Inactivated vaccines against adenoviruses were licensed initially for parenteral use more than 20 years ago. However, the detection of a living monkey virus (SV40) in such inactivated vaccine preparations and the consistency in their protective efficacy against acute respiratory illness necessitated their withdrawal from the civilian market in the 1960s. Subsequently, live mucosal vaccines were developed against several adenovirus serotypes (types 4, 7, and 21), but the use of these vaccines has been restricted largely to military populations in whom these serotypes cause a large share of acute respiratory disease (Top *et al.*, 1971). Mucosal immunization with enteric-coated live adenovirus preparations has been highly effective against acute respiratory disease caused by adenoviruses in military recruits (Dudding *et al.*, 1973). After oral immunization with type 21 vaccine and after natural infection with virus of type 1, 4, 6, or 7, the characteristics of the serum antibody response appear to be similar to those of the responses to other mucosal viral infections, particularly with respect to the development of IgM and IgG antibody responses. The SIgA and, frequently, the secretory IgG antibody responses have been observed regularly in the nasal secretions after natural infection (Ogra *et al.*, 1980). After immunization with enteric-coated vaccines, SIgA antibody is detected regularly in feces; however, nasal secretions do not manifest significant adenovirus-specific SIgA antibody activity. The adenoviruses types 1, 2, and 5 that are associated with childhood illnesses have been shown to be safe and immunogenic when administered to adult volunteers using the same technique of enteric immunization (Steinhoff,

1991). However, the approach of enteric immunization has not been used in children.

The precise role of serum rather than secretory nasopharyngeal antibody in adenovirus-induced respiratory disease remains to be defined. After natural infection, homotypic reinfection is a rare phenomenon. On the other hand, after enteric immunization, homotypic reinfection occurs frequently in association with shedding of virus in the respiratory tract, although clinical illness is rare. These observations suggest that other mechanisms, such as serum antibody or T cell-mediated immunity, also may play a role in the mechanisms of mucosal defense in adenovirus infections. Unfortunately, no information is available about the development and function of adenovirus-specific cell-mediated immune response after natural infection in humans.

#### 5. Rabies Vaccine

Animal rabies is endemic in virtually all parts of the world. Human infection continues to be a uniformly fatal disease. Attempts at reducing the animal reservoir of the disease have been frustrated by the multiplicity of animal species in which the virus replicates (Baer, 1988). Vaccinia virus recombinants expressing rabies virus glycoproteins have been utilized as a replicating vaccine, administered orally in wild animals. Immunization with one such glycoprotein vaccine in raccoons induced specific neutralizing antibody to rabies virus in serum (Rupprecht *et al.*, 1986). The animals resisted rabies virus challenge 28 and 205 days after immunization. Significantly, however, oral immunization with other attenuated antigenic variants of rabies virus (strain CVS-11 or ERA) failed to induce significant seroconversion (Rupprecht *et al.*, 1986). Although oral immunization with recombinant rabies vaccine appears to be highly successful in such experimental settings, information concerning the development of SIgA antibody response is not available at this time.

#### 6. Simian and Human Immune Deficiency Viruses

Although on a world-wide scale more than 70% of AIDS cases are acquired by the heterosexual route of transmission (Padian, 1987; Johnson 1988; Piot *et al.*, 1988; Alexander, 1990; Naz and Ellaurie, 1990), the role of mucosal immunity and development of vaccines that may be effective in the prevention of sexually acquired disease have not received due attention (McGhee and Mestecky, 1990, 1992). However, an animal model has clearly demonstrated that systemically immunized rhesus macaques that are protected against systemic challenge with simian immunodeficiency virus (SIV) develop infection when the virus is introduced in the vagina or urethra (Miller *et al.*, 1989). In view of the relative independence of systemic and mucosal immune compartments, future immunization efforts should be aimed at inducing protective immunity in both compartments. Whether SIgA anti-SIV- or anti-HIV-specific antibodies neutralize corresponding viruses before they infect susceptible cells in the genital tract (T cells, macrophages, Langerhans cells, and probably epithelial cells) or also neutralize virus intracellularly has not been established. Further, the role

of mucosal cytotoxic T cells in the prevention of spreading of infection by eliminating infected cells has not been established.

Exploration of immunization routes that lead to the preferential induction of immune responses in genital tract secretions and tissues should receive further attention. In macaques, combination of oral–vaginal and rectal immunizations has yielded promising results (Lehner *et al.*, 1992a,b).

## B. Influenza Virus

Several studies performed in animal models indicate that mucosal antibodies, especially SIgA, play a prominent role in the prevention of influenza virus infection of the upper respiratory tract (Shvartsman and Zykov, 1976; Liew *et al.*, 1984; Small, 1990; Renegar and Small, 1991a,b); systemic antibodies and cell-mediated immunity are apparently more important in the recovery phase from the infection and in prevention of viral pneumonia (Liew *et al.*, 1984). Antibodies against both hemagglutinin (HA) and neuraminidase (NA) of influenza protect mice from experimental infection. Antibodies against HA are thought to neutralize viruses whereas anti-NA is thought to prevent release of viruses from infected cells (Askonas *et al.*, 1982).

Oral administration of live virus or inactivated vaccine (Bergmann and Waldman, 1989) to mice results in HA virus-specific antibodies in lung lavage fluids. Since influenza vaccine is only moderately immunogenic, mucosal adjuvants such as cholera toxin (Chen and Quinnan, 1989) have been used in oral immunization protocols. In one study (Moldoveanu *et al.*, 1993), the use of microencapsulated influenza vaccine in mice preserved immunogenicity of vaccine given orally or by the systemic route and also resulted in higher serum and secretory antibody levels, which persisted longer than when an unencapsulated vaccine was used.

Humans orally immunized with inactivated influenza vaccine exhibited an SIgA antibody response in nasal and other external secretions (Bergmann *et al.*, 1986; Waldmann *et al.*, 1986; Bergmann and Waldman, 1989). Higher oral doses induced better responses in the age groups most commonly afflicted, that is, the elderly and children with chronic bronchitis, both of which responded well to the oral vaccine (Bergmann and Waldman, 1989). Several studies also have been performed of aerosol immunization with attenuated virus, a procedure that presumably immunizes via BALT. Nasal washes of these vaccinees contain high titers of SIgA and anti-HA and lesser amounts of IgM and IgG (Murphy *et al.*, 1982; Murphy and Clements, 1989). Individuals who developed nasal SIgA anti-HA also developed serum IgA and anti-HA responses (Brown *et al.*, 1985).

In summary, ample evidence supports the conclusion that oral immunization with killed virus, intranasal (BALT) immunization with attenuated strains, or perhaps combinations of the two, should provide SIgA immunity in the upper respiratory tract.

## C. Bacterial Vaccines

Mucosal immunizations with numerous bacterial species and their products have been explored in humans and in animals for more than 100 years (for reviews, see Gay, 1924; Besredka, 1927; Mestecky and McGhee, 1989). Although the list of bacterial species used for mucosal immunization includes some 17 important mucosal and systemic pathogens, we discuss only those that have been used in human orally delivered vaccines.

### 1. Salmonella

Salmonellae effectively colonize the gastrointestinal tract in a species-specific fashion, for example, *S. typhi* affects humans whereas *S. typhimurium* causes mouse typhoid (Curtiss *et al.*, 1989). Further, these bacteria can penetrate into the Peyer's patches and can reach systemic tissues via the mesenteric lymph nodes and the bloodstream. The advantages of using *Salmonella* in antigen delivery is reviewed elsewhere (Curtiss *et al.*, 1989; Cardenas and Clements, 1992). Thus, vaccines for immunity to typhoid have been developed and, in some instances, have been given by the oral route (Kantele *et al.*, 1986). The avirulent galactose epimeraseless (*gal E*) *S. typhi* Ty21a was field tested extensively and shown to be safe and to induce immunity when given systemically (Levine *et al.*, 1986). However, when Ty21a was given by the oral route, it was less effective; multiple oral doses were required. Nevertheless, a number of attenuated *Salmonella* strains and mutants are being tested and hold promise for use as oral vaccines (Curtiss *et al.*, 1989).

### 2. Cholera

A major cause of severe diarrheal disease in developing countries is cholera, which is produced by the enterotoxigenic strains of *V. cholerae*. Partially protective SIgA antibodies are found in the intestine of those who recover and may work synergistically with antibodies to cholera toxin and to surface antigens to provide protection (Holmgren *et al.*, 1989). Two types of oral cholera vaccines currently are being tested: mutant cholera strains that colonize the gut and induce a local antibody response (Levine *et al.*, 1983) and a combined vaccine consisting of killed cholera vibrios and purified B toxin subunit (Clemens *et al.*, 1988). The latter vaccine has been field tested extensively in cholera endemic areas, and has been shown to give rise to a long-lasting protective immunity (Holmgren *et al.*, 1989).

### 3. Shigellosis

The *Shigellae* are gram-negative pathogens that penetrate through the epithelial cells in the large intestine and induce bacillary dysentery. Most efforts toward development of immunity have involved attenuated oral vaccines (Hale and Formal, 1989). The bacterium contains a large (120–140 mDa) plasmid that encodes invasion plasmid antigens (*ipa*), permitting the construction of enteroinvasive vaccines using *Esche-*

*richia coli* and *Salmonella* as recipients. The plasmid has been transferred to *E. coli* K-12, and conjugal transfer of *His* and *Pro* markers from *Shigella flexneri* into the *E. coli* yielded a vaccine strain (EC104) that expressed *Shigella* antigens (Hale and Formal, 1989). This strain has been used to immunize monkeys orally, but resulted in a high incidence of diarrhea when tested in humans. The Ty21a *gal E* mutant of *S. typhi* has been used as a recipient of a 120-mDa plasmid of *Shigella sonnei*, which encodes the O-polysaccharide side chain of the somatic antigen. This oral vaccine provided 40% protection from challenge by virulent *S. sonnei*. Thus, oral vaccines with recombinant bacteria containing *Shigella* plasmids are promising and ultimately may induce protection from bacterial dysentery.

#### 4. *Haemophilus influenzae*

*Haemophilus influenzae* [nontypable (NTHI)] has been used as a component of oral vaccine given to human volunteers as a protective measure against acute bronchitis (Clancy *et al.*, 1989). Killed NTHI vaccine was given 3 times in tablets. Previous studies (Clancy *et al.*, 1983) from the same group of investigators revealed that oral immunization induces haemophilus-specific SIgA in saliva of vaccinees. However, no difference in NTHI colonization of throats of orally immunized or placebo-administered individuals were noted (Clancy *et al.*, 1989).

#### 5. *Streptococcus mutans*

Mutants streptococci are involved in the development of dental caries. Numerous studies performed in the last 20 years have shown that oral immunization of human volunteers with formalin-killed *S. mutans* and with certain bacterial products such as enzyme glucosyltransferase induces enzyme-neutralizing antibodies in saliva and reduces *S. mutans* counts in dental plaque (Russell and Mestecky, 1986; Taubman and Smith, 1989; Michalek and Childers, 1990; Russell, 1992). Further, *S. mutans*-specific SIgA antibodies were detected in tears, colostrum, and milk as well as parotid, submandibular, and submaxillar saliva of vaccinees (Mestecky *et al.*, 1978; Gregory *et al.*, 1985; Czerkinsky *et al.*, 1987). Although the mechanisms involved in the protection against dental caries have not been established convincingly, antibodies apparently play a dominant role.

## V. SUMMARY

The selective induction of humoral and cellular immune responses in mucosal tissues is desirable for the prevention of various systemic as well as predominantly mucosa-restricted infections. The enormous surface area of mucosal membranes is protected primarily by antibodies produced locally by large numbers of plasma cells distributed in the subepithelial spaces of mucosal membranes and in the stroma of secretory glands. In contrast to the large variety of currently available injectable vaccines that stimulate systemic immunity,

vaccines administered nonparenterally to stimulate mucosal immunity preferentially are used infrequently.

Current knowledge of the origins and migratory pathways of B and T lymphocytes destined for mucosal tissues indicates that the development and application of vaccines to exploit the remarkable principles of the common mucosal immune system will achieve the ultimate goal—protection of mucosal membranes.

# Antigen Delivery Systems: New Approaches to Mucosal Immunization

Suzanne M. Michalek · John H. Eldridge · Roy Curtiss III · Kenneth L. Rosenthal

## I. INTRODUCTION

The concept of vaccination as a means to eradicate disease began almost 200 years ago when Jenner showed that inoculation of a child with cow pox provided protection from a lethal small pox infection. Progress in this area moved slowly for many years. In fact, only during the past few decades have notable advances been made in the development of vaccines, that is, in the formulation of new ones and the improvement of existing ones, through the application of modern technology. In designing a vaccine, several aspects that need to be considered are its safety for use in animals (including humans), the convenience and cost of reproducibly generating the vaccine in large quantities, and its effectiveness in inducing the desired host response. Another important consideration is the route of immunization. Most infectious diseases involve colonization of or invasion through mucosal surfaces by the pathogen; therefore, developing methods for the induction of mucosal immune responses that will serve as a first line of defense is important. Oral administration of antigen has been shown to result in the induction of mucosal IgA antibodies in our external secretions (Mestecky, 1987; McGhee and Mestecky, 1990). This route of immunization has advantages over other means because the vaccines can be administered easily and have, potentially, no side effects. However, major limitations are the acidic pH and the presence of degradative enzymes in the gastrointestinal tract, which can break down the immunogens prior to antigen uptake and presentation to lymphoid cells in IgA inductive sites, for example, the gut-associated lymphoid tissue (GALT). Perhaps for these reasons, particulate antigens, especially when presented as viable organisms, are effective in inducing local and generalized secretory and systemic immune responses. At least three possible reasons exist to explain why particulate antigens are more effective oral immunogens than soluble antigens. First, the size of these macromolecular complexes may allow them to survive more effectively in low pH, bile salts, and proteolytic enzymes of the stomach and gastrointestinal tract. Second, at least some particulates are adsorbed through the M cells into the Peyer's patches with greater efficiency than soluble molecules, thus providing a higher local antigen concentration within this mucosal immune inductive site. Third, the major portion of an ingested soluble protein antigen will cross the epithelial barrier of the

gut in the form of amino acids and low molecular weight peptides. The recognition of these peptides by gut lymphoid cells at sites other than the inductive environment of the Peyer's patches has been proposed as the stimulus initiating systemic tolerance after antigen feeding (Bland and Warren, 1986), and may provide a negative signal to the mucosal immune system as well. This information and the availability of modern technology have facilitated the development of antigen delivery systems with immunopotentiating activity for the induction of protective mucosal and systemic immune responses against microbial pathogens. Antigen delivery systems that have received considerable attention for their use in vaccine development are liposomes, biodegradable microspheres, and recombinant *Salmonella* and viral vectors.

## II. LIPOSOMES AS VACCINE DELIVERY SYSTEMS

### A. Introduction

Since the discovery by Bangham and co-workers (1965) that the addition of water to a flask containing a film of phospholipids resulted in the appearance of microscopic closed vesicles, liposomes have been studied extensively for use in targeted drug delivery and more recently as vaccine delivery systems. A number of aspects pertaining to the usefulness of liposomes as vaccine delivery systems are listed in Table I; several of these are discussed further in a subsequent section. Briefly, liposomes can act as immunoadjuvants in potentiating immune responses. Therefore, the amounts of antigen needed to induce a response are smaller when incorporated into liposomes than when given alone. Liposomes also can convert nonimmunogenic substances into immunogenic forms, for example, by rendering soluble substances particulate in nature. A variety of substances can be incorporated into liposomes including multiple antigens, adjuvants, and substances such as antibodies to cell-surface antigens for targeted delivery. Liposomes are taken up by macrophages and by M cells (specialized epithelial cells covering Peyer's patches) for antigen processing or presentation to other lymphoid cells for the induction of immune responses. Liposome also can present antigens to lymphoid cells directly

**Table I** Usefulness of Liposomes as a Delivery System and Immunoadjuvant for Vaccine Development

1. Small amounts of antigen may be suitable as immunogen
2. Nonimmunogenic substances may be converted to immunogenic forms (e.g., soluble antigens can be rendered "particulate" in form)
3. Adjuvants can be incorporated into the aqueous phase or membrane of liposomes containing antigens
4. Targeting agents can be incorporated into liposomes for delivery to specific host cells
5. Can be administered safely by oral or systemic routes for the induction of antibody responses to the incorporated antigen in external secretions or serum, respectively
6. Are taken up by macrophages and M cells and can substitute for antigen-presenting cells
7. Can mediate DNA or RNA transfection of cells

for the induction of immune responses. Since liposomes can be composed of substances (e.g., phospholipids) that constitute host cells, they should represent nontoxic, safe, and efficacious vaccine delivery systems for use in animals, including humans. Liposomes also have been shown to mediate DNA or RNA transfection of cells and may represent a useful means of transfer of genetic material encoding vaccine antigens. For more detailed discussion of this subject, the reader is referred to extensive reviews by others (Felgner *et al.*, 1987; Ostro, 1987; Swenson *et al.*, 1988; Gregoriadis, 1990; New, 1990; van Rooijen, 1990; Alving, 1991).

### B. Properties of Liposomes

Liposomes are composed of a bilayered (bimolecular sheet) phospholipid membrane (lamella) forming vesicles enclosing and surrounded by an aqueous solution (Figure 1). The amphipathic nature of phospholipid molecules accounts for the spontaneous formation of vesicles, with the hydrophilic (water-soluble or polar) head portion oriented toward the aqueous phase and the hydrophobic (water-insoluble) tail pointing into the bilayer. Thus, in preparing liposome vaccines, water-soluble substances can be incorporated into the enclosed aqueous space whereas lipid-soluble molecules can be added to the solvent during vesicle formation and incorporated into the lipid bilayer. Almost any substance, regardless of its solubility, size, shape, or electric charge, can be incorporated into liposomes as long as it does not interfere with vesicle formation.

Depending on conditions used for production, liposomes can vary in size from 0.01  $\mu\text{m}$  (Cornell *et al.*, 1982) to 150  $\mu\text{m}$  (Pagano and Weinstein, 1978) (red blood cells are  $\sim 10 \mu\text{m}$  in diameter), as well as in form. The two standard forms of liposomes are multilamellar and unilamellar (Figure 1). Multilamellar vesicles (MLV) have several lipid bilayers separated by thin aqueous phases. Unilamellar vesicles have a single bilayer membrane surrounding an aqueous core and are characterized as being small (SUV) or large (LUV). Liposomes

**Figure 1** Schematic depiction of the two basic forms of liposomes. The small unilamellar vesicle (SUV) illustrates the bilayered membrane composed of dipalmitoyl phosphatidylcholine (DPPC) surrounding an aqueous core. The multilamellar vesicle (MLV) is characterized by several lipid bilayers separated by thin aqueous phases.

somes can be prepared to vary in their membrane stability, fluidity, and permeability depending on their lipid content (e.g., ratio of phospholipid to cholesterol). The incorporation of charged amphiphiles renders the liposomal surface positively or negatively charged. Each of these properties influences how effective a liposome preparation will be as a delivery system.

Several procedures for producing liposomes have been described (reviewed in Bangham *et al.*, 1974; Pagano and Weinstein, 1978; Kirby and Gregoriadis, 1984; New, 1990); however, a commonly used method involves sonication of the aqueous phospholipid suspension. The liposomes generated by this method are heterogeneous in size and form. For vaccine delivery systems, techniques must be used that reproducibly generate liposome preparations of controlled size and composition. Microemulsification of liposome suspensions is one technique that reproducibly results in homogeneous liposomes. The liposomes are produced in a pressurized chamber and, by controlling the pressure and cycling time, small unilamellar liposomes of the desired diameter are generated (Mayhew *et al.*, 1984; Childers *et al.*, 1989). This procedure has been used extensively to generate liposomes containing antigens, especially mutans streptococcal antigens, for use as oral vaccines (reviewed by Michalek *et al.*, 1989; Michalek and Childers, 1990). Another method for preparing liposomes involves the generation of dehydrated-rehydrated vesicles (Gregoriadis *et al.*, 1990; reviewed by Gregoriadis, 1990). This procedure has been shown to result in high-yield entrapment of drugs and has been used to incorporate reproducibly various substances such as tetanus toxoid, influenza virus subunit peptides, recombinant hepatitis B surface antigen, *Leishmania major*, antigens and poliovirus. A direct comparison of the various liposome preparations for their effective use as vaccine delivery systems for the induction of protective immune response remains to be done.

### C. Processing of Liposome Vaccines

Several explanations have been proposed for how liposomes can be effective delivery systems and adjuvants for the induction of immune responses (reviewed by Gregoriadis, 1990; van Rooijen, 1990; Alving, 1991). Liposomes, regardless of their composition and size, can adsorb to most cells and release their incorporated substances, which then can act on the cell. Liposomes also can be taken up by macro-

phages and other phagocytic cells in the blood, lymph, and various tissues (e.g., lymph nodes, liver, and spleen) with the subsequent release of antigen. The liver and spleen take up nearly all liposomes given by the intravenous route, whereas most liposomes injected via the subcutaneous or intramuscular route are retained at the site of injection and are taken up by infiltrating macrophages. The ability of antigen presenting cells to take up and process antigens associated with liposomes more efficiently for enhanced immune responses is another explanation for the immunoadjuvant property of liposomes. The liposomes also have been suggested to act directly in presenting antigen to lymphoid cells for the induction of responses. Further studies are necessary, however, to better define the mechanism(s) involved in the adjuvanticity of liposomes.

Although the fate of liposomes given orally remains controversial, vesicles composed of cholesterol and phospholipids are resistant to detergents or phospholipases and are also more resistant to degradation by enzymes in the gastrointestinal tract. In extensive studies in an experimental rat model (Childers *et al.*, 1990), liposomes have been shown to be taken up by M cells present in the epithelium covering the

Peyer's patches (Figure 2). The liposomes are detected in endosomes in the M cells and appear to be transversing the cell, moving toward the underlying lymphoid cells. The presentation of antigen within liposomes to lymphoid cells in this IgA-inductive tissue can result in a mucosal immune response as manifested by the appearance of IgA antibodies in external secretions.

#### D. Liposome Vaccines in Vivo

During the past decade, numerous studies have been performed to establish the usefulness of the liposome vaccine delivery system in inducing protective immune responses against various infectious diseases. Although studies frequently have involved systemic routes of administration, evidence is accumulating that demonstrates that liposomes can serve as carriers of antigens and as adjuvants for inducing enhanced mucosal immune responses when given as an oral vaccine. Table II lists several, but not all, studies that have used liposomes as vaccine delivery systems. In the oral immunization studies, mucosal IgA immune responses were

induced; in some cases the induction of the response correlated with protection against disease. In these studies and in those involving systemic routes of liposome vaccine administration, the spatial arrangement of the antigens within liposomes and the characteristics of the vesicles such as size and number of lamellae were not actually determined. Researchers generally accept that a physical association between the liposome membrane and antigen (as opposed to their simple mixing) is an important consideration in formulating a delivery system for inducing immune responses. Antigen can be incorporated into the aqueous phase of the vesicles, adsorbed onto their surface, partitioned into the bilayers (hydrophobic antigens), or covalently coupled to a membrane component. The specific formulation of liposome delivery systems may differ for the development of vaccines that are effective in

inducing protective immunity against different infectious organisms. Further studies will be required to resolve this issue.

### III. BIODEGRADABLE MICROSPHERES

#### A. Introduction

As first suggested by Strannegard and Yurchinson (1969), the particulate form of an antigen may enhance its effectiveness as an oral immunogen. Currently, the only approved method to adjuvant vaccines for human use is to adsorb protein antigens onto aluminum salts to create a particulate. These particulates potentiate the antibody response after sys-

temic administration through the creation of an antigen depot, the induction of inflammation at the site of injection, and the directed delivery of the particulate antigen into the draining lymph nodes. However, the size and properties of aluminum compounds are sensitive to slight changes in the conditions of their preparation and their age (Nail *et al.*, 1976a,b), and they are not effective carriers for mucosal immunization. Among the approaches under investigation to improve vaccine delivery to systemic and mucosal lymphoid cells is the generation of polymeric particulate adjuvants.

Litwin and Singer (1965) demonstrated a modest enhancement in the circulating antibody response to human gamma globulin adsorbed onto polystyrene latex particles that had been administered intravenously to rabbits. This adjuvant activity was shown to be dependent on the adsorption of the antigen to the particles, was most apparent at limiting antigen doses, and was equivalent when particles of various diameters from 0.05 to 1.3  $\mu\text{m}$  were tested. In contrast, Kreuter *et al.* (1986, 1988) reported that subcutaneous injection of mice with bovine serum albumin (BSA) adsorbed to either poly(methylmethacrylate) or polystyrene particles potentiated the anti-BSA response to a greater extent than adsorption to aluminum hydroxide. The possibility of using polymeric particles coated with antigen for the induction of a mucosal antibody response was reported by Cox and Taubman (1984), who stated that the oral administration of dinitrophenyl-bovine gamma globulin (DNP-BGG) on 1- to 3- $\mu\text{m}$  glutaraldehyde-activated polyacrylamide beads was generally more effective in eliciting a salivary IgA anti-DNP response than was an equivalent dose of the soluble DNP-BGG. However, no supporting data were provided in this communication, so determining the degree to which the mucosal response was potentiated is impossible. More recently, O'Hagan *et al.* (1989a) tested 0.1- and 3- $\mu\text{m}$  poly(butyl-2-cyanoacrylate) particles with adsorbed ovalbumin (OVA) as carriers for mucosal immunization. When orally administered on 4 consecutive days to primed rats, both the 0.1- and the 3- $\mu\text{m}$  OVA-coated particles induced the appearance of specific IgA antibodies in saliva; the 0.1- $\mu\text{m}$  particles also induced a serum IgG response. In contrast, oral boosting with soluble OVA was without effect.

### **B. Immunization Studies with Antigens Incorporated within Polymeric Particulates**

Although clearly synthetic polymeric particulates with antigen adsorbed to their surface can serve as adjuvants that may enhance systemic or mucosal immune responses, many antigens will not adsorb effectively to their surface. Further, the exposed antigen is subject to elution or degradation after *in vivo* administration, an especially important consideration in the case of oral immunization. Incorporation of the vaccine within the polymer can allow virtually any antigen to be used, providing protection from degradation and control over the time of release. Several antigen-containing polymer systems have been investigated, some of which are listed in Table III with the conditions used to evaluate their effectiveness and the major experimental findings.

## **1. Antigens Incorporated within Polymeric Agglomerates and Implantable Pellets**

Methylmethacrylate was polymerized by gamma irradiation in the presence of whole formalin-inactivated influenza virions (Kreuter and Speiser, 1976) or split influenza vaccine (Kreuter *et al.*, 1976) to yield agglomerates of poly(methylmethacrylate). After subcutaneous administration to guinea pigs or intraperitoneal administration to mice, the vaccine-polymer agglomerates were shown to elicit serum hemagglutination inhibition titers that exceeded those induced by equivalent doses of the free or aluminum hydroxide adjuvanted vaccines. Incorporation of the vaccines into the polymer by this approach was suggested because the adsorption of antigens to the agglomerate after polymerization provided less adjuvant activity. The vaccine-containing agglomerates exhibited a delay in the time of the antibody response relative to the other vaccine forms.

Preis and Langer (1979) used a solvent casting process to produce 0.3-mm pellets of ethylene-vinyl acetate copolymer, each of which contained 100  $\mu\text{g}$  BSA. Subcutaneous implantation of one pellet per mouse was shown to elicit a circulating anti-BSA response, as measured by indirect hemagglutination, which was equivalent to that stimulated by two injections, each of which contained 50  $\mu\text{g}$  BSA emulsified in complete Freund's adjuvant (CFA). The authors proposed that the immunopotential afforded by this delivery system resulted from prevention of antigen degradation and sustained release by diffusion through the copolymer. In a subsequent modification of this approach, BSA-containing pellets were prepared with a novel biodegradable polymer, CTTH-iminocarbonate, formed by linking tyrosine dipeptide units together through hydrolytically labile bonds between the tyrosine side-chain groups (Kohn *et al.*, 1986). This polymer was chosen for evaluation because the degradation products include derivatives of L-tyrosine, which have been reported to exhibit adjuvant activity. Following implantation, the BSA-containing CTTH-iminocarbonate pellets were shown to induce substantially enhanced antibody responses relative to the same dose of free BSA. Although the CTTH-iminocarbonate pellets did not potentiate the humoral response to the same extent as the previously described BSA-containing ethylene-vinyl acetate pellets (Preis and Langer, 1979), their *in vivo* biodegradation obviated the need for surgical removal.

## **2. Antigens Incorporated within Polymeric Microspheres**

Incorporation of vaccines within polymeric microspheres can provide a system combining the advantages of a particulate adjuvant, which protects and controls the release of the antigen, with ease of administration by injection or mucosal application. Microencapsulation involves the coating of a bioactive agent, such as a vaccine, in a protective wall material that is generally polymeric in nature. The microsphere product is a free-flowing powder of spherical particles that can be produced across a size range from <1  $\mu\text{m}$  to as large as 3 mm in diameter. The systems that have been investigated for vaccine delivery include microspheres formed by cross-

linking natural substances such as starch or albumin and synthetic polymers.

In an attempt to produce a biocompatible microsphere antigen delivery system from a natural substance, Artursson *et al.* (1986) formulated 0.5 to 2.0- $\mu\text{m}$  microspheres containing human serum albumin (HSA) from acryl starch activated with ammonium peroxydisulfate and cross-linked with *N,N,N',N'*-tetramethylethylenediamine. When administered to mice by intramuscular or intravenous injection, the HSA-polyacryl starch microspheres stimulated a circulating anti-HSA antibody response that reached and remained for >200 days at approximately 500-fold the peak level induced by the injection of free HSA. However, an antibody response to the cross-linked starch was demonstrated in inhibition of

antibody binding studies. In another approach that investigated the use of a natural substance under conditions under which it is normally nonimmunogenic, Martin *et al.* (1988) intramuscularly immunized rabbits with 100- to 200- $\mu\text{m}$  microspheres containing Nodamura virus, that were formed by glutaraldehyde cross-linking of autologous rabbit serum albumin (RSA). In this system, the circulating antiviral antibody response was low and responses also were detected to glutaraldehyde cross-linked RSA. Thus, although the number of studies examining cross-linked natural substances to formulate vaccine-containing microspheres has been limited, the induction of antibody responses to the microsphere matrix is a problem that appears to preclude their application in human immunization.

O'Hagan *et al.* (1989b) examined the ability of antigen-containing synthetic polymer microspheres to potentiate salivary and plasma antibody responses. Oral administration of 1 mg OVA entrapped in polyacrylamide microspheres on each of 4 consecutive days to rats that had been primed previously by intraperitoneal injection of OVA in saline generated a statistically significant salivary IgA response, in the absence of a rise in circulating antibodies, 65 days following oral boosting. These microspheres were macroporous particles of 2.55- $\mu\text{m}$  mean diameter with the OVA partially exposed on their surface. Control animals that received soluble OVA as the oral booster did not respond. These authors did not report on the adjuvant activity or tissue reactivity after systemic injection of these polyacrylamide microspheres, but the known neurotoxicity of polyacrylamide bars this formulation from all but experimental applications.

More recently, considerable effort has been placed in the evaluation of microspheres formulated from poly(DL-lactide-co-glycolide) (DL-PLG) for the parenteral and enteral delivery of vaccines because of the proven biocompatibility and biodegradability of this copolymer. DL-PLG is in the class of copolymers from which resorbable sutures, resorbable surgical clips, and controlled-release drug implants and microspheres are made (Redding *et al.*, 1984). These polyesters are approved for and have a 30-year history of safe use in humans. After introduction into the body, DL-PLG induces only a minimal inflammatory response and biodegrades through hydrolysis of ester linkages to yield the normal body constituents lactic and glycolic acids (Tice and Cowsar, 1984; Visscher *et al.*, 1987; Figure 3). Further, the rate at which DL-PLG biodegrades is a function of the ratio of lactide to glycolide in the copolymer (Miller *et al.*, 1977), thus determining the time after administration when release initiates as well as the subsequent rate of release.

Altman and Dixon (1989) examined the immune response induced by immunization with peptide 72 (p72), a 28-amino-acid peptide from the surface glycoprotein of hepatitis B virus, conjugated to tetanus toxoid (p72:TT). Subcutaneous injection of mice with p72:TT incorporated into 50- to 100- $\mu\text{m}$  DL-PLG microspheres that were designed to release the antigen at a uniform rate over a period of 1–12 months resulted in a very weak primary antibody response. However, the microencapsulated p72:TT retained antigenicity, as judged by the ability to prime for an anamnestic secondary response. Further, if the microencapsulated p72:TT was injected in an inflammatory vehicle such as incomplete Freund's adjuvant (IFA), a high primary antibody response was induced, suggesting that the difference seen between these noninflammatory controlled release DL-PLG microspheres and the previously described pellets (Preis and Langer, 1979; Kohn *et al.*, 1986) may be related to inflammation induced by the implants.

In contrast to the results obtained with the relatively large DL-PLG microspheres investigated by Altman and Dixon (1989), the systemic administration of staphylococcal enterotoxin B (SEB) (Eldridge *et al.*, 1989, 1990a,b, 1991a,b, 1992), influenza vaccine (Moldoveanu *et al.*, 1989, 1992), simian immunodeficiency virus (SIV; Marx *et al.*, 1993), and OVA (O'Hagan *et al.*, 1991a,b) in 1- to 10- $\mu\text{m}$  DL-PLG microspheres resulted in strongly potentiated primary antibody

**Figure 3** Synthesis, structure, and biodegradation products of poly(D,L-lactide-co-glycolide) (DL-PLG). Polymerization of D,L-lactide and glycolide, the respective cyclic dimers of lactic and glycolic acids, into the high molecular weight DL-PLG through ionic, ring opening, addition polymerization. On exposure to water, this aliphatic polyester degrades through hydrolysis of ester linkages to yield the biocompatible products lactic and glycolic acids.

responses without the need for an additional vehicles. In the case of SEB toxoid, mice immunized with 50  $\mu\text{g}$  vaccine in 1- to 10- $\mu\text{m}$  DL-PLG microspheres mounted a neutralizing plasma antitoxin response that was equivalent in level and duration to that induced by the same dose of toxoid emulsified in CFA without a significant inflammatory response (Eldridge *et al.*, 1991b). This antibody level was 512-fold and 64-fold that induced by soluble and alum-precipitated toxoid, respectively. Similar immunopotential was obtained in rhesus macaques immunized by the intramuscular injection of microencapsulated SEB toxoid or whole formalin-inactivated SIV (Marx *et al.*, 1993). Direct comparison of the antibody responses elicited by subcutaneous immunization with 1- to 10- $\mu\text{m}$  versus 10- to 110- $\mu\text{m}$  microspheres, formulated from the same lot of DL-PLG and containing the same percentage of SEB toxoid by weight, demonstrated that the 1- to 10- $\mu\text{m}$  microspheres provided approximately 20-fold greater immune enhancement (Eldridge *et al.*, 1991b). This enhanced potentiation by the <10- $\mu\text{m}$  microspheres correlated with the phagocytosis and transportation of a large number of these particles, but not those >10  $\mu\text{m}$ , to the lymph nodes draining the injection site. These data suggest that the efficient delivery of vaccine by the <10- $\mu\text{m}$  microspheres into antigen-presenting cells, which then carry it to an immune inductive environment, is a more effective approach to the

enhancement of antibody responses than the depot release of free antigen provided by larger microspheres, and a probable explanation for the poor adjuvancy observed in the studies by Altman and Dixon (1989).

An additional difference in the behavior of <10- $\mu\text{m}$  versus >10- $\mu\text{m}$  microspheres noted in the studies by Eldridge *et al.* (1991b) was an accelerated rate of antigen release by the smaller microspheres after *in vivo* administration, presumably as a result of phagocytosis. This difference formed the basis for the design of a single-injection multiple-release microsphere formulation consisting of a mixture of 1- to 10- $\mu\text{m}$  and 20- to 50- $\mu\text{m}$  microspheres containing SEB toxoid (Eldridge *et al.*, 1991a). Mice injected with this mixture of microspheres mounted a biphasic antitoxin response in which the first phase of antibody increase corresponded to the release of vaccine from the 1- to 10- $\mu\text{m}$  component. The second phase corresponded to the release of vaccine from the 20- to 50- $\mu\text{m}$  microspheres and stimulated an anamnestic secondary rise in antitoxin levels. These results indicate that blends of DL-PLG microspheres differing in their size or lactide-to-glycolide ratio are capable of functioning as adjuvant systems with the ability to provide one or more discrete booster releases of antigen after a single administration.

To evaluate the possibility of using DL-PLG microspheres as vehicles for oral immunization, the adsorption of fluorochrome-containing microspheres was studied in mice (Eldridge *et al.*, 1989, 1990a). At various times after oral administration, the gut and other lymphoid tissues were serially frozen, sectioned and the microspheres within tissue were observed by fluorescence microscopy. At early time points, tissue penetration in the gut was restricted to the Peyer's patches (Figure 4), only microspheres  $\leq 10 \mu\text{m}$  in diameter were adsorbed, and the adsorbed microspheres were within Peyer's patch macrophages. With increasing time after administration, the number of microspheres in the Peyer's patches fell and they were observed sequentially in the mesenteric lymph nodes and spleen, suggesting that orally delivered microspheres could be capable of delivering vaccine antigens to both mucosal and systemic immune inductive tissues. When mice were given three oral administrations, at 30-day intervals, of SEB toxoid in 1- to 10- $\mu\text{m}$  DL-PLG microspheres, they exhibited a steady rise in their plasma levels of IgG antitoxin and significant levels of SIgA antitoxin in saliva, gut fluids, and bronchial-alveolar fluids 20 days after the third dose (Eldridge *et al.*, 1989, 1991a). In contrast, mice orally immunized with nonencapsulated SEB toxoid mounted only a weak IgM response in plasma and none in mucosal secretions. In similar experiments, Moldoveanu *et al.* (1989, 1992) have examined the immune response to influenza virus vaccine encapsulated in 1- to 10- $\mu\text{m}$  DL-PLG microspheres. Their studies have shown that systemic immunization with microencapsulated influenza potentiates the plasma hemagglutination inhibition titer, that encapsulation protects influenza vaccine from acid degradation, and that oral boosting with encapsulated vaccine is particularly effective in the induction of salivary IgA anti-influenza antibodies.

To date, the studies with DL-PLG microspheres have served to illustrate the potential of this approach to mucosal immunization with nonliving vaccine antigens. Current stud-

ies in this area are being directed toward microsphere adsorption from the gut, a process that is enhanced by increased microsphere hydrophobicity (Eldridge *et al.*, 1990a); alternative routes of mucosal administration such as respiratory tissues (Eldridge *et al.*, 1991a); and multirelease formulations for mucosal immunization.

## IV. AVIRULENT *SALMONELLA* STRAINS AS LIVE VECTOR ANTIGEN DELIVERY SYSTEMS

### A. Introduction

The concept of using avirulent *Salmonella* mutants as oral vaccine delivery systems began almost a decade ago (Formal *et al.*, 1981; Curtiss *et al.*, 1983; Curtiss, 1986; reviewed by Curtiss, 1990; Hackett, 1990). This idea was based on separate and yet interrelated areas of research. *Salmonella typhi* and *S. typhimurium* are pathogenic bacteria in humans and mice, respectively. Virulent strains of *Salmonella* colonize in the intestine and then migrate to deeper tissues, especially the spleen and liver, which can lead to a bacteremia and subsequent death (Collins and Carter, 1972). The findings of Carter and Collins (1974) demonstrated the initial site of *S. typhimurium* infection is the GALT, which is also a major IgA inductive site. This identification and the ability to attenuate *Salmonella*, in conjunction with the development of genetic techniques to incorporate recombinant DNA into these *Salmonella* mutants, prompted the use of avirulent *Salmonella* strains as potential live vectors for expression of cloned genes specifying colonization or virulence antigens of other pathogens. These antigen delivery systems could be administered orally to induce mucosal IgA responses locally in the intestine and in other secretions, as well as systemic humoral and cellular immune responses.

For the development of an oral *Salmonella* vaccine, several facts must be considered. Oral vaccines consisting of killed *Salmonella* are poor immunogens, whereas the live organism is very effective in inducing mucosal immune responses, presumably because of their ability to colonize in the gastrointestinal tract. However, the systemic dissemination of *Salmonella* organisms can result in death as a result of the effects of the endotoxin load. Therefore, a live vaccine strain must be completely avirulent to the host and yet highly immunogenic for the induction of the desired immune responses. For safety of the vaccine strain, it should have two or more attenuating deletion mutations to preclude loss of the avirulence phenotype by reversion or gene transfer. The vaccine vector-carrier strain should be effective in expressing, in the animal host, cloned genes encoding virulence factors of other pathogens at adequate levels and in appropriate form for the induction of immune responses that render the host protected against infection and disease.

The following sections discuss characteristics of several avirulent *Salmonella* mutants and the effectiveness of recombinant avirulent *Salmonella* strains as bivalent vaccine delivery systems for the induction of immune responses protective against various pathogens. The reader is referred to a review

### **B. Avirulent *Salmonella* Mutants**

Several avirulent mutants of the human pathogen *S. typhi* and of the murine pathogens *S. typhimurium* and *S. cholerae-*

*suis* have been derived and characterized for their potential usefulness as vaccine delivery systems (Table IV). The *galE* mutants of *Salmonella* are unable to synthesize the enzyme UDP-galactose epimerase. These mutants are defective in lipopolysaccharide (LPS) biosynthesis (rough) when grown in the absence of galactose, but synthesize a complete LPS (smooth) when grown in the presence of galactose. *Salmonella typhimurium galE* mutants are avirulent and retain their

<sup>b</sup> When combined with  $\Delta$ *cya* and  $\Delta$ *crp* mutations.

immunogenicity, as exemplified by their ability to induce responses protective against challenge with virulent *Salmonella* strains (Germanier, 1972; Germanier and Furer, 1971; Hone *et al.*, 1987). However, the *S. typhi* Ty21a *galE* vaccine strain (Germanier and Furer, 1975) is undoubtedly avirulent and immunogenic because of mutations in addition to *galE*, since *S. typhi galE* generated by recombinant methods causes typhoid fever in human volunteers (Hone *et al.*, 1988). Also the *galE* mutants of *S. choleraesuis* are virulent, probably because of their requirement for only low amounts of galactose for complete LPS synthesis (Nnalue and Stocker, 1986). Little information is available regarding the ability of *galE* mutants to colonize the gut or deeper tissues such as the spleen.

The  $\Delta$ *aroA* mutants of *S. typhimurium* (Hoiseh and Stocker, 1981) are avirulent primarily because of their requirement for *p*-aminobenzoic acid (PABA) which is not provided by the animal host. These mutants can colonize the gut and the spleen, and have been shown to be immunogenic. A  $\Delta$ *aroA* mutation also has been shown to be attenuating for *S. choleraesuis* in mice (Nnalue and Stocker, 1987). The addition of the  $\Delta$ *purE* mutation to a  $\Delta$ *aroA S. typhi* strain leads to hyperattenuation with very low immunogenicity (Levine *et al.*, 1987). *Salmonella typhi* strains with  $\Delta$ *aroC* and  $\Delta$ *aroD* mutations are avirulent and immunogenic in humans, but nevertheless are capable of causing fever and adverse reactions when given at high doses (Tacket *et al.*, 1992).

During the past several years, mutants defective in global gene regulation have been evaluated for influencing colonization and virulence (reviewed by Curtiss, 1990), leading to the discovery that  $\Delta$ *cya*  $\Delta$ *crp S. typhimurium* mutants unable to synthesize cyclic AMP (cAMP) and the cAMP receptor protein (CRP) (Pastan and Adhya, 1976) are highly attenuated for infection in mice and induce a protective response against challenge with a virulent strain when fed orally to mice (Curtiss and Kelly, 1987; Curtiss *et al.*, 1988). These mutants grow slowly *in vitro* and *in vivo*, which may contribute to their attenuation. A  $\Delta$ *cya*  $\Delta$ *crp S. typhi* mutant is both aviru-

lent and immunogenic in human volunteers (Tacket *et al.*, 1992) but, unlike the  $\Delta$ *aroC*  $\Delta$ *aroD S. typhi* strains, causes symptoms in some volunteers and is not as immunogenic at the dose given as would be desirable (Tacket *et al.*, 1992). An additional mutation that diminishes the ability of *Salmonella* to colonize deep tissues (*cdt*) completely eliminates any adverse reactions without diminishing immunogenicity (S. M. Kelly and R. Curtiss III, unpublished observations).

*Salmonella typhimurium phoP* mutants, prepared to eliminate nonspecific acid phosphatases in strains to use for transposon *TnphoA* mutagenesis, are avirulent when administered to mice by oral or intraperitoneal routes (Galan and Curtiss, 1989), which may be the result of an inability to multiply in macrophages (Fields *et al.*, 1986). These mutants can induce an immune response that is protective against challenge by virulent *Salmonella* (Galan and Curtiss, 1989). Mutants that constitutively express the *phoP* gene lead to the complete activation of some *Salmonella* genes and the complete shut down of others (Miller and Mekalanos, 1990). These *phoP*<sup>c</sup> mutants are totally avirulent and highly immunogenic for mice; however, these mutants revert at high frequency to a form that is virulent (Miller and Mekalanos, 1990).

Dorman *et al.* (1989) have demonstrated that *S. typhimurium* mutants with mutations in the *ompR* gene are avirulent and highly immunogenic. The *ompR* gene product is part of a two-component regulatory system that affects the regulation of genes for a number of outer membrane proteins (*ompC* and *ompF*), as well as influencing expression of other genes whose expression is dependent on changes in osmolarity.

### C. Bivalent *Salmonella* Vaccine Strains

Several attenuated *Salmonella* mutant strains have been shown to be effective as live antigen delivery systems for potential vaccine development (Table V). These mutants can be detected in GALT following oral administration to the

host, but do not cause systemic disease. In several of these studies, mucosal immune responses as well as serum antibody and cell-mediated immune responses have been induced that were specific for the *Salmonella* and the foreign antigen(s) expressed by the carrier strain. However, several questions remain unanswered regarding the usefulness of this antigen delivery system in animals, including humans. Whether the amount, form, or location (e.g., cytoplasmic, periplasmic, or surface) of the heterologous virulence antigen(s) expressed by the *Salmonella* vector will influence the nature or magnitude of the immune response is still unknown. The mutation(s) induced to render the *Salmonella* safe for vaccine use may limit the expression of the cloned virulence antigen or the ability of the expressed antigen to induce a protective immune response. Further information is needed on the nature of the antigen and the use of adjuvants in these delivery systems for optimal immunization. In this regard, through immunological and molecular biological techniques, we can define T- and B-cell epitopes of the antigen involved in the induction of mucosal responses and can incorporate the gene encoding these regions into the *Salmonella* vector. Also, genetic fusion of the gene encoding the antigen to the gene encoding the B subunit of cholera toxin or *Escherichia coli* enterotoxin may result in an enhanced specific immune response (adjuvant effect). Further studies will be required to define the feasibility, safety, and effectiveness of these approaches in inducing the desired host response. Also determining whether *Salmonella* vaccine strains can induce tolerance or suppress the induction of a response based on

host susceptibility to components of the vector, such as LPS, or to the expressed cloned antigen(s) will be important. The effect of the host immune response to the *Salmonella* vector and the expressed cloned antigen on subsequent immunizations with *Salmonella* and the same or different expressed cloned antigens or adjuvants will require further investigation to define strategies for developing live vaccine delivery systems for optimal induction of protective host responses to microbial pathogens.

## V. USE OF RECOMBINANT VIRAL VECTORS FOR MUCOSAL IMMUNIZATION

### A. Introduction

Advances in molecular biology and the development of genetic engineering techniques allow the insertion of genes encoding immunologically important antigens into viruses. Such recombinant viral vectors should function as live subunit vaccines and should share the advantages of live attenuated viral vaccines without the possibility of reversion. Recombinant viral vaccines have the advantage of being inexpensive to produce and deliver and have the important property of being able to induce high levels of humoral and cell-mediated immunity. Indeed, inserted viral gene products will be synthesized endogenously and processed in cells infected with a live recombinant vector, thus resulting in anti-

gen presentation to T cells in the same fashion as natural infection. An ideal virus vector should readily admit insertion of foreign DNA sequences, be nonpathogenic, and be capable of eliciting protective immunity to foreign antigens or pathogens in the host. Viral vectors that have been well studied include vaccinia virus (Mackett *et al.*, 1982) and adenovirus (Graham, 1990). Vaccinia virus vectors capable of expressing as many as four distinct antigens at the same time have been constructed (Moss and Flexner, 1987), including information encoding antigens from pathogenic organisms as well as immunomodulatory molecules such as cytokines (Ramshaw *et al.*, 1987). The tremendous potential of vaccinia virus as a single-inoculation multivalent vaccine is attractive. Although limited in the amount of foreign genetic information that can be inserted, adenoviruses have the same advantages and can be used as oral vaccines (Graham, 1990).

The study and application of live recombinant viral vectors as mucosal vaccines is in its infancy. Indeed, although many studies have been performed that test the efficacy of recombinant viral vaccines to protect animals after mucosal immunization, these studies have not critically examined the induction of mucosal immune responses or the mechanisms of protection (Ogra *et al.*, 1989).

Our intention here is not to comprehensively list all studies that have examined the use of recombinant viruses after mucosal vaccination. Rather, we highlight some of the systems that are providing the major impetus for further investigations concerning the use of recombinant viruses in eliciting mucosal immunity.

### **B. Recombinant Rabies Virus Vectors: Bait to Prevent the Bite**

Rabies remains a major public health problem in many parts of the world, including Europe and North America, where infected wild animals constitute a significant reservoir for the virus. Experience has shown that control of rabies in wildlife cannot be achieved by reducing the reservoir species through hunting, poisoning or gassing. Instead, immunization of wild reservoir animals offers an alternative approach (Steck *et al.*, 1982). Clearly, the only realistic route for the vaccination of large numbers of wild animals is oral administration of vaccine, which was first attempted by Baer *et al.* (1971) in North America and by Mayr *et al.* (1972) in Europe. Oral vaccination is achieved by placing vaccine in sponge baits that are coated with wax containing beef tallow or fish oil and tetracycline as a biomarker. The tetracycline allows identification of animals that have ingested the bait by fluorescence of their teeth. Using this method, acceptance rates of bait ingestion of about 70% have been achieved in a number of wild animal populations (Johnston *et al.*, 1988). In small-scale field trials, live attenuated rabies virus vaccine introduced in baits was used successfully to vaccinate foxes in Europe (Steck *et al.*, 1982; Schneider and Cox, 1983; Pastoret *et al.*, 1987; Brochier *et al.*, 1988). Unfortunately, other mammalian species such as the skunk and raccoon, which are major rabies virus vectors in North America, have been re-

fractory to efficient oral immunization against rabies (Rupprecht *et al.*, 1986). Additionally, the stability of attenuated rabies virus is poor, attenuated virus remains pathogenic to some rodents, and reversion to virulence occurs at a significant frequency (Kieny *et al.*, 1988). Finally, inactivated rabies virus has been shown to be ineffective when administered orally (Kieny *et al.*, 1988).

To improve the safety, stability, and efficacy of the vaccine used in the field, several recombinant viruses containing the rabies virus glycoprotein gene have been constructed (Kieny *et al.*, 1984). Initial studies demonstrated that intradermal or footpad inoculation of rabbits and mice with a vaccinia-rabies glycoprotein (VRG) recombinant virus resulted in high concentrations of rabies virus neutralizing antibodies (Wiktor *et al.*, 1984). Subsequently, administration of  $10^8$  plaque-forming units (pfu) of VRG subcutaneously, intradermally, or orally to foxes was shown to elicit the production of titers of rabies neutralizing antibodies equal or superior to those obtained with conventional vaccine, and was shown to confer complete protection to severe intracerebral challenge with street rabies virus (Blancou *et al.*, 1986). More recently, virus isolation, immunofluorescence, and polymerase chain reaction (PCR) were used to show that VRG could be detected in the buccal mucosa and tonsils of foxes for only 48 hr following oral immunization (Thomas *et al.*, 1990), thus minimizing the risk of additional spread or recombination with other orthopoxviruses.

Rupprecht *et al.* (1986, 1988) demonstrated that raccoons, a major rabies virus vector in North America, fed bait containing VRG developed rabies neutralizing antibodies and resisted street rabies virus infection for up to 6 months after feeding. This observation was important, since live attenuated rabies vaccine administered orally failed to immunize raccoons. This study also demonstrated that a minimum virus-neutralizing antibody titer may not be applicable as an indication of adequate animal vaccination. Clearly, virus-neutralizing antibody alone is unsuitable as the sole criterion of successful rabies immunization in all species. Further studies have shown that cats, dogs, skunks, and badgers also can be immunized effectively against rabies with VRG by the oral route (Tolson *et al.*, 1987; Koprowski, 1989). However, higher doses of VRG ( $10^{9.6}$  pfu) appeared to be required to generate antibodies in dogs and badgers (Koprowski, 1989).

In addition to recombinant vaccinia virus, other recombinant vectors capable of expressing rabies glycoprotein have been developed, including recombinant human adenovirus type 5 (Prevec *et al.*, 1990) and raccoon poxvirus vectors (Esposito *et al.*, 1988). Recombinant adeno-rabies virus has been shown to elicit neutralizing antibodies and protection against rabies virus challenge following oronasal immunization in mice, dogs, skunks, foxes, and raccoons (Prevec *et al.*, 1990). Similarly, raccoons fed sponge baits loaded with raccoon poxvirus recombinants expressing rabies glycoprotein developed high levels of neutralizing antibodies and were protected from lethal street rabies virus challenge (Esposito *et al.*, 1988). Thus, a vast number of species have been shown to be immunized effectively and protected against rabies following oral administration of live recombinant viral vaccines.

### C. Recombinant Adenovirus Vaccines: A Natural Mucosal Immunogen

The use of vaccinia virus vectors is well advanced and their efficacy as recombinant vaccines has been demonstrated in numerous systems. Nevertheless, problems of toxicity may limit their acceptance for widespread use. Further, distinct viral vectors may be required for different pathogens and multiple vectors may be necessary to boost immunized individuals. The approach that we are investigating involves the use of recombinant human adenoviruses as potential vaccines. We have focused on the use of human adenovirus type 5 (Ad5). Ad5 is a nononcogenic virus that causes mild respiratory illness in humans (Rubin and Rorke, 1988). Human adenoviruses have been well characterized both genetically and biochemically, and methods to construct recombinant vectors are well established (Graham and Prevec, 1990). One advantage to adenoviruses as vaccines is the fact that they may be administered orally, a vaccination route that may be critical in generating immunity to viruses that are transmitted mucosally (Couch *et al.*, 1963). Indeed, a single oral administration of live adenovirus type 4 and 7 vaccine in enteric-coated capsules was shown to be safe and effective in suppressing adenovirus-induced acute respiratory disease in millions of United States military recruits without evidence of adverse reactions (Top *et al.*, 1971a,b). From these studies we conclude a benign gut infection with adenovirus types 4 and 7 induced neutralizing antibodies and protection of the lungs from infection with these viruses, thus supporting the concept of the common mucosal immune system (McDermott and Bienenstock, 1979). These results suggest that oral immunization with adenovirus recombinants may induce mucosal immunity at distant mucosal sites such as the respiratory and genital tracts.

Respiratory syncytial virus (RSV) is one of the leading causes of pediatric viral respiratory tract disease worldwide (McIntosh and Chanock, 1985; Murphy *et al.*, 1988). Conventional approaches to RSV vaccine development have not been successful. For example, developing attenuated RSV strains for vaccination has not been possible and parenteral administration of formalin-inactivated RSV was associated paradoxically with enhanced disease after subsequent natural infection. Therefore, live recombinant vaccinia and adenoviruses that express the glycoproteins of RSV were constructed. After intranasal inoculation of mice, vaccinia recombinants expressing the G protein of RSV generated antibody against RSV and protection against intranasal challenge (Stott *et al.*, 1986). Intranasal administration to cotton rats of Ad5 recombinants capable of expressing RSV F glycoprotein (Ad5-F) was shown to be three- to fourfold more immunogenic than Ad5-F administered intraduodenally (Collins *et al.*, 1990). Interestingly, although administration of Ad5-F by either route did not induce detectable levels of RSV neutralizing antibodies, intranasal administration provided complete protection, whereas immunization by the intraduodenal route conferred incomplete but significant resistance. Additional studies (Hsu *et al.*, 1991) demonstrated that recombinant adenovirus types 4 and 7 of RSV F glycoprotein

protected dogs from challenge after intratracheal inoculation. Ferrets immunized intranasally with these vectors also showed an 80–100% reduction in challenge virus titer, despite the fact that neutralizing antibodies to RSV were not detected (Hsu *et al.*, 1991).

After intranasal administration, recombinant adenovirus capable of expressing vesicular stomatitis virus (VSV) glycoprotein was shown to immunize and protect a number of animal species, including mice, dogs, calves, and piglets, from challenge with wild-type rhabdovirus (Prevec *et al.*, 1989). Moreover, oral hepatitis B virus (HBV) vaccines based on live recombinant adenovirus types 4 and 7 have been developed and shown to protect hamsters (Morin *et al.*, 1987) and chimpanzees (Lubeck *et al.*, 1989) from acute clinical disease following HBV challenge.

Most of the studies concerning mucosal vaccination with recombinant viral vectors have focused on the generation of serum neutralizing antibodies and protection against challenge. Few studies have focused on the generation of mucosal IgA or on the generation of antiviral cytotoxic T lymphocytes (CTLs) after mucosal vaccination. McDermott *et al.* (1989b) have shown that recombinant adenovirus containing the glycoprotein B gene of herpes simplex virus (HSV) was able to protect mice from a lethal challenge with HSV-2. This protection appeared to be primarily T-cell mediated (McDermott *et al.*, 1989a). We used the same vector (AdHSVgB) to demonstrate that intranasal inoculation primed mice for the generation of anti-HSV CTLs. This anti-HSV CTL activity was detected in both the spleens and local lymph nodes of recombinant adenovirus-immunized mice (Gallichan *et al.*, in press). Thus, we have shown that mucosal vaccination with a recombinant adenovirus vector primes mice for both a systemic and local T cell-mediated immune response. The stability of adenoviruses, as well as their ease of propagation and administration, holds promise that they may be highly suitable for widespread vaccination programs against mucosal infections.

### D. AIDS and STDs: The Challenge of Mucosal Immunity

The World Health Organization has estimated that 80% of human immunodeficiency virus (HIV) transmission worldwide is heterosexual. Heterosexual transmission is becoming increasingly important in developed countries as the epidemic progresses (Forrest, 1991). Most of the efforts on candidate HIV vaccines have concentrated on the systemic route of vaccination. However, since systemic and mucosal immune systems are compartmentalized, parenterally administered vaccines do not consistently induce mucosal immunity and are poorly effective against mucosal pathogens. This conclusion was confirmed by the observation that rhesus macaque monkeys immunized with whole inactivated SIV vaccines, which provide protection against low-dose intravenous challenge with cell-free SIV, did not protect against low-dose intravaginal challenge (Sutjipto *et al.*, 1990).

These results suggest that oral or locally administered vaccines may be necessary to induce effective immunity against

these sexually transmitted viruses, perhaps because of the common mucosal immune system that permits the generation of immune responses to mucosally presented antigens at distant mucosal surfaces (McDermott and Bienenstock, 1979). Initial studies have shown no significant mucosal antibody response in gastrointestinal, salivary, or genital secretions of rhesus monkeys given microencapsulated inactivated whole SIV orally (Miller and Gardner, 1991). Interestingly, however, mice inoculated intravaginally with live virulence-attenuated HSV generated intravaginal anti-HSV IgA and CTLs and were protected against intravaginal challenge with wild-type HSV-2 (McDermott *et al.*, 1984). These studies suggest that live virus vectors that infect and replicate within the mucosa, particularly the genital mucosa, may induce strong local immune responses.

Clearly, the ability of recombinant viral vaccines able to express SIV and HIV gene products after mucosal immunization should be evaluated to determine whether genital mucosal immunity and protection against genital mucosal infection can be elicited (Miller and Gardner, 1991). In particular, examination of adenovirus recombinants, which are known to induce strong mucosal protective immunity in the lung after oral administration, or recombinants of HSV should be examined. Recombinant adeno-HIV (Prevec *et al.*, 1991) and adeno-SIV have been produced. We demonstrated that adeno-HIV was able to induce a humoral immune response to HIV core proteins in mice and rhesus macaque monkeys (Prevec *et al.*, 1991). We intend to utilize adeno-SIV recombinants in studies concerning the generation of mucosal immunity and protection from mucosal SIV challenge. The urgency of our need for a vaccine against AIDS should serve as a major impetus for studies concerning the use of live recombinant viral vectors to generate mucosal immunity.

### Acknowledgments

The studies on liposome, biodegradable microspheres, and *Salmonella* vaccine delivery systems were supported in part by U.S. Public Health Service Grants DE 08182, DE 09081, DE 08228, DE 00232, AI 28147, DE 06669, and DE 04217 from the National Institutes of Health and Contract DAMD17-86-6162 from the U.S. Army Medical Research Acquisition Activity. The authors thank Noel Childers and Jenny Katz for their critical assessment of this review and Vickie Barron and Amie Stoppelbein for secretarial support.

# Mucosal Adjuvants

Charles O. Elson · Mark T. Dertzbaugh

## I. INTRODUCTION

Adjuvants are agents that enhance immune responses. Adjuvants stimulate an immune response that is of greater magnitude than the response that occurs when the antigen is given alone. Many if not most antigens yield only weak or poor immune responses when given by themselves. The need for strong and reliable adjuvants has been accentuated by modern molecular techniques that generate weakly immunogenic recombinant proteins or peptides from pathogens for use in vaccines, leading to a renewed interest in vaccine adjuvants, particularly those that can be used in humans (Hooper, 1991). Adjuvants have been shown to affect virtually every measurable aspect of antibody response, including the kinetics, duration, quantity, isotype, and avidity as well as the generation of neutralization or protection. Adjuvants have been shown to affect specificity of antibody responses as well, that is, they alter the selection of epitopes of complex antigens to which antibody will be directed (Hui *et al.*, 1991). Adjuvants also can enhance the development of cell-mediated immunity, both delayed hypersensitivity mediated by CD4 cells and cytotoxic lymphocyte responses mediated by CD8 cells. However, the number of adjuvants that stimulate cell-mediated immune responses tends to be smaller than the number of those that stimulate antibody formation.

Although adjuvants have been used empirically by immunologists for many years, the mechanisms by which they act are not well understood. Part of the problem has been that the adjuvants themselves have been very complex, making the evaluation of mechanisms difficult (Waksman, 1979). More highly purified molecules have been isolated from traditional adjuvants, for example, muramyl dipeptide from mycobacteria and monophosphoryl lipid A from endotoxin, simplifying the dissection of their effects and making elucidation of the mechanisms more probable. The reader is referred to several reviews on adjuvants (White, 1967; Waksman, 1979; Warren *et al.*, 1986; Spriggs and Koff, 1991) for a detailed discussion, but a number of themes or concepts have emerged that will be addressed here. Waksman (1979) has made the point that one must define the target cell on which the adjuvant acts, the distribution of the adjuvant in relation to the location of those target cells, the function of the target cell affected by the adjuvant, and the cellular and molecular mode of action of the adjuvant on the target cell. This information is either rudimentary or nonexistent for most adjuvants. Clearly the best understood adjuvants have a multiplicity of effects on

immune cells and different adjuvants can have very divergent effects on the same cells. Potential mechanisms of adjuvant activity after systemic administration are shown in Table I. The possible effects of a given adjuvant are complex, may overlap, and are likely to be multiple. Many adjuvants are surface active agents or surfactants, but how this characteristic translates into these cellular and molecular mechanism is unclear.

Although many if not all of these mechanisms are likely to apply to mucosal adjuvants as well, there is a profound dearth of data and information on agents with mucosal adjuvanticity. This is not because such agents are not needed, because it is remarkably difficult to deliberately immunize for mucosal responses. However, many pathogens either invade through or cause disease at mucosal surfaces. Aside from ease of administration by the mucosal route, mucosal immunization has a distinct advantage. Unlike injectable forms of antigen, which confer primarily systemic immunity, mucosal immunization confers two types of immunity: systemic and mucosal. Mucosal immunity is responsible for protecting the mucosal surface of the host from pathogens and toxins, primarily through the production of secretory IgA. This antibody is elicited only by direct stimulation of mucosal lymphoid tissue.

Most protein antigens are not only poor immunogens when given mucosally but, in fact, induce tolerance instead. Mucosal adjuvants must overcome this potential outcome of mucosal antigen exposure. (The reader is referred to other chapters in this volume that discuss in detail the mucosal immune system, oral immunization, and oral tolerance.) An important concept for this discussion is that of the common mucosal immune system, in which immunization of one mucosal surface also sensitizes other mucosal surfaces at remote sites. This paradigm has formed the basis for a strategy of oral immunization in which the antigen is delivered into the intestine, which has the greatest amount of mucosal lymphoid tissue, to prime the entire mucosal immune system. Such priming is followed by local mucosal or systemic boosting. The intestine is a very harsh environment for most antigens because of its intrinsic properties as a digestive organ. An antigen must survive luminal enzymes, bile salts, trapping by mucus, and propulsion by intestinal motility to be taken up by M cells in the follicle-associated epithelium and be delivered to the gut-associated lymphoid tissue (GALT). Antigen delivery systems and adjuvants are considered in separate chapters of this volume, but this separation may not

reflect reality. Injections of antigen into Peyer's patches can generate IgA responses (Andrew and Hall, 1982), so simple delivery of antigen into GALT may be sufficient to generate mucosal responses to some antigens. In addition, lipopolysaccharide (LPS) present in the gut lumen in large quantities may serve as an adjuvant locally in GALT. Once in GALT, antigens must undergo the various processing and presentation steps by accessory cells, presentation to helper T cells, stimulation of specific B cells, and so on. Each of these steps could potentially be affected by mucosal adjuvants. Different mucosal surfaces have different microenvironments, so mucosal adjuvants may have different effects at different mucosal sites.

The remainder of this chapter reviews current knowledge about mucosal adjuvants. The relatively sparse number of agents that are discussed and the relative paucity of information about them illustrates how much need and opportunity exists for more work in this area.

## II. CHOLERA TOXIN AND *ESCHERICHIA COLI* HEAT-LABILE TOXIN

Cholera toxin (CT) has been shown to enhance the immunogenicity of relatively poor mucosal immunogens when mixed or conjugated together with them and given orally. Thus, CT and its B subunit (CTB) have generated a great deal of interest as potential adjuvants for oral vaccines (Dertzbaugh and Elson, 1991). CT is one of the most potent mucosal immunogens yet identified. Its immunogenic properties (Pierce and Gowans, 1975; Pierce and Cray, 1982; Elson and Ealding, 1984a,b, 1985, 1987), including prolonged mucosal memory (Lycke and Holmgren, 1986a), are exactly those desired for an effective oral vaccine. Whether these properties extend to the antigens for which CT acts as an adjuvant is unknown, but early data suggest that this does occur.

The molecular structure of CT has been characterized extensively (Betley *et al.*, 1986). This toxin is composed of A and B subunits. The toxigenic A subunit (28 kDa) is involved in the ADP-ribosylation of the adenylate cyclase regulatory

protein Gs. The A subunit (CTA) is cleaved posttranslationally into the A1 and A2 peptides, the former of which is toxigenic. Crystallographic data on the closely related *E. coli* heat-labile toxin indicate that the A2 peptide mediates the association of the A1 peptide with the binding subunits (Sixma *et al.*, 1991). CTB is a homopentamer of five identical noncovalently associated subunits (11.6 kDa) that serve as the carrier for the A subunit. The CTB pentamer binds to the monosialoganglioside GM1 (Cuatrecasas, 1973) that is present on all nucleated cells, including intestinal epithelial cells. Such membrane binding may induce a conformational change that allows the A1 peptide to penetrate the cell (Cuatrecasas, 1973). The exact mechanism of entry is unknown, but may involve endocytosis and transcytosis in endosomes (Lencer *et al.*, 1992).

Enterotoxigenic strains of *E. coli* produce several types of heat-labile enterotoxin (LTs), some of which are highly homologous to CT and others that differ in their protein sequence and carbohydrate-binding specificities (Fukuta *et al.*, 1988). LT-I toxin of *E. coli*, which is highly homologous to CT, has been used with success as an adjuvant (Clements *et al.*, 1988). Although these two toxins will be discussed together and are assumed to be equivalent in this section, the protein sequence of LT-I B subunit does differ by 20% from CTB (Dallas and Falkow, 1980). Thus, the two proteins may have some different properties as mucosal adjuvants. Another toxin of interest is Shiga toxin, which has been demonstrated to elicit potent SIgA responses when administered to the intestine and may show promise as yet another oral adjuvant (Keren *et al.*, 1989).

### A. Cholera Toxin as a Mucosal Adjuvant: General Characteristics

The initial demonstration of the adjuvant effects of CT was in studies on whether the feeding of CT resulted in oral tolerance. CT was fed to mice either alone or with the unrelated protein antigen keyhole limpet hemocyanin (KLH). CT did not induce oral tolerance to itself and, when both proteins were fed together, abrogated tolerance to KLH (Elson and Ealding, 1984a). At the same time, CT also induced an intestinal SIgA response to KLH that did not occur when KLH was fed alone. The ability of CT to act as a mucosal adjuvant has been confirmed since by a number of other investigators with a variety of antigens (Table II).

The ability of CT to act as a mucosal adjuvant depends on a number of parameters. To induce immunity to the target antigen, CT must be administered simultaneously with the antigen (Lycke and Holmgren, 1986b). In addition, both the antigen and CT must be administered by the same route, that is, mucosally. Giving CT and the antigen by different routes is not effective, suggesting that CT alters the mucosal lymphoid tissue in a manner that favors responsiveness to the antigens presented to it. Given orally, CT may provide the necessary signals that alter the regulatory environment of GALT from one of suppression to one of responsiveness. The dose of CT required for the adjuvant effect is not clearly defined, and may vary depending on the antigen involved. Although

very small amounts of CT suffice to potentiate the immune response to CTB, much larger amounts have been used to enhance mucosal responses to viruses. Because CT induces long-term immunological memory as an antigen (Lycke and Holmgren, 1986a), one might expect memory to be generated when CT is used as an adjuvant and recent data indicates that this is the case (Vajdy and Lycke, 1992). The adjuvant effect observed for CT also probably depends on the type of antigen administered. CT has been used with success orally with proteins and viruses, and parenterally as a vaccine carrier for polysaccharides (Robbins *et al.*, 1989). Despite these successes, we and others have been unable to stimulate SIgA responses to ovalbumin when it is mixed and given orally with CT (Wilson *et al.*, 1990; C. O. Elson, unpublished observation), so the adjuvanticity of CT may not apply to all antigens. The suitability of a given antigen for this method will probably have to be determined empirically. The adjuvanticity of CT may be related to and dependent on its immunogenicity: the response of mice to KLH given with CT orally was significantly higher in H-2 congenic mouse strains, which are high responders to CT, than in strains that are low responders to CT (Elson, 1992). The LPS gene locus also seems to influence CT adjuvanticity (Elson, 1992).

CT possesses the B- and T-cell epitopes required to elicit systemic immunity; as such, it has been used effectively as a carrier for several parenterally administered experimental vaccines (Que *et al.*, 1988; Szu *et al.*, 1989; Cryz *et al.*, 1990). Clearly CT generates a strong mucosal and systemic response to itself when coadministered as an adjuvant. Whether the strong immunogenicity of CT will limit its effectiveness as an adjuvant has yet to be determined.

### B. Role of Cholera Toxin Subunits in Mucosal Adjuvanticity

Although CT has definite mucosal adjuvanticity in mice, whether similar effects would occur in humans is not known. However, from a practical perspective, the use of holotoxin is not feasible in humans because of its toxicity (Levine *et al.*, 1983). One approach being explored to resolve this problem is the use of nontoxic B subunit instead. McKenzie and Halsey (1984) were the first to report that horseradish peroxidase (HRP) chemically conjugated to CTB elicited higher antibody levels in the gut and serum than were observed after feeding either HRP alone or an unconjugated mixture of HRP and

CTB. Since then, the use of CTB as a vaccine adjuvant has been examined by others with mixed success. In one report, mixtures of KLH and CTB were unable to stimulate immunity to KLH unless very small doses (<50 ng) of holotoxin were added (Lycke and Holmgren, 1986b); however, KLH conjugated to CTB was not tested. The use of CTB conjugates has been reported to be effective in some cases (Bessen and Fischetti, 1988; Tamura *et al.*, 1988), but not in others (Liang *et al.*, 1988; Czerkinsky *et al.*, 1989). The poor responses that have been observed with CTB conjugates in some cases may be the result of the coupling procedure. The degree of cross-linking and the coupling procedure used can affect the immunogenicity of protein conjugates significantly (Verheul *et al.*, 1989). Genetic fusion of peptides to CTB has been accomplished, generating chimeric neoantigens (Sanchez *et al.*, 1988; Schodel and Will, 1989) that are immunogenic when fed to mice (Dertzbaugh *et al.*, 1990).

Few data are available to date on the role of the A subunit. In mice, the holotoxin is consistently more potent than the B subunit, both for immunogenicity and adjuvanticity. Liang *et al.* (1989a) concluded that GM1 binding but not toxic activity was necessary for the mucosal adjuvanticity of CT–Sendai virus conjugates. Conversely, Lycke *et al.* (1992) found that E coli LT with a single amino acid mutation in the A subunit (112<sup>Glu→Lys</sup>) was unable to act as an adjuvant. This question remains to be answered. Further work is necessary to determine whether CTB can replace holotoxin as an adjuvant and to define the role of the A subunit.

### C. Site of Adjuvant Activity

The requirement for CT to be given at the same time and by the same route as antigen indicates that its adjuvant effect is exerted at the mucosal surface, but the exact site is unknown. As discussed earlier, our current understanding is that the induction of mucosal immune responses occurs in GALT and requires the transport of antigen by specialized M cells into the underlying lymphoid follicles, where antigen processing and presentation to antigen-specific T cells and B cells presumably occurs. We assume that the adjuvant effect of CT is exerted in these lymphoid follicles, but we acknowledge that no direct evidence for this assumption exists. Gut epithelial cells can act as antigen-presenting cells (APCs) *in vitro*, although the functional effect of that presentation has been suppression (Bland and Warren, 1986; Mayer and Schlien, 1987). Gut epithelial cells bind the great majority of CT and, in an immunohistochemical light microscopic study, CT was present within epithelial cells as well as within mononuclear cells in the underlying lamina propria (Hansson *et al.*, 1984). In addition, CT has been reported to increase intestinal permeability to luminal antigens (Lycke *et al.*, 1991). Thus, the epithelium and the lamina propria are both possible sites for CT adjuvanticity.

### D. Antigen Uptake into Follicles

One reason proposed for the effectiveness of CT and CTB as oral immunogens is their ability to bind to epithelial cells

and thus persist at mucosal surfaces; the same may be true for their adjuvant function. Increased uptake into intestinal follicles may be an important mechanism by which CT potentiates the immune response to particulate antigens to which it is conjugated. Colloidal gold particles 8–12 nm in size to which CT had been conjugated selectively localized to the M cells of the follicle-associated epithelium after being administered into the murine intestine (M. Neutra, personal communication), whereas soluble CT was bound diffusely to the microvillous surface of all enterocytes. This result suggests that CTB bound to particles does not bind efficiently to GM1 ganglioside in the enterocyte brush border, perhaps because the particles do not efficiently penetrate the mucus coat (which is sparse over the follicle-associated epithelium) or because the GM1 ganglioside of M cells, with their less developed glycocalyx, may be more available to the particles than the GM1 ganglioside of the epithelial cell microvilli. This observation may pertain to the results of Liang *et al.*, who found that GM1 binding but not toxic activity was necessary for the mucosal adjuvanticity of CT–Sendai virus conjugates, and indicates that the mechanism of CT adjuvanticity for particulate antigens may be different from that for soluble antigens.

## E. Cellular Targets of Adjuvanticity

### 1. Antigen-Presenting Cells

Little is known about the mechanism of antigen processing in GALT. Mucosal antigens must be presented to T cells in the context of the appropriate major histocompatibility complex (MHC) Class II molecules (Elson and Ealding, 1985). CT and CTB do not alter macrophage APC antigen uptake or processing *in vitro* (Woogen *et al.*, 1987) or MHC Class II expression (Bromander *et al.*, 1991). However, CT has been shown to stimulate the production of interleukin 1 (IL-1) *in vitro*, an effect that may enhance antigen presentation (Lycke *et al.*, 1989). Bromander *et al.* (1991) have presented evidence that part of CT adjuvanticity is the result of its potentiation of antigen presentation by enhanced IL-1 production. Stimulation of APCs may be a major mechanism of CT adjuvanticity; however, the results obtained *in vitro* may not correspond with events *in vivo* with chronically stimulated APCs.

### 2. T Cells

After an exogenous antigen is taken up and processed by APCs, it is re-expressed on the cell surface as peptide fragments in association with MHC Class II molecules. The peptide fragments lie in a cleft in the MHC Class II molecule and the T-cell receptor recognizes both the foreign peptide and adjacent facets of the self MHC Class II molecule (Unanue and Cerottini, 1989). Such triggering of T cells is a critical step in the induction of immune response because T cells play an important regulatory role, both positive and negative, the outcome of which determines whether a response occurs and, if so, how large it will be. The experimental basis for these statements rests on work done with systemic lymphoid tissue, but the same also appears to hold true

for immune responses in mucosal tissues. Not only is the response to CT itself T cell dependent (Lycke *et al.*, 1987), but it is also genetically restricted by MHC Class II molecules (Elson and Ealading, 1985; Elson and Solomon, 1990). The same rules are likely to apply also to protein antigens for which CT is acting as a mucosal adjuvant.

Mucosal lymphoid follicles contain both CD4 helper cells and CD8 cytotoxic suppressor cells. Murine CD4 helper T cells have been subdivided further into Th1 and Th2 subtypes based on the pattern of cytokines that they secrete (Mosmann and Coffman, 1989). The Th1 helper cells secrete IL-2 and interferon  $\gamma$  (IFN $\gamma$ ) whereas Th2 cells produce IL-4 and IL-5. The latter cytokines have been shown to be important in generating IgA responses *in vitro* (Murray *et al.*, 1987); interestingly, this Th2 subtype may be expressed preferentially in mucosal follicles such as Peyer's patches. Whether one or the other of these subtypes is stimulated preferentially by CT as an immunogen or as an adjuvant is currently unknown and awaits study. CT appears to be able to stimulate the Th2 helper cell subtype *in vivo* because CT given orally stimulates not only a secretory IgA response but also an equally strong plasma IgG1 anti-CT response, which are associated with the Th2 function (Elson *et al.*, 1988).

Feeding CT to mice induced oral tolerance to DTH, but not for antibody responses to CT (Kay and Ferguson, 1989), suggesting that mucosal CT may inhibit the Th1 cells but not Th2 cells. CT does inhibit Th1 clones preferentially *in vitro* (Gajewski *et al.*, 1990). However, as an adjuvant CT seems able to boost either Th1 or Th2 responses. Xu Amano *et al.* (1993) found that CT augmented a predominant Th2 response when tetanus toxoid (TT) was given mucosally but also augmented Th1 responses when TT and CT were given together parenterally. Much needs to be learned about the effect of CT and CTB on cytokine expression by both CD4 and CD8 T cells, effects that are likely to be extremely important in the net effect of these molecules in GALT.

One hypothesis for the mucosal adjuvanticity of CT is that it may alter the T-cell regulatory environment within mucosal lymphoid follicles, for example, the inhibition of suppressor cells. The addition of both CT and CTB to lymphocytes *in vitro* is quite inhibitory (Woogen *et al.*, 1987) and preferentially inhibits the CD8<sup>+</sup> T-cell subset (Elson *et al.*, 1990). Some *in vivo* evidence in a graft vs. host system suggests that CT inhibits suppressor cells (Lange *et al.*, 1978). Consistent with this finding, we have found, in an adoptive transfer system, that feeding of KLH to mice generates suppressor T cells that inhibit both a secretory IgA and a plasma IgG response to KLH but that feeding of both KLH and CT eliminates this suppression (C. O. Elson, S. P. Holland, M. Dertzbaugh, C. Cuff, and A. Anderson, unpublished data). The *in vitro* inhibition of T-cell activation by CTB has features that suggest that similar inhibition may occur *in vivo* because it can be accomplished with brief pulses lasting only minutes and the concentrations required should be achievable *in vivo*. These data collectively support the notion that regulatory inhibition of T-cell subsets is an important feature in both the mucosal immunogenicity and the adjuvanticity of CT.

Most of the work done with CT has focused on the antibody response. Little is known about the delayed hypersensitivity

(DTH) response to CT. In other systems, DTH responses are regulated independently of humoral responses, so one cannot extrapolate results with antibody responses to DTH. Supporting this point are data of Kay and Ferguson (1989a,b), mentioned earlier who found that feeding CT or its toxoid prior to systemic immunization induced oral tolerance for the DTH response but not for the antibody response to CT. Experiments with cell transfer indicated that this oral tolerance for DTH involved the induction of suppressor cells. Interestingly, the T cells that suppress DTH reactions are CD4<sup>+</sup> whereas the T cells that suppress antibody responses are CD8<sup>+</sup>. Whether CT would have similar effects as a mucosal adjuvant, that is, induction of antibody but not cellular responses to a second antigen, is unknown. This attribute may be desirable for some vaccine candidates and undesirable for others, such as those for intracellular pathogens. This question will need to be addressed in each system to determine how DTH responses are affected by CT.

### 3. B Cells

Many stages of B-cell development must be traversed before reaching the antibody-secreting plasma cell. The major steps of B-cell development, including isotype commitment or switching, clonal expansion, and terminal differentiation are all dependent on and regulated by various cytokines that act on B cells at defined stages of development (Tesch *et al.*, 1986). For example, IgE and IgG1 isotype production is enhanced preferentially by IL-4 (Snapper and Paul, 1987) and IgA isotype is enhanced by IL-5 (Murray *et al.*, 1987) and by TGF $\beta$  (Coffman *et al.*, 1989). CT could affect any one or more of these steps. Precisely how CT interacts with B cells or with the critical cytokines that regulate them has only just begun to be examined.

CT may possess some pharmacological activity that drives B cells toward IgA-committed precursors. Lebman *et al.* (1988) have shown that CT given intraduodenally can change the isotype pattern displayed by Peyer's patch B cells primed for an unrelated hapten from IgM to IgG and IgA after antigen-dependent clonal expansion *in vitro*. CT appears to alter nonspecifically the responsiveness of Peyer's patch B cells to isotype switching signals present in the *in vitro* cultures, perhaps by a direct effect on B cells or by the effect of CT on cytokine-mediated signals within the Peyer's patch. Lycke and Strober (1989) have shown that CT enhances the effect of both IL-4 and IL-5 on purified B cells stimulated by LPS *in vitro*. In the presence of CT, IL-4 enhanced IgG1-producing B cells 3- to 4-fold; IL-5 had a similar effect on IgA-producing B cells. These results suggest that CT promotes isotype switching of surface IgM<sup>+</sup> B cells in synergy with interleukins, at least to a moderate extent, but determining the exact molecular mechanism involved awaits molecular genetic analysis. The interaction of CT and interleukins on B cells of GALT *in vivo* must be explored further to understand the process that drives B cells to commit to a predominantly IgA isotype expression.

Little information is available concerning the effects of CT on B-cell clonal expansion. Woogen *et al.* (1987), found that CT inhibited proliferation of purified B cells *in vitro* when they were stimulated polyclonally by either anti-IgM or LPS;

CTB inhibited B cells stimulated by anti-IgM but not by LPS. Lycke *et al.* (1989) also found that CT inhibited the B-cell proliferative response to LPS, but observed a mild stimulatory effect on B-cell proliferation relative to the control if the culture period was prolonged to 6 days and low doses of CT were used. The effects of CT on B-cell proliferation *in vivo*, particularly after the brief exposures expected there, remains to be determined. Certainly the large numbers of plasma cells producing anti-CT in the lamina propria after oral immunization with CT, which has been estimated at up to 5% of the total at the peak of the response, indicates that clonal expansion occurs and is vigorous *in vivo*. The effect of CT on terminal differentiation of B cells has yet to be examined.

### F. Summary

Much remains to be learned about the mechanisms of CT immunogenicity and adjuvanticity, including the relative contributions of the two subunits. The dose, timing, route, antigen type, and genetic background of the host are all important variables. Indications are that the mechanism of CT adjuvanticity involves multiple aspects of immune induction in the mucosa, including increased uptake of antigen; enhancement of IL-1 production by APCs; altered regulation by T cells, especially inhibition of CD8 suppressor cells; stimulation of B-cell switching to IgA and IgG; and possibly, enhancement of B-cell clonal expansion. Different components of these multiple effects may be of more importance for some antigens than for others.

## III. IMMUNOSTIMULATING COMPLEXES

Immunostimulating complex (ISCOM) is a term coined by Morein to describe 40-nm cage-like particles that form spontaneously on mixing cholesterol with the saponin, Quil A (Morein, 1987). Protein antigens can be incorporated in such particles, and the Quil A serves as a built-in adjuvant. The incorporation of the protein into ISCOMs is via hydrophobic interactions; however, a wide variety of proteins can be incorporated by palmitic acid of the protein before incorporation, or acidification to expose hydrophobic groups in conjunction with the addition of phosphatidyl choline (Morein *et al.*, 1990; Mowat and Donachie, 1991). Much smaller amounts of antigen are effective in ISCOMs that are needed for oil adjuvants (Nagy *et al.*, 1990). ISCOMs have been used effectively parenterally in a variety of species including mice, cats, sheep, cattle, and monkeys (Morein, 1990).

ISCOMs stimulate a strong antibody response in all immunoglobulin classes (Lovgren, 1988). They also strongly stimulate cell-mediated immunity, as measured by proliferative T-cell responses and delayed hypersensitivity (Fossum *et al.*, 1990). Perhaps a unique feature of ISCOMs is their ability to induce CD8<sup>+</sup> cytolytic T lymphocyte (CTL) responses. Thus, a single subcutaneous immunization of mice with

ISCOMs containing either purified human immunodeficiency virus (HIV) gp160 or influenza hemagglutinin resulted in priming of HIV-specific or influenza-specific CD8<sup>+</sup> MHC Class I-restricted CTLs (Takahashi *et al.*, 1990a). This result indicates that ISCOMs somehow cause exogenous proteins to enter the endogenous pathway of antigen processing. The Quil A component appears to be essential for this effect because it does not occur with simple liposomes or with free palmitic acid antigen (Mowat and Donachie, 1991). The ability of ISCOMs to stimulate cytolytic T cells may be unique among adjuvants and has generated much interest in this adjuvant system, particularly for vaccination against viral pathogens.

