immune regulation through the production of regulatory cells and cytokines.

The liver and intestine exchange immunological information via the portal vein and bile. Since some immunological responses in the liver are associated with pathological conditions in the intestine, both organs are likely to act in concert to coordinate some of their immune responses. In this chapter, we describe the production and function of cytokines in the liver and intestine using the paradigm of parasitic infestations to illustrate the dynamic immunological interventions between these tissues.

## II. OVERVIEW OF CYTOKINE PRODUCTION

Cytokines are soluble small-to-intermediate sized proteins produced by a variety of cells in response to injury, infection, or antigenic challenges. These molecules can function in an autocrine, paracrine, or endocrine fashion, the latter being relevant to the communication between the gut and the liver. Their functions are diverse and include the regulation of growth, differentiation, and function of a variety of immune cells (Arai *et al.*, 1990; Finkelman *et al.*, 1991). Cytokines also help orchestrate numerous interactions between the immune system and physiological processes by altering the microenvironment and biomatrix surrounding these cells. Most of what we know about the effects of cytokines is related to inflammatory events, whereas relatively little is known about the function of these molecules under physiological conditions (Arai *et al.*, 1990).

The number of well-characterized cytokines has grown tremendously during the last 5 years. Two important developments that have helped elucidate the role of these factors in the immune response are the availability of recombinant

cytokines and neutralizing antibodies. Among the best characterized cytokines are interferon (IFN $\alpha$ ,  $\beta$ ,  $\gamma$ ), tumor necrosis factor (TNF), lymphotoxin (LT), interleukins (IL) 1–12, and growth factors including epidermal growth factor (EGF), platelet-derived growth factor (PDGF), and transforming growth factors (TGF), as well as granulocyte–macrophage (GM-CSF), granulocyte (G-CSF), and macrophage (M-CSF) colony stimulating factors (reviewed by (Arai *et al.*, 1990; Finkelman *et al.*, 1991; Mosmann and Moore, 1991). In addition to these mediators, an entirely new class of cytokine has been discovered and characterized, describing a group of small secreted chemotactic factors referred to as the platelet factor 4 (PF4) superfamily (Schall, 1991). All these molecules share a similar primary structure and have a four-cysteine motif. The superfamily has two major subclasses: those with a "Cys–X–Cys" structure include PF4 and IL-8 and those with a "Cys–Cys" structure including the RANTES/SIS cytokines. These cytokines act on a wide range of cells and collaborate in a cytokine network with neuroendocrine factors, adhesion molecules, and nonpeptide factors to influence the function of cells bearing the appropriate receptors and to modify the inflammatory or immune responses in tissues.

The complexities of the cytokine network, including the cascades of events that lead to the indirect effects of a cytokine, are sometimes difficult to dissect and evaluate. This complexity can be illustrated by cytokine production by monocytes, T cells, and mast cells in the intestine and liver. Using the tools at hand, a framework that describes the source and effects of many cytokines can be drawn and the link between the gut and liver can be exposed.

## III. INITIATION OF CYTOKINE PRODUCTION: INTERACTIONS AMONG CELLS AND ANTIGEN

Cells in the intestine are involved in the absorption of nutrients, motility, and immune functions; all these functions are coordinated by nerves, hormones, cytokines, or other factors (Marshall *et al.*, 1989; Kiyono *et al.*, 1991; Strober *et al.*, 1991). To develop a model of cytokine function in the gut and liver, we first consider the distribution of monocytes, T cells, and mast cells; their response to nematode infesta-

tion; the progressive increase in cytokine synthesis; and their effects.

The primary immune inductive sites in the intestine are aggregates of lymphocytes and antigen-presenting cells and include the Peyer's patches. Other antigen presenting cells, lymphoid cells, and leukocytes (including mast cells or their precursors) are scattered diffusely throughout the lamina propria and epithelium (effector sites).

Although the liver is composed largely of parenchymal cells, an enormous complement of immune or inflammatory cells is also present. The major antigen-presenting cell is believed to be the Kupffer cell. T and B lymphocytes, natural killer cells, and other inflammatory cells including the occasional mast cell are also found. Lymphocytes and other inflammatory cells are found primarily in the portal triads, adjacent to the biliary tracts and throughout the parenchyma (Jones and Altorfer, 1988). Plasma cells also are found near biliary spaces, but this observation is relatively rare under normal circumstances. One question that arises is whether hepatic lymphocytes are trapped from peripheral and portal blood or whether the liver has its own endogenous population of lymphoid cells. The enrichment for B and T cell precursors in the liver, particularly in infancy, suggests that the liver is not merely a sink for trapped lymphocytes from the blood, but does actively accumulate cells with a particular function. Further, this organ contains a proportionally larger number of B cells than blood or spleen (Manning *et al.*, 1984). Collectively, these observations suggest that the liver has the cellular capacity to respond to antigens and cytokines by mediating cytotoxic activity, antibody production, and the release of cytokines.

Stimulation of the intestinal cells by luminal antigen is believed to occur primarily in the inductive sites (Ernst *et al.*, 1988). These aggregates lie below specialized epithelial cells (M cells) that act as preferential sampling sites of luminal antigen (Owen and Jones, 1974; Neutra *et al.*, 1987; Pappo *et al.*, 1988). Some antigen also crosses intact or disrupted epithelium and contributes to the stimulation of naive or sensitized cells in the epithelium or the underlying lamina propria (Bland and Warren, 1986; Mayer *et al.*, 1991). Antigen-stimulated lymphocytes or cytokines reach the portal circulation and traffic to the liver. Alternatively, this immunological information may enter the lymph or blood and eventually reach the liver via the hepatic artery. In either case, substantial communication occurs between the intestine and the liver after antigenic stimulation.

An interesting consequence of the response of the liver to luminal antigens is the induction of oral tolerance, which is a state of reduced responsiveness (Ernst *et al.*, 1988) that is believed to be beneficial to the host by limiting immune responses to the myriad of enteric antigens. The role of the liver in this process has been implicated by experiments in which the portal circulation was made to bypass the liver prior to oral immunization (Cantor and Dumont, 1967). Moreover, immunization with alloantigens into the portal vein inhibits subsequent graft rejection (Qian *et al.*, 1987). Thus, by dealing with the immunogenicity of luminal antigens, the liver is linked quite closely to the intestine. Although cellular

studies have verified these results, little information is available on the factors or cytokines that may be mediating this process.

#### IV. INITIATION OF CYTOKINE PRODUCTION: ACUTE INFLAMMATION

In response to parasitic or other infections and injuries, the host responds initially with an acute inflammatory response (Fey and Gauldie, 1990; Heinrich *et al.*, 1990; Stadnyk and Gauldie, 1991). The acute inflammatory response may be divided into the local inflammatory response—coagulation, kinin generation, phospholipid metabolism with vasodilation and cellular emigration—and the systemic acute phase response—fever, leukocytosis, changes in the concentrations of plasma heavy metals, and increased plasma levels of a number of hepatocyte-derived proteins (Gauldie *et al.*, 1989; Heinrich *et al.*, 1990; Stadnyk and Gauldie, 1991). These two responses are not clearly separable since many of the systemic changes seen during local inflammation are the result of the production of mediators at the primary site of inflammation. The systemic component of acute inflammation, that is, increases in the plasma "acute phase reactants" (APR), has received considerable attention as a marker for the detection of inflammation.

Corticosteroids have a direct effect on the regulation of many genes in the liver, but may make a greater contribution by enhancing the effects of other factors such as IL-6 (Baumann and Gauldie, 1990). IL-1 and TNF also have the ability to regulate APR; however, neither could regulate the full response *in vitro*, even in the presence of corticosteroids. IL-6 (also referred to as hepatocyte stimulating factor) acts via a heterodimeric receptor to activate nuclear factors that regulate the expression of acute phase protein genes (Gauldie *et al.*, 1989; Heinrich *et al.*, 1990; Richards *et al.*, 1991). This activity of IL-6 is mimicked by leukemia inhibitory factor (LIF), IL-11, and oncostatin M (OM), which also can synergize with IL-1 or TNF and corticosteroids. IL-1, IL-6, LIF, OM, and IL-11 all act through separate receptors, meaning a broad range of factors can contribute independently in response to inflammation regardless of the tissue affected and differences in local cytokine responses.

The hepatocytes respond to these factors in a specific manner as a result of direct, additive, synergistic, or inhibitory actions of the cytokines (Stadnyk and Gauldie, 1991). Type I acute phase proteins include opsonins, complement components, and transport proteins and are stimulated by combinations of cytokines such as IL-1 and IL-6. Type II proteins include fibrinogen, haptoglobin, and all the antiproteases and are stimulated only by IL-6 or IL-6-like cytokines. Other cytokines, including IFN $\gamma$  and TGF modulate the hepatic response (Zuraw and Lotz, 1990). The complexity of the interactions is illustrated further by the fact that IL-1 can inhibit the effect of IL-6 induction on some type II proteins. Thus, in predicting the response of hepatocytes, one must consider which factors are released at the site of inflammation

as well as their sequence of release, which contribute to the network of signals that reach the liver.

The cells producing cytokines that regulate gene expression in the liver are quite diverse (Andus *et al.*, 1991; Stadnyk and Gauldie 1991). Macrophages, both resident tissue and circulating (monocytes), provide a link between the inflammatory response and immune system by antigen presentation and activation of lymphocytes. Through the secretion of cytokines, especially IL-1 and TNF, macrophages communicate with other tissues to elicit systemic inflammatory changes (Andus *et al.*, 1991). Other cells involved at the site of inflammation also may participate in the acute phase response through the release of cytokines. These cells include lymphocytes, neutrophils, and platelets; stromal cells such as fibroblasts, endothelial cells, and smooth muscle cells; and epithelial cells such as keratinocytes.

## V. CYTOKINE PRODUCTION IN RESPONSE TO INFECTION WITH NEMATODES

Several parasitic infections cause intestinal inflammation and permit studies on the impact of cytokine production during inflammation. Two nematode infections of the rodent with similar but distinct life cycles are *Nippostrongylus brasiliensis* and *Trichinella spiralis*. Subcutaneously administered infectious L3 stage larvae of *N. brasiliensis* have an obligatory host lung stage before they arrive as L4 stage larvae in the small intestine. In that site, the worms mature to adults and live in the proximal jejunum where they mate and secrete eggs prior to expulsion. In contrast, infective larvae (L4) of *T. spiralis* recovered from skeletal muscle of mammals are ingested, allowing them to undergo rapid molts in the proximal jejunum. Subsequently, the worms mature and mate; newborn larvae (L1) arise few a days later. L1 larvae migrate via the portal vein to skeletal muscle throughout the host, where they encyst. The adults of the two species occupy a different niche within the host intestine: *N. brasiliensis* remains in the intestinal lumen, usually at the base of the villi, whereas *T. spiralis* lives within the epithelium (Stadnyk and Gauldie, 1991).

During infection with *N. brasiliensis*, alveolar macrophages become activated and spontaneously secrete IL-1 and IL-6 during the passage of the larvae through the host lungs. These cells continue to secrete increased amounts of these cytokines while the parasite inhabits the intestine (Stadnyk and Gauldie, 1991), leading to changes in serum APR. IL-1 and IL-6 were detected in the supernatants of cultures of isolated intestinal cells from normal animals, and levels were increased in cultures from rats infected with *N. brasiliensis*. In contrast, no APR changes occur and neither alveolar nor peritoneal macrophages from *T. spiralis*-infected rats secrete greater than normal amounts of IL-1 or IL-6, whereas the intestinal cell cytokine levels from animals infected with *T. spiralis* were reduced compared with normal levels. However, cells in the infected intestine are capable of producing IL-1 and IL-6 (and other cytokines) *in vitro* but do not appear

to be activated *in vivo* during intestinal pathology caused by *T. spiralis* or, most significantly, during the inflammation induced by direct intestinal infection with the L4 stage of *N. brasiliensis*. These observations suggest that tissue activation and cytokine secretion occur because of the effects of parasite migration through the lung and that the inflamed intestine does not generate an acute phase response to nematode infection, as might have been predicted.

Other cells also may produce cytokines during nematode infections. Intraepithelial lymphocytes (IEL), found at the basolateral surfaces of epithelial cells, have been shown to produce several different cytokines including IL-2, IL-3, IL-5, IL-6, IFN $\gamma$ , TNF $\alpha$ , and TGF $\beta$  in the absence of parasitic infection (Dillon *et al.*, 1987; Barrett *et al.*, 1990; Taguchi *et al.*, 1990). The epithelium itself also has been shown to produce EGF/urogastrone in humans (Wright *et al.*, 1990) and IL-6 in freshly isolated cell preparations (K. Beagley, personal communication). Although these cytokines and their potential effects are impressive, few studies have evaluated this condition *in situ*. Part of this response may reflect the effects of cell isolation and manipulation *in vitro*.

IEL deserve special attention since they have interesting cytoplasmic granules, appear to be thymus independent, and express novel surface antigens including T-cell repertoires that are not found elsewhere in the body (Lefrancois, 1991). The large population of Thy1<sup>-</sup>CD8<sup>+</sup> IEL has been shown to mediate antibody enhancement in orally tolerized animals, but IEL-derived cytokines have not been implicated directly (Fujihashi *et al.*, 1990). IFN $\gamma$  (Zhang and Michael, 1990) and TGF $\beta$  (L. Zettel and P. Ernst, unpublished observations) have been shown to prevent or reverse tolerance, since both these cytokines are produced by IEL they may contribute to the enhancement of antibody responses. Since IELs are mostly CD8<sup>+</sup>, their ability to produce so many cytokines may compensate for the absence of CD4 helper T cells (Th) in this compartment. Since nematodes and other pathogens are found in close association with the epithelium, the IEL may have evolved an important role in the host response to infections through cytokine generation and other functions.

Most analyses of T-cell function in parasitized animals have focused on cytokine production by Th cells from the spleen or mesenteric lymph node, providing an interesting model of Th cell heterogeneity and its implications for function. Studies have shown that Th cells segregate into subsets based on their cytokine profile (Mosmann and Coffman, 1987). Thus, Th1 cells are a source of IL-2, IL-3, IFN $\gamma$ , LT, GM-CSF, and TNF- $\beta$ . In turn, Th2 cells produce IL-3, IL-4, IL-5, IL-6, IL-10, GM-CSF, and TNF (Mosmann and Moore, 1991). Interestingly IL-10, which is produced by Th2 but not Th1 cells, leads to the inhibition of Th1 cell development but not that of Th2 cells (Mosmann and Moore, 1991). During infection with *N. brasiliensis* or *T. spiralis*, mice mount a strong Th2 cell-like response in their spleen or mesenteric lymph nodes, including the ability to synthesize more IL-4 and IL-5 while producing less IFN $\gamma$  and IL-2 (Pond *et al.*, 1989; Street *et al.*, 1990; Mosmann and Moore, 1991).

## VI. EFFECTS OF CYTOKINE PRODUCTION DURING INFECTION WITH NEMATODES

The characteristics of Th2 stimulation during nematode infection include elevated IgE antibody production, eosinophilia, and mastocytosis (Finkelman *et al.*, 1988,1991; Coffman *et al.*, 1989; Wang *et al.*, 1989; Madden *et al.*, 1991; Urban *et al.*, 1991). These immunological manifestations are explained by the production of IL-3, IL-4, and IL-5, which can contribute to these changes. Evidence implicating cytokine control of the immune response *in vivo* in some nematode infections comes from experiments in which various neutralizing antibodies have been injected into an animal. Several studies have shown that either anti-IL-4 or anti-IL-3 antibody can inhibit partially the induction of mucosal mastocytosis in *N. brasiliensis*-infected mice, and that a combination of these two antibodies blocks the *N. brasiliensis*-induced increase in mucosal mast cell number by approximately 90% (Finkelman *et al.*, 1991). The injection of anti-IL-4 and anti-IL-4 receptor monoclonal antibodies into mice infected with *N. brasiliensis* or *H. polygyrus* totally blocks the IgE responses to both primary and secondary inoculations. Likewise, a neutralizing anti-IL-5 monoclonal antibody has been shown to block peripheral blood and tissue eosinophilia completely in mice infected with *N. brasiliensis* (Coffman *et al.*, 1989). Remarkably, treatment with anti-IL-5 antibodies does not block expulsion of *N. brasiliensis*; however, the expulsion is inhibited completely by an anti-CD4 antibody (Katona *et al.*, 1988). The cytokine IFN $\alpha$  appears to inhibit the development of blood and solid tissue eosinophilia, at least in *N. brasiliensis*-infected mice (Finkelman *et al.*, 1991). Thus, CD4<sup>+</sup> T cells, by some mechanism other than the induction of eosinophil, mast cell, or IgE responses, make an essential contribution to protective immunity in *N. brasiliensis*-infected mice. Interestingly, clearance of *H. polygyrus* is blocked by anti-IL-4 antibody (Urban *et al.*, 1991), showing that mechanisms of protection differ.

IL-3 production by IELs also may lead to local mast cell hyperplasia induced by these infections. Mast cells also produce a range of cytokines (Gordon *et al.*, 1990) and, since the IELs contain a vast number of mast cell precursors that are able to differentiate during nematode infestations (Crapper and Schrader, 1983; Guy-Grand *et al.*, 1984), they also may contribute to additional cytokine production.

In addition to the alterations in the immune and inflammatory response, infection with intestinal nematodes has been shown to affect intestinal physiology. Changes observed in association with mucosal inflammation are consistent with the prediction that lymphocytes or mast cells in the epithelium and lamina propria may modulate epithelial proliferation, differentiation, and function. This hypothesis is supported by studies showing altered epithelial structure and function after challenge with antigen in sensitized animals (King and Miller, 1984; Harari *et al.*, 1987; Patrick *et al.*, 1988; Crowe *et al.*, 1990), as well as by reports that cytokines or mast cell mediators modulate the expression of secretory component and major histocompatibility (MHC) Class II molecules on enterocytes (Sollid *et al.*, 1987; Kvale *et al.*, 1988; Phillips *et al.*, 1990) and enterocyte function (Barrett, 1991).

Complementing these responses to antigen in the epithelium, smooth muscle contractility also is altered by antigen in sensitized animals (Palmer and Castro, 1986). This altered contractility may involve the effects of mast cells or T cells (Vermillion *et al.*, 1989,1991) on sodium pump activity (Muller *et al.*, 1989) or impaired neurotransmitter release (Collins *et al.*, 1991). At least some of these changes do not require contact with the parasite, since uninfected segments of intestine experience similar alterations in physiological function (Marzio *et al.*, 1990). These observations suggest that inflammatory mediators or cytokines from mast cells or T cells may act as hormones and modulate distant tissues. A coordinated physiological response mediated by the immune system during infection with intestinal nematodes could assist in the catharsis associated with the expulsion of these parasites.

## VII. EXTENSION TO THE LIVER

Two reviews (Andus *et al.*, 1991; Richards *et al.*, 1991) have summarized the effects of a number of cytokines on the liver (see Table I). These authors have emphasized three aspects about the interactions between the liver and cytokines, including (1) cytokines as signal molecules reaching the liver from extrahepatic inflammatory sites and leading to changes in hepatocyte metabolism, including the acute phase response; (2) the role of the liver as a source and scavenger of cytokines; and (3) the role of cytokines during diseases of the liver itself.

The liver responds quite dramatically to intestinal infection with nematodes. For example, mast cells are increased in the portal areas of the liver of rats infected with *N. brasiliensis* (Figure 1) or *Taenia taeniaeformis* (Ishiwata *et al.*, 1991). As noted earlier, mast cells rarely are seen in the normal liver, either as young mast cells in the space of Disse (Balabaud *et al.*, 1988) or as mature mast cells in the perisinusoidal space (Jezequel *et al.*, 1986). Our studies suggest that some of these mast cells in normal or parasitized animals may arise from hepatic precursors in response to an increase in mast cell growth factors emanating from the intestine or hepatic T cells (see Table II).

The function of hepatic mast cells is unclear, although their presence during nematode infection reflects the ability of the liver to respond to intestinal sensitization. After the administration of 48/80, histamine is released by hepatic mast cells into the bile. Using a more physiological stimulus, feeding ovalbumin to sensitized animals also causes an increase in biliary histamine (G. D. F. Jackson *et al.*, unpublished observations). Presumably, histamine and other mediators from mast cells contribute to changes in the liver including altered blood flow, the accumulation of inflammatory cells, and possibly chronic changes such as fibrosis through the production of TNF or TGF $\beta$  by mast cells. Since significant synthesis and transport of IgA also occurs in the liver of rodents (Manning *et al.*, 1984), the exchange of immunological information between the liver and intestine via the portal circulation and the bile may play a role in host resistance.