Mucosal adjuvanticity of ISCOMs also has been demonstrated, although in a limited number of studies to date. An experimental influenza virus vaccine administered intranasally on two occasions generated high levels of antibody and protection against challenge infection that was equivalent to that after subcutaneous immunization (Lovgren *et al.*, 1990). Mowat and colleagues have reported that administration of ovalbumin (OVA) in ISCOMs converts the response from the oral tolerance that is seen when OVA is fed alone to a state of antibody and cell-mediated immunity and, after repeated feeding, the generation of OVA-specific CTLs. After several administrations orally, strong secretory IgA antibody responses to OVA could be detected in intestinal washings. Thus, the oral administration of OVA in ISCOMs generated a wide spectrum of humoral and cellular immune responses (Mowat and Donachie, 1991; Mowat *et al.*, 1991). Finally, parenteral immunization in the pelvic presacral space with sheep erythrocyte membrane proteins in ISCOMs generated significant IgA titers in vaginal fluid against this antigen in mice (Thapar *et al.*, 1991). Thus, ISCOMs may be useful at a number of mucosal surfaces, and the mucosal route may help avoid the toxicity that has been observed after the parenteral use of these particulates in small animals. Such toxicity may limit the usefulness of this adjuvant. However, immunostimulatory but nontoxic fractions of Quil A have been identified that may reduce or eliminate this potential problem (Kensil *et al.*, 1991). These early studies suggest that ISCOMs may be a very useful adjuvant system for generating mucosal responses.

## IV. BACTERIAL LIPOPOLYSACCHARIDE AND LIPID A

The adjuvant activity of LPS was demonstrated first by Johnson *et al.* (1956). An unusual feature of its adjuvanticity relative to other agents is that it can be delivered at a site and a time different from antigen (Ulrich *et al.*, 1991). LPS has multiple effects on the immune system, including the stimulation of macrophages and their production of cytokines such as IL-1 and colony stimulating factor (CSF), mitogenicity for B cells, alteration of MHC Class II expression on APCs, the stimulation of IFN $\gamma$  production, and the stimulation of delayed hypersensitivity (Ohta *et al.*, 1982; Warren *et al.*, 1986). Despite its potent adjuvant effects, LPS has

been used as an adjuvant only experimentally because of its toxicity. The lipid A component of LPS is its active moiety, that is, the administration of purified lipid A can reproduce all the toxic and biological effects of LPS (Chiller *et al.*, 1973).

Many studies have been done on chemical modifications of lipid A in an effort to find a less toxic but still immunostimulatory compound (Takayama *et al.*, 1981; Takada and Kotani, 1989). Multiple such forms of lipid A have been produced and some have undergone fairly extensive testing as nontoxic but effective immunological adjuvants. One of these, monophosphoryl lipid A, has been shown to have many of the adjuvant effects of lipid A or LPS itself, that is, it stimulates macrophages to release IL-1, tumor necrosis factor  $\alpha$  (TNF $\alpha$ ), and CSF, increases production of IFN $\gamma$  *in vivo*, and can increase the nonspecific resistance of mice to bacterial infection (Ulrich *et al.*, 1991). This material can be combined with other adjuvants and has been given safely to humans.

Relatively little work has been done to test such lipid A derivatives as mucosal adjuvants. LPS increased serum antibody against inhaled bovine serum albumin (BSA) or OVA when it was included in the inhalant (Mizoguchi *et al.*, 1986), and enhanced the anti-BSA response after oral administration of BSA in liposomes (Ogawa *et al.*, 1986). These studies suggest that monophosphoryl lipid A may be an effective adjuvant at mucosal surfaces; however, its effects appear complex. Studies in rodents suggest that LPS depresses the response to certain antigens such as sheep red blood cells (SRBC) given orally; the administration of LPS to germ-free mice causes oral tolerance to SRBC when these were fed subsequently to the same mice (Michalek *et al.*, 1983a). In addition, the IgA immune responses in LPS-resistant C3H/HeJ mice are greater than the responses of their LPS-responsive C3H/HeN counterpart, suggesting that LPS induces mucosal hyporesponsiveness in the latter (Babb and McGhee, 1980; Kiyono *et al.*, 1980, 1982). Coadministration of LPS or lipid A orally with myelin basic protein (MBP) to rats enhanced the generation of oral tolerance to this antigen; in contrast, LPS given subcutaneously at the time of antigen feeding abrogated oral tolerance to MBP (Khoury *et al.*, 1990). Other investigators have reported that administration of LPS intravenously to mice abrogates humoral (IgG) but not cellular (DTH) oral tolerance to OVA (Mowat *et al.*, 1986). These studies illustrate that the effects of LPS or lipid A at mucosal surfaces are complex and require further study. The effect of LPS or lipid A on different forms of antigen and at various mucosal surfaces, including those that are not normally bathed in bacterial endotoxin, need to be defined. Because antigen and LPS or lipid A do not need to be given by the same route, combined parenteral and mucosal administration may be effective in stimulating mucosal responses, as has been found in studies with *Shigella* LPS (Keren *et al.*, 1988). Finally, lipid A derivatives can be combined with other adjuvants. Such combinations may have much greater efficacy than lipid A alone. The availability of the nontoxic lipid A derivatives for use in humans makes a re-examination of their mucosal adjuvant effects a high priority.

## V. *BORDETELLA PERTUSSIS* PERTUSSIGEN

*Bordetella pertussis* whole cell bacteria have been used parenterally as a vaccine against pertussis and as an adjuvant for other antigens. Obviously this material is a complex mixture, including LPS as well as variable amounts of pertussis toxin. Pertussis toxin (pertussigen) has been crystallized (Munoz *et al.*, 1981) and its gene cloned (Locht *et al.*, 1986). This substance has many biological effects, probably related to its ability to bind to signal transducing G proteins in a diverse number of cell types. Pertussigen has been tested in purified form and was found to have adjuvant activity. Pertussigen particularly enhances the cell-mediated immune response as measured by increased delayed skin responses to soluble antigens and increased inflammatory responses such as footpad swelling after injection of Freund's complete adjuvant. These effects of pertussigen appear to be mediated through T cells because footpad swelling does not occur in athymic nude mice. *Bordetella* and pertussigen both increase IgG and IgE responses to antigens and have been reported to be able to abrogate humoral (Herzenberg and Tokuhisa, 1982) and cell-mediated (Tamura *et al.*, 1985) tolerance to antigens in some systems, an effect of some interest for mucosal immunity because of the propensity for tolerance induction by antigen feeding. Similar to LPS or lipid A, pertussigen can be given by a different route and at a different time than antigen and still exert its adjuvant effects.

The data on its mucosal adjuvanticity are sparse. One can induce IgE antibody responses to OVA in rats by feeding OVA and administering pertussigen either intradermally, intraperitoneally, or orally (Bazin and Platteau, 1976; Jarrett *et al.*, 1976). The IgE isotype is not one that vaccines usually are intended to induce, so the value of this ability of pertussigen is questionable. Perhaps related to its ability to induce IgE responses or, alternatively, to induce DTH, immunization with nematode worm antigens plus pertussigen stimulated resistance to two different intestinal nematodes in rodents (Murray *et al.*, 1979; Mitchell and Munoz, 1983). When SRBC antigen plus pertussigen was delivered to nasal mucosa, a strong respiratory immunization in mice was induced (Birnbaum and Pinto, 1976).

The propensity for this agent to produce adverse effects is a real concern. *Bordetella pertussis* vaccine has been associated with severe reactions in humans, including encephalopathy (Cavanagh *et al.*, 1981). These potential toxicities may be lessened by administration via a mucosal route; however, in the intestine, pertussigen has induced hypersecretory responses to some inflammatory mediators and neurotransmitters and this responsiveness may be prolonged (Crowe *et al.*, 1990). These and other potential adverse reactions with pertussigen are likely to limit its usefulness as an adjuvant even by mucosal routes, except for experimental use.

## VI. AVRIDINE

Avridine [*N,N*-dioctadecyl *N',N'*-bis(2-hydroxyethyl)propanediamine] is a synthetic lipoidal amine developed as an

inducer of interferon production. However, this molecule subsequently was found to possess properties that made it potentially useful as a vaccine adjuvant, especially as a mucosal adjuvant. Its adjuvant activity probably is related to its ability to stimulate interferon production and thus up-regulate antigen presentation by macrophages.

When administered intraduodenally, avridine has been shown to enhance the uptake, localization, and retention of antigen in Peyer's patches (Anderson *et al.*, 1985). One of the ways in which avridine may exert this effect is by slowing the rate of degradation of antigen, as has been observed for microcapsules.

Avridine has been used to protect mice against aerosol challenge with Rift Valley Fever virus (Anderson *et al.*, 1987). Formalin-inactivated virus was combined with avridine and administered either subcutaneously (sc) or intraduodenally (id). The use of avridine was found to stimulate production of both secretory IgA and serum IgG. The response elicited by id administration was found to protect the mucosa from aerosol challenge, but also increased the predilection of the mice to develop encephalitis on parenteral challenge. Further, the survival rate was only 62% for mice immunized id compared with a survival rate of 100% for mice immunized sc. The reason for this effect is not clear, but it suggests that mucosal vaccination can have both positive and negative consequences, depending on the agent and the adjuvant being used for vaccination.

The effectiveness of avridine as an adjuvant reportedly is increased by incorporating it into liposomes (Pierce and Sacci, 1984). When avridine-containing liposomes were coadministered with cholera toxin, the efficiency of priming for an anamnestic response increased 5- to 7-fold. No such adjuvant effect was observed for the liposomes alone. Interestingly, cholera toxin did not have to be incorporated into the liposomes for this effect to occur. However, neither avridine nor the liposomes had any effect on the strength of the immune response to either primary or secondary exposure to cholera toxin. In general, most antigens have been found to elicit better immunity in GALT when packaged in liposomes. However, as described earlier, cholera toxin is a unique antigen with respect to mucosal immunity, and is not representative of most antigens administered orally.

Somewhat surprising was the reported effectiveness of avridine as an adjuvant for influenza virus (Bergmann and Waldman, 1988). Coadministration of killed virus with avridine-containing liposomes orally was reported to enhance the IgA response in the respiratory tract. However, no antibody response was detected in the serum. This observation is unusual, since most mucosally administered vaccines elicit both secretory and systemic immunity. Further, most orally administered vaccines require boosting locally to stimulate appreciable secretory immunity in remote mucosal sites.

An interesting study examined the effectiveness of avridine as an adjuvant for eliciting secretory immunity in tears (Peppard *et al.*, 1988). Dinitrophenyl (DNP)-*Pneumococcus* was coadministered with or without avridine-containing liposomes by ocular-topical (ot) or oral routes. When DNP-*Pneumococcus* was administered without avridine-containing liposomes, whether administered to the eye or

orally, IgA responses were detected in tears. However, the antibody response in tears was always greater by the ot route. In contrast to the results observed for respiratory IgA, the use of avridine-containing liposomes reduced the IgA antibody response found in tears, compared with antigen alone, when administered either ot or orally. However, the serum IgG response was increased slightly when avridine was coadministered with the antigen.

In summary, avridine has shown some promise as a vaccine adjuvant, and currently is being used as an adjuvant for parenterally administered veterinary vaccines. Although avridine clearly is able to stimulate mucosal immunity at some sites, its ability to stimulate systemic immunity via mucosal immunization is less clear.

## VII. MURAMYL DIPEPTIDE

Muramyl dipeptide (MDP; *N*-acetyl muramyl-L-alanyl-D-isoglutamine) is derived from the cell wall of mycobacteria, is the smallest structural component of the cell wall that still retains adjuvant activity, and is one of the active components contained in Freund's complete adjuvant. The effectiveness of Freund's as an adjuvant for parenterally administered vaccines is well documented. Freund's has been used extensively for experimental vaccines and immunotherapy. Although several reports are available on the use of MDP as a mucosal adjuvant, the literature is not nearly as extensive as it is for parenterally administered vaccines.

In several instances, oral administration of MDP has been used to stimulate nonspecific immunity to bacteria and to tumor cells. Oral administration of MDP to mice protected them against challenge with *Klebsiella pneumoniae* (Parant *et al.*, 1978) and increased cytolytic activity after intravenous challenge with tumor cells (Okutomi *et al.*, 1990). In both cases, the increase in nonspecific immunity was probably the result of induction of cytokines. MDP is known to be a potent inducer of IL-1, which can up-regulate macrophages and T cells. Although not directly relevant to mucosal immunity, these results do show that MDP is absorbed by the gut and suggest that it can affect the immunoregulatory environment of the mucosa-associated lymphoid tissue.

MDP has been used as an adjuvant for intravaginal immunization in mice (Thapar *et al.*, 1990a). Multiple large doses of horse ferritin were combined with aluminum hydroxide, muramyl dipeptide, monophosphoryl lipid A, or cholera toxin. Although MDP was not the most effective adjuvant for this route, it was shown to potentiate the secretory immune response to horse ferritin. Depending on the route of immunization chosen, the level and isotype of antibody to horse ferritin varied (Thapar *et al.*, 1990b). Pelvic immunization induced greater IgA and IgG responses in the vagina than did intravaginal immunization. Although IgG responses were elevated only slightly relative to sc-immunized mice, the IgA response was elevated dramatically by pelvic immunization.

MDP also has been used as an adjuvant for oral immunization (Michalek *et al.*, 1983b). Trinitrophenyl (TNP)-haptentated whole cells or cell wall from the cariogenic bacterium

*Streptococcus mutans* combined with MDP was administered intragastrically to mice. MDP boosted anti-TNP IgA responses in LPS-responsive C3H/HeN mice, but not in LPS-unresponsive C3H/HeJ mice. The salivary immune response to *S. mutans* whole cells or cell walls in gnotobiotic rats was augmented more than 2-fold when coadministered orally with MDP. The use of MDP in combination with *S. mutans* resulted in a significant reduction in bacterial colonization of the tooth surface and number of carious lesions produced (Morasaki *et al.*, 1983). MDP augmented the mucosal immune response to *Neisseria gonorrhoeae* major outer membrane protein when given into the intestine or injected directly into Peyer's patches (Jeurissen *et al.*, 1987). Lipophilic derivatives of MDP have been synthesized and tested for their mucosal adjuvant activity. Some enhanced the mucosal response of rats to the soluble protein BSA when coadministered in saline; others were active only when incorporated with antigen in liposomes (Ogawa *et al.*, 1986).

The observations just discussed suggest that MDP can be taken up by mucosal surfaces and can stimulate both secretory and systemic immunity to antigens coadministered with it. The mechanism of action at these sites is unknown, but is probably due, at least in part, to the ability of MDP to induce IL-1 production and increase processing and presentation of antigen by macrophages.

## VIII. MISCELLANEOUS ADJUVANTS

Many different compounds have been examined for their potential to act as adjuvants. In general, the literature on the use of these compounds as mucosal adjuvants is sparse. Items included on this list are nonionic block copolymers, vitamin A, synthetic double-stranded polyribonucleotide complexes such as poly I:C (an interferon inducer), polyacrylic compounds, glucan analogs, pyran copolymers, and proteosomes (peptide-multimeric protein complexes). The utility of these compounds has yet to be established, although these and a number of others appear interesting.

# Monoclonal Secretory IgA for Protection of the Intestinal Mucosa against Viral and Bacterial Pathogens

Jean-Pierre Kraehenbuhl • Marian R. Neutra

## I. ROLE OF SECRETORY IgA IN INTESTINAL PROTECTION: UNRESOLVED ISSUES

### A. Current Views of the Role of IgA

Secretory IgA is the major class of immunoglobulin found in the secretions bathing mucosal surfaces in the normal gastrointestinal tract, in part because immunoglobulin transport across epithelial surfaces into secretions is a receptor-mediated process requiring specific interaction of polymeric immunoglobulins (primarily dimeric IgA) with the polymeric immunoglobulin receptor (Kraehenbuhl and Neutra, 1992a; Mostov *et al.*, 1980, 1984). In addition, monomeric IgG that enters secretions through fluid-phase transport or paracellular leakage is degraded readily by proteases in the intestine, whereas dimeric or polymeric SIgA resists hydrolysis (Lindh, 1975). Since SIgA has at least four antigen binding sites, it should be more effective than IgG in forming microbe-antibody complexes and aggregating intestinal pathogens. Whether the polymeric nature of sIgA is essential to its protective function, however, has not been proven.

The mechanisms by which IgA may prevent epithelial contact and mucosal disease are discussed in detail in Chapter 11 but are summarized here to provide background for specific studies using monoclonal IgAs. Bacteria aggregated by IgA may be unable to exploit motility and chemotactic mechanisms to move through mucus and toward epithelial targets (McCormick *et al.*, 1988). Aggregates of bacteria, viruses and macromolecules would be cleared efficiently from the lumen by peristalsis, and clearance is thought to be enhanced by entrapment of IgA-microbe complexes in the interstices of the mucus gel (Neutra and Forstner, 1987). Although a specific interaction of IgA and mucus glycoproteins has been proposed (Creeth, 1978), it has not been confirmed in studies using highly purified mucins (Crowther *et al.*, 1985). Evidence also suggests that IgA can protect epithelial surfaces by specifically blocking the microbial adhesins required for attachment (Williams and Gibbons, 1972). This hypothesis has been difficult to test, however, since most bacteria can use multiple adhesion mechanisms, and polyclonal SIgAs in secretions are directed against multiple antigens and epitopes. This idea

is difficult to prove even with monoclonal IgAs, because the large size of dimeric or polymeric immunoglobulins may sterically hinder microbial binding sites even when directed against a nonadhesive component.

Secretory IgA has been found, in most studies, to lack complement-fixing, opsonizing, and direct bacteriocidal activity (Mestecky, 1988; Childers *et al.*, 1989; Kerr, 1990). These characteristics are consistent with its function in the external milieu, usually in the absence of serum proteins and macrophages. On the other hand, SIgA in the lumen may interact with molecules in milk such as lactoferrin and lactoperoxidase and enhance their bacteriocidal activities (Arnold *et al.*, 1980; Tenovuo *et al.*, 1982). In addition, evidence suggests that SIgA can enhance antibody-dependent cytotoxicity by mucosal lymphocytes, and has been suggested to somehow "arm" lymphocytes in the lumen and thus promote direct killing of bacteria (Tagliabue *et al.*, 1985).

### B. Importance of Specific IgAs in Protection

Testing of these ideas has been hampered by the limited availability of specific dimeric IgAs in quantities sufficient for *in vivo* and *in vitro* experimentation. Monoclonal IgA antibodies were generated against viral pathogens that colonize and invade mucosal surfaces of the respiratory system (see Chapters 29 and 30). These reagents were used to show that IgAs can indeed provide protection against airway infection and subsequent pulmonary disease, whether applied passively to mucosal surfaces (Mazanec *et al.*, 1987) or secreted actively into the airways after intravenous injection (Renegar and Small, 1991). Passive application of corresponding monoclonal IgGs also was protective, however, suggesting that the dimeric nature of IgA may be important only in insuring transepithelial delivery and increasing protease resistance. On the other hand, precisely measuring local concentrations of secreted immunoglobulins in the microenvironment of epithelial surfaces and within the mucus coat requires special techniques (Haneberg *et al.*, in press). Experiments often involve application of large amounts of exogenous antibodies to the luminal side of the mucus blanket.

In the intestine, abundant evidence is found that SIgA in secretions is associated with protection against enterotoxigenic and invasive enteric pathogens (Levine *et al.*, 1983, 1988), but whether SIgA alone can provide such protection has not been clear. Transport of enteric bacteria and viruses by M cells and subsequent "sampling" by cells in organized mucosal lymphoid tissues generally results in production of both IgG- and IgA-producing cells, and in some cases also induces cell-mediated immunity. After oral immunization or natural disease, the presence of all these types of immune protection, as well as nonimmune protection mechanisms, complicates the analysis of IgA action. In addition, the SIgA response *in vivo* is polyclonal and, although the antigen specificities have been documented partially, in some cases (Sears *et al.*, 1984; Svennerholm *et al.*, 1984; Cancellieri and Fara, 1985; Tacket *et al.*, 1990), little information is available concerning the exact epitopes that are present after intestinal passage and M cell transport and that are most immunogenic in the mucosa (for review, see Kraehenbuhl and Neutra, 1992b; Neutra and Kraehenbuhl, 1992). Finally, the relative protective capacities of individual SIgAs have not been tested systematically or compared in the intestinal system. These issues must be addressed for each of the many bacterial, viral, protozoal, and parasitic pathogens that colonize the intestinal lumen, infect the intestinal mucosa, or use the intestinal epithelium as an invasion route.

### C. Role of IgA in Modulating the Mucosal Immune Response

Secretory IgA antibodies in mucosal or glandular secretions are able to bind to the apical membranes of M cells in follicle-associated epithelia and enter organized mucosal lymphoid tissue from the lumen by M-cell transepithelial transport (Roy and Varvayanis, 1987; Weltzin *et al.*, 1989). This transport allows secretory IgA and sIgA-antigen complexes to interact with lymphocytes and antigen-presenting cells that express IgA binding sites. IgA binding sites (FcA receptors) on T- and B-cell subsets have been detected in peripheral and mucosal lymphoid tissue from several species (Kerr, 1990). Once transported into organized mucosal lymphoid tissue, IgA antibodies (associated or not with antigen) could mediate several functions. First, they may modulate the immune response in the organized mucosal lymphoid tissue: polymeric but not monomeric IgA is known to up-regulate FcA receptors on cloned T cells (Kiyono and McGhee, 1987). Some of the T cells in Peyer's patches expressing FcA receptors are able to function as helper cells, increasing the number of IgA-positive B cells (Kiyono *et al.*, 1984). Pre-incubation of these T helper cells with IgA, however, blocks this response (Kiyono *et al.*, 1985). Second, since antigen-SIgA complexes are transported across M cells into the underlying lymphoid tissue (Weltzin *et al.*, 1989), FcA receptors on antigen-presenting cells (B cells and macrophages) may facilitate uptake and processing of antigens. In this way, re-uptake of secreted IgA may constitute an amplification loop, enhancing the immune response and con-

tributing to secondary responses. Finally, IgA re-uptake by M cells may regulate an immune response through the idiotypic network. Anti-idiotypic IgA antibodies in glandular and mucosal secretions could follow the M-cell uptake pathway to prime the mucosal immune system actively. Such a mechanism has been proposed to explain why breast-fed infants that acquire the IgA repertoire of their mothers via milk respond to parenteral or peroral vaccines (Hanson *et al.*, 1990). Whether the anti-idiotypic network can be used in mucosal vaccine strategies remains to be established.

## II. GENERATION AND ANALYSIS OF MONOCLONAL IgA

### A. Development of Methods for Production of IgA Hybridomas

Conventional systemic immunization methods followed by fusion of spleen cells with myeloma cells yields IgA hybridomas only rarely. We now recognize that mucosal immunization, and the isotype switch that occurs under the influence of specific cytokines in the organized mucosal lymphoid tissue, is a prerequisite for generation of IgA-committed lymphoblasts (Kiyono *et al.*, 1984; McGhee *et al.*, 1989). These lymphoblasts are known to migrate from inductive sites in the mucosa to regional mesenteric lymph nodes, to proliferate and there to return via the bloodstream to mucosal effector sites (Craig and Cebra, 1971). Several investigators have exploited this migration phenomenon to obtain IgA hybridomas. For example, IgA hybridomas were generated by fusion of spleen cells from mucosally immunized mice (Colwell *et al.*, 1986; Mazanec *et al.*, 1987). Fusion of cells from mesenteric lymph nodes and thoracic duct lymph (Styles *et al.*, 1984; Rits *et al.*, 1986) or a mixture of cells from mesenteric lymph nodes and Peyer's patches (Komisar *et al.*, 1982) also yielded significant numbers of IgA hybridomas. We have found that fusion of Peyer's patch cells alone provides a very efficient means of generating IgA hybridomas, and that immunization by gastric intubation or intraluminal injection alone, without intraperitoneal priming, is effective (Weltzin *et al.*, 1989; Winner *et al.*, 1991; Michetti *et al.*, 1992; Apter *et al.*, 1993a). In our experience, direct injection into Peyer's patch tissue is less effective, presumably because the immune response is most efficient when M cells deliver the immunogens directly to organized assemblies of antigen-processing and presenting cells (Ermak *et al.*, 1990). Cells are isolated 5 days after the last peroral immunization by excision of Peyer's patch mucosa and digestion in collagenase, followed by maceration of the tissue. Released cells are fused with mouse myeloma cells using standard procedures. In our hands, at least 50% of the pathogen- or antigen-specific hybridomas generated by this method are of the IgA type. When *Salmonella typhimurium* was used as mucosal immunogen, all 48 stable anti-*Salmonella* hybridomas obtained produced IgA antibodies (Michetti *et al.*, 1992).

### B. Evaluation of Monoclonal IgAs

The antigen specificities of mucosally derived IgA antibodies are determined using standard immunochemical assays such as enzyme-linked immunosorbent assay (ELISA), Western immunoblot, and immunoprecipitation. Before evaluating their function in protection, however, these antibodies must be shown to be structurally and functionally analogous to the IgAs produced by normal subepithelial plasma cells. To verify the molecular forms of IgA produced, antibodies concentrated from IgA hybridoma supernatants are separated by gradient SDS-PAGE under nonreducing conditions and visualized by immunoblot analysis (Weltzin *et al.*, 1989; Winner *et al.*, 1991). We have found that almost all IgA hybridomas derived from Peyer's patch cells produce IgA primarily in dimeric form, with some monomers and higher polymers. IgAs metabolically labeled in hybridoma culture, when injected intravenously into rats, were transported efficiently into bile and recovered as dimers and polymers with molecular weights that increased by an amount consistent with the addition of secretory component (SC) during transport across hepatocytes (Weltzin *et al.*, 1989). This result confirms that the monoclonal IgAs are recognized by polymeric immunoglobulin receptors and can be transported into secretions, either by hepatocytes and epithelial cells *in vivo* or by epithelial cells in culture, as described subsequently.

## III. EXPERIMENTAL METHODS FOR TESTING PROTECTIVE FUNCTIONS OF MONOCLONAL IgA

### A. Passive Oral Administration *in Vivo*

SIgA functions on mucosal surfaces. Passive application of monoclonal IgA or IgG antibodies to respiratory mucosa provides protection against viral infection. Thus, assuming that oral ingestion of specific IgAs might protect against enteric infections seems reasonable. The environment of the gastrointestinal tract lacks the specific IgA proteases produced by certain *respiratory* pathogens, but is extremely rich in digestive proteases that readily degrade IgG and monomeric IgA (Brown *et al.*, 1970; Underdown and Dorrington, 1974; Lindh, 1975). Secretory polymeric IgA is relatively resistant to these enzymes; secretory IgA of human milk can survive the stomach and intestine since it can be recovered from feces (Cancellieri and Fara, 1985; Hanson *et al.*, 1990). Ingestion of human milk from orally immunized mothers that contained natural polyclonal secretory IgA against *Vibrio cholerae* lipopolysaccharide (LPS) has been shown to protect infants against cholera (Glass *et al.*, 1983).

Monoclonal IgA lacks secretory component, however, and would be degraded more readily in the gastrointestinal tract (Underdown and Dorrington, 1974; Lindh, 1975). Although dimeric IgA is more stable than monomeric IgG, the exact survival time of dimeric monoclonal IgA without SC in the human stomach and intestine is not known. A more difficult

problem is that of achieving effective predictable antibody distribution over the lining of the entire 4.5 m of human intestine after an oral dose, and correctly timing the oral IgA to coincide with local microbial challenge. Whereas normally secreted IgA antibodies are delivered into intestinal crypts and directly onto epithelial surfaces, orally administered IgA might never reach these sites. Despite these concerns, evidence suggests that oral monoclonal IgA can protect the intestinal mucosa passively. For example, studies in our laboratories showed that, in suckling mice (in which protease activity is low), a single oral dose of monoclonal IgA provided passive protection against viral and bacterial challenge for up to 3 hr. Further, human serum immunoglobulins (primarily IgG), fed with infant formula, appeared to prevent intestinal disease in high risk infants (Eibl *et al.*, 1988).

### B. Hybridoma "Backpack" Tumor Method

To achieve continuous widespread delivery of monoclonal IgA into secretions, we took advantage of the facts that hybridoma cells can form immunoglobulin-producing tumors *in vivo* (Harris *et al.*, 1982) and that circulating dimeric IgA binds to epithelial pIg receptors and is transported into secretions (Jackson *et al.*, 1977). Serum antibodies can diffuse readily to IgA-transporting epithelial cells in the liver and intestine because capillaries in these tissues are fenestrated (with the exception of Peyer's patches; Allen and Trier, 1991). When IgA-producing hybridoma cells are injected subcutaneously on the upper backs of adult BALB/c mice, well-organized tumors with blood and lymphatic vessels form within 1–2 weeks. In newborns, the cells grow in a more dispersed fashion under the loose dorsal skin. In adult mice, increasing levels of specific monoclonal IgA in serum were shown to be accompanied by increasing levels in secretions (Winner *et al.*, 1991). In contrast, antibodies from IgG-producing hybridoma tumors enter secretions in low amounts despite very high blood levels. Thus, with the IgA hybridoma backpack tumor method, monoclonal IgA can be delivered continually into secretions via the physiological route, with addition of secretory component. Mice bearing hybridoma tumors are not strictly analogous to normal immunized mice secreting endogenous IgA, however. In a normal mucosal immune response, dimeric IgA is produced locally by subepithelial plasma cells and blood levels of IgA are relatively low (Mestecky, 1988) whereas, in "backpack" mice, blood and tissue levels of monoclonal antibody may be very high (Winner *et al.*, 1991). This method nevertheless allows for assessment of the protective capacities of specific SIgA antibodies in the absence of other immune protection mechanisms, and has been applied in studies of several pathogens that can colonize or invade the mouse intestine.

### C. Epithelial Monolayers *in Vitro*

The development of improved epithelial cell culture systems and the availability of well-characterized lines of human intestinal epithelial cells have opened the way for new *in*

*in vitro* approaches to analysis of mucosal immune protection. Certain cell lines and subclones derived from human colon carcinomas form confluent polarized monolayers in culture that display many of the features of the normal differentiated intestinal epithelium (Rousset, 1986; Huet *et al.*, 1987; Madara *et al.*, 1987; Neutra and Louvard, 1989). Although these cell lines do not strictly replicate normal cell phenotypes and do not reproduce the complex microenvironment of mucosal surfaces, they provide valuable models in which to test the interactions of microbial pathogens and toxins with epithelial cells and the ability of IgA to prevent these interactions.

Confluent MDCK (Madin-Darby canine kidney) cells and Caco-2 (human colon carcinoma) cells have been used to evaluate *Salmonella* factors involved in attachment and invasion (Finlay *et al.*, 1988; Finlay and Falkow, 1990; Lee and Falkow, 1990). Studies in our laboratories have shown that monolayers of subcloned HT29 cells, representing either absorptive cell or goblet cell phenotypes in various stages of differentiation, also can be infected by *S. typhimurium*. The presence in the apical medium of specific monoclonal IgAs directed against a surface component of *S. typhimurium* significantly reduced epithelial infection in both MDCK and HT29 cells. Relatively high concentrations of antibody were required, however, perhaps because the nonimmune protection mechanisms such as peristalsis and clearance that operate in concert with IgA *in vivo* are not present *in vitro*.

In other studies, monoclonal IgA directed against the B subunit of cholera toxin protected confluent polarized T84 cell monolayers against toxin binding, and thus also prevented the toxin-induced chloride secretory response (Apter *et al.*, 1991). Some epithelial cell lines or clones express endogenous polymeric immunoglobulin receptors and are capable of vectorial IgA transport (Roa *et al.*, 1987); others can be transfected with receptor cDNA to induce receptor expression (Hirt *et al.*, 1992). This approach allowed testing of epithelial protection during active IgA secretion *in vitro* (Mazanec *et al.*, 1992). In addition, this model has been used to demonstrate transport of IgA immune complexes from the basolateral to the apical compartment, suggesting that IgA secretion may serve to clear antigens or pathogens from the interstitial compartment (Kaetzel *et al.*, 1991).

## IV. EVALUATION OF IgA PROTECTION AGAINST ENTERIC PATHOGENS

### A. *Vibrio cholerae*

*Vibrio cholerae* causes disease by colonizing the epithelial surface of the intestinal mucosa and secreting cholera toxin that binds with high affinity to a specific ganglioside, GM1, in cell membranes. Entry of vibrios into the luminal microenvironment is associated with expression of the *ToxR* gene product, which in turn regulates several other genes including those involved in adherence, colony formation, and toxin production (Taylor *et al.*, 1987; Miller *et al.*, 1989). *Vibrio cholerae* infection or immunization with bacterial cells and

toxin evokes SIgA directed against both toxin and bacterial surface components including LPS. SIgA secretion is associated with protection against subsequent challenge (Cash *et al.*, 1974; Levine *et al.*, 1983; Svennerholm *et al.*, 1984). The relative importance of specific IgAs in protection, however, was not established. Both cholera toxin and *V. cholerae* bind to M cells and are transported efficiently into Peyer's patch mucosa, so both would be expected to evoke specific IgA lymphoblasts. We used such cells to generate hybridomas that produce monoclonal IgAs directed against a strain-specific carbohydrate epitope of bacterial LPS that is exposed on the bacterial surface (Winner *et al.*, 1991), and against the binding subunit of cholera toxin (CTB) (Apter *et al.*, 1991). We then tested the protective capacities of these IgAs against virulent organisms and toxin *in vivo* and *in vitro* (Apter *et al.*, 1991).

Using the hybridoma backpack tumor system in suckling mice, we showed that secretion of monoclonal SIgA directed against a single Ogawa strain-specific LPS epitope protected mice against oral challenge with 100 times the LD<sub>50</sub> of virulent Ogawa organisms (Winner *et al.*, 1991). Protection was specific, since mice were not protected by secretion of irrelevant IgAs and anti-LPS tumors failed to protect against virulent *V. cholerae* of the Inaba strain (Winner *et al.*, 1991). Secretion of anti-CTB IgA from hybridoma tumors, in contrast, failed to protect against the same challenge (Apter *et al.*, 1991), presumably because anti-LPS IgA effectively aggregates vibrios in the lumen and prevents colonization (Manning, 1987) whereas antitoxin IgA permits colonization. Once colonies are established, the secreted antitoxin IgA may not be of sufficient concentration or affinity to intercept toxin secreted directly into the enterocyte glycocalyx on the mucosal surface. In addition, SIgA may not diffuse readily into the extracellular pilus-rich matrix of established bacterial colonies.

The same monoclonal IgAs were tested for their ability to provide passive oral protection against live organisms or purified toxin. Oral administration of a single dose of as little as 5 µg anti-LPS IgA prevented *V. cholerae*-induced diarrheal disease, but only when the bacterial challenge was given within 3 hr of the IgA (Apter *et al.*, 1991), confirming the need for repeated administration or continuous secretion of IgA to compensate for peristalsis and clearance. Oral delivery of up to 80 µg antitoxin IgA failed to protect against live vibrios, but did provide some protection against oral challenge with the ED<sub>50</sub> (5 µg) of toxin alone. Collectively, these studies indicate that anti-LPS SIgA is much more efficient than antitoxin SIgA in providing protection against virulent *V. cholerae*. This result is consistent with evidence from oral cholera vaccine trials in which antibodies against the bacterial cells were found to be an important component in protection (Levine *et al.*, 1988; Holmgren *et al.*, 1989; Kaper, 1989).

### B. *Salmonella typhimurium*

*Salmonella typhimurium* infection in mice is analogous to *Salmonella typhi* infection (typhoid fever) in humans. Both cause lethal systemic disease by invading the intestinal mu-

cosa via the M cells of Peyer's patches and also via enterocytes (Takeuchi, 1975; Hohmann *et al.*, 1978; Kohbata, 1986) and then spreading via the bloodstream to the liver, spleen, and other organs. We used this model to test whether secretory IgA alone can prevent infection of the mucosa by an invasive organism and hence prevent systemic disease (Michetti *et al.*, 1992). Hybridomas were generated after oral immunization of BALB/c mice with attenuated mutant strains of *S. typhimurium* and 48 stable IgA-producing cell lines were obtained. One of these, called Sal 4, produced monoclonal dimeric IgA directed against a surface carbohydrate epitope present on wild-type organisms.

Sal 4 IgA was tested for protection in adult mice using the hybridoma backpack tumor method (Michetti *et al.*, 1992). As control, a *S. typhimurium* mutant was identified and characterized that lacked the epitope and "escaped" IgA-mediated aggregation *in vitro*, but was nevertheless fully virulent. Backpack tumor-bearing mice challenged with wild-type organisms were protected against systemic disease, whereas those challenged with the "escape" mutant were infected consistently. When using this method with invasive organisms, however, recall that abnormally high levels of specific IgA are present in the blood and tissues of tumor-bearing mice that might provide protection after invasion has occurred. Mice with Sal 4 tumors, however, were not protected against intraperitoneal challenge with *S. typhimurium*. Further, tumor-bearing mice showed a dramatic decrease in *S. typhimurium* recovered from Peyer's patch mucosa. Thus, secreted monoclonal IgA, not the circulating antibody, provided the protection observed. These experiments confirm that SIgA protects by preventing access of organisms to the mucosal surface.

### C. Quantitative Aspects of IgA Protection

New approaches such as monoclonal IgA antibodies *in vitro* and a novel "wick" method for sampling of undiluted fluids from mucosal surfaces (Haneberg *et al.*, in press) can now be used to estimate the concentrations of IgA required to protect mucosal surfaces *in vivo*. For example, 4-5 dimeric IgA molecules per cholera holotoxin, or one antibody dimer per B subunit, were required to protect cultured monolayers of T84 enterocytes against toxin-induced chloride secretion (Apter *et al.*, 1991). However, approximately 500,000 specific monoclonal IgA molecules per bacterium were required to protect MDCK cell monolayers against *Salmonella typhimurium* (Michetti *et al.*, 1992). Specific IgA concentrations attained *in vivo* may also be in the  $\mu\text{g}$  range. Undiluted mucous secretions harvested by wicks directly from the surface of the small intestinal mucosa of cholera toxin-immunized adult mice contained up to 80  $\mu\text{g}/\text{ml}$  of specific anti-cholera toxin IgA. In mice bearing IgA hybridoma tumors, 10 to 15  $\mu\text{g}/\text{ml}$  of monoclonal IgA antibody was measured in the same secretions. Lower IgA concentrations could be protective *in vivo* when nonspecific protection mechanisms such as mucus and peristaltic clearance are also at play.

## V. STRATEGIES FOR PRODUCTION OF ENGINEERED SECRETORY IgA

In the studies described earlier, monoclonal IgA was administered passively to mucosal surfaces or delivered into secretions of BALB/c mice from hybridoma backpack tumors. The tumor method allows identification of protective antibodies that might be used for passive protection in other species. If IgA antibodies are to be used for this purpose, they should be most effective if secretory component is attached to the antibody, to confer protease resistance.

### A. Cloning of the Polymeric Immunoglobulin Receptor and Secretory Component

During normal secretion of dimeric or polymeric IgA, SC is added during receptor-mediated transepithelial transport across mucosal and glandular tissue (Kraehenbuhl and Neutra, 1992a). SC corresponds to the five immunoglobulin-like domains of the polymeric immunoglobulin receptor, and is generated by proteolytic cleavage of the receptor either during transport or at the luminal epithelial cell surface (Mostov *et al.*, 1984; Schaerer *et al.*, 1990). This receptor has been cloned and its primary sequence established in rabbit (Mostov *et al.*, 1984; Schaerer *et al.*, 1990), rat (Banting *et al.*, 1989), and human (Krajčič *et al.*, 1989). IgA binds to the outermost Ig-like domain of the receptor (Frutiger *et al.*, 1986). After cleavage of the receptor, a disulfide bond is formed between cysteine residues on the fifth domain of SC and on the Fc portion of one of the IgA monomers. Domains 2, 3, and 4 of SC do not participate in binding but are required to position the cysteine residues involved in disulfide bonds (Solari *et al.*, 1985). A three-dimensional molecular model of the Ig-like domains of SC has been derived from the SC sequence, and from the crystal structure of the immunoglobulin  $V_{\kappa}$  light chain and the first immunoglobulin-like domain of CD4. The IgA binding site is situated on the first 30 amino acids of domain 1, and corresponds to the first  $\beta$  strand and the loop situated between the first and second  $\beta$  strands (Bakos *et al.*, 1991). In CD4, the analogous loop is involved both in major histocompatibility complex (MHC) Class II interaction and in binding of HIV gp120.

Transfection of several cell types with the cDNA encoding the pIg receptor has resulted in production of membrane-bound receptor and cleaved free SC that can recognize dimeric IgA. These cells include fibroblasts (Dietcher *et al.*, 1986), myeloma cells (P. Michetti and J. P. Kraehenbuhl, unpublished results), epithelial cells including MDCK (Casanova *et al.*, 1990; Hirt *et al.*, 1992, 1993), and mammary epithelial cells (Schaerer *et al.*, 1990). In all cases, the receptor was cleaved to produce SC that was released into the medium; in the case of epithelial cells, cleavage and release was polarized as in normal epithelia.

### B. Methods for Addition of SC to Monoclonal IgA

Three approaches have been developed in our laboratories to generate complexes of recombinant SC and monoclonal

IgA: coculture of epithelial monolayers and IgA hybridoma cells, transfection of hybridoma cells with cDNA encoding SC, and mixing of recombinant SC with IgA *in vitro*. All three strategies require the insertion of SC cDNA into efficient expression vectors.

The coculture method essentially replicates normal epithelial transport *in vivo*. Epithelial cells such as MDCK cells have been transfected by us and others with rabbit or human pIg receptor cDNA (Casanova *et al.*, 1990). We used an inducible expression vector that contains a kidney-specific MTV promoter and a glucocorticoid-responsive element (Hirt *et al.*, 1992). Stable transfected epithelial cells were grown on permeable substrates (Transwell filter units) to confluency, and pIg receptor expression was induced. We and others have shown that trafficking of the receptor in the MDCK cell system reflects the behavior observed in normal intestinal epithelial cells (Casanova *et al.*, 1990). When these epithelial monolayers were cultured with IgA-producing hybridoma cells embedded in a collagen gel in the lower chamber of the Transwell device, IgA antibodies were transported efficiently and recovered on the apical side, associated both covalently and noncovalently with SC (Hirt *et al.*, 1993). Although this system produced only 0.1–0.2  $\mu\text{g}$  SIgA per  $5 \times 10^6$  MDCK cells per 24 hr, it provided a source of pure monoclonal SIgA assembled in the normal physiological manner for the first time.

We also have shown that SC cDNA can be introduced into myeloma cells and expressed under the influence of a  $\mu$  enhancer. This result led to a second approach for production of engineered SIgA in which IgA-producing hybridoma cells were transfected with the cDNA encoding SC. In this case, the cDNA was inserted into vector containing a  $\mu$  enhancer element and an SV40 promoter. Although one might expect that expression of recombinant SC in hybridoma cells might impair normal IgA assembly, in fact large amounts of complexes containing both SC and IgA were produced by the transfected cells. Preliminary experiments indicate that these molecules exhibit higher resistance to proteases *in vitro* than does IgA produced by nontransfected hybridoma cells. This system might prove to be a valid one for production of engineered SIgA, but whether the assembly of SC and IgA is exactly analogous to that of normal SIgA produced *in vivo* remains to be established.

The third approach may prove to be less complex and more practical, and involves *in vitro* assembly of recombinant SC and monoclonal IgA dimers produced separately by hybridoma cells and one of several transfected cell lines. Although transfected myeloma cells and other cell types can produce free SC, we have attempted to increase the efficiency of SC production by inserting cDNA into the vaccinia virus genome using, as vector, a plasmid containing an efficient vaccinia promoter flanked by thymidine kinase sequences required for homologous recombination. Significant amounts of SC were recovered in the supernatant of infected HeLa cells in suspension and in CV-1 anchorage-dependent cells. Recombinant SC produced in this system binds noncovalently to monoclonal IgA dimers produced by hybridoma cells. The engineered SIgA molecules produced through these three procedures now must be tested *in vivo* and *in vitro*

to assess their stability as well as their protective properties.

## VI. CONCLUSIONS

Monoclonal IgA antibodies may be used in the future to passively protect immunologically naive children and immunocompromised individuals against mucosal infections. The monoclonal antibody technology reviewed in this chapter could also contribute important information for the design of novel mucosal vaccines. Protective epitopes on pathogenic microorganisms identified using monoclonal IgA antibodies could be subsequently inserted into vaccine vehicles that are transported into organized mucosal lymphoid tissues. In addition, the use of monoclonal IgAs *in vitro* as well as *in vivo* will serve to better define the role(s) of secretory antibodies in preventing adherence and invasion of mucosal tissues by pathogens.

### Acknowledgments

We thank the current and former members of our laboratory who contributed to the work discussed here: R. Weltzin, L. Winner, J. Mack, P. Michetti, H. Amerongen, W. Lencer, F. Apter, R. Hirt, and E. Schaefer. The collaboration of J. Mekalanos, M. Mahan, and J. Schlauch is gratefully acknowledged.

# Gut-Associated Lymphoid Tissue

Thomas T. MacDonald · Jo Spencer

## I. INTRODUCTION

The mucosal immune system consists of a series of coordinated and specialized lymphoid tissues with the complex task of protecting the most vulnerable of the surfaces of the body that interact with the external environment. The gut associated tissues (Peyer's patches, appendix, colonic and cecal patches, isolated lymphoid aggregates) in conjunction with mesenteric lymph nodes and the lymphoid elements of gut epithelium and lamina propria account for the bulk of the body's lymphoid mass. In comparison, the contribution of other secondary lymphoid organs such as the spleen and other lymph nodes is minor.

The organized lymphoid structures of the gastrointestinal tract have anatomical features in common that distinguish them from other secondary lymphoid tissues. The most obvious of these common features is the lack of a defined capsule or afferent lymphatics and the presence of a specialized covering epithelium (follicle-associated epithelium, FAE) which facilitates the transmission of antigen from the gut lumen. In this chapter, the term gut-associated lymphoid tissue (GALT) is used to describe any organized aggregate of lymphoid tissue with a specialized FAE. Large numbers of lymphoid/myeloid cells are also present in the mucosa between the follicular structures in the epithelium and lamina propria; these are considered independently. The possible role of the epithelium itself in mucosal immunology is discussed as well.

## II. STRUCTURE AND CELLULAR COMPOSITION OF ORGANIZED GUT-ASSOCIATED LYMPHOID TISSUE IN HUMANS

### A. Stomach

The normal stomach mucosa is devoid of organized lymphoid tissue and lymphoid/myeloid cells are sparse in the lamina propria. A scattering of T cells is seen in the lamina propria; a few are found in the epithelium. In the lamina propria, IgA plasma cells predominate over IgM and IgG cells. In chronic gastritis, plasma cells of all isotypes increase, but the increase in IgG cells is especially profound (Brandtzaeg, 1987). An increase in epithelial T cells is seen also

(Kazi *et al.*, 1989). A striking feature of the stomach is the acquisition of organized lymphoid aggregates in association with *Helicobacter pylori* infection (Figure 1). In children, this aggregation is especially striking and leads to antral nodularity that is visible at gastroscopy (Wyatt and Rathbone, 1988; Hassall and Dimmick, 1991). Whether this acquired lymphoid tissue functionally resembles Peyer's patches, has an M-cell containing FAE, and is capable of generating a secretory IgA response to gastric antigens remains to be established. B cells have been identified in the gastric epithelium close to follicles in *H. pylori* gastritis (Wotherspoon *et al.*, 1991).

### B. Peyer's Patches

The organized lymphoid tissue of the small intestine was described first by de Peyer in 1667. Structurally, Peyer's patches are organized areas of lymphoid tissue in the mucosa of the small bowel. These patches usually contain follicle centers and well-defined cellular zonation (Figure 2). These areas are overlain by a specialized lymphoepithelium without crypts or villi.

The epithelial cells overlying the follicle are derived from crypts of Lieberkuhn adjacent to the follicles. Follicle-associated epithelium is different from columnar villus epithelium because it is cuboidal, contains few goblet cells, and does not contain secretory component (Bjerke and Brandtzaeg, 1988). In addition, specialized "M" cells, also derived from adjacent crypts (Bye *et al.*, 1984), so called because they have microfolds rather than microvilli on their surface, are found (Owen and Jones, 1974). M cells have a number of morphological and functional specializations—attenuated processes to adjacent cells and very close association with lymphocytes. Clusters of CD3<sup>+</sup> T cells lie next to M cells in the epithelium, which can be identified by their lack of brush border alkaline phosphatase (Bjerke *et al.*, 1988). Significant numbers of CD4<sup>+</sup> T cells are found in follicle epithelium compared with villus epithelium. M cells are deficient in cytoplasmic acid phosphatase and microvillus-associated alkaline phosphatase (Owen *et al.*, 1986). These cells are also probably HLA-DR<sup>-</sup> (Bjerke and Brandtzaeg, 1988), so they are unlikely to play a role in antigen presentation but are more likely a portal of entry for some types of antigen into the dome area of the follicle. This role has been clearly shown for reovirus in mice, which only adheres to and penetrates

**Figure 1** Acquired lymphoid tissue in the stomach of a patient with *Helicobacter pylori* gastritis. Note the large reactive follicle center. Hematoxylin and eosin stain (H&E),  $\times 100$ .

**Figure 2** Histological appearance of Peyer's patch in human terminal ileum. H&E,  $\times 27$ .

the M cells of the FAE (Wolf *et al.*, 1981); poliovirus (Sicinski *et al.*, 1990); and horseradish peroxidase, which also is taken up preferentially by M cells (Owen, 1977).

At birth, approximately 100 Peyer's patches with five follicles or more exist in human small intestine; the majority of these Peyer's patches are found in the distal small intestine (Cornes, 1965a). The number of Peyer's patches increases to 225–300 in the whole small intestine by late adolescence and then decreases with increasing age, so the small intestine from 90-yr-old individuals has roughly the same number of Peyer's patches as at birth (Cornes, 1965b). The assumption by Cornes that five or more follicles are necessary before a lymphoepithelial structure can be called a Peyer's patch is arbitrary; to categorize even a single nodule as a Peyer's patch is reasonable provided FAE is present. In normal intestine, all organized mucosal follicles can be shown to have FAE, if the tissue is properly oriented for sectioning. Many Peyer's patches with one to four follicles are evident in small intestine, both macroscopically and microscopically; Cornes' estimates, although useful for comparative studies, seriously underestimate the amount of organized lymphoid tissue in the human gut.

### 1. Morphological and Immunohistochemical Characteristics of Human Peyer's Patches

The most prominent feature of Peyer's patches is the follicle center, containing centrocytes and centroblasts. The follicle center is surrounded by a mantle of small lymphocytes that merge into the mixed-cell zone of the dome. The dome area also contains plasma cells, dendritic cells, macrophages, and small cells with cleaved nuclei (centrocyte-like cells) that infiltrate the overlying epithelium. These centrocyte-like cells can be identified immunohistochemically as B cells in frozen sections (Spencer *et al.*, 1986b). B cells are rarely seen in villus or crypt epithelium, if at all.

### 2. T-Cell Populations in Peyer's Patches

Immunohistochemical staining of Peyer's patches with anti-CD3 monoclonal antibodies shows T cells to be present in the greatest density in the areas surrounding the high endothelial venules (HEV; Figure 3). Interleukin 2 (IL-2) receptor positive T cells are also present in this area. T cells are also present surrounding the follicle, in the mixed-cell zone in the dome, and in the lymphoepithelium (Spencer *et al.*, 1986b). In humans, in contrast to mice, the T-cell zone extends between the follicle center and the muscularis mucosa. Occasional T cells are seen in the follicle center. Most of the T cells are CD4<sup>+</sup>.

### 3. B Cells and Plasma Cells in Peyer's Patches

Human Peyer's patches contain large numbers of B cells (Figure 4). The narrow mantle zone surrounding the follicle center is composed of cells expressing surface IgM or IgD (Figure 5). The B cells that surround the mantle zone, are present in the mixed-cell zone of the dome, and infiltrate the epithelium, do not express IgD but do express sIgM or sIgA (Spencer *et al.*, 1986b). A major difference between rodent and human Peyer's patches is that, in humans, cells with

**Figure 3** Immunohistochemical localization of CD3<sup>+</sup> cells in human Peyer's patch. Most T cells are in the interfollicular zones. Immunoperoxidase,  $\times 26$ .

surface IgD are restricted to a narrow zone around the follicle center whereas, in rats, the majority of the B cells surrounding the follicle centers, including those in the dome and dome epithelium, express sIgM and sIgD (Spencer *et al.*, 1986c). Germinal center formation is not seen in Peyer's patches of the fetus and only occurs after antigenic exposure at birth (Bridges *et al.*, 1959).

Most of the cells with abundant cytoplasmic immunoglobulin are in the dome area in human Peyer's patches. Most contain IgA with fewer cIgM cells (Spencer *et al.*, 1986b). Some workers have reported that cIgG plasma cells are as abundant as cIgA cells in the dome (Bjerke and Brandtzaeg, 1986). Cells with cIgA also exist in the T-cell zone surrounding the HEV, but the dense accumulation of IgA-containing immunoblasts around the HEV in rodents is not seen in humans (Spencer *et al.*, 1986c).

#### 4. Macrophages and Accessory Cells in Peyer's Patches

In humans, B cells, activated T cells, dendritic cells, follicular dendritic cells, and macrophages express Class II mole-

**Figure 4** Immunohistochemical localization of B cells (CD20<sup>+</sup>) in human Peyer's patch. Immunoperoxidase,  $\times 25$ .

cules necessary for antigen presentation to CD4<sup>+</sup> T cells. All these cell types are present in normal Peyer's patches. Numerous nonlymphoid HLA-DR<sup>+</sup> cells with cytoplasmic processes are present in the dome area of human Peyer's patches and in the T-cell zones. The HLA-DR<sup>+</sup> cells in the dome do not stain with antimacrophage markers such as RFD7 or lysozyme (although these cells are abundant in adjacent lamina propria), but do stain with S-100 (Spencer *et al.*, 1986b). These cells are probably dendritic cells but the HLA-DR<sup>+</sup> cells between the follicles in the T-cell zones are probably interdigitating cells. The dome epithelium itself is also HLA-DR<sup>+</sup> (Spencer *et al.*, 1986a) and also may be capable of presenting antigen to the numerous lymphoid cells in the epithelium. The presence of dendritic cells in the mixed-cell zone of the dome, immediately underlying the M cells, which are Class II<sup>-</sup>, suggests that in Peyer's patches most antigen presentation takes place in the dome region.

### C. Organized Lymphoid Tissue of the Colon

Organized lymphoid tissue in human colon was described first by Dukes and Bussey (1926), who counted the number of single lymphoid follicles in human colon of different ages. These investigators showed in children, eight follicles per square centimeter of colonic mucosa, which decrease to three per square centimeter in older persons. Aggregates of follicles akin to those seen in the multifollicular Peyer's patches in the small bowel are not seen in human colon. The bulk of the lymphoid tissue in colonic lymphoid follicles lies below the muscularis mucosa, the follicles producing points of discontinuity in the latter (O'Leary and Sweeney, 1986). Unless colonic lymphoid tissue is oriented properly, it may appear as though it has no FAE. Serial sections, however, of reoriented blocks invariably reveals FAE (Figure 6). Normally, only about 1% of colonic follicles contain a germinal center, but a characteristic of Crohn's disease of the colon is that the percentage of lymphoid follicles containing a germinal center is increased dramatically (O'Leary and Sweeney, 1986). In addition, numerous ectopic lymphoid follicles occur within the inflamed mucosa. Aphthous ulceration overlying colonic lymphoid follicles is the earliest sign of Crohn's disease of the colon (Rickert and Carter, 1980). Colonic lymphoid follicles also have a dome epithelium with M cells, similar in many regards to the specialized lymphoepithelium overlying Peyer's patches, although, in proportion to the mass of lymphoid tissue, colonic FAE is less than that of Peyer's patches (Jacob *et al.*, 1987). The number of follicles is greater in the rectum than in the colon, and FAE of rectal follicles contains more M cells than FAE in the proximal colon.

### D. Appendix

The human appendix is a blind sac, 5–8 cm long, extending from the cecum near the ileocecal junction. The most striking feature of the appendix is the presence of numerous lymphoid nodules separated by regions of lamina propria, into which the glandular crypts penetrate. The types of cells and the zonal arrangement are very similar to those of human Peyer's

**Figure 5** Mantle and dome regions of a human Peyer's patch. (A) Stained with CD20, B cells are seen in the follicle, mantle zone, and extending into the dome epithelium. (B) Stained with anti-IgD, the mantle zone is seen to be strongly IgD<sup>+</sup>, but the follicle center cells and most of those in the dome are IgD<sup>-</sup>. Immunoperoxidase,  $\times 100$ .

patches. The most prominent feature of the lymphoid nodules is the reactive follicle center, surrounded by a narrow mantle of cells that merges with the mixed-cell zone below the epithelium. The mantle and mixed-cell zone contain CD4<sup>+</sup> T cells but are mostly IgM<sup>+</sup>IgD<sup>-</sup> B cells (Spencer *et al.*, 1985). The FAE that contains T and B cells is often HLA-DR<sup>+</sup>. The T-cell zone lies mostly between the follicle center and the muscularis mucosa (Figure 7). Lysozyme-containing macrophages are uncommon in the dome region; most of the HLA-DR<sup>+</sup> cells with cytoplasmic processes stain with S-100 and are probably dendritic cells (Spencer *et al.*, 1985). S-100<sup>+</sup> cells occasionally can be seen in the epithelium.

IgG-producing plasma cells predominate in the region immediately adjacent to the follicles and in the dome, but the majority of plasma cells in the lamina propria between the follicles are IgA producing (Bjerke *et al.*, 1986).

### III. INTESTINAL MUCOSA

#### A. Gut Epithelium as a Lymphoid Organ

The mucosa between the follicles makes up most of the mass of the intestine. Extensive lymphoid/myeloid elements are found in the connective tissue of the lamina propria; numerous lymphocytes (mostly T cells but never B cells, macrophages, or plasma cells) are found in the gut epithelium. Small bowel villus enterocytes also express HLA-DR (Scott *et al.*, 1980). Thus, both the gut epithelium and the lamina propria may be sites at which mucosal immune responses may be initiated.

#### 1. Class II Gene Expression in the Epithelium

The expression of Class II major histocompatibility complex (MHC) products on gut epithelium was seen first in the

**Figure 6** Colonic lymphoid follicle. Arrow shows the small follicle-associated epithelium (FAE). H&E,  $\times 100$ .

guinea pig (Wiman *et al.*, 1978) and later in human small intestine (Figure 8; Scott *et al.*, 1980). In humans, normal large intestine and stomach epithelium are HLA-DR<sup>-</sup> (Selby *et al.*, 1983b; Spencer *et al.*, 1986d), as are crypt epithelial cells. Peyer's patch epithelium is also HLA-DR<sup>+</sup> (Spencer *et al.*, 1986a), although in the rat it appears to be HLA-DR<sup>-</sup> (Mayrhofer *et al.*, 1983). HLA-DR expression in the human fetal gut epithelium first appears at 19–20 weeks gestation (MacDonald *et al.*, 1988). In humans, normal small intestinal epithelial cells are HLA-DP<sup>-</sup> and -DQ<sup>-</sup> (Scott *et al.*, 1987).

Epithelial HLA-DR expression in humans is increased in chronic inflammatory bowel disease (Selby *et al.*, 1983b), celiac disease (Arato *et al.*, 1987), gastritis (Spencer *et al.*, 1986d), and autoimmune enteropathy (Mirakian *et al.*, 1986). In untreated celiac disease expression of HLA-DP and -DQ on the surface epithelial cells is also common in some patients (Scott *et al.*, 1987). In patients with ulcerative colitis in whom intestinal inflammation has been reduced by steroids, the epithelium becomes HLA-DR<sup>-</sup> (Poulsen *et al.*, 1986). Similar

changes in Class II expression are seen in rat intestinal epithelium during small intestinal inflammation caused by *Trichinella spiralis* infection and graft-versus-host disease (Mason *et al.*, 1981; Barclay and Mason, 1982).

Interferon gamma (IFN $\gamma$ ) can increase HLA-DR expression on human transformed intestinal epithelial cell lines and on rat epithelial cell lines (Cerf-Bensussan *et al.*, 1984; Sollid *et al.*, 1987). Activation of lamina propria T cells in explants of human small intestine with mitogens *in vitro* results in IFN $\gamma$  production and an increase in HLA-DR expression by crypt epithelial cells (MacDonald *et al.*, 1988). Thus good, but circumstantial, evidence exists that increased epithelial HLA-DR expression during inflammation is caused by local production of IFN $\gamma$  by activated mucosal T cells. Whether the increased HLA-DR expression is of any pathogenic significance or is merely an epiphenomenon is unknown. Indeed, we know very little about the control of gene expression in intestinal epithelial cells in normal and pathological conditions. The increased HLA-DR expression by enterocytes in

**Figure 7** T cells in human appendix. Immunoperoxidase with anti-CD3,  $\times 100$ .

**Figure 8** HLA-DR expression in normal human small intestine. The epithelium is strongly positive, as are many cells in the lamina propria. Immunoperoxidase,  $\times 100$ .

inflammation is not the only change, since increased expression of secretory component on villus cells also occurs in celiac disease (Scott *et al.*, 1981).

## 2. T-Cell Populations of the Gut

### Epithelium—Intraepithelial Lymphocytes

If epithelial cells can present enteric antigens, the most likely cells to be stimulated will be intraepithelial lymphocytes (IEL), situated basally above the basement membrane (Figure 9). The majority of IELs in humans use the  $\alpha\beta$  T cell receptor (TcR) (Brandtzaeg *et al.*, 1989). These cells are unusual because oligoclonal expansion of certain V $\beta$  genes appears to occur in healthy individuals (Balk *et al.*, 1991; Spencer *et al.*, 1991b). Only about 10% of IELs in healthy individuals use the  $\gamma\delta$  TcR (Groh *et al.*, 1989; Jarry *et al.*, 1990), and the function of these cells in humans is still unclear. An important difference between blood  $\gamma\delta$  TcR<sup>+</sup> T cells and those in the gut epithelium is that, whereas most of these cells in the blood use the V $\delta 2$  gene product, those in the gut use the V $\delta 1$  gene product (Spencer *et al.*, 1989; Halstensen *et al.*, 1989). Differences also exist in CD45 expression between epithelial  $\alpha\beta$  TcR<sup>+</sup> and  $\gamma\delta$  TcR<sup>+</sup> T cells. Only about half the  $\alpha\beta$  TcR<sup>+</sup> IELs are CD45R0<sup>+</sup>, whereas the majority of the  $\gamma\delta$  TcR<sup>+</sup> IELs are CD45R0<sup>+</sup> (Halstensen *et al.*, 1990).

The distribution of cells expressing different forms of the TcR has been examined in disease states.  $\gamma\delta$  TcR<sup>+</sup> IELs are not increased in inflammatory bowel disease (Fukushima *et*

*al.*, 1991), but are increased dramatically in untreated celiac disease (Spencer *et al.*, 1989; Halstensen *et al.*, 1989). This increase, however, is not specific for celiac disease since, in severe cases of cow milk sensitive enteropathy, the most important differential diagnosis of celiac disease in children,  $\gamma\delta$  TcR<sup>+</sup> T cells also are raised in number in the epithelium (Spencer *et al.*, 1991a).

In untreated celiac disease, the number of  $\alpha\beta$  TcR<sup>+</sup> IELs coexpressing CD45R0 increases to 75%, whereas the number

**Figure 9** Intraepithelial lymphocytes in human small intestine. Most lie basally within the epithelium. H & E,  $\times 64$ .

of  $\gamma\delta$  TcR<sup>+</sup> IELs coexpressing CD45RO actually decreases to 59% (Halstensen *et al.*, 1990).

### 3. Function of Class II Molecules on Epithelial Cells

That normal small intestinal enterocytes could present nominal antigen (ovalbumin) to antigen-primed T cells was demonstrated first in the rat (Bland and Warren, 1986a). Somewhat surprisingly, the cells induced to proliferate were CD8<sup>+</sup> and were capable of antigen-specific suppressor activity (Bland and Warren, 1986b). In humans, isolated intestinal epithelial cells can act as stimulators in the mixed lymphocyte reaction (MLR) and also can present the antigen tetanus toxoid to syngeneic peripheral blood T cells (Mayer and Schlien, 1987). The cells responding to allo-determinants on epithelial cells in the MLR were CD8<sup>+</sup>, which classically would be expected to respond to Class I MHC differences. However the proliferation of CD8<sup>+</sup> cells in the MLR was inhibited by anti-Class II antisera. CD8<sup>+</sup> cells activated by epithelial cells in the MLR were potent suppressors of polyclonal B-cell proliferation. To our knowledge, no data are currently available on antigen presentation by enterocytes to IELs, so these cells may respond differently.

The functional consequences of increased epithelial Class II expression for mucosal immunity are unclear. In humans, enterocytes from patients with inflammatory bowel disease (IBD) preferentially activate allogeneic CD4<sup>+</sup> lymphocytes with profound helper activity, whereas enterocytes from control patients activate allogeneic CD8<sup>+</sup> lymphocytes with suppressor activity (Mayer and Eisenhardt, 1990). Puzzlingly, enterocytes from patients with IBD have this property regardless of whether or not the bowel is inflamed, indicating that an inherent function of their epithelial cells rather than increased Class II expression is responsible for this phenomenon. In mice, increased epithelial Class II expression (induced by systemic administration of IFN $\gamma$ ) increases the antigen-presenting capacity of enterocytes and also renders mice less susceptible to oral tolerance (Zhang and Michael, 1990). These data might suggest that increased epithelial Class II expression leads to sensitization to enteric antigens and therefore might play a role in intestinal inflammation. The nature of the restriction element for T cells in the gut epithelium, and the role of MHC products in antigen presentation in the gut, is an area of great interest since gut epithelium in humans is among the few sites at which the nonclassical MHC molecule CD1d (Blumberg *et al.*, 1991) is expressed.

#### B. Intestinal Lamina Propria

The lamina propria is the layer of connective tissue between the epithelium and the muscularis mucosa. This layer is made up of smooth muscle cells, fibroblasts, lymphatics, and blood vessels, and makes up the villus core over which the absorptive epithelial cells migrate from the crypts to the villus tips. The most striking feature of adult human large and small intestinal lamina propria is the infiltrate of lymphoid/myeloid cells. The large numbers of macrophages, dendritic cells, and T cells in the lamina propria make it likely that antigen crossing the epithelium may be processed and pre-

sented to lamina propria CD4<sup>+</sup> T cells. These cells could provide B cell help, as well as function in mucosal cell-mediated immunity.

### 1. Plasma Cells in the Lamina Propria

As first observed almost 25 years ago, the major plasma cell isotype and, hence, the major immunoglobulin isotype in the intestinal secretions is IgA (Tomasi *et al.*, 1965; Crabbe and Heremans, 1966). IgA plasma cells make up 30–40% of the mononuclear cells in human intestinal lamina propria and small B cells make up 15–45% of the cells (MacDonald *et al.*, 1987). In the jejunum, around 80% of the total plasma cells secrete IgA, around 18% secrete IgM, and only 3% secrete IgG (Crabbe and Heremans, 1966; Brandtzaeg, 1987). These same relative proportions are seen also in the ileum and the colon, although fewer IgM plasma cells exist there than in the proximal small intestine. In addition, immediately adjacent to lymphoid follicles throughout the gut is an increase in IgG plasma cells (Bjerke and Brandtzaeg, 1986). IgD and IgE plasma cells are very uncommon. Most of the plasma cells, regardless of isotype, are found in the region around the crypts. Slightly more than half the IgA plasma cells in the gut secrete IgA2 (Crago *et al.*, 1984), in contrast to tonsils and lymph nodes in which most IgA is IgA1. In addition, the majority of IgA secreted by the plasma cells is dimeric IgA; 100% of IgA2 immunocytes are J-chain positive and 88% of IgA1 immunocytes are J-chain positive (Kett *et al.*, 1988). Dimeric IgA binds specifically via a J-chain–secretory component interaction to the basolateral aspect of crypt epithelial cells and is actively transported into the lumen.

No plasma cells exist in the lamina propria at birth (Perkkio and Savilahti, 1980) although a rapid expansion occurs after birth. Also, a dramatic reduction in IgA plasma cells occurs in the lamina propria of children with defunctioned colostomies (Wijesinha and Steer, 1982).

### 2. T Cells in the Lamina Propria

Immunohistochemical staining reveals that most of the T cells in the lamina propria are CD4<sup>+</sup> (Janossy *et al.*, 1980). Lamina propria CD4<sup>+</sup> T cells differ from blood CD4<sup>+</sup> T cells because the former do not bear the human homology of the murine lymph node homing receptor, Leu8 (Berg *et al.*, 1991). By immunohistochemistry, virtually no lamina propria T cells in normal bowel are CD25<sup>+</sup> (Choy *et al.*, 1990); however, by fluorescence activated cell sorting (FACS) analysis on isolated cells, about 10% are CD25<sup>+</sup> (Schreiber *et al.*, 1991). Equal numbers are CD45RA<sup>+</sup> and CD45RO<sup>+</sup>, indicating that some may be memory cells (Halstensen *et al.*, 1990). Many studies have been done in which functional aspects of lamina propria T cells have been examined. All these studies, however, have utilized a technique in which the final cell preparation is virtually all small mononuclear cells with no plasma cells (Bull and Bookman, 1977). Since cells isolated from the lamina propria would be expected to contain many plasma cells, the so-called lamina propria T cells used in all these studies may, in fact, be derived from blood in the tissues, from the lymphatics, which are filled with lymphocytes in diseased bowel, or from Peyer's patches. The presence of T

cells in the lamina propria is not totally dependent on luminal antigen, since they are present in the fetus (Spencer *et al.*, 1986e,f), but their numbers do increase after birth. The presence of plasma cells in the lamina propria, however, is antigen dependent.

### 3. Macrophages and Dendritic Cells in the Lamina Propria

Most of the HLA-DR<sup>+</sup> cells in the lamina propria of the large and small intestine are macrophages and dendritic cells (Selby *et al.*, 1983a). Note, however, that the distinction between these two cell types in the lamina propria is vague and controversial. Isolating these cells in any great number is virtually impossible, so most studies have used immunohistological or immunochemical techniques to characterize these cells. HLA-DR<sup>+</sup> antigen-presenting cells such as skin Langerhans cells, veiled cells, and interdigitating cells can be recognized by their long cytoplasmic protrusions, few lysosomes, strong presence of membrane ATPase, and weak or absent acid phosphatase activity. Cells with these characteristics cannot be isolated from normal human colon or ileum but can be isolated readily from Crohn's disease tissue (Wilders *et al.*, 1984).

The relative proportions of dendritic type cells to phagocytic type cells in human gut is unclear. Wilders *et al.* (1984) showed that, at the tops of the villi in normal intestine, a population of HLA-DR<sup>+</sup>, strongly acid phosphatase positive cells exists. These cells are probably phagocytic macrophages identical to the population of 25F9<sup>+</sup> cells (a marker of mature macrophages) also identified in human small intestine (Hume *et al.*, 1987). Wilders *et al.* (1984) also reported that HLA-DR<sup>+</sup>, weakly acid phosphatase-positive cells were sparse in normal intestine but were more abundant in Crohn's bowel, throughout the full mucosal thickness. In contrast, Selby *et al.* (1983a) reported that, in the normal human small intestine, 80–90% of the HLA-DR<sup>+</sup> histiocytes were weakly acid phosphatase-positive, weakly nonspecific esterase-positive, and strongly membrane ATPase-positive, suggesting that these cells are dendritic cells. In normal colon, Selby also reported that most of the HLA-DR<sup>+</sup> cells were strongly acid phosphatase- and esterase-positive and were weakly ATPase-positive. This work indicates that, in the small bowel, most of the HLA-DR<sup>+</sup> accessory cells are antigen-presenting cells, whereas in the large bowel most are phagocytic.

### 4. Changes in Lamina Propria Cell Populations in Disease States

Many studies have been done on the changes in the lamina propria cellular infiltrate in disease states. Reviewing these studies in detail is beyond the scope of this chapter. In general, these studies have been uninformative with respect to understanding gastrointestinal disease. In the food-sensitive enteropathies and inflammatory bowel diseases, an increase in lamina propria T cells occurs and CD4<sup>+</sup> cells still predominate. In inflammatory bowel disease, lamina propria CD4<sup>+</sup> cells show increased levels of activation antigens (Choy *et al.*, 1990; Schreiber *et al.*, 1991), and show increased reactivity to

recall microbial antigens (Pirzer *et al.*, 1991). Lamina propria plasma cells of all isotypes also are increased in celiac disease, Crohn's disease, ulcerative colitis, and in the stomach in gastritis (Brandtzaeg, 1987). Several striking features of this condition are worth noting. Adjacent to fissures in Crohn's disease is a dramatic increase in IgG plasma cells (Brandtzaeg, 1987) and, in both ulcerative colitis and Crohn's disease, increased proportions of IgA1 plasma cells are seen (Kett and Brandtzaeg, 1987).

# Alpha Chain Disease and Related Lymphoproliferative Disorders

Jean-Claude Rambaud • Jean-Claude Brouet • Maxime Seligmann

## I. ALPHA CHAIN DISEASE

Heavy chain diseases (HCD) are lymphoproliferative disorders of B cells that are characterized by the production of immunoglobulin (Ig) molecules consisting of incomplete heavy chains devoid of light chains.

Alpha chain disease ( $\alpha$ HCD; Seligmann *et al.*, 1968) is by far the most frequent type of HCD.  $\alpha$ HCD involves primarily the IgA secretory system. The vast majority of patients is affected with the digestive form of  $\alpha$ HCD, which primarily involves the small intestine and the mesenteric lymph nodes.

### A. Pathology

The pathological features of  $\alpha$ HCD are, in most cases, in accordance with their initial description (Rambaud *et al.*, 1968; Galian *et al.*, 1977). Apart from a few cases described in this chapter,  $\alpha$ HCD involves the whole length of the small intestine, except sometimes the terminal ileum, without intervening normal mucosa. Three grades of increasing malignancy can be recognized. At stage A, the cellular infiltrate is localized mainly to the mucosa, with occasional limited infiltration of adjacent submucosa. Villi are more or less shortened and widened; crypts are sparse and atrophic; and lamina propria is infiltrated massively by mature and occasional younger plasma cells (Figure 1). Stage C corresponds to an immunoblastic lymphoma with plasmacytoid features (Figure 2), either forming discrete ulcerated tumor(s) or extensively infiltrating long segments of the small intestine (Figure 3). Stage B is intermediate between A and C. The infiltrate largely invades at least the submucosa; plasma cells are frankly dystrophic and some large immunoblastic or centroblastic-like cells are observed, usually located in the deeper area of the infiltrate and sometimes clustering in small nodules. Occasionally numerous reactive follicles may be observed within mucosa or submucosa at stages A and B (Isaacson *et al.*, 1989; Price, 1990).

Mesenteric lymph nodes usually (but not always at stage A) are involved in the pathological process. According to the cell type of the infiltrate and to the degree of architectural disorganization, three histological stages (A, B, and C) equivalent to those described in the small intestine can be identified. Spreading to other lymph nodes (retroperitoneal, mediastinal, and peripheral lymph nodes), other parts of the

digestive tract (stomach, colon, Waldeyer's ring), and other organs such as liver, spleen, bone marrow, pleura, or central nervous system initially was considered to be very rare, except when enteric lesions were at stage C (Seligmann *et al.*, 1969; Rambaud and Matuchansky, 1973; Reyes *et al.*, 1985; Kumar *et al.*, 1988).

Histological lesions may progress at a given site from stage A to B or from stage B to C, but of utmost importance for proper pretherapeutic staging is the fact that different stages can be found at the same time in different organs or lymph nodes or even at different sites within the same organ.

This overview of  $\alpha$ HCD pathology requires some additions. In very few patients, intestinal lesions apparently spare the duodenum or even the jejunum or, in contrast, are limited to a short segment of the latter (Nemes *et al.*, 1981). Spread of the disease in the digestive tract outside the enteromesenteric area is not so uncommon, even at stage A. This spread usually concerns gastric or colorectal mucosa; in some cases the disease is confined to these organs, sparing the small bowel (Rambaud and Halphen, 1989). In stomach, numerous signet-ring cells can be admixed with plasma cells (Tungekar, 1986). Other rare primary localizations of  $\alpha$ HCD are the respiratory tract (Seligmann and Rambaud, 1978) and the thyroid (Tracy *et al.*, 1984). In a single case, the disease appeared to involve peripheral non-mucosa-associated lymphoid tissue only (Takahashi *et al.*, 1988).

In a few instances, plasma cells synthesizing the  $\alpha$ HCD protein were limited to a continuous band in the superficial part of the intestinal mucosa. The deeper zone was infiltrated by centrocytic-like cells forming lymphoepithelial lesions; the immunohistological study of these cells showed their common clonal origin with plasma cells. In addition, multiple reactive nonneoplastic follicles were present in the mucosa and submucosa. These follicles tended to be more or less penetrated by the centrocytic-like cell infiltrate. This peculiar pattern of  $\alpha$ HCD pathological lesions was observed initially by Galian *et al.* (1977) and Nemes *et al.* (1981), but was reemphasized and better characterized by Isaacson *et al.* (1989). For these authors, these peculiar forms of  $\alpha$ HCD merely reflect the similarity between  $\alpha$ HCD and the Western gastrointestinal lymphomas of the mucosa-associated lymphoid tissue (MALT) type. Indeed, Isaacson *et al.* (1989) and Price (1990) reported the presence, in usual pathological forms of  $\alpha$ HCD at stages A and B, of well-demarcated foci

**Figure 1** Alpha chain disease at stage A. Histological pattern of the jejunal mucosa. A lymphoepithelial lesion is indicated by the arrow. Hematoxylin and eosin (H&E),  $\times 115$ . *Inset*: Detail of the plasma cell infiltrate. H & E,  $\times 950$ .

of centrocytic-like cells centered around crypts and forming characteristic lymphoepithelial lesions (Figure 1).

Few cytogenetic studies have been performed; karyotypic abnormalities involving chromosome 14 have been observed (Gafer *et al.*, 1980), including rearrangements of 14q32 (Berger *et al.*, 1986).

### B. Epidemiology

The age distribution of  $\alpha$ HCD is in sharp contrast with that of multiple myeloma as well as that of intestinal lymphomas occurring in western Europe. The great majority of patients is between 15 and 35 years old, with a slight preponderance in males. The geographical origin of the patients is very peculiar. Table I shows the geographical distribution of 130 cases that had been reported, or diagnosed in our laboratory, prior to 1978. Since then, several hundred cases have been recorded in the same and other countries from Africa, Central and South America, the Indian subcontinent, the Middle East, the Far East, and southern and eastern Europe. Obviously a wide spectrum of racial and ethnic origin exists. Most patients originated from and had been living in areas with a high degree of infestation by intestinal microorganisms. In

**Figure 2** Alpha chain disease at stage C. Histological pattern of the jejunal cellular infiltrate (immunoblastic lymphoma). H & E,  $\times 840$ . *Inset*: Malignant immunoblast. H & E,  $\times 744$ . Reprinted with permission from Navab *et al.* (1978).

addition, many of these patients were of low socioeconomic background and were exposed to conditions of poor hygiene.

These epidemiologic features and the complete remissions achieved at the early stage of the disease by antibiotic treatment alone strongly suggest that environmental factors, providing local and protracted antigenic stimulation, play an important role in the pathogenesis of  $\alpha$ HCD. No specific microorganisms could be found by bacteriological, virological, or parasitological studies (Harzic *et al.*, 1985). The postulated antigenic stimulation by such agent(s) may have occurred many years before the disease became clinically manifest, particularly during infancy. The absence of the Fab region in the  $\alpha$ HCD protein precludes its use for identifying

<sup>b</sup> Respiratory form of the disease.

putative antigenic stimuli. The environmental factors could trigger the clonal proliferation directly or, alternatively, could represent only predisposing factors. In either case, that the plasma cell proliferation resulting from this postulated antigenic stimulation appears to lead, in these patients to the production of an HCD protein rather than of a whole myeloma globulin is remarkable. Indeed, we know of only two patients with the typical clinicopathological pattern of  $\alpha$ HCD in whom a complete monoclonal IgA was found in serum (Chantar *et al.*, 1974; Tangun *et al.*, 1975) whereas, in another patient with the same features, a  $\gamma$ HCD protein was demonstrated in the serum and intestinal cells (Bender *et al.*, 1978). In a few other patients with similar features, the massive small intestinal plasma cell infiltrate was polyclonal with high plasma levels of polymeric IgA (Brandtzaeg and Baklien, 1977; Gilinsky *et al.*, 1985; Colombel *et al.*, 1988).

The association with an underlying immunodeficiency that could be the result of malnutrition, especially in early infancy (Dutz *et al.*, 1971), or of genetic factors is not ruled out. In fact, the role of environmental factors does not exclude the possibility of predisposing genetic factors, although no familial cases have been reported and although the search in Tunisia by the Tufra Group for serum Ig abnormalities in the patient's relatives has been negative, as have HLA typing studies.

### C. Laboratory Diagnosis

#### 1. Serum and Other Fluids

The demonstration, by immunochemical methods, of the presence of Ig  $\alpha$  heavy chains devoid of light chains in the

serum (or jejunal fluid) is mandatory for the diagnosis of  $\alpha$ HCD.

The abnormal Ig chains are not evidenced by serum electrophoresis in nearly half the cases (Seligmann *et al.*, 1979). When detectable by this procedure, the pathological protein rarely, if ever, shows the discrete narrow spike suggestive of a monoclonal Ig abnormality. Instead,  $\alpha$  chains feature a broad band that may extend from the  $\alpha_2$  to the  $\beta_2$  region. This remarkable electrophoretic behavior of  $\alpha$ HCD may be related to the tendency of these chains to polymerize or to their high carbohydrate content (Seligmann *et al.*, 1979).

The identification of the  $\alpha$ HCD proteins therefore relies on serum immunoelectrophoresis, immunoselection, or immunofixation. The pathological protein may escape detection by the first method when its serum concentration is low. Moreover, lack of precipitation of the abnormal protein with anti-light chain antisera may be observed for some monoclonal IgA myeloma proteins (Seligmann *et al.*, 1969). Immunoselection combined with immunoelectrophoresis allows the detection of  $\alpha$ HCD proteins in most cases (Doe *et al.*, 1979). This technique, however, requires rather large amounts of highly selected antisera to  $\kappa$  and  $\lambda$  light chains, capable of precipitating completely all monoclonal and polyclonal Ig molecules. Finally, immunofixation (O'Reilly *et al.*, 1981) is easier to perform, is sensitive, and allows the detection of  $\alpha$ HCD when the level of polyclonal IgA is low or when the migration of the pathological protein extends beyond the  $\beta$  region. All  $\alpha$ HCD proteins appear to belong to the  $\alpha_1$  subclass; no  $\alpha_2$  HCD protein has been found in over 100 studied cases (Seligmann, 1977). Since one-third of the normal secretory IgA molecules belong to the  $\alpha_2$  subclass, this finding is obviously significant, although it remains unexplained.

Of note, other serum Ig abnormalities may be found in  $\alpha$ HCD. Serum levels of normal polyclonal Ig molecules of all classes may be reduced independent of the protein-losing enteropathy. In addition, serum monoclonal IgG were disclosed in four cases of  $\alpha$ HCD.

The  $\alpha$ HCD protein, bound to the secretory piece, is present in significant amounts in the jejunal fluid of patients with the digestive form of  $\alpha$ HCD (Seligmann *et al.*, 1969). The immunochemical techniques used for the detection of  $\alpha$ HCD protein are the same as for serum; however, jejunal fluid must be collected carefully and concentrated to avoid protein degradation. In some patients with the clinicopathological features of  $\alpha$ HCD, the pathological protein can be found in the jejunal fluid but cannot be detected in the serum (Rambaud *et al.*, 1983).

In almost all instances of  $\alpha$ HCD, only minimal amounts of HCD are present in the urine and monoclonal light chains are always absent.

#### 2. Cellular Studies

The study of proliferating plasma cells or immunoblasts by conventional immunofluorescence or immunoperoxidase techniques, on cell suspensions (from lymph nodes or bone marrow) or histological sections, demonstrates the presence of intracytoplasmic  $\alpha$  heavy chains in the absence of light

chains in most cases (Preud'homme *et al.*, 1979). However, exceptions to this pattern do exist since  $\kappa$  light chains were found in the cytoplasm or at the surface of the proliferating plasma cells in three cases of  $\alpha$ HCD (Preud'homme *et al.*, 1979). Immunohistochemical studies permit the detection of the rare cases of nonsecretory  $\alpha$ HCD, in patients with the characteristic clinicopathological pattern but without detectable  $\alpha$ HCD protein in the serum or jejunal fluid (Rambaud *et al.*, 1983; Matuchansky *et al.*, 1989). In one such case, molecular studies identified the mechanism responsible for the absence of secretion (Cogné and Preud'homme, 1990): a deletion had occurred of the polyadenylation site for secretory  $\alpha$ 1 chain mRNA; however, the membrane form of the abnormally short  $\alpha$  heavy chain was produced.

#### D. Structure of the $\alpha$ HCD Protein and Productive $\alpha$ Genes

Most HCD proteins consist primarily of the Fc region and have a normal carboxyl terminal. The missing portion of the heavy chain therefore usually is located within the Fd fragment (Seligmann *et al.*, 1979). Indeed, most  $\alpha$ HCD proteins lack the variable and first constant domains. In four of five  $\alpha$ HCD proteins studied in our laboratory (Seligmann *et al.*, 1979), the sequence started with a valine residue corresponding to position 222 of the  $\alpha$ 1 heavy chain, that is, the first amino acid of the hinge region. In the fifth case, the normal hinge region sequence was preceded by a short stretch of amino acids whose sequence did not belong obviously to Ig-related sequences (Wolfenstein-Todel *et al.*, 1974). Sub amino-terminal sequences of unknown origin also have been found in some cases of  $\gamma$ - and  $\mu$ HCD (Franklin and Frangione, 1975; Seligmann *et al.*, 1979; Barnikol-Watanabe *et al.*, 1984).

Of note, the sequence of  $\alpha$ HCD proteins was difficult to assess because of technical difficulties in the isolation of the pathological protein or because of the existence of a heterogeneous amino-terminal sequence most likely created by limited proteolytic cleavage of the amino-terminal end of the hinge region (Seligmann, 1977). Biosynthesis experiments indicated that HCD proteins are not a mere degradation product of a normal chain, but that truly short heavy chains are synthesized by the cells (Buxbaum and Preud'homme, 1972).