**Table I** Cytokines Affecting the Liver<sup>a</sup>

Cytokine	Main source
IL-1	Monocytes, endothelium, smooth muscle, keratinocytes
IL-2	Lymphocytes
IL-6	Monocytes, lymphocytes, fibroblasts, endothelium, smooth muscle, keratinocytes
TNF $\alpha$	Monocytes
LIF/HSF III	Tumor cells
IL-11	Stromal cells, T cells, monocytes
Oncostatin M	Stromal cells, T cells, monocytes
IFN $\alpha/\beta$	Mononuclear cells
IFN $\gamma$	T lymphocytes
EGF	Gastrointestinal glands
TGF $\alpha$	Fibroblasts, embryonic cells, keratinocytes, monocytes
TGF $\beta$	Monocytes, platelets, hemopoietic cells, lymphocytes, placenta, keratinocytes, kidney, fibroblasts, bone
FGF	Endothelial cells, pituitary cells
PDGF	Platelets, monocytes
IGF-1	Hepatocytes, tumor cells
IGF-2	Liver, yolk sac

<sup>a</sup> Modified with permission from Andus *et al.*, (1991).

In some other parasitic diseases, cytokines produced in the liver may act directly to clear the liver of parasites. IL-1, IL-6, IFN $\gamma$ , and TNF directly or indirectly interfere with the development of malaria parasites in the liver via an L-arginine-dependent effector mechanism (Nussler *et al.*, 1991). Similarly, both the sporozoites and the erythrocytic stages of malaria parasites have been established to modulate the hepatic phase of malaria by cytokines (notably IFN $\gamma$ , TNF $\alpha$ , and IL-6), either directly or as a result of a cascade of events (Mazier *et al.*, 1990). Th2 cytokines have been suggested to be selectively induced during infection with

**Table II** Frequency of Mast Cell Precursors in Mononuclear Cells from Liver and Peripheral Blood of Normal CBA Mice<sup>a</sup>

Origin of cells	Frequency/10 <sup>6</sup> cells (95% confidence interval)
Perfused liver	148 (107–189)
Nonperfused liver	357 (289–425)
Peripheral blood	115 (94–137)

<sup>a</sup> Purified mononuclear cells from normal spleen were cultured in the presence of interleukin 3 (WEHI-conditioned media) using limiting dilution as described elsewhere (Crapper and Schrader, 1983). Based on the presence of colonies of mast cells individual wells were scored and the frequency of mast cell precursors was calculated.

*Schistosoma mansoni* (Pearce *et al.*, 1991) and IL-5 production is associated with the eosinophilia. However, anti-IL-5 antibody *in vivo* can decrease the number of eosinophils but has no other effect on the appearance of the hepatic granulomas.

Additional evidence suggests that cytokines can be produced in the liver and modulate other functions in this site. After immunization of rats, the number of cells expressing CD25 (IL-2 receptor) increases from 10 to 24% (G. D. F. Jackson *et al.*, unpublished observations). This increase is associated mainly with CD8<sup>+</sup> cells in the portal region. This evidence of activation again suggests that local cytokine production by immune or inflammatory cells or other nonparenchymal cells occurs in the liver, in agreement with the observations that cytokines such as TNF $\alpha$ , IL-1, and IL-6 are produced by hepatic mononuclear cells (Decker, 1990), whereas parenchymal and fat-storing cells may produce these as well as fibroblast growth factor (FGF), TGF $\alpha$ , and IFN $\alpha$  (Northemann *et al.*, 1990). In turn, perisinusoidal cells are the major source of circulating insulin-like (IGF-1) (Murphy *et al.*, 1987) and also can express TGF $\beta$ 1 (Nakatsukasa *et al.*, 1990). Hepatic sinusoidal endothelial cells produce cytokines such as a basic FGF-like molecule (Rosenbaum *et al.*, 1989). Liver parenchymal cells also have been shown to express IL-8 genes *in vitro*, implying that the liver may participate in inflammatory processes by the production of leukocyte chemotactic factors. From these reports, we can see that antigen or inflammatory signals emanating from the gut via the portal circulation clearly stimulate host of cytokine responses in the liver.

Cytokines affect many metabolic functions of the liver including its amino acid, protein, lipid, and carbohydrate metabolism. Mineral metabolism, detoxification, and bile excretion also may be influenced by certain cytokines. Carbohydrate metabolism is increased by several cytokines including IGF-1, IL-6, EGF, and IGF-2 (Andus *et al.*, 1991). In particular, IL-6 can stimulate hepatic glucose release from pre-labeled glycogen pools *in vitro*; likewise, antisera to this cytokine significantly decrease monocyte-derived glucose-releasing factor (GFR) activity, implicating IL-6 as a glucoregulatory factor that acts by inhibiting glycogen synthase (Ritchie, 1990). In addition, lipid metabolism is raised by IL-1, IFN $\alpha$ , TNF $\alpha/\beta$ , and IFN $\gamma$ . TNF increases serum triglyceride levels *in vivo* by stimulating hepatic lipogenesis and very low density lipoprotein (VLDL) production. However, IL-4 has been found to block the effect of TNF, IL-1, and IL-6 on lipogenesis but to have no effect on the ability of IFN $\gamma$  to stimulate this response (Endo, 1991; Grunfeld *et al.*, 1991). Thus, the liver can respond in a number of ways to cytokines produced in response to local or intestinal inflammation by altering its immunological characteristics, inflammatory response, and metabolic processes.

## VIII. SUMMARY

Infection with intestinal nematodes has been a useful tool in exploring the peculiarities of cytokine production and func-

**Figure 1** Hepatic mast cell response during intestinal inflammation. Histological sections of liver from mice infected with *N. brasiliensis* were prepared and stained with toluidine blue. A marked increase in mast cells was observed, particularly close to the portal triad as seen in cross (A) or longitudinal (B) sections. Mast cells rarely are seen in uninfected mice.

tion. Although the acute inflammatory response may not be invoked during the intestinal phase of a nematode infection, a significant activation of Th2 cells appears to occur that could account for the characteristic changes in the intestinal mucosa and possibly the mastocytosis in the liver. Interestingly, Th2 cells also are believed to enhance IgA responses through the production of IL-4, IL-5, and IL-6; however, the immunological picture observed during a mucosal IgA response and nematode infestation could not be more different. Clearly, a significant gap exists in our current understanding of the control of mucosal immunity. Cytokines produced in the intestine and liver are quite pleiotropic and the discrete expression of genes encoding cytokines or their receptors may combine with tolerogenic mechanisms involving the liver to focus a response toward the desired end point. In view of the protective responses governed by cytokines, a better understanding of cytokine regulation and the manner in which their pleiotropic effects are prevented certainly will be a key issue for future research.

Studies of the local and systemic effects of intestinal nematodes constitute a useful approach to demonstrating the immunological link between the intestine and the liver. The nature of the interaction can include an exchange of antigen, hematopoietic precursors, immune cells, or potent intercellular messengers such as cytokines. Additional knowledge about the intestinal–hepatic axis could facilitate the successful development of oral vaccines and intestinal transplantation.

### Acknowledgments

The studies summarized in this chapter were supported in part by the Medical Research Council of Canada.

# Cytotoxic Lymphocytes in Mucosal Effector Sites

Steven D. London

## I. INTRODUCTION

Lymphocytes that express cytotoxic function are a major component of the immune system. Cytotoxic lymphocytes can be classified broadly into two groups based on their antigenic specificity. The first group is antigen specific and is thought to be involved in the rejection of tissues expressing nonself major histocompatibility complex (MHC) antigens (alloantigens). Antigen-specific cytotoxic cells also are thought to be important in the elimination of cells infected with a wide number of intracellular pathogens via recognition of pathogen-specific antigens (nominal antigens) complexed with self MHC molecules. Antigen-specific cytotoxic T lymphocytes (CTL) are T-cell receptor bearing CD3<sup>+</sup> T lymphocytes. These cells are usually CD8<sup>+</sup> and are restricted by MHC Class I molecules. However, CD4<sup>+</sup> MHC Class II-restricted CTLs also have been found to exist as a subpopulation of CTLs. The second group of cytotoxic effector cells includes a variety of cell types that are not antigen or MHC restricted and often exist in the absence of specific infections or diseased states. In this chapter, I review the cytotoxic lymphocyte compartment of mucosal tissues with emphasis on antigen-specific cytotoxic cells. Although the primary focus of this review is the CTLs, a description of nonspecific cytotoxic cells in mucosal tissues is also included. The presence of nonspecific cytotoxic cells in mucosal tissues may indicate that they play a functional role in protection of mucosal areas. In addition, their presence should be appreciated since they can complicate the detection of specific cytotoxic effector cells in specific CTL assays.

## II. NONSPECIFIC CYTOTOXIC CELLS IN GUT MUCOSAL TISSUES

Several different types of nonspecific cytotoxic cell have been described based on target preference, surface phenotype, and responsiveness to various biological factors. Natural killer cells (NK) lyse Yac-1 targets and express asialo-GM1, NK-1 antigen, and low levels of Thy 1 antigen. These cells are responsive to interferon and interleukin 2 (IL-2) *in vitro* (Welsh, 1984; Brooks and Henney, 1985). Natural cytotoxic cells (NC) lyse WEHI-164 targets, are negative for the NK cell markers, and are responsive to IL-2 and IL-3 *in vitro* (Stutman *et al.*, 1978; Lattime *et al.*, 1983). Spontane-

ously cytotoxic T lymphocytes (SC) were described initially as arising from splenocytes cultured in the absence of mitogen, antigen, or interleukins. These cells bear high levels of Thy 1 and lyse P-815 cells (Ching *et al.*, 1977). The origin of and interrelationship among these cytotoxic cells is not clear, and is complicated by observations of the breakdown in specificity of cultured antigen-specific CTLs (Wilson and Shortman, 1984). The levels of these types of nonspecific cytotoxic activity have been analyzed in various mucosal lymphoid populations. Peyer's patch lymphocytes obtained from conventionally reared mice have been shown to contain undetectable levels of cytotoxic activity to the NK-sensitive target Yac-1 in 4-hr (Tagliabue *et al.*, 1981, 1983/1984) or 16-hr (Tagliabue *et al.*, 1983/1984) <sup>51</sup>Cr release assays. NK activity was not induced by a 24-hr incubation of Peyer's patch lymphocytes with a source of IL-2 or IL-3 (Tagliabue *et al.*, 1983/1984). However, the incubation of Peyer's patch lymphocytes with irradiated peritoneal exudate cells and 10% concanavalin A (Con A)-conditioned medium has been shown to result in the generation of cytotoxic activity to Yac-1 target cells (London *et al.*, 1986). These results may be analogous to the observation that Peyer's patches lack terminally differentiated B cells (plasma cells) although they are capable of generating antibody secreting cells in *in vitro* cultures (Kiyono *et al.*, 1982). In contrast to NK cytotoxicity, normal Peyer's patch lymphocytes lyse the NC-sensitive target WEHI-164 in 16-hr <sup>51</sup>Cr release assays. Peyer's patch lymphocytes have higher levels of NC activity than either spleen or peripheral lymph node lymphocytes (Tagliabue *et al.*, 1983/1984). Peyer's patch lymphocytes obtained from conventionally reared mice also were found to contain a population of novel naturally cytotoxic effector cells that have been termed natural cytotoxic T cells (NCTC) (Gautam *et al.*, 1986). NCTC effector cells were able to lyse a wide variety of syngeneic and allogeneic tumor cell lines as well as syngeneic or allogeneic Con A-induced T lymphoblasts. These cells are characterized as plastic nonadherent, nylon wool adherent Thy 1<sup>+</sup> Ia<sup>+</sup> asialo-GM1<sup>+</sup> T cells (Gautam *et al.*, 1986) and have been identified in several inbred strains of mice. Of all lymphoid tissues tested, only Peyer's patch lymphocytes were found to contain NCTC activity.

In addition to Peyer's patch lymphocytes, intraepithelial lymphocytes (IEL) have been analyzed for the presence of naturally occurring cytotoxic cells. NC (Tagliabue *et al.*, 1983/1984) activity has been observed in purified populations of unprimed IELs. Whereas IELs of normal mice do not

express cytotoxicity toward the SC target P-815 (Goodman and Lefrancois, 1988), such cytotoxicity can be elicited *in vitro* by culturing IELs in the presence of Con A-conditioned medium (Ernst *et al.*, 1985) or *in vivo* after immunization by the combined feeding and parenteral inoculation of allogeneic splenocytes or tumor cells (Klein and Kagnoff, 1984). The literature regarding the presence of NK cytotoxicity among IELs is more complex, with some reports of this activity in normal mice (Petit *et al.*, 1985; Tagliabue *et al.*, 1981, 1982, 1983/1984; Klein, 1986) and some reports of this activity only in mice experimentally stimulated with allogeneic splenocytes or tumor cells (Klein and Kagnoff, 1984; Carman *et al.*, 1986; Goodman and Lefrancois, 1988). The inconsistent finding of NK activity in isolated IELs may be related to differences in environmental conditions. For example, specific pathogen-free mice and germ-free mice, compared with conventionally reared mice, have lower numbers of IELs and phenotypically altered IEL populations (Carman *et al.*, 1986; Lefrancois and Goodman, 1989; Guy-Grand *et al.*, 1991a). Utilizing an antigen nonspecific "redirected" cytotoxicity assay, some investigators have reported that the cytotoxic potential of IELs is unrelated to gut antigen stimulation (Guy-Grand *et al.*, 1991b) whereas others have shown a striking environmental influence on the cytotoxic potential of particular IEL subpopulations (Lefrancois and Goodman, 1989). The redirected cytotoxicity assay has demonstrated clearly that IELs from conventionally reared mice are constitutively lytic (Lefrancois and Goodman, 1989; Viney *et al.*, 1990; Guy-Grand *et al.*, 1991b). Thus, environmental factors may have a strong influence on the nature and immune potential of IELs, so these factors should be considered in the planning and interpretation of experiments involving IELs. In addition, these results suggest that the activation of nonspecific cytotoxic effector populations that occurs during an antigen-specific response may be a nonspecific defense mechanism that is important for the protection of the gut mucosa from infection with environmental pathogens.

The cytotoxic lymphocyte response to gut mucosal infection with an enteric murine coronavirus, mouse hepatitis virus (MHV), has been analyzed. Although an antigen-specific CTL response was not detected, a novel non-MHC-restricted cytotoxic IEL effector cell population has been identified that is highly cytotoxic to target cells infected with this virus (Carman *et al.*, 1986). These predominantly asialo-GM1<sup>+</sup> Thy 1<sup>-</sup> Lyt 1<sup>-</sup> Lyt 2<sup>-</sup> cytotoxic effector cells were present in immune and normal mice. Elimination of asialo-GM1<sup>+</sup> cells *in vivo* resulted in an increased persistence of virus in gut tissues as well as decreased cytotoxic activity of isolated IELs to MHV infection *in vitro* (Carman *et al.*, 1986). Although MHV-specific CTLs have been difficult to demonstrate and MHV-specific CTL clones have been obtained only recently (Yamaguchi *et al.*, 1988), antibody-independent B lymphocyte-mediated lysis of MHV-infected cells has been shown to occur (Wysocka *et al.*, 1989). This lysis is likely to be mediated by selective fusion of B lymphocytes and MHV-infected cells, facilitated by the neutral pH membrane-fusing activity of MHV E2 protein. Note that a similar mechanism of nonspecific cytolysis may control MHV infection at mucosal surfaces and that this activity is carried

out by a unique cell population present only in the intestinal epithelium.

### III. GUT MUCOSAL CYTOTOXIC T LYMPHOCYTES

#### A. Allospecific Cytotoxic T Lymphocytes

Kagnoff and Campbell (1974) were the first to demonstrate that Peyer's patch lymphocytes express CTL activity by generating allogeneic specific CTLs in secondary mixed lymphocyte reaction (MLR) of cultured Peyer's patch lymphocytes from normal mice. The precursor CTLs were identified as T cells by pretreatment with anti-theta serum and complement (Kagnoff and Campbell, 1974). Intraperitoneal injection or chronic feeding of MHC disparate tumor cells (EL-4 cells into BALB/c mice) was found to increase the level of allogeneic cytotoxicity developed in secondary MLR cultures of primed rather than normal Peyer's patch lymphocytes, suggesting that the gut mucosal application of stimulator cells results in an increase in precursor frequency (Kagnoff, 1978). In contrast to tumor cells bearing major MHC differences, tumor cells bearing minor MHC differences induced a CTL response in Peyer's patches after intraperitoneal priming but not after chronic feeding (Kagnoff, 1978).

The intraperitoneal injection of allogeneic tumor cells has been shown to generate allogeneic specific CTLs recoverable from IELs and lamina propria lymphocytes (LPL) 6–11 days after immunization (Davies and Parrott, 1980, 1981; Parrott *et al.*, 1983). This cytotoxic activity was observed without re-stimulation of isolated effector cells in an *in vitro* MLR. Control mice do not respond to allogeneic targets, and the subcutaneous route of immunization does not generate high levels of CTL activity in the gut mucosa (Davies and Parrott, 1981; Parrott *et al.*, 1983). LPLs contained the highest levels of cytotoxic activity of all tissues tested after intraperitoneal immunization; this cytotoxicity lasted for prolonged periods (>40 days; Parrott *et al.*, 1983). The phenotype of both alloantigen-specific effectors and precursor CTLs (pCTLs) generated *in vitro* in primary isolated IEL MLR cultures was shown to be Thy 1<sup>+</sup> Lyt 2<sup>+</sup> (Ernst *et al.*, 1986). The frequency of alloantigen-specific pCTLs was found to be approximately threefold higher among unfractionated splenocytes than in isolated IELs (Ernst *et al.*, 1986).

Alloantigen-specific CTL clones have been obtained from isolated IELs derived from BALB/c mice that were immunized twice, intragastrically and intraperitoneally, with allogeneic tumor cells (EL-4) (Klein *et al.*, 1985; Klein and Kagnoff, 1987). Two types of effector clone were generated: (1) clones that were antigen specific with respect to proliferation and cytolytic activity and (2) clones that were antigen specific for proliferation but were not cytolytic when maintained in 4% Con A-conditioned medium. When cultured in the presence of 25% Con A-conditioned medium for 4 days, these clones exhibited broad lytic potential and were cytotoxic for EL-4 cells, P-815 cells (SC), and Yac-1 cells (NK), as well as for syngeneic and allogeneic lipopolysaccharide

(LPS) blasts. Although one clone (D3) was reported lytic for syngeneic LPS blasts, it does not lyse itself when  $^{51}\text{Cr}$ -labeled D3 cells are used as targets. The phenotype of both types of clones was Thy  $1^+$  Lyt  $2^+$  (Klein *et al.*, 1985; Klein and Kagnoff, 1987). These broadly cytotoxic clones may be an *in vitro* counterpart of the broadly cytotoxic NCTC cells observed in normal Peyer's patches. The presence of broadly cytotoxic cells in gut mucosal tissues might be one mechanism by which mucosal tissues are protected from infection with particular intracellular pathogens.

### B. Vaccinia Virus-Specific Cytotoxic T Lymphocytes

Although early studies have indicated that gut mucosal tissues have the capability to contain CTLs, whether mucosal application of antigen is a necessary prerequisite for the generation of CTL activity in these tissues is not clear. Further, the generation of allospecific CTLs with precursors that are present at an extremely high frequency (Lindahl and Wilson, 1977) may not be a good indication of the potential of Peyer's patches to generate CTL activity directed to nominal antigens associated with environmentally encountered pathogens. Gut mucosal infection with vaccinia virus has provided direct evidence that some gut associated tissue contains virus-specific CTLs. After enteric injection, mesenteric lymph node lymphocytes had a strong vaccinia-specific T helper cell and CTL response (Issekutz, 1984). Vaccinia-specific T helper cell and CTL responses were not observed in Peyer's patches. Since Peyer's patches are one source of lymphocytes that migrate to the mesenteric lymph nodes, one interpretation of these results is that Peyer's patches are an inductive site from which virus-specific Th cells and CTLs were stimulated. In this scenario, the absence of detection of these cells in Peyer's patches is a consequence of their rapid migration to mesenteric lymph nodes.

### C. Reovirus-Specific Cytotoxic T Lymphocytes

Reovirus serotype 1, strain Lang (reovirus 1/L), is a naturally occurring enteric virus that is stable within the gastrointestinal tract (Sabin, 1959; Rubin and Fields, 1980). The observation that reovirus 1/L preferentially binds to and is transported from the intestinal lumen into Peyer's patches through microfold (M) cells (Wolf *et al.*, 1981, 1983) and its ability to stimulate the appearance of IgA-committed memory cells in Peyer's patches and distal lymphoid tissues after intraduodenal immunization (London *et al.*, 1986) suggest that reovirus 1/L is an effective mucosal immunogen. Further, the marked expansion of cells expressing the GCT antigen (an antigen present on subpopulations of CD8 $^+$  T and germinal center B cells) after a single intraduodenal application of reovirus 1/L provides additional evidence of the ability of reovirus 1/L to stimulate Peyer's patch T and B cell subpopulations acutely (London *et al.*, 1990).

In studies aimed at analyzing the potential of gut mucosal tissues to generate virus-specific CTLs, researchers found that a single intraduodenal application of reovirus 1/L generates the appearance of detectable levels of virus-specific cyto-

toxicity in Peyer's patch and mesenteric lymph node lymphocytes on *in vitro* re-stimulation (London *et al.*, 1986). Although this was the first demonstration of virus-specific pCTLs in Peyer's patches, these results confirm those found with vaccinia virus infection and offer further support that the CTL response observed in mesenteric lymph nodes in both systems may have originated from migrating Peyer's patch lymphocytes. Peyer's patch effectors show the surface phenotype of CTLs (Thy  $1^+$  Lyt  $2^+$ ), are MHC restricted, and are virus-specific (London *et al.*, 1986). In addition, the phenotype of the pCTLs prior to their *in vitro* stimulation also was shown to be Thy  $1^+$  Lyt  $2^+$  (London *et al.*, 1990). Although the virus-specific cytotoxic cells derived from Peyer's patches were found not to be selective for the immunizing serotype of reovirus, as was reported previously for nonmucosal lymphocytes (Finberg *et al.*, 1979), they were not cross-reactive with unrelated virus antigens (London *et al.*, 1986). The lack of serotype specificity was found not to be unique to Peyer's patch-derived lymphocytes but also was displayed by intraperitoneally primed splenocytes (London *et al.*, 1986, 1989a) and is similar to the CTL response observed with a number of other viruses, including two other members of the Reoviridae family of viruses: blue-tongue virus (Jeggo and Wardley, 1982) and Group A rotavirus (Offit and Dudzik, 1988) (see subsequent discussion).

Since reovirus-specific pCTLs have been demonstrated in Peyer's patches, determining whether they were generated locally or whether they represent a population of lymphocytes stimulated elsewhere that have localized preferentially in the patch was of interest. Two observations suggest that the former possibility occurs: (1) Peyer's patches contain virus-specific helper activity that has been shown to be required for the generation of effector CTLs on *in vitro* re-stimulation in the reovirus system (London *et al.*, 1986) and (2) significantly higher levels of virus-specific cytotoxicity are generated from cultures of Peyer's patches than from peripheral lymph nodes 2–6 days after intraduodenal immunization (London *et al.*, 1986). The frequency of reovirus-specific pCTLs in these tissues was confirmed directly. A 100-fold difference in frequency ( $1675/10^6$  CD8 $^+$  Peyer's patch lymphocytes vs.  $17/10^6$  peripheral lymph node CD8 $^+$  lymphocytes) was found 6 days after enteric immunization. In addition, the gradient of pCTLs that initially was established early after infection was found to exist for a prolonged period after the single intraduodenal injection of reovirus 1/L. The frequency of pCTLs was an order of magnitude greater in Peyer's patches than in peripheral lymph nodes (14.5-fold higher;  $1235/10^6$  CD8 $^+$  vs.  $85/10^6$  CD8 $^+$ ) 6 months after reovirus infection (London *et al.*, 1986).

In addition to the pCTLs in Peyer's patches, virus-specific pCTLs also occur as a component of the IEL compartment. MHC Class I antigen-restricted reovirus-specific effector CTLs are generated from *in vitro* cultured IELs 1 week after the intraduodenal application of reovirus 1/L (London *et al.*, 1989b). IEL effectors have been shown to be Thy  $1^+$  CD8 $^+$  lymphocytes, and reovirus-specific IEL pCTLs also are likely to express the Thy 1 antigen (C. Cuff, D. H. Rubin, and J. J. Cebra, unpublished observation). The frequencies of pCTLs in the epithelial and Peyer's patch lymphoid compart-

ments are similar (100–300/10<sup>6</sup> CD8<sup>+</sup> Peyer's patch lymphocytes vs. 50–200/10<sup>6</sup> CD8<sup>+</sup> IEL lymphocytes) 1 week after intraduodenal immunization (Cebra *et al.*, 1991). IEL pCTLs have been observed to persist for up to 4 weeks (Cebra *et al.*, 1991; C. Cuff, D. H. Rubin, and J. J. Cebra, unpublished observation). Since IELs are an enriched source of  $\gamma\delta$  T-cell receptor (TcR)-bearing lymphocytes, determining whether IEL reovirus-specific effector or precursor CTLs expressed this or the more common  $\alpha\beta$  TcR was of interest. Collectively, the following observations strongly suggest the latter: (1) >90% of TcR<sup>+</sup> cells express the  $\alpha\beta$  TcR in *in vitro* cultured IEL preparations that also have been shown to contain reovirus-specific cytotoxic activity; (2) oral infection of germ-free mice with reovirus 1/L results in a marked increase of  $\alpha\beta$ -expressing lymphocytes in the epithelium that can be stimulated *in vitro* to generate reovirus-specific CTLs; and (3) adoptive transfer of normal Peyer's patch lymphocytes to mice that harbor the severe combined immunodeficiency defect (SCID), followed by oral reovirus infection 2 days later, results in an increase in the number of IELs, many of which express the  $\alpha\beta$  TcR (Cebra *et al.*, 1991; C. Cuff, D. H. Rubin, and J. J. Cebra, unpublished observation).

The ability of adoptively transferred Peyer's patch lymphocytes to respond to reovirus infection and repopulate the gut epithelium of SCID mice confirms studies suggesting that Peyer's patch lymphocytes are able to populate the gut epithelium with thymodependent lymphocytes (Guy-Grand *et al.*, 1991a, and references therein). In addition, the adoptive transfer of reovirus-immune Peyer's patch lymphocytes into SCID mice prevents the establishment of a disseminated infection in these immunodeficient mice (George *et al.*, 1990). The transfer of CD8<sup>+</sup> GCT<sup>+</sup> reovirus-immune Peyer's patch lymphocytes, but not naive lymphocytes or B cells, contains disseminated reovirus infection in SCID mice 1 week after challenge (A. George, D. H. Rubin, and J. J. Cebra, unpublished observation). Thus, this cell population, which has been shown to include both reovirus-specific precursor and effector CTLs (London *et al.*, 1990), contains virus-specific effector cells that are functionally relevant and important in the containment of virus infections *in vivo*. Similarly, the adoptive transfer of reovirus-immune Thy 1<sup>+</sup> CD8<sup>+</sup> IELs confers protection on neonatal mice when challenged with a lethal neurotropic strain of reovirus (Cuff *et al.*, 1991).

The presence of precursors for virus-specific CTLs, diffusely scattered in the intestinal epithelium, and the ability of enterically applied reovirus 1/L to generate a CTL response in Peyer's patches that can persist for many months demonstrates that a CTL response exists among the repertoire of immune responses that can occur in Peyer's patches and the gut epithelium. For viruses that initially impinge on the wet epithelium, the presence of virus-specific CTLs and natural effector (i.e., NK) cells at this location could result in the local containment, limitation, and resolution of the infectious agent rather than its dissemination. The ability to mount a mucosal CTL response may be advantageous to the host, because local containment could prevent sequelae associated with infection at distal sites.

#### D. Rotavirus-Specific Cytotoxic T Lymphocytes

Gut mucosal infection with rotavirus provides another informative viral stimulus for the study of gut mucosal immunity. Rotaviruses, like reoviruses, are members of the Reoviridae family of nonenveloped doubled-stranded RNA viruses. These viruses share similar structural features and replicative strategies, yet their interaction with the gut mucosa is strikingly different. Whereas reovirus infection of the gut mucosa is a potent stimulator of virus-specific and nonspecific responses, the virus infection is subclinical and is resolved in the gut within 10–12 days (Cebra *et al.*, 1991). In contrast, gut mucosal infection with rotavirus results in a generalized infection of small intestinal villous epithelial cells and can cause acute viral gastroenteritis in humans and animals (Offit and Dudzik, 1989a, and references therein).

Infection of mice with several strains of rotavirus is a potent inducer of virus-specific CTLs. Rotavirus infection by either oral or parenteral route elicits effector CTLs in multiple lymphoid tissues that can be detected without *in vitro* amplification (Offit and Dudzik, 1988, 1989b; Offit and Svoboda, 1989; Offit *et al.*, 1991b). Effector and precursor CTLs are serotype nonspecific Thy 1<sup>+</sup> CD8<sup>+</sup> lymphocytes (Offit and Dudzik, 1988, 1989b; Offit and Svoboda, 1989; Dharakul *et al.*, 1991; Offit *et al.*, 1991a). Although these effectors usually are elicited by infection with replicating virus, inoculation with noninfectious virus has been shown to be capable of eliciting rotavirus-specific CTLs (Offit and Dudzik, 1989a).

The tissue distribution of rotavirus-specific CTLs has been analyzed after various routes of immunization. The salient observations from these studies follow: (1) Six days after oral immunization, effector CTLs were detected among Peyer's patch, mesenteric lymph node, LPL, spleen, and IEL lymphocyte populations (Offit and Dudzik, 1989b; Offit *et al.*, 1991b). (2) Six days after intraperitoneal or subcutaneous immunization, effector CTLs were detected among Peyer's patch, mesenteric lymph node, LPL, spleen, and peripheral lymph node lymphocytes. Effector CTLs were observed in IELs after intraperitoneal but not subcutaneous immunization (Offit and Dudzik, 1989b; Offit *et al.*, 1991b). (3) Four weeks after oral, intraperitoneal, or subcutaneous immunization, pCTLs (as assayed by *in vitro* culture) were detected in Peyer's patch, mesenteric lymph node, LPL, spleen, and peripheral lymph node but not IEL lymphocyte populations (Offit and Dudzik, 1989b; Offit *et al.*, 1991b). (4) IEL effector CTLs obtained from orally infected mice were shown to be CD3<sup>+</sup> and express the  $\alpha\beta$  form of the TcR (Offit *et al.*, 1991b). (5) When the frequency of pCTLs was analyzed 3, 6, and 21 days after immunization, the site of rotavirus infection determined that pCTL first appeared in Peyer's patch and mesenteric lymph nodes three days after oral infection. Three days after footpad infection, pCTLs were detected first in the inguinal peripheral lymph node. At six days, pCTLs were 30-fold higher in Peyer's patches after oral infection and ~7-fold higher in inguinal peripheral lymph node after footpad infection. However, by 21 days, pCTLs were distributed uniformly throughout the lymphoid system (with the excep-

tion of IEL), regardless of the route of immunization (Offit and Dudzik, 1988; Offit *et al.*, 1991b). Thus, in contrast to results obtained with gut mucosal reovirus infection, which suggested that the route of immunization may be important for the generation and maintenance of a gut mucosal CTL response, the route of immunization with rotavirus does not appear to be as important for the generation of disseminated gut mucosal responses. The lack of persistence of rotavirus-specific pCTLs in the epithelium also contrasts with results obtained with gut mucosal reovirus infection. These discrepancies are likely to be the results of differences in virus dissemination and interaction with the immune system, and suggest that different strategies for particular mucosal pathogens may be devised that elicit protective T-cell immunity at mucosal surfaces.

The potential functional relevance of rotavirus-specific CTLs has been demonstrated in two animal model systems. In the first example, Thy 1<sup>+</sup> CD8<sup>+</sup> splenocytes obtained from intraperitoneally immunized mice passively protect suckling mice against diarrhea induced by rotavirus challenge (Offit and Dudzik, 1990). In the second, rotavirus infection was cleared in SCID mice after the transfer of immune CD8<sup>+</sup> splenic lymphocytes from intraperitoneally immunized histocompatible mice (Dharakul *et al.*, 1990, 1991). Interestingly, CD8<sup>+</sup> immune splenocytes or Thy 1<sup>+</sup> CD8<sup>+</sup> IELs obtained from orally immunized mice only temporarily cleared rotavirus infection of SCID mice (Dharakul *et al.*, 1990, 1991). Whether the suboptimal ability of orally immunized spleen and IELs to contain rotavirus infection in SCID mice is a result of intrinsic differences in cell population after oral or intraperitoneal immunization or is simply a technical problem remains to be resolved.

#### IV. PULMONARY CYTOTOXIC CELLS

The lung is another mucosal site that has been shown to contain nonspecific and specific cytotoxic effector cells. Natural killer cell activity is normally present in the lung and is enhanced after influenza infection in mice (Wyde *et al.*, 1977). Seven days after infection with influenza virus,  $\gamma\delta$  TcR-expressing cells are found to predominate in the lungs of mice (Carding *et al.*, 1990). Although these cells are not constitutively cytotoxic when recovered directly from the respiratory tract, cytotoxic function can be induced by culturing them in the presence of monoclonal antibody to CD3 and low concentrations of IL-2 (Eichelberger *et al.*, 1991a). Although the function of these  $\gamma\delta$  TcR-expressing cells remains an enigma, they may have a role in the containment and resolution of infections in the lung by either cytolytic or noncytolytic (i.e., secretion of cytokines) mechanisms.

Antigen-specific CTLs also have been shown to be a component of the immune repertoire of the lung. Immunization with allogeneic tumor cells by both the intratracheal and the intraperitoneal route have resulted in the accumulation of alloantigen-specific CTLs in the lung and spleen (Liu *et al.*, 1982, and references therein). Viral-specific CTLs also are

generated after pulmonary infection with several viruses that replicate in the respiratory epithelium. For example, influenza virus-specific precursor and effector CTLs are found in the lung shortly after intratracheal infection (Bennink *et al.*, 1978; Ennis *et al.*, 1978; Yap *et al.*, 1978a; Allan *et al.*, 1990). The ability of adoptively transferred influenza virus-specific CTLs to limit viral replication in the pulmonary tract has been shown (Yap *et al.*, 1978b; Lukacher *et al.*, 1984; Taylor and Askonas, 1986). However, recent data suggest that CTLs are not the sole effectors capable of terminating influenza infection. For example, adoptive transfer of influenza virus-specific MHC Class II-restricted Th clones allows athymic mice to recover from pulmonary influenza virus infection in the absence of MHC Class I-restricted CTLs (Scherle *et al.*, 1992). Clearance of influenza virus infection also has been reported in normal mice depleted of CD8<sup>+</sup> T cells *in vivo* and in transgenic mice, homozygous for a  $\beta_2$ -microglobulin gene disruption, that lack functional Class I MHC glycoproteins and CD8<sup>+</sup>  $\alpha\beta$ <sup>+</sup> T cells (Eichelberger *et al.*, 1991b). Pulmonary infection with respiratory syncytial virus (RSV) also has been shown to elicit the generation of precursor and effector CTLs in the lungs and spleen of mice (Bangham *et al.*, 1985; Taylor *et al.*, 1985; Gupta *et al.*, 1990). The appearance of CD8<sup>+</sup> lymphocytes in the lungs of RSV-infected mice correlates with the elimination of infectious virus from the pulmonary tract (Kimpen *et al.*, 1991). *In vivo* depletion of CD8<sup>+</sup> T cells suggests that their presence is important for the cessation of viral replication in the lung (Graham *et al.*, 1991). In a number of studies, the transfer of RSV-specific CTLs has been shown to be capable of clearing virus from the lungs of mice (Cannon *et al.*, 1987; Munoz *et al.*, 1991; Nicholas *et al.*, 1991; Trudel *et al.*, 1991). Although transferred CTLs limit viral replication in the pulmonary tract, some studies have correlated their transfer with increased pulmonary disease (Cannon *et al.*, 1988; Graham *et al.*, 1991).

#### V. CONCLUSIONS

The idea that both antigen-specific and nonspecific cytotoxic cells are an integral component of mucosal tissues is becoming increasingly evident. Although much research has focused on the gastrointestinal and respiratory tracts, cytotoxic cells are likely to be components of the immune repertoire of other mucosal tissues. The specifics of the cytotoxic response are likely to vary depending on the nature and location of the immune stimulus. For example, studies of the eye have revealed site-specific immunoregulation of CTL development and have demonstrated the presence of the less commonly observed CD4<sup>+</sup> MHC Class II-restricted CTLs in mucosal tissues. In the eye, the placement of tumor cells in two anatomically distinct regions (anterior chamber and subconjunctiva) elicits tumor-specific pCTLs (Ksander and Streilein, 1990, and references therein). However, the pCTLs differentiate into cytotoxic effector CTLs only in the subconjunctiva, thereby allowing tumor rejection to occur only in this site. Recurrent herpes simplex virus-1 (HSV-1) infection

of the corneal stroma of the eye often results in stromal pathology and, ultimately, in vision impairment. HSV-1-specific MHC Class II-restricted CD4<sup>+</sup> CTLs have been implicated as constituting one of the mechanisms leading to stromal immunopathology in herpetic infections (Doymaz *et al.*, 1991).

A better understanding of how to stimulate cytotoxic cells in mucosal tissues, their recirculation pathways between mucosal and systemic tissues, and their function in mucosal sites is warranted since these cells may limit pathogens or may be involved in pathogenesis at mucosal sites. The series of observations that CTLs are elicited in response to a number of nonviral intracellular pathogens suggests that such cells might be a more generalized component of the immune system. CTL responses have been identified for the protozoan parasites *Leishmania* (Smith *et al.*, 1991) and *Toxoplasma gondii* (Hakim *et al.*, 1991; Khan *et al.*, 1991), for malaria *Plasmodium berghei* circumsporozoite protein (Aggarwal *et al.*, 1990, and references therein), and for the gram-positive bacterium *Listeria monocytogenes* (Pamer *et al.*, 1991). In studies of immunity to malaria, researchers found that oral immunization with attenuated *Salmonella typhimurium* recombinants containing the full-length *P. berghei* circumsporozoite gene induces protective immunity against intravenous sporozoite challenge in the absence of antibodies. Immunity was found to be mediated through the induction of circumsporozoite-specific CD8<sup>+</sup> CTLs (Aggarwal *et al.*, 1990). Thus, the mucosal application of *S. typhimurium*, a bacterium known to interact with Peyer's patches, is capable of inducing a systemic CTL response that can control heterologous infections. This elegant study suggests that oral *Salmonella* vectors may be useful for the generation of specific CTL responses, which may be useful for the containment of viral or nonviral infections of mucosal or systemic tissues.

### Acknowledgments

The author would like to thank Drs. John J. Cebra, Donald H. Rubin, Christopher F. Cuff, and Anna George for providing unpublished data for this chapter.

# Mucosal Immunity to Viruses

Brian R. Murphy

The mucosal surfaces of the body, including primarily the respiratory and gastrointestinal tracts, are infected readily with a wide variety of DNA and RNA viruses. Important viral pathogens of mucosal surfaces such as paramyxoviruses and rotaviruses cause serious disease on first infection. In contrast to the lifelong immunity induced by viruses such as measles virus and polioviruses that cause systemic disease, mucosal immunity is usually more transient, so reinfection by mucosal pathogens is common. Disease often occurs during reinfection but is usually less severe than that experienced during first infection. Several general observations of the effectiveness of the mucosal immune system in altering the course of viral infection follow: (1) In the absence of antibody, severe disease can occur. (2) In the presence of low to moderate levels of antibody, infection results in a milder illness. (3) In the presence of intermediate levels of antibody, an asymptomatic infection occurs. (4) In the presence of high levels of antibody, infection can be prevented (Ogra and Karzon, 1969b). Because of the difficulty in maintaining a very high level of mucosal immunity, the major function of the mucosal immune system appears to be that of converting a severe infection into a mild or asymptomatic one. The high volume, rapid transit time, and hostile environment of the respiratory and gastrointestinal tracts most likely contribute to the inability to maintain high levels of mucosal antibodies.

In this quantitative balance between virus and host, the host calls on the cellular and humoral immune systems to limit the extent of virus replication, to clear virus, and to prevent reinfection. Although the secretory IgA system has evolved specifically to protect mucosal surfaces, significant contributions to mucosal immunity are made by the cellular arm of the immune system and by the transudation of antiviral IgG antibodies onto mucosal surfaces.