The latter results were confirmed by the nucleotide sequence analysis of the  $\alpha$  mRNA and of the rearranged productive  $\alpha$ 1 genes from invaded mesenteric lymph nodes. In three reported cases (Bentaboulet *et al.*, 1989; Tsapis *et al.*, 1989; Cogné and Preud'homme, 1990) as well as in eight additional patients (Fakhfakh *et al.*, 1992), the  $\alpha$  mRNA was short, lacking the whole  $V_H$  and  $C_{H1}$  segments. A striking additional feature of these  $\alpha$  mRNAs was the presence, at their 5' ends, of a 20- to 80-nucleotide stretch that had no homology with Ig or non-Ig sequences stored in data banks. This sequence of unknown origin was in frame with that of the hinge,  $C_{H2}$ , and  $C_{H3}$   $\alpha$  domains. Therefore, a proteolytic cleavage must take place within the cell since the serum protein usually is devoid of an abnormal amino-terminal sequence. However, such inserted sequences might account for those rare proteins

with such an unusual amino-terminal end (see previous discussion). Biosynthesis studies in one case showed two different  $\alpha$  chains of slightly different molecular masses, which may correspond to the two species of  $\alpha$  chains (Tsapis *et al.*, 1989). Of note, no homology existed between the inserted sequences from different patients (which might have provided a clue about the pathogenesis of  $\alpha$ HCD).

Analysis of the sequence of the productive  $\alpha$ 1 chain genes in three cases indicated that these non-Ig sequences arise by various mechanisms. In two cases, the extra sequence found in the mRNA originated from part of a very long sequence (289 and 360 bp) that replaced the  $V_H$  gene (Tsapis *et al.*, 1989; Cogné and Preud'homme, 1990). In the other case (Bentaboulet *et al.*, 1989), the mRNA insert corresponded to two composite exons from the  $J_H$  region, including a 62-nucleotide insertion of unknown origin. Again, analysis of the inserted sequences at the DNA level yielded no indication of their possible derivation. The lack of a  $C_{H1}$  domain was related to a deletion event affecting the whole  $C_{H1}$  exon in two cases and the 5' end of the  $C_H$  exon in the third case. Analysis of the flanking sequences of these deletions provided no clue about the mechanism underlying this event. Another remarkable feature of these altered  $\alpha$ 1 genes was a high degree of mutation affecting primarily the  $J_H$  region, which retains a low homology (66–90%) with its germ-line counterpart. These alterations within the  $J_H$  region appear to be a common feature of sequenced  $\gamma$ - and  $\alpha$ HCD productive genes (Cogné *et al.*, 1989); these changes result in an unusual splicing, using alternative splice sites and eliminating a large part of the remnant  $V_H$  and  $J_H$  segments. In addition, we sequenced a nonfunctional  $\alpha$ 1 gene implicated in a t(9,14) translocation and found strikingly similar abnormalities, including a high number of mutations and a deletion of the 3' end of a  $V_H$  rearranged gene (Pellet *et al.*, 1990).

Interestingly, the single nucleotide sequence established for a rearranged  $\kappa$  light chain gene in cells from a patient with  $\gamma$ HCD exhibited similar features (Cogné *et al.*, 1988a), indicating that these unusual genetic alterations took place in different genetic loci located on different chromosomes. With respect to  $\alpha$ HCD we observed, in all eight cases studied, the presence of rearranged  $\kappa$  genes and of nonproductive  $\kappa$  mRNA (Fakhfakh *et al.*, 1992).

Overall, the study of nucleic acids in  $\alpha$ HCD as well as in other varieties of HCD has not yet generated comprehensive insights into the pathogenesis of these disorders. The abnormalities are distinct from those of mouse plasmocytoma and bear some similarities to those of cells from some nonsecreting lymphoma cell lines that produce truncated  $\mu$  chains in the absence of light chains (Cogné *et al.*, 1988b).

#### E. Clinical Features

The usual presentation of  $\alpha$ HCD is remarkably uniform; its pattern has not been modified noticeably since its early description (Rambaud *et al.*, 1968; Rambaud and Seligmann, 1976; Gargouri and Amor, 1982). The onset is usually gradual, but may be abrupt. The time from appearance of the first symptom to diagnosis ranges from 1 month to 6 years; an

intermittent clinical course is not rare. Table II gives the frequency of presenting symptoms and signs in two series of patients. In fact, two clinical patterns can be distinguished.

In the majority of patients diagnosed in developed countries of western Europe, the clinical presentation is chronic diarrhea with evidence of malabsorption. However, a profuse watery diarrhea may be observed; water and electrolyte imbalance may result in atypical presentations, such as nephrogenic diabetes insipidus (Economidou *et al.*, 1976). Apart from signs of protein-caloric malnutrition and specific deficiencies, finger clubbing is the single frequent physical finding, present more often than in any other enteric disease.

The second presentation pattern usually follows the neglected or misdiagnosed preceding one, but in rare cases may occur first. This presentation is the result of the occurrence, usually at stage C, of digestive tract tumors or of voluminous abdominal adenomegalies and their complications. Abdominal examination often finds abdominal masses; surgical emergencies may be due to intestinal intussusception or perforation of ulcerated lesions, but rarely to digestive hemorrhage. Pains may simulate acute appendicitis or pancreatitis and are related to lymph node necrosis. Chronic obstruction as a result of stenosing infiltration or masses has been also observed. Pathological study of surgical resection or biopsy is essential for diagnosis.

Some patients, often with this "tumoral" syndrome and usually at stage C, may present with signs of tumoral dissemination to liver, spleen, Waldeyer's ring, peripheral lymph nodes, or bone marrow. The rare isolated gastric localizations of  $\alpha$ HCD are revealed by epigastric pain, vomiting, and often weight loss.

## F. Digestive Investigations

Usual biological investigations confirm the malabsorption syndrome and protein-losing enteropathy (Table III). The frequent increase in alkaline phosphatase initially was considered of intestinal origin, but this symptom later proved to be rare; the source of the enzyme is mainly hepatic. Owing to the proposed etiopathogenesis of  $\alpha$ HCD, results of parasitological (Table III), bacteriological, and virological studies are interesting, although rather disappointing (Harzic *et al.*, 1985). Bacterial colonization of the jejunal lumen is found in the majority of patients, but usually is moderate and anaerobes are absent. D-Glucose and [ $^{14}$ C]glycyl-cholyl breath test are negative. *Giardia lamblia* and isolated cases of infestation by various parasites are present in one-third of patients (Rambaud and Seligmann, 1976). Nevertheless, clinical symptoms and laboratory evidence of malabsorption and plasma protein digestive loss usually improve strikingly after a short course of antibiotic and antiparasitic treatment, without or before any apparent change in the small bowel mucosal lesions (Rambaud *et al.*, 1978). This amelioration must be kept in mind for patient follow-up.

Small intestinal radiographs usually show enlarged duodenal and jejunal folds and a polypoid pattern, with diffusion of lesions to the whole small bowel length. Radiographs also may show stenosis caused by lymph nodes compression or

infiltrating lesions, ulcerations or defects, or internal fistulas (Navab *et al.*, 1978; Matsumoti *et al.*, 1990).

Since  $\alpha$ HCD nearly always affects the duodenum and jejunum, endoscopy with biopsies, using a long-ending view instrument and immunohistochemistry, is a major tool for its diagnosis. In the experience of the Tunisian-French Lymphoma Study Group Tufrali (Halphen *et al.*, 1986), the sensitivity of this method for diagnosis was 0.92, with no false positives. Among the macroscopic patterns, the infiltrative one was the most sensitive (0.8) and specific (0.96) in differentiating so-called Mediterranean lymphoma (see subsequent text) from other small intestinal lesions, but was unable to distinguish between  $\alpha$ HCD and other diseases covered by this imprecise denomination. Ileocoloscopy with systematic biopsies, even in the absence of macroscopic abnormalities, is necessary to ascertain the extent of the disease, even at stage A. Such biopsies are also required for careful stomach examination during upper endoscopy. In the pure gastric localizations of  $\alpha$ HCD, thick, rugae, erosive "gastritis," and some ulcers localized in the antrum have been described (references in Rambaud and Halphen, 1989).

### G. Course and Treatment

The spontaneous course of  $\alpha$ HCD may be relentless or interrupted by periods of clinical improvement often induced by blind antibiotic treatment. The length of the delay between the first symptom and diagnosis does not correlate with the pathological stage of the disease at the time of diagnosis (Rambaud and Halphen, 1989). Death may occur at any stage because of complications (infections, hypoglycemia, surgical emergency) or because of cachexia due to malabsorption and tumor growth. A single case of spontaneous, apparently complete remission, without control small intestinal biopsy, was reported after withdrawal from an unfavorable environment (Sala *et al.*, 1983).

Treatment may prevent the often fatal outcome. The modalities of treatment depend on a precise knowledge of the extent and histological stage of the disease. Because of the frequent asynchrony of the histological lesions between sites, laparotomy according to a precise protocol (Tabbane *et al.*, 1988) is necessary, except in patients displaying stage C peripheral lesions. The follow-up should include a periodic search for  $\alpha$ HCD protein in serum and urine, intestinal absorption tests, small intestinal X-rays, upper esophagogastrroduodenal endoscopy, and ileocoloscopy with multi-level biopsies studied by immunohistochemical techniques.

Our present therapeutic guidelines, drawn from a personal series of 19 patients, Tufrali Group experience (Ben-Ayed *et al.*, 1989), the series of 20 patients published by Martinez and Chantar (1983) and a pool of 40 individual well-studied cases from the literature references in Rambaud and Halphen, 1989) are described here.

Patients with stage A lesions limited to the gut and to mesenteric lymph nodes should be treated first by oral antibiotics, including metronidazole, which also eradicates the frequent infestation by *Giardia lamblia*. Any other parasite should be eradicated as well. Of 28 patients, 39% achieved a

complete clinical, histological, and immunological remission with antibiotic therapy alone, including a case treated without tetracycline. Antibiotics usually have a dramatic effect on the malabsorption syndrome, whether or not a true remission of the disease will be obtained.

The duration of treatment before complete remission was assessed varied from 5 to 36 months; the actual delay for obtaining the remission could have been shorter. Invasion of the submucosa by the plasma cell infiltrate, involvement of mesenteric lymph nodes or other parts of the digestive tract, and the presence of cellular atypias at histological or electron microscope examination do not preclude the efficacy of oral antibiotics. In view of the possible and unpredictable evolution of stage A lesions to overt malignancy, chemotherapy should not be instituted too late in unresponsive patients. When a complete remission of the disease is obtained, maintenance antibiotic therapy does not seem necessary.

At stages B and C, antiparasitic and antibiotic treatments are also useful since they may improve the malabsorption syndrome. Patients with stage B lesions, or with stage A lesions without marked improvement after a 6-month course of antibiotic treatment or a complete remission within 12 months, should be given combination chemotherapy. Again, some patients will not improve, even after salvage chemotherapy. Some of these patients progress to stage C lesions and die, whereas others apparently remain at stage A and remain asymptomatic for long periods of time on tetracycline treatment.

At stage C, patients with disseminated immunoblastic lesions of the small intestine require an intensive chemotherapy regimen to the extent allowed by their nutritional state. When a focal tumor is found, its surgical resection followed by combination chemotherapy including an anthracycline may induce a complete and prolonged remission.

The overall complete remission rate in all Tunisian patients was 52% (64.3% for stages B and C), with a median survival of 67% at 3 years. Relapses, sometimes after a long disease-free interval, may occur after treatment at any stage of the disease. Since most patients are young, those with disseminated stage C lesions that show a good response after four cycles of conventional or salvage chemotherapy could be submitted to autologous bone marrow transplantation (Perrot *et al.*, 1988).

Supportive therapy by intravenous infusion of water, electrolytes, calcium and magnesium salts, blood, or albumin and, in some cases, enteral or total parenteral nutrition is often necessary before laparotomy and during the early period of treatment.

## II. RELATIONSHIP BETWEEN ALPHA CHAIN DISEASE, IMMUNOPROLIFERATIVE SMALL INTESTINAL DISEASE, AND "MEDITERRANEAN" LYMPHOMA

Since the first publications on  $\alpha$ HCD (Rambaud *et al.*, 1968; Seligmann and Rambaud, 1969), the similarity of its epidemiology and clinical pattern with those of "Mediterra-

nean" lymphoma described previously in Israel (Ramot *et al.*, 1965; Eidelman *et al.*, 1966) was stressed; most of these lymphomas were suggested, to be in fact,  $\alpha$ HCD (Seligmann and Rambaud, 1969; Rambaud and Matuchansky, 1973). Because of the frequent absence of adequate immunochemical studies, a World Health Organization (1976) memorandum stated that all "Mediterranean" lymphomas the pathology of which was identical to that of  $\alpha$ HCD, whether or not  $\alpha$ HCD protein was synthesized by proliferating cells, should be named Immunoproliferative Small Intestinal Disease (IPSID). Further experience revealed that most cases of IPSID were, in fact,  $\alpha$ HCD, including rare cases in which the abnormal protein was absent from serum but detected in the gastric (Coulbois *et al.*, 1986) or jejunal (Rambaud *et al.*, 1983) juice or only at a cellular level (Rambaud *et al.*, 1983; Matuchansky *et al.*, 1989). However, in a few similar patients, proliferating cells synthesized other monoclonal Igs or polyclonal IgA (Rambaud and Halphen, 1989).

Does IPSID include all the previously described "Mediterranean" lymphomas? Rambaud *et al.* (1982) reported four young patients, born in countries in which IPSID is observed, with a clinical history and presentation identical to those of this syndrome. However, the pathological lesions, consisting of extensive follicular lymphoid hyperplasia of the small intestine associated in one case with multicentric follicular center cell (or centrocytic-like?) lymphoma, were quite different from those of  $\alpha$ HCD. Immunological studies were unable to disclose  $\alpha$ HCD protein synthesis or primary Ig deficiency. Review of the literature revealed that previously reported cases of this disorder, which should not be confused with multiple lymphomatous polyposis of the gut, had been observed primarily in the same epidemiological context as IPSID.

Thus, one of the goals of the Tunisian–French Intestinal Lymphoma Study Group was to reevaluate prospectively in Tunisia the nosology of Mediterranean lymphoma. All subsequent patients referred to the group with the suspicion of intestinal lymphoma, from 1981 to 1985, were investigated thoroughly. All those who proved to suffer from a small intestinal lymphoma were submitted to detailed immunological investigations, and all but one had a laparotomy. Among the 55 patients, 39% had IPSID and in all of them  $\alpha$ HCD protein synthesis was demonstrated; 46% showed an extensive cellular proliferation infiltrating all or the proximal half of the small intestinal mucosa and submucosa, consisting of benign-appearing follicular lymphoid structures surrounded and more-or-less destroyed by a low-grade malignant lymphoid proliferation consisting of small cleaved cells (Cammoun *et al.*, 1989). Gross tumor foci of usually higher malignancy than the diffuse lesions were found in association with the latter proliferation in nearly 50% of cases (Figure 4). No evidence of production of  $\alpha$ HCD protein was observed in any of these patients. A provisional denomination of "non-IPSID extensive small intestinal lymphoma" (ESIL) was proposed (Rambaud and Halphen, 1989). Finally, 15% patients had a Western type, that is, localized small intestinal lymphoma, associated in three cases with extensive villous atrophy of the mucosa. Note that Tunisian patients with IPSID and those with non-IPSID extensive small in-

# Gastritis and Peptic Ulcer

Bertil Kaijser

## I. INTRODUCTION

The idea that bacteria or immunological factors might play an important role in the pathogenesis of gastritis and ulcus duodeni or ventriculi has attracted researchers for many years. Autoimmunity has been studied, as has the role of eosinophilia. Little attention has been paid to early descriptions of spiral bacteria in human biopsy specimens from gastric mucosa (Freedberg *et al.*, 1940). In 1982, a gram-negative microaerophilic curved rod was cultured successfully by Robert Warren in Perth, Australia, in biopsy specimens from patients with histological signs of gastritis (Warren, 1983). This event was the start of the new perspective of the pathogenesis of gastritis and ulcus, in which bacteria have been accepted to play an important role. The first report was followed by a number of publications confirming the idea.

## II. MICROBIOLOGY

The curved rod that was isolated originally was named *Campylobacter pylori*. Intense scrutiny of its taxonomic features compared with other *Campylobacter* species showed major differences between *C. pylori* and true *Campylobacter* with respect to ultrastructure, cellular fatty acid composition, respiratory quinones, growth characteristics, RNA sequencing, and enzymes. Distinct from most other bacteria and especially other *Campylobacter*, *C. pylori* possesses a potent urease activity, a property that also might have important pathogenic implications. This cell surface enzyme is composed of two subunits of approximately 30 and 60 kDa; the genes that encode this enzyme have been sequenced (Clayton *et al.*, 1990; Dunn *et al.*, 1990). The unique characteristics of the bacterium has motivated formation a new genus; the organism is now called *Helicobacter pylori* (Goodwin *et al.*, 1989).

Bacteria closely related to *H. pylori* have been found in the stomach of primates (Baskerville and Newell, 1988), whereas other *Helicobacter* species such as *H. mustelae* have been isolated in the stomach of ferrets; *H. felis* has been isolated from cats (Lee *et al.*, 1988; Fox *et al.*, 1990).

Curved rods other than *H. pylori* have been found in a few humans with gastritis, but the significance of this result is not clear (Dye *et al.*, 1989).

## III. EPIDEMIOLOGY

Several investigations have shown a relationship between age and prevalence of *H. pylori* in healthy individuals (Dooley *et al.*, 1989). In the age group under 30 years, prevalence is not higher than 10% whereas, in the age group of 50–60 years and older, corresponding figures are more than 60%. Race and socioeconomic circumstances influence the prevalence also (Megraud *et al.*, 1989). In several publications, persons with duodenal ulcer (prevalence of *H. pylori* close to 100%) or gastric ulcer (prevalence of *H. pylori* approximately 80%) clearly have been shown to harbor *H. pylori* significantly more often than age-matched healthy controls (Wyatt, 1989).

The mode of transmission of *H. pylori* is known not in detail. Person-to-person transmission seems likely, since clustering of cases has been reported in families or nursing homes (Drumm *et al.*, 1990). Infection from environmental sources is also possible. The bacteria have not, however, been isolated in environmental sources such as water, food, or domestic animals. They have not been found in stools of humans. Transmission via endoscopes has been suggested, and gastroenteroscopists have been shown to have a higher prevalence than corresponding control individuals (Mitchell *et al.*, 1989).

## IV. PATHOGENESIS

*Helicobacter pylori* clusters around the junctions between cells and never penetrates the cells. The bacteria also may harbor in metaplastic gastric epithelium of the esophagus or duodenum (Steer, 1975; Talley *et al.*, 1988). They are never found in the blood and rarely are found in other parts of the body (de Cothi *et al.*, 1989; Dye *et al.*, 1989). *Helicobacter pylori* has been reported to induce intense inflammatory reaction with dominating neutrophils in the antrum and in the body of the stomach, sometimes followed by hypochlorhydria. *Helicobacter pylori* also has been suggested to produce a protein capable of inhibiting parietal cell function (Cave and Vargas, 1989). Biopsy specimens from gastritis patients with *H. pylori* show focal epithelial cell damage and inflammatory response in the lamina propria consisting of mononuclear cells and granulocytes. A marked systemic IgG and IgA response accompanies the inflammatory reaction to *H.*

*pylori*, including T lymphocyte and plasma cell proliferation (Perez-Perez *et al.*, 1988; Evans *et al.*, 1989).

The capacity of *H. pylori* to escape the bactericidal activity of gastric acid juices, and to colonize the epithelium and thereby damage epithelial cells and induce an inflammatory reaction has attracted the interest of many researchers. Possible virulence factors such as urease, adhesins, proteases, phospholipases, and cytotoxins have been suggested. The production of a very potent urease might protect the bacteria against the gastric acid. Patients with active duodenal ulcers and *H. pylori* have been reported to secrete more acid and release more gastrin (Levi *et al.*, 1989).

## V. DIAGNOSIS

The most reliable procedure for diagnosis is the isolation of *H. pylori* from biopsy specimens taken from the relevant epithelium. The clinical drawback is that biopsies are required; no other specimens are adequate. A less sensitive and specific procedure is the biopsy-urease test (McNulty *et al.*, 1989). A medium containing urea with pH-sensitive dye is inoculated with the mucosal biopsy specimen. Urease in a positive specimen splits the urea and causes raised pH via production of ammonia. A color indicator reacts to the increased pH. Another noninvasive test is the urea breath test (Graham *et al.*, 1987). <sup>14</sup>C-Labeled urea is given perorally with liquid. If urease activity is in the stomach, labeled CO<sub>2</sub> is split off and expired in the breath, from which it can be recorded with a mass spectrometer. A third noninvasive method, reliable and increasingly used, is the antibody determination (see subsequent section).

## VI. IMMUNOLOGY

Serum antibody response against *H. pylori* antigen has been measured using several different antibody techniques such as agglutination, complement fixation, enzyme-linked immunosorbent assays (ELISA), and immunoblotting (Jones *et al.*, 1986; Bolton and Hutchison, 1989; Kosunen *et al.*, 1989; Reiff *et al.*, 1989). Different antigen preparations have been used, for example, whole cell antigens, glycine extracts, urease antigen, 120-kDa protein, and sonicated bacteria (Hirschl *et al.*, 1988; Bolton and Hutchinson, 1989). Crude antigens often have shown cross reactions with other bacteria.

IgG antibodies have been shown to be recorded significantly more often in patients with active chronic gastritis than in patients with normal morphology. The antibodies, furthermore, appear significantly more often in patients with *H. pylori* than in bacteria-negative patients (Perez-Perez *et al.*, 1988; Evans *et al.*, 1989). An increased level of IgA antibodies often is seen simultaneously with IgG antibodies. High levels of IgM antibodies are less common, which might indicate that the infection is a chronic one in most cases. A certain overlap of increased antibody titers is found in dis-

eased and healthy persons, complicating the predictive value of the antibody test.

After treatment of patients with antimicrobial drugs the increased antibody levels, mainly IgG and IgA antibodies, decrease in 1–2 months (Vaira *et al.*, 1988; van Bohemen *et al.*, 1989). The patients who become free of *Helicobacter* as a consequence of antimicrobial treatment are expected to show even lower antibody level within the next 6 months. In patients in whom the bacteria remain, a new antibody increase might be expected (Oderda *et al.*, 1989). Immunological methods, that is, antibody determination, rather than cumbersome endoscopic methods can be used to screen the pertinent patient group with gastroenterological disease. This technique is especially valuable in younger patients, in whom the finding of low antibody level is a satisfactory result and need not be followed by endoscopy with biopsy to rule out malignancies. Follow-up of patients treated with antimicrobial drugs also can be performed very well by antibody determination.

Why the local immune response of the mucous membrane cannot clear the gastrointestinal tract of *H. pylori* without antimicrobial treatment is still unclear. *Helicobacter pylori* gastritis is apparently an immunopathological disease. Most of the morphological and histological changes can be accounted for by most immune response mechanisms. Activation of the inflammatory reaction and self-damaging mediators such as complement factors, interleukin 6, and so on are important. An autoimmune component seems probable.

In all discussions of "new" infectious diseases, the question is raised whether or not a protective immunity is possible. In terms of cost-benefit, considerations of this kind are most relevant. The induction of prophylactic immunity against *H. pylori* seems unlikely. Urease was suggested as a vaccine candidate (Pallen and Clayton, 1990). However, animal experiments with other urease-producing *Helicobacter* species have shown that urease-producing microorganisms have no marked toxic effect on the mucous membrane.

An induction of immune response to *H. pylori* already has been shown and has no influence on the eradication of the bacteria—they are already there. Furthermore, the bacteria apparently induce an inflammatory reaction with immunopathological effects. If vaccination were possible, it would have to be done in young individuals with no *H. pylori* present.

## VII. TREATMENT

*Helicobacter pylori* bacteria are sensitive *in vitro* to most commonly used antimicrobial drugs such as ampicillin, cefalosporins, erythromycin, penicillin, quinolones, and tetracyclines (Goodwin *et al.*, 1986). They are resistant to nalidixic acid, trimethoprim, sulfonamides, and vancomycin.

Despite the good *in vitro* results, the treatment *in vivo* does not always eradicate the bacteria. Reasons for failure might be development of resistance or loss of activity in the presence of acid. Better results have been obtained with

combinations of drugs such as bismuth salts and amoxicillin or tinidazole or amoxicillin and tinidazole (Marshall *et al.*, 1988; Rauws *et al.*, 1988; Oderda *et al.*, 1989). Even greater effectiveness has been achieved using triple therapy of bismuth salts, amoxicillin or tetracycline, and metronidazole. In 90% or more cases, the patient was cleared after treatment (Borody *et al.*, 1988; Börsch *et al.*, 1988). Another very promising therapy study combining omeprazole and amoxicillin showed a marked effect on eradication and ulcer relapse during a 6-month follow-up (Unge *et al.*, 1991).

## VIII. CONCLUSION

Based on extensive studies since the first report in 1983, *H. pylori* evidently play an important role in the etiology of gastritis and peptic ulcer. *Helicobacter pylori* is found in the mucous membrane of the stomach or duodenum in patients with gastritis or peptic ulcer more commonly than in healthy people. The prevalence increases with age and is high in some ethnic groups. *Helicobacter pylori* induce an inflammatory reaction with immunopathological effects. An increased antibody level, mainly IgG and IgA, is seen in the serum of the patients. This antibody response has an important diagnostic value. However, the immune response does not eradicate *H. pylori*. Treatment of patients has been discussed extensively. A combination of bismuth and one or two antimicrobial drugs, preferably metronidazole and amoxicillin or omeprazole in combination with amoxicillin, has been suggested.

# The Role of the Mucosal Immune System in Ulcerative Colitis and Crohn's Disease

Hans-Christian Reinecker · Stefan Schreiber · William F. Stenson · Richard P. MacDermott

## I. INTRODUCTION

Because of the continuous exposure of the intestine to a wide variety of bacterial, viral, and dietary antigens, host defense mechanisms are constantly necessary and depend on essential functions mediated by the intestinal mucosal immune system. The mucosal immune system has developed a unique set of immunological protective mechanisms and effector capabilities that normally prevent damage to the intestine but, in the case of inflammatory bowel disease (IBD), may perpetuate and exacerbate intestinal injury. In healthy individuals, nutrients must be allowed to cross the interface of the external environment (the gut lumen) and the intestinal mucosa while injurious agents must be prevented from entering effectively and specifically (Tomasi *et al.*, 1965; Mestecky and McGhee, 1987; Brandtzaeg *et al.*, 1988). Thus, a critical function of the normal mucosal immune system is to recognize and neutralize specifically infectious agents and potentially injurious toxins or antigens (Hanson *et al.*, 1980; Underdown and Schiff, 1986). Discrimination between self and nonself is vital so host tissues are not damaged while host protective defense mechanisms are being employed. In ulcerative colitis and Crohn's disease, the normally protective inflammatory response is not down-regulated and the highly activated effector cells produce prolonged and intense damage of the intestine. Advances in our understanding of normal immune and inflammatory processes in the intestinal mucosa have provided new insights into the immunopathogenic mechanisms involved in autoimmune and chronic inflammatory gastrointestinal diseases such as ulcerative colitis and Crohn's disease (MacDermott and Stenson, 1988a,b).

An effective immune response begins with the specific processing of antigens by monocytes and macrophages, which endocytose large molecules and infectious organisms such as bacteria and viruses (Unanue and Allen, 1987). After lysosomal processing, smaller fragments are generated that interact with major histocompatibility complex (MHC) Class II or Class I determinants. Antigen recognition events by lymphocytes involve the antigen-specific T-cell receptor-CD2 complex. The T-cell receptor complex specifically recognizes Class II cell surface determinants in conjunction with antigen fragments on the macrophage surface. Other cell types, in addition to the macrophage, now are known to have Class II antigens on their surfaces and to be capable of

antigen presentation. The gastrointestinal tract in particular is populated by many potential antigen-presenting cells, including epithelial cells and endothelial cells as well as dendritic cells and macrophages. The presence of a variety of antigen-presenting cells further enhances the ability of the intestine to mount specific mucosal immune responses against the many different luminal antigens to which it is exposed (Bland and Warren, 1986a,b). Specific antigen recognition is pivotal to the normal function of T cells, which both regulate immune responses through T helper cell function and serve as effector cells by carrying out T cell-mediated cytotoxicity.

Cytokines are produced by macrophages (Dinarello, 1988) and T cells induce B cells to mature into plasma cells and to secrete immunoglobulins. Presentation of antigens to B cells initiates an orderly and precise sequence of events during which genes that encode for variable regions are joined with genes that encode the constant regions of heavy and light chains of immunoglobulins. This rearrangement of genes results in the formation of specific DNA that produces a specific messenger RNA that allows a B cell to secrete an isotype- and subclass-defined antibody that is specific to the initiating antigen. The normal gastrointestinal immune system has unique mechanisms that allow mucosal B cells to "switch" from predominantly IgM production to IgA production (Kawanishi *et al.*, 1983a,b). A series of cell- and cytokine-mediated regulatory events is involved in the production of IgA, which is the major mucosal protective immunoglobulin. Within normal human mucosal lymphoid follicles, T-cell subsets produce specific B-cell switch, differentiation, and growth factors that regulate IgA production by B cells (Coffman *et al.*, 1987).

T-cell recognition functions are controlled by the formation of a T-cell receptor complex with two polypeptide chains (alpha and beta) that have variable regions. Sensitized T cells recognize specific antigens in conjunction with MHC Class II molecules. Helper T lymphocytes then are stimulated by interleukin 1 (IL-1) released from antigen-activated macrophages (Dinarello, 1988). Increased production of IL-2 by T cells further stimulates helper T cells to undergo cell cycle progression and clonal expansion (Smith, 1988). Specific helper T cells lead to enhanced production of immunoglobulins. Therefore, carefully regulated expansion of immunoglobulin-producing B cells in the mucosa by T cell-derived

cytokines (Strickland *et al.*, 1974) normally occurs in response to specific infectious agents or stimulating antigens to provide a protective immune response.

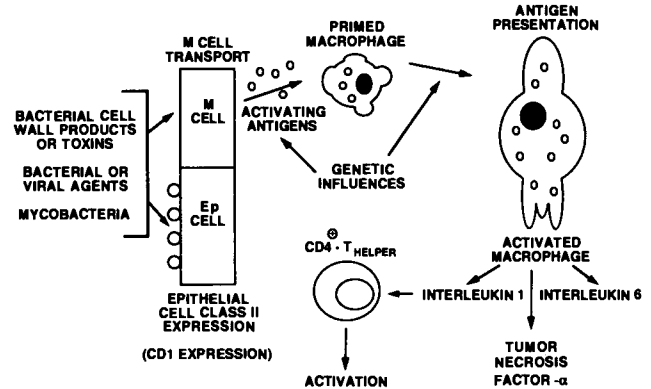

In ulcerative colitis and Crohn's disease, the normal sequence of T-cell and B-cell regulating events is altered so an up-regulated immune and highly activated chronic inflammatory response ensues.

Although the specific and effective protection provided by the normal immune response in the intestine does not lead to injury to the surrounding tissue in ulcerative colitis and Crohn's disease, the continuous production of chemotactic cytokines, pro-inflammatory cytokines, inflammatory mediators, and other injurious molecules leads to damaging rather than healing processes. The normal protective mucosal immune response should be down-regulated when it is no longer needed, but in IBD the continuous up-regulation of the immune response results in highly activated specific and non-specific damage to the surrounding intestinal tissue. In the remaining sections of this chapter, we discuss recent progress that has been made in our understanding of the role of the mucosal immune system in ulcerative colitis and Crohn's disease.

## II. PERIPHERAL BLOOD LYMPHOCYTE ACTIVATION

Initial descriptions of immunological alterations in IBD focused on peripheral blood lymphocyte function (Strickland *et al.*, 1974; Thayer *et al.*, 1976; Auer *et al.*, 1978, 1979). Auer and co-workers (Auer *et al.*, 1978, 1979) demonstrated that, in patients with long-term steroid-treated Crohn's disease, lymphocytopenia and a decrease in T cells occurred that was dependent on disease duration whereas, in new-onset untreated Crohn's disease patients, no alterations were found. More recent studies (Selby and Jewell, 1983; Yuan *et al.*, 1983) using monoclonal antibodies against T lymphocytes and their subsets have not demonstrated any differences between IBD patients and controls. Therefore, attention now has turned to the concept that, although the absolute number of certain types of lymphocytes may not differ from normal in IBD, the functional state and degree of activation may be altered (Figure 1).

Raedler and co-workers (Raedler *et al.*, 1985a,b, 1986, 1988; Schreiber *et al.*, 1991) and Pallone and co-workers (Fais *et al.*, 1987; Pallone *et al.*, 1987) have demonstrated the increased state of activation of peripheral blood T cells in IBD. Using the T9 antigen, which is identical to the transferrin receptor and is expressed during early lymphocyte activation, Raedler and colleagues observed that 24% of active Crohn's disease peripheral blood T lymphocytes express early activation markers (Raedler *et al.*, 1985b). The extent of peripheral blood T-lymphocyte activation was dependent on disease activity; only 10% of T cells expressed the T9 antigen in inactive Crohn's disease (Raedler *et al.*, 1985b; Schreiber *et al.*, 1991). Peripheral blood T-cell activation was not specific for IBD, but was observed also in a variety of autoimmune diseases including systemic lupus erythematosus, rheuma-

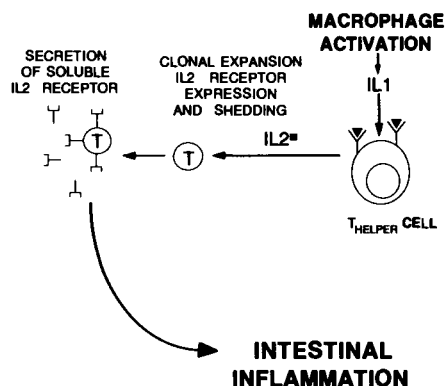

**Figure 1** Activating events in IBD. Bacterial cell wall products, infectious agents, and/or toxins can be transported across M cells or presented by class II antigens on epithelial cells to prime and activate macrophages. After antigen presentation, the primed and activated macrophages synthesize and secrete a variety of molecules, including pro-inflammatory cytokines such as interleukin 1, interleukin 6, and tumor necrosis factor  $\alpha$ . The pro-inflammatory cytokines in turn activate a number of important cell-mediated events and processes, including CD4<sup>+</sup> T helper cells in the intestine. In IBD, therefore, macrophages and lymphocytes are in a highly activated and up-regulated state with the resultant secretion of numerous pro-inflammatory and immunoregulatory molecules.

toid arthritis, and Behcet's disease. In contrast, peripheral blood T-cell activation was not increased in bacterial or viral colitis (Raedler *et al.*, 1985a). Interestingly, in IBD, a high percentage of activated T9 antigen-positive T cells coexpressed Fc receptors for polymeric IgA (Fc $\alpha$  receptor), which was not observed in the autoimmune disorders that also exhibited increased peripheral blood T-cell activation (Raedler *et al.*, 1985a, 1986, 1988; Schreiber *et al.*, 1991).

The work of Pallone and co-workers (Fais *et al.*, 1987; Pallone *et al.*, 1987) demonstrated that, in Crohn's disease, the T9 antigen in conjunction with other early lymphocyte-activation markers is expressed in increased proportions on both peripheral blood mononuclear cells and isolated intestinal lamina propria mononuclear cells. This work indicated that heightened cellular activation processes in IBD may be important in the intestine. The observation that a high percentage of activated peripheral blood T cells expresses Fc $\alpha$  receptors and exhibits the functional capability of up-regulating IgA secretion *in vitro* provides intriguing evidence that either particular subpopulations in the peripheral blood are activated or activated intestinal lymphocyte populations can migrate from inflamed intestine into the peripheral blood compartment during IBD.

Mueller *et al.* (1990) demonstrated increased serum levels of soluble IL-2 receptor in Crohn's disease patients (Figure 2). Soluble IL-2 receptor can be shed from the surface of T cells or macrophages during cellular activation. The authors also observed an enhanced capacity of Crohn's disease peripheral blood mononuclear cells to secrete soluble IL-2 receptor *in vitro*, both spontaneously and after stimulation with phytohemagglutinin (PHA). Moreover, Crabtree and co-workers found that increased serum levels of soluble IL-2

**Figure 2** T cell-mediated immunity in IBD. With macrophage activation and the subsequent secretion of pro-inflammatory cytokines such as interleukin 1 (IL1), intestinal T helper cells are highly activated. The increased state of activation of intestinal T cells can be determined by demonstrating activation antigen markers on the cell surface. Subsequently, clonal expansion occurs because of the increased production of interleukin 2 (IL2) and interleukin 2 receptors on intestinal lymphocytes. With activation and expansion of the intestinal T cell repertoire, soluble interleukin 2 receptors are secreted and shed from T cells so they circulate in the serum. The expression and secretion of soluble interleukin 2 receptors as well as TNF- $\gamma$  and IL-6 may provide a convenient and reliable immunologic marker of intestinal inflammation in ulcerative colitis and Crohn's disease patients in the future.

receptor correlated with the inflammatory activity in Crohn's disease patients (Crabtree *et al.*, 1990). This work indicates that activated lymphocytes in IBD may be able to modulate the immune response by the synthesis and secretion and/or shedding of biologically active molecules. Moreover, measurement of these molecules, such as soluble IL-2 receptor or cytokines produced by activated mononuclear cells, ultimately may provide useful serum markers to correlate the level of tissue inflammation with an ongoing active disease state.

We have demonstrated (Schreiber *et al.*, 1992) an enhanced capacity of isolated IBD intestinal lamina propria mononuclear cells to release soluble IL-2 receptor spontaneously. Enhanced secretion of soluble IL-2 receptors by intestinal mononuclear cells is not specific to either ulcerative colitis or Crohn's disease, but also can be observed in colonic diverticulitis. These studies suggest that activation events observed in the peripheral blood may be related to ongoing inflammatory events in the diseased intestine. This hypothesis also is supported by *in vivo* studies by Mahida *et al.* (1990), who demonstrated that soluble IL-2 receptor is secreted from the inflamed intestine into portal vein blood in Crohn's disease patients.

### III. INTESTINAL LYMPHOCYTE ACTIVATION

Immunohistological studies have characterized the numbers and types of inflammatory cells in diseased IBD mucosa (Selby *et al.*, 1984; Fais *et al.*, 1987; Kontinen *et al.*, 1987;

MacDonald *et al.*, 1990a), but have yielded conflicting results regarding intestinal lymphocyte activation in Crohn's disease and ulcerative colitis (Figure 1). Although a number of groups have described the increased expression of lymphocyte activation antigens (including 4F2, transferrin receptor, IL-2 receptor, and HLA-DR; Pallone *et al.*, 1987; Allison *et al.*, 1990a; MacDonald *et al.*, 1990), other observations have not demonstrated a rise in activated mucosal lymphocytes (Selby *et al.*, 1984). Allison *et al.* (1990) observed increased T-cell activation in IBD mucosa as demonstrated by the appearance of CD7 but, in contrast, increased IL-2 receptor expression was not seen. Fais and Pallone (1989) noted that intestinal epithelial cells may be capable of expressing activation antigens such as 4F2 and transferrin receptor during active IBD.

We have used flow cytometric analysis of isolated colonic lamina propria mononuclear cells to demonstrate that lymphocyte activation antigens including the IL-2 receptor, the transferrin receptor, and the 4F2 antigen are expressed in increased percentages of intestinal B cells and T cells, as well as in CD4<sup>+</sup> and CD8<sup>+</sup> T lymphocyte subpopulations, in both active ulcerative colitis and Crohn's disease (Schreiber *et al.*, 1991a). Moreover, 5-aminosalicylic acid (5-ASA), which can be used successfully in the treatment of intestinal inflammation in IBD, inhibits lymphocyte activation and antibody secretion by mitogen-stimulated peripheral blood cells (MacDermott *et al.*, 1989; Schreiber *et al.*, 1991b). Collectively, these studies provide evidence that activation of B- and T-cell populations occurs in the intestine as well as in the peripheral blood of patients with IBD. James and co-workers reported elevated levels of IL-2 mRNA in the mucosa of Crohn's disease patients (Figure 2), but not in that of patients with ulcerative colitis (James *et al.*, 1991).

James and co-workers (Kansas *et al.*, 1985; James *et al.*, 1986; Kanof *et al.*, 1988; James, 1991) have demonstrated that, in contrast to peripheral blood, only a small number of normal lamina propria T cells expresses the Leu8 molecule. Most lymphocytes within the intestine, therefore, are of the Leu8<sup>-</sup> CD4<sup>+</sup> phenotype and, thus, may be able to enhance B-cell activation and immunoglobulin secretion (Kansas *et al.*, 1985; James *et al.*, 1986; Kanof *et al.*, 1988; James, 1991). This result may help explain the heightened state of intestinal B-cell activation and differentiation in normal human intestine. Moreover, the functional capabilities of CD4<sup>+</sup> Leu8<sup>-</sup> T cells in IBD intestinal mucosa constitute an important area for future studies.

### IV. HOMING OF LYMPHOBLASTS

Follicle-associated epithelium contains microfold (M) cells that are derived directly from undifferentiated immature epithelial stem cells in the crypts that surround Peyer's patches. M cells cover the lymphoid follicles in the gastrointestinal tract and provide a site for the selective sampling of intraluminal antigens (Owen and Jones, 1974), which then are transcytosed into the underlying lymphoid tissues of Peyer's patches (Wolf *et al.*, 1981). Among the characteristic morphological features that distinguish M cells from absorptive epithelial

cells is the presence of fewer, shorter, and wider microvilli (Owen and Nemanic, 1978). Vesicles in the M-cell cytoplasm transport antigens through the cell. The antigens then come into contact with lymphocytes and macrophages that have migrated into an intercellular space or central hollow that indents into the M cell (Bockman and Cooper, 1973). M cells themselves do not have Class II antigens on their surfaces and do not process or present antigens. M cells, thus, primarily perform a transport function by moving selected antigens from the lumen into the mucosa, so subsequent macrophage processing and antigen presentation in the intestinal lymphoid follicles will initiate a specific mucosal immune response. Among the infectious agents known to be transcytosed by M cells are reoviruses, *Vibrio cholerae*, and mycobacteria. Similarly, large molecules, including horseradish peroxidase, ferritin, and certain lectins, also are transcytosed by M cells.

Antigen-stimulated lymphocytes from intestinal lymphoid follicles then begin a "maturational journey," in which they leave the intestinal tract and migrate into afferent lymphatics that drain into mesenteric lymph nodes (Bienenstock *et al.*, 1978; Dunkley and Husband, 1987). Lymphocytes then enter efferent lymphatics and pass through the thoracic duct into the peripheral blood. During this process, the lymphocytes mature into T-cell and B-cell lymphoblasts. B lymphocytes become surface IgA-bearing lymphoblasts after being promoted to switch their immunoglobulin isotype by regulatory ("switch") T cells within the Peyer's patch (Kawanishi *et al.*, 1983a,b; Cebra *et al.*, 1984). B lymphoblasts mature into IgA-secreting plasma cells after homing to mucosal sites. The homing of lymphoblasts results in mature B cells arriving at a variety of secretory sites (Bienenstock *et al.*, 1978; Mestecky, 1987) by interactions between specific "homing antigens" (Jalkanen *et al.*, 1986,1988) on the surfaces of the lymphoblasts and "addressins" (Streeter *et al.*, 1988), specific receptors on the surfaces of high endothelial venules. Thus, a selective recognition of lymphocyte-specific proteins by intergrin family adhesion molecules found on endothelial cells in specific organs regulates the distribution of lymphoid effector cells to the intestine and other mucosal secretory sites. Lymphoblasts recirculate or "home" to the sites of the original antigenic stimulation as well as to other mucosal secretory sites. In humans, the cell interaction, adherence, and extravasation process is mediated by an 85- to 95-kDa class of lymphocyte surface glycoprotein that defines "homing receptors" for high endothelial venules and is present on normal human mucosal lamina propria lymphocyte populations (Jalkanen *et al.*, 1986,1988; Hamann *et al.*, 1988). IgA B cells preferentially migrate to mucosal secretory lymphoid sites, whereas T cells primarily home to peripheral lymph nodes. These differences in migration between B cells and T cells, as well as differences in the migration of lymphoblasts based on their tissue of origin, are due to cell surface homing receptor interactions with high endothelial venules (Streeter *et al.*, 1988).

Antigenic stimulation and chronic inflammation result in a rapid increase in the number of high endothelial venules (identified morphologically by their typical cuboidal, plump appearance). Increase in the number of high endothelial ven-

ules is caused by both enhanced differentiation and stimulation of proliferation (Jalkanen *et al.*, 1986,1988). Cytokines, including IL-1, interferon gamma (IFN $\gamma$ ), and tumor necrosis factor (TNF- $\alpha$ ), increase lymphoblast adherence to endothelial cells, trigger the development of endothelial cell differentiation markers, and enhance the expression of endothelial adhesion molecules. Increased expression of adhesion molecules on endothelial cells allows an increase in the influx of antigen-specific sensitized lymphocytes, as well as monocytes and granulocytes, into areas of chronic inflammation or areas in which cell-mediated host defense processes are needed. High endothelial venules increase in number in areas that are in close proximity to developing granulomas. The presence of high endothelial venules thus is associated closely with dense lymphocytic infiltrates, particularly when the mononuclear cell-mediated processes are persistent. Although most studies to date have focused on the maturation and homing events related to lymphocytes (Jalkanen *et al.*, 1986,1988; Hamann *et al.*, 1988; Streeter *et al.*, 1988), the migration of granulocytes and macrophages into tissue sites also is regulated by interactions with similar endothelial cell adhesion molecules. Therefore, different cell surface receptors now are known to be involved in determining which lymphocytes become localized to both normal and inflamed intestine.

After antigenic stimulation in the gastrointestinal tract, IgA lymphoblasts also circulate to a number of other mucosal secretory sites including breast, lung, and eye, where antigen-specific antibodies are secreted (Bienenstock *et al.*, 1978; Mestecky, 1987). Homing of stimulated lymphoblasts to mucosal secretory sites allows the secretion of protective antibodies directed against antigens within the gastrointestinal lumen into lung, breast, and eye fluids. Once lymphoblasts have "homed" to the gastrointestinal mucosa and have matured into effector cells, they provide protective immunity within the lamina propria. The appearance of Fc $\alpha$  receptor-expressing activated T cells in the peripheral blood of IBD patients, as well as the enhanced IgA secretion by peripheral blood B cells during active disease, may be related to the outpouring of activated lymphoblasts from involved intestine and their participation in the homing process in active IBD (MacDermott *et al.*, 1981,1983; Raedler *et al.*, 1985a,1986,1988; MacDermott, 1988; MacDermott and Stenson, 1988b; Schreiber *et al.*, 1991). Further, we have observed in collaborative studies with the Jalkanen laboratory that activated lymphoblasts from the intestine also will adhere to human synovial tissue, raising the possibility that altered cell homing to the synovium could lead to the joint manifestations (arthralgias) observed in active IBD.

## V. ALTERATIONS IN IMMUNOGLOBULIN SYNTHESIS AND SECRETION

Long-standing IBD is characterized by a mixed cellular infiltrate composed predominantly of B cells and T cells. The B cells normally are arrayed in areas subjacent to ulcerations in IBD, whereas T cells are found around granulomas and

in submucosal areas of Crohn's disease lesions. In the normal intestine, IgA-positive B cells predominate. In IBD, however, IgG-containing cells are increased more than other plasma cell types and are present in deeper tissue layers (Brandtzaeg *et al.*, 1988). The intestinal lumen contains numerous immunogenic molecules that physiologically stimulate the normal mucosal immune system, which reacts by mounting a protective immune response. The normal protective mucosal immune response is characterized by a number of features: It is effective, selective, controlled, and localized. These properties are, in part, mediated by IgA, the major immunoglobulin in the normal intestine. IgA protects passively by aggregation and immune exclusion rather than by activation of the complement cascade or induction of an intense inflammatory response, which could cause localized tissue damage.

In IBD, on the other hand, the mucosal immune system exhibits a markedly heightened IgG immune response because of defective or altered immunoregulation. Our studies have provided evidence for the presence of highly activated T cells and B cells, as evidenced by the heightened spontaneous immunoglobulin secretion observed from intestinal and peripheral blood mononuclear cells, particularly of IgG and IgG subclasses (MacDermott *et al.*, 1981; MacDermott, 1988; MacDermott and Stenson, 1988b). We have observed that peripheral blood mononuclear cells (PBMNs) from patients with new-onset untreated IBD display a strikingly high level of spontaneous IgG, IgA, and IgM secretion compared with PBMNs from normal individuals, which demonstrate little spontaneous secretion of antibodies (MacDermott *et al.*, 1981, 1983; MacDermott, 1988; MacDermott and Stenson, 1988b). The pattern of markedly elevated spontaneous immunoglobulin secretion is not unique to IBD PBMNs, since we have observed the same secretion pattern from normal human rib bone marrow mononuclear cells, as well as from PBMNs obtained from patients with systemic lupus erythematosus and Henoch-Schoenlein purpura (Alley *et al.*, 1982; Beale *et al.*, 1982; MacDermott *et al.*, 1983). Raedler *et al.* (1985a, 1988) reported increased numbers of Fc $\alpha$  receptor-bearing activated T lymphocytes in the blood of IBD patients. The increased numbers of Fc $\alpha$  receptor-positive activated T cells in IBD may contribute to the enhanced secretion of IgA (Raedler *et al.*, 1985a, 1988).

Intestinal mononuclear cells have unique capabilities and differ in their functional characteristics from PBMNs (MacDermott *et al.*, 1981; 1983; 1986; 1987; MacDermott, 1988; Scott *et al.*, 1986). Intestinal mononuclear cells from normal mucosa spontaneously secrete enormous amounts of IgA (MacDermott *et al.*, 1983, 1986). Both phenotypic and functional parameters indicate an increased state of activation of normal lamina propria T and B cells, which may be induced through continuous antigenic stimulation by luminal antigens (Peters *et al.*, 1989). This hypothesis is supported by the demonstration of a higher degree of activation antigen expression (IL-2 receptor and transferrin receptor) on normal colonic lamina propria lymphocytes compared with lymphocytes from the normal small intestine. The enhanced *in vivo* activation of normal intestinal B lymphocytes in comparison

to PBMNs may lead to heightened spontaneous *in vitro* immunoglobulin secretion (Schreiber *et al.*, 1991). IBD intestinal mononuclear cells exhibit decreased spontaneous IgA secretion (MacDermott *et al.*, 1983; 1986) but exhibit instead markedly increased IgG secretion compared with control intestinal mononuclear cells (Scott *et al.*, 1986; MacDermott and Nahm, 1987).

Changes in IgA subclass secretion in IBD are consistent with the migration of monomeric IgA- and IgA1-secreting cells from peripheral blood into the diseased intestine and could represent a normal mucosal response to intestinal antigens or pathogens related to IBD (MacDermott *et al.*, 1986). The integrity and function of the mucosal immune system is critically dependent on complex regulatory events that sustain a continuous IgA-mediated immune response. The decrease in dimeric IgA and IgA2 in IBD could lead to less effective antigen exclusion and decreased host protection by the mucosal immune response (MacDermott *et al.*, 1986). The overall decreased IgA production (MacDermott *et al.*, 1983; 1986), coupled with a shift leading to an increase in the percentage of monomeric IgA and IgA1, results in a local dimeric IgA and IgA2 deficiency in IBD (MacDermott and Nahm, 1987) that could lead to an impairment of critical mucosal immune defense mechanisms.

When compared with normal control intestinal mononuclear cells, IBD mononuclear cells show a marked increase in spontaneous secretion of IgG (Scott *et al.*, 1986). The greatest increase in spontaneous IgG secretion is seen in ulcerative colitis intestinal mononuclear cells because of the secretion of large amounts of IgG1 with a concomitant increase in IgG3 secretion. Crohn's disease intestinal mononuclear cells exhibit increased IgG secretion, primarily because of IgG1 and IgG2 (Scott *et al.*, 1986). We have observed similar alterations in IgG subclass concentrations in the sera of active untreated IBD patients, thus underscoring the *in vivo* relevance of our *in vitro* findings (MacDermott *et al.*, 1988).

Increased total IgG and IgG subclass secretion by isolated IBD intestinal mononuclear cells *in vitro* is most likely the result of increased numbers and altered ratios of intestinal plasma cell populations in IBD. The total lymphocyte number has been observed to be four times greater than normal in intestinal specimens from patients with both ulcerative colitis and Crohn's disease (Brandtzaeg *et al.*, 1974; Baklien and Brandtzaeg, 1975; Rosedrans *et al.*, 1980; Scott *et al.*, 1983; Keren *et al.*, 1984; Van Spreuwel *et al.*, 1985); the major increase occurs in IgG-containing cells. Compared with control specimens, the numbers of IgG-containing cells were 30 times greater whereas numbers of IgA-containing cells were 2 times greater and those of IgM-containing cells 5 times greater than normal. The increased *in vitro* secretion of total IgG and IgG subclasses from IBD intestinal mononuclear cells most likely is related to the increased percentage of IgG-containing cells present *in vivo* in inflamed mucosa. Kett *et al.* (1987) have observed increased IgG1-containing cells in ulcerative colitis patients and increased IgG2-containing cells in Crohn's disease patients. Finally, Badr-el-Din *et al.* (1988) have provided evidence for defective IgA production

in ulcerative colitis. Disease specificity control studies by Van Spreeuwel *et al.* (1985) have revealed that, in comparison with IBD biopsies, significantly fewer IgG-containing cells were found in biopsies of patients with acute infectious colitis.

The analysis of immunoglobulin isotype regulation may provide important clues for the delineation of new pathophysiological principles in IBD. Traditionally, IgA has been viewed as the major protective mucosal immunoglobulin of the intestine. Now, in IBD, IgG and its subclasses appear to play a very important role in injurious pathophysiological processes. The study by Kaulfersche *et al.* (1988) assessed lamina propria mononuclear cell heterogeneity and demonstrated that T- and B-cell populations in IBD lamina propria appear to be polyclonal in nature. The question that remains, therefore, is whether or not IgG secretion in IBD might be restricted clonally and, thus, represent a defined response against a group of specific antigens or might be a markedly up-regulated nonspecific response to common luminal agents that are potent inducers of inflammation.

Intriguing questions regarding the pathophysiology of IBD are raised by the observation that IgG subclasses represent discrete and specific immune responses. Different antigens and mitogens induce antibody responses restricted to particular IgG subclasses in both murine and human systems (Gronowicz and Couthino, 1976; Skakib and Stanworth, 1980; Slack *et al.*, 1980; McKearn *et al.*, 1982; Scott and Nahm, 1984). IgG1 and IgG3 antibodies account for the predominant IgG response to proteins and T-cell dependent antigens (Skakib and Stanworth, 1980; Heiner, 1984; Oxelius, 1984). Both IgG1 and IgG3 are better complement pathway activators and opsonins than IgG2 and IgG4 (Skakib and Stanworth, 1980; Waldmann *et al.*, 1983; Heiner, 1984; Oxelius, 1984). IgG2 provides the predominant IgG response to carbohydrates and many bacterial antigens. IgG2 and IgG4 deficiencies therefore are associated with recurrent bacterial infections (e.g., otitis media, pneumococcal respiratory tract infections, pericarditis, meningococcal infections) and with some rare inherited immunodeficiency disorders (such as ataxia telangiectasia and Wiskott-Aldrich syndrome). The increased production of IgG2 in Crohn's disease therefore may represent an inappropriate immune response that could partially contain, but not eradicate, a chronic infectious process (MacDermott and Nahm, 1987). Delineation of the stimuli and antigens that induce increased secretion of IgG subclasses in intestinal mucosa may provide valuable insights into possible etiologic and immunopathogenic aspects of IBD (MacDermott and Nahm, 1987).

We now know that (1) intestinal mononuclear cells in health and disease constitute a unique immunological compartment with distinct functional capabilities; (2) major alterations occur with respect to spontaneous antibody secretion in IBD, thereby demonstrating potential regulatory defects in the mucosal immune system in IBD; (3) within the intestine involved with disease itself, major alterations in antibody secretion occur, particularly with respect to IgA and IgG subclasses; and (4) further research addressing the specificity and func-

tion of IgG antibodies secreted in IBD may delineate important effector mechanisms.

## VI. COMPLEMENT PATHWAY ACTIVATION IN INFLAMMATORY BOWEL DISEASE

Complement pathway activation, by either the classical or the alternative pathway, leads to the generation of products that not only maintain normal host defense integrity, but also result in inflammation and tissue destruction. Products of the complement activation pathway include large fragments of C<sub>3</sub> (i.e., C<sub>3b</sub>, C3bi) that have considerable opsonic activity and small, low molecular weight fragments (from both C3 and C5) that can stimulate leukocytes directly and possess chemotactic activity. Human C3a, C4a, and C5 can activate smooth muscle cells, small blood vessels, mast cells, and basophils directly, whereas phagocytes respond only to C5a via specific receptors (Stoughton, 1972; Petersson *et al.*, 1975; Grant *et al.*, 1976; Siraganian and Hook, 1976; Hartman and Glovsky, 1981; Stimler *et al.*, 1981, 1983; Yancey *et al.*, 1985). Investigators have proposed pathogenic roles for complement system molecules in IBD, but the nature and extent of their involvement in the immunopathophysiology of IBD is still undefined. Some of the clinical findings and histological changes that occur in IBD are consistent with the biological activities of C3a, C4a, C5a, and C3b. Phagocytosis of bacteria and cellular debris occurs at an accelerated rate during intestinal inflammation, in part because of opsonization by complement components, as well as increased priming and activation of monocytes and macrophages. Synergism of IFN $\gamma$  and C5a also may be of great importance in IBD with respect to the induction of leukotriene release (Nielson *et al.*, 1988). Moreover, C5a, like LTB<sub>4</sub>, is a potent chemotactic agent for neutrophils and increases vascular permeability (Wilkinson, 1982; Charo *et al.*, 1986). Neutrophils demonstrate distinct polarization and enhanced aggregation as well as increased adherence after activation by C5a (Ward and Newman, 1969; Craddock *et al.*, 1977, 1978; Fernandez *et al.*, 1978; Smith *et al.*, 1979; Hammerschmidt *et al.*, 1980; Perez *et al.*, 1980; Tonnesen *et al.*, 1984; Charo *et al.*, 1986), a mechanism that may contribute to the large number of neutrophils present in IBD mucosa. Thus, the pathophysiological and histological changes seen in IBD may be caused, in part, by the biological activities of C3b and C5a coupled with other potent inflammatory mediators such as leukotriene B<sub>4</sub> (LTB<sub>4</sub>) released in response to bacterial cell wall components.

Several studies have found normal levels of C3 and C4 in the peripheral blood of IBD patients. The state of activation of the alternative pathway in IBD has been reported in different studies to be decreased, normal, or increased (Lake *et al.*, 1979; D'Amelio *et al.*, 1983; Elmgreen, *et al.*). In support of decreased activation of the alternative pathway is a study that observed the depression of properdin and properdin convertase, in addition to diminished consumption of C3-C9 after incubation with cobra venom of sera from patients with Crohn's disease and ulcerative colitis (Lake *et al.*, 1979;

D'Amelio *et al.*, 1983). C5a activity was reported to be diminished in Crohn's sera; decreased consumption of the major complement component C3 was noted; and, finally, a reduced generation of C5a after stimulation was seen (D'Amelio *et al.*, 1983). In other studies, an increased level of activation of complement pathways in IBD (Hodgson *et al.*, 1977; Elmgreen *et al.*, 1983; Simonsen and Elmgreen, 1985; Peterson *et al.*, 1988) was demonstrated. After radioiodinated C3 was injected intravenously, both the synthesis and the catabolism of C3 were found to be increased in patients with Crohn's disease and ulcerative colitis, suggesting an increased state of complement pathway activation (Hodgson *et al.*, 1977; Simonsen and Elmgreen, 1985). The levels of C3c in Crohn's disease patients were 10-fold greater than those in healthy persons or ulcerative colitis patients (Elmgreen *et al.*, 1983). C3c levels did not correlate with disease activity in Crohn's disease. In another study, levels of C3d were elevated in 6 of 20 patients with Crohn's disease, as were those of C4 in 9 of 20 cases (Peterson *et al.*, 1988). Moreover, levels of C3d correlated with C4d concentrations in patient sera. Elevated levels of C3c in Crohn's disease suggest hypercatabolism of C3 and activation of the complement cascade in IBD. Elevated levels of C3d and C4d underscore activation of the classical pathway in Crohn's disease.

Studies by Halstensen *et al.* (1990) have demonstrated the possible direct role of complement in tissue destruction in ulcerative colitis. The authors used monoclonal antibodies against a neoepitope, only expressed by activated C3b and the cytolytically active terminal complement complex, to identify potential complement-induced damage in tissue sections from inflamed IBD intestine. Of 11 patients with ulcerative colitis, 9 showed activated C3b deposited apically on the surface epithelium of involved mucosa, whereas no deposits were seen in 31 matched noninflamed specimens or in 16 of 17 healthy controls. Moreover, a striking colocalization of IgG1, activated C3b, and terminal complement complex was observed in 4 of the 11 ulcerative colitis patients. Thus, IgG1, secreted into the lumen during ulcerative colitis, may provide a mechanism for contiguous bowel involvement seen via complement activation. Further, an increased vascular deposition of terminal complement complex in both ulcerative colitis and Crohn's disease (Halstensen *et al.*, 1989a) could be demonstrated. Interestingly, 5 of 10 ulcerative colitis specimens and 1 of 5 Crohn's disease samples contained terminal complement complex located outside the blood vessels in the mucosa or the submucosa. In IBD, significantly more C3c reactivity was associated with terminal complement complex deposition, thus indicating continuous complement activation and deposition within the blood vessel wall (Halstensen *et al.*, 1989b). These findings are consistent with the *in vivo* studies by Ahrenstedt *et al.* (1990), who found that both C3 and C4 levels in jejunal perfusates of Crohn's disease patients were increased compared with healthy controls (Ahrenstedt *et al.*, 1990). A major role for complement activation in IBD, therefore, could be participation in the acute effector events of tissue destruction. In addition, complement as part of immune complexes could lead to enhanced phagocytosis and

could participate in the *in vitro* release of potent mediators such as LTB<sub>4</sub> by neutrophils (Nielson *et al.*, 1986).

## VII. GRANULOCYTE AND MACROPHAGE FUNCTION

During active ulcerative colitis and Crohn's disease, large numbers of neutrophils and monocytes leave the bloodstream and migrate into the inflamed mucosa and submucosa (Figure 3). These cells carry out a series of destructive effector events, and continue to migrate on through the bowel wall into the intestinal lumen. The biological events that occur during inflammation are the result of a multiplicity of interacting mediators and autacoids (auto-pharmacological substances that exert a potent local activity). The regulatory events that control the level of inflammation can be divided into three areas (Figure 3): (1) the process of adhesion and migration through the intestinal mucosa, (2) the secretion of cytokines by lymphocytes, monocytes, and macrophages, and (3) the pro-inflammatory role of lipid mediators such as leukotrienes, prostaglandins, and platelet activating factor (PAF).

**Figure 3** Phagocytic activation and inflammatory events in IBD. Bacterial cell wall products from the intestine prime monocytes and granulocytes to increase the expression of adhesion molecules with increased recognition of endothelial cell receptors. Macrophages and granulocytes migrate from the capillaries and venules into the intestinal lamina propria, from which they migrate into the intestinal lumen through the intestinal wall. The primed macrophages and granulocytes within the intestinal lamina propria are activated by bacterial cell wall products such as lipopolysaccharide (LPS) and peptidoglycans (PG), as well as by the chemotactic product FMLP, to release a variety of pro-inflammatory cytokines and mediators including interleukin 1 (IL1) tumor necrosis factor (TNF), interleukin 6 (IL6), platelet activating factor (PAF), leukotrienes (LT), and prostaglandins (PG/TX). In addition, destructive molecules such as oxygen radicals and proteases are produced. The involvement of granulocytes and macrophages in inflammatory bowel disease adds an acute inflammatory component to the chronic cell-mediated intestinal injurious processes involved in IBD.

Polymorphonuclear leukocyte (PMN) function initially was evaluated in IBD by assessing migration, chemotaxis, adherence, and phagocytosis. Studies by Rhodes and co-workers suggested intrinsic abnormalities of PMN function in IBD, and also revealed that inhibitors of chemotactic factor activity are present in the sera of Crohn's disease and ulcerative colitis patients (Rhodes *et al.*, 1981; Wandall and Binder, 1982). Interestingly, no functional difference between PMNs from normal controls and those from IBD patients were observed with respect to phagocytic capacity or chemotaxis induced by zymosan-activated serum or casein (Morain *et al.*, 1981).

Saverymuttu *et al.* (1985a,b) subsequently carried out a series of pivotal functional studies in which peripheral blood phagocytes (granulocytes and monocytes) were isolated, labeled *in vitro* with <sup>111</sup>indium-labeled tropolonate, and reinjected into the patient. The migration of the labeled cells was assessed with time, using a whole body gamma-radiation camera. In 20 of 22 patients with Crohn's disease, over 90% of radiolabeled phagocytes accumulated rapidly in the inflamed intestine (Saverymuttu *et al.*, 1985a). A similar study conducted in 15 ulcerative colitis patients showed enhanced migration into areas of inflamed bowel (Saverymuttu *et al.*, 1985b). These studies established the greatly increased migration of monocytes, macrophages, and PMNs into the intestine, which occurs in IBD, and showed that monitoring phagocytic cell movement could be of potential value in the clinical assessment of IBD patients (Saverymuttu *et al.*, 1985a,b). These findings also indicated the likely central importance of granulocytes and macrophages in mediating inflammation in IBD (Saverymuttu *et al.*, 1985a,b). The introduction of <sup>99m</sup>technetium-labeled hexamethyl propylene amine oxine as a leukocyte label in Crohn's disease by Schoelmerich *et al.* (1988) refined the technique and further eased the assessment of phagocytic cell migration in IBD. The selective labeling of mononuclear phagocytes (monocytes) by <sup>99m</sup>T-labeled stannous colloid likewise has improved our understanding of macrophage migration in IBD (Pullman *et al.*, 1988).

The binding of phagocytes to blood vessel endothelial cells, followed by migration into the diseased bowel, is mediated through well-characterized adhesion molecules (Figure 3) including LFA-1 (lymphocyte function-associated antigen 1; CD11a) which binds to ICAM-1 (intercellular adhesion molecule 1; CD54). Although great advances have been made regarding our understanding of the integrin family of cell surface molecules, their participation in intestinal inflammation is only now being examined. Studies by Malizia *et al.* (1991) have demonstrated that, during IBD, the expression of ICAM-1 on endothelial cells increases dramatically and is accompanied by an increase of CD11a on mononuclear phagocytes. This study demonstrated the potential importance of adhesion molecules in mediating granulocyte and monocyte influx into the diseased intestine, which promises to be one of the central areas for future investigation of the immunopathogenesis of IBD, as well as for the development of new treatment strategies.

## VIII. PRO-INFLAMMATORY CYTOKINES

Lymphocytes and macrophages synthesize and secrete a number of potent pro-inflammatory mediators (Figure 1) after stimulation and activation by molecules that are present in large amounts in the intestinal lumen, such as bacterial cell wall products (Fiocchi, 1989). Inflammatory events are mediated in part by the multitude of effects and actions of IL-1 (IL-1 $\alpha$  and IL-1 $\beta$ ), IL-6, and TNF $\alpha$  (cachectin). When the two forms of IL-1 ( $\alpha$  and  $\beta$ ) are compared, they exert very similar functions despite their different sources and their structural dissimilarities. The best known activities of IL-1 include the induction of fever ("endogenous pyrogen"), the stimulation of acute-phase protein synthesis, and the initiation of critical lymphocyte activation events. TNF, which shares only 3% homology with IL-1, is identical to "cachectin," which causes hemodynamic shock and cachexia associated with various disease states.

Human T-cell activation requires both a cross-linking mechanism for the T-cell antigen-receptor complex and the presence of IL-1 which, under physiological conditions, are both provided by the macrophage. In addition to macrophages, B cells, astrocytes, mesangial cells, keratinocytes, and endothelial cells also can act as accessory cells by producing or expressing membrane-bound IL-1. IL-1 also promotes B-cell activation and differentiation, particularly when acting in synergism with IL-4. Moreover, IL-1 can induce other B cell-regulating factors such as IFN- $\gamma$  and IL-2 as well as IL-6. Finally, IL-1 will act in an autocrine loop on the macrophage itself, and will stimulate further IL-1 production as well as induce prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) and granulocyte-macrophage colony stimulating factor (GM-CSF) secretion.

Work by Isaacs and co-workers (Isaacs *et al.*, 1990) as well as by Rachmilewitz and co-workers (1991; Ligumsky *et al.*, 1990) has focused on cytokines involved in the initiation of intestinal lymphocyte activation. Ligumsky and co-workers (1990) detected increased levels of IL-1 in inflamed mucosa from patients with both Crohn's disease and ulcerative colitis. Moreover, *in vitro*, increased amounts were synthesized in cultured biopsies as well, indicating that mucosa-resident cells secrete IL-1. Isaacs and co-workers (1990) as well as Stevens and co-workers (1990) demonstrated that IL-1 mRNA was present in the mucosa of a majority of IBD patients. Increasing interest therefore has focused on the role of pro-inflammatory cytokines in the initiation and enhancement of intestinal inflammatory processes.

In IBD intestinal mucosa, increased quantities of IL-1 $\beta$  mRNA have been detected, presumably produced by mononuclear phagocytes (Ligumsky *et al.*, 1990). Mahida and co-workers (1989) studied IL-1 $\beta$  release from isolated intestinal lamina propria mononuclear cells and observed enhanced spontaneous secretion by monocytes from IBD patients, compared with normal controls. Lipopolysaccharide (LPS) further enhanced IL-1 $\beta$  production by IBD lamina propria mononuclear cells but not by those from normal controls (Mahida *et al.*, 1989). Moreover, depletion of macrophages abolished IL-1 $\beta$  secretion (Mahida *et al.*, 1989). Satsangi and

co-workers (1987) demonstrated that PBMNs from Crohn's disease patients secrete increased amounts of IL-1, both spontaneously as well as after being stimulated with LPS, compared with normal controls. Cominelli and co-workers demonstrated that increased IL-1 concentrations play a key role in the pathogenesis of rabbit immune complex colitis and that tissue levels of IL-1 correlate with the severity of inflammation (Cominelli and Dinarello, 1989; Cominelli *et al.*, 1990). IL-1 mRNA was detectable as early as 4 hr after induction of colitis, indicating that IL-1 gene expression occurs as a very early event in experimental immune complex colitis (Cominelli *et al.*, 1990). The rise in IL-1 preceded the increase of PGE<sub>2</sub> and LTB<sub>4</sub>. Moreover, treatment with IL-1 receptor antagonist (IL-1ra) reduced the extent and severity of the inflammatory response associated with immune complex colitis in rabbits (Cominelli *et al.*, 1990).

Studies by Isaacs *et al.* (1992) using the polymerase chain reaction (PCR) to detect cytokines in intestinal lamina propria showed a more frequent presence of IL-1, IL-6, and TNF $\alpha$  in Crohn's disease and ulcerative colitis patients compared with normal patients. We have observed that lamina propria mononuclear cells isolated from endoscopic biopsies from patients with active IBD spontaneously secreted high amounts of IL-1 $\beta$  (Reinecker *et al.*, 1993).

MacDonald and co-workers (1990b) investigated the secretion of TNF $\alpha$  in IBD using a spot enzyme-linked immunosorbent assay (ELISA) technique. In Crohn's disease and in a subgroup of ulcerative colitis patients, TNF $\alpha$ -secreting intestinal mononuclear cells were increased in frequency in comparison with normal controls. We have found very low spontaneous *in vitro* release of TNF $\alpha$  from lamina propria mononuclear cells isolated from endoscopic biopsies from normal donors and IBD patients (Reinecker *et al.*, 1993). However, stimulation of lamina propria mononuclear cells with pokeweed mitogen (PWM) induced an enhancement of TNF $\alpha$  release that was significantly higher in IBD than in normal controls (Reinecker *et al.*, 1993).

IL-6 also can be released by monocytes as one of the pro-inflammatory cytokines, and is involved in regulating the final maturation of B cells into antibody-forming plasma cells (Hilbert, 1989). IL-6 shares a number of characteristics with granulocyte colony stimulating factor (G-CSF) and can be induced *in vitro* by IL-1 $\beta$  (Yasukawa *et al.*, 1987). Shiota and co-workers (1990) reported that normal epithelium can express IL-6 as well as its receptor, a finding that may be of importance in IBD. Moreover, Mitsuyama *et al.* (1991) reported increased serum levels of IL-6, in Crohn's disease and ulcerative colitis patients, that decline with treatment of the patients. Increased levels of IL-6, spontaneously secreted by lamina propria mononuclear cells from ulcerative colitis patients, were observed by Kusagami *et al.* (1991). We have observed an enhancement of IL-6 secretion by lamina propria mononuclear cells in ulcerative colitis but not in Crohn's disease patients or normal controls (Reinecker *et al.*, 1993).

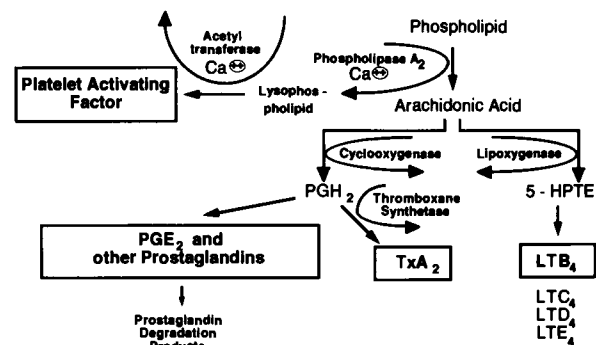

Intriguingly, many of the biological activities of IL-1, IL-6, and TNF $\alpha$  overlap, particularly those leading to amplification of immunological and inflammatory processes. TNF $\alpha$  and IL-6 share many of the systemic properties and functions

of IL-1, including the enhancement of cellular catabolism, induction of acute phase proteins, and pyrogenic activity. TNF $\alpha$  activates endothelial cells and can induce IL-1 and IL-6. Both IL-1 and TNF $\alpha$  stimulate PGI<sub>2</sub>, PGE<sub>2</sub>, and PAF secretion by cultured endothelial cells. Therefore, sustained inflammation leading to tissue destruction in IBD could be mediated to a significant extent by the potent biological activities of IL-1, IL-6, and TNF $\alpha$ .

## IX. PROSTAGLANDINS

Mucosal hyperemia, increased microvascular permeability, and edema are typical changes seen in a variety of intestinal inflammatory states, independent of the cause. Soluble lipid mediators released during the process of inflammation (Figure 4) can induce inflammatory tissue damage *in vivo*. These molecules cause tissue edema by increasing vascular (postcapillary venule) permeability to albumin and other macromolecules and cause hyperemia by inducing vasodilation. Other functional changes (including diminished salt and water absorption) that are characteristic of intestinal inflammation also may be related to soluble mediators, but their pathogenesis is less clear.

Arachidonic acid is liberated from the second carbon in phospholipids by a specific enzyme, phospholipase A<sub>2</sub>. Whereas the remaining lysophosphatide can undergo further degradation or subsequently can be acetylated to form PAF, arachidonic acid can enter two principal metabolic pathways, the cyclooxygenase and the lipoxygenase pathways (Bach, 1982; Parker, 1984). The pathway leading to prostaglandin synthesis is initiated by the enzyme cyclooxygenase, which

**Figure 4** Arachidonic acid metabolism in IBD. Attention has focused on the inflammatory mediators that are synthesized and secreted by the phagocytic cells during intestinal inflammation. The metabolism of arachidonic acid by the cyclooxygenase pathway results in prostaglandins such as PGE<sub>2</sub>, whereas metabolism via the lipoxygenase pathway results in leukotriene products such as LTB<sub>4</sub>, as well as other breakdown products. In addition, platelet activating factor is produced. All three inflammatory mediators (PGE<sub>2</sub>, LTB<sub>4</sub>, and PAF) are produced in large amounts during the intestinal inflammatory process in patients with ulcerative colitis and Crohn's disease. Current and future pharmacologic interventions directed against arachidonic acid metabolism pathways are being developed.

catalyzes the transformation of arachidonic acid into unstable endoperoxides and then into prostaglandin G<sub>2</sub> (PGG<sub>2</sub>) and prostaglandin H<sub>2</sub> (PGH<sub>2</sub>), from which PGE<sub>2</sub>, PGD<sub>2</sub>, PGF<sub>2α</sub>, PGI<sub>2</sub>, and thromboxane A<sub>2</sub> (TxA<sub>2</sub>) are derived (Bach, 1982; Parker, 1984). Almost all mammalian cells, including intestinal epithelium and cells associated with inflammatory events (i.e., macrophages, platelets, endothelial cells, mast cells), are capable of producing prostaglandins (Bach, 1982; Parker, 1984).

An alternative metabolic pathway for arachidonic acid is provided by the enzyme 5-lipoxygenase. The first product of the action of 5-lipoxygenase on arachidonic acid is a short-lived hydroperoxide metabolite, which again is transformed by 5-lipoxygenase to the epoxide leukotriene A<sub>4</sub> (LTA<sub>4</sub>). Subsequent reaction products include LTB<sub>4</sub> and a series of metabolites (Figure 4)—LTC<sub>4</sub>, LTD<sub>4</sub>, and LTE<sub>4</sub> (Bach, 1982; Lewis and Austen, 1984; Parker, 1984; MacGlashin *et al.*, 1986). On release into the extracellular space, these leukotrienes can be oxidized (i.e., by interaction with myeloperoxidase and H<sub>2</sub>O<sub>2</sub>) to sulfoxide metabolites. However, 5-lipoxygenase and subsequent enzymes of this pathway have been shown to exist definitely only in a small number of cell types, including neutrophils, eosinophils, basophils, monocytes, macrophages, and mast cells (Lewis and Austen, 1984; MacGlashin *et al.*, 1986). Moreover, the key enzyme, 5-lipoxygenase, can utilize other unsaturated fatty acids in addition to arachidonic acid, thus leading to different products.

Eicosanoids, including dietary compounds such as the omega-3 unsaturated fatty acids contained in fish oil, have unique biological properties: They are not stored in tissues but are synthesized *de novo* in response to stimulation (Douglas, 1985). Furthermore, cell-cell interactions involving products of the eicosanoid pathway are of increasing interest. Some cells will synthesize *de novo* their own eicosanoid precursors from arachidonic acid, others will acquire precursors from neighboring cells in close physical proximity, thus leading to different final products (Douglas, 1986). The pattern of eicosanoid production is tissue specific and most of these short-lived mediators exert their action only in the immediate microenvironment of the secreting cell. In most cases, eicosanoids are not the sole mediators of a certain function, but act in synergy with other regulatory mechanisms (Bach, 1982; Lewis and Austen, 1984; Parker, 1984; MacGlashin *et al.*, 1986; Douglas, 1985).

Prostaglandins, in particular those of the E series, have biological properties that can induce some of the morphological changes observed in inflamed tissue, for example, enhanced microvascular permeability and subsequent edema, vasodilation, and induction of pain (Bach, 1982; Parker, 1984). Physiological concentrations of PGE<sub>2</sub> have little effect, whereas pharmacological concentrations may impair electrolyte and water transport.

Clearly IBD is associated with increased levels of prostaglandin production. Elevated levels of prostaglandins (primarily PGE<sub>2</sub>) are found in the stool, venous blood, and rectal mucosa in IBD, and elevated levels of metabolites are found in urine (Sharon *et al.*, 1978; Gould, 1981; Gould *et al.*, 1981). When incubated *in vitro*, biopsies of rectal mucosa from patients with ulcerative colitis contain increased amounts of

PGE<sub>2</sub> and TxB<sub>2</sub> (Sharon *et al.*, 1978). An *in vivo* estimate of prostaglandin synthesis by rectal mucosa is achieved using a dialysis bag that is filled with buffer and placed into the patient's rectum (Lauritsen *et al.*, 1985). Prostaglandin levels in IBD, whether in mucosa, serum, or rectal dialysate, correlate with disease activity; successful medical management results in a reduction in prostaglandin levels (Rampton *et al.*, 1980; Lauritsen *et al.*, 1985).

The source of the prostaglandins in colonic mucosa in IBD is not well defined; epithelial cells, endothelial cells, fibroblasts, and mononuclear inflammatory cells all can produce prostaglandins. From isolation studies, intestinal mononuclear cells appear to be responsible for as much as or more prostaglandin synthesis than intestinal epithelial cells (Zifroni *et al.*, 1983). This finding is consistent with studies of inflammatory cells in other organ systems in which mononuclear cells were found to be the major source of prostaglandin synthesis (Bach, 1982; Parker 1984).

However, evidence against a significant primary role for prostaglandins as pro-inflammatory mediators in IBD also exists. Clinical evidence comes from a few small studies of nonsteroidal anti-inflammatory drugs (NSAIDs), particularly indomethacin, in IBD (Levy and Gaspar, 1975; Gilat *et al.*, 1979; Campieri *et al.*, 1980; Gould *et al.*, 1981). Indomethacin and other NSAIDs are potent inhibitors of cyclooxygenase but not lipoxygenase (Vane, 1971). Use of these drugs in rheumatoid arthritis and other inflammatory diseases results in both decreased prostaglandin synthesis and clinical improvement, effects that helped establish a role for prostaglandins as important mediators of inflammation. In contrast to their usefulness in rheumatoid arthritis, NSAIDs have no role in the medical management of IBD. Small trials of indomethacin administered orally (Lauritsen *et al.*, 1985) and rectally (Levy and Gaspar, 1975; Sharon *et al.*, 1978; Flower and Blackwell, 1979; Gilat *et al.*, 1979; Campieri *et al.*, 1980; Rampton and Sladen, 1981; Hawkey, 1982; Terano *et al.*, 1984) revealed no improvement in ulcerative colitis. Moreover, some reports have suggested that both indomethacin and flubiprofen, another NSAID, may cause clinical deterioration in ulcerative colitis, despite the decrease in prostaglandin production (Campieri *et al.*, 1980; Gould *et al.*, 1981; Rampton and Sladen, 1981, 1984). The failure of NSAIDs to induce clinical improvement in IBD, despite their inhibition of prostaglandin production, suggests that prostaglandins and other inflammatory mediators such as PAF and leukotrienes may all need to be inhibited to reduce tissue injury.

These clinical observations are also compatible with reports characterizing PGE<sub>2</sub> as an anti-inflammatory agent in the regulation of mononuclear cell activation. PGE<sub>2</sub>, as well as glucocorticoids or  $\alpha$ -fetoprotein, down-regulates HLA Class II expression on activated macrophages and thus impairs their ability to present antigen (Hokland *et al.*, 1981; Madsen *et al.*, 1981; Snyder *et al.*, 1982). PGE<sub>2</sub> inhibits the release of inflammatory mediators from stimulated leukocytes via induction of cAMP (Zurier *et al.*, 1974). Prostaglandins of the E series, as well as prostacyclin (PGI<sub>2</sub>), inhibit leukocyte chemotaxis (Gallin *et al.*, 1985), adherence to various substrates including endothelium (Boxer *et al.*, 1980), phagocytosis (Cox and Karnovsky, 1973), and generation

of toxic oxygen radicals (Lehmeyer and Johnston, 1978). Proliferative responses of human lymphocytes to mitogens, lymphocyte-mediated cytotoxicity, and antibody production are all inhibited by PGE<sub>2</sub> (Goldyne and Stobo, 1981). Moreover, anti-inflammatory effects of PGE<sub>2</sub> can be confirmed *in vivo*: PGE<sub>2</sub> compounds suppress adjuvant arthritis (Aspinall and Cammarata, 1969; Glenn and Rohloff, 1971; Zurier *et al.*, 1973), carrageenan-induced inflammation (Glenn and Rohloff, 1971; Zurier *et al.*, 1973), and immune complex-induced inflammation (Kunkel *et al.*, 1979). An anti-inflammatory effect produced by PGE<sub>2</sub> may be of importance in spontaneous remissions in IBD. PGE decreases the affinity of neutrophil formyl methionyl-leucyl-phenylalanine (FMLP)-receptors (Fantone *et al.*, 1983), resulting in decreased neutrophil degranulation (Fantone *et al.*, 1981), which may be another role for anti-inflammatory actions of prostaglandins of the E series in IBD.

## X. LEUKOTRIENES

Whereas the cyclooxygenase pathway is present in almost all mammalian cells, the 5-lipoxygenase pathway is found primarily in cells of bone marrow origin involved in the inflammatory process (i.e., mast cells, neutrophils, monocytes, and macrophages; Borgeat and Samuelsson, 1979; Stenson and Parker, 1984). The major products of the 5-lipoxygenase pathway (Figure 4) are 5-hydroxy-6,8,11,14-eicosatetraenoic acid (5-HETE) and LTB<sub>4</sub>, LTC<sub>4</sub>, LTD<sub>4</sub>, and LTE<sub>4</sub>. LTB<sub>4</sub> and, to a lesser extent, 5-HETE exert potent chemotactic activities on neutrophils. LTB<sub>4</sub>, in the presence of neutrophils, also induces enhanced vascular permeability. The sulfidoleukotrienes induce smooth muscle contraction in the lung, blood vessels, and gastrointestinal tract (Buckell *et al.*, 1978; Stenson and Parker, 1984).

Incubation of IBD mucosa with radiolabeled arachidonic acid results in the synthesis of large quantities of LTB<sub>4</sub> and 5-HETE and smaller quantities of PGE<sub>2</sub> and TxB<sub>2</sub> (Sharon and Stenson, 1984). IBD mucosa produces larger quantities of lipoxygenase and cyclooxygenase products than does normal mucosa. Patterns of arachidonate lipoxygenase metabolism are similar for ulcerative colitis and Crohn's disease. Lipid extracts of IBD mucosa contain large amounts of LTB<sub>4</sub>, up to 50-fold as much as normal mucosa (Rampton and Sladen, 1984). A concentration of 250 ng LTB<sub>4</sub>/g, as typically found in IBD mucosa, is equivalent of a concentration of  $5 \times 10^{-7}$  M, which is well within the range of biological activity of LTB<sub>4</sub>. Levels of both PGE<sub>2</sub> and LTB<sub>4</sub> were markedly higher in rectal dialysates from ulcerative colitis patients and declined to normal levels after treatment with a short course of prednisolone (Lauritsen *et al.*, 1985).

The presence of large numbers of neutrophils and mononuclear phagocytes in IBD mucosa suggests that a chemotactic factor (or factors) is present in IBD mucosa that induces neutrophils to migrate out of the circulation and into the tissue. LTB<sub>4</sub> is a potent chemoattractant for human neutrophils (Ford-Hutchinson *et al.*, 1984); however, other chemotactic compounds (IL-8, MCP-1) are present in IBD mucosa.

In an attempt to sort out the contributions of various chemotactic factors for neutrophil infiltration in IBD, a study was done using homogenized IBD mucosa as the chemotactic stimulus for <sup>51</sup>Cr-labeled neutrophils in a Boyden chamber, revealing that most of the chemotactic activity is lipophilic and coelutes with LTB<sub>4</sub> standards in reverse-phase high performance liquid chromatography (HPLC) (Stenson, 1988). If the findings using the *in vitro* assay for neutrophil chemotaxis in the Boyden chamber can be extrapolated to the *in vivo* situation, one could argue that LTB<sub>4</sub> is the chemotactic mediator that, in addition to adhesion molecules, is primarily responsible for neutrophils leaving the circulation and entering the intestinal tissue in IBD. The generation of LTB<sub>4</sub> is certainly not the initiating event in IBD, nor is it specific to IBD.

Although the role of LTB<sub>4</sub> in IBD has been studied most extensively, preliminary reports are available of a possible role for the sulfidoleukotrienes (LTC<sub>4</sub>, LTD<sub>4</sub>, LTE<sub>4</sub>; Peskar *et al.*, 1985). Crohn's colitis mucosa produced 3-fold more sulfidoleukotrienes than normal mucosa produced under both stimulated and unstimulated conditions (Peskar *et al.*, 1985). The predominant sulfidoleukotriene found was LTE<sub>4</sub>, suggesting that released LTC<sub>4</sub> is degraded rapidly by peptidases.

## XI. PLATELET ACTIVATING FACTOR

The ability to induce platelet aggregation and granulocyte activation by PAF led to its recognition as a potent inflammatory mediator. The primary pathway of PAF biosynthesis is by reacylation at the 2 position of the lysophosphatide produced by phospholipase A<sub>2</sub>. Degradation of PAF occurs via deacetylation by acetylhydrolase.

PAF can be synthesized by a variety of cell types including PMNs, macrophages, mast cells, eosinophils, basophils, endothelial cells, and platelets. PAF actually consists of multiple species, including saturated homologs and unsaturated analogs, as well as derivatives from lysophosphatides with polar head groups other than choline (Mueller *et al.*, 1984; Ludwig and Pinckard, 1987; Oda *et al.*, 1985; Weintraub *et al.*, 1985; Satouchi *et al.*, 1985; Ramesha and Pickett, 1987). Some of the pro-inflammatory activities of PAF include induction of aggregation, chemotaxis, and chemokinesis of PMNs (McManus *et al.*, 1980; Pinckard *et al.*, 1980; Shaw *et al.*, 1981); monocyte aggregation and initiation of superoxide secretion (Ingraham *et al.*, 1982; Yasaka *et al.*, 1982; Hartung, 1983; Hartung *et al.*, 1983; Gay *et al.*, 1986); and the induction of prostaglandin and leukotriene release by eosinophils, neutrophils platelets, endothelial cells, monocytes, and epithelial cells (Lin *et al.*, 1982; O'Flaherty *et al.*, 1984; Bussolino *et al.*, 1985; O'Flaherty, 1985; Brock and Gimbrone, 1986; Brunynzeel *et al.*, 1986). Direct contraction of vascular smooth muscle also can be induced, as can enhanced vascular permeability and intestinal edema (Sanchez-Crespo *et al.*, 1982; Hartung *et al.*, 1983). Some of these effects may involve cyclooxygenase-derived arachidonic acid products or histamine as secondary mediators (Humphrey *et al.*, 1982; Archer *et al.*, 1985; Hwang *et al.*, 1985).

The role of PAF in IBD is just beginning to be studied

(Figure 4). The studies by Eliakim *et al.* (1988) suggest the involvement of PAF as a pro-inflammatory mediator in IBD, which can be reduced in activity by steroids and 5-ASA. Thus, the role of PAF in IBD deserves intensive future investigation, particularly with respect to the different derivatives of PAF. PAF activity may contribute significantly to the inflammatory changes seen in IBD. The biological function of PAF is related closely to the prostaglandins and leukotrienes, which can be induced by PAF and can induce PAF synthesis as well (Shaw *et al.*, 1981; O'Flaherty *et al.*, 1984; O'Flaherty, 1985; Sun and Hsueh, 1988). Little is known currently about the mechanisms that may regulate PAF synthesis and degradation in IBD. The use of specific PAF antagonists in the treatment of IBD patients constitutes an important area for future clinical investigation.

## XII. CONCLUSION

Within the gastrointestinal tract, many different cell types contribute to the development of a successful mucosal immune response. M cells within the follicle-associated epithelium overlie Peyer's patches and can mediate the transcytosis of antigens and infectious agents to the underlying cells of the mucosal immune system. Immature cells within Peyer's patches (lymphoid follicles) are stimulated to recognize specific antigens but, instead of migrating directly to adjacent lamina propria, these cells migrate out of the gastrointestinal tract. Maturation and activation occurs while the cells are traversing through the lymphatic system. After subsequent circulation of stimulated lymphoblasts in the peripheral blood, mature activated T and B cells "home" to the intestine as specific effector cells.

In addition to producing specific cytokines that regulate cell function, lamina propria and intraepithelial T cells also secrete nonspecific inflammatory mediators, such as IFN $\gamma$ , that enhance antigen-presenting capabilities through the increased expression of Class II MHC determinants on epithelial cells and other cell types.

The intestine is fully capable of mounting an intense protective inflammatory reaction in response to infectious agents or injurious substances. Antigen presentation by intestinal macrophages triggers the production of cytokines and inflammatory mediators. Antibodies leading to complement pathway activation produce chemotactic factors and activate macrophages and granulocytes to produce pro-inflammatory cytokines and other destructive molecules. Eosinophils and mast cells are also important cell types in the intestinal immune response. The final manifestations of intestinal inflammation are, in large part, the result of the production of a wide variety of pro-inflammatory cytokines, chemotactic cytokines, and inflammatory mediators such as prostaglandins, leukotrienes, and PAF.

Intestinal inflammation in IBD is characterized by the increased activation of B and T lymphocytes in both peripheral blood and intestinal lamina propria. Activation events lead to the secretion of soluble IL-2 receptors, TNF- $\alpha$ , and IL-6, which can be detected in diseased intestine and peripheral blood and may serve as important markers of disease activity.

During active IBD, the homing to mucosal sites of lymphoblasts involved in the regulation and production of IgA is altered. Not only can increased spontaneous secretion of IgA by peripheral blood mononuclear cells be found, but IgA synthesis by intestinal lamina propria mononuclear cells is decreased in favor of immunoglobulins of the IgG-isotype. Whereas in Crohn's disease the enhancement of IgG secretion is mostly in the form of IgG<sub>2</sub> and IgG<sub>1</sub>, in ulcerative colitis a particular increase of IgG<sub>1</sub> and IgG<sub>3</sub> is observed. Through activation of complement components, the dramatic increase in IgG may contribute to the tissue destruction seen in IBD.

Monocytes and granulocytes appear to cause pivotal initiating events and enact specific effector mechanisms by migrating in large numbers into the intestinal mucosa during chronic inflammation. Because macrophages and granulocytes secrete large amounts of pro-inflammatory cytokines, lipid autacoids, and toxic metabolites, they contribute significantly to the heightened state of activation of the mucosal immune system in IBD. The investigation of important new areas, including the mechanisms leading to activation and amplification of inflammatory events as well as to the down-regulation of mucosal immune responses, will provide novel therapeutic approaches in the future.

# Malabsorption Syndromes and Intestinal Protein Loss

*D. Nadal · C. P. Braegger · P. Knoflach · B. Albini*

## I. INTRODUCTION

Absorption of nutrients and the permeability of the intestines are affected by a variety of disorders involving the immune system (Doe and Hapel, 1983; Kalser, 1985b; Wright and Heyworth, 1989). Conversely, malabsorption and malnutrition may impact the status of the immune system and, thus, the gut-associated lymphoid tissue (GALT) (Doe and Hapel, 1983; Chandra and Wadhwa, 1989). Further, increased permeability of the intestines to microbial and nutrient antigens can lead to enhanced and abnormal immune responses (King and Toskes, 1985; Cunningham-Rundles, 1987). In this chapter, we discuss malabsorption, immunologically mediated diseases leading to malabsorption, intestinal protein loss, and the effects of malabsorption and increased leakiness of the intestines on the immune system.

Malabsorption syndromes are defined by the failure of the patient to absorb ingested nutrients appropriately. Inappropriate absorption can occur in a wide variety of conditions with a broad spectrum of pathogenic mechanisms (Doe and Hapel, 1983; Kalser, 1985b; Wright and Heyworth, 1989). Malabsorption, on the other hand, may result in a gamut of effects, ranging from isolated deficiencies, such as occult anemia, to life-threatening conditions. Most severe malabsorption syndromes are characterized clinically by abdominal distention, diarrhea, progressive loss of weight, malaise, borborygmi, and, in children, failure to thrive (Frazer, 1956). Passage of abnormal stools is important diagnostically for many of the syndromes; the characteristics of the stools reflect the nature of the unabsorbed foodstuff. The stools often are bulky, yellow to grey, greasy, and soft. Bowel movements tend to be frequent.

Lymphoid cells represent one-fourth of all cells of the mucosa (Kagnoff, 1981). Therefore, that GALT is integrated closely in the homeostasis of the gastrointestinal tract and that it is involved in the pathogenesis of a large number of gastrointestinal diseases is not surprising. Malnutrition, on the other hand, can lead to a dysregulation of the immune response and, thus, to a dysfunction of GALT (Doe and Hapel, 1983; Chandra and Wadhwa, 1989). A brief look at some salient features of nutrient uptake by the gut should provide a starting point for the discussion of malabsorption syndromes.

## A. Absorption of Nutrients

The primary function of the gut to assimilate nutrients is accomplished in two stages, digestion and absorption (Kalser, 1985a). In the first "intraluminal" stage, ingested food is broken down into smaller molecules. In the second "intestinal" stage, the foodstuff thus prepared reaches the body fluids by passage across the intestinal mucosal epithelium and subsequently is removed from the intestines via capillaries and lymphatics to reach blood circulation. The passage across enterocytes may be effected passively by diffusion or actively by transport mechanisms. Although absorption occurs preferentially in the small intestines, many cells and tissues of the gut and of other organ systems contribute to the assimilation process. Thus, fat assimilation requires integration of the functions of the liver and the biliary tract, the pancreas, the jejunum, and the ileum. Integration and regulation of these diverse activities involves hormonal networks and neural interactions; these two systems affect the immune system and thus also GALT. Immune effectors may be involved in the triggering of other components of the gastrointestinal tissue; thus, release of mucus from goblet cells may be induced by immune complexes (Walker *et al.*, 1977) or via anaphylactic responses (Lake *et al.*, 1980).

In the stomach, ingested fat is emulsified, hypertonic nutrients are diluted, protein digestion is initiated by pepsin, and intrinsic factor, necessary for the absorption of vitamin B<sub>12</sub> in the small intestine, is produced. Arrival of food in the duodenum triggers release of gut hormones, which coordinate output of pancreatic enzymes and bile and may increase secretion of immunoglobulins by GALT (Freier *et al.*, 1989). The multitiered regulation of digestion and absorption is illustrated vividly by the interaction of enterocyte peptidases and pancreatic proenzymes. The brush border-associated enteropeptidase is necessary to activate trypsin (Rinderknecht, 1986). Therefore, impaired protein digestion may reflect a variety of defects: injury to enterocyte brush border, genetically determined enteropeptidase deficiency of enterocytes, as well as disorders of the exocrine pancreas.

Enterocyte brush border membranes contain a number of peptidases that brake down both large proteins and oligopeptides (Erickson and Kim, 1990). Peptidases are also present in the enterocyte cytoplasm.

Carrier-mediated transport through enterocytes is available for single amino acids and for an as yet unknown number of small peptides (Erickson and Kim, 1990). Patients with defects in transport systems for single amino acids (e.g., cystin) still can absorb the amino acid as component of oligopeptides (Steinhardt and Adibi, 1986). Iron and calcium are absorbed most efficiently in the most proximal portion of the intestines. Most other nutrients, water, and solutes are taken up with highest efficiency in the jejunum. The ileum is the primary site of absorption of vitamin B<sub>12</sub> and of bile salts. The colon is a relatively impermeable barrier for most nutrients. However, sodium and organic acids can be absorbed, and protons can be secreted into the lumen (Kalser, 1985a,c).

Appropriate absorption of food components depends (1) on their adequate preparation, that is, digestion or conjugation with appropriate factors in the intestinal lumen; (2) on the structural and functional integrity of the mucosal epithelium; and (3) on the removal of absorbed moieties by body fluids, predominantly via lymphatics. Absorption may be accomplished by diffusion or solvent drag, occurring preferentially along intercellular spaces, or by active transport employing carrier molecules and occurring across intestinal epithelial cells. For each component of food, that is, fat, protein, carbohydrate, solutes, and water, a well-defined and, in general, distinct pathway for assimilation exists. However, absorption of one food component may influence uptake of other nutrients; in this way, fat-soluble vitamin uptake is determined by the efficiency of fat absorption.

### **B. Absorption of Nutrients and Immunity**

In addition to absorption, the gastrointestinal tract also has other functions, prominent among which is the elimination of environmental noxae and parasites (Hanauer and Kraft, 1985; Kagnoff, 1989a).

The gastrointestinal tract can be envisioned as an invagination of the environment into the host's body. The gut mucosa indeed is the largest host interphase with the outside world. This interphase has two functions: (1) it is a barrier to deleterious outside stimuli and (2) it is the site of active exchange. Since molecules have to pass through the mucosal epithelium, this area lacks the mechanical protection that the multilayered and keratinized epithelium of the skin can provide, which may explain the accumulation of a variety of nonspecific host defense mechanisms in the gut, as well as the tremendous accumulation of immunologically reactive cells. Saliva, mucus, gastric juice, and bile salts, in conjunction with peristalsis, epithelial cell turnover, and low phagocytic potential of epithelial cells, are well designed to prevent foreign particulate matter and macromolecules from entering the mucosa. Obviously, GALT, divided into its two compartments, the intraepithelial lymphocytes (IEL) and the lamina propria lymphocytes (LPL), contributes a stacked specific defense mechanism encompassing humoral and cellular immunity (see Sections A–C of this handbook).

Some of the immune effectors may play a direct role in assimilating nutrients. Thus, macromolecules, on complexing with IgA, are impaired in their adherence to intestinal epithe-

lial cells. At the same time, complexing with IgA may enhance the intraluminal digestion of nutrients (Walker and Bloch, 1983), and binding of antigens by SIgA will reduce the potential to initiate IgG responses. Secretory antibodies and IEL may be essential to reducing systemic immunization to the contents of the intestines. IgA present in milk may play an important role for the immunoregulation of the newborn. (Ahlstedt *et al.*, 1977; Crago and Mestecky, 1985).

### **C. Immunity and Malabsorption**

The immune system can be involved in the pathogenesis of malabsorption syndromes (1) by interfering with digestion (e.g., antibodies to the intrinsic factor in pernicious anemia); (2) by mediating epithelial cell damage; (3) by interfering with the removal of absorbed food-derived moieties; and (4) by allowing microbial overgrowth. Mechanisms of malabsorption also may facilitate the entry of antigenic material into the mucosa and thus induce overstimulation of the immune system. Finally, malabsorption leading to malnutrition may interfere with the normal life cycle and responsiveness of immunologically reactive cells of GALT and of the immune reactivity in general.

Clinically, malabsorption may be defined as the presence of unabsorbed food components in the stool, accompanied by weight loss or failure to gain weight on an appropriate diet (Kalser, 1985b; Wright and Heyworth, 1989). Sometimes gastrointestinal manifestations are lacking or remain subclinical. Depending on the site of involvement along the digestive tract and on the extent of the damage, malabsorption may involve one or more of the constituents of food: carbohydrates, proteins, fats, small organic compounds such as vitamins, and minerals. Exquisitely "specific" malabsorption is exemplified by vitamin B<sub>12</sub> deficiency leading to pernicious anemia. On the other hand, panmalabsorption encompasses all foodstuffs to a lesser or greater degree. Diverse etiologies and pathogenic pathways may result in the same or similar nutrient deficiencies; one disease may express, in various patients and at different times, various degrees and types of malabsorption, as seen, for example, in celiac disease.

The traditional pathophysiological classification of malabsorption syndromes is based on the stage of nutrient uptake affected (Kalser, 1985b; Wright and Heyworth, 1989). The intraluminal stage may be affected either in its digestive phase or by decreased availability of ingested nutrients (Wright and Heyworth, 1989). Similarly, the intestinal stage may be deranged, by interference either with digestion at the level of the epithelial cells or with movement across the epithelium. Finally, the transport stage may be affected, most frequently, via lymphatics. However, several malabsorption syndromes exist in which a clear-cut assignment to one of these groups is not possible and in which additional as-yet-unknown factors may be involved (Kalser, 1985b; Wright and Heyworth, 1989).

Diseases evolving from disorders affecting the intraluminal stage have been reviewed extensively elsewhere and will not be discussed further. In this chapter, delineating selected aspects of malabsorption confined to the intestinal stage and

to lymphatic transport (Table I) seems appropriate. Malabsorption at the intestinal stage often involves deficient carbohydrate digestion at the brush border of epithelial cells or impaired transport of fat or proteins through these cells. The impairment of transport mechanisms may be restricted to a single substance. Finally, transfer of fat and proteins from the mucosa to other organ systems for metabolism or storage may be hampered by obstruction of capillaries or intestinal lymphatic vessels.

## II. MALABSORPTION SYNDROMES

In an attempt to classify malabsorption syndromes involving immune mechanisms from the perspective of pathogenesis, the syndromes may be categorized as (1) diseases definitively associated with infectious agents; (2) syndromes possibly associated with microbes; and (3) disorders not associated with infectious agents (Table II).

### A. Malabsorption Syndromes Associated with Infectious Agents

Chronic infection of the small intestine is the leading cause of malabsorption. Malabsorption after infection is found in apparently immunocompetent as well as in immunocompromised hosts. Malabsorption in immunodeficient hosts indeed results most often from the increased susceptibility to

infection and the direct action of the microorganisms on the small intestines. However, this does not always seem to be the case; malabsorption without demonstrable infection has been reported repeatedly in various immunodeficiency syndromes (Doe, 1983; Brown and Strober, 1988). The epidemic of acquired immunodeficiency syndrome (AIDS; for review, see Kotler, 1991a) has increased the number of patients suffering from malnutrition dramatically. Since this latter topic is of great importance and rather new, it will be discussed in some detail. The outcome of malabsorption may be complicated by the complex metabolic changes induced by the reactions of the host to infectious agents (Beisel, 1987). Changes occur in the hormonal homeostasis, carbohydrate metabolism, and nitrogen balance. Other than the mildest infections usually entail anorexia, and, with fever, increased oxygen consumption (~ 13% increase per 1°C). In recurrent or chronic infectious diseases, both the host defense and general nutritional status may be critically reduced, especially in children and adolescents.

### 1. Gastroenteritis in the Immunocompetent Host

With fully functioning specific and nonspecific host defense, acute gastroenteritis is a self-limited disease of short duration. Malabsorption usually does not develop in such patients. Long-lasting, chronic, or recurrent infections, on the other hand, can lead to malabsorption, especially in children (Owen, 1989). Pathogenic determinants that lead to protracted diarrhea are not fully understood. Protein-calorie mal-

**Table I** Classification of Malabsorption Syndromes<sup>a</sup>

Stage of absorption	Defects	Prototype diseases
Maldigestion	Pancreatic secretions Mechanical/microclimate derangements Brush border enzymes	Chronic pancreatitis, pancreatic neoplasm, cystic fibrosis Postgastrectomy syndrome, enzyme inactivation, Zollinger-Ellison syndrome, congenital enterokinase deficiency Disaccharidase deficiencies, lactase, sucrase-isomaltase, trehalase deficiency peptidase deficiencies
Malabsorption: Intestinal Stage	Intraluminal derangements Mucosal cells  Vasculature Food allergy Systemic diseases  Genetic disorders (single enzymes)  Unclassified	<u>Bacterial overgrowth</u> , ileal dysfunction, hepatocellular disease, cholestasis <u>Gluten-induced enteropathy</u> , <u>tropical sprue</u> , short bowel syndrome, <u>endocrinopathies</u> , <u>drug-induced disease</u> (Neomycin, Colchicine), acute bacterial enteritis, <u>Crohn's disease</u> , <u>Mediterranean lymphoma</u> , <u>Kaposi sarcoma</u> , <u>adenocarcinomas</u> , <u>dermatitis herpetiformis</u> , <u>psoriasis</u> , <u>Köhler-Dager syndrome</u> Radiation enteritis, chronic mesenteric vascular insufficiency <u>Milk allergy</u> , <u>protein-losing enteropathy with allergy</u> <u>Dysgammaglobulinemias</u> , <u>alpha heavy chain disease</u> , <u>systemic lupus erythematosus</u> , <u>scleroderma</u> , <u>autoimmune and immune complex vasculitides</u> , <u>mastocytosis</u> , <u>amyloidosis</u> , <u>malnutrition (exogenous)</u> Hartnup disease, cystinuria, vitamin D, magnesium deficiencies, chloridorrhea, <u>vitamin B<sub>12</sub> malabsorption</u> , abetalipoproteinemia, glucose-galactose malabsorption <u>Whipple's disease</u> , congenital malrotation of intestines, idiopathic steatorrhea
Transport Stage	Lymphatic obstruction	Retroperitoneal malignancy, intestinal lymphangiectasia, heart insufficiency, <u>sarcoidosis</u>

<sup>a</sup> Syndromes discussed in this chapter are underlined.

**Table II** Malabsorption Syndromes with Known or Likely Links to the Immune System

Category	Syndrome	Histopathology	Distribution
Associated with infectious agents	Infections in immunocompetent host	Variable villous flattening, inflammation, usually few microbes	Localized, patchy
	Infections in immunodeficient host (including AIDS)	Variable villous flattening, epithelial defects, weak inflammatory response, few plasma cells. Lymphocytes; no granulomata, usually many microbes	Patchy-diffuse
Presumably associated with infectious agents	Tropical sprue	Shortened and thickened villi, plasma cells in LP increased in numbers	Diffuse, proximal jejunum
	Whipple's disease	Numerous PAS-positive foamy macrophages	Patchy
	Sarcoidosis	Lymphatics obstructed, lymph node involvement	Patchy
No association with infectious agents	Gluten-induced enteropathy (including dermatitis herpetiformis)	Flat mucosa, crypt hyperplasia, increased IEL, increased plasma cells in LP	Diffuse-patchy, proximal jejunum
	Cow's milk intolerance	Similar to above	Similar to above
	Crohn's disease	Noncaseating granulomas with giant cells; epithelial disruption; T cells predominate surrounding ulcers	Patchy, small intestines
	Immunoproliferative small intestinal diseases	Thick, indurated segments of small intestines; extensive infiltrates with lymphocytes, immunoblasts, plasma cells; reduced crypts and villi, sometimes flat mucosa, ulcers	
	Eosinophilic gastroenteritis	Eosinophil granulocytes in lamina propria	Patchy
	Connective tissue diseases Pernicious anemia	Collagen accumulation in lamina propria None in small intestinal mucosa	Patchy-diffuse

nutrition seems to predispose to chronic diarrhea by inducing changes in the intestinal mucosa (Gracey, 1981). There is thinning of the gut wall, flattening of villi, and a cuboidal to squamous "metaplasia" of enterocytes. Inflammatory infiltrates in the *lamina propria* also are seen frequently in children with protein-calorie malnutrition, suggesting decreased host-defense. In severe protein-calorie defects, cell-mediated immunity (Seth *et al.*, 1982) is more likely to be affected than humoral immunity. It seems, therefore, that malnourishment is a primary factor predisposing to chronic diarrhea, both by direct effects on the intestinal mucosa and by impairment of host defense. The spiral of deficiency of nutrients leading to chronic diarrhea, which results in malabsorption, which aggravates the malnutrition, is a major killer of children in the developing countries of this world. Children with persistent diarrhea and malnutrition have recently been shown to be frequently infected with *Giardia lamblia*. Of interest are reports that children with giardiasis of short duration had IgG and IgA antibodies to a 57 kDa *Giardia* heat shock protein (HSP), whereas patients with chronic infections lacked the IgA response to this antigen (Char *et al.*, 1993). Since IgM class antibodies to this moiety were abundant in these patients, the authors of this report suggest a derailed switch from IgM to IgG and IgA in these subjects; this defect must be antigen specific, however, since total immunoglobulin isotypes were elevated in these children. Minute and very spe-

cific immunodeficiencies thus may exist in patients that are routinely declared "immunocompetent."

In *Giardia lamblia* infestation, diarrhea results from disruption of the brush border of epithelial cells and disaccharidase (Veghelyi, 1939; Cortner, 1959; Meyer and Radulescu, 1979). In some studies, these parasites also have been found within the intestinal mucosa (Brandborg *et al.*, 1967; Hoskins *et al.*, 1967; Morecki and Parker, 1967). Yeast infection and bacterial overgrowth may coexist with *G. lamblia* infestation. Co-infections as well as creation of mechanical barriers to absorption (Erlandsen and Chase, 1974; Poley and Rosenfield, 1981), competition for nutrients (Yardley and Bayless, 1967; Cowen and Campbell, 1973), and alteration of intestinal motility (Castro *et al.*, 1976) have been proposed as pathogenic mechanisms leading to malabsorption in these patients. In this infestation, IELs seem to be increased in density (Dobbins, 1986), suggesting a contribution of the immune system to the pathogenesis of malabsorption or to its perpetuation.

Extensive involvement of the small intestines in gastrointestinal tuberculosis may cause steatorrhea and other manifestations of malabsorption (Shin *et al.*, 1988) as a consequence of impaired lymphatic transport from the gut, especially when the mesenteric lymphatic system is involved ("tabes mesenterica"; Gorbach, 1989). In addition, intestinal luminal obstruction may lead to bacterial overgrowth (King

and Toskes, 1985). Although many patients with gastrointestinal tuberculosis have no symptoms, the increasing incidence of tuberculosis in the United States (Bloom and Murray, 1992) may enhance the relevance of this condition for medical professionals in the near future. Overgrowth of bacteria that occurs in surgical patients with blind loops or short bowel may lead to malabsorption (Weser, 1976). However, note that malabsorption is seen only infrequently in infections or infestations of immunocompetent, well-nourished hosts.

## 2. Gastroenteritis in the Immunocompromised Host

The immunocompromised host is susceptible to a wider range of microorganisms than the immunocompetent individual; the infections in patients with immunodeficiencies tend to be protracted, recurrent, or chronic. Usually, these infections do not resolve completely even with aggressive antimicrobial treatment. The spectrum of potential pathogens obviously depends on the nature of the underlying immune defects (Doe, 1983; Doe and Hapel, 1983; Brown and Strober, 1988; Kagnoff, 1989a).

**a. Primary immunodeficiencies.** Many of the congenital deficiencies of the host defense system may lead to malabsorption (Demarchi *et al.*, 1983; Kagnoff, 1989a). The importance of an intact immune system is demonstrated by the high prevalence of gastrointestinal disease in patients with immunodeficiency, even when nonspecific defense mechanisms are functioning (Brown and Strober, 1988). Incidence and frequency of malabsorption varies among the distinct entities. Immunodeficiencies of B cells and immunoglobulins are more common than deficiencies of the T-cell system (Figure 1; Stiehm, 1990). Malabsorption deficiency occurs less frequently in patients with isolated immunoglobulin deficiencies than in children with severe combined immunodeficiency.

In general, the severity of the intestinal involvement correlates well with the extent of the immunodeficiency. However,

**Figure 1** The frequency of primary immunodeficiencies categorized according to the host defense mechanisms. (Reproduced with kind permission of the author and publisher from Stiehm, 1990.)

severe immunodeficiencies may not be associated with intestinal disease, suggesting that local immune responses may be dissociated from systemic immunity; this option has been shown convincingly in the case of IgA. Patients with reduced serum IgA concentrations may have normal secretory IgA, and individuals with reduced secretory IgA may show normal serum IgA concentrations (Strober *et al.*, 1976). Thus, evaluation of the local status of GALT often is necessary to understand the underlying defect of the immune system.

IgA deficiencies, in Caucasians the most common (1 : 500) and fortunately usually the most benign of primary immunodeficiencies (among Japanese, the incidence is much lower; Kanoh, 1991), only seldom lead to gastrointestinal disease (Fisher *et al.*, 1982; Kagnoff, 1989a). However, IgA deficiencies may be associated with nodular lymphoid hyperplasia of the intestines (Brown and Strober, 1988), inflammatory bowel disease (IBD; Hodgson and Jewell, 1977; Doe and Hapel, 1983), and disaccharidase deficiencies (Dubois *et al.*, 1970). Patients with IgA deficiency also may have a propensity for infestation with *G. lamblia*. Although isolated deficiency of the secretory piece has been described (Strober *et al.*, 1976), the patient developed diarrhea and intestinal candidiasis but not malabsorption. Ample evidence exists for "immune exclusion breakdown" in IgA-deficient patients (Soothill *et al.*, 1976; Cunningham-Rundles *et al.*, 1979; Cunningham-Rundles, 1987). However, conclusive demonstration of a direct relationship between IgA deficiency and immune exclusion breakdown still is lacking (Brown and Strober, 1988). Similarly, the increased incidence of food allergies in IgA-deficient patients requires further analysis to understand the mechanism linking the two phenomena (Cunningham-Rundles *et al.*, 1979).

In patients with X-linked hypogammaglobulinemia, described by Bruton (1952) and characterized by Good and his collaborators (Peterson *et al.*, 1965), gastrointestinal disorders become seldom manifest. In a few patients, inflammation of the colonic mucosa, acute or chronic rotavirus infection (Saulsbury *et al.*, 1980), infestation with *G. lamblia*, bacterial overgrowth (Ament *et al.*, 1973), or lactase deficiency (Dubois *et al.*, 1970) is apparent.

Much more frequent are gastrointestinal disorders in patients with common variable hypogammaglobulinemia (CVH). In a study of 50 patients with this primary immunodeficiency, 60% had diarrhea and 40% had malabsorption (Hermans *et al.*, 1976). In CVH, the lamina propria of the intestine usually shows a reduction in numbers of plasma cells of all isotypes (Brown *et al.*, 1972a,b). There may be a partial villous atrophy, which does not improve with gluten restriction (Brown *et al.*, 1972a). IBD may occur in patients with CVH more frequently than in immunocompetent individuals (Kagnoff, 1989a). Bacterial overgrowth is documented in CVH patients (Brown *et al.*, 1972b; Hermans *et al.*, 1976), and infections with *Helicobacter jejuni* may resemble IBD when lasting over prolonged periods of time (Ahnen and Brown, 1982). In CVH, *Shigella* and *Salmonella* also may be seen (Hermans *et al.*, 1976; Ahnen and Brown, 1982). Over 65% of patients with CVH have an infestation with *G. lamblia*; this protozoan causes extensive tissue damage in some of these patients (Brown *et al.*, 1972b; Ament *et al.*,

1973; Hermans *et al.*, 1976). In addition, cryptosporidiosis (Current *et al.*, 1983) and strongyloidiasis (Brandt de Oliveira *et al.*, 1981) have been reported in CVH patients.

Interestingly, pernicious anemia and atrophy of the entire stomach mucosa, associated with normal gastrin levels, occurs frequently in CVH patients (Twomey *et al.*, 1969; Brown *et al.*, 1972a). CVH patients may show intestinal nodular lymphoid hyperplasia (Hermans *et al.*, 1976). The nodules contain many IgA-bearing B cells but few mature IgA-producing plasma cells. The striking difference in the frequency and severity of gastrointestinal symptoms and malabsorption between CVH and X-linked hypogammaglobulinemia is still puzzling, but may find an explanation in the concomitant T-cell derangements of CVH.

Congenital thymic aplasia, described by DiGeorge (1968), sometimes manifests with malabsorption as well as other gastrointestinal symptoms (Cleveland, 1975). Similarly, chronic mucocutaneous candidiasis may lead to carbohydrate intolerance, iron deficiency, and diarrhea (Asquith, 1979; Brown and Strober, 1988).

Combined B- and T-cell defects lead in many patients to severe gastrointestinal disorders, including severe malabsorption. Jejunal villi may be shortened and the mucosa may show appreciably increased numbers of vacuolated macrophages and tissue edema (Brown and Strober, 1988; Kagnoff, 1989a). Some patients with Nezelof's syndrome, a T-cell deficiency associated with variable B-cell defects (Stiehm, 1990), have malabsorption (Ament, 1975). Ataxia telangiectasia, a T-cell deficiency often combined with IgA deficiency, may develop mild malabsorption (Ament *et al.*, 1973). Steatorrhea and vitamin B<sub>12</sub> deficiency have been described in the Wiskott-Aldrich syndrome, encompassing a T-cell defect and decreased IgM synthesis (Ament *et al.*, 1973).

In chronic granulomatous disease, phagocyte deficiency in which the oxidative metabolism is disturbed in neutrophilic granulocytes (Stiehm *et al.*, 1989a), steatorrhea and panmalabsorption have been seen (Ament and Ochs, 1973). Lipid-filled pigmented macrophages similar to those observed in Whipple's disease appear sometimes in the mucosa. Some patients with this disorder may have lesions resembling those of Crohn's disease (Werlin *et al.*, 1982).

Whereas in most primary immunodeficiency patients with gastrointestinal symptoms, intestinal infections are the likely causes of malabsorption, others have malabsorption without any such apparent infection. The pathogenic mechanisms involved in the latter conditions are not known.

Since mucosal lesions in primary immunodeficiency syndromes often are patchy and therefore can be missed easily, several biopsies should be taken of the same patient. *In situ* hybridization techniques may be useful for the identification of infectious agents in tissue samples. Correction of the immunodeficiency, for example, replacement of immunoglobulin, often reverses malabsorption and histological changes.

**b. Secondary immunodeficiencies.** Secondary or acquired immunodeficiencies develop in the wake of a host of infections and other diseases. In the following section, malabsorption associated with AIDS and with some neoplasms will be

discussed. Malabsorption and intestinal protein loss as causes of impaired immune responsiveness are covered in Section IV of this chapter.

*i. The acquired immunodeficiency syndrome (AIDS).* AIDS increasingly has gained in importance among secondary immunodeficiencies. AIDS patients often have involvement of the gastrointestinal system (Friedman-Kien, 1981; Gottlieb *et al.*, 1981; Fischel *et al.*, 1990; Kotler, 1991a). The spread of AIDS during recent years has contributed appreciably to the number of individuals suffering from chronic diarrhea and malabsorption syndromes. Whereas AIDS was defined originally in developed countries by Kaposi sarcoma and *Pneumocystis carinii* pneumonia, in Africa and Caribbean countries, AIDS is most impressively defined by the "enteropathic" variant, consisting of chronic diarrhea (more than 30 days of diarrhea over a 2 month period), wasting, and fever (Keusch *et al.*, 1992).

Studies performed in industrialized as well as developing countries have documented gastrointestinal dysfunction in 50–90% of individuals testing positive for antibodies to the human immunodeficiency virus (HIV) (Malenbranche *et al.*, 1983; Budhrajia *et al.*, 1985; Friedman and Owen, 1989). and 30–60% have malabsorption (Brasitus and Sitrin, 1990). Several mechanisms have been postulated in attempts to explain the high rate of intestinal dysfunction in this immunodeficiency. The gut is a major route of infection in AIDS, which has been considered one of the factors leading to the high incidence of intestinal derangements in this disease (Kagnoff *et al.*, 1991). Nevertheless, in patients with blood-borne HIV infection, for example, hemophiliacs, intestinal involvement is high also (Okubo and Yasunaga, 1991). Table III lists the main pathogens responsible for gastrointestinal morbidity in AIDS, as well as the currently available methods for their detection and the therapy regimens—in part still experimental—for their eradication. A depletion of helper T cells in the mucosa was hypothesized to lead to impaired immune responses to antigenic moieties and mitogens. This immunodeficiency could render the patients susceptible to infection with opportunistic and nonopportunistic intestinal pathogens (Brown and Strober, 1988). These pathogens then could lead to debilitating diarrhea and malabsorption. Alternatively, HIV infection of small intestinal mucosal cells could be responsible for malabsorption directly (Nelson *et al.*, 1988; Fox *et al.*, 1989; Ullrich *et al.*, 1989; Yolken *et al.*, 1991). AIDS patients also have anorexia, resulting in severe malnutrition in conjunction with malabsorption. Diarrhea and loss of body weight are the most common clinical manifestations of gastrointestinal AIDS; in Africa, AIDS often is called "Slim's disease" (Greene, 1988).

The ratio of CD4<sup>+</sup> to CD8<sup>+</sup> cells, which is decreased severely in the blood of AIDS patients, has been reported to be decreased (Rodgers *et al.*, 1986) or increased (Kotler *et al.*, 1986) in the intestinal mucosa. In another study (Riecken *et al.*, 1991), a decrease of CD4<sup>+</sup> LPLs has been demonstrated in patients with AIDS, but this decrease was much smaller than that seen for blood lymphocytes. At the same time, a significant increase of CD8<sup>+</sup> cells was seen (Riecken *et al.*, 1991). Interestingly, the activation marker

**Table III** Diagnosis and Treatment of Intestinal Infections in Patients with AIDS

Organism	Diagnosis	Treatment
<b>Fungi</b>		
<i>Candida</i> sp.	SS: gram, culture	Nystatin, Amphotericin B, Fluconazole, Clotrimazole
<b>Protozoa</b>		
<i>Cryptosporidium</i>	SS or DA: Ziehl-Neelson, monoclonal antibody; SBB with histology	Experimental: Spiramycin, Transfer Factor, Hyperimmune Bovine Serum and Colostrum, Monoclonal Antibodies, Somatostatin
<i>Iso spor a belli</i>	SS or DA: Ziehl-Neelson, modified acid-fast	Trimethoprim-Sulfamethoxazole
<i>Microsporidia</i>	SS or DA: Chromotropy; SBB	None proven
<i>Giardia lamblia</i>	SS or DA: microscopy or ELISA	Metronidazole, Quinacrine-HCl, Furazolidone
<i>Strongyloides stercoralis</i>	SS or DA for rhabditiform larvae; SBB	Thiabendazole
<b>Viruses</b>		
Cytomegalovirus	SBB	Gancyclovir, Foscarnet
Herpes simplex		Acyclovir
<b>Bacteria</b>		
<i>Mycobacterium Avium-intracellulare</i>	SS or DA: Ziehl-Neelson, culture or genome detection	Rifampin or Rifabutin + Clofasimine, Ethambutol, Ethionamide, Streptomycin and Clarythromycin
<i>Mycobacterium tuberculosis</i>	SS or DA: Ziehl-Neelson, culture or genome detection	Isoniazid, Rifampin, Pyrazinamide, Streptomycin
<i>Salmonella typhimurium</i>	SS: gram, culture	Antibiotics
<i>Shigella</i>	SS: gram, culture	Antibiotics

DA, duodenal aspirate; SBB, small bowel biopsy; SS, stool smear.

CD25 is expressed on fewer T cells in the mucosa of AIDS patients than in that of healthy subjects (Riecken *et al.*, 1991). The same authors suggested that CD4<sup>+</sup> cells in the mucosa may be less susceptible to HIV-induced cell death, but may respond to HIV infection by improper activity.

The number of IgA-producing intestinal plasma cells has been found to be decreased (Kotler *et al.*, 1987) or normal (Rodgers and Kagnoff, 1987) in AIDS patients compared with normal individuals. A study of the parotid glands of AIDS patients suggests that IgA production may be reduced severely; Muller *et al.* (1991) have found a decrease of both IgA1 and IgA2 concentrations in the secretion of this gland. This local mucosal reduction of IgA was accompanied by a significant increase of serum IgA, but correlated well with decreased CD4:CD8 ratios for blood T cells (Muller *et al.*, 1991). Immune complexes, predominantly consisting of IgA1 (Jackson *et al.*, 1988), have been demonstrated in some AIDS patients. The impact of circulating immune complexes on tissue lesions and immunoregulation in AIDS is not yet understood.

A direct pathogenic effect of HIV on gastrointestinal tract cells in AIDS patients has not yet been demonstrated convincingly, albeit several findings do suggest such an effect (Kotler *et al.*, 1984; Rodgers *et al.*, 1986; Brown and Strober, 1988). Intestinal disease has been shown to occur often in patients with AIDS who do not have other intestinal infections (Kotler *et al.*, 1984). However, inability to demonstrate infectious agents may not be equated with absence of the infectious agents.

Genetic material of HIV has been reported in the intestinal epithelium of AIDS patients (Mathjis *et al.*, 1988; Nelson *et al.*, 1988), and HIV core antigen (p24) has been found in

various cell types of the intestinal mucosa (René *et al.*, 1988; Reka *et al.*, 1989; Ullrich *et al.*, 1989). Scientists generally agree that 20–40% of patients with AIDS have HIV-infected mononuclear cells in the lamina propria of the intestines (Fox *et al.*, 1989), even early in the disease. Some colonic epithelial cell lines can be infected with HIV (Kagnoff *et al.*, 1991). HIV seems to attach to some cell lines via CD4. HIV infection of the line HT29, however, cannot be inhibited by antibodies to CD4 (Kagnoff *et al.*, 1991). Whether infection of epithelial cells with HIV is important in the pathogenesis of intestinal disorders of AIDS patients is not known, since the consequences of infection of mucosal cells with HIV are not understood as well as those of infection of systemic lymphocytes and macrophages (Kotler, 1991b). Recently, no significant difference in D-xylose uptake could be detected in patients with or without HIV gp41 in their duodenal mucosa (Ehrenpreis *et al.*, 1992). In this study, HIV was present only in lamina propria mononuclear cells, and not in neuroendocrine cells or enterocytes. Presence of HIV in enterocytes was associated with the most severe malabsorption in another group of AIDS patients (Heise *et al.*, 1991); localization of HIV in enterocyte, however, seems to be a rare event, since four out of five patients with HIV in the small intestine had the viral antigens only in infiltrating mononuclear cells. Heise *et al.* (1991) conclude that infection of the intestines with HIV is an early event and that infection of enterocytes alters their differentiation and function, which leads to malabsorption.

The histopathology of HIV-associated intestinal disorders may suggest a difference between directly HIV-induced tissue lesions and those mediated by secondary intestinal infections. Partial villous atrophy combined with crypt hyperplasia

seems characteristic in patients with the latter, whereas patients without detectable secondary infections seem to show minimal villous atrophy and reduced mitotic figures in the crypt. Kotler *et al.*, (1984) have shown extensive degeneration of intestinal crypt cells among patients with AIDS, with a presentation reminiscent of graft-versus-host reactions (Sapin *et al.*, 1977). Lactase and  $\beta$ -glucosidase, as well as alkaline phosphatase, deficiencies in intestinal epithelium of AIDS patients suggest delay of intestinal epithelial cell maturation. In six AIDS patients with fat malabsorption, only the two patients infected with opportunistic enteropathogens (*Cryptosporidium* spp. and *Isospora belli*) had abnormal ileal absorptive functions (Kapembwa *et al.*, 1990). These data suggest that in nonsuperinfected AIDS gastroenteritis, only the upper jejunum is involved in malabsorption, whereas superinfection extends the involvement to the ileum.

Among the most frequently diagnosed intestinal parasites of AIDS patients are *Cryptosporidium*, *Isospora belli*, *Microsporidium* (Levine, 1980), *G. lamblia*, and *Strongyloides stercoralis* (René *et al.*, 1991). The relative importance of other agents such as *Blastocystis hominis*, *Dientamoeba fragilis*, *Balantidium coli*, and nonpathogenic *Entamoeba* strains has not yet been clarified. In immunocompetent patients, infestation with these pathogens usually responds well to therapy and is of short duration; in AIDS patients, the course is protracted and severe.

*Cryptosporidium*, known prior to 1982 almost exclusively as an animal pathogen (Current *et al.*, 1983; Navin and Juraneck, 1984), increasingly causes disease in immunocompetent and immunocompromised humans (René *et al.*, 1991). In immunologically competent patients, this parasite causes mild diarrhea, nausea, abdominal cramps, anorexia, and low grade fever. In immunodeficient hosts, the organism often leads to a devastating disease manifesting with protracted diarrhea and malabsorption (Soave *et al.*, 1984; Navin and Juraneck, 1984; René *et al.*, 1989, 1991); up to 25 bowel movements per day have been reported in *Cryptosporidium*-infected AIDS patients (Whiteside *et al.*, 1984). The diarrhea most likely is of the enterotoxin-induced secretory type (Friedman and Owen, 1989; René *et al.*, 1991); however, enterotoxin secretion by *Cryptosporidium* has not yet been shown conclusively. Note that immunocompetent individuals infested with *Cryptosporidium* report a history of contacts with animals; such an association is lacking in AIDS patients. Cryptosporidiosis in AIDS patients is unremitting and, in general, refractory to therapy.

*Isospora belli*, rare in immunocompetent individuals, causes chronic profuse watery diarrhea in AIDS patients, resulting in dehydration, weight loss, and steatorrhea (DeHovitz *et al.*, 1986), especially in patients in developing countries (DeHovitz *et al.*, 1986; Sevankambo *et al.*, 1987). *Microsporidium* has been reported to play a pathogenic role in malabsorption syndromes of AIDS (Desportes *et al.*, 1985; Dobbins and Weinstein, 1985; Orenstein *et al.*, 1990). On the other hand, *G. lamblia* and *Entamoeba histolytica* do not show a more severe progression in AIDS patients than in immunocompetent hosts (René *et al.*, 1991), a puzzling finding.

One of the first clinical manifestations of the decay of

immune functions in HIV-infected patients is the colonization of the gastrointestinal tract by *Candida* species (René *et al.*, 1991). Most commonly, *Candida* is found in the oral cavity and in the esophagus, the latter causing odynophagia and dysphagia (Klein *et al.*, 1984; René *et al.*, 1991). Ulcers in the mouth and the esophagus rarely spread to the submucosa or to distant organs. The normal function of neutrophilic granulocytes in AIDS patients may explain the relatively successful containment of *Candida*. Although the gastrointestinal tract cannot be cleared completely of this yeast, response to treatment often is good. *Candida* has not been shown to cause severe malabsorption.

*Salmonella typhimurium* and *Shigella flexneri* have been demonstrated in the feces and blood of patients with AIDS (Soave *et al.*, 1984; Dobbins and Weinstein, 1985; Glaser *et al.*, 1985; Jacobs *et al.*, 1985; Whimbey *et al.*, 1986; Baskin *et al.*, 1987). Antibiotic-resistant *Heliobacter jejuni* has been seen to persist in a patient with AIDS (Dworkin *et al.*, 1986; Whimbey *et al.*, 1986; Laughon *et al.*, 1988). Rather frequently, patients with bacterial intestinal infections and AIDS have atypical mycobacteria (Damsker and Bottone, 1985; Roth *et al.*, 1985), most common among which is *Mycobacterium avium-intracellulare*; *Mycobacterium malmoense* and, most recently described, *Mycobacterium ganavense* may be involved more often than yet recognized. These microorganisms are found in lymph nodes, bone marrow, spleen, liver, and the stool of some AIDS patients. Clinically, intestinal mycobacterial infection in AIDS is characterized by diarrhea. Despite large numbers of acid-fast microorganisms, a striking absence of granulomatous tissue lesions can occur in this syndrome (Shin *et al.*, 1988) *Mycobacterium tuberculosis* has joined HIV in a diabolic marriage, causing outbreaks of multidrug-resistant tuberculosis in HIV-positive patients (Chaisson, 1993). The rapid progression of *M. tuberculosis* infections in immunodeficient patients enhances propensity for development of multidrug resistance. Most recently, the mutual enhancement of *M. tuberculosis* and HIV infections has become better understood. Wallis *et al.* (1993) have obtained elegant data suggesting that PPD stimulates peripheral blood mononuclear cells to produce large amounts of tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ); TNF- $\alpha$  up-regulates HIV expression *in vitro*, and it can be hypothesized that co-infection with *M. tuberculosis* thus may enhance HIV-disease progression. On the other hand, Forte *et al.* (1992) showed that T-cell mediated destruction of macrophages harboring mycobacteria was significantly impaired in patients infected with HIV. *M. tuberculosis* in AIDS most commonly involves the lungs, but extrapulmonary involvement is not unusual.

*Cytomegalovirus* (CMV) is by far the most frequent opportunistic virus in gastrointestinal disorders of AIDS (Figure 2; Welch *et al.*, 1984). Severe CMV disease occurs virtually only in severely immunocompromised hosts. The gastrointestinal disease may involve the stomach, duodenum, and colon and, most frequently, the rectosigmoid (Centers for Disease Control, 1982; Frank and Raicht, 1984; Meiselman *et al.*, 1985). Histological findings include isolated viral inclusion bodies, vasculitis, and inflammatory cell infiltrates as well as ischemic and gangrenous lesions (Clayton, 1991). The clinical

**Figure 2** CMV enteritis. A 45-year-old male with 3 weeks of malaise, diarrhea, and weight loss. The X-ray shows dilatation, fluid retention, and marked edema of the jejunum (arrow) with only mild fold prominence in the ileum (open arrow). [Reproduced from Baer, J. and Hilton, S. (1991). Radiologic changes in AIDS. In "Gastrointestinal and Nutritional Manifestations of the Acquired Immunodeficiency Syndrome" (D. P. Kotler, ed.). Raven Press, New York, with the kind permission of the authors and the publisher.]

presentation varies from asymptomatic infection to debilitating enteritis, colitis, or even perforation of the bowel (Foucar *et al.*, 1981; Frank and Raicht, 1984). Sometimes the CMV infection mimics IBD (Brown and Strober, 1988). Bacteremia with enteric organisms may accompany CMV enteritis and colitis. The diagnosis relies on virus culture from biopsy material and demonstration of inclusion bodies in tissue sections (René *et al.*, 1991). Blood culture is not useful, since many patients have CMV in the blood without any disease (Masur and Fauci, 1989). For treatment, 9(1,3-dihydroxy-2-proepoxymethyl)guanine (DHPG, Ganciclovir; Koretz *et al.*, 1986) and phosphoformate (Foscarnet) are used (Weber *et al.*, 1987). Life-long suppression of the virus may be necessary.

*Herpes simplex* virus infects perioral and perianal regions, the rectum, the oropharynx, and the esophagus of patients with AIDS (Siegal *et al.*, 1981; Goodell *et al.*, 1983; René *et al.*, 1991). Lesions are hemorrhagic, ulcerative, or necrotic. Acyclovir-resistant herpes simplex virus infections usually can be treated with foscarnet or vidarabine (Safrin *et al.*, 1991).

In patients with Kaposi's sarcoma (Kaposi, 1872) of the gastrointestinal tract, malabsorption has been described (Bryk *et al.*, 1978), as has protein-losing enteropathy (Perrone *et al.*, 1981; Laine *et al.*, 1987) and intestinal perforation (Mitchell and Feder, 1949) or obstruction (White and King, 1964). Non-Hodgkin's lymphomas, a rather common and often fatal complication of AIDS, involve the gastrointestinal tract in up to 25% of cases (Ziegler *et al.*, 1984; Ioachim *et al.*, 1985). These lymphomas are usually of the B-cell type, show a translocation between chromosomes 8 and 14 (Peterson *et al.*, 1985; Berheim and Berger, 1988), and may arise from polyclonal B-cell stimulation by Epstein-Barr virus (EBV) and other viral agents (Knowles *et al.*, 1989). The intestinal lesions may lead to bleeding, perforation, and retroperitoneal lymphadenopathy (Potter *et al.*, 1984; Subar *et al.*, 1991).

Since Zidovudine (AZT) is associated with hematologic toxicity, it is likely that this drug also interferes with the rapidly proliferating intestinal epithelium. Fortunately, however, clinical trials have not documented any significant adverse intestinal reactions to AZT therapy (e.g., Volberding *et al.*, 1990), and Ullrich *et al.* (1992) report even trends of morphologic and functional normalization of small intestines in HIV-antibody positive patients with gastrointestinal involvement without secondary enteric infections, when treated with AZT. This data would be in good agreement with reports on weight gains in AIDS patients upon AZT treatment (Yarchoan *et al.*, 1986); they are, however, statistically not significant and have to be interpreted with caution.

*ii. Neoplastic diseases not associated with AIDS.* Some patients with lymphomas, lymphosarcomas, thymomas, or chronic lymphatic leukemia may lose their ability to synthesize one or more classes of immunoglobulins (Brown and Strober, 1988). The resulting hypoglobulinemia may increase their susceptibility to intestinal infections and lead to malabsorption. Increased immunoglobulin catabolism, sometimes seen in patients with severe burns, nephrotic syndrome, or protein-losing enteropathy, may initiate the same chain of events.

## **B. Malabsorption Syndromes Possibly Associated with Infectious Agents**

The syndromes discussed in the following section—tropical sprue, Whipple's disease, and sarcoidosis—long have been considered potentially related to infections. Definitive demonstration of such an association, however, has not yet been accomplished, with the possible exception of Whipple's disease.

### **1. Tropical Sprue**

Within weeks, months, or, more commonly, 1–2 yr of arrival, visitors to the tropics may develop tropical sprue (Sheehy, 1985; Klipstein, 1989). The illness is characterized by acute onset with an episode of explosive diarrhea that resolves within a week into chronic gastrointestinal symptoms, including abdominal distension and cramps. Many patients develop milk intolerance because of lactase deficiency

(Klipstein, 1989); some individuals manifest alcohol intolerance (Klipstein, 1989). After 1–3 months, the folate stores of the body are depleted. Anorexia, malabsorption, and progressive weight loss follow. Glossitis and, eventually, symptoms of anemia occur 1–3 months later (Gardner, 1958). Adults are affected more often than children. The disease may occur as a single case, or in epidemics (O'Brien and England, 1971; Jones *et al.*, 1972). Formerly, the condition was believed to develop exclusively in European travelers or immigrants, but now the disease is recognized to affect native populations of the endemic, (i.e., tropical) areas even more often (Thomas and Clain, 1976).

The epidemiological aspects of tropical sprue strongly suggest an infectious cause. However, no single specific infectious agent has been isolated to date (Sheehy 1985; Klipstein, 1989). Contamination of the small intestines by coliform bacteria including *Klebsiella pneumoniae*, *Escherichia coli*, and *Enterobacter cloacae* (Gorbach *et al.*, 1969) has been considered to play a role in the pathogenesis of tropical sprue because these bacteria synthesize enterotoxins and ethanol, which are able to damage intestinal mucosa (Klipstein *et al.*, 1973, 1978). Also, a not-yet-identified virus may be associated with this disease. Dietary lipids may have some relevance for the pathogenesis. Secondary folic acid deficiency seems to play a perpetuating role, since treatment with folic acid may lead to resolution of the disease (Chuttani *et al.*, 1968).

Pathophysiologically, tropical sprue is characterized by impaired production of intrinsic factor and hydrochloric acid by the stomach and net secretion of water and electrolytes by the jejunum (Corcino *et al.*, 1983). Malabsorption of carbohydrates, amino acids, fat, fat-soluble vitamins, vitamin B<sub>12</sub>, and bile salts occurs (Klipstein, 1989). In chronic disease, megaloblastic anemia develops because of deficiency of folic acid and vitamin B<sub>12</sub>. In 50% of the patients, hypoalbuminemia and decreased serum concentrations of cholesterol are seen; one-third of patients present with a mild hypocalcemia.

Diagnosis of tropical sprue is based on the exclusion of other pathognomonic entities such as intestinal infestation by parasites and small intestinal contamination with coliform bacteria. The mucosa shows lengthening of the crypts, broadening and shortening of the villi (which are usually thickened and coalesce to form leaves), and infiltration by cells characteristic of chronic inflammation. These changes are seen already early in disease. Less than 10% of the patients have a classical "flat mucosa". Jejunal biopsy allows differentiation from gluten enteropathy (flat villi), infiltrative disorder (lymphoma), and Whipple's disease. The optimal treatment consists of oral folic acid (5 mg/day for 6 months), tetracycline (250 mg qid for 1 month, followed by 250 mg bid for 5 months), and 1000 µg vitamin B<sub>12</sub> several times initially and then at monthly intervals (Klipstein, 1989). Clinical improvement with the appropriate treatment gives final evidence for the correctness of the diagnosis.

## 2. Whipple's Disease

Recently, the etiologic agent of Whipple's disease or intestinal lipodystrophy, first described in 1907 (Whipple, 1907), has been tentatively identified as *Tropheryma whippelii*. The

disease has not been reproduced in animals; clinically, the disorder commonly is defined as a systemic bacterial illness affecting primarily middle-aged Caucasian males (Dobbins, 1985). Affected individuals have a history of intermittent arthralgia in several joints, lasting for years. The actual illness develops gradually with diarrhea turning into steatorrhea in 93% of the patients, with subsequent weight loss and a deterioration of the patients' general status. Normocytic and normochromic anemia is noted in 90% of the patients. Half the patient population demonstrates hypotension and hyperpigmentation. Other clinical manifestations include low grade fever, peripheral lymphadenopathy, and neurological abnormalities. A few patients have Whipple's disease without gastrointestinal involvement (Mansbach *et al.*, 1978). Most frequently, such extragastrointestinal Whipple's disease seems to involve neural tissue (Feurle *et al.*, 1979; Brown *et al.*, 1990; Wroe *et al.*, 1991; Amarenco *et al.*, 1991). In some cases, diagnosis may be delayed when gastrointestinal involvement occurs only after many years. Thus, IgA nephropathy and hypercalcemia have been reported to precede gastrointestinal symptoms of Whipple's disease by 2 to 5 years (Stoll *et al.*, 1993), and chronic polyarthritis by 16 years in one patient (Scheib and Quinet, 1990).

The diagnosis is established by small bowel biopsy; the disease shows, in the proximal small intestine, typical club-shaped villi and a lamina propria replete of macrophages loaded with sickle-form particles (SPC cells) intensively stained by periodate–Schiff reagent (PAS) (Sieracki and Fine, 1959). Such SPC cells are found in virtually all organs, but most prominently in the lamina propria of the small intestine and its lymphatic drainage, the heart valves, and the central nervous system.

Electronmicroscopically, the Whipple organism resembles structurally intact or degenerating bacteria (Dobbins and Kawanishi, 1981). The bacillus is gram positive, and is present not only in macrophages but also in intestinal epithelial cells, lymphatic and capillary endothelial cells, smooth muscle cells, polymorphonuclear leucocytes, plasma cells, mast cells, and IELs. The nucleotide sequence of bacterial 16 S ribosomal DNA from the intestinal biopsy of a patient with Whipple's disease was shown to have close relation to *Rhodococcus*, *Streptomyces*, and *Actinobacter* genera, and weaker homology with mycobacteria (Wilson *et al.*, 1991). One year later, Relman *et al.* (1992) reported on a 1321-base-long bacterial 16S rRNA sequence amplified by PCR from duodenal tissue of a patient with Whipple's disease. Subsequently, it was shown that the same sequence was present in intestinal tissue of all five patients studied with Whipple's disease, but in none of the 10 patients with other diseases. Phylogenetic analysis suggested that the bacterium is a gram-positive actinomycete, unrelated to any of the known genera. This bacterium (as yet uncultured) was named *Tropheryma whippelii*.

Most patients respond to treatment with antibiotics. Currently, the recommended regimen is penicillin G (1.2 million Units/day) and streptomycin (1.0 g/day) for 10–14 days, followed by trimethoprim/sulfamethoxazole for 1 yr (Trier, 1989a).

### 3. Sarcoidosis

Sarcoidosis may involve, among other organs, the gastrointestinal tract (Fick and Hunninghake, 1988); the stomach is the most common gastrointestinal site. However, small intestinal involvement also has been described and may cause malabsorption and protein-losing enteropathy (Sterling, 1951). Differential diagnosis includes Crohn's disease. Colonic sarcoidosis is seen only infrequently. The words of Longcope and Freiman (1952), that "the etiology of sarcoidosis still is obscure," remain valid. Within lesional tissue, acid-fast coccobacillary microorganisms have been seen (Canturee, 1982). These findings are compatible with the presence of wall-deficient bacteria, most likely related to mycobacteria or non-diphtheria *Corynebacterium* species. However, mycobacteria, especially atypical mycobacteria, have been associated most frequently with sarcoidosis (Vanek and Schwarz, 1970; Mitchell *et al.*, 1992; Saboor *et al.*, 1992). Nevertheless, convincing evidence for a pathogenic role of these microorganisms has never been established. Twenty years ago, combined infection with mycobacteria and viruses has been suggested to explain the pathogenesis of sarcoidosis (Hanngren *et al.*, 1974). *Bacillus Calmette-Guerin* (BCG) vaccination in individuals with virus-induced T-cell impairment has been proposed to lead to sarcoidosis. In addition to microbial agents, chemicals and drugs have been discussed in the framework of a pathogenesis for sarcoidosis, as have allergy and autoimmunity (Fick and Hunninghake, 1988). Sarcoidosis occurs in a familial pattern (Prendville *et al.*, 1982) and some clinical manifestations have been associated with HLA-encoded antigens.

The granulomatous lesions of sarcoidosis are characterized by large numbers of T cells. These T cells are predominantly carrying  $\alpha/\beta$  TcR on their surface, as do the T cells in granulomata of tuberculosis (Tazi *et al.*, 1991), and they show signs of recent antigenic stimulation (Du Bois *et al.*, 1992). As in many other inflammatory conditions, increased expression of adhesion molecules is seen in sarcoidosis, where it may contribute to extravasation, aggregation in tissue and granuloma formation (Shakoor and Hamblin, 1992). Similarly most likely reflecting inflammation, alveolar macrophages in sarcoidosis have been shown to release spontaneously tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin 1 (IL-1) (Strausz *et al.*, 1991), and prostaglandin E<sub>2</sub> (PGE<sub>2</sub>); however, there was no correlation between the amount of inflammatory mediators released and clinical status of disease or steroid usage (Pueringer *et al.*, 1993). Of more potential interest for the understanding of the pathogenesis of tissue lesions in sarcoidosis is a report on a defect at the level of G-proteins in peripheral blood lymphocytes of patients with sarcoidosis (Nemoz *et al.*, 1993). These authors hypothesize that a defect in the negative control of adenylate cyclase, mediated by the inhibitory G-protein G<sub>i</sub>, prevents the lowering of cAMP necessary for normal mitogenic responses of blood lymphocytes. In addition, both cAMP and cGMP phosphodiesterase activities were found decreased in blood lymphocytes of sarcoidosis patients.

The small intestine malabsorption in this disease arises

indirectly, through lymphatic obstruction following mesenteric lymph node enlargement. Dilated lacteals can be seen in patient intestinal biopsies (Sprague *et al.*, 1984).

### C. Malabsorption Syndromes Not Associated with Infectious Agents

Several malabsorption syndromes are not related to infectious agents but are associated with immune responses and heightened activity of GALT. These conditions comprise a heterogeneous group of diseases, usually with poorly understood pathogenesis, and present with a gamut of tissue lesions (Table II). In some of these syndromes, immunoreactive cells could be the primary mediators of the pathogenesis; in others, exogenous noxae, primarily extraintestinal diseases, and inborn errors of metabolism may be of etiological importance.

#### 1. Gluten-Induced Enteropathy

The first description of "sprue" is attributed to Aretus of Cappadocia (1856), who lived in the second century of our era. Nevertheless, the formal definition of gluten-induced enteropathy (GIE; synonyms: celiac disease, celiac sprue) still is not fully satisfactory and its causes are poorly understood. Gee (1888) described the clinical manifestations of GIE in pediatric patients; Thaysen (1932) gave the classical description of this syndrome in adults. In the early 1950s, Dicke (1950) established the association between the clinical syndrome and the intake of wheat and some other cereal grains through epidemiological analysis. He and his co-workers (van de Kamer *et al.*, 1953) subsequently recognized gluten as the major component of cereals involved in GIE. Finally, Paulley (1954) published an extensive study on the histopathology of this disease.

The major clinical manifestations of GIE result from the malabsorption of nutrients, predominantly involving the proximal small intestine. The disease is defined further by characteristic, but not specific, changes of the small intestinal mucosa, namely deepening of crypts and loss of villi ("flat mucosa"), and by striking improvement of clinical and histological presentation on withdrawal of gluten from the diet (Falchuk, 1983; Cooke and Holmes, 1985; Mike and Asquith, 1987; Trier, 1989b, 1991). Diagnostic criteria rely on these characteristics [Working Group of European Society of Pediatric Gastroenterology and Nutrition (WGESPNG), 1991]. The additional requirement to demonstrate deterioration of mucosa on gluten challenge (Meuwisse, 1970; Bramble *et al.*, 1985) has been questioned (McNeish *et al.*, 1979; WGESPNG, 1991). A workshop on diagnostic criteria of celiac disease, organized by the European Society of Pediatric Gastroenterology and Nutrition in 1989, stressed the contribution of recently developed serological tests to the diagnosis of GIE (WGESPNG, 1991). Antiglutin (Schmitz *et al.*, 1978), anti-reticulin (Mäki *et al.*, 1984), and anti-endomysial (Chorzelski *et al.*, 1984; Kumar *et al.*, 1989) antibodies of the IgA isotype have proved to be reliable indicators of sensitization to gluten at the time of diagnosis (WGESPNG, 1991),

with the exception of GIE in individuals with hypogammaglobulinemia or IgA deficiency.

It is important to emphasize that, in addition to full-blown celiac disease, a host of clinical presentations may be associated with gluten hypersensitivity. These include dermatitis herpetiformis (see subsequent text), recurrent aphthae, IgA nephropathy, and arthritides (Ferguson *et al.*, 1993; Marsh, 1993). Some patients may present with more atypical and diffuse symptoms, such as malaise, psychological problems, abdominal pain, and ill-defined growth defects (Collin *et al.*, 1990). Finally, 50–60% of patients with gliadin hypersensitivity are asymptomatic. All these conditions could be subsumed under the term “gluten sensitivity complex.” Ferguson *et al.* (1993) have proposed recently to subdivide “permanent gluten sensitive enteropathy” (i.e., celiac disease) into “active,” “silent,” “latent,” and “potential.” This may be helpful in the understanding of the pathogenesis of this group of diseases.

Malabsorption in GIE results from the drastic decrease of absorptive surface and from derangements and loss of the epithelial cell brush border and its enzymes. Clinically, severity of symptoms spans a wide range, reflecting, at least in part, the extent of the intestinal lesions. Thus, GIE may present as isolated iron or folate deficiency anemia without any gastrointestinal symptoms. On the other end of the spectrum are failure to thrive, in pediatric patients, and devastating life-threatening panmalabsorption with secondary involvement of many organ systems. In its long-term evolution, GIE has proven more variable than previously thought (Schmitz *et al.*, 1978; Kamath and Dorney, 1983; Mäki and Visakorpi, 1988; WGESPGN, 1991).

Histology of the small intestinal tissue lesions presents as villous atrophy, crypt epithelial cell hyperplasia, crypt hypertrophy, and changes in the lymphoid-cell population of the mucosa. Mucosa of patients with GIE was shown to produce six times more epithelial cells than healthy mucosa per time unit (Watson and Wright, 1974), with a doubling of the rate of cell division and a 3-fold increase in numbers of proliferating cells. Numbers of undifferentiated crypt cells and frequency of mitoses among crypt cells are increased significantly (Padykula *et al.*, 1961; Yardley *et al.*, 1962). The ultrastructure of crypt epithelial cells usually is normal (Rubin *et al.*, 1966). The populations of goblet and Paneth cells also seem comparable to those of healthy subjects. However, endocrine cells appear to be increased in numbers in the mucosa of GIE patients with severe lesions (Polak *et al.*, 1973). This increase may result from impaired release of cholecystokinin and secretin from such cells. The cuboidal surface epithelial cells display degenerative changes: prominent loss of organelles, accentuation of lysosomes, swelling of mitochondria and endoplasmic reticulum, incomplete development of the terminal web, and staining variability and electron density of the cytoplasm (Rubin *et al.*, 1966). Importantly, microvilli are short, irregular, fused, or absent. In addition, thinning of the glycocalyx occurs. The density of CD8+ and  $\gamma/\delta$  TcR+ IELs and mucosal mast cells (Strobel *et al.*, 1983) is increased in untreated patients with GIE; however, the total number of lymphoid cells per area remains in the normal range, reflecting the severely decreased area

of intestinal surface (Ferguson and Murray, 1971; Holmes *et al.*, 1974). Plasma cells are much more abundant in the lamina propria mucosae of GIE patients than in that of healthy individuals, whereas lymphocytes tend to appear in lower than normal numbers (Holmes *et al.*, 1974). The mucosal cellular infiltrates usually show high numbers of neutrophilic and eosinophilic granulocytes and mast cells (Marsh and Hinde, 1985). Succinctly, the histopathology of GIE has been described as “extensive villous atrophy with hyperplasia of the crypts and an abnormal surface epithelium” (Marsh, 1988). Remember that the mucosal lesions in GIE are rather variable in character, severity, and extent (Mäki and Visakorpi, 1988), and that the same patients may have, concomitantly, several types of intestinal lesions (Roy-Choudhury *et al.*, 1967). Flat mucosa most often is found only in the proximal portion of the jejunum and, even here, distribution of lesions may be patchy (Thompson, 1974). Recently, the spectrum of the interrelated patterns of mucosal tissue lesions seen in GIE have been classified by Marsh (1992a, 1992b) as follows: infiltrative, infiltrative-hyperplastic, flat-destructive, and irreversible hypoplastic atrophic, spanning the gamut of isolated increase of IEL to the end-stage disease with progressive intestinal failure.

The pathophysiological mechanisms leading to malabsorption, in addition to simply decreased absorptive surface, result from a variety of derangements of the intestinal epithelial cell involving the microenvironment defined by the brush border and its enzymes (Padykula *et al.*, 1961; Dissanyake *et al.*, 1974; Bramble *et al.*, 1985) and the glycocalyx (Rubin *et al.*, 1966). The microenvironment (or microclimate) defined by the glycocalyx seems essential to normal absorption of neutral molecules. The pH of the microenvironment has been shown to be changed strikingly in GIE patients compared with healthy subjects (Lucas *et al.*, 1978). In addition, decreased activity or lack of enzymes, most importantly of the brush border, must contribute to impaired uptake of nutrients (Padykula *et al.*, 1961; Dissanyake *et al.*, 1974; Bramble *et al.*, 1985). Indeed, this enzymatic activity may be reduced by 90% in GIE. Further, lysosomal enzymes are increased and may contribute to the production of abnormal, potentially toxic metabolites, as well as to absorption of such moieties. In addition to malabsorption proper, maldigestion also may occur; thus the intraluminal pH in the proximal small intestine is higher than normal in untreated GIE patients, and the bacterial flora of the intestines may be changed.

Intensive research over the last four decades has allowed the formulation of several hypotheses attempting to explain the pathogenesis of GIE. One of the major problems, as is often the case in such endeavors, is the difficulty in differentiating primary pathogenic factors from those arising as secondary phenomena during the disease.

Central in the discussion of pathogenesis is the clearly established association of GIE and gluten. Gluten makes up 90% of wheat flour protein; it is a heterogeneous preparation of proteins that can be separated into an ethanol-soluble fraction termed gliadin and an insoluble fraction, glutenin. Gliadin itself consists of over 40 moieties that can be grouped into four categories (Kasarda *et al.*, 1984). A-gliadin, which is a major component of alpha gliadin, has been shown to

activate GIE (Kagnoff, 1989b). Closely related to gliadin are the prolamins of rye, barley, and oats, which also may induce intestinal damage.

Even though demonstration of a direct toxic effect on mature normal enterocytes still is lacking (Davidson and Bridges, 1987), direct toxic action on fetal animal or human intestinal epithelial cells and cultured tumor cells has been documented for enzymatic digests of gluten (gluten fraction III) (Dissanyake *et al.*, 1974) and fraction 9 of gliadin (Townley *et al.*, 1973). Subsequently, lack of a normally present peptidase on jejunal mucosal tissue was suggested to explain the accumulation of these toxic products of gluten. This "missing enzyme hypothesis" still has not received substantial support from available data. Since enzymatic activities that are depressed in untreated GIE return in most cases to normal values, after exclusion of gluten from the diet, with the possible exception of lactase, the enzymatic defects seem likely to be secondary to GIE. A primary lack of peptidases has not been documented yet in patients with GIE. Similarly, carbohydrase deficiency, implicated by others (Phelan *et al.*, 1977) in the toxogenesis of gluten, still remains a possible but rather unlikely candidate. Since lactase levels remain low even after histological normalization of the mucosa, lactase deficiency may be an enhancing or precipitating factor in the pathogenesis of GIE (McNicholl *et al.*, 1976).

Weiser and Douglas (1976) have proposed a lectin-like harmful action of gluten on intestinal epithelial cells; this interaction could involve incomplete glycoproteins on immature epithelial cells. Such moieties do indeed occur in large numbers in GIE mucosa, and immature epithelial cells have been shown to have increased reactivity to several known plant lectins, and lectin interaction can induce cell death. On the other hand, stress to enterocytes during enteric infections, inflammation, or increased gluten intake, could derange glycosyl transferases of intestinal epithelial cells and interfere with the synthesis of oligosaccharide side chains of cell surface glycoproteins. This original hypothesis has gained support by the demonstration that mucosa of patients with celiac disease indeed binds the gluten fraction Glyc-Gli (Douglas, 1976).

Increased permeability of the mucosa has been repeatedly demonstrated in GIE patients (e.g., Parkins, 1960). Green and Wollaenger (1960) showed hypoalbuminemia in 60% of celiac disease patients in the United States; more recently, Bai *et al.* (1991) reported decreased serum albumin in 54% of Argentinian patients. Increased intestinal permeability has been proposed as a factor in the pathogenesis of GIE. It was suggested that facilitated influx of gluten or prolamins-derived peptides may lead to enhanced or deregulated immunological reactivity in the mucosa, or to direct toxicity. However, evaluation of the impact of hyperpermeability on the development of GIE remains difficult. On one hand it seems probable that untreated patients have more permeability disturbances than treated patients (e.g., Bai *et al.*, 1991); this suggests that permeability changes observed in GIE are secondary to the tissue lesions in the mucosa. On the other hand, a recent report (van Elburg *et al.*, 1993) on sugar absorption in patients with celiac disease showed a significantly increased ratio of lactulose vs. mannitol in the urine of patients as well as their

relatives; this suggests that asymptomatic relatives of GIE patients may have increased intestinal permeability, and that such hyperpermeability may contribute to the pathogenesis of GIE.

Involvement of immune reactions in the pathogenesis of GIE is evidenced by a large number of observations (Kagnoff 1989a,b; Cole and Kagnoff, 1985; Marsh, 1989; Brandtzaeg *et al.*, 1991). However, it still seems difficult to assign convincingly to any of the collected data a definitive place and value in the pathogenesis of GIE and to formulate a hypothesis compatible with the great majority of observations. Over the past few years, many studies have evaluated exciting aspects of the immune response in GIE. In the following section, we review the major of the findings and hypotheses proposed for an immunopathogenesis of GIE.

Any role for atopic and anaphylactic reactivity in the pathogenesis of GIE remains to be established. Some researchers have reported a significant increase of asthma, eczema, and urticaria in patients with GIE compared with the healthy population (Friedman and Hare, 1965; Hodgson *et al.*, 1976; Williams *et al.*, 1984). Others could not confirm these results (Cooper *et al.*, 1978). However, improvement of eczema has been reported on gluten withdrawal (Cooper *et al.*, 1978). A child on a gluten-free diet was reported to develop systemic anaphylaxis after introduction of small amounts of gluten ("gluten shock"; Krainick *et al.*, 1958). However, no differences in serum IgE concentrations exist between patients with GIE and normal controls (Williams *et al.*, 1984), and antibodies of the IgE isotype that react with wheat proteins were not elevated in the circulation of patients with GIE (Bahna *et al.*, 1980). Immediate hypersensitivity skin tests with gluten were not detectable in these patients (Baker and Read, 1976). On the other hand, IgE-producing cells increase in numbers in the jejunal mucosa of both untreated and treated patients with celiac disease (Scott *et al.*, 1983). Gluten challenge leads to further increase of frequency of IgE-producing plasma cells (O'Donoghue *et al.*, 1979). A Type I hypersensitivity reaction, according to Gell and Coombs, has been described in patients with GIE; mast cell degranulation and increased concentrations of histamine and 5-hydroxytryptamine occur in the intestinal lesional mucosa, followed by influx of eosinophilic granulocytes (McLaughlin *et al.*, 1983; Strobel *et al.*, 1983). Collectively, these data suggest a secondary rather than a primary involvement of atopic reactions in GIE. Atopy in GIE possibly results from increased permeability of the gut to various allergens.

Numbers of IgA, IgG and IgM-producing plasma cells are increased in lesional mucosa of GIE; (Brandtzaeg *et al.*, 1991). Concurrently, the percentage of plasma cells producing antibodies to gliadin is increased in GIE mucosa (Brandtzaeg *et al.*, 1991). In some patients with dermatitis herpetiformis, IgA and IgM isotype antibodies to gliadin are demonstrable in the intestinal fluid only (Kett *et al.*, 1990). Since this disease is related closely to, or a variant of, celiac disease, this finding has been interpreted to suggest that IgA and IgM gliadin antibodies in the intestinal lumen are the hallmark of early GIE (O'Mahony *et al.*, 1990; 1991; Brandtzaeg *et al.*, 1991; Ferguson *et al.*, 1993; Marsh 1993). As the disease progresses, IgA isotype antibodies to gliadin increase

in circulation also, whereas IgM isotype antibodies do not (Baklien *et al.*, 1977). Since IgM has a stronger affinity for secretory component (SC) than IgA, IgM may be excreted efficiently into the intestinal lumen whereas IgA is inhibited from reacting with SC and thus finds its way into circulation (Brandtzaeg, 1985). Importantly, SC shows an enhanced expression on intestinal epithelial cells in GIE (Kvale *et al.*, 1988), and J chains are expressed more densely in IgA-producing cells in GIE patients than in healthy individuals (Kett *et al.*, 1990). Ultimately, however, more IgG- than IgA-producing cells are specific for gliadin (5.7% vs. 1.6%; Brandtzaeg and Baklien, 1976). These antibodies may contribute to the pathogenesis of GIE by interacting with gliadin adsorbed to epithelial cells or by formation of immune complexes. Terminal complement components (TCC) have been demonstrated in subepithelial sites of GIE mucosa (Brandtzaeg *et al.*, 1991). Complement-mediated lysis and sublytic effects of the membrane attack complex (MAC; Morgan *et al.*, 1988) could contribute significantly to the desquamation of surface epithelium observed in GIE (Brandtzaeg *et al.*, 1991). Alternatively, antibodies to gliadin may collaborate with K cells in antibody-dependent cellular cytotoxicity (ADCC). The only skin test reactivity documented to date in patients with GIE is an Arthus-like reaction against gliadin (Baker and Read, 1976; Anand *et al.*, 1977), which could suggest a major role for immune complexes in GIE tissue lesions. Finally, polymeric IgA has been shown to activate and degranulate neutrophilic and eosinophilic granulocytes, which could enhance the overall inflammatory response and damage epithelial cells (Abu-Ghazaleh *et al.*, 1989).

In addition to a possible role in the pathogenesis of GIE, several antibodies promise to play increasingly important roles in the diagnosis of celiac disease and related syndromes (WGESPNG, 1991; Ferguson *et al.*, 1993). In addition to antibodies to gliadin (Schmitz *et al.*, 1978), antibodies to reticulin (Mäki *et al.*, 1984), and antibodies to smooth muscle endomysium (Chorzelski *et al.*, 1984; Kumar *et al.*, 1989) have contributed significantly to the confirmation of diagnosis of celiac disease and dermatitis herpetiformis. Antibodies to endomysium (Figure 3) have proven to be of especially high specificity and sensitivity (Kumar *et al.*, 1989); their involvement in the immune reactions of GIE, however, remains to be investigated further.

Great potential for improved understanding of various syndromes of gluten sensitivity as well as for the institution of gluten free diet offer reports on a characteristic pattern of antibodies to food antigens detected in jejunal fluid and whole gut lavage fluids (reviewed in Ferguson *et al.*, 1993 and Marsh, 1993). Gliadin-specific antibodies of the IgA, but most impressively, of the IgM isotype were detected in a small group of patients with *dermatitis herpetiformis* lacking enteropathy (O'Mahony *et al.*, 1990) as well as patients with active, silent, latent, or potential celiac disease (O'Mahony *et al.*, 1991; Ferguson *et al.*, 1993). These pattern of antibodies was termed "celiac-like intestinal antibody" or "celiac-associated intestinal antibody pattern" and given the ominous acronym "CIA." Most recently, an extensive study was conducted on the presence of CIA, with special emphasis on celiac disease patients with normal jejunal biopsy histology

**Figure 3** IgA-antibodies to endomysium from a patient with GIE. Indirect immunofluorescence on monkey esophagus. (Microphotograph kindly supplied by Dr. V. Kumar, Buffalo, New York.)

(Arranz and Ferguson, 1993). In addition to antibodies to gliadin, the intestinal fluid contained also increased titers of IgM class antibodies to ovalbumin and  $\beta$  lactoglobulin. Antibodies to food antigens have been described in a number of diseases. Thus, Knoflach *et al.* (1987) showed impressive amounts of circulating IgM-class antibodies to a number of milk antigens, including  $\beta$  lactoglobulin, in adult patients with inflammatory bowel disease (IBD), and a somewhat distinct pattern was seen in sera of pediatric IBD patients by Lerner *et al.* (1989). Occurrence of food antibodies in a variety of intestinal disorders suggests that at least some of them may be secondary to widely shared defects of intestinal function (e.g., increased permeability leading to enhanced penetration of the mucosa by antigens). The preferential increase in IgA and, most impressively, IgM antibodies may represent a characteristic mucosal antibody response pattern present in many diseases. However this may be, studies of CIA and of antigliadin antibodies in circulation (Ferguson *et al.*, 1993; Marsh, 1993) should open up new diagnostic potentials, especially in conjunction with other parameters, and help us define what may be called in future "gluten-sensitive disease complex."

An early influx of lymphocytes into the epithelium of small intestinal crypts has been demonstrated in elegant experiments (Marsh, 1988, 1989). This event is followed by crypt cell hyperplasia and crypt hypertrophy, and by villus atrophy.

Especially in flat mucosa, CD3<sup>+</sup>CD45RO<sup>+</sup> cells are frequent, attesting to T cell activation (Scott *et al.*, 1987). IELs also show morphological signs of activation (Spencer *et al.*, 1989a). The number of T  $\gamma\delta$  cells has been shown to be increased among IELs (Halsensten *et al.*, 1989b; Spencer *et al.*, 1989b; Brandtzaeg *et al.*, 1991; Kutlu *et al.*, 1993). A high percentage of these cells employs the variable delta 1 gene (V $\delta$  – J $\delta$ ,2), suggesting that a large proportion of these cells has a limited specificity (Spencer *et al.*, 1989a). The T  $\gamma\delta$  cells could react with heat-shock protein (HSP; Born *et al.*, 1990) on stressed cells (Evans *et al.*, 1990; Brandtzaeg *et al.*, 1991). Indeed, HSP has been detected on jejunal epithelium of patients with GIE.

Enhanced T counter-suppressor cell activity among IELs (Brandtzaeg *et al.*, 1991) could contribute to an abrogation of oral tolerance, including that to gliadin. The abrogation of oral tolerance also could result from the increased expression of HLA-DR antigens on intestinal epithelial cells; several cytokines are known to mediate increased expression of HLA-encoded moieties (Scott *et al.*, 1987). Therefore, that increased HLA-DR antigen expression parallels the increase in numbers of CD3<sup>+</sup>CD45RO<sup>+</sup> cells in GIE is of special interest (Scott *et al.*, 1987; Schreiber *et al.*, 1991). Obviously, cytokine production by activated T cells may have a wide range of effects, for example, induction of hyperplasia of crypt cells, increase of permeability of the intestinal epithelium, and stimulation of B cells and effector T cells (Brandtzaeg *et al.*, 1991).

Striking is the association of GIE with genetic markers (Falchuk *et al.*, 1972; Keuning *et al.*, 1976; Demarchi *et al.*, 1983). An extended HLA haplotype (Howell *et al.*, 1988) seems characteristic in GIE patients (Tosi *et al.*, 1983; Cole and Kagnoff, 1985; Corazza *et al.*, 1985; Alper *et al.*, 1987). The genetic markers include HLAB8 (Class I region) and SC01 in the adjacent Class III region. The strongest association between disease and major histocompatibility complex (MHC) haplotype is found in Class II moieties; these molecules are also of special interest in relation to immune responses, since Class II molecules participate in cell interactions, especially during antigen presentation. Of Caucasian patients with GIE, 80–90% show HLA-DR3 and HLA-DQw2 markers, whereas these markers are found in only 20% of healthy Caucasians. More recently, restriction fragment length polymorphism (RFLP) analysis using restriction endonuclease *Rsa* I defined a polymorphic 4-kb genomic DNA fragment in over 90% of HLA-DR3-/DQw2<sup>+</sup> patients with celiac disease, but only in 30% of healthy patients with this HLA haplotype (Howell *et al.*, 1986). The 4kb fragment is part of a gene encoding a HLA-DP  $\beta$  chain (Howell *et al.*, 1988). In addition, a similar polymorphism was suggested for the HLA-DP  $\alpha$  chain-encoding gene (Hitman *et al.*, 1987; Kagnoff, 1989b).

Genes outside the HLA haplotype also seem to be involved in GIE, as was suggested by the much higher concordance rate for GIE among monozygotic twins (~75%) than among HLA-identical siblings (~40%) (Polanco *et al.*, 1981; Schols and Albert, 1983). Similarly, among individuals sharing the susceptibility HLA haplotype, disease manifests more frequently in the patients' family members than in nonrelated

subjects (Kagnoff, 1989b). Thus, immunoglobulin heavy chain allotypic markers may show association with celiac disease (Kagnoff *et al.*, 1983; Weiss *et al.*, 1983). Particular MHC Class II gene products may enhance the presentation of selected environmental epitopes to T cells, and distinct immunoglobulin genes may up-regulate the magnitude and increase specificity of host antibody responses. The importance of environmental factors in the pathogenesis of GIE, however, is demonstrated clearly by the discordant pairs of monozygotic twins (Polanco *et al.*, 1981).

Kagnoff and co-workers (1984) have demonstrated a homology between amino acid sequences of A-gliadin and a dodecapeptide of the E1b protein of adenovirus type 12. These authors also showed that untreated patients with celiac disease had significantly more frequently infections with adenovirus type 12 than controls (Kagnoff *et al.*, 1987). Further, the homology region seems to be an antigenic determinant (Kagnoff *et al.*, 1987; Karagiannis *et al.*, 1987). Kagnoff and co-workers (1987) have proposed that such cross-reactive epitopes on microbial, most likely viral, moieties may trigger the reactivity to gliadin.

Several other factors may influence the immune response in GIE. Exorphins, opioid agonists similar to  $\beta$ -casomorphin, have been shown to be generated during digestion of gluten (Zioudrou *et al.*, 1979; Morley *et al.*, 1983). These molecules are known to influence, among others, the proliferation of LPLs. In addition, bacterial and nutrient antigens passing more easily through the intestinal epithelium in GIE patients than in healthy subjects could engage the immune system and contribute to its deregulation.