## I. CELLULAR ANTIVIRAL IMMUNE MECHANISMS OPERATIVE ON MUCOSAL SURFACES

Natural killer (NK) cells, major histocompatibility complex (MHC) Class I-restricted CD8<sup>+</sup> cytotoxic T cells (Tc) and MHC Class II-restricted CD4<sup>+</sup> helper T cells (Th) each can function as antiviral effector cells against viruses that infect mucosal surfaces.

### A. NK cells

Humans with an inherited deficiency of NK cells experience more severe herpes virus infections than normal individuals (Biron *et al.*, 1989). The infected individuals eventually clear the virus infection in a fashion comparable to that of immunocompetent hosts. These observations suggest that NK cells, which do not exhibit virus-specific antiviral activity, can play an important early role in limiting the extent of certain mucosal viral infections.

### B. Tc Cells

Tc cells appear to be the major T cell effector with antiviral activity (Yap *et al.*, 1978; Kast *et al.*, 1986; Taylor and Askonas, 1986; Dharakul *et al.*, 1990; Offit and Dudzik, 1990; Munoz *et al.*, 1991). The Tc cell receptor recognizes a short peptide derived from an endogenously produced viral protein in the context of the MHC Class I  $\beta_2$ -microglobulin heterodimer expressed on the surface of an infected cell (Madden *et al.*, 1991). Since the MHC Class I restriction elements are present on almost all cells except neurons, Tc cells can exert their antiviral effects against almost all infected cells of mucosal surfaces. Since viral infection of a cell generally is required for antigen presentation by the MHC Class I  $\beta_2$ -microglobulin heterodimer, clearly Tc cells cannot function to prevent infection, but must function to eliminate cells already infected or, alternatively, to restrict virus replication in cells already infected. The net effect of Tc cell activity is preventing further spread of virus and terminating infection in cells already infected. Passive transfer of Tc-cell clones to animals results in restriction of virus replication in mucosal epithelial cells, demonstrating the functional capabilities of this T-cell subset (McDermott *et al.*, 1987; Cannon *et al.*, 1988; Mackenzie *et al.*, 1989; Munoz *et al.*, 1991). Tc cell antiviral activity generally is associated with the clearance of virus and the reduction of virus-associated pathology (Lukacher *et al.*, 1984; Mackenzie *et al.*, 1989; Munoz *et al.*, 1991). However, disease enhancement was seen in one viral infection after passive transfer of large numbers of respiratory syncytial virus-specific cloned Tc cells that were capable of clearing virus infection (Cannon *et al.*, 1988).

The time course of Tc-cell activation during viral infection is consistent with this predominant role in clearance of virus infection. Primary (also called direct) Tc cell cytotoxic activ-

ity of pulmonary lymphocytes peaks early during paramyxovirus (respiratory syncytial virus) infection (day 7) and declines to barely detectable levels by day 12 (Anderson *et al.*, 1990). Thus, restriction of virus replication in mucosal tissues mediated by Tc cells is active early during the acute stage of the virus infection, but this activity wanes rapidly by day 28 (Connors *et al.*, 1991). These observations suggest that the Tc-cell component of the immune response is operative primarily during the early phase of infection from the time just before peak titers of virus are reached to the time virus-infected cells are cleared, and later exists in an inactive (or memory) state (Connors *et al.*, 1991; Nicholas *et al.*, 1991). For viruses that replicate rapidly at mucosal surfaces, such as influenza viruses and paramyxoviruses, the proliferation of memory Tc cells is unlikely to be sufficiently rapid to alter significantly the peak titer of virus achieved in the respiratory tract (McMichael *et al.*, 1983; Endo *et al.*, 1991; Webster *et al.*, 1991). However, Tc cells actively generated from memory cells may reach levels that accelerate viral clearance (McMichael *et al.*, 1983). Since disease is experienced when peak titers of viruses are attained, immunization with antigens that induce predominantly Tc activity in the absence of antibody is, not surprisingly, much less successful in restricting replication of challenge virus and preventing illness than immunization that induces a sustained antibody response (Andrew *et al.*, 1987; Endo *et al.*, 1991; Webster *et al.*, 1991).

### C. Th Cells

Although Th cells are known to provide help to B cells, thereby augmenting antibody response, Th cells themselves have been shown to have direct antiviral activities *in vivo* (McDermott *et al.*, 1987; Taylor *et al.*, 1990). The contribution made by the direct antiviral activity of the Th response to the overall immunity that is induced appears to be of lower magnitude than that of the Tc cells consistent with the more limited distribution of its restricting element, the MHC Class II  $\alpha,\beta$  heterodimer, which is present predominantly on B lymphocytes and antigen-presenting cells such as macrophages and dendritic cells. In addition to having antiviral activity, Th cells also can mediate immunopathology (Leung and Ada, 1980; Taylor *et al.*, 1990).

Animals depleted of either Th or Tc cells prior to infection with influenza A viruses can, however, clear virus at rates similar to those of fully immunocompetent animals (Lightman *et al.*, 1987; Eichelberger *et al.*, 1991a,b), indicating that the immune system is functionally redundant; multiple components from both the humoral and the cellular immune systems contribute to clearance of infection.

## II. IgG ANTIBODIES ON MUCOSAL SURFACES

IgG antibodies present in the blood can gain access to mucosal surfaces by passive diffusion and can exert antiviral

activity. Much of the IgG antibody present at mucosal surfaces is derived from serum, as indicated by the following observations: (1) A linear relationship exists between titer of serum and nasal wash IgG influenza virus antibodies (Wagner *et al.*, 1987). (2) The ratio of IgG1/IgG3 influenza virus-specific antibody is similar in serum and nasal washes (Wagner *et al.*, 1987). (3) The active transport of IgG antiviral antibodies across mucosal surfaces occurs infrequently, if at all, whereas transport of IgA and IgM antibodies is the rule (Murphy *et al.*, 1982). Although most of the IgG present in mucosal secretions is derived by transudation from serum, virus-specific IgG antibodies produced by the mucosa also can contribute to total antiviral activity in mucosal secretions (Ogra *et al.*, 1974; Johnson *et al.*, 1986; McBride and Ward, 1987). Further, in IgA-deficient patients, mucosal production and secretion of IgG and IgM antiviral antibodies can compensate for the deficiency of production and secretion of IgA antibodies (Ogra *et al.*, 1974).

The antiviral activity of IgG antibodies against viruses that replicate on mucosal surfaces has been documented following transudation of antibodies that are derived from three different sources: (1) antibodies produced by the host (Clements *et al.*, 1986); (2) maternally derived antibodies (Lepow *et al.*, 1961; Puck *et al.*, 1980; Reuman *et al.*, 1983,1987); and (3) passively transferred polyclonal or monoclonal antibodies (Bodian and Nathanson, 1960; Ramphal *et al.*, 1979; Prince *et al.*, 1985; Offit *et al.*, 1986; Besser *et al.*, 1988). The IgG antiviral antibodies can prevent infection (Lepow *et al.*, 1961), decrease virus replication (Bodian and Nathanson, 1960; Lepow *et al.*, 1961; Prince *et al.*, 1985; Clements *et al.*, 1986), and eliminate or lessen the severity of disease (Puck *et al.*, 1980). In the case of respiratory viruses, serum IgG antibodies restrict virus replication in the lung more effectively than in the trachea or nose (Ramphal *et al.*, 1979; Prince *et al.*, 1985). Further, passively transferred IgG antibodies restrict the replication of poliovirus to a greater extent in the throat than in the lower intestinal tract (Bodian and Nathanson, 1960). These data suggest that a gradient exists regarding the ability of serum IgG derived antibodies to restrict virus replication on mucosal surfaces; this gradient is lung > nasopharynx > lower intestinal tract (Sabin *et al.*, 1963a,b; Reuman *et al.*, 1983; Murphy *et al.*, 1986a,b,1988,1989; Kimman *et al.*, 1987,1989; Johnson *et al.*, 1988). One possible explanation for this gradient is that serum antibodies can diffuse more readily across alveolar walls than across the mucosa of the upper respiratory tract and that the hostile environment of the gastrointestinal tract and the dilution of the IgG antibodies with the intestinal secretions further limit the effectiveness of passively derived IgG antibodies at this site. The mechanism of the antiviral activity of IgG antibodies *in vivo* is related to direct neutralization of virus infectivity, as evidenced by the restriction of respiratory syncytial virus replication in the lungs of passively immunized rodents depleted of complement, and by the finding that F(ab)<sub>2</sub> fragments of IgG can restrict pulmonary virus replication as effectively as whole IgG molecules. Thus, complement-dependent immune cytolysis and antibody-dependent cell cytotoxicity are not required for the antiviral

activity of IgG antibodies (Prince *et al.*, 1990). However, complement appears to be necessary for the efficient clearance of influenza A virus infection in mice (Hicks *et al.*, 1978).

Many viruses infect mucosal surfaces during the first 6 months of life when maternal IgG antibodies are present. In addition, immunizing infants with live poliovirus vaccine when passively acquired maternal antibodies are present is routine. For these reasons, interest has arisen in studying the effect of passively derived IgG antibodies on the development of immunity to viral infections. Such antibodies clearly can significantly modify the immune response to viruses that replicate on mucosal surfaces. The magnitude of the mucosal and systemic antibody response to a viral infection that takes place in the presence of passively acquired IgG antibody can be reduced significantly despite a high level of virus replication (Sabin *et al.*, 1963a; Murphy *et al.*, 1986a; Kimman *et al.*, 1987). However, a secondary IgG antibody response is seen in subjects immunosuppressed by passively transferred IgG antibodies on rechallenge with virus or antigen, even in subjects who failed to mount a detectable primary antibody response (Sabin *et al.*, 1963b; Reuman *et al.*, 1983). Despite the reduction in magnitude of the primary antibody response to initial infection in such subjects, partial resistance to subsequent challenge is evident (Sabin *et al.*, 1963a; Reuman *et al.*, 1983; Murphy *et al.*, 1989). The suppressive effect of passively acquired IgG antibody on the induction of resistance to challenge is greatest when viral antigen is administered parenterally rather than mucosally (Murphy *et al.*, 1989). A secretory IgA response still can develop in individuals whose IgG antibody response is suppressed by passively derived IgG, suggesting that the mucosal IgA antibody response is suppressed less easily by passive IgG antibody than is the systemic IgG response (Jayashree *et al.*, 1988; Kimman and Westenbrink, 1990). This finding provides a partial explanation for the development of mucosal resistance to infection in the presence of maternally derived antibodies.

A second way in which passively derived IgG can modify the antibody response to virus is altering the functional activity (i.e., quality) of the antiviral antibodies that are induced (Murphy *et al.*, 1988). The neutralizing activity of a given amount of virus antigen-specific antibody is decreased markedly when the viral infection occurs in the presence of passively derived IgG antibodies (Murphy *et al.*, 1988). The mechanisms by which passively acquired IgG antibodies mediate their effects on the magnitude and quality of the antibody response remain to be defined.

### III. MUCOSAL IgA ANTIBODY RESPONSE

Although passively transferred IgG antibodies and Th and Tc effector cells contribute to mucosal immunity, the major mediators of resistance to viral infection on mucosal surfaces are IgA antibodies. IgA antiviral antibodies are likely to play major roles in clearance of viral infections, modification of the severity of disease on reinfection, and prevention of infection on reexposure to virus.

#### A. Viral Antigens Recognized by IgA Antibodies

The major viral antigens that induce a protective antibody response are the surface glycoproteins of viruses that contain lipid envelopes or the proteins present on the surface of icosahedral viruses. IgA antibodies recognize the same viral antigens as IgG antibodies; evidence is accumulating that they also recognize the same epitopes on these glycoproteins. For instance, polyclonal IgA antibodies, like polyclonal IgG antibodies, recognize the hemagglutinin of influenza virus (Murphy *et al.*, 1982; Clements *et al.*, 1986); the gp70 (fusion) and gp90 (attachment) glycoproteins of respiratory syncytial virus (Murphy *et al.*, 1986b); the gp340 of Epstein-Barr virus (Yao *et al.*, 1991); the VP1, VP2, and VP3 of polioviruses (Zhaori *et al.*, 1989); and the VP4 of VP7 of rotaviruses (Conner *et al.*, 1991; Shaw *et al.*, 1991; Richardson and Bishop, 1990). In general, the specificity of the neutralizing activity of IgA and IgG antibodies for antigenically related variant viruses appears to be similar (Buscho *et al.*, 1972; Richman *et al.*, 1974), that is, the mucosal IgA antibody response does not appear to be more broad than the systemic IgG antibody response. However, the antigens of viruses that replicate on mucosal surfaces can be modified by intestinal enzymes to expose new epitopes on the surface proteins of such viruses. Thus, the immunogenicity of a virus that replicates in the intestinal tract can differ from that of a parenterally administered inactivated vaccine produced from tissue-culture grown virus. For example, the mucosal IgA response to the poliovirus VP3 protein—which is cleaved by intestinal enzymes following oral administration of live virus, thereby exposing unique epitopes on the protein—is greater than that following immunization with inactivated virus given parenterally (Zhaori *et al.*, 1989), despite the finding that the mucosal IgA responses to VP1 and VP2 are comparable for the two conditions.

The IgA antibody response to the attachment and fusion glycoprotein antigens on respiratory syncytial virus is depressed during infection of infants that have maternal antibodies. Further, the age of the subject correlates with the response to the fusion protein, and the level of maternally derived antibodies is related inversely to the response to the G glycoprotein (Murphy *et al.*, 1986a). Thus, factors influencing IgA responses to viral glycoproteins are complex; protein structure, age of host, and presence of passively acquired IgG antibody all contribute to the magnitude and quality of the response.

IgA monoclonal antibodies to viruses that infect mucosal surfaces have been produced to define further the antigens and epitopes seen by IgA antibodies (Maoliang, 1986; Weltzin *et al.*, 1989; Lyn *et al.*, 1991). The same antigens and epitopes appear to be recognized by IgG and IgA monoclonal antibodies. Variants selected with neutralizing IgA and IgG monoclonal antibodies have been shown to have identical reactivity patterns against a panel of monoclonal antibodies (Maoliang, 1986) or to have identical amino acid substitutions (Lyn *et al.*, 1991). Some epitopes of the HN glycoprotein of Sendai virus are recognized by IgA antibodies but not by IgG antibodies; however, a large panel of IgG and IgA monoclonal

antibodies must be analyzed to determine whether any epitopes or antigenic sites on viral proteins are seen exclusively by IgA antibodies (Lyn *et al.*, 1991). The mechanism of heavy chain switching, in which the antibody binding regions are maintained but constant regions of the heavy chains are exchanged, is compatible with the observations just outlined, namely, that IgG and IgA in general have similar specificities for viral antigens and their epitopes.

### B. Time Course of the Mucosal IgA Response to Viral Infection

The mucosal IgA response to viral infection is rapid after first infection and can be detected as early as day 3 following infection (Blandford and Heath, 1972; Rubin *et al.*, 1983). The time course for an idealized mucosal IgA response is given in Figure 1. The primary response peaks within the first 6 weeks and can decrease to a low, often barely detectable, level by 3 months (Buscho *et al.*, 1972; (Sonza and Holmes, 1980; Kaul *et al.*, 1981; Friedman, 1982; Friedman *et al.*, 1989; Bishop *et al.*, 1990; Coulson *et al.*, 1990; Nishio *et al.*, 1990). This short duration of the primary mucosal antibody response is compatible with the susceptibility to reinfection that is common for viruses that infect mucosal surfaces. Reinfection results in a secondary antibody response, indicating immunological memory characterized by a rapid rise in IgA antibody titer, a rise to a higher peak titer, and maintenance of detectable levels of antibody over a longer period of time (Buscho *et al.*, 1972; Kaul *et al.*, 1981; Wright *et al.*, 1983; Merriman *et al.*, 1984; Yamaguchi *et al.*, 1985; Bishop *et al.*, 1990; Coulson *et al.*, 1990).

In addition to a mucosal IgA response, a serum IgA response occurs after mucosal viral infection. The latter appears to be more sustained than the mucosal response (Friedman *et al.*, 1989). A correlation between the magnitude of the serum and mucosal IgA antiviral antibody responses has been observed in some instances, suggesting that some of the serum IgA antibody is a spill-over from mucosal sites (Burlington *et al.*, 1983). The polymeric structure of postinfection antiviral serum IgA antibodies is consistent with a mucosal origin of B cells that secrete IgA antibody into the systemic circulation since serum IgA antibodies are generally monomeric (Brown *et al.*, 1985; Ponzi *et al.*, 1985). However,

polymeric IgA serum antibodies can be induced by parenteral immunization of immune individuals with inactivated influenza virus vaccine (Brown *et al.*, 1987), suggesting that memory IgA cells of mucosal origin might seed systemic sites after infection and that antigenic stimulation of such cells yields IgA antibodies with a polymeric nature and subclass that are characteristic of mucosal IgA antibodies. The detection of IgA-producing B lymphocytes in the peripheral blood or spleen after mucosal viral infection or immunization with inactivated antigen is compatible with this suggestion (Yarchoan *et al.*, 1981; Czerkinsky *et al.*, 1987; London *et al.*, 1987). The number of these B cells peaks early within the first 2 weeks after antigenic stimulation and decreases rapidly thereafter. These circulating cells could seed not only systemic sites but also mucosal sites at locations other than the site of antigenic stimulation (Czerkinsky *et al.*, 1987).

The number of virus-specific IgG-, IgA-, or IgM-secreting B cells at mucosal sites of virus replication has been studied in both the lungs and the small intestine, and differences were noted. An IgG B-cell response predominated in the lungs (Jones and Ada, 1986) whereas an IgA B-cell response predominated in the intestine (Merchant *et al.*, 1991).

### C. Local Nature of the Mucosal IgA Antibody Response

Evidence for the existence of a common mucosal immune system comes from the observation that immunization of a mucosal site often leads to detectable immune responses at distant mucosal sites (Mestecky, 1987). This seeding of distal mucosal sites is likely to be the result of trafficking of locally stimulated mucosal B lymphocytes to distant sites, where they reside as IgA plasma cells actively producing antibody or as memory B cells (Rudzik *et al.*, 1975; Czerkinsky *et al.*, 1987; Mestecky, 1987). Such trafficking of antiviral IgA-producing cells can occur from the gastrointestinal tract mucosa to the respiratory tract mucosa and perhaps vice versa (Waldman *et al.*, 1986; Chen *et al.*, 1987; Hirabayashi *et al.*, 1990). Although this common mucosal system exists, it appears to be relatively inefficient at protecting sites not directly stimulated with antigen (Ogra *et al.*, 1969b; Smith *et al.*, 1970; Nedrud *et al.*, 1987). Oral immunization with live adenovirus vaccine in enteric coated capsules selectively

Figure 1 Time course of mucosal IgA response to viral infection.

infects the lower intestinal tract and induces a fecal IgA and serum IgG antiviral antibody response, but fails to induce a detectable nasal wash IgA antibody response (Smith *et al.*, 1970; Scott *et al.*, 1972). In contrast, live adenovirus vaccine administered to the upper respiratory tract induces a vigorous nasal wash antibody response (Smith *et al.*, 1970). In a similar study with live poliovirus virus vaccine in infants, selective infection of the colon via a colostomy orifice resulted in a vigorous neutralizing IgA antibody response in the colon, but not in the nasopharynx (Ogra *et al.*, 1969b). When the upper respiratory tract of these infants was challenged with poliovirus vaccine, vaccine virus replicated to high titer in the pharynx but the colon was resistant to replication to vaccine virus, as indicated by absence of virus shedding from the lower gastrointestinal tract (Ogra *et al.*, 1969b). Similar studies with rotavirus infection in infants and children demonstrated that the IgA antiviral response in the duodenum, which is the major site of viral replication, was greater than that in saliva, a distant mucosal site not known to support rotavirus replication (Grimwood *et al.*, 1988). In experimental studies in rodents, immunization of the gut with inactivated parainfluenza virus vaccine plus adjuvant was less protective than intranasally administered vaccine (Nedrud *et al.*, 1987). However, a protective response to influenza virus infection in the lung was observed after oral immunization of mice (Chen *et al.*, 1987). These studies in humans and animals suggest that induction of protective mucosal IgA responses at distant mucosal sites is likely to be difficult to achieve and that augmentation of the distant IgA response by immunological adjuvants is likely to be required.