On the basis of the large but somewhat scattered portfolio of data on the pathogenesis of GIE, a comprehensive hypothesis can be envisioned. The initial event in GIE must be the coming together of genetic predisposition and environmental factors. The genetic predisposition could be some defect of the intestinal enzymes crucial in detoxifying gluten metabolites as well as a predisposition of the immune system, for example, enhanced gliadin presentation to T cells, abnormally active T counter-suppressor cells among IELs, and so on. The triggering event could be a lectin-like or toxic activity of gluten as well as its immunogenic property; alternatively, cross-reactive microbial epitopes, such as adenovirus type 12 E1b protein, could activate an immune response to gluten. The immune reactivity, induced either as a primary pathogenic mechanism or in response to lectin- or toxin-induced tissue damage, could lead to crypt cell hyperplasia and degeneration of surface epithelial cells by the action of cytotoxic T cells, cytokines, and antibodies or immune complexes activating complement or interacting with K cells in ADCC. Stimulating the immune response further, cytokines could enhance expression of MHC Class II antigens and modulate changes in immunologically reactive cells. The deleterious effect of the immune response could be amplified further by the induced expression of HSPs (Born *et al.*, 1990) on stressed cells and the interaction of T  $\gamma\delta$  or other cells with these moieties. The destruction of brush border and degenerative changes in intestinal epithelial cells, as well as the ultimate loss of intestinal surface, possibly resulting from a combined onslaught of toxic and lectin-like gluten moieties and immune

reactants, then causes malabsorption, which is the major clinical manifestation of GIE.

A two-stage model of GIE pathogenesis has been proposed by O'Mahony *et al.* (1990), comprising latent and fully expressed disease. The first stage is characterized by a genetically determined abnormal interaction of the immune system with gluten, without full-blown lesions in the gut, (e.g., T-cell activation in the mucosa without other changes, or isolated increased density of IEL). The second stage of severe or full intestinal involvement ("celiac disease" proper) could be triggered by a number of environmental factors or changes of endogenous regulatory mechanisms, illustrated by Ferguson *et al.* (1993) as episode of hyperpermeability, nutrient deficiency, increased dietary gluten, impaired intraluminal digestion of ingested gluten, adjuvant effects of intestinal infection and a HLA associated gene. Even though the interphase of these two stages of GIE probably still is very fuzzy, this hypothesis provides a workable framework for further research and is well supported by clinical and animal research. Clinically, the more recent realization of the high frequency of individuals showing abnormal immune response to gluten and other prolamins without manifest enteropathy fits well the two stage concept. In animal experiments, Troncone and Ferguson (1991) have shown that enteropathy in mice sensitized to gliadin does not occur after simple feeding of gliadin, but requires "triggering" factors, such as those associated with intestinal anaphylaxis or graft-versus-host reactions. The exact mechanisms that come to bear in this events are not well understood but could be enhanced antigen presentation, T-cell recruitment, enhanced expression of MHC class II antigens, etc. As such triggering events, obviously, inflammation induced by antibody or cell mediated mechanisms may be of importance.

Avoidance of gluten-containing food is the treatment of choice and results in complete restoration of absorptive function and reparation of the mucosal structure. In severe cases, patients should be supplemented with essential nutrients such as vitamin B<sub>12</sub>. In some patients with transient adrenal insufficiency resulting from malnutrition, corticosteroids may be beneficial. Importantly, in patients with malnutrition, that is, before the effects of gluten-free diet have set in, parenteral, rather than oral administration of drugs seems preferable since drugs, like nutrients, may be absorbed abnormally in GIE patients (Trier, 1989b).

As bleak as the prognosis may be for unrecognized or inadequately treated GIE, the promptly diagnosed and treated patient with the disease, whether child or adult, has a very good to excellent prognosis. Only seldom may complications of GIE, such as peripheral neuropathy, not resolve completely (Trier, 1989b), and only few patients develop refractory sprue (Rubin *et al.*, 1970; Trier *et al.*, 1978) or ulcerations and strictures of the small intestine (Bayless *et al.*, 1967). A propensity for malignancies, however, is present in an appreciable number of GIE patients (Holmes *et al.*, 1976; Selby and Gallagher, 1979) and their relatives (Stokes *et al.*, 1976; Holmes and Thompson, 1992). Whether gluten-free diet influences these predispositions is not yet fully established (Holmes *et al.*, 1989).

## 2. Dermatitis Herpetiformis

Dermatitis herpetiformis (Alexander, 1975; Cooke and Holmes, 1985; Jordon and Provost, 1988) is a skin disease closely related in its intestinal manifestations to celiac sprue. This disorder is characterized by chronic papulovesicular lesions located symmetrically on elbows, knees, buttocks, sacrum, face, scalp, neck, trunk, and sometimes oral cavity. The vesicles are subepidermal. The lesions are associated with intense pruritus. IgA deposits are found around microfibrillar bundles in the dermal papillary tips and along the anchoring fibrils on the basement membrane (Katz and Strober, 1978). Complement is activated (Provost and Tomasi, 1974; Katz *et al.*, 1980), and circulating immune complexes containing IgA occur in 40% of patients (Hall *et al.*, 1980; Zone *et al.*, 1980). IgA is found in lesional and extralesional skin (Chorzelski *et al.*, 1971), suggesting that the induction of tissue lesions relies on additional pathogenic factors, a situation similar to that seen in GIE (O'Mahony *et al.*, 1990). The etiology and pathogenesis of this disease still remains poorly understood. The hypotheses proposed to explain celiac disease also may apply to dermatitis herpetiformis. Of patients with this skin disorder, 90% have patchy duodenal and jejunal atrophy (Brow *et al.*, 1971) that cannot be distinguished from the lesions of celiac disease. However, gastrointestinal clinical symptoms, that is, diarrhea, fatigue, abdominal distension, and pain, are infrequent. Nevertheless, steatorrhea is seen often, usually combined with iron and folic acid malabsorption (Katz and Strober, 1978). In addition to malabsorption, protein loss into intestines as well as dapsone therapy may contribute to hypoalbuminemia (Cooke and Holmes, 1985; see Section III of this chapter).

Gluten-free diet is successful in restoring the intestinal tissue to normalcy more often than affecting skin lesions. However, all patients that show gluten-dependent improvement of skin lesions also have improvement of mucosal lesions (Cooke and Holmes, 1985). Gluten has not been found in the skin lesions (Cooke and Holmes, 1985).

## 3. Cow's Milk and Soy Protein Intolerance

Although food allergies may lead sometimes to fatal or near-fatal anaphylactic reactions, most often in children and adolescents (Sampson *et al.*, 1992), most food allergens (e.g., shellfish, fish, eggs, and nuts) do not lead to malabsorption. However, ingestion of cow's milk or soy bean protein may be associated with intestinal symptoms. Both food intolerance (i.e., a process induced by direct toxicity) and food allergy, (i.e., a process involving immune reactivity) could result in deranged mucosal absorption and permeability (F. Shanahan, 1993). Classically a time-limited condition of infancy (Walker-Smith *et al.*, 1978), cow's milk protein intolerance presents with jejunal mucosal lesions comparable to those of GIE (Kuitunen *et al.*, 1973; Walker-Smith *et al.*, 1978). However, the numbers of IELs usually are not as high as those seen in the intestinal epithelium of GIE patients (Walker-Smith *et al.*, 1978). In some patients, milk intolerance is combined with gluten sensitivity. Malabsorption may be induced by mechanisms similar to those operating

in GIE (see Section II.C.1.). Patients may respond to soy protein with jejunal mucosal lesions comparable to those of cow's milk protein and gluten intolerance (Donavan and Torres-Pinedo, 1987). The treatment of choice for food intolerance and allergy is avoidance diet.

#### 4. Crohn's Disease

The etiology and pathogenesis of chronic idiopathic IBD still are not well understood (Donaldson, 1989; Kagnoff, 1989a). However, increasing evidence suggests that the immune system plays an important role in the pathogenesis of the diseases. The two main diseases—Crohn's disease and ulcerative colitis—could be caused by two distinct pathogenic mechanisms. This topic is reviewed in detail in Chapter 38 of this volume, so a brief review will suffice here.

The early histopathology of Crohn's disease suggested a link to intestinal tuberculosis (Crohn *et al.*, 1932). This link, however, could not be substantiated. Only recently, a series of reports reawakened the hypothesis that mycobacteria may be an etiological agent in Crohn's disease (Burnham and Lennard-Jones, 1978; Chiodini, 1988). Currently, observations are accumulating which again caution against a pathogenic link between these bacteria and the disease (Ibbotson *et al.*, 1992; Stainsby *et al.*, 1993). Similar was the fate of other bacteria or viruses implicated over the years in the pathogenesis of Crohn's disease, and thus the quest for a microbial pathogenesis of this inflammatory bowel disease still remains in limbo. Both humoral and cell-mediated immune abnormalities have been described in Crohn's disease. Although circulating immune complexes seem not to be increased significantly in frequency or amount in patients with IBD (Soltis *et al.*, 1979; Knoflach *et al.*, 1986b), *in situ* formation of these reactants seems possible (Figure 4; Knoflach *et al.*, 1989), especially since complement activation has been suggested by demonstration of TCC and C3b in lesional tissue of both ulcerative colitis (Halstensen *et al.*, 1990) and Crohn's disease (Halstensen *et al.*, 1989b,c). The histopathological lesion of Crohn's disease consists of deep ulcers in the transmurally inflamed intestinal wall. Sankey *et al.* (1993) have shown that the earliest mucosal changes in Crohn's disease may be an accumulation of eosinophilic macrophages, defective basement membranes and ruptured capillaries with hemorrhages and fibrinol plugs containing platelet antigens. The vascular lesions could be, it seems, immunologically mediated, possibly facilitated by the abnormal reactivity of platelets in Crohn's disease (Webberley *et al.*, 1993). These reports suggest to look more towards the vasculature than the intestinal lumen in the quest for the early pathogenesis of Crohn's disease.

Many features of a response involving CD4<sup>+</sup> T cells have been reported. Increased Class II MHC expression is seen on intestinal epithelial cells (Selby *et al.*, 1983; Brandtzaeg *et al.*, 1987,1989; Morise *et al.*, 1991), many of the T cells of the lamina propria express interleukin-2 receptors as markers of activation (Schreiber *et al.*, 1991; Sengu *et al.*, 1991; Choy *et al.*, 1990), and high concentrations of soluble interleukin-2 receptor have been detected in serum of patients with active Crohn's disease (Brynskov and Tvede, 1990;

**Figure 4** Colon of a patient with Crohn's disease. Granular IgG deposits along the intestinal basement membrane  $\times 80$ . [Reproduced with kind permission from Knoflach, P., Albini, B. and Weiser, M. M. (1989). Experimental immune complex disease of the intestine. In "Immunology and Immunopathology of the Alimentary Canal" (B. Albini, R. J. Genco, P. L. Ogra, and M. M. Weiser, eds), Marcel Dekker, Inc., New York and Basel.]

Müller *et al.*, 1990). Macrophages are activated, and tumor necrosis factor (TNF) can be detected in sera from patients with Crohn's disease (Brandtzaeg *et al.*, 1991; Murch *et al.*, 1991), as well as in their lesional mucosa (MacDonald *et al.*, 1990) and feces (Braegger *et al.*, 1992). Lesional endothelin-1 production by activated macrophages and endothelial cells may contribute to vasculitis in chronic IBD by inducing intestinal vasoconstriction and ischemia (Murch *et al.*, 1992). These findings have been interpreted to suggest a primary T-cell hypersensitivity in Crohn's disease. Interestingly, the most exciting studies now are on cytokines (Fiocchi, 1993), adhesion molecules, and immune effectors. Such studies can best be done in animal models, and the re-evaluation of classical, and the search for new, models of IBD should allow dissection of the extremely complex interplay of exogenous and endogenous factors in this disease complex.

The severe nutritional problems common in patients with Crohn's disease have a multifactorial pathogenesis (Table IV; Donaldson, 1989). Most important are deficiencies arising from anorexia and dietary restrictions (Sitrin *et al.*, 1980). However, the extensive inflammatory cellular infiltrates and the severe damage to the intestinal tissue impair absorption of several nutrients, especially carbohydrates and lipids, as

**Table IV** Malabsorption, Mucosal Permeability Change, and Malnutrition in Crohn's Disease

Clinical sign	Primary factor	Mechanisms
Malnutrition	Anorexia Bacterial overgrowth	Inadequate intake of nutrients Altered bile salt metabolism (fat) Enhanced intraluminal catabolism (carbohydrates, protein)
Maldigestion	Mucosal inflammation	Disaccharidase deficiency Obstruction of lymphatics (fat) Derangement of epithelium and lamina propria (panmalabsorption) Enhanced catabolism of various moieties
Malabsorption	Therapy	Dietary restrictions Surgery: loss of absorptive surface (vitamin B <sub>12</sub> malabsorption; panmalabsorption; bacterial overgrowth, see above) Sulfasalazine: Competition for folate conjugase binding sites (vitamin B <sub>12</sub> malabsorption)
Mucosal permeability change	Mucosal inflammation	Diarrhea: fluid and electrolyte loss Protein loss: disruption of epithelium (ulcers) Immunologically mediated change of protein permeability Lymphatic obstruction Blood loss: iron deficiency, protein deficiency, reduction of lymphocyte numbers.

well as water- and lipid-soluble vitamins. Disaccharidase deficiency is common in these patients. On the other hand, Crohn's disease patients frequently have a normal absorption of vitamin B<sub>12</sub>.

Stasis of intestinal content caused by stenoses and strictures leads to bacterial overgrowth and panmalabsorption (Donaldson, 1989). Entero-enteric or entero-cutaneous fistulas may dramatically reduce the length of bowel with absorptive capacity. Therapy of Crohn's disease can add to malabsorption; surgical resection or bypass operations reduce further the absorptive surface available (Donaldson, 1989), and administration of sulfasalazine may impair uptake of folate, possibly by competition for sites on intestinal folate conjugase (Franklin and Rosenberg, 1973; Selhub *et al.*, 1978). Lymphatics in these patients are often obstructed, which may impair fat absorption significantly (Donaldson, 1989).

In addition to malabsorption, the changes in intestinal mucosal permeability may lead to protein losing enteropathy (see Section III) and may allow increased stimulation of the immune system to otherwise-excluded antigens, which may explain the significant increase in circulating antibodies to cow's milk reported in adult (Knoflach *et al.*, 1987) and pediatric (Lerner *et al.*, 1989) patients with IBD. It is interesting that the characteristic intestinal fluid pattern of antibody described for celiac disease and its related disorders as well as IBD show impressive increases of IgM class antibodies to food antigens (Arranz and Ferguson, 1993). These similarities may suggest that permeability changes in these intestinal diseases are epiphenomena (i.e., common pathways of pathogenesis). However, some evidence suggests that permeability changes may antedate Crohn's disease (see Section III) and that such changes, as speculated also for celiac disease, may be a predisposing factor for disease manifestation.

## 5. Immunoproliferative Intestinal Diseases

Especially in countries located around the Mediterranean Sea, premalignant and malignant lymphomas of GALT have been reported, predominantly among underprivileged young adults 10–30 years of age (Rimbaud *et al.*, 1968; Seligmann and Rimbaud, 1969; Rimbaud *et al.*, 1990). These proliferative disorders, primarily of B cells, often are associated with intestinal parasitic infestation (Rimbaud and Seligmann, 1976). More than one-third of the patients have *G. lamblia* in their gastrointestinal tract. The disease most often is seen in the small intestines, which can be involved along the whole length; other segments of the gastrointestinal tract are involved only infrequently (Rimbaud, 1983). This syndrome has been termed "Mediterranean lymphoma" (ML; Rimbaud *et al.*, 1968). A similar presentation has been reported for a nosological entity called "alpha heavy chain disease" ( $\alpha$ HCD; Seligmann *et al.*, 1968; Seligmann and Rimbaud, 1969). For some time, the exact relationship between ML and  $\alpha$ HCD remained open, since 70% of patients with ML were reported to lack  $\alpha$  heavy chains in the serum. The lack of demonstrability, however, could be a function of limits on the sensitivity of the assays used to demonstrate  $\alpha$  heavy chains (Rachmilewitz and Okon, 1985). In general,  $\alpha$ HCD was thought to be either a subclass of immunoproliferative intestinal diseases or the same entity as ML (World Health Organization, 1976). Currently,  $\alpha$  HCD, with predominantly B-cell proliferation, is frequently termed immunoproliferative small-intestinal disease (IPSID), whereas the bulk of what was formerly called ML, with diffuse cellular proliferation involving intestinal mucosa and without  $\alpha$  heavy chain production, is termed "non-IPSID lymphoma" (Strober and James, 1992). Even though there are histological presentations preferred in IBSID and non-IPSID lymphomas, there is enough overlap to treat them here as one histopathological entity.

The intestines show diffuse thickening and induration of the affected intestinal segments and flat mucosa (Figure 5). Extensive cellular infiltration of the lamina propria is seen and, late in the disease, of the submucosa as well. In the early stages of the disease, infiltrating cells are polymorphic. The infiltrates consist of large and small lymphocytes, immunoblasts, plasma cells, granulocytes, and, sometimes, multinucleated giant cells (Rachmilewitz and Okon, 1985). The plasma cell lineage usually shows a variety of maturation stages, but sometimes rather uniformly mature plasma cells are seen. Later in the disease, the cells infiltrate the muscularis propria and may reach serosal fat (Rachmilewitz and Okon, 1985). Widespread lesions take on the typical appearance of immunoblastic lymphomas (Selzer *et al.*, 1979). Serum electrophoresis detects a protein in the  $\alpha 2$  and  $\beta 2$  region that reacts with antibodies to the  $\alpha$  chain but not with antibodies to  $\kappa$  or  $\lambda$  chains (Selzer *et al.*, 1979). Serum concentrations of IgG and IgM usually are depressed (Rachmilewitz and Okon, 1985). In some patients, other truncated heavy chains ( $\mu$  and  $\gamma$ ) are demonstrable.

The primary clinical manifestation of IPSID and non-IPSID is severe malabsorption and diarrhea. Mild anemia, hypoalbuminemia, electrolyte imbalance, and low serum concentrations of lipids and cholesterol may occur. D-Xylose absorption, Schilling tests, and other assays of absorptive function tend to be abnormal. Serum often contains high concentrations of the intestinal isotype of alkaline phosphatase. Steatorrhea and creatorrhea usually exist (Rachmilewitz and Okon, 1985).

The cellular infiltrates mentioned earlier reduce the number of crypts and villi; in some patients, a flat mucosa as a result of complete villous atrophy is seen. The surface epithelium may be deranged and ulcerated. In this disease, malabsorption seems to be brought about primarily by the

direct effect of proliferating cells of the B-cell lineage on the surrounding tissue and cells. In addition, the stagnant loop syndrome seen in this disease may contribute to the derangements of absorption (Doe and Hapel, 1983).

The heavy chains of immunoglobins in IPSID are truncated and often begin at sites of interdomain and exon boundaries (Korsmeyer, 1989). The molecular defects in HCD have been elucidated to some degree for  $\mu$ - and  $\gamma$ HCD (Alexander *et al.*, 1982; Bakhshi *et al.*, 1986; Guglielmi *et al.*, 1988); similar defects can be expected in  $\alpha$ HCD, although the defects are multiple and varied. Bakhshi *et al.* (1985) have reported an aberrant RNA splice between the leader sequence and the constant region in  $\mu$ HCD. A small DNA insertion and deletion event removed a J4 donor splice site; thus an aberrant RNA splice between the leader region and the first exon ( $C_H1$ ) of  $C_\mu$  arose. A recognition sequence for signal peptidase was created at the fifth amino acid residue of  $C_\mu$ . As a result, a shortened  $\mu$  chain was produced that lacked the V region and therefore did not bind light chains. In a  $\gamma$ HCD, sequences probably of nongenomic origin were placed into a V region by a number of insertion and deletion events. Downstream, the  $C_H1$  splice site was eliminated by an abnormal switch (Guglielmi *et al.*, 1988). A splice resulted between leader and hinge exon; the  $\gamma 1$  protein amino-acid sequence indeed began inside the hinge region. In conclusion, the genomic defect in HCD seems to involve elimination of donor or acceptor splice sites through insertion and deletion events, inappropriate rearrangement, or somatic mutation. As a consequence, the leader exon is spliced to the next available Ig exon. Since the synthesized heavy chain proteins always are small, post-synthetic degradation seems not to be prominent as a mechanism of shortening the heavy chain in HCD (Korsmeyer, 1989).

Whereas  $\mu$ HCD plasmacytic elements synthesize light

**Figure 5** Jejunal biopsy specimen from a patient with alpha heavy chain disease. Extensive infiltration of the lamina propria by a polymorphous infiltrate. Villi are short and wide, number of crypts is reduced, and in one area, there is complete villous atrophy (arrow). [From Rachmilewitz, D. and Okon, E. (1985). Primary small intestinal lymphoma. In "Bockus Gastroenterology" (J. E. Berk, ed.), W. B. Saunders, Co., Philadelphia, with kind permission from the authors and the publisher.]

chains and result in Bence–Jones proteins in the urine of the patients (Korsmeyer, 1989), most  $\gamma$ - and  $\alpha$ HCD patients do not produce light chains. In the latter, a dual defect involving both heavy and light chains has been postulated. Further, Wilde and Milstein (1980) have shown that free intact  $\gamma$  chains are toxic for cells. Light chain defects are most likely the primary events in  $\gamma$ - and  $\alpha$ HCD; the simultaneous defects in heavy and light chains could be the results of hypermutational mechanisms in  $\alpha$ - and  $\gamma$ -synthesizing B cells that are absent from  $\mu$ -producing cells (Korsmeyer, 1989). In  $\alpha$ -HCD, a variety of forms of heavy chain molecules appear in intestinal fluid, and a recent case report may shed some light on this aspect of the pathogenesis (Lucidarme *et al.*, 1993).

The diagnosis of IPSID and non-IPSID relies on multiple small intestinal biopsy. In IPSID, Ig heavy chains can be detected in serum and in the jejunal fluid. The serum concentrations of the abnormal protein usually fall as the disease progresses, and the plasmocytic elements become less differentiated. Mild forms of the disease may be treated with antibiotics. This could suggest participation of infectious agents in the pathogenesis of these syndromes. Without significant decrease in the synthesis of the abnormal  $\alpha$  heavy chain molecule over 3 months, chemotherapy should be instituted (Rachmilewitz and Okon, 1985). Distinct palpable lymphomas should be removed surgically. The severe malabsorption should be treated by administration of fluids and electrolytes as well as blood units. Hyperalimentation sometimes is necessary (see Chapter 36).

## 6. Other Malabsorption Syndromes

Several other diseases involve the immune response and may manifest with malabsorption. Eosinophilic gastroenteritis is a disease of unknown etiology, associated with eosinophilic granulocytes infiltrating the mucosa of the esophagus, stomach, and small and large intestines. Peripheral eosinophilia and elevated serum IgE concentrations are common (Klein *et al.*, 1970; Johnstone and Morson, 1978; Zora *et al.*, 1984). The patients have abdominal pain, nausea and vomiting, diarrhea, protein-losing enteropathy, and malabsorption with steatorrhea. Often, eosinophilic gastroenteritis occurs in conjunction with asthma, eczema, or rhinitis (Cello, 1979). Tissue injury in eosinophilic gastroenteritis was suggested to involve a major basic protein released from eosinophilic granulocytes (Zora *et al.*, 1984). Diagnosis is made by biopsy of lesional tissue. Steroid treatment may be beneficial. Attempts to institute elimination diets usually are not successful, but the prognosis is favorable, although the disease may become chronic. (For the discussion of this disease and of food allergies in general we refer the reader to Chapter 40 of this volume.) A possible role of *hypochlorhydria*, *chronic gastritis*, and *Helicobacter* infection on mineral and amino acid absorption has been recently proposed (Cater, 1992). In chronic alcohol abuse, malabsorption may have several pathogenic roots (Roggin *et al.*, 1961; Rubin *et al.*, 1972). Primarily, pancreatic insufficiency and maldigestion are made responsible for the steatorrhea of alcoholics. Toxic epithelial cell damage may cause D-xylose, thiamine, and methionine malassimilation. In addition, small bowel motility may be increased and contribute to the diarrhea. Since immunologi-

cal derangements have been described in chronic alcoholic abuse (MacGregor, 1986; Chadha *et al.*, 1991), we cannot exclude a contribution of a deregulated immune system to the malabsorption in such patients. Malabsorption can also be seen in autoimmune diseases of endocrine organs, for example, Grave's disease (Thomas *et al.*, 1973; Shater *et al.*, 1984), thyroiditides (Siurala *et al.*, 1968), Addison's disease (McBrien *et al.*, 1963), hypoparathyroidism (Clarkson *et al.*, 1960; Arulanantham *et al.*, 1979), and diabetes mellitus (Wruble and Kalser, 1964). Connective tissue diseases, such as progressive systemic sclerosis (Akesson *et al.*, 1985), systemic lupus erythematosus (Bazinet and Marin, 1971), rheumatoid arthritis (Dyer *et al.*, 1970), and Reiter's syndrome (Mielants *et al.*, 1985), may show malabsorption. In many of these disorders, increased deposition of collagen fibers in the small intestines may be of importance in the pathogenesis of malabsorption. However, systemic effects of the diseases on the immune system also may contribute significantly to bacterial overgrowth of the intestines and to malabsorption. Finally, many vasculitides may involve the small intestines and lead to malabsorption, for example, polyarteritis nodosa, Wegener's granulomatosis, and Henoch–Schoenlein purpura. In all these syndromes, immune responses likely are involved (Camilleri *et al.*, 1983).

With increasing age, the nutritional status of the individual tends to decrease (Webster *et al.*, 1977; Feibusch and Holt, 1982). This malnutrition of aging can be explained to a large extent by the anorexia that arises in old age. However, bacterial overgrowth also is seen frequently in the intestines of the elderly. Here, immunological changes of old age (DeWeck, 1984) could contribute to the malnutrition by facilitating bacterial infections of the intestines. However, mucosal immunity in aging is only poorly understood and seems not to reflect systemic changes. Using whole gut lavage, Arranz *et al.* (1992) obtained evidence for changes in IgA secretion and numbers of IEL in aged humans. Others have seen little changes of MALT with aging. As in all studies on aging, the species studied may yield results not applicable to other species. Recently, Taylor *et al.* (1992), using monkeys, showed that aging compromises gastrointestinal mucosal immune response. Whether there is malnutrition simply associated with aging in healthy individuals is not clear. Thus, Holt and Balint (1993), reviewing intestinal lipid absorption, could not find conclusive evidence for malabsorption in the aged.

## D. Concluding Remarks

Malabsorption thus is observed in a large number of syndromes involving immune reactivity. The mechanisms by which immune reactions may contribute to malabsorption are varied and include humoral and T cell-mediated responses. As an indirect effect, deficiencies and dysregulation of the immune system contribute significantly to bacterial overgrowth and facilitate opportunistic infections and infestations of the small intestines, which then lead to inflammatory changes and malabsorption. On the other hand, infiltration of the small intestinal mucosa with immunoreactive cells, as seen in  $\alpha$ HCD, may contribute to malabsorption by the derangement of tissue structure. Further, immune effector

mechanisms—be they mediated by cytotoxic antibodies, ADCC, immune complexes, or delayed hypersensitivity mediated by CD4<sup>+</sup> or cytotoxic T cells and possibly natural killer (NK) cells—may damage or destroy intestinal epithelial cells and other structures of the mucosa and thus interfere with normal absorption. Proliferation of lymphocytes may obstruct the transport of absorbed nutrients; derangements of lymphatics may have the same effects. Finally, intraluminal antibodies may impede the absorption of nutritional moieties, increase their intraluminal digestion, or react with transport molecules, such as the intrinsic factor for vitamin B<sub>12</sub>, and thus prevent their uptake. Still understood only in the most superficial way, the interaction of the immune system with gut and other hormones and the nervous system could contribute significantly to disturbances of the homeostasis of the small intestines and, thus, also to malabsorption. Further research is needed to obtain insight into the various pathways of immunologically mediated pathogenesis of malabsorption in the various nosological entities.

### III. PROTEIN-LOSING GASTROENTEROPATHY

Many serum proteins are synthesized in the small intestinal mucosa, most importantly lipoproteins, complement components, and immunoglobulins. The gut also seems to play a role in the catabolism of plasma proteins (Waldmann, 1985). Most importantly, protein loss occurs also through the mucosa (i.e., there is an efflux of plasma proteins into the intestinal lumen). Healthy subjects show an enteric loss of plasma proteins of usually less than 1–2% of the body pool per day (Editor, 1959). In addition to being a site of synthesis and catabolism as well as protein loss into the intestines, the mucosa is a primary site of absorption of the products of protein digestion. Therefore, obviously, the gastrointestinal tract plays a significant role in the homeostasis of plasma proteins.

Hypoproteinemia without plasma protein loss into the urine and with normal rates of plasma protein synthesis was described in the 1950s. Albright *et al.* (1949) were the first to demonstrate convincingly a major role of catabolism, rather than of deficient synthesis, in this condition. The loss of plasma protein into the intestinal lumen, however, was described first by Citrin *et al.* (1957). Since then, the term “protein-losing gastroenteropathy” denotes a gamut of gastrointestinal syndromes associated with excessive loss of plasma proteins into the intestinal lumen (Editor, 1959).

Protein loss into the intestinal fluid can be demonstrated by several methods (Jeffries, 1989), most of which require the use of radioactive markers. <sup>51</sup>Cr-labeled albumin (Waldmann, 1961); <sup>51</sup>CrCl (Rootwelt, 1966; van Tongeren and Major, 1966; Walker-Smith *et al.*, 1967), which labels plasma proteins, predominantly albumin and transferrin, *in situ* in the patient; radioiodinated serum proteins (Sterling, 1951); as well as other radiolabeled plasma proteins (MacFarlane, 1957) have been used to measure intestinal loss in humans and animals. Most promising for clinical studies is the use

of  $\alpha_1$  antitrypsin, which does not require radioactive markers (Bernier *et al.*, 1978; Thomas *et al.*, 1981). Tc-99m albumin scintigraphy can now be used to localize the site of protein loss in the gut (Oommen *et al.*, 1992).

Many gastrointestinal diseases manifesting malabsorption (see Section II) also show protein-losing enteropathy. Selected syndromes involving responses of immunoreactive cells directly or indirectly and often associated with protein-losing enteropathy are summarized in Table V. The end result of protein-losing enteropathy is hypoproteinemia. This condition manifests as dependent edema following decreased colloid osmotic pressure of plasma and fluid transudation (Jeffries, 1989). Decreased plasma concentration of albumin in most patients is accompanied by diminished levels of fibrinogen, lipoproteins,  $\alpha_1$  antitrypsin, transferrin, ceruloplasmin, and, importantly, globulin (see Section IV). Blood clotting factors also are lost, but plasma proteins with a long half-life are affected more severely than those with a short half-life. The loss into the intestines, in contrast to many instances of proteinuria, is not selective regarding molecular size of the proteins; small and large proteins seem to be lost without preference (Jeffries, 1989).

With the exception of IgA and IgM bound to SC, intestinal epithelial cells are not known to transport any plasma proteins

**Table V** Syndromes Associated with Protein-Losing Enteropathy and Probable Involvement of the Immune System

---

Syndromes with disruption of intestinal epithelium:
Acute infectious enteritis
Chronic ulcerative jejunitis
Crohn's disease
Ulcerative colitis
Kaposi's sarcoma
Enteropathies in immunodeficient patients
Syndromes with impaired transport via lymphatics:
Intestinal lymphangiectasia
Tuberculosis ( <i>tuberculosis mesenterica</i> )
Infections of mesenteric lymph nodes
Whipple's disease
Lymphomas
Syndromes with unknown mechanism of intestinal protein loss:
Gluten-induced enteropathy
Allergic protein-losing gastroenteropathy
Eosinophilic gastroenteritis
Tropical sprue
Giardiasis
Campylobacter infection
Schistosoma-associated polyposis coli
Dermatitis herpetiformis
Enteropathies in immunodeficient patients
Connective tissue disease
$\alpha$ Chain disease
Vasculitides
Rheumatoid arthritis
Nephrotic syndrome
Autoimmune diseases
Antibiotica-induced pseudomembranous colitis
Arsenic and heavy metal poisoning

---

actively into the lumen of the gut. Cells, and the intercellular spaces sealed off by apical junctional complexes, present a formidable barrier to protein efflux. Protein loss seems most likely to occur through rapid shedding of the epithelial cells, especially at the tips of the villi. Granger *et al.* (1976) have shown, in an experiment using Evans blue as an albumin tracer, that the villus tips of canine intestines were the sites of the most active protein transfer into the lumen. Extravasation of protein was detected by this method only with an experimentally increased venous pressure. This mechanism most likely plays a role in mucosal diseases without ulceration and in diseases with lymphatic obstruction (see Table V). With extensive erosions of the intestinal mucosa, protein oozes out of the lesional tissue, often accompanied by bleeding. The mechanisms leading to protein loss into the intestinal lumen can be summarized as follows: (a) lymphatic obstruction; (b) mucosal ulceration or erosion; (c) enterocyte damage or increased turnover; and (d) leakage between enterocytes. Vascular derangements obviously can contribute to protein loss by increasing tissue fluid pressure, as well as by inflammation.

Immunologically mediated lesions of intestinal epithelial cells and their supportive structure may contribute in a variety of reactions to protein loss. Cellular and humoral immune mechanisms, involving cytokines and inflammatory mediators, are likely to be involved. Protein loss is seen in bacterial overgrowth of the small intestine and in viral and parasitic infections, and often accompanies primary and secondary immunodeficiency syndromes (Waldmann, 1985). Protein loss is frequent in allergic enteropathies, for example, cow's milk intolerance, and often is seen in GIE and dermatitis herpetiformes with intestinal involvement, in vasculitides, and in graft-versus-host disease developing after bone marrow transplantation (Epstein *et al.*, 1980; Jafri *et al.*, 1990). Many patients with IBD show protein loss, even in the absence of ulcerative lesions (Holman *et al.*, 1959; Steinfeld *et al.*, 1961). In Crohn's disease, there is a general hyperpermeability, and molecules can penetrate mucosa from the intestinal lumen easier than in healthy individuals. Interestingly, larger probes penetrate the mucosa better than smaller ones (Hollander, 1993). Of great interest for the understanding of the pathogenesis of this disease is the current discussion on altered barrier functions in the mucosa of healthy relatives of patients with Crohn's disease (Mayer *et al.*, 1993). In systemic lupus erythematosus (SLE), the paradigm of a primarily immune complex-mediated connective tissue disease, intestinal protein loss may occur with or without proteinuria and may lead to severe hypoproteinemia (Bazinet and Marin, 1971; Trentham and Masi, 1976; Brentjens *et al.*, 1977). Weiser *et al.* (1981) have shown the association of intestinal protein loss with intestinal venulitis characterized by immune deposits, that is, most likely, an immune complex-mediated venulitis (Figure 6).

In most of the patients with PLE and SLE—most of them young women—the mechanism leading to PLE is not well understood, since overt signs of intestinal vasculitis are missing (Perednia and Curosh, 1990). Possible candidates for this mechanism are intestinal lymphangiectasia, mucosal defects, chronic lupus enteritis (Nadorra *et al.*, 1987), and cytokine

**Figure 6** Thickened basement membranes in the intestines of a patient with systemic lupus erythematosus and protein-losing enteropathy. [Reproduced from Weiser, M. M., *et al.* (1981). *Gastroenterology* 81, 570, with kind permission from authors and the publisher.]

induced capillary leakiness. Protein losing enteropathy may be associated with chronic interstitial cystitis and paralytic ileus in a subgroup of SLE patients usually responsive to steroid therapy (Meulders *et al.*, 1992). Protein losing enteropathy occurs also in Henoch-Schönlein's Purpura (Reif *et al.*, 1991) and other disorders related to the group of connective tissue diseases (e.g., Tsutsumi *et al.*, 1991; Stark *et al.*, 1992).

Knoflach *et al.* (1989) studied mercuric chloride-induced enteropathy of rats (Sapin *et al.*, 1977; Knoflach *et al.*, 1986a). In this model, linear immune deposits, predominantly of IgA, had been documented along the intestinal basement membrane by Andres (1984). A shift from these linear and not complement-activating deposits to granular and complement-activating (Figure 7) deposits of IgG along the intestinal basement membrane entails significant increase of protein loss into the intestines (Knoflach *et al.*, 1989) that is accompanied by influx of granulocytes into subepithelial sites of intestinal mucosa and increase of mitotic figures among crypt epithelial cells, suggesting immune complex-mediated tissue injury and accelerated turnover of intestinal epithelial cells. The mechanism responsible for the change in the intestinal immune deposits, especially the switch from complement nonactivating to activating immunoglobulin deposits, is not yet under-

**Figure 7** Complement C3 deposits in the small intestines of a rat with HgCl<sub>2</sub>-induced protein-losing enteropathy.

stood. It may be of importance, however, that rats with mercuric chloride-induced immune complex disease have anti-idiotypic antibodies as well as IgG rheumatoid factors several weeks into the experimental protocol (unpublished observations, Miyata, and Milgrom). This model seems to offer a well-defined approach to the study of immune complex-mediated protein loss into the intestines and may be of interest in increasing our understanding of heavy metal-induced, immunologically mediated injury of the gut. These studies on mercuric chloride-induced mucosal lesions have been confirmed and extended by others (Mathieson *et al.*, 1992; Hultman and Enestrom, 1992; Böhme *et al.*, 1992). Itoi *et al.* (1989) have, indeed, shown deposits of IgG, IgM, and C3 in capillary walls in the intestines of a patient with protein-losing enteropathy. Studies using gut lavage in patients with IBD have shown a close correlation of protein loss into the intestinal fluid and disease activity (O'Mahony *et al.*, 1991b; Choudari *et al.*, 1993). One could speculate that events similar to those leading to protein loss in the experiments of Knoflach *et al.* (1989) could operate also in IBD. Most recently, Halstensen *et al.* (1993) have demonstrated co-localization of IgG<sub>1</sub>, terminal complement components and the 40 kDa "putative autoantigen" on the surface of colonic epithelial cells of patients with active ulcerative colitis. This finding supports the notion that an autoimmune reaction contributes to the pathogenesis of ulcerative colitis, and that complement activating antigen-antibody complexes may occur in active disease. Protein loss, especially in the presence of defects of the epithelium and bleeding into the intestines, may be associated

with loss of blood cells, including lymphocytes (Douglas *et al.*, 1976).

#### IV. EFFECTS OF MALABSORPTION AND INTESTINAL PROTEIN LOSS ON THE IMMUNE SYSTEM

Malabsorption and protein-losing gastroenteropathy can lead to severe protein-energy malnutrition. However, even mild protein-energy malnutrition and selected nutrient deficits can have serious effects on the immune system (Doe and Hapel, 1983).

With severe protein loss into the intestinal lumen, hypogammaglobulinemia ensues, usually affecting IgG most severely because of its relatively slow rate of synthesis (Waldman and Strober, 1969). Whereas the hypogammaglobulinemia itself tends to have little impact on the health of the patient, a combination with malabsorption and loss of immunoreactive cells (Douglas *et al.*, 1976)—as observed, for example, in IBD, GIE, and intestinal lymphangiectasia—can induce overt secondary immunodeficiency (Sorensen *et al.*, 1985).

Obviously, malnutrition also influences GALT. Only scant data are available on this aspect of mucosal immunity, but the still preliminary results of human and animal experiments suggest a decreased secretory IgA response (Chandra, 1975); decreased numbers of IELs and LPLs (Barry and Pierce, 1979; Chandra, 1979), especially IgA-producing plasma cells; impeded migration of labeled mesenteric lymphoblasts in the entero-systemic cycle (Chandra, 1983); and decreased mucosal NK-cell activity (Chandra and Wadhwa, 1989). Several reviews are available on the topic of the effect of nutrient deficiency on the immune system (Chandra and Chandra, 1986; Chandra, 1989; Chandra and Wadhwa, 1989). A consequence of malnutrition is atrophy of lymphoid tissue. In the lymph nodes and the spleen, predominantly T cells are diminished in numbers. Helper T cells are affected more than T suppressor cells in protein-losing enteropathy (Muller *et al.*, 1991). Lymphocyte proliferation and other functions seem to be impaired, not only because of lack of nutrients, but also because of possible production of inhibitory factors. Delayed hypersensitivity skin tests are weak or negative in many malnourished individuals. Although humoral antibody-mediated responses tend to remain much longer intact than T cell-mediated reactivity, some evidence is available for inhibition of antibody formation to particular antigens, for example, *Salmonella typhi*; antibodies, even when produced in normal quantities, may have lower affinities. An increased incidence of immune complexes is seen in malnourished patients. Phagocytosis and availability of complement components are decreased by nutrient deficit. Vitamin B<sub>6</sub> deficit also has been shown to decrease lymphocyte stimulation responses (Chandra and Wadhwa, 1989).

Kowdley *et al.* (1992) have shown polyneuropathy and impairment of T-cell function in the wake of intestinal fat malabsorption and subsequent vitamin E deficiency; correction of the vitamin deficiency also led to improvement of the

T cell function. Diseases of the gastrointestinal tract often are associated with defective splenic function (Corazza and Gasbarrini, 1983); malabsorption as well as protein and lymphocyte loss may account for some aspects of these disorders. The combination of immunodeficiency, infection, malnutrition, and malabsorption creates a fatal spiral of mutually enhancing pathological processes, as seen most dramatically in AIDS and in other conditions (e.g., chronic diarrhea of childhood).

## V. SUMMARY

Immune reactions may contribute to malabsorption (Section II), intestinal protein and lymphocyte loss (Section III), and increased influx of antigens (Cunningham-Rundles, 1987) in several diseases. Conversely, malabsorption and protein loss may lead to malnutrition and, thus, to derangements and deficiencies of the immune system. A vicious cycle may be established that insures chronicity of disease and continued deterioration. Obviously, infectious agents often participate in this deleterious interaction of the immune system and the gut, leading to derangements of intestinal permeability and absorptive functions. Improved understanding of mucosal immunity is needed to enhance development of new diagnostic and therapeutic tools in gastroenteropathies associated with malabsorption or protein loss.

# Food Allergy

Dean D. Metcalfe

## I. INTRODUCTION

Food allergy is a term applied to an immunological reaction to a food or food additive that occurs only in some individuals and is unrelated to a physiological effect of the substance. The term "food allergy" is synonymous with the phrase "food hypersensitivity." "Food intolerance" is a general term describing an abnormal physiological response to an ingested food or food additive that is not immunological in origin (Anderson, 1986). Under the term "food allergy" are several distinct clinicopathological entities, including classic immediate reactions to foods, eczema, eosinophilic gastroenteritis, and the food-induced enterocolitis syndrome.

The prevalence of food allergy in the general population has not been determined. However, two prospective surveys reported that 23–28% of parents believe their children had experienced at least one adverse reaction to food (Kayosaari, 1982; Bock, 1987). After evaluation, only approximately one-third of the complaints could be reproduced and only 2–4% of these children experienced reproducible allergic reactions to foods. Similar studies of food allergy are not available in adult populations, although allergic reactions to foods in adults generally are believed to occur less frequently than in children. The prevalence of reactions to food additives, assessed by questionnaire and compared with the number that could be confirmed by a double-blind challenge in a group of 18,582 respondents, has been estimated at 0.01–0.23% (Young *et al.*, 1987). In summary, 2–4% of children and even fewer adults suffer from food allergies; the prevalence of reactions to food additives is less than 1%.

## II. IMMEDIATE REACTIONS TO FOODS

IgE-mediated immediate hypersensitivity reactions are the basis for the majority of allergic reactions to foods. Such reactions occur within minutes of consuming a food to which a given individual is sensitive. These reactions occur in all age groups and may involve multiple target organs. These responses appear to be IgE dependent and involve the release of chemical mediators of inflammation from mast cells and basophils.

Patients who develop immediate reactions to foods are usually atopic to begin with (Atkins *et al.*, 1985). Patients who develop food allergies tend to be individuals with severe

respiratory allergies and a greater number of positive skin tests (Fiorini *et al.*, 1990). Thus, patients with food allergies, although representing a subgroup of atopic individuals, appear to have severe allergies in general and more difficulty regulating IgE levels in response to environmental antigens.

### A. Pathogenesis

Immediate hypersensitivity reactions to foods are caused by the production of IgE in response to specific food antigens. This food-specific IgE then binds to mast cells in the gastrointestinal mucosa as well as elsewhere. On subsequent exposure to a specific food antigen, the potential exists for IgE-dependent mast cell activation. This process is influenced by age, digestive processes, and gastrointestinal permeability.

Both nonspecific and specific barrier systems limit ingress of intact proteins. After ingestion, food initially is subjected to stomach acid and pepsins, pancreatic enzymes, and intestinal peptidases. Large proteins generally are degraded into peptides and amino acids. Mucosal epithelial cells absorb amino acids and small peptides. Antigenic proteins and peptides that successfully traverse the mucosal epithelial barrier elicit an immune response. This response, in part, leads to the secretion of antigen-specific IgA onto the mucosal surface. This IgA further complexes with specific antigens and helps prevent their absorption. Abnormalities in these systems associated with achlorhydria, cystic fibrosis, selective IgA deficiency, or immaturity of the gut may result in increased antigenic penetration of the gastrointestinal barrier. Substances such as alcohol, aspirin, and tobacco are examples of exogenous substances that may reduce gastric mucus and disrupt the epithelial barrier.

Clinical evidence supports the concept that food antigens do indeed penetrate the normal gastrointestinal tract. When 65 adults were sensitized intradermally with serum from a fish allergic individual and then fed raw fish (Prausnitz–Küstner test), 94% developed a wheal-and-flare response at the sensitized site. Reactions developed within 15–60 min of the ingestion of fish. No reactions were observed at control sites (Brunner and Walzer, 1928). Wilson and Walter (1935) also reported that 74% of children sensitized with serum from an egg-allergic subject exhibited wheal-and-flare responses at sites of sensitization after consuming eggs. Intravenous injection of the protein nitrogen equivalent of 1/44,000 of a peanut

kernel reportedly is sufficient to elicit a wheal-and-flare response at a passively sensitized skin site (Walzer, 1942).

Local mucosal reactions reminiscent of those that follow mast cell degranulation in human skin have been reported *in vivo* after passive sensitization of human ileum and colonic mucosa. Local reactions after passive sensitization could be induced by ingestion or by direct application of the antigen. Human jejunal mucosal mast cells also have been reported to degranulate *in vitro* in IgE-dependent reactions (Selbekk *et al.*, 1978).

The increased susceptibility of young infants to food allergic reactions is believed to be the result of both immunological immaturity and immaturity of the gastrointestinal barrier. In genetically predisposed infants, ingested antigens consequently may stimulate production of food-antigen-specific IgE antibodies or other abnormal immune responses. Prospective studies suggest that exclusive breast-feeding promotes the development of oral tolerance and prevents some food allergy and atopic dermatitis in infants and young children (Zeiger *et al.*, 1989). This protective effect may be the result of decreased exposure to foreign proteins, passive protection provided by breast milk SIgA, and soluble factors in breast milk that induce earlier maturation of the gut barrier and the infant immune response.

Several studies have demonstrated increased lymphocyte proliferation after food antigen stimulation *in vitro* in patients with food allergy. However, *in vitro* T-cell responses also commonly are found in normal individuals. Whether these T-cell responses *in vitro* represent an immunopathogenic marker or simply reflect a response to increased antigen penetration of the gastrointestinal tract is not clear.

### B. Food Allergens

Only a few foods provoke the majority of immediate hypersensitivity reactions to foods. In children, foods most commonly incriminated include egg, milk, peanut, tree nuts, and, less commonly, fish, soy, shrimp, and pea (Bock, 1986). Other foods also have been incriminated, including wheat, chicken, and turkey, leading to the conclusion that many individuals under the appropriate circumstances can develop IgE-dependent reactions to any one of a number of diverse

food groups. The prevalence of reactions to specific foods depends, in part, on the eating habits of a given population; for example, fish allergies appear to be more prevalent in Scandinavian countries (Aas, 1966) and soybean allergy is more common in Japan (Moroz and Yang, 1980).

Infants with food allergies tend to outgrow certain food sensitivities, particularly those to milk and eggs (Bock, 1982). Some adults also may lose food sensitivity if they practice rigorous food avoidance for a period of time. Pastorello *et al.* (1989) demonstrated by a double-blind food challenge that, out of 10 adults with food sensitivity, 1- to 2-yr avoidance of specific foods led to tolerance of the food in 4 patients. Thus, at least a subgroup of adults appears to lose the food allergy after a period of food avoidance. However, the data also show that several adults continued to be sensitive despite food avoidance. Further evidence supporting the latter observation is provided by a study of the natural history of shrimp hypersensitivity (Dual *et al.*, 1990). Baseline levels of shrimp-specific IgE did not appear to be altered in the long term by isolated shrimp challenges.

Several specific food antigens responsible for immediate IgE-mediated food reactions have been isolated and characterized, including allergens from codfish (Aas and Jebsen, 1967; Elsayed and Bennich, 1975), shrimp (Hoffman *et al.*, 1981; Nagpal *et al.*, 1989), peanuts (Sachs *et al.*, 1981), and soybeans (Moroz and Yang, 1980). These water-soluble food allergens tend to be relatively resistant to acid and to proteolytic enzymes (Table I). Protein fractions from cow's milk and egg also have been examined for antigenicity. Cow's milk consists of casein (80%) and whey (20%).  $\beta$ -Lactoglobulin and  $\alpha$ -lactalbumin are the principal proteins in whey.  $\beta$ -Lactoglobulin is a glycoprotein with a molecular weight of 18,263;  $\alpha$ -lactalbumin has a molecular weight of 14,174; and bovine serum albumin consists of a polypeptide with a molecular weight of 67,000. Positive skin tests have been reported to occur in response to casein,  $\alpha$ -lactalbumin,  $\beta$ -lactoglobulin, and bovine serum albumin in milk-allergic children in approximately equal numbers (Goldman *et al.*, 1963b). Positive oral challenges have been reported in response to all fractions tested, but  $\beta$ -lactoglobulin produced the highest rate of positive challenges (Goldman *et al.*, 1963a). Individuals reactive to egg are usually sensitive to the egg white. Oval-

Table I Common Food Allergens

Allergen	Source	Molecular weight	Composition	Characteristics	Reference
Antigen M (Gad c I)	Codfish	12,328	113 Amino acids, 1 glucose	Parvalbumin; chelates calcium; relatively acid and protease resistant	Aas and Jebsen (1967); Elsayed and Bennich (1975)
Antigen I	Shrimp	42,000	Dimer	Heat labile	
Antigen II (Pen i I)	Shrimp	38,000	96% protein; 4% carbohydrate	Heat stable	Hoffman <i>et al.</i> (1981); Nagpal <i>et al.</i> (1989)
Peanut I	Peanut	20,000; 30,000	Two bands	Relatively acid, protease, and heat resistant	Sachs <i>et al.</i> (1981)
Kunitz soybean trypsin inhibitor	Soybean	20,500	Polypeptide chain, two disulfide bridges	Relatively acid and protease resistant	Moroz and Yang (1980)

bumin and ovomucoid are the primary allergens in egg white protein. Both are present in uncooked and cooked egg. Conalbumin (ovotransferrin) is also allergenic. Lysozyme appears to be much less allergenic (Yunginger, 1991).

Related foods sometimes contain allergens that cross-react clinically. Cross-reactive allergens have been reported in certain foods and pollens, for example, in melons, banana, and ragweed pollen; celery and mugwort pollen; and apple, carrot, hazelnut, and birch pollen. Food-allergic patients should be evaluated by history and/or with oral food challenges to determine whether foods within similar food groupings are capable of causing clinical reactions.

### C. Clinical Manifestations

Immediate hypersensitivity reactions to food antigens are evidenced by a spectrum of signs and symptoms from abdominal pain to anaphylaxis. Reactions are influenced by factors including the age of the patient and the quality and quantity of food ingested. The presence of other medical problems also must be considered.

The oropharynx is the initial site of exposure to food antigens. Edema and pruritus of the lips, oral mucosa, and pharynx may be reported since the food contacts the mucosal surfaces. Such reactions are transient and may not be followed by other allergic manifestations. The term "oral allergy syndrome" has been suggested for the clinical situation dominated by oropharyngeal symptoms. The oral allergy syndrome consists of the development of oropharyngeal symptoms most commonly associated with the ingestion of fruits or vegetables. Symptoms include tingling, pruritus, and angioedema of the lips, and occasionally throat tightness, facial flushing, and oral mucosal blebs and hoarseness (Enberg, 1991). Symptoms usually occur within 5–30 min of exposure to the inciting food. Foods such as apple, which cross-reacts with birch, or watermelon and cantaloupe, which cross-react with ragweed, have been suggested to be more likely to induce symptoms. This observation suggests a relationship between the oral allergy syndrome and allergic rhinitis. However, oropharyngeal symptoms may be a prelude to other symptoms of food allergy.

Entry of food into the stomach and intestine may result in nausea, cramping, pain, abdominal distension, vomiting, flatulence, and diarrhea. Symptoms of gastrointestinal involvement may be the only expression of food hypersensitivity. However, this condition alone is unusual.

Food allergy usually also is expressed in one or more extraintestinal target tissues. The basis of reactivity of one system over another has not been determined. The skin is a common target organ in food allergy. Skin reactions consist of acute urticaria, acute angioedema, and, much less frequently, chronic urticaria. In one study of adults with recurrent urticaria, food allergy was demonstrated as the cause in only 1.4% (Champion *et al.*, 1969). Clinically significant food hypersensitivity has been estimated to exist in approximately 20% of children and 10% of adults with atopic dermatitis (Hanifin, 1984). Because of the unique features of eczema, this condition is discussed in a separate section. Asthma and

rhinitis secondary to food hypersensitivity are more common in children (Bock *et al.*, 1978) than in adults (Van Metre *et al.*, 1968).

Systemic anaphylaxis associated with allergy to ingested foods generally occurs within 1–30 min but rarely has been reported hours after ingestion of the offending food (Golbert *et al.*, 1969). The first anaphylactic episode may be unexpected or may be preceded by minor symptoms such as abdominal discomfort or urticaria on previous exposure to the food. Anaphylaxis may be evidenced clinically by tongue itching and swelling, palatal itching, throat itching and tightness, wheezing and cyanosis, chest pain, urticaria, angioedema, abdominal pain, vomiting, diarrhea, hypotension, and shock. Severe life-threatening reactions most often are associated with the ingestion of peanuts, nuts, fish, and crustacea. Fatal reactions from the onset may progress rapidly or begin with mild symptoms and then progress to cardiorespiratory arrest and shock over 1–3 hr. Systemic anaphylaxis also has been reported only after ingestion of food followed by exercise. In some cases, symptoms occur only after eating certain foods but in other individuals no specific food can be identified, although the association of the meal with exercise did predispose to anaphylaxis (Dohi *et al.*, 1991).

### D. Laboratory Procedures

Laboratory procedures supporting the diagnosis of food hypersensitivity rely on the identification of antigen-specific IgE to water-soluble allergens in extracts of foods. In the case of skin testing, the IgE examined is fixed to skin mast cells. *In vitro* tests identify antigen-specific IgE in serum. Laboratory tests such as total IgE determinations and eosinophil counts do not correlate with immediate hypersensitivity reactions to foods.

Skin testing with food extracts consists of the application of extracts to the dermis. Such testing is the most reliable method of demonstrating specific IgE antibodies. The routine method is the puncture or prick skin test, in which a drop of food extract is placed on the skin. The skin is then punctured through the drop with a sterile needle. Extracts for testing usually are supplied as 1:20 w/v extracts in 50% glycerine. Skin testing using 1:1000 or 1:100 w/v extracts may be performed by the intradermal technique. However, intradermal tests are more likely to produce clinically irrelevant positive tests (Bock *et al.*, 1977) and are associated with a higher frequency of systemic reactions that, in rare instances, have been fatal. Allergic reactions to foods are unusual in the face of negative skin tests (false negatives). Food extracts including nuts, egg, milk, soy, and fish induce reactions that correlate reliably with allergic manifestations. Patients should never be advised that they are allergic to certain foods solely on the basis of positive skin tests, because skin tests may be positive in the absence of symptomatic food allergy (false-positive tests). In cases of the oral allergy syndrome, the use of extracts of fresh fruits and vegetables is often necessary to exclude IgE-mediated food hypersensitivity. Skin testing is not feasible or recommended in some clinical situations. Thus, in patients with extensive skin disease or significant

and prolonged dermatographism, or in patients in whom exposure to minute quantities of a specific food resulted in a life-threatening reaction, *in vitro* diagnostics are used to demonstrate food-allergen-specific IgE.

The radioallergosorbent test (RAST) is an *in vitro* test that is considered less sensitive than skin testing. Although modifications of the RAST procedure have been made, all involve antigens coupled to a solid phase (e.g., paper disk). Patient sera are reacted with the solid phase and, after washing, the amount of bound IgE antibodies is calculated by adding labeled anti-human IgE antibodies. The enzyme-linked immunosorbent assay (ELISA) is a variation on this theme. The amount of antigen that binds to the plastic surface of a microtiter plate used in the ELISA assay is generally lower than that bound by coupling in the RAST. Thus, the number of available antibody sites may be lower and the test may be more subject to inhibition by antigen-specific IgG.

Basophil degranulation tests sometimes are employed in the evaluation of allergic reactions to foods. In this test, heparinized venous blood (or separated blood leukocytes) is incubated with extracts of suspected foods. Histamine will be released into the supernatant fluid and may be measured as an index of reactivity if antigen-specific IgE is present on the basophils that interacts with allergens in the added food extract. Basophil degranulation tests are comparable in outcome to the RAST. Interestingly, a high spontaneous *in vitro* release of histamine from basophils occurs in subjects allergic to foods who ingest them on a frequent basis (Sampson *et al.*, 1989).

### E. Diagnosis

The evaluation of a possible food allergy uses medical history, physical examination, and relevant laboratory studies. Reactions or diseases that sometimes mimic food allergy must be eliminated. The diagnosis in some instances must be confirmed by double-blind food challenge.

A comprehensive history of each reaction is obtained first, including its clinical features, severity, duration, extent, and response to therapeutic intervention. The patient should be questioned to determine whether the reaction was associated with exercise. Details on how the food was prepared, including whether it was consumed raw or cooked, must be determined. A suspected food may fail to lead consistently to an allergic reaction. Reasons for this inconsistency include the amount consumed (larger amounts are more likely to induce reactions), the presence of other simultaneously ingested foods that may delay digestion, and the possibility that concomitant medications such as antihistamines may have masked the reaction. When evaluating an adverse reaction to a food, the patient and physician must consider a number of other diseases, anatomic defects, and reactions to additives, toxins, and contaminants that may in some way mimic an allergic reaction (Table II).

Several enzyme deficiencies mimic or may complicate gastrointestinal inflammatory diseases. For instance, abdominal cramps, bloating, and diarrhea accompany the ingestion of milk and milk products in individuals with lactase deficiency.

**Table II** Differential Diagnosis of Food Allergy<sup>a</sup>

Enzyme deficiencies	Endogenous chemicals
Lactase deficiency	Caffeine
Sucrase deficiency	Tyramine
Phenylketonuria	Phenylethylamine
Gastrointestinal disease	Theobromine
Hiatal hernia	Tryptamine
Peptic ulcer	Alcohol
Gallbladder disease	Histamine
Postsurgical dumping syndrome	Toxins
Neoplasia	Bacterial toxins
Inflammatory bowel disease	Botulinum
Pancreatic insufficiency	Staphylococcal toxin
Additives and contaminants	Endogenous toxins
Dyes	Certain mushrooms—
Tartrazine	alpha-amanitine
Exogenous chemicals	"Shellfish"—saxitoxin
Monosodium glutamate	Ichthyotoxin
Sulfiting agents	Fungi
Nitrates and nitrites	Aflatoxin
Antibiotics	Ergot
	Physiological reactions
	Bulemia
	Anorexia nervosa

<sup>a</sup> Adapted with permission from Sampson and Metcalfe (1991).

Deficiencies such as galactose-4-epimerase (galactosemia) may be diagnosed in infancy as a result of vomiting and diarrhea after milk ingestion. Cystic fibrosis initially may be confused with a food-induced malabsorption syndrome because of associated pancreatic enzyme deficiency.

Symptoms accompanying a number of gastrointestinal diseases initially may be attributed to food allergies. Chronic cough and wheezing secondary to aspiration may occur with hiatal hernia, pyloric stenosis, and, rarely, an H-type tracheoesophageal fistula. Overfeeding and chalasia are estimated to occur in up to 50% of newborns and result in vomiting associated with feeding (Sampson and Metcalfe, 1991). Particularly in adults, abdominal pain following meals may be due to peptic ulcer disease or cholelithiasis.

Drugs, dyes, additives, bacteria, and bacterial products occasionally are present in foods. Milk from cattle has been contaminated with bacitracin, penicillin, and tetracycline used to treat bovine diseases. Tartrazine yellow (FD&C Yellow Dye No. 5) is a rare cause of hives. Sulfiting agents used to reduce spoilage of such foods as lettuce and shrimp; to inhibit undesirable microorganisms during fermentation, as in wine making; to sanitize food containers; and to prevent oxidative discoloration of foods have been demonstrated to induce problems reminiscent of allergic diseases (Taylor *et al.*, 1991). Foods that may have higher amounts of sulfiting agents include salads, dehydrated potatoes, fruits, vegetables, wines, shrimp and other seafood, baked goods, tea mixes, and vegetable and fruit juices. Asthmatic patients in some instances experience wheezing and associated anaphylactoid symptoms and signs after challenge with potassium metabisulfite (Stevenson and Simon, 1981). Monosodium glutamate in sufficient quantity (usually greater than 6 g) can lead

to a transient syndrome consisting of a warmth or burning sensation (especially over the head and shoulders), stiffness or tightness, extremity weakness, pressure, tingling, headache, light-headedness, and gastric discomfort, occurring approximately 15 min after ingestion. Monosodium glutamate also is said to induce wheezing in some asthmatics (Allen, 1991).

Toxins ingested in foods may induce signs and symptoms closely resembling allergic reactions. In scombroid poisoning, ingestion of fish containing high levels of histamine is followed shortly by symptoms including diffuse erythema and headaches. Scombroid fish commonly implicated include tuna, skipjack, and mackerel. Nonscombroid fish implicated include mahi mahi, sardines, anchovies, and herring (Saavedra-Delgado and Metcalfe, 1993). Ciguatera poisoning is seen especially in the Caribbean and Pacific islands. Symptoms include tingling of the lips, tongue, and throat, followed by nausea, vomiting, abdominal pain, diarrhea, headache, and chills, fever, and myalgias. The toxin is produced by algae that are eaten by small herbivores off the reef; these in turn are consumed by carnivorous fish. Paralytic shellfish poisoning is caused by ingestion of bivalve mollusks (especially mussels, clams, oysters, and scallops) contaminated with dinoflagellates of the genus *Gonyaulax*, which produce neurotoxins. When these dinoflagellates "bloom," they lead to a red to reddish-brown discoloration of the water known as a "red tide." Amnesic shellfish poisoning is an acute illness characterized by gastrointestinal symptoms and neurological abnormalities including seizures, coma, disorientation, and loss of memory after the ingestion of mussels. This disease is caused by domoic acid, a potent neurotoxin produced by the bloom of the pennate phytoplanktonic diatom *Nitzia pungens*.

If the relationship between ingestion of foods and symptoms is unclear, elimination diets may be warranted. The possibility of establishing a diagnosis by the use of such diets is higher when fewer foods are responsible for the symptoms. Elimination diets followed by the return of suspect foods to the diet should be applied only in situations in which symptoms are not life-threatening, as in chronic hives or rhinitis. Before any elimination diet is initiated, the patient should remain on the usual diet for 1–2 wk. During that time, the patient records the type and amounts of foods ingested and the occurrence and character of adverse reactions. This record is useful in searching for suspect foods and in establishing baseline symptoms against which the success or failure of elimination diets can be measured. If symptoms fail to appear within this baseline period, the occurrence of symptoms is too infrequent to be appreciated during the period of an elimination diet. If no more than a few foods are suspected to cause the symptoms, the initial elimination diet may consist of removing these foods.

If removal of selected foods from the diet is not successful in eliminating symptoms or if symptoms are unlikely to be caused by foods, as in chronic urticaria, a severely limited diet sometimes is warranted. Severe elimination diets, especially in children, are used for only short periods. Extensive elimination diets for infants under 3 months of age consist of milk substitute alone; for 3–6 months of age, milk substi-

tute and rice cereal; for 6 months to 2 yr, milk substitute with vitamin supplement, rice cereal, applesauce, pears, carrots, squash, and lamb (Crawford, 1980); and for older children and adults, lamb and rice. Continuation of symptoms while patients are on restricted diets indicates that the symptoms are not caused by foods. If symptoms resolve on the restricted diet, resumption of a normal diet should be accompanied by a return of symptoms; subsequent resumption of the restricted diet should alleviate these symptoms. Such cycling reproducibly should eliminate or provoke symptoms to allow the conclusion that symptoms are caused by foods. If a relationship to diet is established, foods, representing food groups eaten by the patient during the control period should be returned individually to the diet in normal amounts at intervals of 3–4 days. Foods returned to the diet without induction of symptoms remain in the diet. Foods provoking symptoms are removed until the procedure is completed. If resumption of symptoms is associated with the introduction of specific foods, this cause-and-effect relationship must be verified by the disappearance of symptoms on elimination of that food.

Double-blind placebo-controlled food challenge (DBPCFC) is the diagnostic procedure by which other diagnostic approaches are judged. DBPCFC is employed in difficult cases in children and adults (Bock *et al.*, 1988). Before DBPCFC, suspect foods should be eliminated for 10–14 days. Antihistamines are discontinued long enough to establish a normal histamine skin test. Other medications are minimized to levels sufficient to prevent breakthrough of acute symptoms. The food challenge is administered in a fasting state, starting with a dose unlikely to provoke symptoms. The dose is then doubled every 30–60 min or more, depending on the type of reaction suspected and the length of time required to produce symptoms. Once the patient has tolerated 10 g lyophilized food blinded in capsules or liquid, clinical reactivity generally is ruled out. If the blinded challenge is negative, the food must be given openly in usual quantities under observation to rule out the rare false-negative challenge. To control for a variety of confounding factors, an equal number of placebo and food antigen challenges is necessary; the order of administration should be randomized. DBPCFCs should be conducted in a clinic or hospital setting, especially if an IgE-mediated reaction is suspected, only if trained personnel and equipment for treating systemic anaphylaxis are present and only with informed consent.

The diagnosis of food allergy is dependent on the history, selective skin tests or RASTs, an appropriate exclusion diet, and blinded provocation. No evidence at this time suggest any diagnostic value for food-specific IgG or IgG<sub>4</sub> antibody levels, measurement of food antigen-antibody complexes, evidence of lymphocyte activation or sublingual or intracutaneous provocation. In gastrointestinal disorders in which pre- and post-challenge biopsy studies are performed for diagnosis, blinded challenge may not be essential.

### F. Therapy

The only proven therapy for food allergy is strict elimination of the offending allergen. However, severe elimination diets may lead to malnutrition or eating disorders, and should

be instituted only with nutritional guidance. Patients must learn to read and understand food labels to detect hidden food allergens. Clinical reactivity to food allergens is generally specific. Patients rarely react to more than one member of a botanical family or animal species. No appropriately designed trial has demonstrated clear efficacy for the use of prophylactic medications, injection immunotherapy, oral desensitization, or subcutaneous provocation and neutralization in the prevention of allergic reactions to foods.

A patient sometimes may consume a food inadvertently to which he or she is sensitive. Treatment for a specific symptom that results from inadvertent exposure is the same as that employed when other factors provoke symptoms. Thus, laryngeal or pulmonary symptoms following an inadvertent food exposure should be treated immediately with epinephrine, bronchodilator therapy, or both. The treatment of food-induced anaphylaxis is essentially the same as that for anaphylaxis caused by a medication or insect sting. A patient with potential anaphylactic reactivity should be taught to self-administer epinephrine, and should have an epinephrine-containing syringe and an antihistamine available at all times. For children, day care centers and schools should have a list of emergency telephone numbers with back-ups to be called in case of incident. Note that a patient may exhibit only mild symptoms in the first few minutes after ingesting a food to which he or she is allergic, but these may be followed 10–60 min later by hypotension and other severe problems. Following self-medication for systemic reactions, the patient should seek medical attention immediately. All patients with IgE-mediated food allergy should be warned about the possibility of developing a severe anaphylactic reaction and should be educated in the appropriate treatment measures to be taken in case of an accidental ingestion (Sampson and Metcalfe, 1992).

### III. ATOPIC DERMATITIS AND FOOD ALLERGENS

#### A. Pathogenesis

Atopic dermatitis is a form of eczema that usually has its onset in infancy. The rash is a pruritic, erythematous, papulovesicular eruption that progresses to a scaly lichenified state. The dermatitis tends to be relapsing. Atopic dermatitis involves the cheeks and extensor surfaces of the arms and legs of infants. In young children, the condition tends to involve flexor surfaces; in teenagers and young adults, the flexor surfaces, hands, and feet are involved. The association with other atopic disease is remarkable; 50–80% of children with atopic dermatitis develop allergic rhinitis or asthma. In addition, 60–70% of children with atopic dermatitis have a family history of allergic rhinitis or asthma (Marsh *et al.*, 1981). In children with atopic dermatitis, approximately one-third can be found to have food-related hypersensitivity reactions (Sampson, 1989).

The histological findings in atopic dermatitis depend on the chronicity of the lesion. Acute lesions demonstrate intracellular edema (spongiosis) and an inflammatory infiltrate of

mononuclear cells in the upper dermis. Chronic lesions show epidermal thickening, increased numbers of mast cells, and decreased numbers of sebaceous glands (Mihn *et al.*, 1976). Dermal deposits of major basic protein have been described (Leiferman *et al.*, 1985). The serum IgE is elevated in most patients with atopic dermatitis. On average, serum IgE levels are higher in patients with atopic dermatitis than in patients with allergic rhinitis or asthma. The serum IgE level typically remains elevated regardless of the clinical state of the atopic dermatitis, although some patients have demonstrated a decrease in serum IgE with healing or remission of their skin lesions.

A relationship between food allergy and atopic dermatitis is supported by the demonstration of rises in plasma histamine after positive oral food challenges in children with atopic dermatitis (Sampson and Jolie, 1984). A relationship of food hypersensitivity to atopic dermatitis also is supported by the results of DBPCFCs in 113 children with severe atopic dermatitis (Sampson and McCaskill, 1985). In this study, 56% of the children exhibited positive food challenges, as manifested by signs and symptoms that included diffuse pruritic erythematous or morbilliform rash, nausea, vomiting, abdominal pain, diarrhea, and bronchospasm. Significantly, egg, peanut, and milk accounted for 42%, 19%, and 11%, respectively, of the positive food challenges. Soy, wheat, fish, chicken, pork, beef, and potato each accounted for 5% or less. When 31 patients were placed on a restrictive diet for 1–2 yr, approximately 40% of the individuals with initial positive food challenges no longer exhibited a positive challenge; most of them showed improvement in their atopic dermatitis.

#### B. Clinical Manifestations

Acute lesions of atopic dermatitis are characterized by erythematous papules, edema, and weeping whereas chronic lesions appear scaly with thickening and hyperpigmentation. Typically, the lesions are preceded by an intense pruritus, resulting in the classic description of “the itch that rashes.” Approximately 60% of atopic dermatitis is manifested during the first year of life; 95% is seen by 5 years of age. In infants, the lesions predominate in the head and neck region, whereas lesions in the flexural regions of the popliteal and antecubital fossae predominate in older children. Atopic dermatitis can have a fluctuating course with improvement of symptoms in the spring and summer. Children with onset of atopic dermatitis after 2 years of age generally have a worse prognosis. In severe cases of atopic dermatitis, 70% have had persistence of their symptoms for 20 years. Overall, 90% of patients with atopic dermatitis can expect improvement of their symptoms with time.

#### C. Diagnosis

Demonstration of the relationship between immediate reactions to foods and eczema requires the elicitation of positive skin tests to foods in question as well as clinical reactions in response to these foods on oral food challenge. Associating specific food allergies with atopic dermatitis is difficult. Many

foods that provoke skin symptoms during a double-blind challenge do not provoke obvious symptoms when the patients consume them on a regular basis. Urticaria is uncommon in children with atopic dermatitis exacerbated by food allergies.

The avoidance of foods shown to induce a positive response on double-blind controlled challenge leads to substantial improvement in the disease. Once a specific food allergen has been avoided for 6–12 months and the patient's skin largely has returned to a normal state, the re-administration of these foods often will precipitate urticarial skin lesions rather than the morbilliform rash that is seen during challenge procedures during active atopic dermatitis.

The differential diagnosis of atopic dermatitis includes seborrheic dermatitis, contact dermatitis, candidiasis, and histiocytosis X. Similar skin lesions also may be seen in patients with the Wiskott–Aldrich syndrome, ataxia telangiectasia, phenylketonuria, X-linked infantile agammaglobulinemia, the syndrome of elevated serum IgE with recurrent furunculosis, and the hyper-IgE syndrome. Initially, the rash of acrodermatitis enteropathica from zinc deficiency may be confused with atopic dermatitis, although its characteristic distribution, other associated symptoms, and a history of a deficient zinc intake allow for differentiation.

#### D. Treatment

When exacerbation of atopic dermatitis has been documented to be related to a specific food allergen, that food should be eliminated from the diet. Symptomatic control of pruritis may be attempted with antihistamines. In severe cases, a brief application of a topical steroid to control a flare of the disease may be warranted. When an infection is suspected, an antistaphylococcal antibiotic may be prescribed. Other general measures include avoidance of irritants, such as soaps and wools, as well as of trauma, as from scratching. Maintenance of skin hydration is an important component of therapy.

## IV. FOOD PROTEIN-INDUCED GASTROENTEROPATHY

Food protein-mediated gastroenteropathy is a disease of infants and children in which a hypersensitivity reaction to a food protein results in damage to the intestinal mucosa and mucosal dysfunction. The best-known food protein gastroenteropathy is that induced by cow's milk protein (Kuitunen *et al.*, 1975; Lake, 1991). Soy protein gastroenteropathy also has been identified and has a similar clinical and histological pattern (Ament and Rubin, 1972). Intolerances to egg, fish, rice, and chicken have been reported (Iyngkaran *et al.*, 1982; Victoria *et al.*, 1982).

#### A. Pathogenesis

The pathogenesis of food protein-mediated gastroenteropathy is unknown. The disease typically resolves with age. Thus, the immaturity of the infant gastrointestinal mucosa and immune system appears to be a factor. Immaturity or

disruption of the normal gastrointestinal mucosal barrier may allow for sensitization to intact food antigens, as suggested by the observation that a protein gastroenteropathy may follow an acute episode of gastroenteritis (Jackson *et al.*, 1983). Likewise, a transient deficiency of secretory IgA may allow more food antigen access to the gastrointestinal mucosa. Histological examination of intestinal biopsies of untreated children with food protein-induced gastroenteropathy has shown an increased number of plasma cells, lymphocytes, eosinophils, and neutrophils in the mucosa and between epithelial cells, consistent with an evolving immune reaction. A cell-mediated delayed hypersensitivity mechanism has been supported by the demonstration of an *in vitro* lymphoblastic transformation to  $\alpha$ -lactalbumin and  $\beta$ -lactoglobulin in 38% of 45 children (1–34 months of age) with cow's milk protein gastroenteropathy. This result compares with a rate of 9.5% in a similar age-matched control group (Scheinmann *et al.*, 1976; Savilahti and Verkasala, 1984).

The role of antibody in the pathogenesis of cow's milk protein gastroenteropathy is unclear. At birth, virtually no infants exhibit serum antibodies against cow's milk proteins but, by age 2 years, 95% of formula-fed children exhibit IgA and IgG antibodies against these antigens. Total serum IgE is often normal, and IgE specific to cow's milk protein is usually absent in affected children (Danneus and Johansson, 1979). Antibodies to cow's milk proteins also have been found in stools of normal children, those recovering from acute gastroenteritis, and those with cow's milk protein gastroenteropathy (Davis *et al.*, 1970).

#### B. Clinical Manifestations

The predominant symptoms of food protein-mediated gastroenteropathy are vomiting, diarrhea, malabsorption resulting in growth failure, and gross or occult stool blood loss resulting in anemia. Subtle symptoms such as irritability or colic may be the initial manifestations in some infants. Symptoms usually appear within 1 month of introducing cow's milk or a cow's milk-based formula into the diet. Gross intestinal bleeding may occur in infants aged 1–5 wk that may mimic necrotizing enterocolitis. Resolution of the intestinal bleeding occurs 24–48 hr after removal of milk from the diet. Radiologic features of four infants with gross intestinal bleeding secondary to cow's milk consumption suggested segmental colitis with short segment colonic spasm as well as mucosal ulceration in two of the four infants (Swischuk and Hayden, 1985). Occult intestinal bleeding in infants 4–12 months of age can result in a hypochromic microcytic anemia, in which associated occasional protein-losing gastroenteropathy may cause periorbital and gross edema from hypoproteinemia. Gastrointestinal blood loss results in iron deficiency anemia with guaiac-positive stools. Carbohydrate malabsorption may be present secondary to an intestinal mucosal injury, as is manifested by stools containing reducing sugars (lactose or sucrose) as well as by a low stool pH. Eosinophilia may be present in some patients. An unusual manifestation of milk hypersensitivity has been described in which precipitating antibodies to cow's milk protein is associated with chronic pulmonary disease (Heiner's syndrome) in children (Heiner *et al.*, 1962).

### C. Diagnosis

The diagnosis of cow's milk protein hypersensitivity requires the demonstration of a relationship between ingestion of cow's milk and symptomatology consistent with intestinal damage. In children exhibiting diarrhea and malabsorption, biopsy of the small intestine usually reveals villous atrophy, primarily in the jejunum. In some children only the colon is involved, manifesting as colitis (Lake, 1991).

Histological evaluation of the intestinal mucosa may be unrevealing in mild cases or may resemble celiac disease. In such instances, oral challenge with cow's milk protein may allow confirmation of the diagnosis. A lactose tolerance test should be performed to rule out lactase deficiency. (If a soy protein gastroenteropathy is being evaluated, a sucrose tolerance test should be performed, since the carbohydrate source in soy formula is sucrose; Ament, 1972). This tolerance test is followed by an oral challenge that is not blinded. The child's stool is carefully followed for weight, presence of blood, pH, and reducing substances. A volume greater than 20 g/kg/day, appearance of blood, or the development of carbohydrate malabsorption as demonstrated by a stool pH below 6.0 or a positive test for reducing sugars is sufficient evidence of cow's milk hypersensitivity. A second approach is to demonstrate a reproducible clinical response in a 48-hr period to three separate cow's milk challenges, with total resolution of symptoms after withdrawal of milk.

### D. Treatment

Treatment is dependent on removal of milk or other sensitizing protein from the child's diet. An elemental formula or formulation or total parenteral nutrition may be required to allow repair of and return of normal function to the gastrointestinal mucosa. Reintroduction of offending protein may be attempted, since protein-mediated gastroenteropathy typically resolves by 18–24 months of age (Walker-Smith, 1986).

## V. EOSINOPHILIC GASTROENTERITIS

Eosinophilic gastroenteritis is a disease characterized by eosinophilic infiltration of the gastrointestinal wall, peripheral eosinophilia, and gastrointestinal symptoms. The sites of involvement of eosinophilic gastroenteritis include the esophagus, stomach, small intestine, colon, and, rarely, extraintestinal organs. Approximately half the cases have allergic features and may be related to food allergy.

The true incidence of eosinophilic gastroenteritis is not known. Males are affected slightly more often than females. Eosinophilic gastroenteritis may occur at any age, although the peak age of onset is in the third decade. Most individuals with food-dependent disease are under the age of 20 years (Johnstone and Morrison, 1978; Thounce and Tanner, 1985).

### A. Pathogenesis

The cause of eosinophilic gastroenteritis is largely unknown, although an IgE-dependent, mast cell-mediated mechanism has been advocated as the immunological basis

of this disorder in some patients with an immunological reaction to food antigen (Caldwell *et al.*, 1978). Atopic diseases, such as childhood food allergies, eczema, allergic rhinitis, bronchial asthma, and urticaria, and a positive family background for allergy are common in patients with eosinophilic gastroenteritis. Moreover, many patients have peripheral eosinophilia, an elevated serum IgE level, and positive RASTs for specific IgE antibodies to food antigens. Results of RASTs or skin tests may be accompanied by a symptomatic response to food challenge (Caldwell *et al.*, 1979).

Participation of a similar allergic mechanism has been demonstrated in cow's milk allergy in childhood. Some children with severe milk allergy present with iron-deficiency anemia and hypoproteinemia, demonstrating that ingested bovine milk protein may cause protein and fat malabsorption. Milk challenge results in an increase of IgE-positive plasma cells, mast cell degranulation, and an infiltration of eosinophils in the small intestinal mucosa (Oyaizu *et al.*, 1985). Eosinophils infiltrating the bowel mucosa are both activated and degranulated; in this way, they may induce tissue damage by releasing eosinophil major basic protein (Keshavarzian, 1985). An ultrastructural study of mucosal eosinophils obtained from damaged duodenum also has shown that the electron core density of eosinophil granules is inverted or absent, and tubulovesicular structures appear. Major basic protein is detected diffusely in the matrix of eosinophil granules and outside of granules in tight association with extragranular membrane formations. In contrast, eosinophil cationic protein and eosinophil peroxidase normally are distributed in the granular matrix, supporting a selective release of eosinophil mediators and a role for major basic protein in tissue damage in eosinophilic gastroenteritis (Torpier *et al.*, 1988). Indeed, many pediatric cases of food protein intolerance, such as milk protein or soy protein intolerance, have been classified as allergic gastroenteropathy when convincing evidence of an allergic mechanism was available and when the clinical findings were those of eosinophilic gastroenteritis. In these cases, the elimination of the incriminated food antigen frequently resulted in improvement (Katz *et al.*, 1984).

All patients with eosinophilic gastroenteritis, however, are not atopic, and all cases cannot be explained by food allergy. Only approximately half the patients with eosinophilic gastroenteritis have findings consistent with atopy. Many patients show no personal or family history of allergy, no positive skin tests for food allergens, no elevation in serum IgE, and no adverse reactions to foods. Even in patients who have suspected food allergies, sequential withdrawal of various food substances may fail to provide amelioration of symptoms, and a poor correlation may exist between the results of skin tests to specific food antigens and the results of an elimination diet. In addition, most patients show no abnormality after extensive immunological studies, including serum IgE, IgM, and IgA levels; complement levels; lymphocyte quantification; and lymphocyte responses to nonspecific mitogens (Elkon *et al.*, 1977).

### B. Clinical Manifestations

Patients with eosinophilic gastroenteritis experience postprandial nausea with vomiting, abdominal pain, diarrhea,

steatorrhea, and weight loss in the adult or growth failure in the child. Both weight loss and growth failure are associated with malabsorption or a restricted caloric intake. Radiologic findings may reveal mucosal edema and coarsening with nodularity of the folds of the small bowel (Goldberg *et al.*, 1973). Muscular disease can precipitate abdominal distress with vomiting from proximal small bowel obstruction. Radiologic features in such cases include evidence of pyloric narrowing and obstruction. Small bowel obstruction is unusual in children. Subserosal disease results in ascites with a marked eosinophilia.

### C. Diagnosis

Significant mucosal disease typically presents with evidence of iron-deficiency anemia, hypoalbuminemia, and hypogammaglobulinemia secondary to a protein-losing gastroenteropathy, steatorrhea, and an eosinophilic leukocytosis. Multiple positive skin tests in response to food extracts may be present. The mucosal form of eosinophilic gastroenteritis disease may be confused with celiac disease, regional enteritis, neoplasms (lymphoma), polyarteritis nodosa, parasites, the hypereosinophilic syndrome, or another protein-losing gastroenteropathy (Robert *et al.*, 1977;

Greenberger and Gryboski, 1978). The diagnosis of eosinophilic gastroenteritis is established with a gastrointestinal biopsy, demonstrating an eosinophilic infiltration of the gastrointestinal wall (Figure 1). Examination of the stool may reveal Charcot-Leyden crystals. An impaired D-xylose absorption secondary to damage of the intestinal mucosa can be present (Cello, 1979).

Eosinophilic gastroenteritis in children may be difficult to differentiate from a transient cow's milk gastroenteropathy of infancy. In a study of 12 children with symptoms and diagnostic findings of eosinophilic gastroenteritis, two groups were clinically distinguishable (Katz *et al.*, 1984). One group of children, all of whom were less than 1 year of age and had no IgE antibodies to milk protein antigens, responded to withdrawal of milk from their diet with resolution of their symptoms. The other group of children was generally older than 1 year of age, demonstrated other atopic symptoms, exhibited IgE to food antigens, and had a poor response to dietary manipulation; this group required oral steroids to control the symptoms. Clinically, the first group of children who responded to cow's milk exclusion was diagnosed as having a cow's milk gastroenteropathy with eosinophilia. The follow-up of the infants with a cow's milk gastroenteropathy revealed that most of these children were able to have milk reintroduced into their diet by 30 months of age.

**Figure 1** Small bowel biopsy. The lamina propria is infiltrated heavily with eosinophilic leukocytes, which contain many eosinophilic granules. The villous architecture is preserved. Hematoxylin and eosin stain (H & E),  $\times 400$ . Reprinted with permission from Min and Metcalfe (1991).

### D. Treatment

Treatment of eosinophilic gastroenteritis is often unsatisfactory. Food hypersensitivity should be ruled out as the precipitating or exacerbating factor in eosinophilic gastroenteritis. History and skin testing or RAST may identify food allergens for a trial of elimination. A trial diet that eliminates multiple food antigens from the diet in a systematic order may be performed when no clear history or evidence of IgE-mediated hypersensitivity is elicited. In patients with eosinophilic gastroenteritis and food sensitivity, the number of foods involved may preclude the long-term use of an elimination diet for symptom control, although improvement may be demonstrated initially. Patients who respond poorly to dietary restrictions as well as those without evidence of food hypersensitivity may require oral steroid therapy. Although this treatment usually results in clinical improvement, the need for long-term steroid therapy is variable. In some cases, steroids eventually may be withdrawn without recurrence of the symptoms. In other cases, withdrawal of steroids is followed by an exacerbation of disease. Individuals with multiple food sensitivities appear to be less likely to have resolution of their eosinophilic gastroenteritis with treatment, perhaps because of persistence of food antigen-induced immunological responses in the gastrointestinal tract. Initially, in adults, prednisone should be instituted to suppress inflammation. As evidenced by improvement of clinical symptoms and resolution of the histological abnormalities, prednisone may be tapered to an every-other-day regimen. When exacerbations occur, a brief burst of steroids is usually sufficient to bring the symptoms under control (Klein *et al.*, 1970; Min and Metcalfe, 1991).