The local nature of the mucosal antibody response, even within the respiratory tract, was observed in two studies. In the first study, the quantity of mucosal antibody in sputum or nasal secretions of volunteers given an inactivated influenza A virus vaccine by aerosol was a function of the size of the aerosolized particles (Waldman *et al.*, 1970). The subjects vaccinated with an aerosol containing small particles that are deposited predominantly in the lung had high sputum but low nasal secretion antibody titers, whereas individuals immunized with large particles that are deposited predominantly in the nose had high nasal but low sputum antibody titers. In the second study, intranasal administration of inactivated influenza A virus vaccine induced a greater nasal wash neutralizing antibody response than salivary antibody response, indicating that the site of antigenic stimulation, that is, the nasal passages, had a greater mucosal response than the distant site, that is, the salivary glands (Waldman *et al.*, 1968). These observations demonstrate that mucosal antibody responses are more localized than systemic antibody responses, which are disseminated via the circulatory system. A partial explanation for the local nature of the mucosal responses comes from the finding that the concentration of virus-specific IgA-producing B cells at the site of antigenic stimulation is much higher than that at more distant sites (Dharakul *et al.*, 1988). Although trafficking of B cells between mucosal sites occurs, the level of antiviral antibody and resistance to infection achieved at distant sites appears to be much less than at sites of direct antigenic stimulation. Mucosal immunization thus is achieved most successfully

by antigenic stimulation of sites directly involved in viral replication.

#### D. Mechanism of Antiviral Activities of IgA Antibodies

The mechanism of neutralization of the infectivity of animal viruses by immunoglobulins is complex; a variety of mechanisms contribute to loss of viral infectivity (Outlaw and Dimmock, 1991). IgA antibodies are able to neutralize the infectivity of viruses efficiently and more closely resemble IgG antibodies in their efficiency of neutralization than do IgM antibodies, which have a lower overall activity (Nguyen *et al.*, 1986; Mazanec *et al.*, 1987; Outlaw and Dimmock, 1991; Renegar and Small, 1991a). IgA antibodies are able to neutralize the infectivity of viruses by several different mechanisms. First, aggregation of virus by IgA antibodies is associated with a decrease in virus infectivity, a finding that contrasts with that for IgM (Outlaw and Dimmock, 1990). Second, IgA antibodies to influenza appear to be more efficient than IgG antibodies in preventing attachment of virus to infected cells by being able to block 70–90% of virus particles from attaching to cell receptors (Outlaw and Dimmock, 1991). The polymeric nature of the IgA molecule is thought to contribute in part to this difference. Third, IgA antibodies can prevent the penetration of attached virus into the infected cell (Nguyen *et al.*, 1986; Outlaw and Dimmock, 1991). Fourth, IgA antibodies, like IgG antibodies, also act to neutralize viruses after penetration of the host cell (Outlaw and Dimmock, 1991). Thus, IgA antibodies appear similar to IgG in their efficiency of neutralization *in vitro*, but because of their polymeric nature appear to be more efficient at preventing attachment of certain viruses to susceptible cells.

IgA antibodies can have other effects on the immune system such as promoting uptake of viral antigens via immunoglobulin receptors present on the specialized absorptive epithelial cells called M cells (Weltzin *et al.*, 1989). Thus, virus neutralized by IgA antibodies whose attachment to specific cell receptors for virus has been blocked still can bind to M cells and be transported to the subepithelial macrophages that are in proximity to M cells. In this manner, viral antigen–IgA immune complexes destined for excretion in stools can gain access to antigen-presenting cells and thereby promote the overall immune response. Thus, IgA antibodies have direct (neutralization) and indirect means of preventing diseases caused by viruses that replicate on mucosal surfaces.

Few studies have compared IgG and IgA antibodies for their efficacy *in vivo*. However, with the availability of neutralizing monoclonal IgA and IgG antibodies directed to the attachment glycoprotein of Sendai virus, researchers have been able to compare the *in vivo* efficacies of IgA and IgG antibodies that have specificity for the same viral glycoprotein (Mazanec *et al.*, 1992). Mice passively immunized intranasally with IgG or IgA antibodies, either before or up to 24 hr after intranasal challenge with Sendai virus, were protected equally against pulmonary virus replication. Monomeric and polymeric IgA antibodies were equally efficacious. These data are consistent with the similarities of IgG and IgA anti-

bodies in their *in vitro* neutralizing activities and their similar abilities to recognize the same antigenic sites and epitopes on viral antigens. In a separate study, a neutralizing polymeric monoclonal IgA anti-influenza A virus hemagglutinin antibody, administered systemically, was able to restrict the replication of influenza virus in the upper respiratory tract of the mouse (Renegar and Small, 1991a). However, a similar effect was not observed when a comparable amount of IgG monoclonal antibody of the same specificity was administered. Thus, the main advantage of IgA antibodies in protecting mucosal surfaces of the respiratory tract appears to be their ability to be transported selectively across mucosal surfaces, not an inherently greater antiviral activity.

### E. IgA Antibodies Are Associated with the Clearance of Infectious Virus from Mucosal Surfaces

The appearance of IgA antibodies in mucosal secretions correlates with the cessation of virus excretion during mucosal viral infections in animals and humans in both the respiratory and gastrointestinal tracts (Figure 2; McIntosh *et al.*, 1978, 1979; Keller and Dwyer, 1968; Ogra, 1970; Corthier and Vannier, 1983). This suggests that the IgA antibodies neutralize the infectivity of viruses present in mucosal secretions and are partially responsible for clearance of infectious virus from such secretions is reasonable. The appearance of virus-IgA or virus-IgM immune complexes at the time of virus clearance is consistent with the role of IgA in resolution of virus infection (Corthier and Vannier, 1983). Whether antibodies produced during the course of viral infection can clear virus-infected cells from mucosal surfaces in the absence of T cells remains to be determined, but antibodies alone can clear systemic viral infections (Levine *et al.*, 1991). As mentioned earlier, animals rendered deficient in Tc or Th cell responses are able to clear virus infection in a manner similar to their fully immunocompetent counterparts (Lightman *et al.*, 1987; Eichelberger *et al.*, 1991a,b), suggesting that antibodies can participate in clearance of virus-infected cells from mucosal surfaces and that they might be sufficient in

this regard. However, the relative roles of IgG and IgA antibodies in such processes remain to be defined. Passive transfer studies of both polyclonal IgA and IgG antiviral antibodies or antibody-producing cells in T-cell deficient animals will be needed to address the question of the role of antibodies in viral clearance.

### F. IgA Antibodies Are the Major Mediators of Mucosal Immunity

Researchers long have recognized that immunization of the mouse by a mucosal route could, under certain circumstances, induce greater resistance to virus infection than systemic immunization and that resistance correlated with the level of mucosal antibodies (de St. Groth and Donnelly, 1950). Since that time, a large body of literature has emerged that associates the level of mucosal antibodies, either neutralizing or IgA antibodies, with resistance to a variety of viral infections in humans and animals (Table I). The resistance associated with IgA antibodies is manifested by prevention of infection or by decreasing the severity of infection. A quantitative relationship exists between the level of mucosal IgA antibodies and the extent of virus replication (Ogra and Karzon, 1969b). This association provides compelling, but not definitive, evidence that IgA antibodies are the primary mediators of mucosal resistance to viral infection. One study even demonstrated that local IgA memory in the absence of detectable IgA antibodies was associated with resistance to viral infection (Kimman *et al.*, 1989). In this instance, a local IgA response to reinfection appeared to be sufficiently rapid to limit the extent of virus replication or, alternatively, undetectable levels of antibody were present that modified the infection.

Definitive proof that IgA antibodies are the mediators of mucosal immunity has been forthcoming. Four studies demonstrate that passively transferred IgA antibodies are associated with resistance to virus infection on mucosal surfaces. (1) Neutralizing monoclonal IgA antibodies to the HN glycoprotein of Sendai virus (a murine parainfluenza virus) could protect against virus infection when administered intranasally

**Figure 2** An idealized viral infection of a mucosal surface in which clearance of infectious virus is associated with the appearance of neutralizing IgA antibodies. The black bar indicates the time when IgA-virus immune complexes are likely to be present.

<sup>b</sup> Serum IgA but not IgG was associated with milder illness.

before virus infection (Mazanec *et al.*, 1987). (2) Intranasally administered polymeric anti-influenza virus IgA antibodies that had been purified from mucosal secretions provided passive protection against virus infection when administered before virus challenge (Tamura *et al.*, 1990). (3) Systemically administered monoclonal polymeric IgA but not monoclonal IgG antibodies against influenza virus passively protected the respiratory tract of the mouse against influenza virus challenge (Renegar and Small, 1991a). (4) Inoculation of hybridoma cells secreting nonneutralizing polymeric IgA antibodies against a reovirus surface protein provided resistance to reovirus replication in the gastrointestinal tract (M. Neutra, personal communication). These studies clearly demonstrate that antiviral IgA antibodies are capable of mediating resistance to mucosal virus infection. Using a different approach, another study demonstrated that the mucosal immunity induced by infection with influenza virus is abrogated by instillation of anti-IgA antibody into the respiratory tract prior to virus challenge (Renegar and Small, 1991b). These data provides convincing evidence that the IgA antibodies induced by prior virus infection are the mediators of resistance to reinfection and that other mediators of antiviral activity such as Tc or Th cells or IgG antibodies make little contribution to resistance. Thus, three major lines of evidence, namely, the consistent association of the level of IgA antibodies with the extent of resistance to virus infection, the mediation of mucosal resistance to virus infection by

passive transfer of IgA antibodies, and the abrogation of infection-induced resistance to virus challenge by anti-IgA antibody treatment of the upper respiratory tract, clearly demonstrate that IgA antibodies are the major mediators of mucosal resistance to viral infections.

In conclusion, both cellular and humoral immune systems participate actively in the resolution of viral infections from mucosal surfaces, including the elimination of virus-infected cells, but T cells are likely to make a greater contribution in this phase of infection. In contrast, IgA antibodies play the major role in resistance to reinfection with a relatively minor direct role contributed by Tc and Th cells and IgG antibodies.

# Passive Immunization: Systemic and Mucosal

Kathryn B. Renegar • Parker A. Small, Jr.

The passive transfer of maternal immunity is responsible for keeping all mammalian species alive. The process of evolution developed effective mechanisms for the passive transfer of both systemic and mucosal immunity from the mother to her offspring. Experimental passive transfer of systemic immunity via serum antibody is well established, but the experimental passive transfer of mucosal immunity has been accomplished only recently. This chapter addresses the contributions of both natural and experimental mechanisms to the study of passive immunization.

## I. NATURAL PASSIVE IMMUNIZATION

### A. Systemic Immunity

The transfer of systemic immunity (IgG) from mother to offspring occurs prenatally via the placenta or yolk sac and after birth via the colostrum. Species vary in the contribution each route makes to the transfer of immunity (Waldman and Strober, 1969) and can be grouped into three categories (Table I) based on this variation.

#### 1. Prenatal Transfer Only

The first group, using prenatal transfer only, includes primates, rabbits, and guinea pigs. Transport of IgG in primates occurs almost exclusively through the placenta. IgG transfer occurs via receptor-mediated transcytosis across the syncytiotrophoblast and transcellular transport through the fetal endothelium (Leach *et al.*, 1990). Human placental transfer of protective IgG antibodies against a number of pathogens including rotavirus (Hjelt *et al.*, 1985), hepatitis B (Hockel and Kaufman, 1986), measles (Lennon and Black, 1986), and group B streptococcus (Baker *et al.*, 1988) has been reported. Prenatal transfer of IgG in the rabbit occurs via the yolk sac and in the guinea pig via both the yolk sac and the fetal gut (Waldman and Strober, 1969).

#### 2. Combined Prenatal and Postnatal Transfer

The group using combined prenatal and postnatal transfer includes rats, mice, cats, and dogs. Prenatal transmission occurs via the yolk sac/placenta and the fetal gut in the rat (Waldman and Strober, 1969). IgG is bound rapidly to receptors on the surface of the yolk sac membrane (Mucchielli *et al.*, 1983), endocytosed in clathrin-coated vesicles,

and, early in gestation, is stored in subapical vacuoles. By late gestation, the antibody has been hydrolyzed or transferred to fetal capillaries (Jollie, 1985). Prenatal transmission in mice occurs by a similar mechanism (Gardner, 1976).

Although placental transfer occurs, studies in rodents have shown that most transport of antibody occurs postnatally from colostrum or milk (Nejamkis *et al.*, 1975; Oda *et al.*, 1983; Kohl and Loo, 1984; Arango-Jaramillo *et al.*, 1988; Barthold *et al.*, 1988; Heiman and Weisman, 1989). Postnatal transmission of systemic immunity from colostrum and milk occurs over a period of 10–21 days, depending on the species, with a gradual decrease in transmission over the last 3 days of the period (Waldman and Strober, 1969), and is limited to antibodies of the IgG class (Hammerberg *et al.*, 1977; Appleby and Catty, 1983). Transport is a receptor-mediated process (Simister and Rees, 1983). In rats, the receptor is found in enterocytes of the proximal intestine during the early postnatal period but is absent after weaning (Jakoi *et al.*, 1985). The receptor is specific for IgG and its Fc fragment and consists of two similar polypeptides of 48,000–52,000 daltons (p51) in association with  $\beta_2$ -microglobulin (Jakoi *et al.*, 1985; Simister and Mostov, 1989). The Fc binding subunit (p51) has three extracellular domains and a transmembrane region, all of which are homologous to the corresponding domains of Class I major histocompatibility complex (MHC) antigens (Simister and Mostov, 1989).

#### 3. Postnatal Transfer Only

Ruminants (cattle, sheep, goats), horses, and pigs (reviewed by Tizzard, 1987) use only postnatal transfer. Transport of colostrum proteins from the lumen of the ileum in ruminants is largely nonspecific but, in the horse and pig, IgG and IgM are absorbed preferentially. Proteins are taken up actively by epithelial cells through pinocytosis and passed through these cells into the lacteals and intestinal capillaries (Tizzard, 1987). Intestinal absorption occurs for only the first 24–48 hours after birth, then the “open gut” closes down and no further transfer from milk or colostrum occurs (Waldman and Strober, 1969; Francis and Black, 1984; Ellis *et al.*, 1986; Tizzard, 1987). Newborn piglets have also been shown to absorb colostrum lymphoid cells during this time period (Tuboly *et al.*, 1988).

Absorption of colostrum immunoglobulin is normally extremely effective, supplying the newborn with serum immunoglobulin (particularly IgG) at a level approaching that found in adults (Tizzard, 1987); however, failure of passive transfer

(FPT) can occur and, when it does, can pose a considerable problem in animal husbandry. About 25% of newborn foals fail to obtain sufficient quantities of immunoglobulin (McGuire *et al.*, 1975; Tizzard, 1987). In the McGuire study (1975), 2 of 9 FPT foals died of infections within a few days of birth and 5 of the remaining 7 developed nonfatal respiratory infections between 2 and 5 weeks of age. McGuire *et al.* (1976) also reported FPT in calves, finding that 85% of calves less than 3 weeks old dying from infectious diseases had significant hypogammaglobulinemia. Although adequate methods to diagnose and treat FPT are available (Tizzard, 1987; Bertone *et al.*, 1988), the phenomenon remains a significant veterinary problem.

### B. Mucosal Immunity

Mother's milk provides passive protection of the mucosal surfaces it contacts. This protection may be mediated by nonspecific factors found in milk, for example, lactoferrin, lysozyme, fatty acids, and complement, or by specific antibody (reviewed by Goldman *et al.*, 1985). The antibody composition of milk differs from that of colostrum (Tizzard, 1987) and the class of protective antibody in milk varies with the species and the route of immunization of the mother. With the exception of IgG in rodents, these protective antibodies are not absorbed systemically by the suckling offspring but exert their protective effect locally by neutralizing viruses or virulence factors and by binding to microbial pathogens to prevent their attachment to the mucosal surface (Goldman *et al.*, 1985). Secretory IgA is especially suited to this protective role since secretory component enhances its resistance to proteolytic enzymes and gastric acid (Kenny *et al.*, 1967; Tomasi, 1970; Zikan *et al.*, 1972; Lindh, 1975) providing extra antibody stability in mucosal secretions.

#### 1. Milk Antibody in Rodents

Rodents have been a popular model for the study of passive transfer of maternal immunity via milk; however, this group of animals has a major drawback as a model for passive mucosal immunity. Rats and mice can actively transport IgG from the gut into the serum for approximately 2 weeks (Sec-

tion I,A,2). Thus, observed protection could be the result of antibody in the milk bathing the mucosal surfaces or of maternal antibody being transported into the serum and secretions of the offspring. This caveat should be kept in mind during the evaluation of the many reports of milk-borne protection in these species. Three rodent models in which protection of mucosal surfaces is due to milk-borne, not serum-derived, antibody are described here.

The predominant immunoglobulin in mouse milk is IgG, although significant levels of IgA can also be present (Ijaz *et al.*, 1987). Protection of infant mice from colonization with *Campylobacter jejuni* can be achieved by the consumption of immune milk at and after the time of bacterial challenge. The milk in this study contained high concentrations of specific IgG antibodies and very little specific IgA antibody; infant mice were not protected by prior consumption of colostrum. Milk antibody was required in the gut lumen for protection to be observed (Abimiku and Dolby, 1987). A similar requirement for antibodies active at the intestinal cell surface in murine immunity to primate rotavirus SA-11 was reported by Offit *et al.* (1984).

In rats, protection against dental caries by milk can be due to IgG or SIgA antibodies, depending on the route of maternal immunization. Rat dams immunized intravenously with heat-killed *Streptococcus mutans* developed IgG antibodies in their colostrum, milk, and serum. Their offspring demonstrated significant protection against *S. mutans*-induced caries formation. Rat dams locally injected in the region of the mammary gland with heat-killed *S. mutans* or fed formalin-killed *S. mutans* developed SIgA antibodies in their colostrum and milk. Their offspring were also protected against caries formation (Michalek and McGhee, 1977). Caries protection in suckling rats theoretically could be due to either bathing mucosal surfaces or antibody leakage into the saliva from the serum. Nonimmune adult rats can be protected from *S. mutans*-induced caries by feeding on lyophilized immune bovine milk or on immune bovine whey containing specific IgG (Michalek *et al.*, 1978a, 1987). Since adult rats are unable to transport orally administered IgG into their serum, protection is from milk-derived antibodies bathing the oral cavity.

#### 2. Milk Antibody in Ungulates

In ruminants (sheep, cattle, goats), the predominant antibody in both colostrum and milk is IgG<sub>1</sub>. The predominant antibody in the colostrum of pigs and horses is also IgG but, as lactation progresses and colostrum becomes milk, IgA predominates (Tizzard, 1987). Protection can be mediated by either antibody class. Whereas bathing of the mucosal surfaces by milk-derived antibodies can provide passive immunity to some pathogens, the high rate of infections in FPT foals and calves shows that milk (mucosal immunity) alone cannot provide complete protection to neonates.

In cattle and pigs, passive immunity against enteric infections with viruses such as rotaviruses and coronaviruses [transmissible gastroenteritis (TGE)] is dependent on the continual presence in the gut lumen of a protective level of specific antibodies (Crouch, 1985). In swine, passive immunity against intestinal infection with the TGE virus is generally more complete in piglets ingesting IgA antibodies than

in those ingesting IgG antibodies, although both classes of antibody are protective. The class of antibody present in sow milk depends on the route of immunization (Bohl and Saif, 1975). In cattle, passive immunity in calf scours (neonatal bovine colibacillosis caused by *Escherichia coli*) correlates with the level of specific IgA antibody in milk (Wilson and Jutila, 1976).

### 3. Milk Antibody in Primates

In primates, IgA is the predominant immunoglobulin in both colostrum and milk (Tizzard, 1987). Both lysozyme and SIgA in human milk remain bioavailable in the digestive tract of the early infant (Eschenburg *et al.*, 1990). Human milk has been shown to contain SIgA antibodies against at least five viruses and nine bacterial pathogens, as well as against fungi, parasites, and food antigens (Goldman *et al.*, 1985). Mucosal immunity to rotavirus, for example, was shown to be transferred to the infant by the SIgA in milk. A positive correlation was found between titers of secretory component in mother's milk and infant feces, and virus-specific IgA was found in infant fecal samples (Rahman *et al.*, 1987). In addition to providing passive mucosal immunity, human breast milk also stimulates the early local production of SIgA in the urinary and gastrointestinal tracts, thus accelerating the development of an active local host defense system in the infant (Prentice, 1987; Koutras and Vigorita, 1989).