# Intestinal Infections

Myron M. Levine • James P. Nataro

## I. INTRODUCTION

Various bacteria, viruses, protozoa, and helminths are capable of causing intestinal infections accompanied by clinical illness in immunologically competent individuals (Table I); this list would lengthen considerably with the inclusion of agents known to cause illness in immunocompromised hosts. These various pathogens cause an array of diarrheal illnesses, dysenteries, enteric fevers, and malabsorptive states. Clearly, discussing every known enteric pathogen or even mentioning them is beyond the scope of this chapter. Instead, we emphasize the common themes encountered among diverse intestinal infections with respect to virulence properties of the etiologic agents, steps in pathogenesis, modes of interaction with the host intestinal mucosa, resultant clinical syndromes, and components of the host immune system that mount putatively protective responses.

**Table I** Some Bacteria, Viruses, Protozoa, and Helminths That Are Incriminated as Causes of Intestinal Illness

<b>Bacteria</b>	
Shigella	<i>Vibrio cholerae</i>
<i>Escherichia coli</i>	O1
enterotoxigenic	non-O1
enteroinvasive	<i>Campylobacter jejuni</i>
enteropathogenic	<i>Yersinia enterocolitica</i>
enterohemorrhagic	<i>Salmonella</i> , nontyphoidal
enteroaggregative	<i>Vibrio parahemolyticus</i>
diffuse-adherent	<i>Vibrio mimicus</i>
<i>Aeromonas hydrophila</i>	<i>Plesiomonas shigelloides</i>
<i>Clostridium difficile</i>	<i>Bacterioides fragillis</i> , enterotoxigenic
<b>Viruses</b>	
Group A rotaviruses	Norwalk-like 27-nm
Group B rotaviruses	gastroenteritis viruses
Astroviruses	Enteric adenoviruses
Pestiviruses	Caliciviruses
	Picobirnaviruses
<b>Protozoa</b>	
<i>Giardia lamblia</i>	<i>Cryptosporidium parvum</i>
<i>Entameba histolytica</i>	<i>Isospora belli</i>
<i>Balantidium coli</i>	
<b>Helminths</b>	
<i>Capillaria philippinensis</i>	<i>Strongyloides stercoralis</i>

## II. EPIDEMIOLOGY

On the global level, diarrheal diseases, dysenteries, and enteric fever are predominantly problems of populations living in less-developed areas of the world, where infants and young children suffer the highest incidence rates. Travelers of all ages from industrialized countries experience high attack rates of diarrheal illness and other enteric infections when they visit such less-developed areas of the world. Intestinal infections constitute a much smaller health problem in industrialized countries. Nevertheless, problems that remain include viral gastroenteritis (e.g., rotavirus in infants), certain foodborne infections (e.g., salmonellosis and campylobacteriosis), and shigellosis in subpopulations in which hygiene is compromised (e.g., children in day care, patients in custodial institutions).

Although the list of etiologic agents capable of causing intestinal infection and disease is long, a relatively small number of pathogens worldwide accounts for the majority of intestinal diseases of public health importance. Those that have been cited as being of paramount public health importance include enterotoxigenic *Escherichia coli*, enteropathogenic *E. coli*, *Shigella*, and rotavirus as causes of endemic diarrheal disease; *Vibrio cholerae* O1 and *Shigella dysenteriae* 1 as causes of epidemic disease; and *Salmonella typhi* as the predominant cause of enteric fever. Agents of lesser importance include *Campylobacter jejuni*, enteric adenoviruses, and *Entamoeba histolytica*. In many industrialized countries, enterohemorrhagic *E. coli*, which causes hemorrhagic colitis and (more rarely) the hemolytic-uremic syndrome, increasingly is being recognized as an important enteric pathogen.

## III. PATHOGENESIS

### A. Virulence Properties

Bacterial enteric pathogens are, arguably, better understood than viral or parasitic infections with respect to their virulence properties and the manner in which they interact with the host intestinal mucosa. Therefore, bacterial enteropathogens are used as examples to illustrate certain fundamental concepts (e.g., the interaction of pathogens with mucosal epithelial cells).

Among the recognized virulence properties elaborated by bacterial enteropathogens are cytotoxic enterotoxins that lead to intestinal secretion (Levine *et al.*, 1983), fimbrial attachment factors that permit adherence to epithelial cells (Knutton *et al.*, 1985), expression of proteins that lead to effacement of the microvilli of enterocytes (Jerse *et al.*, 1991), expression of certain outer membrane proteins that allow the bacteria to be internalized by epithelial cells (Isberg and Leong, 1990; Miller *et al.*, 1990), cytotoxins that suppress protein synthesis and lead to cell death (Brown *et al.*, 1980), and expression of proteins that allow survival within the phagolysosomes of macrophages (Fields *et al.*, 1989; Miller, 1991). Bacterial enteropathogens often possess several distinct virulence properties, the particular array of which markedly affects the mode of interaction of the pathogen with the intestinal mucosa of the host as well as the clinical syndromes caused, Table II lists some of the most important bacterial enteric pathogens and the virulence properties they are known to possess.

Two pathogenic motifs encountered recurrently among diverse bacteria are (1) mechanisms to adhere to mucosa and (2) elaboration of toxins. Adherence to mucosal epithelium allows the bacteria to counteract peristalsis, an important and effective nonspecific defense mechanism of the proximal small intestine. Bacteria have developed a variety of distinct means to achieve adherence; sometimes initial adherence represents a preliminary step to more intimate attachment or to actual invasion of epithelial cells. Many bacterial enteropathogens express fimbrial attachment factors. Fimbriae (also called pili) are hairlike appendages that radiate from the surface of bacteria and are composed of thousands of protein subunits stacked end-on-end to result in long filaments that can bind to specific receptors on enterocytes. Fimbriae that serve as attachment factors are found, for example, in enterotoxigenic *E. coli* (Evans *et al.*, 1975; Levine *et al.*, 1983, 1984), enteropathogenic *E. coli* (Giron *et al.*, 1991), enterohemorrhagic *E. coli* (Karch *et al.*, 1987), enteroaggregative *E. coli* (Vial *et al.*, 1988; Nataro *et al.*, 1992),

diffuse adherence *E. coli* (Bilge *et al.*, 1989), and *V. cholerae* O1 (Taylor *et al.*, 1987). After contact with epithelial cells, some bacteria, such as *Shigella*, *Salmonella*, and *Yersinia enterocolitica*, are internalized by the epithelial cells (Levine *et al.*, 1983). In each instance, the bacteria must express specific outer membrane proteins that are involved in the internalization process (Hale *et al.*, 1983; Elsinghorst *et al.*, 1989; Isberg and Leong, 1990; Miller *et al.*, 1990) the epithelial cell plays an active role in the process. Certain other bacterial enteropathogens demonstrate an intimate form of attachment to epithelial cells in which the outer membrane of the enterocyte appears to wrap partially around the bacterium, giving the impression that the bacterium is perched on a pedestal of enterocyte membrane (Rothbaum *et al.*, 1983).

The second recurring pathogenic motif is the elaboration of toxins. Enterotoxins that resemble cholera toxin and LT (the heat-labile enterotoxin of enterotoxigenic *E. coli*) in structure, pharmacological properties, and immunological properties are produced by *C. jejuni* (Ruiz-Palacios *et al.*, 1983), *S. typhimurium* (Finkelstein *et al.*, 1983), and *Vibrio mimicus* (Chowdhury *et al.*, 1987), for example. Small peptide heat-stable enterotoxins (ST) are elaborated by enterotoxigenic *E. coli*, *Y. enterocolitica* (Delor *et al.*, 1990), *Citrobacter freundii* (Guarino *et al.*, 1987), non-O1 *V. cholerae* (Arita *et al.*, 1986), and enteroaggregative *E. coli* (Savarino *et al.*, 1991). Enteroinvasive *E. coli* and *Shigella* now are recognized to elaborate enterotoxins as well (Fasano *et al.*, 1990).

The genes encoding virulence properties of bacterial enteropathogens often are located on plasmids. Genes encoding other virulence factors, as well as regulatory genes that control the plasmid genes, often are found on the bacterial chromosome. Some bacterial pathogens exhibit "coordinate regulation of virulence properties," in which regulatory genes sense a change in the environment and generate a cascade effect in which the transcriptional promoters of certain genes are activated while those of others are suppressed (Miller *et al.*, 1989).

**Table II** Virulence Properties of Some Major Bacterial Enteropathogens

Pathogen	Fimbrial colonization factor	Intimate attachment	Effacement of microvilli	Enterocyte invasion	Toxins			
					LT	ST or ST-like	Other	Potent cytotoxins
<i>Escherichia coli</i>								
enterotoxigenic	+	-	-	-	+	+	-	-
enteroinvasive	-	-	-	+	-	-	+	-
enteropathogenic	+	+	+	+/-	-	-	?	-
enterohemorrhagic	+	+	+	-	-	-	-	+
enteroaggregative	+	-	-	-	-	+	-	?
diffuse adherence	+	-	-	-	-	-	?	?
<i>Shigella dysenteriae</i> 1	-	-	-	+	-	-	+	+
<i>Shigella</i> , other	-	-	-	+	-	-	+	-
<i>Salmonella</i> , nontyphoidal	?	-	-	+	Some	-	-	-
<i>Yersinia enterocolitica</i>	-	-	-	+	-	Some	-	-
<i>Campylobacter jejuni</i>	-	-	-	+	+	-	-	+/-

## B. Modes of Interaction with the Host Mucosa

The various bacterial enteric pathogens can be categorized on the basis of the manner in which their virulence properties interact with the intestinal mucosa of the host and on their degree of invasiveness.

### 1. Mucosal Adherence and Enterotoxin Production

Pathogens in this class, exemplified by *V. cholerae* O1 and enterotoxigenic *E. coli* (ETEC), adhere to the mucosa of the proximal small intestine before elaborating enterotoxins that lead to intestinal secretion (Levine *et al.*, 1983). In each instance, the attachment or colonization factor consists of one or another type of fimbria that adheres to specific receptors on the enterocytes. The fimbrial colonization factor of *V. cholerae* O1 is the toxin co-regulated pilus (TCP), so-called because its expression is controlled by the same regulatory gene (*toxR*) that controls expression of cholera toxin (Taylor *et al.*, 1987). A series of antigenically distinct fimbrial colonization factors is found in ETEC. Some fimbriae are rigid structures 6–7 nm in diameter, whereas others consist of thin flexible fibrillae that are ~3 nm in diameter (Levine *et al.*, 1984). The plasmids that encode the fimbrial subunits often also carry genes encoding enterotoxins (Levine *et al.*, 1983). Certain colonization factor antigen fimbriae are associated with particular O:H serotypes of ETEC.

Although cholera or ETEC infection can result in copious diarrhea, virtually no morphological damage to the intestinal mucosa is evident in such infections; functionally, such infections can be considered intracellular intoxications leading to disruption of biochemical pathways within enterocytes. Cholera toxin and LT activate adenylate cyclase within enterocytes, leading to an intracellular accumulation of AMP. The consequence is that enterocytes in the crypts secrete and those of the villus tips manifest diminished absorption. The ST of ETEC is a small peptide consisting of 18 or 19 amino acids, rich in cysteines. ST activates guanylate cyclase, leading to an intracellular accumulation of GMP; this effect also culminates in net secretion to the gut.

### 2. Intimate Mucosal Adherence and Effacement of Microvilli

Enteropathogenic *E. coli* (EPEC) of classical O:H serotypes that originally were incriminated as causes of infant diarrhea in the 1940s and 1950s exhibit a multistep pathogenesis. Plasmid-encoded bundle-forming fimbriae (BFP, bearing some genetic relatedness to TCP) result in a preliminary adherence to epithelial cells (Giron *et al.*, 1991). This is followed by an intimate attachment mediated by a 94-kDa outer membrane protein called intimin (Jerse *et al.*, 1990; Donnenbert and Kaper, 1992). The gene encoding this protein is located on the EPEC chromosome (Jerse *et al.*, 1990). Nevertheless, the same EPEC Adherence Factor (EAF) plasmid (Nataro *et al.*, 1987) that carries genes encoding the fimbrial attachment factor (Giron *et al.*, 1991) also regulates expression of the 94-kDa protein. Yet other genes encode proteins that result in the effacement of the microvilli of the enterocyte. This process may be mediated by protein kinases

that cause an intracellular accumulation of Ca<sup>2+</sup> (Baldwin *et al.*, 1991). Transmission electron microscopy reveals occasional EPEC bacteria within vacuoles internalized by the enterocytes (Donnenberg *et al.*, 1990). Note that the 94-kDa protein intimin bears considerable DNA homology to invasins, outer membrane proteins expressed by *Yersinia pseudotuberculosis* and *Y. enterocolitica* (Jerse *et al.*, 1990) that are involved in invasion of epithelial cells.

### 3. Intimate Mucosal Adherence, Effacement of Microvilli, and Production of Potent Cytotoxins

Enterohemorrhagic *E. coli* (EHEC), a new category of pathogen recognized only since the early 1980s, manifests an unusual interaction with the intestinal mucosa consequent to the interplay of several virulence properties. Novel fimbriae (the expression of which requires the presence of a 60-MDa plasmid) are believed to foster initial attachment to epithelial cells (Karch *et al.*, 1987). Ultimately, the expression of phage-encoded potent Shiga-like cytotoxins (O'Brien *et al.*, 1984) is thought to cause death of enterocytes in the colon, leading to sloughing of these epithelial cells and denudation of the mucosa (Pai *et al.*, 1986). In animal models of EHEC infection (Tzipori *et al.*, 1986, 1987), intimate attachment and effacement of microvilli is observed. Indeed, the EHEC chromosome harbors a gene bearing close homology to *eae* of EPEC and is believed to encode a protein similar to intimin. Note, however, that although intimate attachment and effacement of microvilli are prominent in animal models of EHEC, they not been observed in biopsy or autopsy specimens of patients with hemorrhagic colitis or hemolytic-uremic syndrome caused by EHEC (Griffin and Tauxe, 1991).

### 4. Expression of Enterotoxin and Potent Cytotoxin

Some enteric pathogens, typified by *Clostridium difficile*, elaborate enterotoxins and potent cytotoxins that lead to enterocyte death and denudation of mucosa, particularly in the colon. *Clostridium difficile* is the predominant pathogen in cases of antibiotic-associated diarrhea and pseudomembranous colitis. The ability of *C. difficile* to grow vigorously in the intestine and to cause disease is promoted strongly by derangement of the normal microflora (Rolfe *et al.*, 1981). *Clostridium difficile* produces at least two exotoxins: the cell-associated cytotoxin/enterotoxin toxin A and the cytotoxin toxin B (Mitchell *et al.*, 1986). When fed intragastrically in animal models, these toxins appear to work synergistically to induce mucosal damage and to induce fluid secretion (Lylerly *et al.*, 1985). In contrast to the bacterial pathogens described earlier, adherence of *C. difficile* to the intestinal mucosa has not been recognized as a prominent component of the organism's pathogenic nature. Few bacteria are noted on pathologic examination of *C. difficile* lesions.

### 5. Enterotoxin Production, Epithelial Cell Invasion, and Intraenterocytic Proliferation

The cardinal feature of *Shigella* and of enteroinvasive *E. coli* (EIEC) is their ability to invade epithelial cells, multiply therein, invoke an inflammatory response characterized by immigration of polymorphonuclear neutrophilic leukocytes,

and cause mucosal ulcerations (Dupont *et al.*, 1971; Hale and Formal, 1986; Yoshikawa *et al.*, 1988). The major sites of intestinal pathology caused by *Shigella* are the colon and terminal ileum. The invasion process is complex and requires the involvement of genes located on the 120- to 140-MDa *Shigella* invasiveness plasmid, as well as chromosomal regulatory genes, and the active participation of the host epithelial cell (Hale and Formal, 1986; Yoshikawa *et al.*, 1988).

*Shigella flexneri* 2a and EIEC have been shown to elaborate enterotoxins that cause intestinal secretion (Fasano *et al.*, 1990). Such enterotoxins can explain the early phase of clinical shigellosis, when watery diarrhea is prominent, prior to the onset of dysentery.

### 6. Mucosal Translocation Followed by Proliferation in the Lamina Propria and Mesenteric Lymph Nodes

Nontyphoidal *Salmonella*, *Y. enterocolitica*, and *C. jejuni* invade enterocytes in membrane-bound vesicles. These organisms migrate intracellularly through the enterocytes in these pinocytotic vesicles from the apical end to the basal extremity to exit finally into the lamina propria, where they elicit a chemotactic response resulting in an influx of polymorphonuclear leukocytes (Levine *et al.*, 1983). These enteric pathogens readily reach the mesenteric lymph nodes, but further invasion accompanied by bacteremia is believed to be relatively uncommon, except in immunocompromised hosts (or in very young infants). *Salmonella* also gains entry to the gut lymphoid tissue after active uptake by M cells that cover the Peyer's patches and other lymphoid tissue.

### 7. Mucosal Translocation Followed by Generalized Infection of the Reticuloendothelial System

*Salmonella typhi* and *Salmonella paratyphi* A and B pass through the mucosa like other *Salmonella*, both by M-cell uptake (Yokoyama *et al.*, 1989) and by pinocytotic vesicles that transmigrate through enterocytes (Levine *et al.*, 1983). However, on reaching the lamina propria, these organisms elicit a chemotactic response that leads to an influx of macrophages (Harris *et al.*, 1972) rather than polymorphonuclear leukocytes. These macrophages ingest the *Salmonella* but, in the nonimmune host, not only do *S. typhi* and *S. paratyphi* readily drain to the mesenteric lymph nodes but some reach the bloodstream via lymphatic drainage through the thoracic duct (Levine *et al.*, 1983). During this silent primary bacteremia, these *Salmonella* spp. are removed by fixed phagocytic cells of the reticuloendothelial system in the spleen, liver, bone marrow, and so on. In the susceptible host, virulence properties possessed by these *Salmonella* allow them to survive within the phagolysosomes of the macrophages (Fields *et al.*, 1989; Miller, 1991). Following an incubation period that usually lasts 8–14 days, the clinical features of enteric fever (typhoid or paratyphoid fever) commence, accompanied by secondary bacteremia.

### 8. Viruses

Among the viruses that cause gastrointestinal disease (Table I), the pathogenesis of rotavirus infection is the best studied (Table I) (Davidson *et al.*, 1977; Mebus *et al.*, 1977;

Estes and Cohen, 1989). Specific rotaviruses of one type or another cause diarrheal disease in many mammals. Rotaviruses consist of nonenveloped double-shelled capsids, ~70 nm in diameter, that enclose an RNA core that is divided into 11 separate segments. Each of the 11 genes encodes a protein, of which 6 form part of the structure of the virus particle. Viral proteins VP1, VP2, VP3, and VP6 form the inner shell of the virus, whereas glycosylated viral proteins VP7 and VP4 on the surface of the virus play critical roles in the attachment and internalization of rotaviruses into enterocytes. The surface-exposed proteins VP4 and VP7, which make up the outer shell of the virion, constitute the major neutralization antigens against which protective antibodies are directed. VP7 contains 326 amino acids, whereas VP4 consists of 775 or 776 amino acids. For rotavirus to be able to infect enterocytes, VP4 must be split by intestinal trypsin into two components (Espejo *et al.*, 1981).

Rotavirus invades enterocytes of the villus tips leading to cell death, sloughing of the dead enterocytes, and denudation of the villus tips (Mebus *et al.*, 1977; Estes and Cohen, 1989). This behavior is accompanied by striking diminutions in the activities of disaccharidases and other enzymes in the affected areas of the intestine. Since villus tip cells represent mature enterocytes that are important for absorption, the loss of absorptive capacity that follows destruction of these cells creates an imbalance with the secreting cells of the villus crypts; the result is net secretion. Visualization of the human infant intestine infected by rotavirus reveals foci of severe pathology intermingled with virtually unaffected areas.

### 9. Protozoa

The best-studied protozoa that cause intestinal disease are *Giardia lamblia*, *E. histolytica*, and *Cryptosporidium parvum*. These protozoa possess adhesion factors that allow them to attach to enterocytes. *Entamoeba histolytica* has been shown to effect mucosal colonization using specific adherence factors and also has been shown to elaborate soluble toxins (Ravdin, 1989). *Giardia lamblia* also adheres strongly to the intestinal mucosa, in this case in the small bowel (Farthing *et al.*, 1986). However, neither invasion nor enterotoxin production has been demonstrated conclusively. Instead, data suggest that the immune response of the host may be important in pathogenesis, as may the ability of the parasite to promote deconjugation of bile salts (Farthing *et al.*, 1985). *Cryptosporidium* effaces microvilli, leading to host-parasite interaction that resembles that of EPEC (Tzipori *et al.*, 1983).

## IV. CLINICAL SYNDROMES

With few exceptions, when the various enteric pathogens listed in Table I cause clinical disease, the result is one or another of the seven distinct syndromes shown in Table III. By far the most common clinical syndrome is "simple diarrhea," characterized by the passage of multiple loose stools (without blood), low-grade fever, malaise, nausea, and some vomiting. Simple diarrheal illnesses usually are self-limited and require only oral rehydration therapy. Most of the patho-

**Table III** Most Common Clinical Syndromes Caused by Enteric Pathogens

Syndrome	Features	Pathogens <sup>a</sup>
Simple diarrhea	Watery diarrhea; nausea; low grade fever	Rotavirus, ETEC, EPEC, <i>Campylobacter jejuni</i> , enteric adenovirus, astroviruses, <i>Shigella</i> , <i>Salmonella</i> , <i>Yersinia enterocolitica</i> , <i>Cryptosporidia</i> , EIEC
Dysentery	Scanty stools with gross blood and mucus; high fever; toxemia; sheets of fecal leukocytes	<i>Shigella</i> , <i>C. jejuni</i> , EIEC, <i>Y. enterocolitica</i>
Persistent diarrhea	Diarrhea > 14 days	EAggEC, EPEC, <i>Giardia lamblia</i>
Hemorrhagic colitis	Copious bloody diarrhea; no fever; no fecal leukocytes	EHEC
Rice water purging	Voluminous Na <sup>+</sup> -rich "rice water" stools	<i>Vibrio cholerae</i> O1, ETEC
Vomiting without diarrhea	Acute, short-lived Persistent	27-nm Norwalk-like gastroenteritis viruses <i>G. lamblia</i> , <i>Strongyloides stercoralis</i>
Enteric fever	Persisting fever; malaise; headache; abdominal discomfort	<i>Salmonella typhi</i> ; <i>Salmonella paratyphi</i> A, B

<sup>a</sup> Abbreviations: ETEC, enterotoxigenic *E. coli*; EPEC, enteropathogenic *E. coli*; EIEC, enteroinvasive *E. coli*; EAggEC, enteroaggregative *E. coli*; EHEC, enterohemorrhagic *E. coli*.

gens listed in Table I can cause this syndrome; perhaps 85% of health care visits for diarrheal illness are the result of clinical infections of this nature and severity.

Some agents, particularly invasive bacterial pathogens, are capable of causing the syndrome of dysentery, that is, the passage of scanty stools containing gross blood and mucus. Dysenteric illnesses tend to be severe and commonly are accompanied by high fever, toxemia, and notable malaise. Approximately 5–10% of patients with diarrheal illness visiting health care facilities in less-developed countries suffer from dysentery. Although *Shigella* is the most common cause of dysentery, *C. jejuni*, *Y. enterocolitica*, and occasionally nontyphoidal *Salmonella* can cause an identical clinical picture. *Entamoeba histolytica* infection also leads to dysentery, but such infections usually are not associated with the high fever, malaise, and toxemia seen with the bacterial dysenteries.

Approximately 5% of episodes of acute diarrhea in less-developed countries persist for more than 14 days, at which point they become defined as "persistent diarrhea." The clinical-epidemiological syndrome of persistent diarrhea carries a poor prognosis for afflicted infants and young children in the developing world (Bhan *et al.*, 1989a); the consequences include malnutrition and death. Until recently, no specific pathogen was associated with this syndrome. However, several reports now have shown a statistically significant association between enteroaggregative *E. coli* (EAggEC) and persistent diarrhea; up to 51% of cases have been attributed to this etiology (Cravioto *et al.*, 1991).

Hemorrhagic colitis is a syndrome caused by EHEC. The salient clinical features include copious bloody diarrhea in the absence of fever (Riley *et al.*, 1983; Griffin and Tauxe, 1991). The copious nature of the bloody diarrheal stools, the lack of fever, and the absence of fecal leukocytes differentiate this syndrome from dysentery caused by *Shigella* or other organisms, which consists of scanty stools, accompanying high fever, and sheets of fecal leukocytes that can be visualized in simple stains of stool mucus. Occasionally, patients with hemorrhagic colitis (or milder diarrheal illness) caused by EHEC proceed to develop the hemolytic-uremic syn-

drome that includes hemolytic anemia, fragmented erythrocytes (schistocytes), severe thrombocytopenia, and acute renal failure (Karmali *et al.*, 1985)

Some intestinal infections, particularly in cholera-endemic areas, are characterized by the passage of voluminous stools resembling "rice water." An older child or adult with cholera can pass stools of 1.0–1.25 liters hourly. Such diarrheal infections, which rapidly lead to severe dehydration, acidosis, and circulatory collapse, must be treated aggressively with rehydration.

Another uncommon syndrome caused by intestinal infection is vomiting in the absence of diarrhea or accompanied by scanty diarrhea. Acute short-lived bouts of "winter vomiting disease" are mainly caused by 27-nm gastroenteritis viruses typified by the Norwalk agent. Persistent vomiting in the absence of diarrheal illness, a particularly uncommon syndrome, usually is associated with duodenitis or jejunitis caused by *G. lamblia* or *Strongyloides stercoralis* infection.

*Salmonella typhi* and *S. paratyphi* A and B cause typhoid and paratyphoid fever, respectively. These conditions represent generalized infections that involve the intestinal lymphoid tissue, the reticuloendothelial system, and the gall bladder. Following a relatively long incubation (usually 8–14 days), the clinical illness commences with fever (that increases in stepwise fashion), abdominal discomfort, and headache. Because these infections are generalized, inappropriate or delayed treatment can result in a wide array of complications. In the pre-antibiotic era, the case fatality rate of typhoid fever was 10–20%.

## V. IMMUNE RESPONSES

The immune responses elicited by various enteric pathogens and their role in protection against subsequent infection vary and depend, to a large extent, on the virulence properties of the agent, the type of host-parasite interaction as described earlier, and the degree of invasiveness. Virtually all intestinal infections prime the intestinal immune system (as

measured by gut-derived IgA-antibody-secreting cells detected in peripheral blood) (Van de Verg *et al.*, 1990; Kantele and Makela, 1991; Quiding *et al.*, 1991) to respond to subsequent contact with antigen by producing specific SIgA antibodies. The impressive capacity of mucosal antibodies to protect is evidenced by the fact that, in experimental challenge studies, passively administered milk immunoglobulin concentrates conferred a very high level of protection to adult volunteers against challenge with ETEC or *Shigella* (Tacket *et al.*, 1988,1992). Similarly, in veterinary studies, piglets or calves nursed by sows or cows that received intramammary immunization with vaccines consisting of purified colonization factor fimbriae were protected highly against otherwise lethal challenge with ETEC bearing the homologous antigenic type of fimbriae (Rutter and Jones, 1973; Acres *et al.*, 1979; Levine, 1981).

Serum antibodies commonly are detected, even after non-invasive intestinal infections. Although serum antibodies are not believed to play an important role in protection against noninvasive infections of the gut, such antibodies often show strong correlations with protection. An example is the correlation between serum vibriocidal antibody and protection against cholera (Mosley *et al.*, 1968a,b; Glass *et al.*, 1985).

An unusual form of antibody-dependent cellular cytotoxicity (ADCC) is seen in *Salmonella* and *Shigella* infections in which antibodies provide the specificity and mononuclear cells mediate the killing of these bacteria (Lowell *et al.*, 1980; Tagliabue *et al.*, 1986; Levine *et al.*, 1987). In general, cytokine-mediated cellular immune responses are important in immunity to *Salmonella*, particularly *S. typhi*.

Increasingly scientists are recognizing that infection with intracellular bacteria can elicit major histocompatibility complex (MHC) Class I-restricted cytotoxic lymphocyte responses of a type that once were thought to occur only in infections by viruses (Kaufmann, 1988). Attenuated *Salmonella* are attractive candidates for "live vectors" or "carrier vaccines" for the expression of foreign antigens (Dougan *et al.*, 1987; Levine *et al.*, 1990). In this regard, note that animals immunized with attenuated *S. typhimurium* expressing the circumsporozoite protein of *Plasmodium falciparum* were shown to develop MHC I-restricted CD8<sup>+</sup> cytotoxic lymphocytes that recognized epitopes of the *P. falciparum* circumsporozoite protein (Aggarwal *et al.*, 1990).

# Liver and Biliary Tract

William R. Brown • Charles D. Howell

## I. IgA IN HEPATOBILIARY DISEASES

### A. Alcoholic Liver Disease

Many attempts have been made to implicate abnormalities in the IgA immune system in diseases of the liver and biliary tract. The most provocative of the putative associations is that of alcoholic liver disease (ALD), which some writers refer to as an IgA-associated disease (Van de Wiel *et al.*, 1987a). Several alterations in serum IgA have been described in ALD. Total serum IgA levels may be elevated (Kutteh *et al.*, 1982; Chandy *et al.*, 1983; Kalsi *et al.*, 1983; Newkirk *et al.*, 1983); the proportions of serum IgA present as polymeric IgA (pIgA) and secretory IgA (SIgA) may be increased, and the ratio of IgA1 to IgA2 may be decreased (Delacroix *et al.*, 1983; Van de Wiel *et al.*, 1987b). Most of these changes, however, are mild and not specific. One piece of evidence favoring a unique link between IgA abnormalities and ALD is that serum IgA concentrations may be increased even in mild ALD (steatosis). In contrast, increased concentrations do not occur in other disease until later, when histopathological abnormalities are more severe. The causes of elevated levels of serum IgA in ALD seem to include a selective and significant reduction in the catabolic rate in conjunction with increased synthesis of pIgA (Delacroix and Vaerman, 1983; Delacroix *et al.*, 1983), impaired removal of plasma pIgA by hepatocytes (Delacroix *et al.*, 1983), and increased spontaneous production of IgA by peripheral blood mononuclear cells (Kalsi *et al.*, 1983; Van de Wiel *et al.*, 1987c). Increased amounts of IgA antibodies against dietary and microbial antigens have been reported in ALD (Bjorneboe *et al.*, 1972; Nolan *et al.*, 1986), leading to the suggestion that the liver fails to extract circulating antigens and gut-derived endotoxins properly, perhaps because of impaired function of hepatic macrophages (Staun-Olsen *et al.*, 1983).

Far more interesting and potentially important than alterations in serum IgA in ALD are the deposits of IgA in the liver, skin, and kidneys of many such patients. IgA deposited in a continuous pattern along the margins of liver sinusoids has been described in about 75% of patients with ALD compared with less than 10% in non-ALD patients (Swerdlow and Chowdhury, 1984, 1983; Van de Wiel *et al.*, 1987b). In addition, the presence of the IgA deposits has been associ-

ated with a higher likelihood of progressive hepatic injury (Swerdlow and Chowdhury, 1984); some authors, however, have reported the common occurrence of IgA deposits in non-ALD individuals, especially those with chronic hepatitis (Amano *et al.*, 1988). The hepatic deposition of IgA in ALD occurs about equally often in all histological expressions (steatosis, fibrosis, hepatitis, and cirrhosis), so this condition may be a consequence of alcohol-induced changes in the liver per se.

Most evidence now indicates that the hepatic IgA deposits in ALD are of the IgA1 subclass (Van de Wiel *et al.*, 1986, 1987b; Amano *et al.*, 1988). The IgA also lacks J chain, does not bind to the polymeric immunoglobulin receptor (secretory component), and therefore appears to be mostly in a monomeric form. That the IgA deposits are predominantly IgA1 raises the intriguing possibility that the deposition is linked to an abnormality in the handling of IgA1 by the asialoglycoprotein receptor. The receptor, expressed on the sinusoidal surface of hepatocytes, functions to remove desialylated glycoproteins from plasma and degrades them in the liver (Ashwell and Harford, 1982). Because of its high content of galactose residues, IgA1 can bind to the receptor (Stockert *et al.*, 1982; Tomana *et al.*, 1988) and stimulate receptor-mediated clearance of the IgA (Tomana *et al.*, 1988). Conceivably, alcohol-induced damage to the hepatocyte membrane could impair such a clearance mechanism and lead to accumulation of IgA1 on the sinusoidal margin. The reported frequency of renal deposits of IgA in ALD varies from more than 50% (Berger *et al.*, 1977; Woodroffe *et al.*, 1981) to less than 20% (Montoliu *et al.*, 1986). Likewise, the severity of the disease also varies from a latent asymptomatic state to a very active proliferative condition. The prevailing opinion is that the deposits are complexes of IgA with various antigens, but no specific antigen has been identified consistently. The characteristics of the IgA renal deposits are now defined fairly conclusively. The IgA most likely is not associated with the polymeric immunoglobulin receptor and is IgA1 (Russell *et al.*, 1986). We have suggested that an abnormality in the handling of IgA1 by the liver in ALD is responsible for the renal accumulation of IgA (Brown and Kloppel, 1989). We speculate that complexes of IgA and the receptor, released from the liver or formed in the circulation, are "trapped" in the renal mesangium.

### B. Primary Biliary Cirrhosis

Marked elevations of SIgA are common in primary biliary cirrhosis (PBC); values greater than 118 mg/ml have been called specific for the disease (Homburger *et al.*, 1984). However, on the basis of several reports, measurement of serum SIgA does not appear to distinguish PBC reliably from other cholestatic diseases. Also, IgA seems unlikely to be linked in any way pathogenically to the biliary ductule injury in PBC, since the disease has been reported in patients with selective and severe IgA deficiency (James *et al.*, 1986; Logan, 1987). However, an interesting relationship between IgA and biliary epithelium has been described. IgA allegedly stimulated the proliferation of extrahepatic bile duct epithelium in mice (Fallon-Friedlander *et al.*, 1987), but that observation subsequently has been refuted convincingly (Solbreux *et al.*, 1991).

### C. Other Obstructive Biliary Tract Disease

Early reports suggested that measurement of IgA, especially SIgA, in serum would be useful in diagnosing extrahepatic biliary obstruction (Thompson *et al.*, 1973; Goldblum *et al.*, 1980) but, regrettably, that is not the case (Kutteh *et al.*, 1982; Delacroix *et al.*, 1983). The failure of SIgA and secretory component to reach high levels in biliary obstructive disease in humans, as they do after bile duct ligation in the rat (Lemaitre-Coelho *et al.*, 1978), no doubt reflects the fact that the human liver normally does not clear much IgA from the circulation (Delacroix *et al.*, 1982).

## II. IMMUNODEFICIENCY AND HEPATOBILIARY DISEASES

Although congenital immunodeficiency states commonly have associated gastrointestinal abnormalities, diseases of the biliary tract and liver ordinarily are not prominently associated. Infrequently, however, selective IgA deficiency may be accompanied by an autoimmune-type liver disease (Brown *et al.*, 1972). Biliary tract sepsis evidently is not a feature of congenital immunodeficiencies or acquired hypogammaglobulinemia.

In contrast to the apparent sparing of hepatobiliary tissues in the immunodeficiencies just mentioned, these tissues are not spared in the acquired immunodeficiency syndrome (AIDS), in which numerous infectious and neoplastic manifestations have been described (Lebovics *et al.*, 1985; Gordon *et al.*, 1986; Cappell *et al.*, 1990; Schaffner, 1990). Since all persons at risk for infection with the human immunodeficiency virus (HIV) also are at risk for hepatitis B virus, this type of hepatitis is, not surprisingly, very commonly associated with the HIV positive condition. However, histological sequelae of the infection (chronic hepatitis) are not common in AIDS patients, perhaps because of the underlying immunoincompetent state. A common finding in the liver of AIDS patients are hepatic granulomas. Often the granulomas

are ill defined or composed of foamy histiocytes, perhaps reflecting the decreased ratio of helper to suppressor type T cells. Infection of the gall bladder or biliary ducts with cytomegalovirus, *Cryptosporidium*, or both agents may occur in AIDS, and obstruction of the ducts with a sclerosing cholangitis-like lesion is a feature of these infections (Margulis *et al.*, 1986; Viteri and Green, 1987). Biopsy of the liver in AIDS patients who have hepatomegaly and unexplained fever often is recommended and may yield a diagnosis but, regrettably, this information usually does not lead to an effective treatment (Cappell *et al.*, 1990; Schaffner, 1990). Kaposi's sarcoma and lymphoma are the most common neoplasms of the liver in AIDS (Friedman, 1988). A list of many of the recognized infections of the liver and bile ducts in AIDS is given in Table I.

## III. AUTOIMMUNE LIVER DISEASES

Primary biliary cirrhosis and idiopathic "autoimmune" chronic active hepatitis are hypothesized to be autoimmune in origin. Both disorders fulfill several of the proposed criteria for an autoimmune disease (Shoenfeld and Isenberg, 1989), including the presence of circulating autoantibodies, cell-mediated immunity to autoantigens, induction of disease in experimental animals by adoptive transfer of T cells or by immunization with self antigens, and the production of autoantibodies and autoreactive cells after immunization of mice. However, the role of the identified autoantigen(s) in disease induction and the immune effector mechanisms responsible for liver injury in both disorders remain undefined. Primary sclerosing cholangitis also is hypothesized to be autoimmune in origin, but will not be reviewed here.

**Table I** Infections of the Liver and Bile Ducts Associated with AIDS

Viral infections	
	Hepatitis B, nonA, nonB (C), D
	Herpes (I, II, and Varicella zoster)
	Cytomegalovirus
	Epstein-Barr virus
Bacterial infections	
	Mycobacteria ( <i>M. avium-intracellulare</i> , <i>M. kansasii</i> , <i>M. tuberculosis</i> )
	<i>Salmonella</i> species
	<i>Vibrio</i> species
Fungal infections	
	Cryptococcosis
	Candidiasis
	Histoplasmosis
	Coccidioidomycosis
Parasitic infections	
	<i>Toxoplasma gondii</i>
	<i>Cryptosporidium</i>

## A. Primary Biliary Cirrhosis

PBC is a chronic cholestatic disease (characterized by impaired excretion of bile acids) of unknown etiology that primarily affects middle-aged females (Sherlock and Scheuer, 1973; Christensen *et al.*, 1980). The fundamental pathological process is T cell-mediated inflammation and destruction of interlobular and septal bile ducts, a process referred to as nonsuppurative destructive cholangitis (Rubin *et al.*, 1965). Similar lesions are observed during chronic graft-versus-host disease (Shulman *et al.*, 1988) and liver allograft rejection (Vierling and Fennell, 1985).

### 1. Clinical Features of PBC

The natural history of PBC includes a preclinical period in which no symptoms of liver disease are apparent (Long *et al.*, 1977; Fleming *et al.*, 1978; Beswick *et al.*, 1985). Up to 50% of patients are diagnosed during this phase of the disorder and may remain free of liver symptoms for at least 10 years. These "asymptomatic" patients are discovered because of elevated liver tests or symptoms of the extrahepatic autoimmune diseases associated with PBC (keratoconjunctivitis sicca or Sjögren's syndrome, scleroderma, autoimmune thyroiditis, seronegative nondestructive arthritis, and Raynaud's phenomenon). As bile duct destruction progresses, symptoms (pruritus and jaundice) and signs of cirrhosis ultimately develop and result in either death or the need for liver transplantation (Christensen *et al.*, 1980; Balasubramaniam *et al.*, 1990).

### 2. Hypergammaglobulinemia and Autoantibodies

In addition to biochemical markers of liver disease (elevated fasting serum bile acids, copper, ceruloplasmin, liver alkaline phosphatase, bilirubin), PBC is characterized by polyclonal hypergammaglobulinemia. Serum IgM, IgG, and IgA all are elevated, but the most striking elevation is in IgM levels, which may be higher than 5 times the normal level (Christensen *et al.*, 1980). Several autoantibodies, including antinuclear, antithyroid, and anti-smooth muscle antibodies, have been reported in PBC; the most notable and relatively disease-specific are the M2 antimitochondrial antibodies (AMA) found in 83–99% of patients (discussed subsequently). The natural history of PBC is the same in patients with and without serum AMA.

### 3. Pathogenesis of PBC

**a. Genetic susceptibility and environmental factors.** The pathogenesis of PBC is undefined. The increased frequency of extrahepatic autoimmune disorders, autoantibody production, abnormalities of T-cell immunity, and absence of a defined infectious, toxic, or metabolic etiology led to the hypothesis that PBC is mediated by autoimmune mechanisms (James *et al.*, 1983). The induction of liver injury is hypothesized to involve an interplay between host susceptibility and an environment factor(s) that triggers the onset of disease. Indeed, an increased frequency of HLA-DRw8 (Gores *et al.*, 1987), -DRw3 (Ercilla *et al.*, 1979), and -DR2 (Miyamori *et al.*, 1983) in patients compared with controls has been reported.

Further, patients and their first-degree relatives have an increased frequency of autoantibodies as well as defective T-cell suppressor activity (Galbraith *et al.*, 1974; Miller *et al.*, 1983). These observations suggest that susceptibility to PBC may be determined by (or linked to) genetic factors.

Clusters of cases in urban areas and near a common water source in one report is consistent with the existence of a yet-to-be defined environmental agent (Hamlyn and Sherlock, 1974), yet such clustering usually is not observed (Lofgren *et al.*, 1985). In addition, reports of an increased frequency of gram-negative bacterial urinary infections (a potential source of sensitization to mitochondrial antigens) in PBC have been refuted (Floreani *et al.*, 1989; Morreale *et al.*, 1989). Nonetheless, AMA-positive sera react with mitochondrial antigens from rough-mutant gram-negative bacteria. Hopf (1989) reported that the feces of PBC patients have increased numbers of rough mutants and that PBC patients have lipid A (endotoxin) deposits in the liver. These results have not been confirmed by others. However, since immunization of rabbits with rough mutants but not wild-type gram-negative organisms results in production of AMAs, sensitization to mitochondria of mutant gram-negative bacteria may be involved in induction of AMA and, possibly, in the pathogenesis of bile duct destruction.

**b. Histological features of PBC.** Liver histology in PBC is characterized by accumulation of mononuclear inflammatory cells in portal triads and inflammation of septal and interlobular bile ducts (Rubin *et al.*, 1965; Ludwig, 1978). Inflammation of bile ducts is associated with necrosis of biliary epithelial cells and ultimately results in destruction of the ducts. Bile duct inflammation occurs in a segmental distribution and varies in intensity along the length of the ducts. Piecemeal necrosis of periportal hepatocytes, portal lymphoid aggregates, and granulomas also are observed. Progressive destruction of bile ducts is accompanied by proliferation of bile ductules and liver fibrosis, and ultimately results in cirrhosis.

T cells with receptors for antigen-major histocompatibility complex (MHC) composed of  $\alpha$  and  $\beta$  heterodimers constitute 81–99% of mononuclear cells in the liver in PBC (Shimizu *et al.*, 1986; Yamada *et al.*, 1986; Krams *et al.*, 1990). The percentage of CD4<sup>+</sup> (MHC Class II-restricted) T cells is generally equal to or greater than that of CD8<sup>+</sup> (MHC Class I-restricted) T cells. CD4<sup>+</sup> and CD8<sup>+</sup> T cells infiltrate the bile duct epithelium, but CD8<sup>+</sup>Leu15<sup>-</sup> (cytotoxic) T cells appear to predominate. Lymphocytes frequently are observed in intercellular spaces between injured and necrotic biliary epithelial cells. Biliary epithelial cells show increased expression of MHC Class I (Shimizu *et al.*, 1986; Calmus *et al.*, 1990) as well as new expression of Class II antigens (Spengler, 1988) and intracellular adhesion molecule 1 (ICAM-1) (Calmus *et al.*, 1990). Periportal hepatocytes also show increased expression of MHC Class I antigens. Increased HLA antigen and ICAM-1 expression, presumably induced by cytokines released locally (Paradis and Sharp, 1989), may allow biliary epithelial cells and hepatocytes to present antigen(s) more efficiently and to stimulate the T-cell response to bile duct

cells and periportal hepatocytes. However, the functions of liver T cells and the significance of increased MHC antigen and ICAM-1 expression in the liver during PBC remain to be clarified.

The hepatic non-T-cell population is composed primarily of plasma cells, with a smaller percentage of natural killer and interstitial dendritic cells (Krams *et al.*, 1990). Deposits of IgG, IgA, and IgM have been observed on biliary epithelial cells (Ghadiminejad and Baum, 1987; Krams *et al.*, 1990). These results suggest that antibody-mediated cellular cytotoxicity, either through complement activation (IgG and IgM) or through the activation of antigen-nonspecific FcR  $\gamma$  positive (NK, macrophage, or K) cells, may be involved in bile duct injury.

**c. Autoantigens in PBC.** The bile duct antigen(s) recognized in PBC is (are) unknown. The large number of autoantibodies in PBC is indicative of a lack of immunological tolerance to the respective antigens. Elucidation of the mechanisms responsible for lack (or loss) of immune tolerance may provide insight into the pathogenesis of bile duct destruction in this disorder. However, only one of the autoantigens identified in PBC (the asialoglycoprotein receptor) is liver specific; only the M2 mitochondrial autoantigens are nearly disease specific. Serum autoantibodies and T-cell sensitization to the asialoglycoprotein receptor (ASGR), a hepatocyte-specific glycoprotein expressed in hepatocyte plasma membranes, have been reported (McFarland *et al.*, 1985; Vento *et al.*, 1986). Recognition of the peptide fragments of ASGR by autoreactive T cells could contribute to destruction of periportal hepatocytes by T cells. However, the ASGR is not expressed by bile duct epithelial cells. ASGR may be shed by periportal hepatocytes, processed by bile duct cells, and presented to ASGR-specific T cells. However, evidence of such a phenomenon is lacking. Further, since sensitization to the ASGR is not specific to PBC, this receptor is not likely to play a primary (initiating) role in the pathogenesis of bile duct destruction.

**d. M2 mitochondrial autoantigens.** Serum complement-fixing antibodies to mitochondria in PBC first were reported by Walker *et al.* (1965). Subsequent studies indicated that AMAs recognize antigens located in the inner membrane of the mitochondria. Based on the pattern of immunofluorescence and reactivity with submitochondrial particles, AMAs can be subdivided into 9 subtypes (M1–9; Berg and Klein, 1989). Subtypes 2, 4, 8, and 9 are observed in PBC. The M2 pattern is most specific for PBC. Immunoblots of submitochondrial fractions with PBC sera show reactivity with five major bands at 70–75, 55–56, 51–52, 48, and 36 kDa (referred to as M2a–e; Bassendine *et al.*, 1989). The genes for the 74-kDa and 52-kDa antigens have been cloned, and recombinant M2 proteins have been produced (Gershwin *et al.*, 1987; Coppel *et al.*, 1988; Yeaman *et al.*, 1988; Van de Water *et al.*, 1989). The M2 antigens are subunits or components of inner membrane enzymes of the 2-oxo acid dehydrogenase complex. This complex includes three enzymes of similar structure and function—pyruvate dehydrogenase (PDH),

alpha-keto acid dehydrogenase, and the oxoglutarate dehydrogenase complex. Each enzyme plays a critical role in intermediary metabolism. Each complex consists of several copies of three subunits termed E1, E2, and E3. The 74-kDa and 56-kDa antigens are the E2 of PDH and a protein X that co-purifies with it. The 52-kDa antigen has been found to be the E2 of alpha-keto acid dehydrogenase; the 48- and 36-kDa antigens are the E1  $\alpha$  and  $\beta$  subunits of PDH (Fussey *et al.*, 1989). Approximately 100% of AMA-positive sera react with at least one of these antigens (90–95% react with the 74- and 52-kDa antigens). Alderruccio *et al.* (1986) have reported that sera from patients with scleroderma also react with the 70–74-kDa submitochondrial antigen recognized by PBC sera. AMA reactivity also is found in other disorders (chronic active hepatitis, systemic lupus erythematosus, rheumatoid arthritis, and Sjögren's syndrome), indicating that M2 AMAs are not specific to PBC. The ability of M2 AMAs to inhibit the activity of inner mitochondrial enzymes indicates that the active sites of the enzymes may be recognized (Van de Water, 1988; Fregeau *et al.*, 1989, 1990a,b). Alternatively, binding of the AMA to its epitope may induce a conformational change that prevents the enzyme from binding to its substrates. The immunoglobulin or B-cell epitope of the 74-kDa E2 of PDH consists of a 75–93 amino acid segment of the lipoic acid domain (Surh *et al.*, 1990). The T-cell epitope(s) has (have) not been identified. Like many autoantigens, the mitochondrial autoantigens in PBC are highly conserved in nature and are present in prokaryotic as well as eukaryotic cells. Additional similarities to other autoantigens include (1) that they are intracellular enzymes composed of multiple subunits and (2) that autoantibodies directed toward these enzymes are directed toward functional sites or domains. However, the role of sensitization to mitochondrial autoantigens in the pathogenesis of PBC is unclear. The occurrence of PBC in the absence of M2 AMA reactivity suggests that an AMA response is not required for induction of PBC. Indeed, immunization of mice with the recombinant 70-kDa human mitochondrial autoantigen results in a high titer AMA response but no liver inflammation. Transfer of peripheral blood mononuclear cells (PBMC) from patients with PBC into severe combined immunodeficient (SCID) mice results in liver lesions that are histologically similar to those in PBC (Krams *et al.*, 1989a). Similar lesions were induced also (albeit much less frequently) by PBMCs from normal subjects, suggesting that graft-versus-host disease may be in part responsible. Van de Water *et al.* (1991) reported that CD4<sup>+</sup> T-cell clones derived from the liver during PBC are sensitized to mitochondrial autoantigens. Whether T-cell sensitization to these antigens is a primary or secondary event in the pathogenesis of bile duct destruction remains to be defined.

**e. Plasma membrane expression of mitochondrial antigens by bile duct.** Studies in yeast indicate that the M2 mitochondrial antigens are encoded by nuclear (and not mitochondrial) DNA, synthesized in the cytoplasm, and transported to the mitochondria. For mitochondrial antigens to be recognized by T cells, they must be presented in association with self-MHC Class I or II antigens on the plasma membrane of

antigen-presenting cells (macrophages, dendritic cells, B cells) or biliary epithelial cells. Two studies suggest that AMAs recognize antigens expressed on the plasma membranes of mammalian hepatocytes (Ghadiminejad and Baum, 1987) and intrahepatic bile duct cells (Krams *et al.*, 1990). These observations suggest that mitochondrial autoantigens are transported aberrantly to the plasma membrane, where they can be recognized by effector T cells or AMAs. Alternatively, a cross-reactive plasma membrane antigen may be recognized. The plasma membrane antigen(s) recognized by AMA-positive sera and the mouse antibody to recombinant autoantigens used in these studies have not been identified. In addition, hepatocytes and biliary epithelial cells from normal subjects and patients with other liver diseases show less intense but similar patterns of staining when reacted with antibodies to mammalian E2 of PDH. Therefore, plasma membrane expression of E2 by bile duct cells and hepatocytes is not sufficient to initiate PBC. Consistent with this notion, Joplin (1991) reported that macrophages in lymph nodes draining the livers of PBC patients stain more intensely with antibodies to E2 than do macrophages from normal subjects and patients with other liver disease. These observations suggest that the release of mitochondrial antigen (and presumably other self components) from senescent and injured liver cells into hepatic lymph is a normal physiological phenomenon. A comparison of the handling of mitochondrial antigens (processing, presentation, accessory signal production) by macrophages of PBC patients compared with that of control subjects may provide insight into the process by which loss of immunological tolerance to self antigens occurs in PBC.

**f. Peripheral blood B- and T-cell activity.** An increase in the mean number of peripheral blood B cells that spontaneously secrete immunoglobulins has been reported in PBC (James *et al.*, 1985; Bird *et al.*, 1988). Immunoglobulin secretion after mitogen stimulation has been either normal or slightly diminished. The percentage of activated peripheral blood B cells in PBC is not increased. These results suggest that immunoglobulin secretion is not the result of an intrinsic defect in B-cell functions. James, 1980a and Suou *et al.*, 1989 have reported that increased Ig secretion is the result of defective CD4<sup>+</sup> (suppressor-inducer) T-cell function. Others (Zetterman and Woltjen, 1980) also have reported defects in inducible T-cell suppressor activity in PBC. However, defective suppressor-inducer T-cell function is not present in all patients. Therefore, other mechanisms must be involved in the induction of hypergammaglobulinemia. Since a similar defect in T-cell suppressor function occurs in disease-free relatives of PBC patients (Galbraith *et al.*, 1974; Miller *et al.*, 1983), other yet-to-be defined factors may be required for the expression of the disease.

Other manifestations of altered immunity in PBC include impaired cutaneous delayed hypersensitivity (skin test anergy) (Fox *et al.*, 1969), decreased mean antibody response after immunization (Fox *et al.*, 1969), defective mitogen-induced lymphocyte blastogenesis (Fox *et al.*, 1973; MacSween and Thomas, 1973), defective recognition of self in autologous mixed-lymphocyte culture (Lindor *et al.*, 1988),

circulating immune complexes, and impaired clearance of C3b-containing immune complexes by Kupffer cells. The role of these factors in the pathogenesis of PBC is also unknown.

**g. Activity of liver-derived T cells.** Studies of T-cell lines propagated from liver biopsies of patients suggest that PBC may be mediated by a limited number of T-cell clones (Moebius, 1990). However, cloned liver T cells consistently show only lectin-dependent cellular cytotoxicity (LDCC) and minimal natural killer and antibody-dependent cellular cytotoxicity (ADCC) activities (Meuer *et al.*, 1988; Hoffman *et al.*, 1989). No spontaneous T cell-mediated cytotoxicity toward a number of mammalian cell lines, including a well-differentiated bile duct carcinoma, has been reported. The lack of classic cytotoxic T lymphocyte (CTL) activity by T-cell lines that presumably are sensitized to bile duct cells is puzzling, but may reflect the use of allogeneic target cells that either do not express the antigen(s) recognized in PBC or do not present the antigen(s) in association with syngeneic HLA antigens. Alternatively, these liver T lymphocytes (LTLs) are propagated in the absence of specific antigen and may not play a role in bile duct destruction. Whether LDCC in these studies is mediated by bile duct-specific T cells is not clear since mitogens may stimulate nonspecific cytotoxic activity *in vitro*. T-cell reactivity toward intrahepatic bile duct epithelial cells has not been reported in PBC, primarily because of the difficulty in obtaining autologous or syngeneic biliary epithelial cells. Saidman *et al.* (1990) have reported that a liver T-cell line proliferates when stimulated with autologous extrahepatic biliary epithelial cells. Since extrahepatic bile ducts are not affected in PBC, the meaning of this observation is unclear.

#### 4. Conclusion

The features of PBC mentioned earlier do not generate a unified hypothesis of its etiology. However, susceptibility to PBC appears to be determined genetically. The factor(s) that acts in association with genetic susceptibility to induce disease is (are) unknown. Bile duct destruction appears to be mediated by CD4<sup>+</sup> and CD8<sup>+</sup> T-cells. Although T-cell destruction of bile ducts appears to be the primary pathogenic process, a bile duct-specific antigen has not been identified and the mechanisms by which T cells mediate bile duct injury are not defined. Circumstantial evidence also suggests that ADCC also may be involved. A better understanding of the function of liver-derived T and non-T cells is necessary to elucidate the immunological effector mechanisms responsible for bile duct destruction. Such studies are not feasible in humans because intrahepatic bile duct cells are not readily available. The surface membrane expression of M2 mitochondrial autoantigens by hepatocytes, bile duct cells, and macrophages of normal individuals as well as patients, and the presence of AMAs in disease-free relatives of patients, casts doubt on (but does not exclude) a primary role for sensitization to mitochondrial antigens in the pathogenesis of PBC. On the other hand, recognition of mitochondrial or other self-peptide fragments may be a secondary mechanism that helps perpetuate or amplify the immune response to bile

ducts. Pursuit of these issues using animal models (graft-versus-host diseases, SCID mouse) of nonsuppurative destructive cholangitis may overcome the limitations of human studies.

## B. Autoimmune Chronic Active Hepatitis

Autoimmune chronic active hepatitis (ACAH) is a clinical syndrome defined by idiopathic, hepatitis B and C virus-negative, chronic active hepatitis that is associated with marked hypergammaglobulinemia, circulating autoantibodies, immune-mediated extraintestinal organ injury, and responsiveness to treatment with immunosuppressive medications (Joske and King, 1955; Bearn *et al.*, 1956; Mackay *et al.*, 1956). In untreated patients with severe ACAH, the natural history is characterized by progressive hepatocyte destruction that results in cirrhosis and high mortality. The clinical and serological features of this syndrome have led to the hypothesis that hepatocyte injury in ACAH is mediated by autoimmune mechanisms. The targeted hepatocyte antigen(s) have not been identified conclusively and the autoimmune effector mechanism(s) responsible for liver injury are undefined.

### 1. Pathogenesis of ACAH

**a. Genetic susceptibility and environmental factors.** The pathogenesis of ACAH also is not defined completely. An increased frequency of HLA-A1, -B8, -DR3, -DR4, and IgG heavy chain Gm a<sup>+</sup>x<sup>+</sup> alleles suggests that susceptibility to ACAH may be determined genetically (Whittingham *et al.*, 1981; O'Brien *et al.*, 1986; Krawitt *et al.*, 1988; Johnson *et al.*, 1991). The occurrence of decreased serum complement components (Vergani *et al.*, 1985) and decreased peripheral blood T suppressor-cell activity (Nouri-Aria *et al.*, 1985; O'Brien *et al.*, 1986; Vento *et al.*, 1986; Krawitt *et al.*, 1988) in patients and first-degree relatives provides additional support for inherited susceptibility to ACAH.

Much attention has focused on the role of environmental agents (especially medications and viral infections) in ACAH. Chronic active hepatitis (CAH) that is both clinically and histologically similar to that in idiopathic autoimmune CAH occurs as idiosyncratic reactions to several prescription medications (i.e., alpha-methyl DOPA, oxyphenistatin, nitrofurantoin; Johnson *et al.*, 1991). In addition, liver lesions during chronic hepatitis B, C, and non-A, non-B infections are frequently indistinguishable from those in ACAH. Therefore, much attention has been focused on a search for a viral etiology of ACAH. An increased frequency of antibodies to measles and persistence of the measles virus genome in lymphocytes (but not hepatocytes) of ACAH patients has been reported (Robertson *et al.*, 1987). Vento and colleagues (1991) have reported that acute hepatitis A may trigger ACAH in disease-free relatives who have defective T-cell suppressor activity. The role of the hepatitis C virus (HCV), the etiologic agent for 70–90% of chronic non-A, non-B hepatitis (both transfusion-related and sporadic cases) has become the focus of many studies. Depending on the population, up to 80% of patients with ACAH have antibodies to recombinant HCV

c100 antigen. In most patients, anti-c100 reactivity appears to be falsely positive (McFarlane *et al.*, 1990; Schvarcz *et al.*, 1990; Czaja *et al.*, 1991; Pohjanpelto *et al.*, 1991), since the antibody HCV titer correlates with the degree of hypergammaglobulinemia and antibody reactivity disappears when disease activity and serum  $\gamma$  globulin levels decrease in response to immunosuppressive therapy. More importantly, in ACAH patients, most anti-c100-positive sera are nonreactive in supplemental HCV antibody tests (i.e., immunoblot and neutralization assays) and do not contain HCV RNA. This result does not apply to Italians with ACAH, in whom antibody to HCV is confirmed using supplemental anti-HCV assays in up to 73% of cases (Lenzi *et al.*, 1990; Magrin *et al.*, 1991; Todros *et al.*, 1991). In addition, Garson *et al.* (1991) have reported HCV RNA in sera of 9 of 13 (69%) selected Italian patients with ACAH. Further, some of these patients have responded to antiviral (but not immunosuppressive) therapy, suggesting that active HCV is responsible for liver disease. Although chronic HCV in Italians can mimic some of the clinical features of ACAH, the lack of response to immunosuppressive medications by definition excludes a diagnosis of ACAH.

In Japanese patients, chronic HCV is associated with production of antibodies to a host (GOR 47-1) autoantigen (Mishiro *et al.*, 1990), suggesting that the hepatitis C infection can induce autoantibody formation. Indeed, GOR and the polyprotein of HCV share considerable homology with the kidney microsomal autoantigen-1 (cytochrome P450 II D6; Manns *et al.*, 1991a,b) that is associated with ACAH. These results provide circumstantial evidence that molecular mimicry of self by viral antigens may result in autoantibody formation in some instances. However, anti-GOR antibodies were not found in patients with ACAH (or PBC). Therefore, no direct evidence is available that HCV infection is an etiological agent in rigorously defined cases of ACAH.

**b. Histological features.** Liver histology shows infiltration and expansion of portal triads by mononuclear inflammatory cells. These cells infiltrate the limiting plate of hepatocytes and induce necrosis of periportal hepatocytes. In severe cases, bridging and multilobular hepatocyte necrosis are observed and indicate a high risk for rapid progression from CAH to cirrhosis. Most lymphocytes in portal tracts and areas of periportal hepatocyte piecemeal necrosis are mature T cells. The representation of T-cell subsets is somewhat controversial. Eggink *et al.* (1982) have reported that CD8<sup>+</sup> cells predominate. Others have shown a more equal percentage of CD4<sup>+</sup> and CD8<sup>+</sup> cells. Natural killer (NK) cells and plasma cells also are present, but at frequencies less than 10%. ACAH is associated with increased expression of Class I and new expression of Class II MHC antigens by hepatocytes, which may allow hepatocytes to present the relevant antigen to liver T cells. T-cell recognition of autologous antigens in association with induced MHC antigens on hepatocytes is hypothesized to be a mechanism of liver cell injury during ACAH. However, the significance of aberrant expression of MHC antigens by hepatocytes is unknown. The presence of NK and plasma cells and immunoglobulin deposits on

hepatocytes (Hopf *et al.*, 1976; Kawanishi and McDermott, 1979; Frazer *et al.*, 1983) also suggest that non-MHC-restricted cytotoxic activity and ADCC may be involved.

**c. Autoantigens in ACAH.** The specific hepatocyte antigen(s) and autoimmune effector mechanism(s) that mediate liver cell injury in ACAH also are undefined. Several autoantibodies and corresponding autoantigens have been identified in ACAH. The list includes antibodies to nuclear (Joske and King, 1955; Penner *et al.*, 1986), mitochondrial (Walker, 1965), smooth muscle (actin) (Whittingham *et al.*, 1966), liver kidney microsomal-1 (i.e., cytochrome P450 II D6; Kyriatsoulis *et al.*, 1987; Peakman *et al.*, 1987; Franch-Codoner *et al.*, 1989), ASGR (McFarlane *et al.*, 1985), and soluble liver (Manns *et al.*, 1987) antigens. In general, these autoantigens and autoantibodies are neither liver, species, nor disease specific. With few exceptions, antibody titers do not correlate with disease activity. Further, all autoantigens identified to date, except the ASGR, are localized to intracellular organelles and not the plasma membrane where they can be recognized by autoantibodies or antigen-specific T cells. Nonetheless, two autoantigens (ASGR and cytochrome P450 II D6) are particularly worthy of further discussion.

The ASGR is a hepatocyte-specific glycoprotein located in the basolateral plasma membrane. Antibodies to the ASGR have been reported during ACAH, chronic active hepatitis B, and PBC and, therefore, are not disease specific (McFarlane *et al.*, 1985). Nonetheless, a feature common to these disorders is inflammatory necrosis of periportal hepatocytes that appear to express more ASGR than do hepatocytes in the centrilobular zone. In addition, peripheral blood and liver T cells of ACAH patients are sensitized to the ASGR (Vento *et al.*, 1986; Wen *et al.*, 1990), and peripheral blood mononuclear cells lyse autologous hepatocytes *in vitro*. Although whether the ASGR is the targeted antigen is not clear in these studies, these observations keep alive the possibility that recognition of the ASGR may result in immune-mediated liver injury in ACAH.

A subgroup of patients with ACAH has been described in whom antinuclear and anti-actin antibodies are absent but in whom antibodies that, by immunofluorescence, react with liver and kidney microsomes (anti-LKM-1; Manns, 1991; Manns *et al.*, 1991a) are present. The antigen recognized by anti-LKM-1 is a 33-amino-acid segment of cytochrome P450 II D6. The smallest epitope is an 8-amino-acid peptide in which a 6-amino-acid sequence is identical to that found in the herpes simplex 1 immediate early antigen 175. In addition, the 33-amino-acid segment includes segments highly homologous to the polyprotein of HCV and the GOR 47-1 autoantigen associated with HCV infection. This finding raises the possibility that sensitization to herpes simplex or HCV antigens triggers induction of antibodies to LKM. Autoantibodies to cytochrome P450 inhibit enzyme activity *in vitro*. However, the enzymatic activity of cytochrome P450 isolated from the livers of patients with antibodies to LKM-1 is normal. Therefore, inhibition of cytochrome P450 by anti-LKM-1 is not significant *in vitro*. Further, a report that LKM-1 antigen is expressed in liver plasma membrane has been disputed (Peak-

man *et al.*, 1987). In light of these results, hypothesizing a role for anti-LKM-1 in the pathogenesis of liver injury in ACAH is difficult.

**d. Peripheral blood B- and T-cell activity.** Increased spontaneous and pokeweed mitogen-induced polyclonal IgG production by PBMCs isolated during ACAH has been reported (Kayhan, 1985). Increased Ig secretion has been attributed to an abnormality in regulatory T-cell function. Indeed, decreased concanavalin A (Con A)-induced and antigen-specific T-cell suppressor activity in patients and first- and second-degree relatives has been reported (Hodgson *et al.*, 1978; O'Brien *et al.*, 1986; Krawitt *et al.*, 1988). However, the relationship between increased Ig secretion and decreased T-cell suppressor activity is undefined.

PBMCs from patients with ACAH are capable of mediating cytotoxic activity toward xenogeneic, allogeneic, and autologous hepatocytes *in vitro* (Thompson *et al.*, 1974; Wands and Isselbacher, 1975; Cochrane *et al.*, 1976; Geubel *et al.*, 1976; Kawanishi, 1977; Kawanishi, and McDermott, 1979). The mononuclear cell subpopulation responsible for peripheral blood cytotoxic activity is a non-T cell that expresses Fc receptor for IgG and mediates ADCC *in vitro* (Vergani *et al.*, 1979; Stefanini *et al.*, 1983; Mondelli *et al.*, 1985). T-cell cytotoxic activity appears to be less important. PBMCs from patients with ALD and chronic non-A, non-B hepatitis also show cytotoxic activity toward autologous hepatocytes (Izumi *et al.*, 1983; Poralla *et al.*, 1984). Further, most of these experiments have assayed adherence of cocultured hepatocytes to measure cytotoxicity. The high rate of spontaneous hepatocyte death in control cultures (Stefanini *et al.*, 1983) suggests that cytotoxicity as defined in these experiments in part reflects cell death of a nonimmune nature. Given the predominance of T cells in the liver during ACAH, the lack of CTL activity toward autologous hepatocytes is perplexing. However, the functions of peripheral T cells may not reflect the functions of liver T cells accurately.

**e. Activity of liver-derived T-cell clones.** T-cell clones derived from the liver during ACAH are also predominantly (75%) CD4<sup>+</sup>. Like peripheral blood T cells, liver T-cell clones also are sensitized to the ASGR and LKM-1 antigen (Lohr *et al.*, 1991; Poralla *et al.*, 1991). However, of 89 liver LKM-specific T-cell clones tested, 24 of 26 CD8<sup>+</sup> and 20 of 63 CD4<sup>+</sup> clones showed only LDCC (Lohr *et al.*, 1991) toward autologous but not allogeneic B cells. Of the remaining clones, 14 showed non-MHC-restricted cytotoxic activity toward NK-sensitive K562 cells. The cytotoxic activity of 5 CD8<sup>+</sup> clones was restricted to autologous Epstein-Barr virus-transformed B cells. Since cytotoxic activity against autologous human hepatocytes was not assessed, the meaning of these results is unclear. The requirement for lectins to induce cytotoxicity and the high rate of non-MHC-restricted killing are perplexing but may be explained by propagation of clones in high dose interleukin-2 in the absence of antigen (autologous hepatocytes). Further, in the absence of challenge with hepatocyte antigens, B cells (normal or immortal-

ized) are unlikely to express the antigens recognized by "hepatocyte-specific" T cells.

## 2. Conclusion

The pathogenesis of ACAH is undetermined. Susceptibility appears to be determined by genetic factors. In some susceptible individuals, a number of environmental agents (medications, viral infections) appear to trigger the onset of disease. However, in the majority of cases, no specific environmental trigger can be identified. In addition, the hepatocyte antigen(s) targeted by the immune system in ACAH has not been identified conclusively. Contrary to histochemical studies, which show a predominance of T cells in the liver, studies of PBMCs suggest that non-T cells are primarily responsible for liver injury in ACAH. However, a complete understanding of the mechanisms involved must include investigations of the functions of T cells isolated from the liver. The ability to clone liver T cells should allow better definition of the roles of T cells in the pathogenesis of ACAH.

# Bronchial Mucosal Lymphoid Tissue

John Bienenstock • Robert Clancy

## I. INTRODUCTION

The lymphoid tissue of the bronchus is linked primarily to mucosal defense against inhaled microbes. Therefore, this tissue is one of a series of integrated units that operate to insure that sterile air is delivered into the gas exchange apparatus of the lungs in such a way that sensitization to inhaled antigen is avoided. The cooperative activity between these different lymphoid units, and their involvement in generating down-regulation of the inflammatory response within various compartments of the bronchopulmonary system, suggests the value of reviewing the bronchial mucosal lymphoid tissue in terms of its relationship with these additional pools of lymphocytes. A second general issue requiring discussion is the relationship within the bronchial mucosa itself between the aggregated collections of bronchial lymphoid tissue that originally were termed the bronchus-associated lymphoid tissue (BALT; Bienenstock, 1984), which constitutes the majority of bronchial mucosal lymphocytes in some species, and the less-organized lymphoid tissue that predominates in others, such as humans (Kyriazis and Esterly, 1970; Emery and Dinsdale, 1973, 1974).

T and B lymphocyte effector mechanisms are generated from bronchial mucosal lymphoid tissue and delivered into the bronchial lumen. The secretory IgA system initially focused attention on a discrete mucosal defense mechanism. An IgA response to luminal antigen plays a key role in local defense in the initial control of microbial colonization (Waldmann and Henney, 1971). The susceptibility of secreted IgA antibody to high zone tolerance (Clancy *et al.*, 1987), the relatively poor immunological memory associated with this isotype (Clancy and Bienenstock, 1976), and the reasonable health of most subjects with IgA deficiency suggest that additional immune mechanisms are crucial to mucosal defense. The vigorous T-cell response to inhaled antigen (Clancy and Bienenstock, 1974) and the capacity of CD4<sup>+</sup> T cells to transfer immunity in animal models of colonization (Wallace *et al.*, 1989, 1991) suggest T cells as candidates for the controllers of infection involving persistent microbes or under circumstances under which a large inoculum of antigen is inhaled.

Communication between the bronchial mucosal lymphoid tissue and distant mucosal sites through an intermucosal cell circuit known as the common mucosal immune system (McDermott and Bienenstock, 1979) involves predominantly a "gut to bronchus" flow of cells originating in Peyer's patches (Scicchitano *et al.*, 1984). Depending on antigen dose and

previous immunological experience, antigen-reactive T cells (Husband *et al.*, 1984) and antibody-secreting B cells (Rudzik *et al.*, 1975a; Scicchitano *et al.*, 1984) can populate bronchial mucosa to modulate immunity, a principle used successfully to develop an oral vaccine that protects against acute bronchitis (Clancy *et al.*, 1985, 1989; Lehmann *et al.*, 1991). Study of animal models in which activated T lymphocytes contribute to mucosal defense suggests that T-dependent neutrophil recruitment is important (Wallace *et al.*, 1991), although additional mechanisms such as secretion of lysozyme from T-cell activated macrophages have been implicated (Taylor *et al.*, 1990).

Communication with other effector mechanisms within the bronchial lumen is indicated by these latter observations. An ascending carpet of mucus contains cells derived mainly from the bronchoalveolar compartment. About 90% of these cells are bone marrow-derived macrophages, whereas the remaining cells are predominantly lymphocytes (Young and Reynolds, 1984). The relationship between the bronchoalveolar lymphocytes and macrophages the two large pools of lymphocytes within the lung interstitium, and the pulmonary circulation are not known (Pabst, 1990), but these larger collections almost certainly play a role in determining the constitutional make-up and function of the bronchoalveolar cell population. The vascular and interstitial pools of cells represent both selective contributions from the systemic pool and an inductive effect of the pulmonary macrophages whereas about half the resident macrophage population is derived from local cell proliferation (Mezzette *et al.*, 1990). About 10–20% of the mucosal interstitium lymphocyte pool is composed of T cells—the expansion of cells bearing V chain determinants in a nonrandom way is consistent with further tissue restrictive elements operating in the lung interstitium (Augustin *et al.*, 1989).

That these effector mechanisms normally operate with minimal inflammation within the bronchial lumen or the bronchial mucosa depends on two factors. First, a series of down-regulating mechanisms restricts cell division and recruitment of nonspecific inflammatory cells. Second, regional lymph nodes rather than the mucosa are primary sites for both antigen handling (Yoshizawa *et al.*, 1989) and induction of immune responses (van der Brugge-Gamelkoorn *et al.*, 1986). The down-regulating mechanisms are linked to the site of deposition of antigen. Thus, allergens deposited in the naso-

pharynx initiate a series of suppressor-cell loops within regional lymph nodes that regulate immediate and delayed hypersensitivity reactions (Sedgwick and Holt, 1985), whereas colonization of the bronchial mucosa is associated with an expanded suppressor T-cell population that inhibits antigen-induced T-lymphocyte proliferation (Pucci *et al.*, 1982; Figure 1). Whether mucosal suppressor cells within the bronchus are activated by presentation of antigen by Class II-bearing epithelial cells, as has been suggested for the gut (Pang *et al.*, 1990), or through the aggregated BALT is not clear. The lumen is protected from inflammation by the antiproliferative effect of T cell-activated alveolar macrophages, which also carry antigen away from the mucosa, to regional lymph nodes (Warner *et al.*, 1981), and upward over the epiglottis into the gut, where aspirated antigen can activate Peyer's patches.

The bronchial mucosal lymphocyte compartment has, therefore, a complex relationship with various lymphocyte populations important in the activation and regulation of bronchial immunity. This collection of cells is a mixture of antigen-reactive, effector, and regulatory lymphocytes, as well as ancillary cells, derived from various mucosal and systemic sources. Early studies on bronchial mucosal lymphoid tissue used animal species with organized BALT, which facilitated an understanding of function, in part by analogy with Peyer's patches in the gut (Bienenstock *et al.*, 1973a,b). Differences between species in the degree of organization of bronchial mucosal lymphoid tissue have led to the idea that early studies on aggregated structures may not be relevant to bronchial immune function, at least in species such as humans, who are not characterized by major BALT development (Pabst and Gehrke, 1990). However, failure to detect BALT in some studies (Pabst and Gehrke, 1990), may reflect sampling error, since BALT has been well described in normal human bronchus (Jeffery and Corrin, 1984), and epithelium covering less-organized aggregates, and even some areas without lymphoid accumulations, including cells that are flattened and possess irregular microvilli and no cilia (Jeffery and Corrin, 1984). Since these cells may transport antigen by pinocytosis (Owen, 1977) and since a network of

Ia antigen-bearing dendritic cells and processes penetrating into the lumen exists (Holt *et al.*, 1985,1988), a classical lymphoepithelium with M cells may not be essential for antigen processing. This chapter continues by describing knowledge gained from the study of classical BALT, and subsequently addresses the issue of interspecies variation in mucosal lymphoid tissue morphology and bronchial mucosal immune function.

## II. CLASSICAL BRONCHUS-ASSOCIATED LYMPHOID TISSUE

The existence of lymphoid aggregates in the bronchial wall was noted in 1867 by Burdon-Sanderson; the observation that they were analogous to the lymphoid follicles found in other mucous membranes such as the tonsil and intestine was made by Klein in 1875 (see Bienenstock, 1984). Recent interest in the lymphoid tissue of the bronchial mucosa began with a systematic study of lymphoid aggregates in experimental animals in 1973 (Bienenstock *et al.*, 1973a,b), when their similarity to Peyer's patches in the gut was noted. Subsequently, BALT was described in a number of species including rats (Bienenstock *et al.*, 1973a; Chamberlain *et al.*, 1973; Fournier *et al.*, 1977), rabbits (Bienenstock *et al.*, 1973a,b; Racz *et al.*, 1977; Tenner-Racz *et al.*, 1979), and mice (Milne *et al.*, 1975), as well as sheep, chickens, and guinea pigs, but has been characterized best in rats and rabbits. Other species, such as pigs, cats, and humans, have few classical BALT aggregates (Jeffery and Corrin, 1984; Daniele, 1988a), although in humans BALT aggregates are well described and, in the pig, infection with mycoplasma was linked to the regular development of BALT (Chu *et al.*, 1989). These and other studies (Bienenstock *et al.*, 1973a,b; Weisz-Carrington *et al.*, 1987) emphasize the importance of antigenic stimulation in the full expression of organized BALT, with, however, considerable species variation. Since much of the current understanding of bronchial mucosal lymphoid tissue comes from study either directly of BALT aggregates or indirectly of lymphocytes derived from bronchial tissues containing numerous BALT aggregates, review of these studies on structure and function provides an excellent model for understanding bronchial mucosal lymphoid tissue.

BALT develops in early postnatal life in most species (Bienenstock *et al.*, 1973a; Milne *et al.*, 1975). Antigen is not necessary for this development since BALT is present in germ-free rats (Bienenstock *et al.*, 1973a) and mice (Milne *et al.*, 1975) as well as in fetal lungs transplanted into syngeneic adults (Milne *et al.*, 1975). BALT development under these circumstances is primitive compared with conventionally raised animals (Bienenstock *et al.*, 1973a), and antigenic challenge (Rudzik *et al.*, 1975a) induces early and hyperplastic BALT. Lymphoreticular aggregates appear at 1 week in humans (Weisz-Carrington *et al.*, 1987), although larger and more confluent aggregates are described with a lymphoepithelium in sudden infant death syndrome (Emery and Dinsdale, 1973), in which intercurrent infection is common. BALT can be identified macroscopically in experimental animals

**Figure 1** The nature of the mucosal lymphoid follicle and the epithelial relationship are seen clearly. Reprinted with permission from Klein (1875).

including rabbits, rats, guinea pigs, and chickens (Bienenstock *et al.*, 1973a) as white patches after acetic acid fixation (Cornes, 1965) for example, 30–50 BALT aggregates appear in adult rats (Plesch, 1982), concentrated around bifurcations in the major bronchus divisions that are, additionally, the sites of impaction of inhaled particles.

Although classical BALT has a structure similar to that of Peyer's patches, division into distinct structural and functional areas is less apparent. The epithelium overlying BALT aggregates is not as specialized and is infiltrated heavily with lymphocytes; scanning electron microscopy shows the presence of M (microfold) cells similar to those described in the Peyer's patch and the bursa of Fabricius (Figure 2) (Bienenstock *et al.*, 1973a,b; Bockman and Cooper, 1973; Bockman and Stevens, 1977). Cells of BALT cluster within a reticulin framework into a "dome" beneath the epithelium and a follicle that is usually single (Bienenstock *et al.*, 1973; Owen and Bhalla, 1983). In the mammalian BALT, germinal centers usually are found only after antigenic stimulation (Bienenstock *et al.*, 1973a). Tenner-Racz and colleagues (1979) described a parafollicular area after immunization, considered to be populated by T cells. Plasma cells are found around the periphery (Bienenstock *et al.*, 1973a; Milne *et al.*, 1975),

whereas cells capable of presenting antigen, including macrophages (Owen, 1977) and follicular dendritic cells (Milne *et al.*, 1975; Holt *et al.*, 1988), appear within BALT. Efferent but not afferent lymphatic vessels are described (van der Brugge-Gamelkoorn and Kraal, 1985).

In rabbit BALT, about 20% of lymphocytes have the T-cell marker rabbit thymic lymphocyte antigen (RTL), a percentage similar to that in the Peyer's patch, but location in a distinct parafollicular area can be recognized only under conditions of antigenic stimulation (Bienenstock *et al.*, 1973b). The presence of high endothelial venules (HEV) and interdigitating dendritic cells are characteristic of T-dependent areas in other lymphoid structures, although the HEV in BALT tends to be more like the structures in mesenteric lymph nodes than those in Peyer's patches (Nash and Holle, 1973), with respect to the immunohistochemical definition of T and B cells clustered about them (Bienenstock *et al.*, 1973a,b). About 50% of the lymphocytes in the BALT of rabbit (Rudzik *et al.*, 1975b) and rat (Plesch, 1982) bear surface immunoglobulin. In the rabbit, equal proportions stain with anti-IgM and anti-IgA, whereas in the rat a minority (15%) reacts with anti-IgA and few (5%) stain with anti-IgE.

Study of the function of BALT has focused on analogy

**Figure 2** A scanning electron micrograph showing the junction between the ciliated and nonciliated lymphoepithelium overlying the BALT follicle immediately below. A morphologic study of rabbit bronchial lymphoid aggregates and lymphoepithelium. *Lab. Invest.* 35, 343–348. © the US and Canadian Academy of Pathology.

with Peyer's patches. Thus, induction of a mucosal immune response and use of the common mucosal system to deliver this response have been prominent. Horseradish peroxidase (HRP) is taken up preferentially by the epithelium over BALT (Fournier *et al.*, 1977), a process that can be enhanced after antigen stimulation with *Bacillus Calmette-Guerin* (BCG), which causes hypertrophy of the specialized epithelium (Tenner-Racz *et al.*, 1979). In this latter study, bacteria were found within BALT macrophages, supporting earlier work (Bienenstock, 1984) that identified BALT as an early site for the uptake of particulate material. Other studies that have demonstrated that epithelial cells can present soluble antigen (Pang *et al.*, 1990) and that a carpet of dendritic cells bearing Class II antigen lies within and beneath the epithelium of species bearing numerous BALT aggregates (Holt *et al.*, 1988), as well as of species such as humans (Holt *et al.*, 1986), raises important questions about the qualitative and quantitative contributions of BALT aggregates to the development of local immunity. The description of numerous non-specialized epithelial cells in the normal human respiratory tract (Daniele, 1988b), and the clear link between the amount of BALT and antigenic stimulus (Meuwissen and Hussain, 1982; Delventhal *et al.*, 1992a,b; Pabst, 1991) support the concept that "classical" BALT is, in part, an adaptation to antigen load, with variable degrees of expression of aggregate structure appearing constitutively. The transformation of young mature epithelial cells into M cells induced by lymphocyte-epithelial contact (Craig and Cebra, 1971) is consistent with this view. Of particular interest with respect to human BALT was a study on chronically inflamed human lungs, in which classical BALT was noted in 8% of 100 patients; in those with an occlusive tumor, BALT was confined to the poststenotic segments (Delventhal *et al.*, 1992b).

A study by Craig and Cebra (1971) gave the first clear indication of the major role mucosal aggregates of lymphoid tissue play in generating mucosal immunity. These investigators used allotypic markers and adoptive transfer of Peyer's patch cells in rabbits to demonstrate that this tissue was an enriched source of IgA plasma cell precursors. Cebra suggested that environmental factors, including antigen and bacterial lipopolysaccharide (LPS), drove B-cell differentiation during an antigen-stimulated clonal expansion, a concept that was consistent with the observation that oral immunization induced an increase in numbers of B cells expressing surface IgA in the Peyer's patch (Fuhrman and Cebra, 1981). Subsequently, Elson *et al.* (1979) demonstrated that IgA "switch" T helper cells within the Peyer's patch directed clonal expansion of IgA-secreting B cells. The isolation of T-cell clones from the Peyer's patch (Kiyono *et al.*, 1982; Kawanishi *et al.*, 1983) that bore receptors for IgA suggested that a number of T-lymphocyte populations may be involved in immunoregulation, possibly by secreting type-specific immunoglobulin-binding factors (Kiyono *et al.*, 1985). The repopulation studies of Rudzik *et al.* (1975a,c), in which bronchial lamina propria cells were transferred to lethally irradiated rabbits, demonstrated IgA-containing plasma cells repopulating the gut and bronchial mucosa. These studies identified the BALT analogous to the Peyer's patch, and provided the information on which the concept of a "common

mucosal immune system" was developed (McDermott and Bienenstock, 1979). Inhaled antigen stimulated T-cell proliferation within the bronchial mucosal lymphocyte population that correlated in time with the appearance of proliferating T cells in the bronchial lumen (Waldman and Henry, 1971; Clancy and Bienenstock, 1974), as well as of T cells secreting cytokines (Clancy *et al.*, 1977) and of cytotoxic T cells (Husband *et al.*, 1983). The contribution of specific T lymphocytes to the common mucosal immune system (Clancy *et al.*, 1977), as well as the specific relocation of influenza-specific T-cell clones to the lung (Bienenstock *et al.*, 1983), is consistent with the observed circulation pathway of T lymphoblasts from mediastinal lymph nodes and thoracic duct lymph that included mucosal surfaces (Guy-Grand *et al.*, 1974; Sprent, 1986), and their origin in part from Peyer's patches (Guy-Grand *et al.*, 1978). The specific role played by aggregates of BALT in the localization of T and B cells in bronchial mucosa is uncertain. The immune functions localized to aggregated lymphoid tissue in the bronchus may be restricted to the generation and distribution of specific T- and B-cell responses to inhaled antigen. The potential for aggregated lymphoid structures to generate suppression within mucosal (Pucci *et al.*, 1982) or systemic tissues (Ngan and Kind, 1978; Richman *et al.*, 1981) is raised by the appearance of antigen-specific suppressor T cells within Peyer's patches. Down-regulation within bronchopulmonary tissues suggests that, indeed, a similar function exists in BALT, as does the rapid development of a state of nonresponsiveness in mucosal T-cell populations following inhalation of antigen (Clancy and Bienenstock, 1974).