## II. EXPERIMENTAL PASSIVE IMMUNIZATION

Since the first transfer of immunity by the injection of serum (von Behring and Kitasato, 1890), passive transfer of humoral immunity has been investigated intensively. The use of specific serum antibody (IgG) to transfer protection to nonimmune individuals has become so routine that it is now common medical practice in, for example, the postexposure prophylaxis of rabies and tetanus and the treatment of snakebite (Arnold, 1982; Centers for Disease Control, 1991a,b).

Local immunity has been correlated with the level of IgA in various secretions (Table II). However, direct demonstration of the mediation of local immunity by injected IgA could not occur until specific transport of passively administered IgA had been confirmed.

### A. Transport of Passively Administered IgA to Mucosal Surfaces

#### 1. Gastrointestinal Tract

In rabbits, rats, and mice, polymeric IgA can be and is transported efficiently from the circulation into the bile via the liver (Orlans *et al.*, 1978,1983; Delacroix *et al.*, 1982; Koertge and Butler, 1986a; Mestecky and McGhee, 1987). These species express secretory component on their hepatocytes (Socken *et al.*, 1979) and, in addition, have polymeric IgA as the primary molecular form in their serum (Vaerman, 1973; Heremans, 1974). Serum IgA is also transported effi-

ciently into bile in cattle (Butler *et al.*, 1986). In fact, most IgA in ruminant bile may be of serum origin.

Transport of serum IgA into bile in humans has been reported (Delacroix *et al.*, 1982; Dooley *et al.*, 1982), although IgA transport is about 50-fold less efficient than in rats and

rabbits. The human biliary IgA level is approximately 20% of the human serum IgA level and, under physiologic conditions, only 50% of human biliary IgA is derived from the serum (Vaerman and Delacroix, 1984). Although transport is possible, passively administered IgA does not reach high levels in human bile. In one study, less than 3% of intravenously injected radiolabeled polymeric IgA was found in human bile after 24 hr (Vaerman and Delacroix, 1984). This subject is reviewed in Chapter 10.

## 2. Saliva

Serum polymeric IgA can be transported into saliva in dogs (Montgomery *et al.*, 1977), monkeys (Challacombe *et al.*, 1978), and humans (Delacroix *et al.*, 1982; Kubagawa *et al.*, 1987). In humans, the amount of IgA acquired from the serum is low (only 2% from the serum) compared with the amount acquired from local production (Delacroix *et al.*, 1982). Transfer of polymeric IgA from serum into canine saliva is a selective process requiring secretory component (Montgomery *et al.*, 1977), whereas transport into oral fluids in monkeys appears to be by leakage from the plasma into the crevicular spaces surrounding the deciduous molars (Challacombe *et al.*, 1978).

## 3. Milk

In sheep, active transport of IgA from the circulation into milk seems likely (Sheldrake *et al.*, 1984); however, studies on the transport of IgA into murine milk have produced conflicting results. Using radiolabeled IgA, Halsey *et al.* (1983) demonstrated in the mouse that IgA can be transported from the circulation into milk during early lactation. Other investigators (Russell *et al.*, 1982; Koertge and Butler, 1986b), using assays based on antibody-binding activity, were unable to show transport of IgA into murine milk. Using radiolabeled IgA, Koertge and Butler (1986b) were able to show that the IgA present in milk was degraded and suggested that the previous study (Halsey *et al.*, 1983) detected only IgA fragments that had been transudated into the milk from the serum and not specifically transported IgA. Passively administered IgA is not transported into the milk of rats (Dahlgren *et al.*, 1981; Koertge and Butler, 1986b).

## 4. Respiratory Tract

Only a limited number of studies on the transport of antibodies into respiratory secretions have been reported, but the results have shown that selective transport of passively administered serum IgA into the respiratory tract is possible in sheep and mice. Because of their importance as background information for the experiments demonstrating the passive transfer of local immunity by IgA, these respiratory transport studies will be addressed in more detail.

**a. Sheep.** Using the intravenous (iv) injection of radioiodinated ovine immunoglobulin, Scicchitano *et al.* (1984) showed that 35% of the IgA in the mediastinal lymph of sheep is plasma derived. These investigators further demonstrated (Scicchitano *et al.*, 1986), by the simultaneous injection of

radiolabeled IgA and radiolabeled IgG<sub>1</sub> or IgG<sub>2</sub>, that IgA is transported selectively into ovine respiratory secretions. Transport of IgA, calculated 24 hr postinjection, was approximately 4.5 times greater than transport of IgG, and the transported IgA was intact in the secretions. Biologic activity of transported IgA was not determined.

**b. Mice.** Mazanec *et al.* (1989) found that, 4–5 hr after the iv injection of radiolabeled monomeric or polymeric IgA anti-Sendai virus monoclonal antibodies into mice, transport of polymeric IgA into nasal secretions was 3–7 times more efficient than transport of monomeric IgA whereas polymeric IgA transport into bronchioalveolar lavages was only 1–3 times more efficient. This difference probably reflects an increased contribution of serum antibody to bronchioalveolar secretions because of the transudation of IgG into alveolar fluids. Transport of polymeric IgA into the gut was 4–5 times more efficient than the transport of monomeric IgA, as expected. The agreement of the nasal secretion and gut transport indices suggests that transport could occur by a similar mechanism. The investigators were unable to demonstrate the presence of functionally intact polymeric IgA in the upper respiratory tract.

The polymeric IgA transported into murine nasal secretions in the studies reported by Renegar and Small (1991a) was, in contrast, functionally intact. To avoid problems associated with the quantitation of intact compared with degraded radiolabeled IgA in secretions (described by Koertge and Butler, 1986b), this study used an anti-influenza enzyme-linked immunosorbent assay (ELISA) to evaluate the transport of monomeric or polymeric IgA or IgG<sub>1</sub> monoclonal anti-influenza antibodies into the nasal secretions of mice. Any antibodies detected by this assay were, of necessity, functional. Nonimmune mice were injected intravenously with influenza-specific monomeric or polymeric IgA or IgG<sub>1</sub> and sacrificed at varying times between 2 and 24 hr postinjection. Nasal wash, serum, and bile samples were collected and assayed by ELISA for anti-influenza antibody. The peak nasal wash polymeric IgA titer was reached 4 hr after antibody injection and was approximately 35 times greater than the nasal wash titer of either monomeric immunoglobulin.

To determine whether polymeric IgA was transported selectively relative to IgG<sub>1</sub>, the investigators injected a mixture of the two monoclonal antibodies intravenously into nonimmune mice and calculated a selective transport index (STI) for nasal antibody for each mouse. An STI greater than 1 indicates that polymeric IgA was transported specifically relative to IgG<sub>1</sub> whereas a value of 1 indicates that the same extent of transport, leakage, or transudation of both polymeric IgA and IgG<sub>1</sub> occurred in that animal. Of the 31 mice studied, 29 showed an STI greater than 1 (average STI at 4 hr was  $36 \pm 19$ ) demonstrating the selective transport of polymeric IgA relative to IgG<sub>1</sub>. Selective transport of polymeric IgA relative to monomeric IgA was also demonstrated.

Thus, transport of serum IgA into nasal secretions is possible in some species. The relevance of this transport to the passive transfer of local immunity will be addressed in Section II,B,2,a.

## B. Protection of Mucosal Surfaces by Passively Administered Antibodies

Studies on the passive transfer of local immunity can be classified into two categories. In the first category are studies in which the antibody is introduced into the local secretions exogenously or mixed with the target pathogen prior to host challenge. The second category includes those studies in which systemically administered polymeric IgA must be transported physiologically (i.e., by secretory component-mediated mechanisms) to its site of activity.

### 1. Exogenously Administered Antibody

The studies in this category have investigated the role of IgA in mucosal immunity by feeding antibody or instilling it intranasally, then challenging, or by administering antibody-pathogen mixtures intranasally.

**a. Oral antibody.** Offit *et al.* (1984) demonstrated the ability of milk-derived IgG and IgA to protect the murine intestine from infection with primate rotavirus SA-11. Suckling mice were protected by milk from dams that had been immunized orally with SA-11 virus. This protective activity was detected in both the IgG and IgA fractions, but the IgA fraction was more potent *in vivo* than the IgG fraction. In newborn mice from immune dams foster-nursed on seronegative dams, the presence of circulating systemic antirotavirus antibodies in high titer did not protect against SA-11 viral infection. Thus, the specific antibody had to be present in the gut lumen to protect the intestinal cell surface from viral infection, and SIgA could mediate this protection.

**b. Intranasal antibody.** Three studies have shown that exogenously administered IgA can protect against intranasal challenge with a pathogen. Bessen and Fischetti (1988) showed that SIgA given by the intranasal route protected mice against streptococcal infection. Live streptococci were mixed with affinity-purified human salivary SIgA or serum IgG antibodies directed toward the streptococcal M6 protein. The mixture was administered intranasally to mice. The SIgA antibody protected against streptococcal infection whereas the serum antibody had no effect. This study suggested that SIgA alone is capable of protecting the mucosa against bacterial invasion.

Mazanec *et al.* (1987) demonstrated that IgA can protect mucosal surfaces against viral infection. Ascites fluid containing IgA anti-Sendai virus monoclonal antibody was administered intranasally to lightly anesthetized mice before and after the mice were challenged intranasally with live virus. Mice were sacrificed 3 days later and lung viral titers were determined. Animals treated with the specific monoclonal antibody were protected against viral infection. Additional work from the same laboratory showed that local immunity to Sendai virus also can be mediated by intranasal IgG (Mazanec *et al.* (1992). Tamura *et al.* (1991) purified anti-

influenza SIgA antibodies from the respiratory tracts of mice immunized with influenza hemagglutinin molecules. This IgA, when given intranasally, protected nonimmune mice from influenza infection. Protection, which was observed up to 3 days after antibody administration, was proportional to the amount of IgA administered and was observed at IgA doses equivalent to naturally occurring antibody titers.

These studies show that local IgA or IgG can protect against viral or bacterial infection of the mucosa. They do not show that physiologically transported (secretory) IgA or serum-derived IgG actually does so. For that demonstration, antibody must be administered parenterally and transported into the mucosal secretions by a physiologic mechanism. The studies presented in the next section satisfy that criterion.

### 2. Systemically Administered Antibody

The definitive studies in this category have involved the respiratory and gastrointestinal tracts, although passive transfer of uterine immunity by polymeric IgA also has been observed (K. B. Renegar, A. C. Menge, P. A. Small, Jr., and J. Mestecky, unpublished results). Work with the respiratory and gastrointestinal tracts will be presented in more detail.

**a. Respiratory tract.** Numerous studies have shown that passively administered serum anti-influenza antibody (IgG) can prevent lethal viral pneumonia (Loosli *et al.*, 1953; Barber and Small, 1978; Ramphal *et al.*, 1979; Kris *et al.*, 1988). Serum antibody, however, does not prevent influenza infection of the upper respiratory tract (Barber and Small, 1978; Ramphal *et al.*, 1979; Kris *et al.*, 1988). Protection of the nose correlates with an increased nasal secretion IgA antibody level (Table II), making influenza an excellent model in which to investigate the hypothesis that nasal immunity is mediated by SIgA.

The first demonstration of the passive transfer of local immunity by physiologically transported SIgA was reported by Renegar and Small (1991a) in the murine influenza model. These researchers showed, as described in Section II, A, 4, b, that intravenously administered polymeric IgA is transported into nasal secretions in a physiologic manner. To determine whether intravenously administered polymeric IgA anti-influenza monoclonal antibody could mediate protection against local influenza virus challenge, passively immunized mice were challenged intranasally while awake with influenza virus. The mice were sacrificed 24 hr later and the amount of virus shed in their nasal secretions was determined. Of the 24 saline-injected control mice, 23 shed virus into the nasal secretions whereas only 5 of the 25 polymeric IgA-injected mice shed virus; those 5 that did shed virus had a low viral titer. The observed protection was significant ( $p < 0.001$ ). Passive immunization with influenza-specific polymeric IgA, therefore, conferred complete protection against viral infection in 80% of the mice and partial protection in the remaining 20%.

To determine whether serum IgG<sub>1</sub> also could confer local protection to influenza challenge, the relative abilities of

equivalent virus-neutralizing doses of influenza-specific polymeric IgA or IgG<sub>1</sub> to protect against influenza challenge were compared. Intravenous polymeric IgA significantly reduced viral shedding compared with either intravenous saline or intravenous IgG<sub>1</sub>. Intravenous IgG<sub>1</sub> also reduced viral shedding ( $p < 0.02$ ); however, the protection against infection was not significant ( $p = 0.5$ ), since viral shedding was prevented in only 1 of 8 mice injected. Additional studies (K. B. Renegar and P. A. Small, Jr., unpublished results) have shown that IgG<sub>1</sub> can also mediate local protection against influenza infection, but 10 times the polymeric IgA protective dose is required to produce this protection.

The passive protection studies showed that IgA can mediate local immunity. To confirm that IgA is the mediator of local immunity, a method to abolish IgA-mediated protection was needed. Mice passively immunized with polymeric IgA were given nose drops of anti-IgA antibody 10 min before and 6 hr after they were challenged intranasally with influenza virus suspended in anti-IgA antiserum. Anti-IgA treatment abrogated IgA-mediated protection in the passively immunized mice (Renegar and Small, 1991a). To show that passive transfer of local immunity by IgA was a reflection of the natural situation, the abrogation technique was extended to mice convalescent from influenza infection (Renegar and Small, 1991b). Nonimmune mice and convalescent mice, that is, mice that had recovered from an influenza virus infection 4–6 weeks earlier and were therefore naturally immune, were treated intranasally with antiserum to IgA or IgG or with a mixture of antisera to IgG and IgM, then challenged while awake with influenza virus mixed with antiserum. Intranasal administration of antiserum was continued at intervals for 24 hr. Mice were killed 1 day after viral challenge, and their nasal washes were assayed for virus shedding (Figure 1). Nonimmune mice all became infected, regardless of whether the virus was administered in saline, normal rabbit serum, or anti-immunoglobulin antiserum. Convalescent mice, as expected, were protected from viral infection. Administration of influenza virus in either anti-IgG or a mixture of anti-IgG and anti-IgM antisera did not affect protection, that is, the convalescent mice were still immune. Administration of virus in anti-IgA antiserum, however, abrogated convalescent immunity. These results show that IgA is the major (if not the sole) mediator of mucosal immunity to influenza virus in the murine nose and suggest that passive immunization mimics the role SIgA plays in natural immunity.

**b. Gastrointestinal tract.** Additional evidence that secretory IgA is the mediator of local immunity comes from studies of the gastrointestinal tract. Polymeric IgA hybridomas against *Vibrio cholerae* were generated and the resulting monoclonal antibodies used to determine whether IgA can mediate immunity toward a bacterial pathogen in the gut (Winner *et al.*, 1991). The investigators selected a clone that produced dimeric monoclonal IgA antibodies directed against an Ogawa-specific lipopolysaccharide carbohydrate antigen exposed on the bacterial surface. These antibodies were able to cross-link bacterial organisms *in vitro*, suggesting that they might be effective in preventing mucosal colonization by the pathogen *in vivo*. To provide continuous physiologic (i.e.,

**Figure 1** Effect of intranasal installation of anti-IgA, anti-IgG, anti-IgM, or NRS on nasal immunity of convalescent mice. Virus shedding from 12 nonimmune saline-treated mice (◆) is shown in the left column. Experiment 1 (●): nonimmune and convalescent mice were treated intranasally with 10  $\mu$ l anti-IgA (anti- $\alpha$ ) and challenged with influenza virus in anti-IgA. Convalescent control mice were treated similarly, except saline was substituted for anti-IgA. Experiment 2 (○): nonimmune and convalescent mice were treated with 20  $\mu$ l anti-IgA (anti- $\alpha$ ). Convalescent control mice were treated similarly with saline. Experiment 3 (▲): nonimmune and convalescent mice were treated with 20  $\mu$ l NRS. Experiment 4 (◇): nonimmune and convalescent mice were treated with 20  $\mu$ l anti-IgG (anti- $\gamma$ ). Convalescent control mice were treated with saline. Experiment 5 (△): nonimmune and convalescent mice were treated with 20  $\mu$ l anti-IgG and anti-IgM (anti- $\gamma + \mu$ ). Convalescent control mice were treated with saline. EID<sub>50</sub>, 50% egg infective dose. Reprinted with permission from Renegar and Small (1991b).

secretory component-mediated) transport of specific antibody into the gut, hybridoma cells were injected subcutaneously into the backs of adult BALB/c mice. These “backpack” tumors released monoclonal IgA into the circulation and the serum IgA was transported into the gut lumen. Neonatal mice bearing these backpack tumors survived challenge with *V. cholerae* whereas neonatal mice bearing backpack tumors of unrelated IgA hybridomas and non-tumor-bearing neonatal mice died. This ingenious model provides the first evidence that secretory IgA alone can mediate mucosal immunity to a bacterial pathogen and serves as the second example of the passive transfer of local immunity by IgA.

### 3. Implications for Passive Immunization

The general approach of passive parenteral transfer of mucosal immunity should be a useful research tool for determining the role of SIgA in protection against other pathogens and at other mucosal surfaces. The possibility of therapy

by passively administered IgA antibody is more problematic. Generation of gastrointestinal protection by feeding specific antibodies is certainly possible and already has been reported in cattle (Tsunemitsu *et al.*, 1989). Passive protection by injection is, however, highly speculative because of the questionable efficiency of transport to the targeted mucosal surface and the potential adverse effects of intravenous IgA antibody. Serum IgA has been associated with both decreased complement activation (Russell *et al.*, 1989) and decreased immune lysis (Griffiss and Goroff, 1983). Systemically administered polymeric IgA may also be highly suppressive of both specific humoral and cellular responses (K. B. Renegar, S. Taylor, and P. A. Small, Jr., unpublished observations). A more thorough knowledge of the role IgA can play in regulating the immune response is needed before passive mucosal immunization via parenteral antibody administration can become an acceptable means of therapy in humans.

# Common Mucosal Immune System and Strategies for the Development of Vaccines Effective at the Mucosal Surfaces

Jiri Mestecky · Rebecca Abraham · Pearay L. Ogra

## I. INTRODUCTION

Mucosal tissues constitute an enormous surface area and serve as primary portals of entry for most infectious agents. The immune response generated as a result of such host-pathogen interactions are targeted primarily to prevent local or systemic disease. That mucosal surfaces constitute an elaborate system of defense mechanisms including the mucosa-associated lymphoid tissue (MALT) is not surprising (Hanson and Brandtzaeg, 1989). However, the impact of the mucosal lymphoid tissues relative to the mechanisms of host-pathogen interaction has been recognized only in the last two decades. Current interest in mucosal vaccines stems, to a large extent, from our new understanding of mucosal immunity (Ogra *et al.*, 1980; Mestecky and McGhee, 1987; McGhee and Mestecky, 1990).

The concept of a common mucosal system has been elaborated by a number of prominent workers (for reviews, see McDermott and Bienenstock, 1979; Phillips-Quagliata and Lamm, 1988; Scicchitano *et al.*, 1988) and has gained wide acceptance in relation to mucosal immunity (Tomasi *et al.*, 1965). This concept refers to a specific defense system that operates at external mucosal surfaces and functions somewhat independently of the immunological reactivity in the systemic sites and the bloodstream. This system includes the inductive sites of the gut-associated lymphoid tissue (GALT), the bronchus-associated lymphoid tissue (BALT), and the immunocompetent elements in the effector sites in the genital mucosa, salivary glands, respiratory tract, pharynx, and mammary glands. The predominant immunoglobulin present in mucous secretions is secretory IgA (SIgA). Other elements of immunity are also present in varying amounts, for example, IgA (serum type), IgG, IgM, T lymphocytes, and components of cell-mediated immunity (Tomasi *et al.*, 1965).