Important cells linked to BALT and the bronchial epithelium are the "granulated lymphocytes" and mast cells in the adjoining mucosa (Sprent, 1986). The heterogeneity of mast cells based on differential sensitivity of rat mast cells in different tissues to various fixation procedures (Enerback, 1966) was extended to demonstrate functional heterogeneity (Befus *et al.*, 1986). Similar heterogeneity based on distinct neutral protease contents (Irani *et al.*, 1986) has been described in humans, particularly for cells within the bronchial mucosa (Shanahan *et al.*, 1987). We described granulated basophil-like cells in and adjacent to BALT follicles and in the epithelium lateral to these follicles (Bienenstock, 1984). Similar cells can be washed from the bronchial lumen; such cells contain histamine and may be sensitized by IgE to release  $\rho$  histamine in response to antigen (Patterson *et al.*, 1974,1977). Ahlstedt *et al.* (1983) showed an increase in these cells after inhalation of antigen that is likely to be influenced by T cells (Ruitenbergh and Elgersma, 1976). Of particular interest is the association between the mast cells in and below the epithelium of the respiratory tract and the nerves, forming a homeostatic regulatory unit (Bienenstock *et al.*, 1988). Many of these epithelial leukocytes have an unusual phenotype related to, but not conclusively demonstrated to be, a part of the T-lymphocyte population (Petit *et al.*, 1985). Indeed the whole question of origin and function of the intraepithelial lymphocyte pool in the respiratory tract is even less clear than it is in the intestine, on which most work has been focused. The demonstration of an expanded population of T-cell receptor-expressing cells in this population (Goodman and Lefrancois,

1988) added an additional facet to the puzzle presented by these cells. Are these cells a population uniquely geared to cope with intraluminal pathogens? Do they represent a thymic-independent T-cell population, developed in a mucosal epithelial environment? Do the variously demonstrated cytotoxic activities have a physiological role (Ernst *et al.*, 1985)?

### III. BRONCHUS ASSOCIATED LYMPHOID TISSUE REVISITED

BALT has been defined classically as an aggregated lymphoid structure separated from the bronchial lumen by a specialized lymphoepithelium. The availability of this relatively organized structure has allowed structural and functional analysis, which has focused in particular on its role in the development of a local immune response to inhaled antigen (Rudzik *et al.*, 1975a). The similarity in structural relationships between BALT and Peyer's patches that have been identified by these studies have given us, by extension, a better understanding of respiratory tract immunity, as was discussed already. Certain differences observed between the two lymphoid structures, often quantitative in nature, have been explained in terms of environmental stimuli associated with gut content. The similarity of structure, however, led to the concept of a common mucosal immune system when the morphological similarities between Peyer's patches and BALT were extended to include the observation that both contained an enriched precursor population of IgA-committed lymphocytes (Rudzik *et al.*, 1975a), that were capable of repopulating mucosal sites of irradiated recipient rabbits. Subsequent studies in sheep (Scicchitano *et al.*, 1984) and rats (van der Brugge-Gamelkoorn *et al.*, 1986) modified the general concept to emphasize a "gut to bronchus" directional flow of activated lymphocytes. Based on these observations, an orally administered, killed, nontypable *Haemophilus influenzae* vaccine was shown to be protective against recurrent episodes of acute bronchitis in carriers of this bacteria with chronic lung disease; the vaccine functioned by reducing the level of bronchial colonization (Clancy *et al.*, 1985, 1989; Lehmann *et al.*, 1991). In an animal model, protection was transferred with primed thoracic duct T cells (Wallace *et al.*, 1989; Lehmann *et al.*, 1991). These observations raise the question of the role played by BALT in localizing gut-derived T and B lymphocytes. Since no afferent lymphatics have been described in BALT, the majority of lymphocytes are likely to reach the bronchial mucosa via binding of specific adhesions to receptors on postcapillary venules with high cuboidal endothelium (Sminia and van der Brugge-Gamelkoorn, 1989), which is the mechanism used by lymphocytes for entry into other lymphoid organs. Adherence *in vitro* by lymphocytes to the HEVs in BALT differs from that in the Peyer's patches, where the majority of adhering cells are B cells (Kieran *et al.*, 1989). The BALT HEVs function more like those of mesenteric lymph nodes (van der Brugge-Gamelkoorn and Kraal, 1985), with equal numbers of T and B lymphocytes adhering. Using peroxidase staining, a selective attachment of B cells bearing  $\mu$  and L chains was described

(Otuski *et al.*, 1989) that is consistent with the pattern of localization of gut-derived IgA-secreting B cells in the sheep respiratory tract, which in form corresponds to the geographic distribution of BALT (Scicchitano *et al.*, 1984).

BALT is likely to play a key role in the localization of both T and B lymphocytes within the bronchial mucosa where, additionally, regulatory T cells (Iwata and Sato, 1991) and a transport epithelium, allowing migration into the bronchial lumen (Bienenstock *et al.*, 1973a,b), are sited conveniently.

Early studies suggesting a regulatory role for BALT (Clancy and Bienenstock, 1974) have been extended by infection and immunization models that have confirmed the narrow antigen dose range that stimulates a local antibody response and a time-frame of T-cell help followed by immune suppression (Iwata and Sato, 1991). Thus, in a rat model of pulmonary infection with *Pseudomonas aeruginosa*, an early dominance of SIgA<sup>+</sup> cells correlated with a predominance of W3/25<sup>+</sup> T cells, which gave way to a dominance of OX8<sup>+</sup> suppressor T cells after 2 weeks, correlating with a decrease in both SIgA<sup>+</sup> cells and inflammatory changes in the lung (Iwata and Sato, 1991). A pro-inflammatory cytokine profile, detected as both RNA expression and cytokine secretion, by T cells cloned from sputum in subjects with chronic bronchial inflammation (G. Pang and R. Clancy, unpublished observations) would indicate that T cells derived from bronchial mucosa that migrate into the bronchial lumen, may play a more prominent role in mucosal defense under circumstances of high dose or chronic antigenic stimulation. A regional distribution of peptidergic nerve fibers within classical BALT, and localization of immunoreactive neuropeptides known to influence lymphocyte physiology in different zones of the BALT (Inoue *et al.*, 1990), suggest important neuroimmunological control mechanisms in the bronchial mucosa. The close connection between BALT and regional lymph nodes, involving efferent lymphatics (van der Brugge-Gamelkoorn *et al.*, 1986), is reflected in the compartmentalized response to bronchial infection that includes both lymphoid structures (Weisz-Carrington *et al.*, 1987). The regional lymph nodes relating to BALT appear to have several important roles. The migratory patterns of lymphocytes in efferent lymphatics are more eclectic than those from mesenteric nodes (Rudzik *et al.*, 1975a; Butler *et al.*, 1982; Spencer and Hall, 1984; Joel and Chanana, 1987; Scicchitano *et al.*, 1988). Clearly, despite the potential of BALT B cells to populate intestinal mucosa (Scicchitano *et al.*, 1988), respiratory tract immunization has little influence on the intestinal immune response (Scicchitano *et al.*, 1984; Bice and Shopp, 1988). The regional node, however, has an important role in establishing a generalized immune response within the lung (Scicchitano *et al.*, 1984) as well as systemic sensitization (Butler *et al.*, 1982; Kattreider *et al.*, 1987; Muggenburg *et al.*, 1987). A second role relates to the generation of an immune response to inhaled antigen. Macrophage-associated antigen transported from the lumen requires cytokine activation for T-cell presentation (Thomas *et al.*, 1974), which occurs within regional nodes. Down-regulation of IgE- and T cell-dependent hyposensitization after inhalation of allergens involves the generation of a suppressor T-cell population in regional nodes of the upper respiratory tract (Holt *et al.*,

**Figure 3** (A) Lymphoid follicle (BALT) protruding into the lumen of a bronchiole from a child with undetermined recurrent pneumonic episodes. (B) High power view of the classic lymphoepithelium. Reprinted with permission from Meuwissen and Hussain (1982).

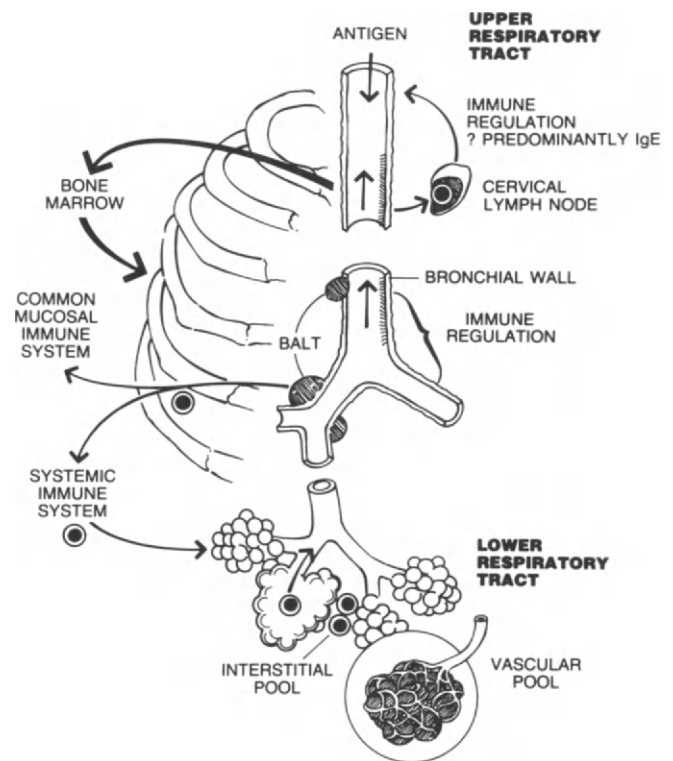

1981). The detection of T-cell populations in Peyer's patches that are capable of mediating down-regulation (Clancy and Pucci, 1978; Kiyono *et al.*, 1980), and the switch toward a T-suppressor phenotype (Iwata and Sato, 1991) in chronic infection in the lung, indicates a regulatory role for BALT, but the relative contribution of BALT compared with the regional lymph node is not clear.

Much of the discussion in this chapter is based on studies involving a variety of species, including humans, that vary considerably in their expression of organized BALT in a physiological state. Several general observations can be made. First, no major differences in mucosal handling of antigen, nor in the development of a local immune response nor participation in a gut-driven common mucosal immune system, are noted among those species in which bronchial lymphoid tissue predominantly occurs in organized BALT and those in which the bronchial lymphoid tissue has less structure. Second, most, if not all, species (including humans) can develop classical BALT structures including a lympho-epithelium under conditions of increased antigen load. In those species with small amounts of BALT, under normal conditions, an adaptive immune function would focus the elements of an immune response into an efficient mechanism for the induction, capture, and delivery of a local mucosal immune response, as well as its control and integration within a broader defense network of lymphoid structures. Third, study of aggregated BALT and cells obtained essentially from these aggregates have given much insight into mechanisms of mucosal defense, both within the bronchopulmonary system and within mucosal tissues in general.

The presence of additional antigen-handling mechanisms within the bronchial mucosa that involve dendritic cells and epithelial cells, and the presence of T- and B-cell effector and regulatory lymphocytes within the bronchial mucosa, however, requires a dissection of the various components of mucosal immunity to determine the degree to which BALT in its classical form encompasses all these functions in one efficient unit. Further, the interdependence of various "pools" of lymphocytes within the lungs (Figure 4), and their functional interaction in health and disease, must be studied carefully. Perhaps particular insight into these interactions could come from careful analysis of cell traffic through the often forgotten regional lymph node, which not only represents a crossroad for lymphocyte traffic but appears to be central to the generation of mucosa-related immune responses, the up- and down-regulation of immune pathways, and the expansion of lung-specific immunity.

**Figure 4** Schematic drawing of the elements of the lung lymphoid tissue. An immune regulation loop involves cervical lymph nodes, particularly relevant to the down regulation of IgE (Holt *et al.*, 1981). The immune regulation loop involving mucosal T lymphocytes is particularly relevant to the inhibition of T cell proliferation (Pucci *et al.*, 1982). The bronchus associated lymphoid tissue (BALT) is a mechanism for effectively generating both T and B lymphocyte immunity in response to luminal antigen, both locally and at distinct mucosal sites. The role of the mesenteric regional lymph node appears crucial to the expansion of mucosa-associated immunity. The exact role of the bronchial and mediastinal nodes is less clear. The interstitial lymphocyte pool is modified in function from that of the circulating blood pool and is at least as large as the latter. Its role within the lung, and its relationship to other "pulmonary lymphocyte" pools, is undefined (Pabst, 1990). The vascular lymphocyte pool has been identified on the basis of cell sequestration studies. Whether this pool represents more than differential cell sequestration or has an important modulatory effect on cell traffic within other lymphocyte pools is not known (Pabst, 1990). The broncho-alveolar cell pool contains 5–10% lymphocytes, whose functions probably involve immunoregulating activities that range from afferent to efferent limbs of the inflammatory response.

# Mucosal Immune Function in Asthma

A. E. Redington • D. B. Jones • S. T. Holgate

The pathogenesis of the asthmatic state represents a complex disease process that involves mast cells, eosinophils, neutrophils, basophils, macrophages, platelets, and T cells in a complex series of cross-interactions, with the participation of a cascade of cytokines, complement factors, and other inflammatory mediators.

The understanding of the cellular interactions in the mucosal compartment of human lung is central to our understanding of the development of the asthmatic process. Studies of immune interactions in the pathological lung must be seen against the background of immune function in normal tissue. Largely for technical reasons, our understanding of the mucosal immune process has lagged behind that of the peripheral immune system. Clearly, however, with respect specifically to the mucosal compartment, the T cell is the major orchestrator of immune function and also represents the cellular component that exhibits antigenic specificity. In this chapter, we initially describe features of the T-cell populations that are characteristic of mucosal sites and subsequently describe changes in these populations and the various cellular interactions that are known to occur after the development of the asthmatic condition.

## I. MUCOSAL T LYMPHOCYTE POPULATIONS

In the literature, investigations of the T-cell component of the mucosal compartment of the gut appear to have proceeded at a faster rate than those relating to lung mucosa. However, based on the rapidly expanding lung literature, clearly general statements can be made that are relevant to both sites. We have adopted this approach to our discussion of mucosal T cells.

### A. T-Cell Development

T lymphocytes undergo maturation within the cortical area of the human thymus, which they enter as committed T-lymphocyte precursors (Janossy *et al.*, 1981). During their passage through the thymus, two important events occur. First, shuffling of genes encoding various components of the T-cell receptors allows the random development of the T-cell repertoire. Second, individual T cells that express self (host)-directed specificity are deleted or inactivated.

The majority of T cells present in the peripheral compartment of the lymphoid system express a surface receptor composed of  $\alpha$  and  $\beta$  polypeptides that are bonded covalently. A minority population expresses a receptor composed of  $\gamma/\delta$  polypeptide chains that may or may not show disulfide linkage. The significance of this population in relation to mucosal sites will be discussed subsequently. In addition to the expression of antigen-specific receptor molecules, the maturation of T cells involves the production of the CD3 molecular complex and its association with the T-cell receptor, as well as the expression of membrane CD4 or CD8 glycoproteins. These molecules, which are members of the immunoglobulin gene superfamily, dictate aspects of antigen recognition by T cells and, in conjunction with CD3, form the basis of early studies of T-lymphocyte subset function.

### B. T-Lymphocyte Subset Markers in Relation to Antigen Experience

Exposure of T cells to antigen is accompanied by changes in the molecular species of CD45 expressed on their surface. CD45, formerly known as leukosialin or leukocyte common antigen, has a short intracellular tail and an extended, heavily glycosylated, extracellular portion that varies in length (Akbar *et al.*, 1988). Changes in CD45 isoforms, which can be expressed variably on different leukocyte subtypes, are achieved largely by alternative splicing but also, as more recent comparisons of human and neonatal T cells have shown, by changes in the rate of turnover of the different subspecies of the molecule (Yamada *et al.*, 1992). Within T cells, the most significant isoform change is from CD45RA to CD45RO, demonstrating the switch from immunological immaturity to immunological experience. The CD45RO population contains the bulk of T cells reactive to recall antigens (Akbar *et al.*, 1988). The CD45RA-CD45RO switch is accompanied by a change in the cytokine profile secreted by the cells on activation (Ferrer *et al.*, 1992).

In mice, CD4<sup>+</sup> T cells are known to be subdivided into two categories, Th1 and Th2, which differ in their capacity to secrete cytokines and also in the efficiency with which they can support delayed type hypersensitivity (Th1) or IgE synthesis (Th2). Experimental studies of these two CD4<sup>+</sup> subsets suggest that the functional differences shown may be significant in the pathogenesis of the asthmatic state (Frew and Kay, 1991; Robinson *et al.*, 1992). Currently, CD45RA

and CD45R0 human T-cell subsets have not been definitively characterized as direct human correlates to murine Th1 and Th2 T cells. Nevertheless, studies of cytokine mRNA production suggest that human T-cell populations containing a high proportion of CD45R0<sup>+</sup> lymphocytes show cytokine secretion patterns that closely resemble those of the murine Th2 subpopulation (Ferrer *et al.*, 1992).

### C. Phenotype of the Intraepithelial T-Lymphocyte Population

The intraepithelial lymphocyte (IEL) population of the human intestine has been investigated extensively; numerous reviews on this topic exist. Both phenotypic and functional investigations of IELs demonstrate selective recruitment of functionally distinct T-lymphocyte subsets (Selby *et al.*, 1981; Harvey and Jones, 1991). In the human intestine, the majority of CD3<sup>+</sup> IELs strongly express CD7, a 40-kDa antigen that has been considered to represent an activation marker (Spencer *et al.*, 1989a). Between 70 and 90% of small intestinal IELs are CD8<sup>+</sup>, although CD8 dominance is less marked in the colon (Trejdosiewicz *et al.*, 1987). A large proportion of intestinal IELs is positive for CD45R0, demonstrating selective recruitment of an antigen-experienced population, and also expresses the antigen recognized by the monoclonal antibody HML1. The molecule identified by HML1 is claimed to be associated intimately with recruitment of lymphocytes into mucosal surfaces (Cerf-Bensussan *et al.*, 1987; Schieferdecker *et al.*, 1990). IELs also show positivity for the  $\beta_1$  integrin VLA-4 (Choy *et al.*, 1990). IELs would, therefore, appear to be well adapted to cell-stroma and cell-cell interactions. Functional studies of intestinal IELs show widely varying results among and within species (Bland and Warren, 1986; Mayer and Shlien, 1987). These differences presumably relate to some genuine interspecies variation but also reflect difficulties inherent in the extraction of IELs from tissue biopsies, as well as wide variation in the experimental design of the functional studies performed. To date, the immunological consensus would appear to be that CD3<sup>+</sup> IELs are, at least in part, responsible for the regulation of oral tolerance in humans. Beneath the intestinal mucosal compartment lies the lamina propria, which contains a much more complex cell mixture in which CD4<sup>+</sup> T cells are more common, as are B lymphocytes, plasma cells, basophils, mast cells, and eosinophils (reviewed by Harvey and Jones, 1991).

In comparison with studies of the human intestine or investigations conducted on bronchoalveolar lavage fluid, immunophenotypic analysis of lymphocyte populations present within human lung tissue of normal histology are infrequent (Azzawi *et al.*, 1990). From the studies that do exist, based either on tissue removed from resection specimens or on biopsies obtained during bronchoscopy, the following general statements can be made. T cells are relatively abundant both in the lung parenchyma and within the epithelial lining of the bronchial wall (Azzawi *et al.*, 1990). Unlike the human intestine, CD8<sup>+</sup> cells are not present in great excess. At least with respect to parenchymal tissue, this absence may reflect dilution by circulating peripheral blood. HML1 is expressed

widely on lung T cells (Cerf-Bensussan *et al.*, 1987); up to 80% of bronchial wall T lymphocytes are CD45R0<sup>+</sup>. As in the human intestine, CD7 is expressed strongly and, at least in histologically normal tissue, CD25 [the interleukin 2 (IL-2) receptor] is shown very infrequently on CD3<sup>+</sup> T cells. From these data, the mucosal compartments of histologically normal human lung and intestine could be considered to contain phenotypically equivalent IEL populations.

### D. T-Cell Receptor Gene Expression in Intraepithelial Lymphocytes

In mice and birds,  $\gamma/\delta$  T-cell receptor-carrying lymphocytes appear to predominate at all mucosal surfaces. These cells have been considered to have a specialized function in the immune surveillance of epithelia (Janeway, 1988). In humans, however,  $\alpha/\beta$ -expressing T lymphocytes represent the predominant mucosal T-cell population in gut (Brandtzaeg *et al.*, 1989; Trejdosiewicz *et al.*, 1989) and in lung (Augustin *et al.*, 1989).  $\gamma/\delta$  Receptors exist in biochemically distinct forms. In the intestine,  $\gamma/\delta$ -positive cells appear to carry the nondisulfide linked heterodimer (Spencer *et al.*, 1989b), in contrast to peripheral blood, suggesting that the small population of  $\gamma/\delta$  positive cells present in humans may have some specialized function.  $\gamma/\delta$ -Positive T cells have been claimed to represent an early form of immune surveillance of epithelial surfaces (Janeway, 1988), based on their appearance early in ontogeny, the demonstration in nude mice that their development may occur independently of thymic influences, and their claimed restricted gene repertoire. Note, however, that a high level of junctional diversity could produce a much higher level of receptor variability than is apparent from the numbers of coding genes.

In contrast to the  $\gamma/\delta$  T-cell receptor, the genomic information encoding the  $\alpha/\beta$  receptor encompasses a large number of V $\beta$  genes. These genes have been placed into 24 subfamilies based on the presence of 75% homology between individual genes at the sequence level (Robinson, 1991). Monoclonal antibodies have been produced that identify a proportion of these V $\beta$  gene families. Although our data are preliminary, by comparison with the peripheral lymphoid system, the V $\beta_6$  and V $\beta_8$  subfamilies appear to be overrepresented in the lung (S. Berry, S. T. Holgate, and D. B. Jones, unpublished observations). Should this prove to be true, preferential usage of individual V gene segments may occur at mucosal sites in addition to preferential selection of T cells with specialized function and phenotype.

### E. Macrophages and Accessory Cells

Macrophages and dendritic cells show much greater phenotypic heterogeneity than lymphocytes. Surface markers vary during maturation, and this plasticity is compounded by the effects of macrophage-mediator and macrophage-cell interactions in tissue sites. The intestinal mucosa contains a population of cells resembling interdigitating reticulum cells that may have a role in the sampling of incoming antigen (Tseng, 1984; Mahida *et al.*, 1989; Harvey *et al.*, 1990). Scav-

enging macrophages are described also that differ in phenotype. Many of these show up-regulation of a range of surface receptors, suggesting an activated state (Selby *et al.*, 1983; Trejdosiewicz *et al.*, 1987). Within the lung, populations can be identified that have the characteristics of antigen-presenting (dendritic) cells as well as phagocytes with varying phenotypes (Spiteri and Poulter, 1991). The precise interaction of these cell populations, in terms of allergen presentation, antigen and cell clearance, and production of inflammatory mediators, and their overall contribution toward the asthmatic process have yet to be determined.

### F. Synthesis

The preceding data clearly demonstrate that unique populations of lymphocytes are recruited selectively to mucosa-associated lymphoid tissue. Also clearly, from the pathological picture seen in asthma, these cells operate in conjunction with a range of inflammatory cells types. In addition, complex mediator interactions occur during the development of lung pathology. In the following sections, we discuss a variety of different cell types and their actions in terms of mediator production and response in the context of asthmatic disease.

## II. IMMUNOLOGICAL MECHANISMS IN ASTHMA

Until recently, asthma was viewed primarily in terms of contraction of bronchial smooth muscle; relatively little attention was paid to the underlying processes responsible. Attempts to define asthma focused on disordered airway function rather than on pathological abnormalities. However, although bronchoconstriction is undeniably important, the causes of airway narrowing are multiple and include, in addition, airway wall edema and hypersecretion of mucus. Another feature characteristic of asthma is nonspecific bronchial hyperresponsiveness, the ability of the airways to respond to a wide variety of stimuli in an exaggerated manner. Using modern techniques, real progress is now being made in unraveling the complex and interrelated events that can explain these disparate features.

Increasing clinical and pathological evidence points to airway inflammation as a basic underlying abnormality. For over a century, scientists have known that the airways of patients with asthma are inflamed. Early postmortem studies on the lungs of patients who died of asthma (Dunnill, 1960; Dunnill *et al.*, 1969) demonstrated extensive inflammation of the airway wall, characterized by infiltration of the tissue with eosinophils and mononuclear cells, extensive loss of the bronchial epithelium, hyperplasia of mucus-secreting cells, hypertrophy of bronchial smooth muscle, and the presence of an exudate within the lumen containing mucus and cellular debris. Asthma also frequently is associated with atopy—the genetic predisposition to produce IgE in response to common environmental allergens—suggesting an association between asthma and immediate hypersensitivity. Finally, drugs with the predominant action of suppressing inflammatory re-

sponses, for example, corticosteroids, sodium cromoglycate, and cyclosporin, are all effective in the treatment of asthma.

Considering these lines of evidence together builds a strong case for implicating inflammatory responses in the disordered airway function of asthma. Until recently, testing this hypothesis directly has not been possible; however, the advent of fiber-optic bronchoscopy has provided an opportunity to obtain bronchoalveolar lavage fluid and mucosal biopsy specimens from patients with asthma, thereby enabling a detailed characterization of the inflammatory response. This approach has been applied both in day-to-day asthma and following bronchial provocation with specific allergen, which results in both early and late phases of airway constriction as well as in an acquired increase in bronchial responsiveness.

Using these techniques, a number of specific cells and mediators stand out as particularly important. These cells and mediators are considered in more detail.

### A. Mast Cells

Mast cells play a central role in allergic reactions involving immediate or type I hypersensitivity responses; asthma is no exception. Good evidence exists that mediators released on activation of mast cells are responsible for the early bronchoconstrictor response provoked by inhaled allergen. These mediators include histamine, prostaglandin (PG) D<sub>2</sub> and its metabolite 9 $\alpha$ ,11 $\beta$ -PGF<sub>2</sub>, and the sulfidopeptide leukotrienes (LTs) C<sub>4</sub>, D<sub>4</sub>, and E<sub>4</sub>. All these molecules are powerful contractile agonists of bronchial smooth muscle and, in addition, are vasodilators and increase microvascular permeability.

Mast cells are found throughout the airway wall, particularly beneath the bronchial epithelium and surrounding the airway smooth muscle. Most of these cells contain tryptase as their only neutral protease, in contrast to mast cells from skin and other connective tissue sites which contain both tryptase and chymase. Although the total number of mast cells does not differ greatly between patients with mild-to-moderate asthma and normal subjects, increased activation of these cells is believed to occur in asthma.

Several lines of evidence support the view that mast cell activation occurs in asthma. First, transmission electron microscopy (Figure 1) demonstrates ultrastructural evidence of mast cell degranulation, with loss of electron density of the characteristic scroll-containing granules and the formation of secretory channels (Beasley *et al.*, 1989a). Second, mast cell-derived mediators such as histamine (Casale *et al.*, 1987), tryptase (Wenzel *et al.*, 1988), and LTC<sub>4</sub> (Lam *et al.*, 1988) are found in increased quantities in lavage from asthmatics compared with normal controls. Finally, bronchial provocation of the airway, either by inhalation challenge or by introduction of the allergen directly onto the airway surface via a bronchoscope, results in an early bronchoconstrictor response accompanied by the release of mast cell-derived mediators including histamine, tryptase, PGD<sub>2</sub>, and leukotrienes (Murray *et al.*, 1986; Wenzel *et al.*, 1988; Miadonna *et al.*, 1990).

Pharmacological manipulation also supports a role for mast cells in mediating the early bronchoconstrictor response. This

**Figure 1** Electron micrograph of a mast cell showing evidence of extensive degranulation.

response can be inhibited effectively by drugs known to inhibit mast cell function, for example, sodium cromoglycate (Atkins *et al.*, 1978), and can be attenuated markedly by mediator antagonists, specifically those directed against histamine H1 (Rafferty *et al.*, 1987), prostanoid TP (Beasley *et al.*, 1989), and leukotriene (Taylor *et al.*, 1991) receptors.  $\beta$ 2 Adrenoceptor agonists such as salbutamol are also powerful inhibitors of the immediate reaction (Cockcroft and Murdock, 1987), probably by a combination of a direct action on bronchial smooth muscle and inhibition of mast cell mediator release. The ability of histamine H1 antagonists (Rafferty *et al.*, 1990) and leukotriene antagonists (Hui and Barnes, 1991) to produce a degree of bronchodilation in symptomatic asthma suggests that mast cell products contribute to airflow obstruction even in the absence of specific antigen challenge.

In addition to the traditional mediators just discussed, evidence indicates that mast cells are also a source of a number of cytokines. Initial work showed that activated murine mast cells generate a wide range of cytokines including IL-1, IL-3, IL-4, IL-5, IL-6, and GM-CSF (Burd *et al.*, 1989; Plaut *et al.*, 1989; Wodnar-Filipowicz *et al.*, 1989). These findings have now been in part extended to human lung mast cells which have been shown to produce TNF $\alpha$  (Ohkawara *et al.*, 1992) and IL-4 (Bradding *et al.*, 1992). The potential implications of these molecules in the inflammatory processes of asthma is currently under investigation but the likelihood is that the role of the mast cell is more far-reaching than has recently been supposed.

Finally, mast cells probably play an important role in exercise-induced asthma (McFadden, 1987). In this case, the immediate stimulus for mast cell activation is believed to be provided by local hypertonicity resulting from water loss from the airway surface. Therefore, not surprisingly drugs such as histamine H1 antagonists (Finnerty and Holgate, 1990) and leukotriene antagonists (Manning *et al.*, 1990) are able to attenuate the bronchoconstrictor response when administered prior to exercise. Sodium cromoglycate, nedocromil sodium, and  $\beta$  agonists are also effective inhibitors of exercise-induced asthma, consistent with their known inhibitory effects on mast cells. Reflex bronchoconstriction

produced by cooling of the airway by inspired air also may contribute to exercise-induced asthma.

## B. Eosinophils

At one time, the eosinophil was believed to be a protective cell in allergic responses but now the opposite is known to be true. The frequent association of asthma with peripheral blood and sputum eosinophilia, the extensive infiltration of eosinophils into the airways of patients dying of acute severe asthma, and the demonstration of the release of eosinophil-derived pro-inflammatory mediators all point to a central role for this cell in contributing to the inflammatory response characteristic of asthma.

Recruitment of eosinophils from the circulation entails a series of separate processes. Initial adherence to endothelium is followed by transendothelial migration and chemotaxis toward the site of inflammation. The process by which eosinophils are slowed down and eventually arrested against the endothelium as they traverse postcapillary venules is dependent on the induction or up-regulation of specific adhesion molecules by activated endothelial cells. These molecules are E-selectin (formerly known as endothelial leukocyte adhesion molecule 1 or ELAM-1; Bevilacqua *et al.*, 1989), which interacts with a carbohydrate ligand known as sialyl Lewis X that is expressed on eosinophils and neutrophils; intercellular adhesion molecule 1 (ICAM-1; Pober *et al.*, 1986), which interacts with molecules of the integrin family, LFA-1 and Mac-1, again expressed on both types of leukocyte; and, finally, vascular cell adhesion molecule (VCAM-1; Bochner *et al.*, 1991), a member of the immunoglobulin superfamily, the ligand of which on the eosinophil is the  $\beta$ 1 integrin VLA-4, which has been shown to be more specific to eosinophil recruitment. Endobronchial provocation of the airways of atopic asthmatics with allergen results in the increased expression of E-selectin and ICAM-1 (evident at 5–6 hr; S. Montefort, unpublished observations) and VCAM-1 (apparent at 24 hr postchallenge; Bentley *et al.*, 1992). Transendothelial migration of leukocytes also is believed to be dependent on interactions with adhesion molecules including ICAM-1 (Smith, 1988).

Within the perivascular space, eosinophils are capable of responding to a variety of chemoattractant factors including C5a, LTB $_4$ , platelet activating factor (PAF), and IL-5. Two factors that have generated interest as potent chemoattractant stimuli for eosinophils are IL-2 (Rand *et al.*, 1991a) and lymphocyte chemoattractant factor (LCF; Rand *et al.*, 1991b). LCF is a 14-kDa highly cationic protein that is thought to be released by activated CD8 $^+$  lymphocytes. This glycoprotein interacts with eosinophils at extremely low concentrations ( $10^{-11}$ – $10^{-12}M$ ) in a process involving CD4, which is expressed on eosinophils as well as on T lymphocytes. An additional finding is that allergen itself can provide a chemotactic stimulus for eosinophils via an interaction with IgE bound to low-affinity cell-surface IgE receptors.

To survive in the airways, eosinophils require the presence of certain cytokines and growth factors. IL-3, granulocyte-macrophage colony stimulating factor (GM-CSF), and

IL-5 all can maintain eosinophils in a viable state in culture (Tai *et al.*, 1991) and are known to be generated within the airway wall in asthma. T lymphocytes probably provide the majority of the IL-5, whereas GM-CSF is likely to be derived additionally from both the monocyte–macrophage population and the bronchial epithelium. Stimulated fibroblasts also can produce GM-CSF (Kaushansky *et al.*, 1988). Eosinophil survival *in vitro* is prolonged by coculture with fibroblasts, an effect mediated by GM-CSF (Owen *et al.*, 1987). This result may be important in light of the population of myofibroblasts beneath the bronchial epithelium.

The mechanisms by which eosinophils become activated are not understood completely. However, these cells appear to possess at least two types of IgE binding site on their surface—low-affinity Fc $\epsilon$ R2 receptors and the carbohydrate binding protein MAC-2 described previously on macrophages (Cherayil *et al.*, 1989)—as well as Fc $\gamma$ R2 receptors for IgG, receptors for IgA, and receptors for certain components of the complement cascade. Different receptors have been shown to be able to mediate the release of different mediators (Tomassini *et al.*, 1991). Further, IL-3 (Rothenberg *et al.*, 1988), IL-5 (Lopez *et al.*, 1988), and GM-CSF (Owen *et al.*, 1987) all can increase the functional activation status of eosinophils.

Once activated, eosinophils represent a potent source of pro-inflammatory mediators (Figure 2), including oxygen radicals, lipids such as LTC<sub>4</sub>, 15-HETE and PAF, and the arginine-rich proteins of the eosinophil granule: major basic protein (MBP), eosinophil cationic protein (ECP), eosinophil-derived neurotoxin (EDN), and eosinophil peroxidase (EPO). These proteins are directly toxic to airway epithelial cells, but an additional source of damage to the epithelium may result from a cognate interaction between eosinophils and epithelial cells, resulting in the induction of epithelial cell-derived proteases (Herbert *et al.*, 1991).

Finally, evidence suggests that eosinophils are an important source of cytokines, in particular IL-3 (Kita *et al.*, 1991), GM-CSF (Kita *et al.*, 1991; Moqbel *et al.*, 1991), IL-5 (Desreumaux *et al.*, 1992), IL-6 (Hamid *et al.*, 1992), transforming growth factor (TGF) $\alpha$  (Wong *et al.*, 1990), and TGF $\beta$

(Ohno *et al.*, 1992; Wong *et al.*, 1991). These cytokines may, in some cases, have important autocrine effects, but also would amplify and prolong the inflammatory response and perhaps contribute to airway fibrosis.

### C. Neutrophils

Traditionally, neutrophils have not been associated with the inflammatory response of asthma, although some evidence implicates them in both occupational asthma (Fabbri *et al.*, 1987) and the late-phase response of allergic asthma (Metzger *et al.*, 1987).

As with eosinophils, their initial recruitment involves the increased expression of endothelial adhesion molecules, including E-selectin and ICAM-1 (Kyan-Aung *et al.*, 1991), and they are influenced by a number of chemotactic factors such as C5a, LTB<sub>4</sub>, PAF, and IL-8. Some of these factors—including C5a, LTB<sub>4</sub>, and PAF—also have the capacity to prime neutrophils for enhanced mediator release. A number of other neutrophil chemotactic activities have been recognized in the serum and lavage fluid of patients with asthma. The molecular identity of these activities will, no doubt, be discovered, as was the newly described monocyte-derived neutrophil-activating peptide 2 (NAP-2) (Walz *et al.*, 1989). Activated neutrophils are capable of generating a number of mediators that might be relevant to the pathogenesis of asthma, including oxygen radicals, LTB<sub>4</sub>, and various granule-derived enzymes such as myeloperoxidase.

Currently, however, the possible importance of neutrophils and of novel mediators such as IL-8 and NAP-2 in asthma remains unclear.

### D. Basophils

Basophils once were considered to be circulating precursors of mast cells, but recently more emphasis has been placed on the differences between these two cells (Henderson, 1990). Like mast cells, however, basophils possess high-affinity IgE receptors and can be activated directly by allergen. Several “histamine releasing factors” also have been described, including NAP-2 (Kaplan *et al.*, 1991) and monocyte chemotactic activating factor (MCAF) (Kuna *et al.*, 1992). Once activated, basophils are capable of releasing a range of inflammatory mediators including histamine, LTB<sub>4</sub>, LTC<sub>4</sub> (but not PGD<sub>2</sub>), as well as various proteases.

A late increase in basophils has been demonstrated in bronchoalveolar lavage fluid after direct allergen challenge via the bronchoscope (Liu *et al.*, 1991). Evidence also exists from the upper airway to implicate basophils in the late-phase response (Bascom *et al.*, 1988). However, the true importance of this potential pro-inflammatory cell in asthma is unknown.

### E. T Lymphocytes

An important advance has been our increasing knowledge about the role of T lymphocytes in initiating and prolonging the inflammatory response in asthmatic airways.

Figure 2 Mediators released by activated eosinophils.

Evidence for the involvement of T lymphocytes in asthma derives from a number of sources. Increased numbers of T lymphocytes expressing activation markers (IL-2R VLA-1 and HLA-DR) (Corrigan *et al.*, 1988) and elevated levels of T-lymphocyte-derived cytokines (Corrigan and Kay, 1990) have been described in the blood of patients with acute severe asthma. Markers of T-lymphocyte activation also have been shown to be increased in bronchoalveolar lavage fluid (Matoli *et al.*, 1991) and in bronchial biopsies (Azzawi *et al.*, 1990) from asthmatics.

Dendritic cells of macrophage lineage are present in large numbers within the bronchial epithelium (Holt *et al.*, 1990) and are responsible for processing antigen and presenting it to T lymphocytes in association with Class II major histocompatibility complex (MHC) determinants. This process may take place locally in the bronchial epithelium, but a more important site is probably local lymphoid tissue after migration of the dendritic cells to that location. Once activated, antigen-specific T lymphocytes undergo selective clonal expansion and proliferation.

In response to allergen challenge, CD4<sup>+</sup> T lymphocytes are recruited from the circulation over a period of 1–12 hr, a process again involving the up-regulation of endothelial adhesion molecules such as VCAM-1 and their interaction with cell-surface ligands. As discussed in the previous section, two types of CD4<sup>+</sup> T lymphocytes have been described in the mouse that differ in their pattern of cytokine secretion (Mosmann and Coffman, 1989). Comparable subsets are believed to exist in humans, and the Th2 subset is believed to be important in asthma. These cells express (in addition to IL-3 and GM-CSF) IL-4, IL-5, IL-6, and IL-10, cytokines that are important for regulation of IgE synthesis by B lymphocytes; for mast cell growth and differentiation; for eosinophil recruitment, survival, and activation; and, in the case of IL-10 (Fiorentino *et al.*, 1989), for inhibition of production of the Th1 subset cytokines, namely IL-2, interferon (IFN) $\gamma$ , and lymphotoxin (LT). Th1 lymphocytes are believed to be involved in delayed type hypersensitivity, so a reciprocal relationship would appear to exist between this type of immune response and allergic inflammation.

### F. Monocytes and Macrophages

Human airway macrophages are derived from circulating monocytes and normally are resident throughout the respiratory tract, both in the lumen and in the airway wall.

The ability of these cells to act as antigen-presenting cells is limited in comparison to that of dendritic cells and their main role in asthma seems to be as primary mediator-secreting cells after activation via their low-affinity IgE receptors. Increased release of macrophage products has indeed been demonstrated in bronchoalveolar lavage fluid from asthmatics after allergen challenge (Tonnel *et al.*, 1983). Increased numbers of macrophages also have been reported in bronchial biopsies from asthmatics (Poston *et al.*, 1992).

Activated macrophages are capable of generating numerous inflammatory mediators including oxygen radicals, leukotrienes, and PAF, as well as many enzymes such as  $\beta$ -

glucuronidase. However, the relative importance of these molecules in comparison with mediators derived from other inflammatory cells is unclear. In addition, macrophages are a potential source of cytokines—both pro-inflammatory, such as IL-1 and TNF $\alpha$ , and fibrogenic, including platelet-derived growth factor (PDGF) and TGF $\beta$ .

Macrophages also may play a part in terminating the inflammatory response in a process known as apoptosis (Cohen, 1991). Aging neutrophils and eosinophils express specific cell-surface markers that are recognized by macrophages. This process is not well understood but appears to involve the macrophage vitronectin receptor and, perhaps, recognition of membrane phosphatidylserine. These granulocytes are phagocytosed and degraded. It is possible to speculate that in asthma, a defect in leukocyte removal may contribute to the disease state.

### G. Platelets and Platelet Activating Factor

During the 1980s, researchers suggested that platelets might have an important pro-inflammatory action in asthma via the production of PAF (Morley *et al.*, 1984). Inhalation of PAF by normal volunteers was reported to be capable of inducing not only acute bronchoconstriction but also a prolonged increase in bronchial responsiveness (Cuss *et al.*, 1986). Other studies, however, have been unable to confirm this result (Lai *et al.*, 1990). More recently, the PAF antagonist WEB 2086 failed to attenuate late-phase bronchoconstriction (Wilkins *et al.*, 1991) and also failed to demonstrate any evidence of therapeutic benefit (Johnston *et al.*, 1992). Despite its undoubted relevant biological actions, PAF now seems unlikely to play a central role in the inflammatory response of asthma.

### H. Bronchial Epithelium

The bronchial epithelium is a major target for the inflammatory response of asthma. Many studies indicate that the bronchial epithelium in asthma is either disrupted or completely absent (Dunnill, 1960; Beasley *et al.*, 1989a; Jeffery *et al.*, 1989).

Under normal circumstances, the integrity of the epithelium is maintained by a variety of adhesive mechanisms (S. Montefort, J. Baker, W. R. Roche, and S. T. Holgate, in press). Tight junctions connect the suprabasal cells distally to form a selectively permeable barrier. Below these connections are intermediate junctions which contain adhesion molecules of the cadherin family, the most important of which is L-CAM or uvomorulin, connected intracellularly to actin filaments. Desmosomes connected the suprabasal cells to each other and to the basal cells. These junctions contain cadherin-like desmosomal glycoproteins or desmogleins linked to an intracellular plaque, made up of at least three desmosomal proteins or desmoplakins, which is itself attached to intracellular intermediate filaments composed of keratin. Finally, hemidesmosomes connect the basal epithelial cells to the basement membrane and contain the integrin  $\alpha_6\beta_4$ .

As discussed previously, the highly cationic proteins of the eosinophil granule are directly toxic to airway epithelial cells. However, a more subtle damaging effect might arise from an interaction between eosinophil and epithelial cells resulting in the induction of epithelial cell-derived proteases (Herbert *et al.*, 1991) such as collagenase, gelatinase, and stromelysin. These enzymes would have the capacity to break the desmosomal links, thereby releasing suprabasal cells from their attachment; indeed, such isolated clumps of suprabasal cells have been observed in bronchoalveolar lavage fluid from asthmatics (Montefort *et al.*, 1992).

The net result of this disruption is impairment of the ability of the epithelium to maintain homeostasis with respect to permeability. Using  $^{99m}\text{Tc}$ -labeled DTPA clearance, increased epithelial permeability has been demonstrated both in stable asthmatics (Ilowite *et al.*, 1989) and during acute attacks (Urzua *et al.*, 1992). Clearly, this event will expose the airway to a range of environmental insults including viral infections and hyperosmolar stimuli provided by exercise.

Myofibroblast proliferation has been demonstrated beneath the epithelium in asthmatic airways (Brewster *et al.*, 1990). These cells may be important in prolonging the survival of both mast cells and eosinophils, thereby maintaining the chronicity of the response, and are also believed responsible for the deposition of collagen types III and V and fibronectin immediately below the basement membrane (Roche *et al.*, 1989; Figure 3). In longstanding poorly controlled asthma, this subepithelial fibrosis could contribute to the development of fixed airways obstruction.

### I. Smooth Muscle

Although recent attention has focused on underlying pathogenic mechanisms, contraction of airway smooth muscle still is of critical importance in producing airway obstruction, both during the early phase and, to a lesser extent, during the late-phase response.

Bronchial smooth muscle is clearly under autonomic control, allowing manipulation by bronchodilator drugs such as  $\beta$ -agonists and anticholinergics. However, this muscle is also under the influence of certain cytokines and growth factors. The actions of PDGF and TGF $\beta$  might account for the smooth muscle hypertrophy and hyperplasia that characterize persistent asthma. TNF $\alpha$  and IL-8 have been shown to be able to up-regulate the expression of substance P and muscarinic M3 receptors on airway smooth muscle, possibly contributing to the pathogenesis of bronchial hyperresponsiveness. A number of other mediators, including tryptase (Sekizawa *et al.*, 1989), also can increase airway smooth muscle responsiveness by a mechanism not currently understood.

### J. Airway Nerves

Sensory nerve endings in the airway have been determined to contain many neuropeptides with important biological effects. These peptides can be released by the spread of nerve impulses antidromically along the nerve plexus in the airway wall, so these nonmyelinated C-fibers can cause neurogenic

**Figure 3** Electron micrograph showing subepithelial collagen deposition.

inflammation (Barnes, 1991). For example, calcitonin gene-related peptide (CGRP) and the related tachykinins substance P and neurokinin A (NKA) are all bronchoconstrictors. In addition, these molecules have actions on the microvasculature; CGRP is a particularly potent and long-lasting vasodilator whereas substance P and NKA increase microvascular permeability. Substance P is also a potent stimulus to mucus secretion and can activate inflammatory cells.

Direct evidence for the involvement of neurogenic inflammation in asthma has been obtained only recently. After allergen challenge, for example, the airway response to inhaled bradykinin, which mediates its effects through stimulation of C-fibers, is increased by several orders of magnitude in comparison with the 2- to 3-fold enhancement observed for methacholine (DjuKanovic *et al.*, 1992), suggesting that, in response to allergen challenge, a change occurs in the sensitivity of the afferent nerves so they respond to lower concentrations of bradykinin.

Nerve growth factors released by T lymphocytes or other inflammatory cells could lead to proliferation of neuropeptide-containing nerves, which might explain why a component of bronchial hyperresponsiveness in chronic asthma appears to be relatively resistant to resolution by

**Figure 4** Network of cellular interactions occurring in allergic inflammation.

corticosteroids (Lundgren *et al.*, 1988). However, currently our understanding of the importance of neuropeptides and neurogenic inflammation in asthma is still at an early stage.

### K. Clinical Implications

Figure 4 shows how the various inflammatory cells in asthma are thought to interact via the generation of cytokines. T lymphocytes are involved centrally through the secretion of cytokines that are responsible for isotype switching of B lymphocytes to make IgE and that have specific activities for mast cells and eosinophils. However, asthma is more than simple inflammation involving mast cells and eosinophils since nerves, smooth muscle, and myofibroblasts are all also important in the response.

Using this diagram as a framework, we can consider the actions of the various anti-asthma drugs.  $\beta$ -Agonists, as powerful bronchodilators and inhibitors of mast cell function, attenuate the early bronchoconstrictor response to allergen challenge but have relatively little effect on the late-phase response (Cockcroft and Murdock, 1987). In contrast, corticosteroids and cyclosporin down-regulate cytokine expression by T lymphocytes, which in turn leads to a decrease in mast cell and eosinophil numbers. Finally, sodium cromoglycate (Holgate, 1989) and nedocromil sodium, long recognized as mast cell stabilizers, now are known to have additional effects on various other cell types.

Clearly, with our improved knowledge about the mucosal immune system and how it becomes disturbed in asthma, real advances are now being made, not only in understanding the nature of this disease but also in providing opportunities for novel therapeutic strategies designed to intervene in the inflammatory cascade in a more specific manner than currently possible.

### Acknowledgments

The authors wish to thank William Roche and David A. Goulding for kindly supplying the electron micrographs used in this manuscript.

# Respiratory Infections

Robert C. Welliver

## I. INTRODUCTION

The respiratory tract is the primary site of entry for numerous microbial pathogens. Many agents initiate replication events on the respiratory mucosa, leading to eventual systemic spread, without producing any clinical disease locally. In other cases, the respiratory tract is the principal target organ of the disease-producing microbe (Table I). Colonization of the respiratory tract with a potentially infectious organism represents a situation in which the invasiveness or virulence of the organism is opposed by local or systemic immunity. In most cases, little or no clinical illness occurs and some persistent immunity may develop, even in the absence of clinically evident infection. Clinical illness apparently results from infection of the uniquely susceptible host, or inoculation with an organism in sufficient quantity or with sufficient virulence to overcome the natural or acquired immunity of the host.

In the United States, upper respiratory tract infections are a common nuisance, representing the most frequent reason for seeking medical attention and disrupting lifestyles by requiring absence from school or employment. Lower respiratory tract infections are relatively uncommon and are usually only life-threatening at the extremes of age. In contrast, in developing countries, respiratory tract infections are second only to gastrointestinal infections as the leading cause of death in infants and children in the first few years of life.

This chapter summarizes the clinical features of viral, bacterial, and mycobacterial infections of the respiratory tract. In addition, the contribution of the immune system to recovery from the infection as well as its role in the pathogenesis of the disease is described.

## II. EPIDEMIOLOGY OF COMMON RESPIRATORY INFECTIONS

Although numerous viruses can result in minor upper respiratory infections, respiratory syncytial virus (RSV) and influenza virus account for the most severe infections in infants and adults, respectively. An estimated 50% of infants in the first year of life acquire RSV infection during their first epidemic exposure; 1–2% of all infants will be admitted to a hospital in the first year of life for lower respiratory disease caused by RSV infection (Beem *et al.*, 1934; Clarke *et al.*,

1978). Influenza viruses cause yearly outbreaks of respiratory illness of varying severity. During 10-wk epidemic periods in 1982 and 1983, approximately 2500 hospitalizations for acute respiratory disease occurred in the Houston area (Glezen *et al.*, 1987). Weekly tabulations of deaths from pneumonia and influenza from large United States cities permit an accurate estimation of influenza virus activity in the community. Reported deaths in excess of expected thresholds correlate well with the occurrence of widespread influenza activity (Langmuir and Housworth, 1969; Glezen *et al.*, 1982). Mortality from infection with each of these agents is most common in individuals with pre-existing heart or lung disease or other underlying illnesses, or in the elderly (Eickhoff *et al.*, 1961; McDonald *et al.*, 1982; Groothuis *et al.*, 1988). *Streptococcus pneumoniae* is the leading cause of otitis media in children, is a major cause of mortality due to pneumonia in infants and the elderly, and is still a common cause of overwhelming bacterial sepsis and meningitis (Austrian and Golb, 1964; Klein, 1981). Tuberculosis, however, probably has accounted for more chronic respiratory illness than any infectious agent, particularly since the era of urbanization and industrialization in the 18th and 19th centuries (Dubos and Dubos, 1952).

## III. VIRAL INFECTIONS

An impressive amount of information has been gathered concerning the role of the immune system in influenza and RSV infections with respect to mechanisms of eradication of primary infection, pathogenesis of severe disease, and prevention of reinfection (Table II). A review of the immune response to infection with these specific agents provides an overall perspective that probably can be applied to infection with other viral agents.

### A. Respiratory Syncytial Virus

#### 1. Clinical Presentation

RSV is the major cause of serious lower respiratory disease in infancy and early childhood. An estimated 28 episodes of lower respiratory disease caused by RSV occur for every 100 children followed through the first 12 months of life. Reinfections in the second year of life are extremely common

**Table I** Pathogens Associated with Different Forms of Respiratory Illness<sup>a</sup>

Form of illness	Pathogen							
	Rhinovirus	Influenza virus	Respiratory syncytial virus	Parainfluenza virus	Adenovirus	<i>Streptococcus pyogenes</i>	<i>Streptococcus pneumoniae</i>	<i>Staphylococcus aureus</i>
Upper respiratory illness	+++	++	++	++	+	0	0	0
Pharyngitis	+	++	+	+	++	+++	0	0
Croup	0	+	+	+++	+	0	0	0
Bronchiolitis or "infectious asthma"	++	+	+++	++	+	0	0	0
Pneumonia	+	+	++	+	++	+	+++	+

<sup>a</sup> 0, Little or no causal relationship to disease at this site; +, occasional relationship; ++, frequent relationship; +++, very common relationship.

and occur with some frequency at all ages (Glezen *et al.*, 1986). Therefore, although most individuals develop relatively mild symptoms at the time of RSV infection, certain individuals seem more prone to develop lower respiratory illness (in particular, bronchiolitis) at the time of RSV infection. The fact that bronchiolitis (as well as croup) can be seen with a wide variety of viral agents suggests that the development of these illnesses is not entirely specific to any feature of RSV, but to a similar feature of a variety of viruses as well as to some unique host component.

Inoculation of RSV occurs through the nasal mucosal surface or through the eye (Hall *et al.*, 1981). The incubation period is assumed to be 4–5 days, at which time the infected child develops symptoms of rhinorrhea, nasal obstruction, and low-grade fever. In most patients, the illness resolves over 7–10 days, but in others the cough becomes progressive and eventually signs of lower respiratory tract involvement appear. At this point, secretions are profuse and contain  $10^5$ – $10^6$  infectious units of virus per milliliter of secretion (Hall *et al.*, 1976). In cases of pneumonia, descent of virus to the lower respiratory tract probably occurs as a result of aspiration. In the syndrome of bronchiolitis, whether disease is entirely the result of spread of virus to the bronchioles or the result of the involvement of the immune response simultaneously is not yet clear. In any case, the child at this point manifests respiratory distress that may be severe. Nasal flaring, dyspnea, and retractions are noted, and auscultation of the chest reveals rhonchi and harsh wheezing. Otherwise the child remains remarkably free of other symptoms. Fevers are usually not marked and the child may be quite active despite the presence of moderate to severe hypoxia, again suggesting that severe illness may be mediated, at least in part, by mechanisms other than progressive viral infection.

## 2. Histopathology

The histological picture of interstitial pneumonia reveals lymphocytes within the alveolar walls and small airways. Engorgement of the capillary bed with edema is also noted. Lymphocytes and plasma cells are recruited into alveolar

walls. The alveolar walls may become increasingly thick and filled with proteinaceous material, and intranuclear or cytoplasmic inclusions and giant cells may be observed (Aherne *et al.*, 1970). Bronchiolitis, in contrast, is characterized by necrosis and sloughing of the respiratory epithelium and plugging of the small bronchioles with fibrin and mucus. An intense peribronchiolar infiltration of lymphocytes and plasma cells occurs, with considerable edema. Localized hyperinflation due to airflow obstruction is characteristic, and atelectasis is common.

## 3. Protective Immune Response

The precise role of RSV-specific antibody in recovery from primary infection is controversial. Local antibody responses, predominantly in the secretory IgA class, appear in the respiratory tract shortly after the onset of primary infection (McIntosh *et al.*, 1979; Kaul *et al.*, 1981). In some studies (McIntosh *et al.*, 1979), viral shedding is terminated at about the time of appearance of antibody-free secretions. However, in other studies (Kaul *et al.*, 1981), antibody is present at a time when substantial quantities of virus are still recoverable from the respiratory tract. Administration of very high concentrations of neutralizing antibody of the IgG isotype to infants with RSV infection did not have a dramatic effect on viral shedding (Hemming *et al.*, 1987). In contrast, the presence of neutralizing antibody in serum correlates with resistance to reinfection (Hall *et al.*, 1991). Although repeated infection tends to result in accelerated local antibody responses (Kaul *et al.*, 1981) and reduced severity of illness, whether local antibody is responsible for protection is not clear. In one study of adults undergoing experimental RSV challenge, specific nasal IgA antibody titers did not correlate with protection against infection (Hall *et al.*, 1991). In other investigations (Mills *et al.*, 1971), neutralizing activity in nasal secretions apparently was related to partial resistance to infection. However, subsequent studies (McIntosh *et al.*, 1979) demonstrated that such neutralizing activity is not necessarily antibody related. Therefore, serum antibody, presumably appearing in the respiratory tract by transudation following infection with RSV,

appears to be better associated with protection against detectable infection than locally synthesized IgA antibody. Nevertheless, even the highest titers of antibody in serum or respiratory secretions do not seem to provide absolute protection against RSV, since as many as 25% of adults can be infected despite very high antibody titers (Mills *et al.*, 1971; Hall *et al.*, 1991).

RSV-specific IgE antibody responses have been documented in respiratory secretions of infants and young children undergoing natural RSV infection (Welliver *et al.*, 1980, 1981; Bui *et al.*, 1987). As with secretory IgA, IgE appears first bound to the surface of RSV-infected cells and later free in secretions (Welliver *et al.*, 1980, 1981). Higher concentrations of RSV-IgE were observed in infants with bronchiolitis in comparison with infants with upper respiratory illness alone (Welliver *et al.*, 1981; Bui *et al.*, 1987). In addition, histamine and various leukotrienes also have been identified in secretions of infants with bronchiolitis (Welliver *et al.*, 1981; Garofalo *et al.*, 1991). Therefore, in certain individuals, RSV infection may elicit the release of chemical mediators of airway obstruction, either directly or by IgE-dependent mechanisms.

Cell-mediated immune mechanisms also may be important in recovery from RSV infection. Individuals with congenital or acquired defects in cell-mediated immune function shed virus for prolonged periods of time and seem to have a greater frequency of development of pneumonia than immunologically intact individuals (Fishaut *et al.*, 1980; Hall *et al.*, 1986). T lymphocytes expressing cytotoxic activity against RSV-infected cells have been demonstrated in human infants, and appear at about the time that viral shedding begins to decrease (Issacs *et al.*, 1987; Chiba *et al.*, 1989). No studies of lymphocytes obtained from the respiratory tract have been completed.

Evidence also suggests exaggerated T-cell responses may result in enhanced lung disease after RSV infection. Reconstitution of RSV-infected mice with cytotoxic T cells that have been stimulated repeatedly with RSV antigen clears virus rapidly from lungs, but results in enhanced mortality and increases histopathological changes in the lungs (Cannon *et al.*, 1988). Whether similar events occur in humans is not known, but infants with RSV bronchiolitis have been re-

ported to have peripheral blood lymphocytes that are more responsive to RSV antigen than similar cells from infants with upper respiratory infection alone due to RSV (Welliver *et al.*, 1979). In addition, recipients of an inactivated RSV vaccine developed evidence of cell-mediated hypersensitivity to RSV after vaccination, and subsequently developed enhanced lung disease when naturally infected with RSV (Kim *et al.*, 1976).

## B. Influenza Virus Infections

### 1. Clinical Presentation

Influenza viruses are responsible for yearly outbreaks of respiratory illness among all age groups. The highest mortality rates are observed in infants and in the elderly. Characteristic "flu-like" symptoms include fever, headache, intense myalgia, and prolonged malaise. Cough may or may not be a prominent finding, especially early in the illness. The principal sites of involvement in most influenza virus infections are the trachea and the bronchi. As with RSV infections, lower respiratory tract illnesses such as pneumonia or wheezing are not as common in otherwise healthy persons. Nevertheless, croup and bronchiolitis may occur in infancy and pneumonia may occur at any age.

### 2. Histopathology

Influenza infection of the respiratory tract results in swelling and desquamation of infected ciliated cells. Airway edema and infiltration by mononuclear and polymorphonuclear cells follows, with extensive sloughing to the layer of the basal cells. Influenza pneumonia is characterized by hemorrhagic alveolar infiltrates, formation of hyaline membranes, and marked lymphocytic infiltration of the interstitium and alveolar walls (Kilbourne, 1987). Increased bronchial reactivity is a frequent complication of influenza infection (Little *et al.*, 1978; Laitinen and Kava, 1980). The increase in bronchial reactivity is associated with loss of the epithelium and may be caused by either exposure of airway irritant receptors (Empey *et al.*, 1976) or a loss of natural inhibitors of airway reactivity (Jacoby *et al.*, 1988). The role of influenza-specific

**Table II** Role of Aspects of the Immune System in Infection Caused by Various Pathogens

Immune system component	Pathogen			
	Respiratory syncytial virus	Influenza virus	<i>Streptococcus pneumoniae</i>	<i>Mycobacterium tuberculosis</i>
Serum IgG antibody	Partially protective	Strongly protective	Strongly protective	Probably not protective
Secretory IgA antibody	Partially protective	Possibly protective	Probably not protective	Probably not protective
Mucosal IgE antibody	Potentially pathogenic	Unknown	Unknown	Unknown
Cell-mediated immunity	Clears primary infection, potentially pathogenic	Clears primary infection, potentially pathogenic	Unknown	Related to immunity

IgE responses and mediator release has not been evaluated extensively for a possible role in inducing bronchial hyper-reactivity.

In contrast to infection with RSV and most other viruses, influenza infection is accompanied by an increased frequency of bacterial superinfection that may be the result of reduced mucociliary clearance after influenza virus infection (Camner *et al.*, 1973), greater damage to the mucosa with resultant diminished resistance to bacterial invasion (Kilbourne, 1987), or suppression of activity of phagocytic cells (Casali *et al.*, 1984; Hartshorn and Tauber, 1988).

### 3. Protective Immune Response

Initial infection with one strain of influenza virus provides partial immunity to reinfection with the same strain. Reinfections are generally asymptomatic (Frank *et al.*, 1979; Sonoguchi *et al.*, 1986). Resistance to reinfection has been attributed to the presence of antibody in serum or respiratory secretions; high titers of antibody at either site appear to be capable of conferring resistance (Clements *et al.*, 1986). Whether local or serum antibody is most efficient in providing protection against reinfection in humans is uncertain.

Antibody to the hemagglutinin of influenza appears to contribute to immunity by preventing attachment of the virus to the respiratory epithelium, whereas antibody to the neuraminidase antigen inhibits cleavage of preformed virus from the cell membrane (Ogra *et al.*, 1977). Virtually no data are available on the role of serum or secretory antibody in recovery from primary influenza virus infection. Minor changes in hemagglutinin structure by variation in amino acid sequences ("antigenic drift") or major changes via genetic reassortment ("antigenic shift") enable the virus to infect previously exposed individuals.

The role of cell-mediated immunity in influenza virus infection has been investigated extensively in mice and, to a lesser extent, in humans. Transfer of primary or secondary influenza-immune splenic cells to mice infected intranasally with influenza virus results in significant clearance of virus from the lung and protection against death in the recipients. T lymphocytes represent the cell population primarily responsible for this immunity (Yap and Ada, 1978). Evidence suggests that the pathogenesis of influenza virus infection may be a reflection of the cell-mediated immune response in the lung. First, influenza virus replicates in and is released from the cells without causing cell death. Second, mice without functioning T cells develop extensive replication of virus in the lung with dissemination to other organs, but develop minimal pulmonary infiltration after influenza virus challenge (Wyde *et al.*, 1977). In contrast, cytotoxic T cells appear in the lungs of immunocompetent mice at the peak of respiratory symptoms and when histopathology in the lung is most prominent (Ennis *et al.*, 1977).

Although such definitive studies have not been repeated in humans, cytotoxic T-cell responses are known to develop in humans after influenza virus infection. Maximal responses occur in the second week after infection (Greenberg *et al.*, 1978). These cytotoxic cells apparently recognize all influenza type A strains but not influenza viruses of other types

or non-influenza viruses. These cytotoxic cells appear to be HLA-restricted and apparently are capable of providing protection against subsequent influenza virus infection, even when influenza-specific serum antibody is undetectable in serum or secretions. These cytotoxic responses are apparently short lived, since only 30% of individuals exposed to a given strain of influenza virus had inducible cytotoxic T-cell activity when tested 5 years later (McMichael *et al.*, 1983). The majority of the cytotoxic T-cell responses appear to be mediated by CD8<sup>+</sup> cells with major histocompatibility complex (MHC) restriction Class I (Fleischer *et al.*, 1985; Yamada *et al.*, 1986).

In addition to specific cytotoxic T cells, nonspecific natural killer cell activity also increases after influenza virus infection in humans. However, the same increase in natural killer activity is observed in humans who continue to shed virus as in those individuals who do not continue to shed virus (Ennis *et al.*, 1981). A sufficiently large viral inoculum may be able to overcome natural killer cell resistance.

Therefore, although data on mucosal cell-mediated immune responses are lacking, cytotoxic T cells circulating in the blood appear to be important in restricting primary viral infection by RSV and influenza, and probably by other viruses. These cytotoxic cells may play some role in protection against reinfection, and are almost undoubtedly responsible for much of the histopathology seen with viral infections of the lung. Some evidence suggests that exaggerated T-cell responses may be responsible for unusually severe forms of infection, both by RSV and by influenza virus.

## C. Bacterial Infections

### 1. Clinical Presentations

Pharyngitis is the most frequent infection caused by direct bacterial effects on the respiratory tract. However, these infections are generally sources of only temporary discomfort and not serious morbidity, in comparison with bacterial infections of the lower respiratory tract. Bacterial infections in the lung and, to a lesser extent, of the trachea are less common but are of greater severity. Most of these infections represent secondary bacterial infection following a precipitating viral infection. Bacterial infections of the lung usually are associated with more prominent fever than are viral infections, with more dyspnea, greater degrees of hypoxia, more prominent radiologic infiltrates, and higher mortality. Typical patients are infants or the elderly, who may or may not provide a history of antecedent viral upper respiratory tract illness. Cough and dyspnea become progressively more prominent, and patients appear more acutely ill.

The mechanism by which viral infections predispose to bacterial superinfection is not yet clear (Table III). Viral infections promote Desquamation of Ciliated Epithelial Cells (Reynolds, 1987) and Diminish Ciliary Function (Carson, 1983) thereby Promoting Bacterial Adherence. However, bacterial superinfection occurs at a later time in the lung. Influenza virus infection down-regulates the antibacterial function of neutrophils (Hartshorn and Tauber, 1988). In addition, virus infections of the lung result in a progressive

**Table III** Secondary Bacterial Invasion of the Lung: Relationship to Viral and Immunologic Events<sup>a</sup>

	Stage of viral infection			
	Infection	Incubation	Replication in lung	Recovery phase
Viral growth	Undetectable	Slight	Maximal	Reduced

<sup>a</sup> See Jakab *et al.* (1980); Jakab (1982).

decrease in virtually all antibacterial functions of pulmonary macrophages. This dysfunction of phagocytic cells coincides with the time at which the lung is most susceptible to secondary bacterial pneumonias, that is, about 7 days after viral infection (Jakab *et al.*, 1980) and a few days after the peak lung titers of virus are achieved. This result implies that susceptibility to bacterial infections is not simply a function of viral replication and tissue destruction in the lung. Cytotoxic immune activity peaks in the lung at about the time that the titer of virus replicating in the lung disappears. Pulmonary macrophage function becomes abnormal at this time, suggesting that cytotoxic activity may suppress macrophage function. Treatment with antilymphocyte serum ameliorates the virus-induced suppression of pulmonary bacterial defenses. However, this phagocytic defect can be re-established after antilymphocyte treatment by addition of specific antiviral immunoglobulin (Jakab, 1982). Although a clear explanation for these findings is not evident, the normal immune response to viral infection does appear in some ways to suppress antibacterial defenses, probably by direct immunological attack on the alveolar macrophages.

## 2. Histopathology

*Streptococcus pneumoniae* is the most frequent cause of bacterial pneumonia. In the earliest stages of pneumococcal pneumonia, bacteria are present in the alveolar spaces. Alveolar capillaries become intensely congested, with extravasation of erythrocytes and neutrophils through the interstitium into the alveolar spaces. The alveoli eventually fill with red cells, white cells, and fibrin. The lesion generally heals without scarring or disruption of the normal architecture (Loosli and Baker, 1962). In pneumonia caused by *Staphylococcus aureus*, persistent scarring of the lung is more likely to occur.

The strikingly toxic appearance of individuals with pneumococcal pneumonia suggests to some investigators that the release of some biologically active compound by pneumococci contributes heavily to the clinical appearance. This possibility is supported by the fact that death can occur days after antibiotic therapy for pneumococcal pneumonia has been started, when tissues are sterile and when the pneumonia is clearing (Austrian and Golb, 1964). The polysaccharide capsule is nontoxic and, to date, no evidence exists that pneumococci produce a toxin that is related to clinical illness

(MacLoud, 1970) nor is evidence available that pneumococci are more readily able to provoke release of tumor necrosis factor (cachectin) or other inflammatory substances than any other bacterial species.

## 3. Protective Immune Response

In adults and children, most pneumococcal infections occur after the recent acquisition of a particular serotype rather than after prolonged carriage of a given serotype (Gray *et al.*, 1980). In addition, overwhelming infection is more common in infants who lack antibody to pneumococcal antigens (Mufson *et al.*, 1974) and in adults with hypogammaglobulinemia or complement deficiencies (Winkelstein, 1984; Gray and Dillon, 1988). These findings suggest that antibody and complement play a major role in resistance to pneumococcal infection. The virulence of pneumococci appears to be related to the polysaccharide capsule. Certain capsular serotypes are highly associated with potential for invasive disease (Austrian and Golb, 1964; Grey *et al.*, 1980). Virulence of encapsulated strains appears to be related to their resistance to phagocytosis. Indeed, the presence of opsonic antibody to a given capsular serotype in serum is required for protection against illness after challenge. Antibodies to cell wall polysaccharides, surface proteins, and phosphocholine also provide lesser degrees of resistance (Briles *et al.*, 1989; Musher *et al.*, 1990). In addition to its antiphagocytic effect, incubation of the pneumococcal capsule with serum destroys some natural antipneumococcal activity (Schweinle, 1986).

Pneumococcal infections, particularly otitis media, also can result in mucosal immune responses. Antipneumococcal antibody of the IgA isotype has been demonstrated in middle ear fluids (Giebink, 1981; Karjalainen *et al.*, 1990), in colostrum, in saliva, and in nasal secretions (Mouton *et al.*, 1970). However, protection against otitis media is correlated with IgG antibody present via transudation rather than with locally formed IgA antibody (Giebink, 1981; Karjalainen *et al.*, 1990).

Immunization with polyvalent pneumococcal vaccines apparently has reduced the mortality from pneumonia in developing countries (Reilly *et al.*, 1981). Whether local or systemic antibody is more important in providing resistance to pneumococcal infection in the lung remains unclear (Bull and McKee, 1929).

## D. Tuberculosis

### 1. Clinical Presentation

Although *Mycobacterium tuberculosis* can spread to virtually all body organs under appropriate circumstances, the primary target organ for disease is the lung. Asymptomatic primary infection occurs after inhalation of bacteria suspended in aerosols. Infection of the lung occurs initially in the subpleural area. A primary complex consisting of the primary subpleural focus, lymphangitis, and regional lymphadenitis is a regular feature of primary lung involvement (Ghon, 1916). Pulmonary tuberculosis also can be arrested at this stage, or it can become progressive with the development of larger alveolar infiltrates or extension of the inflammatory focus into the bronchus, causing bronchial obstruction or atelectasis. The location of the primary focus close to the pleural area frequently results in irritation of the pleural surface and development of pleural effusions. The initial primary focus can undergo liquefaction and the development of cavitory lesions. These lesions contain high numbers of tubercle bacilli with a propensity to spread to other areas of the lung. Enlarging primary foci also can rupture into the pleural cavity, causing pneumothorax or even a fistula through the chest wall. Children and adults with primary foci alone may remain asymptomatic or develop only progressive weight loss. In contrast, individuals with primary progressive pulmonary tuberculosis or cavitory lesions usually have much higher fevers, much more prominent cough, and profound malaise and weight loss. Tuberculosis was often fatal in the pre-antibiotic era, and profound scarring of the lung was prominent among survivors. In addition, dissemination to bones, joints, and other organs including the brain was not unusual, with severe long-term consequences.

### 2. Histopathology

An inflammatory focus consisting primarily of macrophages occurs in the area where tubercle bacilli are inhaled into the alveoli. These macrophages then change into epithelioid cells, forming tubercles. These nodules may disappear or develop central caseation. The caseous lesions, characteristic of tuberculosis, contain enormous numbers of tubercle bacilli. These bacilli may enter the regional lymphatic vessels and spread to regional lymph nodes. Caseating granulomas, appearing at the primary site or along the routes of drainage to the lymph nodes, also may calcify. Evidence of dermal hypersensitivity develops within 3–10 weeks of initial infection. The radiographic appearance of prominent lymphadenitis, in contrast to the relatively insignificant size of the initial focus, suggests that hypersensitivity responses also occur in the lungs. As noted earlier, bronchial obstruction can result from compression of the airway by the enlarged lymph nodes. Alternatively, the adjacent infection can destroy the cartilaginous component of the airway or caseous material may perforate into the bronchus, forming semiliquid plugs. Collapse of the lung distal to the site of the obstruction is common.

In adults, reactivation of pulmonary tuberculosis acquired in earlier life is the most common form of tuberculosis. The lesions in the lung in active "adult" tuberculosis are probably

caused by reactivation of primary foci with spread to new areas of lung (Stead, 1967). The lesions in adults are smaller than those in children and are less likely to spread to lymph nodes or to other organs. Protracted cough, persistent high fevers, chest pain, and hemoptysis are the most common clinical manifestations of tuberculosis in adults.

Certain races appear to be more disposed to infection with *M. tuberculosis* than others on similar exposures (Stead *et al.*, 1990). Malnutrition appears to be associated with an increased risk of infection and, in particular, vitamin D deficiency may be associated with increased susceptibility to tuberculosis (Rook, 1988). In addition, patients on immunosuppressive medications or with underlying diseases associated with immunosuppression are at a greater risk for developing severe forms of tuberculosis.

### 3. Protective Immune Response

The findings just described suggest that cell-mediated immunity is important in resistance to tuberculosis and in recovery from infection. Tuberculin-specific cell-mediated and humoral immune responses have been evaluated in individuals with various forms of tuberculosis (Table IV). Anergy, both to tuberculin and to unrelated antigens, seems to be related to the severity of illness. In one study, only 2 of 10 individuals with miliary tuberculosis had positive cutaneous reactions to tuberculin, whereas 14 of 15 individuals with active pulmonary tuberculosis and 20 of 22 healthy controls who probably had been infected with tuberculosis early in life had positive cutaneous reactions (Bhatnagar *et al.*, 1977). Tuberculin anergy apparently is more likely to be noted during the first few weeks of acute pulmonary tuberculosis than during convalescence (Daniel *et al.*, 1981). *In vitro* lymphocyte transformation assays also have been used to assess cell-mediated immune function in tuberculosis (Cox *et al.*, 1981). These *in vitro* responses correlate quite well with skin test reactivity, and are occasionally positive when skin tests are negative.

Serologic tests also have been developed for diagnosis of tuberculosis. These tests include passive hemagglutination techniques using PPD-coated red blood cells (Bhatnagar *et al.*, 1977) and enzyme-linked immunosorbent assays (ELISA) (Daniel *et al.*, 1981; Benjamin and Daniel, 1982). These serologic tests have not been useful in the diagnosis of tuberculosis because of a high degree of cross-reactivity of antibodies directed against *M. tuberculosis* with other environmental or "atypical" mycobacteria. Antigen 5 appears to be somewhat more specific for *M. tuberculosis* than for other mycobacterial antigens (Benjamin and Daniel, 1982). Analysis of antibody responses in individuals with tuberculosis reveals the opposite of the findings for cell-mediated immunity, that is, individuals with remote asymptomatic infection have very low levels of antibody despite their strong cutaneous reactivity. Antibody titers are somewhat higher in individuals with acute or resolving primary pulmonary tuberculosis, and are the highest in individuals with miliary tuberculosis (Bhatnagar *et al.*, 1977; Lenzini *et al.*, 1977; Daniel *et al.*, 1981).

The observed immunological aberrations in tuberculosis return to normal with recovery from disease, that is, evidence of cell-mediated immunity is present in essentially all individ-

**Table IV** Humoral and Cell-Mediated Immunity to *Mycobacterium tuberculosis* in Different Stages of Illness<sup>a</sup>

	Asymptomatic infection	Primary pulmonary tuberculosis	Miliary or disseminated disease	Convalescence
Antibody titers to <i>M. tuberculosis</i>	Low	Mildly increased	Markedly increased	Mildly increased
Cell-mediated responsiveness	Present	Generally present	Diminished	Generally present

<sup>a</sup> See Bhatnager *et al.* (1977); Lenzini *et al.* (1977); Daniel *et al.* (1981).

uals who have recovered from acute tuberculosis whereas antibody titers fall with recovery (Bhatnagar *et al.*, 1977; Daniel *et al.*, 1981). These observations suggest that the immunological abnormalities are a result of tuberculosis rather than a cause of invasive infection.

Although cell-mediated immunity appears to be the principal means of protection against invasive tuberculosis, whether macrophages (Patterson and Youmans, 1970) or lymphocytes (Lefford *et al.*, 1973) are primarily responsible for tuberculocidal activity is not clear. Each of these cell types has been shown to have some activity in eradication of infection, but has not been shown clearly to have tuberculocidal activity. In addition, humans appear to have significant natural immunity to tuberculosis (Kallmann and Reisner, 1943; Skamene, 1989). When one monozygotic twin became infected with tuberculosis, the other twin was more likely to be infected than when one of a pair of dizygotic twins became infected (Kallmann and Reisner, 1943).

Despite the correlation of cell-mediated hypersensitivity with clinical phases of illness, cell-mediated hyperresponsiveness has never been demonstrated conclusively to be responsible for immunity. In fact, numerous experiments have demonstrated a clear dissociation of hypersensitivity and immunity in tuberculosis (Rich and McCordock, 1929). Some experiments have indicated that macrophages have minor intrinsic ability to inactivate *M. tuberculosis*, and that this capability can be enhanced by interaction of macrophages with tuberculin-sensitized T cells (Wilson *et al.*, 1940). However, this degree of tuberculocidal activity is rather limited and probably does not account for the fairly solid immunity resulting from tuberculous infection. Production of lymphokines from sensitized T lymphocytes seems more likely to play an important role in restriction of immunity to tuberculosis (Youmans, 1975; Rook *et al.*, 1986), perhaps recruiting a variety of inflammatory cell types.

# Inhalant Allergy and Hypersensitivity Disorders

*Bengt Björkstén*

## I. INTRODUCTION

Asthma is the most common chronic debilitating disease in children and one of the major causes of repeated absence from work in adults. IgE antibodies play an important role in childhood asthma and are considered to be at least a contributing factor in over 80% of the cases. In adults, atopy and other confirmed allergy are much less common causes of asthma.

Immunologically triggered immediate type hypersensitivity reactions seem to be mediated exclusively by IgE antibodies. Although other homocytotropic antibodies have been described in humans, their role in disease is still obscure. Other hypersensitivity diseases of the lung are much less common in children. In adults, however, allergic alveolitis and other hypersensitivity disorders constitute a large proportion of occupational diseases of the respiratory tract. The pathogenesis of these conditions includes a strong immunological component, although the precise underlying mechanisms are not fully understood.

The presentation in this chapter is limited to disorders of the respiratory tract in which immunological mechanisms and allergic reactions play a dominating role. Although inhaled allergens are well established to cause symptoms not only in the respiratory tract, for example, dermatitis and severe systemic reactions such as anaphylaxis, these conditions are beyond the scope of this chapter.

## II. DEFINITIONS

In this chapter, asthma is defined as reversible episodes of severe wheezy breathlessness. Such patients may be atopic or nonatopic, depending on whether antibodies of the IgE isotype are involved. However, even in atopic patients, the allergens precipitating an attack are not always known. No clinically discernible difference exists between the two. Further, in both types of patients, attacks of varying severity usually are triggered by inhaled irritants, and airway hyperresponsiveness (BHR) is characteristic of all patients. This hyperreactivity expresses itself clinically by bronchial and nasal obstruction after exposure to various nonspecific stimuli such as cold, humid, or polluted air, physical exercise, and emotional stress. BHR can be verified objectively in the laboratory by provocation tests with cold air, various compounds including histamine, and exercise.

Sensitization, as proven by the demonstration of low levels of IgE antibodies directed against environmental allergens, appears to be part of the normal immune response. In most instances, at least in children, these antibodies are only temporary since continued IgE antibody formation is suppressed rapidly. However, when genetically predisposed individuals are exposed to an allergen at a time when the regulation of the immune system is impaired, higher levels of IgE antibodies that persist for a long time may appear. The more susceptible to sensitization the individual is, the lower the allergen dose needed for this response to occur. The fact that an individual is sensitized does not, however, mean that clinical symptoms such as allergic disease will develop.

## III. GENETIC BACKGROUND OF ALLERGIC DISEASE

Phenotype and genotype are two terms used when describing the genetics of an illness. The first term represents the observed manifestations of the disease, whereas genotype describes the underlying structural lesion in the DNA. Allergy (atopy) can be defined in several ways, and the phenotype is highly variable. Nevertheless, however defined, allergy is well known to be much more common in individuals with a family history of allergy. Thus, the likelihood of allergy appearing in a child is elevated if one of the parents is allergic, and reaches over 50% if both parents are allergic (Björkstén and Kjellman, 1992). If both parents are allergic with the same disease, then the chance of allergy in their child is increased further and reaches over 70%. A strong genetic influence also is seen in asthma, independent of other atopic manifestations.

Several studies have addressed the mode of inheritance for elevated serum IgE and for IgE antibody formation against individual allergens. Studies of serum IgE levels in families with allergic individuals have not revealed any simple pattern of Mendelian inheritance, although in most of the studies data best fit a condition of one or two loci that determine high IgE levels and are, in turn, influenced by other genes.

Immune responses, including IgE antibody formation, against at least some major allergens are partially HLA determined (Marsh, 1990). Thus, significant relationships have been demonstrated between haplotypes DR2/Dw2 and DR5 and responsiveness to some major ragweed allergens and

between DR3/Dw3 and antibody responses to grass. A genetic linkage was suggested in some atopic families between allergy and a gene on the long arm of chromosome 11. However, this result could not be confirmed in any of three other studies performed by other investigators. Thus, the genetics of allergy remain poorly understood.

#### IV. NATURAL HISTORY OF ALLERGIC DISEASE AND EPIDEMIOLOGICAL ASPECTS

The highest incidence (new cases appearing during a given year) of allergy appears in infants and adolescents. The prevalence of a disease, that is, the presence of symptoms at any time during the past 12 months, depends on the incidence, the age of the subjects, and the natural history of the disease, including healing and change to a latent phase. The accumulated incidence (sick presently or previously) of a disease in a particular region therefore should increase with age, unless a dramatic reduction has occurred in the prevalence as a consequence of efficient prevention, reduced exposure to allergens, or adjuvant factors, or improved treatment.

The clinical symptoms of allergic disease vary with age. Symptoms from the skin, such as dermatitis and urticaria, and gastrointestinal tract dominate in infants and the offending allergens mainly are introduced with food. After infancy, inhaled allergens become increasingly more common as triggers of symptoms, and after the age of 3 the appearance of new food allergies is not common.

From the second year of life, wheezing becomes increasingly common. Wheezy bronchitis occurs before 18 months of age in up to 20% of all young children. In most cases, the episodes of wheezing are not associated with development of asthma. The wheezing is, however, diagnosed as asthma when the episodes of wheezing recur three times, and as soon as a relationship is determined to exposure to a particular allergen. Wheezing in older children often is associated with asthma. The prevalence of asthma then increases to a peak level in school children and declines after puberty. Through adolescence, asthma is associated with allergy in up to 80% of the patients and IgE antibodies can be demonstrated in most patients. In young adults with asthma, an IgE-mediated component is also present in the majority of the patients. After the age of 50, however, allergy is less common.

Allergic rhinoconjunctivitis is not commonly seen before 5–6 years of age, and then increases to a peak prevalence in adolescence. In adults, particularly in middle-aged and old patients, the etiology of rhinitis is usually nonallergic.

Scandinavian studies show a total accumulated incidence of one or more of the allergic diseases in over 30% of adolescents and young adults (Björkstén and Kjellman, 1989). In prospective studies, the prevalence of asthma in childhood is 3–5% whereas the accumulated incidence is around 8%. Similar and higher figures have been reported from other industrialized countries. In a few studies, the incidence of allergic disease has been studied repeatedly over 10–20 years with a similar methodology. These studies all indicate a true increased incidence over time, although none of the investiga-

tions conclusively proves this statement. The incidence of allergic disease is higher in boys than in girls, at least in infants and young children. In adolescents, however, no sex differences seem apparent. Children with biparental family history of allergic disease begin to have symptoms at an earlier age than children with less pronounced or no family history of allergy.

#### V. ENVIRONMENTAL FACTORS IN THE DEVELOPMENT OF ALLERGIC DISEASE

Several studies strongly indicate that the prevalence of allergic diseases is increasing in many parts of the world. Since the human genotype has not changed appreciably over the past few generations, we can assume that the increase is caused by environmental influence. Available epidemiological data strongly suggest that the development of allergic disease is enhanced when a genetically predisposed individual is exposed to allergens in the presence of various environmental adjuvant factors that may enhance sensitization (Munir and Björkstén, 1992). According to this hypothesis, the impact of the environment is best studied in individuals with a family history of allergy or in individuals who previously have shown allergic symptoms. The impact of the environment may begin before birth. Thus, maternal immunity, tobacco, smoking, and medication appear to affect the likelihood of allergic disease in the offspring (Hattevig and Björkstén, 1993).

##### A. Early Exposure to Antigens

Early weaning to cow's milk formulas has been associated with an increased rate of allergic disease. However, many studies also have been done in which prolonged breast-feeding was not associated with less allergy than early administration of cow's milk formulas. The explanation for the apparently conflicting results seems to lie in selection of patients for the studies, the necessity for other dietary precautions, and self-selection bias. Studies showing a protective effect of prolonged exclusive breast-feeding have included infants with a genetic propensity to allergy rather than an unselected group of infants. Also, the breast-feeding in these cases was associated with an avoidance of other foods, for example, juices and solid foods. Critical reviews indicate, however, that even under the best circumstances the effect of breast-feeding on the development of atopy or allergy is limited to risk individuals and that it appears merely to delay rather than prevent the onset of allergy.

Several possible explanations are available for the protective role of breast milk against allergy, including low content of allergens, protection against intestinal and respiratory infections, passive transfer of immunity from the mother by secretory IgA antibodies, and transfer of components that stimulate the maturation of the infantile immune system. Human milk is well established to contain food antigens similar to cow's milk proteins and egg if these items are ingested by the mother, which may sensitize the breast-fed baby. The

small amounts of allergens that may be present in breast milk can, thus, be sufficient to cause a high grade of sensitization in a genetically predisposed infant, and even to evoke allergic symptoms during lactation.

The effect of maternal hypoallergenic diet during the lactation period has been addressed recently. Both studies show that maternal avoidance of certain allergenic foods such as eggs, cow's milk, fish, soy, and peanuts was associated with less allergic disease for the first years of life in their babies. Also, the disease tended to be less severe in babies of mothers who had adhered to the diet (Hattevig *et al.*, 1989; Zeiger *et al.*, 1992).