## II. ORIGIN OF MUCOSAL ANTIBODIES

Early studies concerning the origin of IgA antibodies in secretions considered the possibility that they are transferred from the circulatory pool (for reviews, see Brandtzaeg, 1985a;

Mestecky *et al.*, 1991a). Infusion of 1–2 liters of plasma into immunodeficient patients resulted in the appearance of immunochemically detectable IgA in the saliva of a few patients (South *et al.*, 1966). Further, finding monoclonal IgA in the saliva of patients with IgA myeloma (Coelho *et al.*, 1974) gave support to the original proposal that mIgA from plasma is polymerized during the secretory component (SC)-mediated transport through the epithelial cells (Tomasi *et al.*, 1965). However, many subsequent studies performed in animal models and in humans clearly have shown that, in most species, plasma-derived IgA contributes only small amounts of IgA to external secretions, except in rabbits, rats, and mice, in which plasma-derived polymeric IgA is transported effectively by hepatocytes that express SC into the bile and ultimately into the intestine (Brown and Kloppel, 1989; Mestecky *et al.*, 1991a). Radiolabeled human IgA injected intravenously into humans appeared in only very small quantities in human nasal secretions, saliva, intestinal fluid, and bile (Delacroix *et al.*, 1982; Jonard *et al.*, 1984; Mestecky *et al.*, 1991a). Even in IgA myeloma patients, whose plasma contained extremely high levels of pIgA, salivary IgA was not elevated and monoclonal IgA detected by anti-idiotypic antibodies constituted only 0.4–3.9% of the total salivary IgA (Kubagawa *et al.*, 1987).

Immunochemical and immunohistochemical studies of SIgA and of mucosal tissues and glands convincingly established that almost all IgA found in external secretions originates from the locally assembled pIgA produced by plasma cells found in abundance in mucosal tissues and secretory glands and is transported selectively (Lawton and Mage, 1969; Bienenstock and Strauss, 1970; Brandtzaeg, 1985a; Mestecky *et al.*, 1991a). However, locally produced pIgA may compete successfully with the plasma-derived pIgA for the epithelial receptor SC. Nevertheless, additional studies of the transport of intravenously injected purified pIgA into IgA-deficient patients should be performed to solve this problem. In normal individuals, such passive immunizations with intravenously administered pIgA appear to be unlikely to provide immunity on mucosal surfaces.

In animals, the transport of plasma-derived pIgA into external secretions is rather controversial. Some investigators (Halsey *et al.*, 1983) demonstrated the transport of pIgA

in external secretions whereas others (Russell *et al.*, 1982; Koertge and Butler, 1986) found that such transport is rather limited.

The importance of local mucosal antigenic stimulation in the respiratory and intestinal tracts has been demonstrated by the observation that the titer of specific IgA antibody to poliovirus is highest in intestinal sites that have direct contact with the poliovirus antigen after segmental colonic immunization of subjects with double-barreled colostomies (Ogra and Karzon, 1971). In other studies, intranasal immunization with inactivated poliovaccine induced a specific nasopharyngeal IgA antibody response, often in the absence of any detectable response in the serum (Ogra and Karzon, 1971). The lack of mucosal antibody-producing plasma cells in germ-free animals and in human neonates is another example of the role of local antigenic exposure in the development of mucosal immunity, since such situations are associated with a significantly reduced mass of microbial and dietary antigens in the respiratory and enteric membranes (Tomasi, 1976).

Sufficient information is not available about the development of other immunoglobulins in the mucosal surface. However, a significant amount of the IgG and IgM antibodies in external secretions of the nasopharynx and intestine appears to be synthesized locally. Some evidence suggests that compensation for IgA antibody in patients with a selective absence or deficiency of IgA is effected largely by the increased local synthesis of IgM and, to some extent, IgG in the secretory sites (Ogra *et al.*, 1974). T lymphocytes and cell-mediated immune responses in the mucosal surfaces also may be local phenomena (Waldman and Ganguly, 1974); they depend on local exposure to antigen, migration recirculation, and homing to other mucosal surfaces after initial antigenic stimulation, a sequence of events that appears to be remarkably similar to that described for IgA antibody (Tomasi, 1976).

### III. COMMON MUCOSAL IMMUNE SYSTEM

The presence of large numbers of Ig-producing cells, mostly of the IgA isotype, in lamina propria of the gastrointestinal and respiratory tracts and in secretory glands was described during the early 1960s (for review, see Heremans, 1974; Lamm, 1976). However, studies of the origin of their precursors, the migratory pathways, and the regulation of local differentiation in IgA-producing plasma cells were initiated in the early 1970s in several laboratories. In both humans and animals, mucosal IgA plasma cells were found to be derived from precursors localized in the IgA-inductive sites, primarily in GALT (Bienenstock, 1985; Phillips-Quagliata and Lamm, 1988; Scicchitano *et al.*, 1988). Further, exposure of such IgA precursor cells to environmental antigens and their subsequent migration to remote mucosal tissues and glands results in dissemination of SIgA-mediated specific immune responses. The physiological importance of these findings is considerable. Stimulation at an IgA-inductive site (e.g., GALT) is likely to lead to the generalized protection of remote sites such as nasopharynx and genital tract; SIgA antibodies in milk of orally immunized mothers may protect

the gastrointestinal and possibly upper respiratory tract of breast-fed neonates (Mestecky, 1987; Mestecky *et al.*, 1991b). Further, the existence of this common mucosal immune system can be exploited in the design of novel types of vaccines that, for example, given orally result in protection at mucosal surfaces and glands (e.g., mammary gland) that are less accessible to local immunization. The site of stimulation and type and delivery of antigen play important roles in the extent of dissemination of SIgA-mediated immune responses and must be given special consideration in design of vaccines effective in the protection of mucosal surfaces (McGhee and Mestecky, 1990).

#### A. Evidence in Animals

In many experimental models, local antigenic stimulation of mucosal surfaces and secretory glands has been demonstrated to result in the production of specific antibodies, not only at the site of stimulation but also in the circulation and in remote external secretions (for reviews see Mestecky, 1987; Phillips-Quagliata and Lamm, 1988; Scicchitano *et al.*, 1988). Heremans and Bazin (1971) showed that the IgA-producing cells in orally immunized germ-free mice are found in the intestinal as well as the extraintestinal lymphoid organs, including mesenteric lymph nodes and spleen, and, in other experiments (Alley *et al.*, 1986), bone marrow. Jacobson *et al.* (1961) noted the ability of Peyer's patches to repopulate other tissues and restore their immunological capacities: mice subjected to total body irradiation, but with shielded Peyer's patches, retained their immune functions. This finding was interpreted as evidence of migration of lymphocytes from Peyer's patches to peripheral organs. However, Craig and Cebra (1971) clearly demonstrated for the first time that Peyer's patches are also an enriched source of precursors of mucosal IgA plasma cells. Adoptive transfer of lymphocytes from Peyer's patches but not peripheral lymph nodes from a donor rabbit into an irradiated recipient resulted in repopulation of the recipient intestine by IgA plasma cells of donor allotype. A host of subsequent studies (for reviews, see Lamm, 1976; Phillips-Quagliata and Lamm, 1988; Scicchitano *et al.*, 1988) convincingly established that—in rabbits, mice, and rats—GALT (with adjacent mesenteric lymph nodes), and in some experiments, BALT (Bienenstock, 1985) contains precursors of IgA plasma cells capable of repopulating intestines, respiratory tract, and salivary, lacrimal, mammary, and cervical glands of the uterus with IgA plasma cells. When peripheral lymph nodes and spleen were used as sources of lymphocytes in these adoptive transfer experiment, few IgA-producing cells were seen in these mucosal tissues and glands. Lymphoblasts displayed a more pronounced homing capacity than unstimulated small lymphocytes, which may explain why mesenteric lymph nodes are often a better source of cells for repopulation studies than Peyer's patches (Lamm, 1976). The local presence of an antigen on mucosal surfaces leads to an additional increase of IgA plasma cells secreting corresponding specific antibodies, apparently because of the local clonal expansion of antigen-specific lymphoblasts arriving to these locales rather than their antigen-driven increased immigration (Husband and

Gowans, 1978). In some experiments, mucosal tissues of orally immunized animals contained IgA cells secreting antibodies specific for the ingested antigen. Transfer of lymphocytes from mesenteric lymph nodes of orally immunized donors into naive recipients yielded similar results (De Buysscher and Dubois, 1978; Weisz-Carrington *et al.*, 1979).

These studies provided a cellular basis for the earlier experiments of Montgomery *et al.* (1974), who stimulated great interest by their demonstration of specific antibodies to dinitrophenylated *Pneumococcus* in milk of lactating rabbits fed this conjugated antigen. Numerous subsequent studies (for reviews, see Mestecky, 1987; Mestecky and McGhee, 1987; Russell and Mestecky, 1988; McGhee and Mestecky, 1992) with oral administration of various particulate and soluble antigens to experimental animals fully confirmed Montgomery's observations and extended them to other external secretions. Elegant experiments from Montgomery's laboratory excluded the possibility that free antigens absorbed from mucosal sites, rather than committed lymphocytes, are carried by the circulation to mucosal sites to initiate local IgA responses (Montgomery *et al.*, 1976). Direct evidence for the importance of Peyer's patch-derived IgA plasma cell precursors in dissemination of SIgA-mediated immune response specific to bacterial antigen was provided by Robertson and Cebra (1976). Two isolated ileal loops—one with and the other without a Peyer's patch—were constructed without the interruption of the flow of blood and lymph. After the

introduction of antigens [dinitrophenylated keyhole limpet hemocyanin (KLH) and *Salmonella typhimurium*] into the loop that contained the Peyer's patch, an SIgA response was detected in both loops whereas these antigens introduced into a loop devoid of Peyer's patches did not induce an immune response. These observations directly implicated Peyer's patches as the sources of precursor cells that are capable of undergoing direct antigen-driven stimulation to proliferate, migrate, differentiate, and repopulate the intestinal lamina propria with cells that secrete *specific* IgA antibodies. Further, IgA from several secretions of a *single* animal orally immunized with the dinitrophenyl hapten on a carrier displayed, on isoelectric focusing, identical spectrotypes, suggesting that IgA cells that populate various exocrine tissues are derived from a common clone (Montgomery *et al.*, 1983). As summarized in several review articles (Lamm 1976; Mestecky, 1987; Mestecky and McGhee, 1987; Phillips-Quagliata and Lamm, 1988; Scicchitano *et al.*, 1988), the concept of a common mucosal immune system was proposed which, in a simplified form, is shown in Figure 1.

### B. Evidence in Humans

Because of ethical and biological limitations, the adoptive transfer of IgA-precursor cells is impossible to perform in humans. Thus, the evidence for the existence of the common mucosal immune system is inevitably indirect. Nevertheless,

**Figure 1** Hypothetical diagram of the common mucosal immune system in humans. Lymphoid cells, presumably from the bone marrow, enter the Peyer's patches (PP) and probably other gut-associated lymphoid tissues (GALT) through high endothelial venules. Under the local influence of T cells and accessory cells, the arriving B cells express surface IgA. Environmental antigens enter Peyer's patches through pinocytotic and phagocytic M cells and interact with resident accessory, T, and B cells. IgA-committed and antigen-sensitized B cells and lymphoblasts leave and enter the regional lymph nodes, then the lymph and circulation. Finally, such cells populate various exocrine glands and mucosa-associated tissues, where terminal differentiation into IgA-secreting plasma cells occurs. In animals, bronchus-associated lymphoid tissues (BALT) apparently play a role analogous to that of GALT.

data accumulated during the last decade lend strong credence to this contention.

External secretions of glands that are remote from the site of antigen stimulation contain natural SIgA antibodies to such antigens. For example, colostrum and milk as well as tears contain high levels of antibodies to an oral bacterium, *Streptococcus mutans* (Arnold *et al.*, 1976; Allansmith *et al.*, 1982). This bacterium colonizes the oral cavity of children only after the eruption of the primary dentition; thus, local stimulation of the immune apparatus of the mammary gland during breastfeeding is unlikely to play a role in the induction of such antibodies. The fact has been well established (Ogra *et al.*, 1983; Ladjeva *et al.*, 1989) that human milk contains SIgA antibodies against a broad spectrum of food and microbial antigens that are encountered by inhalation and ingestion. Thus, in the absence, or presence in low titers, of corresponding antibodies in serum, the most probable explanation for the presence of specific SIgA antibodies in these external secretions would consider the dissemination and lodging of antigen-sensitized IgA-committed antibody-forming cells to mucosal tissues and glands.

Evidence for this hypothesis was strengthened further by a number of oral immunization studies (for reviews, see Mestecky, 1987; Mestecky and McGhee, 1987, 1989; McGhee and Mestecky, 1992). Live or killed microorganisms or their antigenic products given by the oral route induced specific SIgA antibodies in milk, tears, saliva, and nasal secretions (Goldblum *et al.*, 1975; Mestecky *et al.*, 1978; Czerkinsky *et al.*, 1987). Such antibodies appeared in parallel in all external secretions examined; corresponding pre-existing serum antibodies usually were not elevated as a consequence of oral immunization (Mestecky *et al.*, 1978; Clancy *et al.*, 1983; Bergmann *et al.*, 1986; Czerkinsky *et al.*, 1987). Further, subsequent oral boosting with the same antigen led to higher levels of SIgA in these secretions, compared with the levels induced by the first ingestion.

Antigens used for such immunizations included whole bacteria [e.g., *S. mutans* (Mestecky *et al.*, 1978; Czerkinsky *et al.*, 1987; Taubman and Smith, 1989), *Haemophilus influenzae* (Clancy *et al.*, 1983)] and their products [e.g., glucosyltransferase (Taubman and Smith, 1989) or carbohydrate antigens (Taubman and Smith, 1989) of *S. mutans*] and live or killed viruses [e.g., poliovirus (Ogra and Karzon, 1969), influenza virus (Waldmann *et al.*, 1986; Bergmann *et al.*, 1986)] as well as their modified antigens (Waldmann *et al.*, 1986). Generally, particulate antigens induce higher responses than corresponding soluble ones probable because of better uptake and limited digestion.

Because cells from human lymphoid tissues are not easily obtainable, cellular studies have been limited to the examination of lymphocytes from the peripheral blood. However, in the IgA cell cycle described earlier IgA-committed cells specific for ingested antigens should be present in the peripheral blood before their emigration to and lodging in the mucosal tissues and glands. This is indeed the case and has been demonstrated in several studies (Czerkinsky *et al.*, 1987, 1991; Kantele, 1990; Quiding *et al.*, 1991).

First, mitogen-stimulated peripheral blood lymphocytes have been shown to secrete predominantly pIgA; the intracellular distribution of IgA subclasses resembles that in secre-

tory tissues (Kutteh *et al.*, 1980). Based on these results, researchers proposed that a large proportion of such cells is composed of precursors of IgA-producing plasma cells that populate mucosal tissues. Therefore, these studies complemented and extended earlier observations of Friedman *et al.* (1975), in which extracorporeal cesium irradiation of peripheral blood of leukemic patients resulted in a decrease in salivary but not serum IgA levels.

Commitment of peripheral blood lymphocytes to secrete IgA antibodies specific for ingested antigen became obvious from several independent experiments. Peripheral blood lymphocytes from volunteers orally immunized with a single dose of combined cholera B-subunit/whole-cell vaccine secreted IgA antibodies to the ingested antigen into tissue culture supernatants (Lycke *et al.*, 1985). When examined on a single-cell level, peripheral blood lymphocytes that secreted specific IgA antibodies were detected in 4 of 6 volunteers who had been immunized orally with enterically coated capsules containing *S. mutans* (Czerkinsky *et al.*, 1987). These cells are detectable in peripheral blood before the appearance of specific SIgA antibodies in external secretions that included saliva and tears. Interestingly, one of the volunteers was IgA deficient, so peripheral blood lymphocytes produced and external secretions contained specific IgM antibodies. Peroral immunization of volunteers with *Salmonella typhi* also led to the transient presence of predominantly IgA-secreting cells in the peripheral blood, but secretory and serum IgA antibodies were absent (Kantele *et al.*, 1986).

In the most recent study (Czerkinsky *et al.*, 1991), specific antibody-secreting cells were detected in cell suspensions of minor salivary glands surgically removed after ingestion of *Vibrio cholerae* vaccine by human volunteers. Sequential experiments revealed that specific IgA antibody-producing cells appear first in the peripheral blood and then in minor salivary glands; corresponding antibodies appeared later in saliva.

Collectively, these experiments strongly suggest that the stimulation of GALT by oral immunization can be exploited for the induction of a secretory immune response to several additional microbial agents that infect mucosal surfaces distant from the gastrointestinal tract.

### **C. How "Common" Is the Common Mucosal Immune System?**

In the original concept of the common mucosal immune system, GALT and BALT served as sources of precursors of the IgA plasma cells from all mucosal tissues and glands. However, several studies have considered the possibility that additional lymphoid tissues may fulfill this function. Surgical removal of visible GALT and extended drainage of the thoracic duct resulted in approximately 50% reduction in the number of IgA plasma cells in the intestinal lamina propria (Heatley *et al.*, 1981). Thus, other sources seem to contribute to the pool of IgA precursor cells (Figure 2).

#### **1. Tonsils**

The tonsils at the top of the digestive and respiratory tracts are exposed continually to antigens in inhaled air and ingested

**Figure 2** Subcompartmentalization in the common mucosal immune system. In addition to gut- and bronchus-associated lymphoid tissues, IgA-inductive sites in the Waldeyer's ring of oropharyngeal lymphoid tissue (nasal, palatine, and lingual tonsils) or rectum also may contribute to the pool of precursor cells that preferentially populate upper respiratory or lower-intestinal and genital tract.

food. They display a unique architecture similar to that of lymph nodes (cell types, development of germinal centers on exposure to antigens; Brandtzaeg, 1985b) and have deep, partly branched crypts that increase their surface area enormously and trap environmental materials. Antigen-processing and-presenting cells as well as T and B cells are represented abundantly in specific tonsillar tissue compartments (Brandtzaeg, 1987). Human tonsillar germinal center cells reveal IgM as the prominent surface isotype, followed by IgA, IgG, and IgD (Tsunoda *et al.*, 1980). Cells from palatine and nasopharyngeal tonsils have been proposed to contribute to the population of cells that supplies distant mucosal sites with IgA precursors, particularly the upper respiratory and digestive tracts (Brandtzaeg, 1987). Supporting circumstantial evidence is based on (1) the expression of intracellular J chain, a probable marker of pIgA synthesis by cultured tonsillar cells (Brandtzaeg, 1987), and the secretion of pIgA into supernatants and (2) the distribution of IgA subclasses with a predominance of IgA1, typical of the upper respiratory and digestive tracts (Brandtzaeg, 1987). In addition, reduced nasopharyngeal antibody response to orally administered live poliovirus was demonstrated in tonsillectomized children (Ogra and Karzon, 1971). Before tonsillectomy, poliovirus IgA antibody was present in appreciable titers in the nasopharynx of all children previously immunized with live attenuated poliovirus vaccine. Significantly, however, after tonsillectomy the pre-existing IgA poliovirus antibody levels in the nasopharynx sharply declined in all the patients studied. Mean antibody titers decreased 3- to 4-fold. Individual titers in several children declined 4- to 8-fold (Ogra and Karzon, 1971).

Note that tonsils are absent from commonly used animals (except rabbits). Although rats have been shown to possess nasal associated lymphoid tissue, which might be an equivalent structure (Evans *et al.*, 1985), intranasal immunization of rats or mice does not result in disseminated antibody response in other mucosal tissues, although responses in the posterior cervical lymph nodes and serum can be demonstrated (Evans *et al.*, 1983; Dunn *et al.*, 1990). The human nasal mucosa also contains T lymphocytes (Chin *et al.*, 1969;

Kapikian *et al.*, 1969; Ogra *et al.*, 1991), HLA-DR expressing dendritic and epithelial cells (Kim *et al.*, 1969), and abundant IgA-secreting plasma cells (predominantly IgA1), which may originate in BALT or tonsillar tissue (Buynak *et al.*, 1979; Belshe *et al.*, 1982). Intranasal immunization in humans has been used particularly against respiratory pathogens (e.g., influenza, parainfluenza viruses) but the responses have been analyzed only in the nasal secretions and serum (Kim *et al.*, 1971; Richardson *et al.*, 1978). We do not know whether the intranasal route of immunization, which most likely involves the nasopharyngeal tonsils, generates antibodies of other mucosal sites. It is possible that specific antibodies induced by intranasal immunization will be restricted primarily to the upper respiratory tract.

## 2. Rectal Lymphoid Tissues

Although Peyer's patches are found primarily in the lower segments of the small intestine, similar structures also occur in the large intestine, especially in the rectum (Strindel, 1935). Such lymphoid follicles, called lymphoglandular complexes, are found in the large intestine with a frequency that increases from colon to rectum. B and T lymphocytes have been detected and IgA-producing plasma cells are quite numerous in the lamina propria (Kett *et al.*, 1986). Interestingly, the distribution of IgA1- and IgA2-producing cells in the colorectum (Crago *et al.*, 1984; Kett *et al.*, 1986) is remarkably similar to that of the female genital tract (Kutteh *et al.*, 1988). Further, the rectum and genital tract have common lymphoid drainage, and venous blood from these tissues avoids the portal vein and, thus, the liver. The rectal route of immunization has been considered in only a few human and animal studies (Forrest *et al.*, 1990; Lehner *et al.*, 1992a,b). When examined (Forrest *et al.*, 1990), external secretions (intestinal juice and saliva) contained antibodies specific for rectally administered antigens. Additional experiments will be necessary to evaluate fully the efficacy of rectal immunization for the induction of specific antibodies in remote external secretions (e.g., tears, milk, and saliva) and in genital secretions. Limited results (Lehner *et al.*, 1992a,b) suggest that this route of immunization may be effective for the induction of virus-specific mucosal antibodies, especially in the female genital tract of monkeys.

## D. Peritoneal Cavity

Results concerning the properties and repopulation potential of Ly-1<sup>+</sup> (CD5<sup>+</sup>, B-1) B cells from the peritoneal cavity of mice have provided new insights into the origin and precursors of IgA plasma cells in mucosal tissues. As many as half the IgA plasma cells found in the murine intestinal wall were derived from a distinct lineage of self-replenishing and long-living peritoneal lymphoid cells (Kroese *et al.*, 1988,1989). Interestingly, sIgA<sup>+</sup> cells constitute no more than 1% of total peritoneal cells; thus, a considerable proportion of IgA plasma cells in the murine gut originating from peritoneal Ly-1<sup>+</sup> B cells is derived from the sIgA<sup>-</sup> population. Subsequently, Solvason *et al.* (1991) demonstrated convincingly that the transfer of omental and peritoneal cells (which did not contain antibody-forming cells) or fetal omental graft from C57BL/

6 × BALB/c mice under the kidney capsule of severely compromised immunodeficient (SCID) mice resulted in the population of the gut with numerous IgA-producing plasma cells. Co-staining with anti-allotypic reagents clearly confirmed their donor origin. Pecquet *et al.* (1992) have reconstituted irradiated Xid mice that are nonresponsive to *S. typhimurium* with peritoneal CD5<sup>+</sup> B cells from responsive CBA/Ca donors and observed a strong mucosal IgA and IgG response to oral immunization with this antigen; such responses were not observed in animals reconstituted with CD5<sup>-</sup> B cells from the bone marrow. An identical pattern of immune responses was observed when phosphorylcholine-bovine serum albumin (BSA) conjugates were used. The authors concluded that the mucosal IgA responses to certain antigens are dependent on the presence of peritoneal CD5<sup>+</sup> cells. Further, intraperitoneal (ip) immunization of animals has been used (Beh *et al.*, 1975; Pierce and Gowans, 1975; Dunkley and Husband, 1990; Thapar *et al.*, 1990) as an extremely effective route of immunization for the induction of both systemic and mucosal immune responses. A vigorous IgA antibody response was promoted by ip priming when the same antigen was given subsequently enterically or systemically. In contrast, primary intraduodenal immunization was substantially less effective. All investigators generally agree that the IgA-secreting plasma cells found in mucosal tissues of animals are derived from two relatively independent sources, Peyer's patches and peritoneum. Although both sources contain precursors of plasma cells that are committed, to a large degree, to synthesis of IgA, their surface phenotypes, maturation pattern, specific antibody repertoires, and stimulation routes are quite different.

The precursors of mucosal IgA plasma cells in humans have been assumed also to originate from Peyer's patches. The possibility that such cells may be derived from the peritoneum has not been considered. Studies of the human mucosal immune system, as related to the IgA plasma cells and CD5<sup>+</sup> cells in individual compartments, are limited. Solvason and Kearney (1992) demonstrated the presence of pro/pre-B cells in fetal omentum and liver as early as 8 weeks gestation; 40% of B cells found in the omentum were CD5<sup>+</sup>. Histochemical examination revealed that the human fetal omentum contains more CD5<sup>+</sup> cells than the liver; the authors (Solvason and Kearney, 1992) propose that this tissue should be considered a primary lymphoid organ and a site of B-cell generation, in addition to the fetal liver and bone marrow. Because Peyer's patches in newborns are not well developed, apparently because of lack of stimulation with luminal antigens, such cells are not likely to be derived from Peyer's patches and must originate elsewhere, perhaps in the peritoneum. Analyses of intestinal B cells from normal adults revealed that 55% of B cell-enriched populations were CD5<sup>+</sup> (Peters *et al.*, 1989). When examined for Ig secretion, the CD5<sup>+</sup> B-cell population contained 4 times the number of IgA-secreting cells than the CD5<sup>-</sup> population. In sum, the evidence derived from studies of the ontogeny of the immune system in humans and animals, the phenotypes of B cells in different lymphoid compartments, immune responses generated by various routes of immunization, and adoptive transfer of B cells obtained from the peritoneum into immunodeficient mice favor the possibil-

ity that IgA-secreting plasma cells in mucosal tissue are derived not only from the Peyer's patches but also from the peritoneum.

## IV. VACCINES BASED ON THE COMMON MUCOSAL SYSTEM

### A. Viral Vaccines

An increased understanding of the general principles of mucosal immunity have led to an exponential expansion in investigative efforts to develop mucosal vaccines (for reviews, see Mestecky, 1987; McGhee and Mestecky, 1990, McGhee *et al.*, 1992). Throughout the last century, many microorganisms and their products have been given by the oral route as potential vaccines (Mestecky and McGhee, 1989; Gilligan and Li Wan Po, 1991). Currently, the vaccines approved for human use contain live adeno and polioviruses, whereas other vaccines such as those against influenza, rabies, hepatitis, respiratory syncytial, rota, and cytomegaloviruses are under investigation (Mestecky and McGhee, 1989; McGhee and Mestecky, 1990; Gilligan and Li Wan Po, 1991; O'Hagan, 1992). Developments with available vaccines and relevant information concerning experimental vaccines are summarized here.

#### 1. Poliovirus

Poliovirus causes an acute infectious disease that, in its serious form, affects the central nervous system causing flaccid paralysis. The introduction of inactivated (Salk) polio vaccine (IPV) in 1955, followed by the trivalent oral (Sabin) poliovirus vaccine (OPV) in 1963, has resulted since 1979 in the elimination of endogenously transmitted paralytic disease caused by wild poliovirus in the United States and in many other parts of the world. However, 5–10 cases of vaccine-associated poliomyelitis occur every year in the United States after immunization with OPV (Ogra and Faden, 1986).

Numerous epidemiological and clinical studies have demonstrated that the extent and nature of circulating antibody responses following parenteral administration of IPV are similar to those following successful immunization with orally ingested OPV (Ogra *et al.*, 1980). The response is characterized by the appearance of serum IgM and IgG in a predictable sequence. IgA is detectable in serum at a later stage and may remain at low levels. OPV induces a state of local resistance in the alimentary tract to subsequent viral reinfection. However, the alimentary immunity after naturally acquired wild virus infection is more profound than after immunization with OPV (Ogra, 1984). In contrast, parenteral administration of IPV affords very little alimentary immunity (Ogra *et al.*, 1980). Experimental studies with OPV and IPV administered to children have shown that OPV elicits development of SIgA antibody to poliovirus in the nasopharynx and intestine 1–3 weeks after immunization, that persist over a period of as long as 5–6 years. Immunization with IPV fails to induce a secretory antibody response in the nasopharynx or intestines. Administration of a large dose of IPV into the nasopharynx

or intestine elicits a local SIgA response without an associated SIgA response in the serum (Ogra *et al.*, 1980). Subsequent studies have demonstrated that reimmunization with IPV-Salk in individuals previously primed with parenterally administered IPV-Salk resulted in a booster effect and modest secretory antibody response. However, reimmunization of IPV-Salk vaccinated subjects with a single booster dose of OPV resulted in a marked enhancement of SIgA antibody response (Ogra, 1984).

Early studies therefore demonstrated the advantages of Sabin OPV administered orally to Salk IPV administered parenterally in inducing an efficient mucosal response. Despite the infrequent use of IPV-Salk in the United States, several European and Scandinavian countries and certain provinces of Canada have relied successfully on the parenteral administration of IPV. In the late 1970s, an enhanced potency preparation of IPV (IPV-EP) was introduced in the United States. Comparative studies have shown that routine parenteral immunization with three doses of the vaccine induces serum antibody responses similar to those after immunization with OPV. Virus-specific neutralizing and enzyme-linked immunosorbent assay (ELISA) antibody activity in nasopharyngeal secretions (NPS) was observed in about 56 and 82% of subjects who received IPV-EP and in 56 and 82% of subjects who received OPV, respectively (Zhaori *et al.*, 1988). In contrast, only 15–20% of IPV-Salk immunized subjects exhibited a neutralizing antibody response, demonstrating the superiority of IPV-EP to IPV-Salk in inducing neutralizing and ELISA secretory antibody responses (Zhaori *et al.*, 1988; Onorato *et al.*, 1991). Elegant studies carried out with OPV or IPV-EP poliovaccines have suggested that other host factors in the mucosa, such as the enzymatic environment, could play an important role in the development of immune response (Roivainen and Hovi, 1988).

During its replication in the gut, OPV as well as naturally acquired wild poliovirus is cleaved by proteolytic enzymes. Such cleavage has been shown experimentally to alter the antigenic nature of the virus (Roivainen and Hovi, 1988). The effects of such interaction and the development of secretory antibody response to poliovirus virion proteins against intact or trypsin-treated poliovirus type 3 have been studied in the nasopharyngeal samples of four groups of infants immunized with OPV, IPV-EP, or a combined vaccination of IPV-EP followed by OPV (Zhaori *et al.*, 1989; Ogra and Garofalo, 1990). ELISA SIgA and, less frequently, neutralizing antibody activity were detected in the NPS in IPV-EP and IPV-Salk vaccinated subjects when tested against the whole virus, compared with a decline in secretory antibody activity when tested against cleaved virus. On the other hand, the secretory antibody activity in NPS samples from OPV vaccinees exhibited a significant increase in neutralizing and ELISA activity against cleaved virus compared with intact virus. These observations suggest that antigenic sites are exposed by trypsin cleavage, in case of live oral vaccine, and elicit a mucosal secretory antibody response. This response is not possible for inactivated vaccines administered parenterally.

The virion proteins of poliovirus also have been characterized and the neutralization antigenic site determined (Emini *et al.*, 1982). The major antigenic site for virus neutralization

appears to be on the capsid protein VP1 of poliovirus type 3. The antibody response in the serum and SIgA to different virion proteins with OPV or IPV or a combination of the two vaccines was studied (Zhaori *et al.* 1989; Ogra and Garofalo, 1990). Infants in both OPV and IPV-EP vaccinated groups developed similar SIgA antibody responses to VP1 and VP2 in the NPS. VP3-specific response was observed in 75% of subjects immunized with OPV. The IPV-immunized subjects exhibited poor VP3 response. Therefore, in addition to VP1 neutralization association, sites associated with VP3 also play an important role in the magnitude and quality of the immune response elicited by immunization with OPV.

Vaccine-associated poliomyelitis is a major drawback of OPV. Several studies (Faden *et al.*, 1990) show that the incorporation of at least one dose of IPV at the start of the immunization schedule could reduce the risk of vaccine-associated poliomyelitis and increase systemic as well as local antibody production. However, the long-term immunity to poliovirus provided by such a combined vaccination schedule has yet to be determined (Faden *et al.*, 1990). In addition, repeated contact with circulating vaccine virus may be important in causing intestinal reinfection and boosting local and humoral immunity, as is possible with such combined vaccines.

Another major concern with OPV is the formation of neurovirulent mutants (revertant virus) as it replicates in the gut. Sabin type 2 and 3 vaccine viruses have been reported to revert to neurovirulent phenotypes (Burke *et al.*, 1988). The types of potential sites of mutations associated with virulence are complex. These sites may include single base substitutions at either the 5' or the 3' noncoding regions of the viral genome (Evans *et al.*, 1985) or changes in the amino acid sequence of capsid proteins (Evans *et al.*, 1983). Prolonged fecal virus shedding has been proposed to be a function of development of revertants (Dunn *et al.*, 1990). However, the frequency of such reversion after different vaccination schedules has not been well defined. Studies carried out in our laboratory (Ogra *et al.*, 1991) have demonstrated that fecal shedding of nonvaccine type poliovirus revertants is not uncommon after immunization with OPV, regardless of prior immunization status. The nature of the virus shed in four groups of infants immunized with OPV, IPV-EP, or a combined vaccination of OPV and IPV-EP were analyzed. In group 1 receiving only one OPV dose, two of three (67%) isolates were nonrevertants. In group 2 receiving two doses of OPV, 11 of 12 (67%) isolates were found to be revertants. In groups 3 and 4, receiving doses of IPV-EP followed by OPV, over 90% of isolates were of the reverted virus types. On examining the frequency of reversion for different serotypes, evidently all type 2 poliovirus isolates tested were revertant types, irrespective of the immunization group. Significantly, all poliovirus type 3 revertants were observed in subjects previously primed with IPV-EP. In addition, nasopharyngeal antibody response was observed more significantly in subjects shedding revertants in the feces, irrespective of prior immunization with OPV or IPV-EP. Therefore, wild (virulent) virus or development of reversion during replication of OPV in the gut may provide a more potent stimulus for induction of mucosal immune response than attenuated

parent strains of vaccine viruses. Although combined immunization with IPV-EP followed by OPV is effective in inducing both systemic and secretory antibody responses, it affords no protection against generation of nonattenuated virulent revertants in vaccinees (Ogra *et al.*, 1991).

## 2. Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) is a major viral respiratory pathogen causing severe lower respiratory tract infection in early childhood. Despite the wide prevalence of RSV disease and a high rate of morbidity and mortality among children, no vaccine is currently available for prevention of this respiratory disease.

The earliest attempt to develop an effective vaccine occurred in the mid-1960s using a formalin-inactivated whole virus vaccine (Chin *et al.*, 1969). The vaccine, when evaluated in field trials, did not elicit any SIgA response nor did it show any immediate untoward effects. Subsequently, however, a number of vaccinees developed an exaggerated form of acute lower respiratory illness following natural exposure to the virus (Kapikian *et al.*, 1969; Kim *et al.*, 1969). Several other attempts were made to develop inactivated or attenuated vaccine, none of which have been successful (Buynak *et al.*, 1979; Belshe *et al.*, 1982). Investigative efforts also were directed at the use of low temperature adapted virus (Kim *et al.*, 1971) or other temperature sensitive mutants of the virus (TS1 and TS2). However, such vaccine candidates also showed poor infectivity and immunogenicity (Wright *et al.*, 1971; Richardson *et al.*, 1978).

RSV encodes for two major glycoproteins: G (G-Gp), which facilitates attachment of virus to the host cell, and F (F-Gp), which mediates spread of infection via cell-to-cell fusion. More recent studies by different workers have shown that these glycoproteins can induce protective immunity against infection with RSV (Routledge *et al.*, 1988). Monoclonal antibodies prepared against either glycoprotein, when passively administered to cotton rats and mice, were found to generate pulmonary resistance to subsequent intranasal challenge with the virus (Walsh *et al.*, 1987). Intranasal immunization with viral proteins was found to induce higher antibody titers in lungs than immunization by the intraperitoneal route. With refinements of molecular techniques, cDNA copies of the mRNAs for both glycoproteins have been cloned and live recombinant vaccinia viruses have been constructed that express RSV F or G glycoproteins. Experimental studies on rodents and monkey produced high titer antibody response to RSV F and G glycoprotein and showed significant resistance to intranasal challenge with RSV (Elango *et al.*, 1986; Stott *et al.*, 1987). However, immunization of chimpanzees with such recombinant viruses failed to induce a high level of RSV-specific antibody and resistance to RSV challenge (Collins *et al.*, 1990).

Experimental immunization of cotton rats with RSV or a live recombinant vaccinia virus expressing the RSV F-Gp via intranasal, parenteral, or enteric routes uniformly resulted in the development of RSV antibody in the serum and respiratory tract that was increased significantly after subsequent intranasal challenge with RSV (Kanesaki *et al.*, 1991). The IgA antibody response in bronchoalveolar fluid was two-

threefold higher after intranasal or enteric immunization than after intradermal immunization. The IgA antibody response in nasal wash was not significantly different among the three immunization groups, although the mean antibody titer was highest in the intranasal immunization group (Kanesaki *et al.*, 1991). Complete resistance to replication of RSV challenge was observed in lungs of cotton rats immunized by intranasal or enteric routes, compared with those immunized intradermally. Enteric or intradermal immunization conferred partial protection on the upper respiratory tract but complete protection was observed after intranasal administration. These studies indicate that although enteric immunization is quite effective in inducing antibody responses in the respiratory tract, intranasal immunization is superior. A combined immunization with both enteric and intranasal routes could, however, afford better antiviral immunity. These findings highlight the importance of immunization or infection of the respiratory tract itself to provide complete immunity (Ogra and Karzon, 1969). Several experimental studies on cotton rats (Wathen *et al.*, 1991), BALB/c mice (Connors *et al.*, 1991), and humans (Hall *et al.*, 1991) also have demonstrated the importance of F and G glycoproteins as protective antigens. In addition to live or inactivated vaccines, subunit vaccines prepared from fusion proteins are also under development (Murphy *et al.*, 1988). Immunostimulating complex (ISCOM) vaccine (Morien *et al.*, 1984), made from fusion protein and nucleoprotein of human RSV, also has been found to induce circulating neutralizing antibody when given by the mucosal intranasal route (Truedel *et al.*, 1990). Intranasal vaccination with ISCOM induced eightfold higher neutralizing antibody titers than live virus vaccine or subunit vaccine with adjuvant (Truedel *et al.*, 1990).

## 3. Rotavirus

Rotavirus is the leading cause of diarrhea in infants and young children worldwide, and represents the single most important cause of morbidity and mortality in children and infants in developing countries (Kapikian *et al.*, 1969). No vaccine has been approved for human use to date.

Rotavirus is a segmented double-stranded RNA virus capable of genetic reassortment, with the potential for antigenic changes. The major inner capsid polypeptide VP6 and, possibly contains the domain for the common group antigen shared by most human and animal rotavirus. Neutralizing antibody responses have been associated with outer capsid polypeptides VP7 and VP3, and hemagglutinin activity with VP3 (Greenberg *et al.*, 1988).

Based on earlier observation (Wyatt *et al.*, 1979), a "Jennerian" approach has been applied to the development of a vaccine for human rotavirus. This approach was possible because human and animal rotaviruses share a common group antigen VP6. A number of candidate vaccines have undergone clinical trials with limited success, including RIT 4374, WC3, MMU 18006, and SA-11. RIT 4374 derived from bovine rotavirus (strain NCDV) provided a high level of protection (88%) against clinically significant diarrhea in children ages 6–12 months (Vesikari *et al.*, 1986). However, the vaccine later failed to provide protection to children under 6 months of age (DeMol *et al.*, 1986). Similar results were obtained

with rhesus rotavirus strain (RRV) MMU 18006 (Christy *et al.*, 1988). The bovine rotavirus vaccine WC3 provided protection against moderate to severe diarrhea in children 3–12 months of age (Clark *et al.*, 1988). Purified empty capsids of verve monkey rotavirus (SA-11) have been evaluated in mice, but no data are available concerning their use in humans. Reassortant vaccines derived from rhesus virus and human rotavirus serotypes 1, 2, and 4 have been tested in adults and infants (Halsey *et al.*, 1988). Oral administration of reassortant vaccines has been found to be effective in inducing antibody seroconversion in over 70% of vaccinees, often associated with significant viral replication and shedding in the feces. The vaccine appears to be tolerated well by both adults and children. A safety tested strain of human rotavirus (CJN) appears to be distinct from other candidate vaccines (Ward *et al.*, 1986). Molecular approaches to vaccine development are also underway. A recombinantly expressed VP4 protein may be considered a viable candidate for rotavirus vaccine in the future (Mackow *et al.* 1990).

The role of SIgA antibody in protection against natural or vaccine-induced rotavirus infection remains controversial (Glass *et al.*, 1986). Several studies have demonstrated the presence of rotavirus-specific SIgA activity in breast milk and significant protection against rotavirus enteritis in breast-fed infants (Sheridan *et al.*, 1984). However, a positive relationship between the levels of fecal SIgA and protection from infection has not been observed consistently (Glass *et al.*, 1986).

#### 4. Adenovirus