Similar to early exposure to foreign antigenic foods, exposure of infants to inhaled allergens may result in sensitization that becomes manifested clinically only several years later. Thus, several clinical studies indicate a period in early infancy during which exposure to inhalant allergens readily may sensitize the baby. The relationship between early exposure to inhalant allergens and allergic disease seems, however, to be limited to children with a congenital propensity for allergy, rather than being present in all children. Reasons for the association between early exposure and disease are poorly understood, since clinical symptoms in response to inhalant allergens usually only appear several years after infancy. Animal experiments may, however, offer an explanation. Holt and associates (1990) have shown that, when young rats of a strain with a low propensity for IgE antibody formation inhale an allergen, they initially respond with a low-grade IgE antibody formation. On repeated exposure, the IgE antibody response is suppressed. In contrast, rats of a strain with a higher tendency to IgE antibody formation respond to repeated exposure with increasing levels of IgE antibodies. Cloning experiments have shown that repeated allergen exposure of normal low-responder rats induces T cells with the capacity to suppress IgE antibody formation, whereas T helper cells are induced in young high-responder rats.

The normal induction of tolerance can be disturbed by exposure to various environmental agents. Thus, if young rats of the low-responder genotype are exposed to tobacco smoke, ozone, or SO<sub>2</sub> (for example) at the time of initial antigen exposure, then repeated exposure to antigen results in prolonged IgE antibody formation. As indicated by clinical observations, these findings in rats also may be relevant for humans.

### B. Nonspecific Factors

In addition to allergens, several environmental factors facilitate sensitization to almost any allergen to which the individual is exposed (Table I). Among these "adjuvant" factors, exposure to tobacco smoke and certain infections appear to play a particular role in early infancy (Munir and Björkstén, 1992). The role of tobacco smoke has been substantiated in several studies in infants, young children, and adults. Therefore, strongly discouraging parents from smoking near a young infant, particularly in families with allergic disease, and regarding smoking and passive smoking as occupational health hazards in adults is reasonable. Other nonspecific fac-

**Table I** Environmental Factors Encountered during Fetal Life and Early Infancy That May Influence the Development of Allergy

Prenatally	In infancy	In children and adults
Placental barrier function?	Early introduction of formula	Exposure to tobacco smoke
Maternal immunity	Amount and quality of breast milk	Exposure to air pollution
Maternal smoking?	Exposure to tobacco smoke	Psychological stress?
Maternal medication	Exposure to outdoor air pollutants	
Maternal health?	Living in tight, poorly ventilated buildings	
	Early exposure to inhalant allergens	
	Infections	
	Neonatal complications	

tors that appear to play a role in allergy include industrial air pollution and living in modern, tight, poorly ventilated houses.

Several studies suggest an association between respiratory infections and appearance of allergic disease. Possible explanations for these observations include that infectious agents may induce an inflammatory reaction in the airways, may alter immune defense, and may act as adjuvants or as allergens. From animal studies, pertussis bacteria are well known to be adjuvants for the induction of IgE antibody formation against various antigens. In humans, whooping cough is associated with a prolonged period of bronchial hyperreactivity, and IgE antibodies against pertussis toxin commonly are encountered in children with whooping cough and after immunization.

All these specific nonallergen environmental influences seem to play a major role only in individuals with a genetically predetermined tendency toward allergic disease. Based on extensive experimental work in rodents and analysis of epidemiological data on the appearance of IgE antibodies in infants and children, researchers have proposed that the capacity to produce IgE antibodies in response to environmental allergens is controlled genetically through the T-cell system (Holt, 1990). The ultimate expression of a genetic potential for high IgE production requires the intervention of additional environmental risk factors (e.g., air pollution). Many of those factors described so far appear to function at a level that enhances contact between the allergen and the immune system, particularly by increasing net flux of inhalant allergen across respiratory mucous membranes. At the time of initial contact with an allergen not previously encountered, the immune system responds to it. A transient IgE production is part of this normal response. In nonatopic individuals, the initial IgE response is self-limiting and is replaced by a life-

long tolerance to the allergen. However, if the individual at the time of initial exposure, for example, in early infancy, is exposed simultaneously to appropriate risk factors, the immune response may, instead, increase steadily and give rise to an expanding pool of memory T cells that effectively prime the immune system, laying the foundation for a state of hypersensitivity to the allergen. Once in allergic inflammatory response to an allergen occurs, this process enhances sensitization to new allergens encountered during the reaction.

## VI. PREVENTION AND TREATMENT OF RESPIRATORY ALLERGY

Obviously the best treatment for all diseases would be prevention. Through primary prevention, sensitization to allergens is avoided. In principle, prevention is only possible in early childhood. As discussed earlier, a period seems to exist early in life during which an individual is particularly susceptible to sensitization. The conditions under which the first exposure to allergens occurs may influence the immune system for a long time, possibly even for life.

Secondary prevention aims at the prevention of symptoms of disease in the already sensitized individual, which can be achieved by avoiding exposure to triggering factors and to allergens against which the individual is sensitized, by drugs, and by other means to reduce hyperreactivity. Clean air, air filters, and elimination of allergen sources at home, in schools, and in working places are all important in this respect. Also, several prophylactic drugs are available on the market, including sodium cromoglycate.

Asthma induced by exercise and cold air often may be prevented by a prolonged warming-up period before exercising and by prophylactic medication through inhalation of a  $\beta$ -2-stimulating agent.

Tertiary prevention aims at reducing permanent damage as a consequence of the allergic disease. The most important measure in this respect is reducing inflammation in the lungs by adequate treatment with corticosteroids. Usually, this treatment can be achieved by inhalation therapy. If such medication is insufficient, oral prednisone should be considered, bearing in mind the potential harmful effects of prolonged systemic treatment with corticosteroids. Other treatment possibilities in severe asthma, if steroid treatment fails or is associated with unacceptable side effects, include methotrexate, chloroquine, cyclosporin A, and intravenous infusion of immunoglobulin. None of these procedures, however, is established in clinical practice and each should be considered only in highly selected cases, preferably as part of clinical research.

## VII. NONALLERGIC RHINITIS

The nose is exposed constantly to allergenic particles as it filters them from inhaled air. Accordingly, it is the site of more allergic symptoms and illnesses than any other organ. In some patients with chronic noninfectious rhinitis, neither an allergic etiology nor evidence of inflammation can be

found. Such patients often act as though they have hyperreactive nasal mucosa with exaggerated responses to a large number of stimuli that are ordinarily tolerated. (Anderson and Pipkorn, 1990).

In the lower airways, bronchial challenge tests with histamine and metacholine can be used to differentiate normal subjects from patients with hyperreactive airways. A similar approach has been taken to test for hyperreactivity of the upper airways with the same agents given in nasal challenge procedures.

Treatment includes environmental control, for example, avoidance of known irritating agents, short-term treatment with nasal decongestants, local steroids, and cromolyn sodium.

## VIII. ALLERGIC ALVEOLITIS OR HYPERSENSITIVITY PNEUMONITIS

Several eponyms for this condition are used in the literature, including farmer's lung, bird fancier's lung, pigeon breeder's disease, saw dust disease, and byssinosis. (Fink, 1983, 1984). All the names give an indication of the conditions under which this disease appears. Some overlap exists between occupational asthma and allergic alveolitis, and episodes of bronchiolitis obliterans can cause diagnostic difficulty. The condition is characterized clinically by acute episodes of tachypnea and dyspnea, often with inspiratory rales and fever, appearing several hours after inhalation of organic dust that contains a wide variety of antigenic material from thermophilic organisms, birds, animal proteins, chemicals, or drugs.

Some of these antigens are encountered only in the working environment. Hypersensitivity pneumonitis also may be caused by inhalation of high doses of fungi, including *Trichosporum*, *Alternaria*, *Aspergillus*, and *Penicillium*. Allergic alveolitis is an important occupational disease and is seen only rarely in children and adolescents. Exposure to birds (pigeon breeder's disease) is the most common and best studied pediatric hypersensitivity pneumonitis. Severe alveolitis has been recorded in mushroom workers. Of more general importance is the occurrence of sensitivity reactions to thermophilic actinomycetes and *Aspergillus* in office cooling systems that use water contaminated with these organisms. Certain drugs, including belomycin, furazolidine, hydrochlorothiazide, and tetracyclines, also have been reported to cause allergic alveolitis after oral ingestion. Because of a delay in onset of symptoms following exposure to the causative agent, the patient may fail to notice a relationship. The symptoms usually resolve within 18 hr of onset but occasionally may persist for several days, unless treated with corticosteroids.

From the clinical perspective, the diagnosis should be suspected from a careful history. Typically, a person working in an exposed environment experiences increasing respiratory symptoms during the week and then improves remarkably over the weekend. Radiologic changes usually consist of patchy diffuse interstitial infiltrates, often more evident in the lower zones of the lungs. Lung function tests reveal

restrictive impairment of pulmonary function with reduced forced vital capacity. Morphological findings always include an interstitial infiltrate. In most cases, pneumonitis, interstitial fibrosis, and bronchiolitis are seen. Edema and pleural fibrosis are other common microscopic findings. Since the clinical radiologic and functional characteristics are sufficiently well defined, a lung biopsy is not usually required to confirm the diagnosis in the presence of a clear history of exposure to a known precipitating agent.

The condition is, at least in part, immunologically mediated. Antigens inducing reactions are small enough to reach the bronchial tree, where they are processed by pulmonary macrophages. High titers of precipitating IgG antibodies against the causative antigens usually are found in the serum. Therefore, a type III reaction long was thought to be the major underlying pathogenic mechanism. These antibodies, however, may also be detected in up to 50% of asymptomatic similarly exposed individuals; therefore their presence is not conclusively indicative of the disease. Patients with farmer's lung disease have broad immune responses with elevated specific antibody levels against many common respiratory viruses and microorganisms compared with healthy persons, possibly indicating abnormal host responsiveness. More likely, the presence of precipitating IgG antibodies simply reflects antigen exposure. Although type III reactions appear to occur in these diseases, experimental and clinical studies indicate that type IV reactions involving monocytes and lymphocytes are more important in the pathogenesis of the pulmonary reaction. Possibly, the precipitating antibodies may play a protective role in antigen-clearing mechanisms. The antibody titers are, however, generally higher in symptomatic individuals.

Like asthma and atopic disease, genetic control of the pulmonary immune response is suggested by studies in humans and animals. However, no link to a particular haplotype has been confirmed to date. Pulmonary damage appears to develop after an immune response that combines both antigen-specific humoral antibodies and cellular hypersensitivity with mononuclear cells releasing lymphokines. Complement activation in the lung and irritant effects of thermophilic agents also may be important. Cellular hypersensitivity to organic dusts may lead to hypersensitivity pneumonitis, after being triggered by a nonspecific inflammatory process such as respiratory infection.

Allergic alveolitis often is associated strongly with the conditions of the workplace. As indicated by the many names given to the condition, a continued exposure to inhalation of organic material, for example, on farms and in saw mills, once was very common. Today, home and office air conditioning systems may present specific hazards of hypersensitivity pneumonitis. This disorder may be a contributing factor to the "sick building" syndrome and, thus, be one of several diseases and symptoms associated with poorly ventilated, faultily constructed buildings.

Although complete recovery from allergic alveolitis does occur, residual abnormality with dyspnea is common. Suspected causative agents may be confirmed by challenge testing after the acute episode is over. The disease can cause long-term effects if repeated exposures occur. Farmer's lung can be prevented entirely by an intensive educational pro-

gram and by wearing a mask when exposure is likely. Families in which severe cases of allergic alveolitis occur as a result of exposure to pet birds should be advised on the importance of avoiding exposure. In homes and offices, care should be taken to avoid microbial contamination of humidifiers, if the machines are used at all.

## IX. OTHER HYPERSENSITIVITY DISORDERS OF THE RESPIRATORY TRACT

Allergic bronchopulmonary aspergillosis (ABA) is an immune bronchial disease that occurs in asthmatics and is characterized by pulmonary infiltrates and eosinophilia in blood and sputum (Slavin, 1985; Massie, 1988). Skin testing with *Aspergillus fumigatus* antigen usually reveals a dual reaction with an immediate (within 20 min) and a late (after 4–8 hr) response. The immediate, and possibly also the late, response is IgE mediated. Also IgG, IgM, and IgA antibodies against the fungus are often detectable, but histological examination does not support their role in the pathogenesis. Roentgenographic findings in ABA vary according to disease activity, and include bronchial wall edema, inflammation, obstruction, and infiltrates, predominantly in the upper lobes. In advanced cases, central bronchiectasia appears as hilar shadows, cavitation, fibrosis, and contracted upper lobes. Determined corticosteroid therapy is the preferred treatment.

The typical patient with chronic obstructive pulmonary disease (COPD) in adults presents with a mixed form of chronic bronchitis and emphysema, with wheezing similar to that in asthma. This condition may be complicated by manifestations of right-sided heart failure. Cigarette smoking is the major cause of COPD. The condition often is lumped together with other obstructive lung disease, including chronic bronchitis and emphysema of various etiologies. Although this assessment may be reasonable with respect to clinical symptoms, this tendency may result in overmediation for the severely emphysematic patient and in inadequate therapy for those with predominant chronic bronchitis. Clinically, physicians often recognize the reversible component of airway obstruction in elderly patients with COPD. Elevated IgE levels in serum also are a common finding, although a search for IgE antibodies against defined allergens in sera is usually negative (Itabaskis *et al.*, 1991). Possibly, the elevated IgE levels are secondary to increased airway mucosal permeability caused by mucosal epithelial damage from chronic inflammation. The goals of treatment of COPD include prevention of progression of the disease, treatment of potentially reversible components of the disease, and teaching patients to participate in their own management.

# Ocular Mucosal Immunity

David A. Sullivan

## I. INTRODUCTION

The secretory immune system of the eye defends the ocular surface against antigenic challenge (Franklin, 1989; Friedman, 1990; Sullivan, 1990). This immunological role is mediated primarily through secretory IgA (SIgA) antibodies, which are known to inhibit viral adhesion and internalization; prevent bacterial attachment, colonization, and activity; interfere with parasitic infestation; and reduce antigen-related damage in mucosal sites (Underdown and Schiff, 1986; Brandtzaeg, 1985; Mestecky, 1987; Mestecky and McGhee, 1987; Brown and Kloppel, 1989; Childers *et al.*, 1989; McGhee *et al.*, 1989; MacDonald *et al.*, 1990). Thus, the ocular secretory immune system appears to protect the eye against allergic, inflammatory, and infectious disease, thereby promoting conjunctival and corneal integrity and preserving visual acuity.

This chapter reviews the immunological architecture and regulation of the secretory immune system of the eye, and explores the impact of ocular infection and autoimmune disease on the structure and function of this system. For information on nonmucosal aspects of ocular immunity, for example, anterior chamber-associated immune deviation and retinal immunology, the reader is referred to several excellent reports (Gery *et al.*, 1986; Streilein, 1987; Usui *et al.*, 1990).

## II. ARCHITECTURE OF THE SECRETORY IMMUNE SYSTEM OF THE EYE

### A. Tissues Involved in Ocular Mucosal Immunity

The principal tissues involved in immunological protection of the ocular surface are the lacrimal gland and the conjunctiva. The lacrimal gland, which serves as the predominant source of tear SIgA antibodies (Sullivan and Allansmith, 1984; Peppard and Montgomery, 1987), is the primary effector tissue in the secretory immune defense of the eye (Franklin, 1989; Friedman, 1990; Sullivan, 1990). This gland contains a diverse array of lymphocytes, including plasma cells, T cells, B cells, dendritic cells, and macrophages (Table I; Figure 1). In humans, plasma cells represent the most numerous lymphocytic population, accounting for more than 50% of all mononuclear cells in lacrimal tissue (Weiczorek *et al.*, 1988). The vast majority of these plasma cells are IgA positive (Franklin *et al.*, 1973; Allansmith *et al.*, 1976a, 1985;

Brandtzaeg *et al.*, 1979, 1987; Gillette *et al.*, 1980; Crago *et al.*, 1984, 1984; Damato *et al.*, 1984; Brandtzaeg, 1985; Kett *et al.*, 1986; Weiczorek *et al.*, 1988) and express an IgA1/IgA2 subclass distribution that is either different from (Kett *et al.*, 1986) or similar to (Crago *et al.*, 1984; Allansmith *et al.*, 1985) that of other mucosal tissues. In addition, a high percentage of lacrimal IgA plasma cells, which are located in the gland's interstitium, synthesizes both J chain and polymeric IgA (pIgA; Brandtzaeg, 1985) that may bind secretory component (SC; Brandtzaeg, 1983). These cells are complemented by limited numbers of IgG, IgM, IgE, and IgD plasma cells (Franklin *et al.*, 1973; Allansmith *et al.*, 1976; Brandtzaeg *et al.*, 1979, 1987; Gillette *et al.*, 1980; Damato *et al.*, 1984; Weiczorek *et al.*, 1988), although the IgD-containing subset may increase during IgA deficiency (Brandtzaeg *et al.*, 1979). The second most frequent lymphocyte population in human lacrimal tissue consists of T cells, which are situated between acinar and ductal epithelial cells, throughout glandular interstitial regions, and within small periductular lymphoid aggregates (Weiczorek *et al.*, 1988; Pepose *et al.*, 1990). The distribution of T cells appears to vary topographically according to specific subclasses, including suppressor/cytotoxic and helper T cells (Weiczorek *et al.*, 1988; Pepose *et al.*, 1990), and presents with an overall helper : suppressor ratio of approximately 0.56 (Weiczorek *et al.*, 1988). Minor or rare populations of lacrimal lymphocytes include surface Ig-bearing B cells, Langerhans-type dendritic cells, monocyte-macrophages, and activated IL-2<sup>+</sup> T cells, which occur almost exclusively in periductular lymphocyte foci (Weiczorek *et al.*, 1988; Pepose *et al.*, 1990). These latter lymphoid aggregates, when present, typically appear as primary follicles without germinal center formation and, theoretically, may be involved in antigen processing (Weiczorek *et al.*, 1988).

The human lacrimal gland also

1. produces lysozyme (Gillette *et al.*, 1980, 1981), and SC (Franklin *et al.*, 1973; Allansmith and Gillette, 1980; Gillette *et al.*, 1980), the pIgA antibody receptor (Underdown and Schiff, 1986; Brandtzaeg *et al.*, 1987; Brown and Kloppel, 1989) in acinar and ductal epithelium
2. synthesizes lactoferrin (Gillette and Allansmith, 1980; Gillette *et al.*, 1980) and convertase decay-accelerating factor, which protects against autologous complement activation (Lass *et al.*, 1990), in acinar cells
3. expresses HLA-DR antigens on B cells, dendritic cells,

ductule epithelium (Wieczorek *et al.*, 1988) and certain acini (Mircheff *et al.*, 1991)

- contains lymphatic channels that drain into local cervical and preauricular lymph nodes (Iwamoto and Jakobiec, 1989)

With respect to human accessory lacrimal tissue, its immunological characteristics appear to be identical to those of the major lacrimal gland (Gillette *et al.*, 1980,1981; Sacks *et al.*, 1986).

Lacrimal tissues of rats, rabbits, cows, and mice also seem to share the immune features of the human gland (Table I). Thus, rat lacrimal glands contain a pronounced population of IgA plasma cells (Gudmundsson *et al.*, 1985a; Sullivan *et al.*, 1986,1990a,1990/91; Allansmith *et al.*, 1987; Hann *et al.*, 1988; Sullivan and Hann, 1989), which undergo a striking age-related increase in density from infancy to adulthood (Hann *et al.*, 1988; Sullivan *et al.*, 1990a). These cells are accompanied by IgG and IgM plasma cells (Gudmundsson *et al.*, 1985a; Allansmith *et al.*, 1987; Hann *et al.*, 1988; Sullivan *et al.*, 1990a), immature suppressor/cytotoxic and helper T cells (Gudmundsson *et al.*, 1988; Pappo *et al.*, 1988; Montgomery *et al.*, 1989,1990), surface Ig-bearing B cells (Pappo *et al.*, 1988; Montgomery *et al.*, 1989,1990) that proliferate in response to mitogen exposure (Pappo *et al.*, 1988), phagocytic macrophages that express Fc receptors and Ia antigens (Pappo *et al.*, 1988), and rare mast cells (Gudmundsson *et al.*, 1984). Moreover, acinar cells from rat lacrimal tissue synthesize and secrete SC (Sullivan *et al.*, 1984b,1990b; Gudmundsson *et al.*, 1985a; Hann *et al.*, 1989, 1991; Kelleher *et al.*, 1991; Lambert *et al.*, 1993) which appears to transport pIgA into tears against an apparent concentration gradient (Allansmith *et al.*, 1987; Sullivan and Allansmith, 1988; Sullivan and Hann, 1989b). Similarly, lacri-

mal glands of cows (Butler *et al.*, 1972), rabbits (Shimada and Silverstein, 1975; Franklin *et al.*, 1979), and mice (McGee and Franklin, 1984) either produce IgA or harbor plasma cell populations that are predominantly IgA positive and, at least in rabbits, contain acinar and ductal cells that produce SC (Franklin *et al.*, 1979). However, periductular lymphoid aggregates appear to be very uncommon in lacrimal tissues of these species, except under pathological conditions (e.g., autoimmune disorders; Kessler, 1968; Mizejewski, 1978; Hoffman *et al.*, 1984; Jabs *et al.*, 1985; Liu *et al.*, 1987; Jabs and Prendergast, 1988; Ariga *et al.*, 1989; Liu, 1989; Vendramini *et al.*, 1991; Sato *et al.*, 1991).

The primary origin of IgA-containing lymphocytes and T cells in the lacrimal gland remains to be determined, but may, in part, be local cervical (Brandtzaeg *et al.*, 1979; Ebersole *et al.*, 1983), distant peripheral (Montgomery *et al.*, 1985; O'Sullivan and Montgomery, 1990), and gut-associated lymphoid tissue (Montgomery *et al.*, 1983; O'Sullivan and Montgomery, 1990), as well as the thoracic duct (O'Sullivan and Montgomery, 1990), spleen (McGee and Franklin, 1984), and mammary gland (Montgomery *et al.*, 1985). The migration of lymphocytes into the lacrimal gland appears to be random (McGee and Franklin, 1984), yet the selective retention and heterogeneous distribution of IgA-containing cells within lacrimal tissue is not random (Sullivan *et al.*, 1990/91) and may be stimulated by antigenic challenge (Jackson and Mestecky, 1981; Allansmith *et al.*, 1987) and regulated by microenvironmental (Franklin, 1981; Pockley and Montgomery, 1990/91a), endocrine (Sullivan *et al.*, 1986; Hann *et al.*, 1988; Sullivan and Hann, 1989a), neural (Walcott *et al.*, 1986; Franklin *et al.*, 1988,1989; Oeschger *et al.*, 1989; Sullivan *et al.*, 1990/91), T-cell (Franklin *et al.*, 1985; Franklin, 1989; Franklin and Shepard, 1990/91), or acinar epithelial-cell (Franklin *et al.*, 1985) signals. The lymphocytic accumulation

**Figure 1** Schematic representation of the secretory immune system of the human lacrimal gland. Topographical features include acinar cells, which contain endoplasmic reticulum (ER) and lysozyme- and lactoferrin-positive zymogen granules (ZG), and synthesize and secrete SC (termed secretory piece); myoepithelial cells, which are adjacent to acinar cells and surrounded by a basement membrane (BM); interstitial plasma cells, which are the primary lymphoid cell and produce principally IgA, but also some IgG, IgM, or IgD; T helper (Th) and suppressor (Ts) cells, which are distributed throughout the interstitium, the intercellular spaces between acinar or ductal cells, and the periductular lymphoid aggregates; B cells (B), OKT6<sup>+</sup> Langerhans-type dendritic cells (DC), and OKM1<sup>+</sup> monocyte-macrophages, predominantly located in periductular lymphoid aggregates, which most often appear as primary follicles without germinal center formation and may be active in antigen processing; and unlabeled darkened cells, which refer to circulating T or B lymphocytes, which may originate in other mucosal tissues (e.g., intestinal Peyer's patch) and, if not retained locally, possibly exit the lacrimal gland through lymphatic channels to regional cervical or preauricular lymph nodes. Immunoglobulin A is secreted by plasma cells (1), bound by SC on the acinar cell basolateral membrane (2,3), transported in distinct vesicles (4), and released at the apical surface as sIgA into tear-containing lumina (5). [This figure has been reproduced and published, courtesy of *Ophthalmology* (1988), 95:100–109.]

in, or adherence to, lacrimal tissue appears to require calcium as well as functional oxidative phosphorylation and contractile microfilament systems, and to depend on cell-surface protein and carbohydrate determinants (O'Sullivan and Montgomery, 1990).

In addition to the lacrimal gland, the conjunctiva has been postulated to play an active role in both inductive and effector

actions of the ocular secretory immune system (Chandler and Gillette, 1983; Franklin and Remus, 1984; Franklin, 1989; Tagawa *et al.*, 1989; Allansmith and Ross, 1991). In support of this hypothesis, the rabbit conjunctiva contains a substantial number of IgA, and occasional IgG and IgM, plasma cells in the substantia propria and numerous T and B cells in specialized lymphoid follicles (Shimada and Silverstein, 1975;

Franklin *et al.*, 1979; Franklin and Remus, 1984). Moreover, rabbit conjunctival B cells may be induced to differentiate into IgA-positive cells by mitogen stimulation (Franklin and Remus, 1984) and the rabbit conjunctival epithelium produces SC (Franklin *et al.*, 1979; Liu *et al.*, 1981). Since investigators also have reported the presence of plasma cells (Allansmith *et al.*, 1976a; Bhan *et al.*, 1982; Tagawa *et al.*, 1989); T cells (Bhan *et al.*, 1982; Sacks *et al.*, 1986; Tagawa *et al.*, 1989); HLA-DR-positive epithelial, stromal (Lee *et al.*, 1990/91), and Langerhans cells; interdigitating dendritic cells; macrophages; neutrophils (Sacks *et al.*, 1986); mast cells (Allansmith *et al.*, 1978a; Allansmith and Ross, 1991); and lymphatic channels (Srinivasan *et al.*, 1990) in human conjunctival tissue, these findings might indicate that the conjunctiva is involved in antigen processing, lymphocyte migration, and ocular secretory immune defense (Chandler and Gillette, 1983). However, this conclusion is somewhat controversial and perhaps not entirely correct.

1. The evidence for plasma cell existence in normal human conjunctiva appears tenuous: plasma cell identification by light microscopy could not be verified by immunofluorescent staining for cell-associated IgA, IgG, IgM, IgD, or IgE (Allansmith *et al.*, 1976b) and plasma cell enumeration in another study was performed with an antibody that cross-reacted with T cells (Bhan *et al.*, 1982). In contrast, more recent investigations have demonstrated a complete absence of plasma cells in conjunctival tissue of humans (Sacks *et al.*, 1986) and rats (Gudmundsson *et al.*, 1985a). Instead, the majority of lymphocytes in human conjunctiva appears to be primarily suppressor/cytotoxic T cells, with a smaller population of helper T cells that are distributed in a subclass-dependent manner throughout the epithelium and substantia propria of the forniceal, tarsal, and epibulbar conjunctiva (Sacks *et al.*, 1986).

2. B cells (Bhan *et al.*, 1982; Sacks *et al.*, 1986) and activated T cells (Sacks *et al.*, 1986) rarely are observed in human conjunctiva.

3. SC is not synthesized or expressed in either human (Allansmith and Gillette, 1980) or rat (Sullivan *et al.*, 1984b; Gudmundsson *et al.*, 1985a) conjunctival epithelium. Although one study has reported SC, as well as IgA and IgG, synthesis in human conjunctival biopsies (Lai *et al.*, 1973), tissue samples may have contained accessory lacrimal tissue.

4. The conjunctival epithelium in humans (Sacks *et al.*, 1986) and rats (Setzer *et al.*, 1987) does not possess specialized cells for antigen sampling, as found in the intestine (Owen, 1977), or lung (Bienenstock, 1985), and appears to limit severely the passage of most antigens because of structural size and molecular weight restrictions (Huang *et al.*, 1989; Kahn *et al.*, 1990). Therefore, the normal human or rat conjunctiva seems unlikely to synthesize IgA, transport IgA antibodies to the ocular surface, or play a direct and significant role in B-cell maturation or migration.

Nevertheless, the conjunctiva does contain the immunological capacity for antigen processing, cell-mediated immunity,

and hypersensitivity responses (e.g., Allansmith *et al.*, 1981, 1983; Chandler and Gillette, 1983; Hann *et al.*, 1985; Cornell-Bell *et al.*, 1986; Sacks *et al.*, 1986; Abelson and Smith, 1991).

As concerns the cornea, this tissue does not actively provide immune protection for the anterior surface of the eye. The cornea possesses interstitial IgA, IgG, IgM, IgD, and IgE (Allansmith *et al.*, 1978b), which appear to originate from serum, diffuse from the limbal to central regions, and require extended time periods (months) for complete turnover (Verhagen *et al.*, 1990). However, lymphocytes (Allansmith *et al.*, 1978b) and differentiated Langerhans cells (Seto *et al.*, 1987) are essentially absent from, and SC is not produced by (Allansmith and Gillette, 1980), the avascular corneal epithelium and stroma. The cornea, though, is certainly susceptible to viral (e.g., Sabbaga *et al.*, 1988; Bale *et al.*, 1990; Pavan-Langston, 1990), bacterial (e.g., Hazlett *et al.*, 1981a; Snyder and Hyndiuk, 1988) or other antigenic (e.g., graft; Smolin and O'Connor, 1981) challenge, and the possible ensuing vascularization or inflammation may impair corneal function and vision significantly (Smolin and O'Connor, 1981; Theodore *et al.*, 1983).

Other tissues, organisms, and factors involved in mucosal defense of the eye (Smolin, 1985) include:

1. the orbital skeletal structure, which minimizes potential trauma
2. the eyelid architecture, which is relatively impermeable to macromolecules
3. the eyelid blink reflex and ciliary movement, which rapidly clear foreign objects from the ocular surface
4. the resident conjunctival populations of nonpathogenic bacteria, consisting of aerobes and facultative and obligate anaerobes, which may curtail the ability of invasive bacteria to attach and colonize (McNatt *et al.*, 1978)
5. the continuous tear flow and reflex tearing, which act to remove microorganisms and cellular debris through hydrokinetics and eventual drainage into the nasolacrimal duct

## **B. Role of the Tear Film in Ocular Surface Defense**

The precocular tear film plays a critical role in the defense of the eye against microbial and antigenic exposure, as well as in the maintenance of corneal clarity and visual ability (Holly, 1987). These functions are extremely dependent on the stability, tonicity, and composition of the tear film structure, which includes an underlying mucin foundation, a considerable middle aqueous component, and an overlying lipid layer (Holly, 1987; Whitcher, 1987). Alteration, deficiency, or loss of the tear film may increase significantly the susceptibility to ocular surface desiccation and infection, corneal ulceration and perforation, and marked visual impairment and blindness (Lamberts, 1983; Whitcher, 1987; Lubniewski and Nelson, 1990).

With respect to immune protection, the tear film contains numerous components (Gachon *et al.*, 1979; van Haeringen, 1981; Bron and Seal, 1986; Smolin, 1987) that combine to

provide both specific and nonspecific immunological activity (Tables II and III). Specific immunity is mediated primarily through the action of IgA antibodies, which are the predominant immunoglobulin in tears of humans (Josephson and Weiner, 1968; Table III) and experimental animals (Butler *et al.*, 1972; Hazlett *et al.*, 1981b; Sullivan and Allansmith, 1985, 1987; Gudmundsson *et al.*, 1985; Wells and Hazlett, 1985; Sullivan and Hann, 1989a; Sullivan *et al.*, 1992a), occur almost entirely in polymeric form (Delacroix *et al.*, 1982; Delacroix and Vaerman, 1983; Gudmundsson *et al.*, 1985a; Allansmith *et al.*, 1985; Coyle *et al.*, 1987, 1989), and originate from local production in lacrimal gland plasma cells (Butler *et al.*, 1972; Chao *et al.*, 1980; Janssen and van Bijsterveld, 1983; Sullivan and Allansmith, 1984; Peppard and Montgomery, 1987). In humans, tear IgA is distributed almost equally among IgA1 and IgA2 subclasses (Delacroix *et al.*, 1982; Fullard and Snyder, 1990; Fullard and Tucker, 1991). Most tear IgA appears to be transported by and bound to SC, which is synthesized and secreted by lacrimal epithelial cells (Franklin *et al.*, 1973; Allansmith and Gillette, 1980; Gillette *et al.*, 1980; Sullivan *et al.*, 1984b; Gudmundsson *et al.*, 1985a; Hann *et al.*, 1989, 1991; Sullivan *et al.*, 1990b; Kelleher *et al.*, 1991; Lambert *et al.*, 1993) and is present in the tear film as an SIgA conjugate or as free SC (Gachon *et al.*, 1979; Delacroix and Vaerman, 1983; Sullivan *et al.*, 1984a; Sullivan and Allansmith, 1984, 1987, 1988; Gudmundsson *et al.*, 1985a; Watson *et al.*, 1985; Sullivan *et al.*, 1988; Coyle *et al.*, 1989; Sullivan and Hann, 1989a). The high concentrations of SIgA coexist with low levels of IgG and very limited quantities of IgM and IgE (Table III; Sullivan and Hann, 1989a; Sullivan *et al.*, 1990c). Tear IgG may be derived, in part, from lacrimal tissue synthesis (Butler *et al.*, 1972; Chao *et al.*, 1980; Janssen

and van Bijsterveld, 1983), after which it moves down a steep concentration gradient into tears (Sullivan and Allansmith, 1988; Sullivan and Hann, 1989a; Sullivan *et al.*, 1990c), as well as from serum, after deposition in and passage through the conjunctival or lacrimal gland interstitium (McGill *et al.*, 1984; Fullard and Snyder, 1990; Fullard and Tucker, 1991; D. A. Sullivan, unpublished data). The source of tear IgM may be lacrimal tissue (Fullard and Snyder, 1990; Fullard and Tucker, 1991), whereas the origin of IgE in normal tears has yet to be determined. No IgD has been detected in the tear film (McClellan *et al.*, 1973; Bluestone *et al.*, 1975; Sen *et al.*, 1976, 1978). It is important to note that the concentration of tear immunoglobulins, as shown in Table III, may be influenced significantly by the method of tear collection, the extent of tear stimulation, and the procedures that involve processing of tear samples (van Haeringen, 1981; Stuchell *et al.*, 1984; Fullard, 1988; Tuft and Dart, 1989; Fullard and Snyder, 1990; Fullard and Tucker, 1991; Kuizenga *et al.*, 1991). In addition, although tear Ig levels do not appear to display diurnal rhythms (Horwitz *et al.*, 1978), IgA concentrations may be exceedingly high after prolonged closure of the eyelids (Sack *et al.*, 1991).

Additional specific and nonspecific agents in human tears that support ocular mucosal immunity follow.

**Table II** Specific and Nonspecific Immunological Factors in Tears of Individuals without Ocular Pathology

Secretory immunoglobulin A	Ceruloplasmin
Monomeric immunoglobulin A	Prostaglandin E <sub>2</sub>
Immunoglobulin G	Tear-specific prealbumin
Immunoglobulin M	Histamine
Immunoglobulin E	Properdin factor B
Secretory component	Leukotrienes
Lysozyme	Complement (C3, C3 activator)
Lactoferrin	Anti-complement factor
$\beta$ -Lysin	Complement decay-accelerating factor
Peroxidase	Superoxide radical producing system
Transferrin	Anti-chlamydial factor
Plasminogen activator	Lysosomal enzymes
$\alpha$ 1-Antitrypsin	Antibiotic-producing bacteria
$\beta$ 2-Macroglobulin	T cells
$\alpha$ 1-Antichymotrypsin	B cells
Inter- $\alpha$ -trypsin inhibitor	Macrophages
$\alpha$ 2-Macroglobulin	Polymorphonuclear leukocytes

1. Lysozyme and lactoferrin, which are secreted by the lacrimal gland (Gillette and Allansmith, 1980; Gillette *et al.*, 1980, 1981), represent major tear components (van Haeringen, 1981; Gachon, 1982/83) and possess antibacterial activity (Smolin, 1987). Lactoferrin also may prevent activation of the classical complement pathway through inhibition of C3 convertase and may modulate ocular inflammatory reactions (Kijlstra, 1990/91).
2.  $\beta$ -Lysin may rupture bacterial cell membranes (Ford *et al.*, 1976). The presence of this substance in human tears is controversial (Selsted and Rafael, 1982; Janssen *et al.*, 1984).
3. Complement factors C3 and C3 activator, properdin and properdin factor B (Chandler *et al.*, 1974; Bluestone *et al.*, 1975; Yamamoto and Allansmith, 1979; Liotet *et al.*, 1982; Ballow *et al.*, 1985; Smolin, 1987), as well as anti-complement (Kijlstra and Veerhuis, 1981) and convertase decay-accelerating (Medof *et al.*, 1987; Lass *et al.*, 1990) factors are present. In certain eye diseases, tear IgA appears to fix complement (Barnett, 1968).
4. Nonlysozyme antibacterial factor (NLAF), which inhibits growth of staphylococci (Thompson and Gallardo, 1941) actually may be  $\beta$ -lysin (Ford *et al.*, 1976); its presence is controversial (van Haeringen, 1981; Selsted and Rafael, 1982; Janssen *et al.*, 1984).
5. Anti-chlamydial factor is a heat-stable substance that reduces *Chlamydia* attachment (Elbagir *et al.*, 1989).
6. Peroxidase (van Haeringen *et al.*, 1979; Fullard and Snyder, 1990; Fullard and Tucker, 1991) may exert bactericidal, viricidal, and fungicidal activity, as observed in other secretions, given appropriate levels of H<sub>2</sub>O<sub>2</sub> and oxidizable cofactors (De *et al.*, 1987). Such peroxidase functions, however, may not operate

through the thiocyanate–H<sub>2</sub>O<sub>2</sub> system, because tear thiocyanate concentrations are suboptimal (van Haeringen *et al.*, 1979).

7. Plasminogen activator (van Haeringen, 1981) is chemotactic for leukocytes (Bron, 1988).
8. Histamine, prostaglandins, and leukotrienes most likely derive from conjunctival mast cell production (van Haeringen, 1981; Gluud *et al.*, 1985; Abelson and Smith, 1991; Allansmith and Ross, 1991).
9. Antiproteases (e.g.,  $\alpha$ 1-antitrypsin) are found (Zirm *et al.*, 1976; van Haeringen, 1981; Liotet *et al.*, 1982).
10. Lysosomal enzymes are present (Yamaguchi *et al.*, 1989).
11. Specific tear prealbumin and transferrin may have antibacterial actions (van Haeringen, 1981; Selsted and Rafael, 1982).
12. Ceruloplasmin may reduce viral infectivity and also may act as a superoxide dismutase (Bron and Seal, 1986).
13. Antibiotic-producing bacteria, primarily staphylococci, apparently occur frequently among ocular flora (Halbert and Swick, 1952).
14. A superoxide radical-producing system, which exhibits bactericidal activity, is situated within conjunctival mucus threads (Proctor *et al.*, 1977).
15. A low density of T and B lymphocytes, plasma cells, macrophages, and polymorphonuclear leukocytes has been identified in the normal tear film (Coyle and Bulbank, 1989).

### III. IMMUNE RESPONSE OF THE OCULAR SECRETORY IMMUNE SYSTEM TO ANTIGENIC CHALLENGE

#### A. Organisms and Naturally Occurring or Induced Antibodies in Human Tears

In human tears, a diverse array of bacterial and viral organisms has been identified, including *Staphylococcus epidermidis*, *Corynebacterium* (Gregory and Allansmith, 1986,1987), *Staphylococcus aureus*, *Pneumococcus*, *Pseudomonas pyocyanea*, *Streptococcus viridans*, *Streptococcus pyogenes*, *Proteus vulgaris*, *Klebsiella pneumoniae*, *Escherichia coli*,  $\alpha$ -hemolytic streptococci (Sen and Sarin, 1982), HTLV-III (Ablashi *et al.*, 1987), hepatitis B virus (Gastaud *et al.*, 1989), coxsackievirus (Langford *et al.*, 1980), herpesvirus 1 (Shani *et al.*, 1985; Fox *et al.*, 1986; Wilhelmus *et al.*, 1986), and cytomegalovirus (Cox *et al.*, 1975). Moreover, lacrimal tissue of healthy adults may contain both cytomegalovirus and Epstein–Barr virus (PePOSE *et al.*, 1990; Pflugfelder *et al.*, 1990a,b). Perhaps in response to these and other microbial exposures, tears may harbor a variety of naturally occurring or induced IgG or SIgA antibodies against numerous antigens, including herpes simplex virus 1 (Little *et al.*, 1969; Norrild *et al.*, 1982; Pedersen *et al.*, 1982; Fox *et al.*, 1986; Coyle and Sibony, 1988), Epstein–Barr virus, varicella

zoster virus, rubella, mumps, cytomegalovirus (Coyle and Sibony, 1988), measles (Coyle and Sibony, 1988; Friedman *et al.*, 1989), adenovirus (Nordbo *et al.*, 1986), influenza virus (Waldman and Bergman, 1987), rhinovirus (Douglas *et al.*, 1967), human immunodeficiency virus (HIV; Liotet *et al.*, 1987), *S. epidermidis*, *Streptococcus mutans* serotypes c and d, a *Corynebacterium* species (Burns *et al.*, 1982; Gregory *et al.*, 1984; Gregory and Allansmith, 1986,1987), *Chlamydia trachomatis* (Treharne *et al.*, 1978; Herrmann *et al.*, 1991), and other allergens (Ballow *et al.*, 1983; Kari *et al.*, 1985). These antibodies, although sometimes expressed in quiescent eyes (Waldman and Bergman, 1987; Coyle and Sibony, 1988), may increase in concentration significantly during active infection (refer to Table VI). The levels of natural tear IgA antibodies against bacterial organisms have been suggested to be either dependent on (Gregory and Allansmith, 1987) or independent of (Burns *et al.*, 1982) local antigenic stimulation.

#### B. Ocular Immune Response to Defined Antigens

Antigenic challenge to the surface of the eye may result in a marked accumulation of specific SIgA, IgG, and IgM antibodies in tears (Table IV); an accelerated and enhanced anamnestic response after secondary exposure (Mestecky *et al.*, 1978; Gregory *et al.*, 1984; MacDonald *et al.*, 1984; Gregory and Filler, 1987; Levenson *et al.*, 1988); and the generation of immune resistance to, and protection against, antigen reapplication (Table V; also Malaty *et al.*, 1988). In addition, definitive ocular immune responses, as well as the possible accumulation of Ig-containing cells in lacrimal tissue (Jackson and Mestecky, 1981; Allansmith *et al.*, 1987), may be stimulated by antigenic challenge to other sites, including subconjunctival, intracorneal, intravitreal, oral, intrabronchial, gastric, intraduodenal, intravenous, subcutaneous, intradermal, or intramuscular sites (Table IV). The nature (e.g., antibody isotype), extent, and kinetics of these immune reactions appear to be very dependent on the form (e.g., live versus inactivated microorganisms; strain), concentration, route, duration, and frequency of antigen administration: potential immune responses may be augmented, intermittent, suppressed, or absent (Banyard and Morris, 1980; Montgomery *et al.*, 1983,1984a,b; Mondino *et al.*, 1987a, 1991; Peppard *et al.*, 1988; Centifanto *et al.*, 1989; Hall and Pribnow, 1989). Moreover, the magnitude of induced ocular immunity may be altered by the use of adjuvants (e.g., Peppard *et al.*, 1988; Peppard and Montgomery, 1990) and may be influenced by the concurrent state of systemic immunity (Waldman and Bergmann, 1987; Bergmann *et al.*, 1987).

The mechanism by which antigenic exposure to the surface of the eye stimulates a local (e.g., IgA) immune response remains to be elucidated. Direct antigen transfer across the conjunctival epithelium (Huang *et al.*, 1989; Kahn *et al.*, 1990) or countercurrent passage through the lacrimal duct (Sullivan *et al.*, 1990c) appears to be restricted severely. Further, the immunological architecture of healthy lacrimal tissue appears to be limited in its capacity to process and present antigen effectively (Weiczorek *et al.*, 1988). Conse-

<sup>a</sup> The route of antigen exposure does not convey information about the frequency of antigen application, that is, antigens may have been administered once or multiple times via the specific route. If different routes were used, the sequence of use is given and the routes are separated by a slash. In addition, if primary and secondary immunizations by one route yielded different responses, a distinction is made between these challenges.

<sup>b</sup> Abbreviations: CFA, complete Freund's adjuvant; IFA, incomplete Freund's adjuvant.

<sup>c</sup> The use of sequential antigen administration at different times is designated by a slash.

<sup>d</sup> Note, oral doses given with cholera toxin.

quently, the ocular secretory immune response to infectious or toxic substances may require antigenic clearance through the nasolacrimal duct and stimulation of gut-associated lymphoid tissue. Consistent with this hypothesis are the following observations:

1. Topical application of noninvasive antigens to the rat ocular surface appears to result in passage through the nasolacrimal canal into the gastrointestinal tract, and not retrograde transfer to the lacrimal gland or lymphatic drainage into local lymph nodes (Sullivan *et al.*, 1990a).
2. Intranasal, oral, or gastric administration of bacteria, viruses, or other antigens may induce the accumulation of specific tear IgA antibodies and the generation of ocular surface protection (Mestecky *et al.*, 1978;

Nichols *et al.*, 1978; Montgomery *et al.*, 1983,1984a,b; Gregory *et al.*, 1984; Bergmann *et al.*, 1986,1987; Czerkinsky *et al.*, 1987; van Zaane *et al.*, 1987; Waldman and Bergman, 1987; Peppard *et al.*, 1988; Peppard and Montgomery, 1990).

This remote-site stimulation most likely would involve IgA lymphoblast migration from mesenteric and peripheral lymph nodes, spleen, and thoracic duct lymph to the lacrimal gland (Montgomery *et al.*, 1983,1985; McGee and Franklin, 1984; O'Sullivan and Montgomery, 1990), followed by local antibody production and transport to the ocular surface. In contrast, the contribution of serum IgA antibodies to ocular surface defense appears to be minimal or nonexistent (Sullivan and Allansmith, 1984; Montgomery *et al.*, 1984a,b; Bergmann *et al.*, 1987; Czerkinsky *et al.*, 1987; Peppard and Mont-

gomery, 1987; Lue *et al.*, 1988). IgG antibodies from serum, however, may play a significant role in certain inflammatory disorders of the eye (Chandler *et al.*, 1974; Mackie and Seal, 1984; Seal, 1985; Wilhelmus *et al.*, 1986; Gupta and Sarin, 1983). Overall, ocular immune protection may be conferred

by both local and distant antigenic exposure; lacrimal tissue acts at least as a recipient of committed IgA-containing cells that elaborate antigen-specific antibodies. However, the development of an optimal strategy to promote secretory immunity in the eye has yet to be established.

### C. Influence of Ocular or Systemic Disease or Contact Lens Wear on the Secretory Immune System of the Eye

As demonstrated in Table VI, various ocular and systemic diseases, as well as contact lens wear, may influence secretory immune expression in the human eye significantly. Thus, bacterial, viral, and fungal infections of the ocular surface; exposure to allergens; endocrine abnormalities; or graft-versus-host disorders may increase levels of specific antibodies, total immunoglobulins, complement proteins, and non-specific immune factors significantly or may induce changes in the lymphocytic profile of the conjunctiva. Interestingly, if pathological alterations are evident in only one eye, immune responses may (Krichevskaya *et al.*, 1980; Shani *et al.*, 1985) or may not (Centifanto *et al.*, 1970; Hall and O'Connor, 1970) occur in the contralateral unaffected eye. With respect to contact lenses, these may bind (Gudmundsson *et al.*, 1985b) and also cause modifications in the concentrations of (Table VI) immune components in the tear film; the precise immunological effects may depend on the composition of lens material, the efficacy of cleaning regimens, and the length of wear (Manucci *et al.*, 1984; Vinding *et al.*, 1987; Temel *et al.*, 1991).

In contrast, such conditions as IgA deficiency, intrauterine infection, ocular surgery, keratoconjunctivitis sicca, malnutrition, and autoimmune disease often may suppress ocular mucosal immunity (Table VI). For example, severe malnutrition may lead to a significant decrease in tear IgA and SC concentrations, a diminished number of IgA-containing cells in lacrimal tissue, and a blunted SIgA antibody response to infectious challenge (McMurray *et al.*, 1977; Watson *et al.*, 1977, 1985; Sullivan *et al.*, 1990d; Sullivan *et al.*, 1993). Similarly, autoimmune disorders such as multiple sclerosis or Sjögren's syndrome may alter or disrupt immune function in the eye significantly. Multiple sclerosis, an autoimmune disease of possible viral origin, is associated with heightened levels of monomeric IgA and lymphocytes, and reduced amounts of SC, in tears of afflicted individuals (Coyle and Sibony, 1987; Coyle, 1989; Coyle and Bulbank, 1989). Sjögren's syndrome, an autoimmune disease that occurs almost exclusively in females, is characterized by a progressive lymphocytic infiltration into the lacrimal gland, an immune-mediated destruction of lacrimal acinar and ductal epithelial cells, decreased tear IgA content, and keratoconjunctivitis, sicca (Tabbara, 1983; Boukes *et al.*, 1987; Moutsopoulos and Talal, 1987; Talal and Moutsopoulos, 1987; Kincaid, 1987). Further, in experimental models of this complex disorder, generation of autoantibodies to (Ohashi *et al.*, 1985) and deposition of IgG, IgA, and complement in ductal epithelial cells of (DeLuise *et al.*, 1982) lacrimal tissue may accompany the striking glandular inflammation (Kessler, 1968; Hoffman *et al.*, 1984; Jabs *et al.*, 1985; Jabs and Prendergast, 1988; Ariga *et al.*, 1989; Vendramini *et al.*, 1991; Sato *et al.*, 1992). The etiology of Sjögren's syndrome may involve the endocrine system (Ahmed *et al.*, 1985, 1989; Raveche and Steinberg, 1986; Nelson and Steinberg, 1987; Talal and Ahmed, 1987; Ahmed and Talal, 1990; Carlsten *et al.*, 1990),

but also may be the result of primary infection with and reactivation of Epstein-Barr virus, cytomegalovirus, herpes virus-6, or retroviruses. These viruses have been identified in lacrimal or salivary tissues of Sjögren's syndrome patients (Burns, 1983; Fox *et al.*, 1986; Fox, 1988; Garry *et al.*, 1990; Krueger *et al.*, 1990; Prepose *et al.*, 1990; Pflugfelder *et al.*, 1990a,b; Mariette *et al.*, 1991) and may stimulate the inappropriate epithelial-cell HLA-DR expression, T helper/inducer-cell activation, B-cell hyperactivity, and autoantibody production evident in these affected tissues (Maini, 1987; Moutsopoulos and Talal, 1987; Fox, 1988; Venables, 1989). In support of this possibility, certain viral infections in experimental animals exert a striking impact on the lacrimal gland and induce a periductular infiltration of plasma cells, lymphocytes, and macrophages; distinct nonsuppurative periductular inflammation; significant interstitial edema; widespread necrosis of the acinar and ductal epithelium; degenerative and atrophic alterations in epithelial cells; diminished tear flow; and keratoconjunctivitis sicca (Jacoby *et al.*, 1975; Lai *et al.*, 1976; Percy *et al.*, 1984, 1990; Green *et al.*, 1989). Moreover, research has demonstrated that herpes viruses (e.g., cytomegalovirus) and coronaviruses (e.g., sialodacryoadenitis virus) may invade and replicate in rat lacrimal gland acinar cells (Huang *et al.*, 1993; Wickham *et al.*, 1992); Epstein-Barr virus may bind to specific receptors in ductal epithelium of the human lacrimal gland (Levine *et al.*, 1990/91); and HIV infection may predispose patients to keratoconjunctivitis sicca (Couderc *et al.*, 1987; Ulirsch and Jaffe, 1987; deClerck *et al.*, 1988; Lucca *et al.*, 1990). However, the precise role of viruses in the induction of autoimmune disease, as well as the mechanism by which viral infection may interfere with lacrimal gland function and immune expression, remains to be determined.

## IV. ENDOCRINE, NEURAL, AND IMMUNE MODULATION OF THE OCULAR SECRETORY IMMUNE SYSTEM

During the past three decades, scientists have recognized increasingly that the endocrine and nervous systems regulate multiple aspects of cellular and humoral immunity. The exact nature of this hormonal and neural control—which influences significantly such parameters as lymphocyte maturation, antigen presentation, lymphokine production, and antibody synthesis—critically depends on the specific signal, target cell, and local microenvironment (Besedovsky and Sorkin, 1977; Comsa *et al.*, 1982; Grossman, 1984; Munck *et al.*, 1984; Payan *et al.*, 1984; Ahmed *et al.*, 1985; Besedovsky *et al.*, 1985; Berczi, 1986; Berczi and Kovacs, 1987; Felten *et al.*, 1987; Jancovik *et al.*, 1987; Weigent and Blalock, 1987; Freier, 1989; Hadden *et al.*, 1989; Talal and Ahmed, 1987; Ahmed and Talal, 1990; Ader *et al.*, 1991). Moreover, this neuroendocrine-immune interrelationship is bidirectional, that is, antigenic exposure also may induce the lymphocytic secretion of lymphokines, hormones, and neuropeptides that directly modulate endocrine and neural function (Besedovsky and Sorkin, 1977; Besedovsky *et al.*, 1985; Cotman *et al.*,

<sup>a</sup> Symbols: ↑: increase; ↓: decrease; ~: no detectable change.

1987; Weigent and Blalock, 1987; Raine, 1988; Freier, 1989; Hadden *et al.*, 1989; Ader *et al.*, 1990,1991; D'Orisio and Panerai, 1990). In fact, researchers have proposed that the immune system serves as a sensory organ, providing input to the endocrine and nervous compartments in response to noncognitive stimuli such as infection (Blalock, 1984). Consequently, an extensive triangular association appears to exist between the endocrine, nervous, and immune systems that acts to promote and maintain homeostasis.

In the secretory immune system, diverse hormones and neural agonists are known to exert a tissue-selective influence that may augment, antagonize, or curtail immunological processes (Stead *et al.*, 1987,1991; Sullivan, 1990; Kelleher *et al.*, 1991; Lambert *et al.*, 1993). Thus, depending on the precise agent and the specific mucosal site, neuroendocrine interactions may significantly modify

1. the accumulation, proliferation, retention, or function of IgA- and IgG-positive cells, T cells, mast cells, eosinophils, basophils, natural killer cells, polymorphonuclear leukocytes, and/or macrophages
2. the synthesis or secretion of IgA and IgG antibodies and cytokines, the expression of major

histocompatibility complex (MHC) Class II antigens, the elaboration and release of SC, and the uptake and transport of pIgA into luminal secretions

3. the adherence and presentation of microorganisms to mucosal cells, the magnitude of neurogenic inflammation, and the extent of local immune protection against infectious agents

In addition, antigen-induced immune responses may alter mucosal neuroendocrine structure, sensitivity, or function significantly (Rowson *et al.*, 1953; Baker and Plotkin, 1978; Botta, 1979; Forslin *et al.*, 1979; Stead *et al.*, 1987,1991; Weisz-Carrington, 1987; Sullivan, 1990; Ader *et al.*, 1991; Kelleher *et al.*, 1991; Bienenstock, 1992; Lambert *et al.*, 1993; McKay *et al.*, 1992; Wira and Prabhala, 1992; Wood, 1992).

With respect to the ocular secretory immune system, endocrine and neural factors appear to exert a dramatic effect on immunological expression and activity (Table VII). However, although this neuroendocrine-immune interrelationship has been shown definitively in eyes of experimental animals, it has yet to be evaluated in humans. In rats, androgens elicit a marked increase in the production and secretion

<sup>a</sup> Symbols: ↑: increase; ↓: decrease; —: no change; blank: not determined.

<sup>b</sup> The stimulatory effects of dihydrotestosterone and cholera toxin were reduced significantly by the presence of carbachol.

<sup>c</sup> Low concentrations of glucocorticoid are required for optimal acinar cell production of SC *in vitro* (Hann *et al.*, 1991).

<sup>d</sup> Insulin's influence has been observed *in vitro* or inferred from studies with diabetic rats (Sullivan and Hann, 1989a; Hann *et al.*, 1991).

of SC by lacrimal gland acinar cells (Sullivan *et al.*, 1984b, 1990b; Kelleher *et al.*, 1991; Hann *et al.*, 1991), enhance the concentration of IgA in lacrimal tissue (Sullivan and Hann, 1989a), and stimulate the transfer and accumulation of SC and IgA, but not IgG, in tears (Sullivan *et al.*, 1984a; Sullivan and Allansmith, 1985; Sullivan and Hann, 1989a). These hormone actions, which may be induced by various androgenic compounds (Sullivan *et al.*, 1988), are not duplicated by estrogen, progestin, glucocorticoid, or mineralocorticoid treatment (Sullivan *et al.*, 1984a, 1990b; Sullivan and Allansmith, 1985). Moreover, the immunological effects of androgens appear to be unique to the eye, because androgen administration does not seem to influence IgA or SC levels in salivary, respiratory, intestinal, uterine, or bladder tissues (Sullivan *et al.*, 1988) and actually suppresses mucosal immunity in the mammary gland (Weisz-Carrington *et al.*, 1978). The mechanism by which androgens regulate ocular SC dynamics may involve hormone association with specific nuclear receptors in lacrimal gland acinar cells, binding of these androgen-receptor complexes to genomic acceptor sites, and promotion of SC mRNA transcription and translation. In support of this hypothesis:

1. saturable, high-affinity, and androgen-specific receptors, which adhere to DNA, have been identified in lacrimal tissue (Ota *et al.*, 1985; Edwards *et al.*, 1990; Rocha *et al.*, 1993)
2. androgens increase mRNA levels in lacrimal glands and stimulate lacrimal glycoprotein synthesis (Quintarelli and Dellovo, 1965; Shaw *et al.*, 1983; Gubits *et al.*, 1984)
3. androgen-induced SC production by acinar cells may be inhibited by androgen receptor (cyproterone acetate), transcription (actinomycin D), or translation (cycloheximide) antagonists (Sullivan *et al.*, 1984b; Lambert *et al.*, 1993). In contrast, the processes underlying androgen action on IgA in the rat eye, as well as hormone enhancement of tear IgA levels in the mouse (Sullivan *et al.*, 1992a) remain to be determined.

Androgen activity also may explain the pronounced gender-related differences in the rat ocular secretory immune system. The number of IgA-containing cells (Sullivan *et al.*, 1986; Hann *et al.*, 1988) and the IgA and SC output (Sullivan *et al.*, 1984b; Sullivan and Allansmith, 1985, 1988) are significantly greater in adult male lacrimal tissue than in that of adult females. This sexual dimorphism also extends to tears in which, from puberty to senescence, free SC and IgA but not IgG occur at considerably higher levels in male rats (Sullivan *et al.*, 1984a, 1990c; Sullivan and Allansmith, 1985, 1988). Indeed, androgen influence may be involved in the distinct gender-associated differences in the structural appearance, histochemistry, biochemistry, immunology, and molecular biological expression of the lacrimal gland in a variety of species, including mice, hamsters, guinea pigs, rats, rabbits, and humans (e.g., Tier, 1944; Martinazzi and Baroni, 1963; Cavallero, 1967; Shaw *et al.*, 1983; Cornell-Bell *et al.*, 1985; Mhatre *et al.*, 1988; Pangerl *et al.*, 1989; Warren *et al.*, 1990; Sullivan and Sato, 1992a). With respect to humans, gender appears to influence (1) the degree of lymphocyte accumulation in the lacrimal gland (Waterhouse, 1963); (2) the IgA concentrations in tear of adults (Sen *et al.*, 1978), but not elderly (Sand *et al.*, 1986); and (3) the frequency of Sjögren's syndrome-related lacrimal gland immunopathology (Tabbara, 1983; Moutsopoulos and Talal, 1987; Kincaid, 1987). Interestingly, androgen administration to animal models of Sjögren's syndrome (i.e., MRL/Mp-lpr/lpr and NZB/NZW F1 female mice) results in an almost complete suppression of autoimmune sequelae in lacrimal tissue (Ariga *et al.*, 1989; Vendramini *et al.*, 1991; Sato *et al.*, 1991, 1992; Sullivan and Sato, 1992a); and an increased output of IgA (Sullivan *et al.*, 1992b).

In addition to androgens, the hypothalamic-pituitary axis appears to play an important role in the expression of the rat ocular secretory immune system. Disruption of this axis by hypophysectomy or extirpation of the anterior pituitary significantly reduces the number of IgA plasma cells in lacrimal tissue, diminishes the acinar cell production of SC, causes a striking decrease in the levels of tear IgA and SC,

and almost completely curtails androgen action on ocular mucosal immunity (Sullivan and Allansmith, 1987; Sullivan, 1988; Sullivan and Hann, 1989a). Moreover, this endocrine disturbance has a marked effect on lacrimal gland structure and function, leading to both acinar cell atrophy (Martinazzi, 1962) and diminished tear output (Sullivan and Allansmith, 1986). The physiological mechanisms responsible for hypothalamic-pituitary involvement in the ocular secretory immune system remain to be elucidated, but may include numerous neuroendocrine and immunological pathways: the hypothalamus and pituitary regulate multiple endocrine circuits, directly influence neural innervation in the lacrimal gland, and clearly modulate immune activity (Hosoya *et al.*, 1983; Wilson and Foster, 1985; Berczi, 1990; Berczi and Nagy, 1990). Further, the hypothalamic-pituitary axis is known to control many hormones, neurotransmitters, and lymphokines that modify androgen and acinar cell function and control mucosal immunity (Mooradian *et al.*, 1987; Sullivan, 1990).

Other studies in experimental animals also have demonstrated that (1) sex steroids may alter the development of allergic conjunctivitis in rabbits significantly (Saruya, 1968) and (2) diabetes may diminish significantly the expression of the secretory immune system of the eye. Thus, in diabetic rats, the density of IgA-containing cells in lacrimal tissue and the concentrations of IgA and SC in tears are reduced significantly (Sullivan and Hann, 1989a). These diabetic effects most likely relate to the absence of insulin, which is essential for optimal SC synthesis by acinar (Hann *et al.*, 1991) as well as intestinal (Buts *et al.*, 1988) cells, and apparently is required for maximal androgen action on target tissues (Jackson and Hutson, 1984). Similarly, both the thyroid and the adrenal glands are necessary to achieve the full magnitude of androgen-induced effects on the secretory immune system of the eye (Sullivan and Allansmith, 1987).

From the perspective of neural regulation, the stromal, periductal, perivascular, and acinar areas of lacrimal tissue are innervated by many parasympathetic, sympathetic, and peptidergic fibers that harbor numerous immunoreactive transmitters, including vasoactive intestinal peptide (VIP), substance P, methionine enkephalin, leucine enkephalin, calcitonin gene-related peptide, and adrenergic and cholinergic agents (Ruskell, 1971, 1975; Uddman *et al.*, 1980; Nikkinen *et al.*, 1984, 1985; Lehtosalo *et al.*, 1987; Uusitalo *et al.*, 1990; Walcott, 1990). These neural agonists are known to control lymphocyte retention or function at other mucosal sites (Otto-way, 1984; Stanisiz *et al.*, 1986; Walcott *et al.*, 1986; Freier *et al.*, 1987; Scicchitano *et al.*, 1988; Hart *et al.*, 1990) and their release may influence the adherence, distribution, or activity of IgA plasma cells or T cells in the lacrimal gland (Franklin *et al.*, 1988, 1989; Oeschger *et al.*, 1989; Sullivan *et al.*, 1990/91). Consistent with this possibility, VIP appears to augment T-cell attachment to murine lacrimal tissue (Oeschger *et al.*, 1989) and systemic administration of the  $\beta$ -adrenergic blocker practolol suppresses human tear IgA levels (Wright, 1975; Garner and Rahi, 1976). However, the nature of the sympathetic-immune interaction requires further clarification, because ocular application of the  $\beta$ -blocker timolol to humans (Coakes *et al.*, 1981) and sympathetic

denervation in rats (Sullivan *et al.*, 1990/91) have no apparent effect on tear IgA content.

VIP and the  $\beta$ -adrenergic agent isoproterenol have been demonstrated to increase, whereas the cholinergic agonist carbamyl choline has been shown to decrease, basal and androgen-stimulated SC production by rat acinar cells (Kelleher *et al.*, 1991). This neural regulation of SC synthesis may be mediated through the modulation of intracellular adenylate cyclase and cAMP activity. In support of this hypothesis, VIP and adrenergic agents are known to enhance (Mauduit *et al.*, 1984; Dartt, 1989), and cholinergic agents possibly suppress (Jumblatt *et al.*, 1990), the generation of cellular cAMP. Further, exposure of lacrimal gland acinar cells to cAMP analogs, cAMP inducers (i.e., PGE<sub>2</sub> and cholera toxin), or phosphodiesterase inhibitors may elevate SC production (Kelleher *et al.*, 1991). This cAMP influence on SC elaboration, although pronounced in the lacrimal gland, is not necessarily reproduced in other mucosal epithelial cells (Lambert *et al.*, 1993).

Additionally, neural pathways are extremely important in the spread of herpes virus infection in the eye (Shimeld *et al.*, 1987) and ocular viral transmission and activity may be modulated by neuropeptides (Herbort *et al.*, 1989). Moreover, although the optic nerve does not appear to regulate the ocular secretory immune system (Sullivan *et al.*, 1990/91), light does seem to control anterior chamber-associated immune deviation (Ferguson *et al.*, 1988), herpes virus-related retinitis (Hayashi *et al.*, 1988), and various parameters of systemic immunity (Maestroni *et al.*, 1987).

The secretory immune system of the eye in experimental animals also may be regulated by lymphokines. For example, interleukins (IL) 1 $\alpha$  and 1 $\beta$  and tumor necrosis factor  $\alpha$  (TNF $\alpha$ ), but not IL-6 or interferon  $\gamma$  (IFN $\gamma$ ), stimulate the acinar cell synthesis and secretion of SC (Kelleher *et al.*, 1991). The regulatory effect of TNF $\alpha$  on acinar cell SC production is similar to that found in colonic cell lines, in which TNF $\alpha$  increases the production, surface expression, and release of SC (Kvale *et al.*, 1988a,b). However, the absence of IFN $\gamma$  effect on SC output by acinar cells is notable because this lymphokine regulates SC dynamics in both intestinal (Sollid *et al.*, 1987; Kvale *et al.*, 1988a) and uterine (Wira and Prabhala, 1992) epithelial cells. Although IL-6 appears to have no influence on lacrimal SC production (Kelleher *et al.*, 1991), both IL-6 and IL-5 stimulate the synthesis of IgA in lacrimal tissue explants (Pockley and Montgomery, 1990/91b) and, in combination, augment the secondary tear IgA antibody response to pneumococcal antigen (Pockley and Montgomery, 1991) and suppress IgG and IgM synthesis in lacrimal tissue (Pockley and Montgomery, 1990/91a). As a further consideration, androgens, VIP, and IL-1 all share the capacity to increase IgA production in specific tissues (Drew and Shearman, 1985; Stanisiz *et al.*, 1986; Crowder *et al.*, 1988; Sullivan and Hann, 1989a); pIgA, in turn, may heighten the monocytic output of TNF $\alpha$  (Deviere *et al.*, 1991). If analogous activity occurs in the lacrimal gland, then various neuroimmunoendocrine factors may control the synthesis of both IgA antibodies and the IgA receptor, leading to enhanced antibody transfer to tears and improved ocular surface defense.

# Mucosal Immunology of the Middle Ear and Eustachian Tube

David J. Lim • Goro Mogi

## I. INTRODUCTION

Our understanding of middle ear immunology is based largely on studies conducted using middle ear effusions and mucosal biopsies collected from patients with otitis media. With the availability of a number of animal models for otitis media, for example, mice, rats, gerbils, and chinchillas, systematic data have been added to our current understanding of the immune mechanisms of the middle ear and eustachian tube (tubotympanum) and of tubotympanum development.

Studies conducted in the early 1970s showed that elevated levels of immunoglobulins, particularly IgG and IgA, in middle ear effusion (MEE) suggested the local synthesis of these immunoglobulins in the mucosa of middle ear (Ishikawa *et al.*, 1972; Mogi *et al.*, 1973; Veltri and Sprinkle, 1973). Liu *et al.* (1975) further demonstrated that the effusion levels of immunoglobulin and lysozyme are much higher than those of the sera and that they increase steadily with advancing age in children, reflecting the development of the local middle ear immune system.

Findings of secretory IgA in MEE (Mogi *et al.*, 1973; 1974; Ogra *et al.*, 1974) further confirmed the presence of a local middle ear mucosal immune system similar to that of other mucosal epithelia. Mogi *et al.* (1974a) isolated secretory IgA from pooled MEEs and demonstrated that its antigenicity and subunit structure are identical or very similar to those of secretory IgA obtained from other external secretions such as saliva, nasal secretion, colostrum, and bronchial fluid. Ogra *et al.* (1974) also detected secretory IgA and secretory component in MEEs and demonstrated that specific antibody activity in MEEs against mumps, measles, rubella, and poliovirus, essentially is limited to IgA. Fluorescent antibody staining of mucosal tissues of the tympanic cavity showed characteristic staining for a secretory component in the surface epithelium (Mogi *et al.*, 1974; Ogra *et al.*, 1974). These data suggest the existence of a distinct secretory immune system in the human middle ear.

The purpose of this chapter is to review available data on immune mechanisms, particularly mucosal immunology of the tubotympanum, and the clinical implications of understanding the immunologic aspects of otitis media.

## II. MUCOUS MEMBRANE OF THE TUBOTYMPANUM

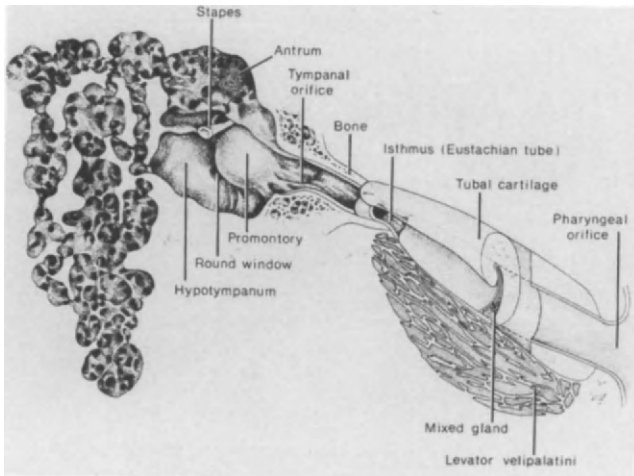

The middle ear consists of the eustachian tube, tympanic cavity, antrum, and mastoid air cells. The eustachian tube can be divided into two parts, cartilaginous and bony. Secretory glands of mixed type exist only in the cartilaginous portion of the eustachian tube (Figure 1). Although these tubotympanal structures are very similar among different species, rodents lack air cells.

Although the nasopharynx is not a part of the middle ear, this site also affects middle ear pathophysiology. Mucous membranes of the tympanic cavity, antrum, and air cells communicate via the eustachian tube with nasopharyngeal mucosa.

The tubotympanal mucosa are basically a respiratory type, although the tympanic cavity, antrum, and air cells are covered mostly by cuboidal or squamous cells with few secretory and ciliated cells (Lim, 1974; Figure 2).

## III. IMMUNOCOMPETENT CELLS IN THE TUBOTYMPANAL MUCOSA

Although many lymphocytes, plasma cells, macrophages, leukocytes, and other inflammatory cells accumulate in inflamed mucosa (Hussi and Lim, 1974; Lim 1974; Mogi *et al.*, 1980), only a few immunocompetent cells (without organized lymphoid follicles) are found in the normal middle ear mucosa. Takahashi *et al.* (1989) investigated immunocompetent cells and inflammatory cells in the middle ear mucosa of normal and nonsensitized BALB/c mice, demonstrating the presence of (in the order of frequency) Mac-1<sup>+</sup>, Lyt-1<sup>+</sup>, IgA<sup>+</sup>, Lyt-2<sup>+</sup>, IgG<sup>+</sup>, and IgM<sup>+</sup> cells. Ichimiya *et al.* (1990) also analyzed quantitatively the immunocompetent cells in the middle ear mucosa of mice bred under germ-free, specific pathogen-free, and conventional conditions. According to their results, mast cells and Mac-1<sup>+</sup> cells exist in the middle ear mucosa of mice bred under all three conditions. The number of mast cells was highest, followed by Mac<sup>+</sup> cells and lymphocytes. As seen in Figure 3, the numbers of lymphocyte subsets are fewer in the middle ear mucosa than in the nasal

**Figure 1** Middle ear, mastoid, and Eustachian tube, demonstrating anatomical landmarks. Reprinted with permission from Lim (1974).

mucosa. Although  $IgA^+$ ,  $IgM^+$ , and  $Lyt-1^+$  cells are seen in the middle ear mucosa of conventional mice,  $IgM^+$  cells exist only in mucosae of specific pathogen-free and germ-free mice. This finding can be interpreted to indicate that, anatomically, the middle ear has less frequent opportunity to be exposed to antigenic stimulation than other areas of the upper respiratory and alimentary tracts. In otitis media-induced mice that have been inoculated with nontypable *Haemophilus influenzae* or lipopolysaccharide (LPS),  $Mac-1^+$  cells were dominant. Although the numbers of  $IgM^+$  and  $Lyt-1^+$  cells increased markedly, the numbers of other lymphocyte subsets did not increase until 14 days after inoculation (Ichimiya *et al.*, 1990). Takahashi *et al.* (1992) induced immune-mediated otitis media in mice using keyhole limpet hemocyanin (KLH) as an antigen and observed immunocytes appearing in the middle ear and eustachian tube. Their results showed that  $Mac-1^+$  cells are the predominant cell type, followed by helper T cells,  $IgG^+$  cells,  $IgA^+$  cells, and  $IgM^+$  cells. Although the difference of infiltrating cell types between these two studies may be related to differences in the procedures to induce otitis media, these findings suggest that the tubotympanum is a potentially immuno-competent organ that can be activated with appropriate antigenic stimulation.

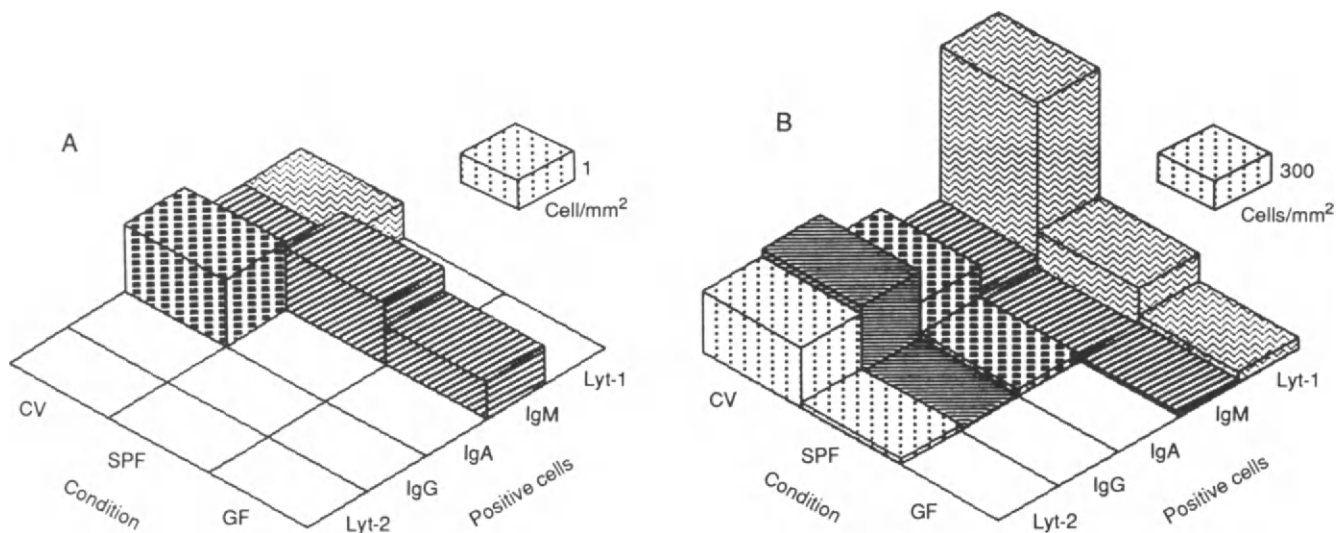

#### IV. MAST CELLS IN THE MIDDLE EAR

Although few immunocompetent cells exist in the normal middle ear mucosa, mast cells have been demonstrated to be found often in the lamina propria of the pars flaccida of the tympanic membrane (Alm *et al.*, 1982) and middle ear mucosa (Widemar *et al.*, 1986). Almost all mast cells that are distributed in the middle ear and eustachian tube mucosa are of the connective tissue type (Watanabe *et al.*, 1991). The exact role of mast cells in normal middle ear mucosa is not yet known. Since mast cells are involved in type I and III allergic inflammatory reactions, these mast cells may be

involved in the pathogenesis of otitis media with effusion (OME). Watanabe *et al.* (1991) investigated the distribution of mast cells in the tubotympanum of both adult and developing guinea pigs, and found a large number of mast cells in the tubotympanic mucosal membrane of the adult but only a few in that of the fetal guinea pig. The middle ear mucosal mast cells accumulate in areas covered with ciliated cells or in areas richly vascularized (Albiin *et al.*, 1986; Watanabe *et al.*, 1991). Jeffrey (1983) suggested that the appearance of mast cells in the airway epithelium is indicative of disease and not a normal feature. One of the major mediators responsible for mast cell accumulation is interleukin 3 (IL-3; Ernst *et al.*, 1987). This lymphokine is derived from many different cells such as T lymphocytes, myeloid cells, and epidermal cells. Judging from the distribution pattern of mast cells in the tubotympanum of developing and adult guinea pigs, one

**Figure 2** Distribution of ciliated cells in the normal human ear, shown graphically between lateral and medial side. Eustachian tube, et; hypotympanum, h; promontory, p; epitympanic recess, e; prominence of facial canal, pfc; antrum, a; mastoid air cells, m. Reprinted with permission from Shimada and Lim (1972).

**Figure 3** Distribution of lymphocyte subsets in the mucosa of murine middle ear and nose. (A) Middle ear. (B) Nose. Conventional mice, CV; specific pathogen-free mice, SPF; germ-free mice, GF. Note that in the nasal mucosa, all lymphocyte subsets are seen in higher numbers than in the middle ear.

can suggest that mast cell precursors are recruited to the tubotympanic mucosa as a result of antigenic stimulation during development, and differentiate into mast cells locally. These cells also may play a role in the local defense system of the tubotympanum. Mast cells may be recruited to the tubotympanum as part of biological defense mechanism in response to the continuous presence of antigenic stimuli. Biologically active compounds of mast cells induce changes in blood flow and permeability, causing the flooding of plasma and leukocytes that facilitates the removal of antigenic substances (Lembeck, 1983).

## V. ROLE OF CIRCULATING ANTIBODIES IN OTITIS MEDIA

Immunity is an important defense system against bacterial otitis media. Immunodeficiency and immaturity of the immune system lead to otitis proneness. Congenital immunodeficiency is causally related to recurrent otitis media (Mogi and Maeda, 1982). Prellner *et al.* (1984) reported that infants with recurrent otitis media have significantly lower IgG antibody levels against pneumococcal capsular polysaccharide 6A or 19F at 1 year of age than those of the control group, but attain normal levels at 8 years of age. Freijid *et al.* (1985) also found that otitis-prone children have lower levels of serum IgG2 subclass, both at 12 months and at 32 months of age, than do age-matched non-otitis-prone children. These findings support the idea that systemic humoral immunity protects the middle ear from bacterial infection, and that certain populations of children may have a delayed immune development of the IgG subclass.

Although overwhelming evidence indicates that specific

antibodies are protective against bacterial otitis media, some evidence also suggests that an immune mechanism may be involved in inducing or sustaining MEE. Experimentally, OME can be produced by inoculating the tympanic cavity with a protein antigen after systemic immunization with the same antigen. Smirnov (1938) induced OME in guinea pigs by inoculating horse serum into the middle ear after systemic immunization. Subsequently, Koch (1947) and Hopp *et al.* (1964) were successful in reproducing these results. Ryan *et al.* (1982, 1986) and Suzuki *et al.* (1988) further investigated immunologically induced otitis media and demonstrated that immune-mediated otitis media cannot be produced without prior systemic challenge. Inoculation of protein antigen into the tympanic cavity after systemic sensitization of the host with the same antigen induced immune-mediated otitis media (Ryan *et al.*, 1986). These data are interpreted to mean that the afferent limb of systemic immunity from the middle ear appears to operate less effectively and rapidly than that from the dermis. Middle ear mucosa responds in a manner that is more similar to that of oral and nasal mucosa than to that of tracheal mucosa (Kasturi and Hannoun, 1977). Immune-mediated otitis media also is produced by injecting a protein antigen into the tympanic cavity of animals that are sensitized passively with antigen-specific IgG antibodies. However, no OME is produced by inoculating the antigen into the tympanic cavity of hosts that are transfused passively with sensitized lymphocytes (Ryan and Catanzaro, 1983; Mogi, 1989). Formation of immune complex, followed by complement activation and the release of granulocyte proteases from neutrophils, is the key factor in the production of immune-mediated OME (Suzuki *et al.*, 1988; Mogi, 1989). Mravic *et al.* (1978) produced inflammatory response in the middle ear by inoculation of the chinchilla bulla with immune complex. Inoculation of immune complexes of pneumococcal antigens (but not IgG

antibodies) into the normal tympanic cavity of nonsensitized chinchillas also produced MEE (G. Mogi *et al.*, in press). Palva *et al.* (1985) found pneumococcal immune complexes in at least 25% of MEEs in patients with chronic OME (secretory otitis media).

Epidemiological and clinical evidence indicates that chronic OME is associated closely with prior episodes of acute otitis media (Groothuis *et al.*, 1979; J. Schwin *et al.*, 1979). In a chinchilla animal model, acute otitis media becomes chronic OME in certain cases (G. Mogi, unpublished data). In this study, chinchillas were immunized systemically with killed *Streptococcus pneumoniae* 19F and then inoculated with live bacteria of the same strain into the middle ear. Of 20 chinchillas, 7 cases became chronic OME, 5 cases showed a drumhead perforation following acute otitis media, 5 animals died, and 2 cases healed within 14 days, and one showed no otitis media. However, of 12 control chinchillas (normal and nonimmunized) receiving live *S. pneumoniae* 19F, 4 chinchillas died, 6 chinchillas healed within 11 days, 1 chinchilla had a drumhead perforation, and one showed no otitis media. None of the control animals developed chronic OME. The formation of the immune complex itself can be viewed as a host defense mechanism to eliminate the antigens. However, during the activation process of this defense mechanism, the activation of the complement system also may have contributed to the initiation and sustenance of inflammatory reactions. Therefore, although humoral systemic immunity is an important defense against infection, its immune reactions can, at the same time, contribute to the pathogenic mechanisms of chronic OME.

## VI. SUPPRESSION OF IMMUNE-MEDIATED OTITIS MEDIA

Oral administration of antigens has been known to lead to immune tolerance. Ueyama *et al.* (1988) investigated the effects of mucosa-derived T suppressor cells on the induction of immune-mediated OME in C3H/He mice bred under specific pathogen-free conditions. Splenic T suppressor cells, which were obtained after oral administration of ovalbumin (OVA), were transferred intravenously into syngeneic mice. The mice receiving the T suppressor cells were immunized with OVA intraperitoneally, followed by instillation of OVA into the tympanic cavity. OME was seen in only 1 of 10 mice receiving splenic T cells from OVA-fed mice, whereas 9 of 10 control mice to which splenic T cells from saline-fed mice were administered developed OME. IgG-mediated OME can be suppressed to a certain extent by the induction of antigen-specific, mucosa-derived T suppressor cells.

## VII. SECRETORY IgA IN MIDDLE EAR EFFUSIONS AND NASOPHARYNGEAL SECRETIONS

A previous study, using a radioactive single radial diffusion technique, reported that the mean value of secretory IgA

concentration in the serous effusions is  $212.7 \pm 13.5 \mu\text{g/ml}$  and  $357.7 \pm 13.2 \mu\text{g/ml}$  in the mucoid effusions (Mogi *et al.*, 1974). Mogi *et al.* (1984) measured secretory IgA and serum type IgA in MEEs using an electro-immunodiffusion method. As shown in Table I, the mean concentration in mucoid MEEs is significantly greater than that in the serous MEEs. Although not statistically significant, the mean concentration of serum type IgA exceeded the value of secretory IgA in both types of MEEs. This finding is in accordance with that reported by Sorensen (1982), who also summarized reported data of concentrations of secretory IgA and IgA in MEEs, nasopharyngeal secretions, and nasal secretions (Sorensen, 1990).

## VIII. LOCAL PRODUCTION OF ANTIBODIES IN THE MIDDLE EAR

*Streptococcus pneumoniae*, nontypable *H. influenzae*, and *Moraxella catarrhalis* are the major pathogens for acute otitis media. On the basis of the presence of specific antibodies in MEEs, these bacteria are also considered causative factors for OME, although bacterial cultures only occasionally demonstrate these bacteria in the MEE (Lim and DeMaria, 1982; Kurono *et al.*, 1988). Investigations of specific antibody activities against these bacteria in the effusions have contributed to our current understanding of the immune mechanism of the middle ear. Whereas specific antibodies in MEE against certain viruses are restricted mainly to IgA class antibodies (Ogra *et al.*, 1974; Meurman *et al.*, 1980; Yamaguchi *et al.*, 1984), those against bacterial antigens belong to IgG, IgA, and IgM classes (Sloyer *et al.*, 1974;1975; Faden *et al.*, 1989a). Liu *et al.* (1975) investigated, immunochemically and bacteriologically, MEEs from children with chronic OME and found that IgA levels are significantly higher in the culture-negative fluids than in the positive effusions, and that bacterial recovery rate is related inversely to the dramatic increase with age of IgA and IgG levels in effusions. Sloyer *et al.* (1974,1975) found specific antibodies against causative pneumococcal serotype in 27% of effusions of patients with acute otitis media taken at the time of diagnosis. These antibodies were IgG, IgM, and IgA classes, but IgA class antibodies were detected more often in MEEs without the simultaneous presence of IgA antibodies in serum. These investigators also found the same results in acute otitis media caused by *H. influenzae*. Faden *et al.* (1989a,b) investigated systemic and local immune responses of young children with recurrent otitis media caused by nontypable *H. influenzae* during and after the infection. However, their results showed that the titer of strain-specific antibody against *H. influenzae* was much higher for the IgG class than for the IgM and IgA classes. Although antibody titers in MEEs declined over time, serum antibody titers remained stable. These researchers suggested that immunity to nontypable *H. influenzae* in the middle ear, in part, reflects systemic immunity. These clinical findings indicate that the local immunity in the middle ear, in conjunction with systemic

**Table I** Mean Levels of Secretory IgA and Serum Type IgA in Middle Ear Effusion<sup>a,b,c</sup>

	Mucoid group (N = 77)		Serous group (N = 41)

immunity, plays an important role in middle ear infection.

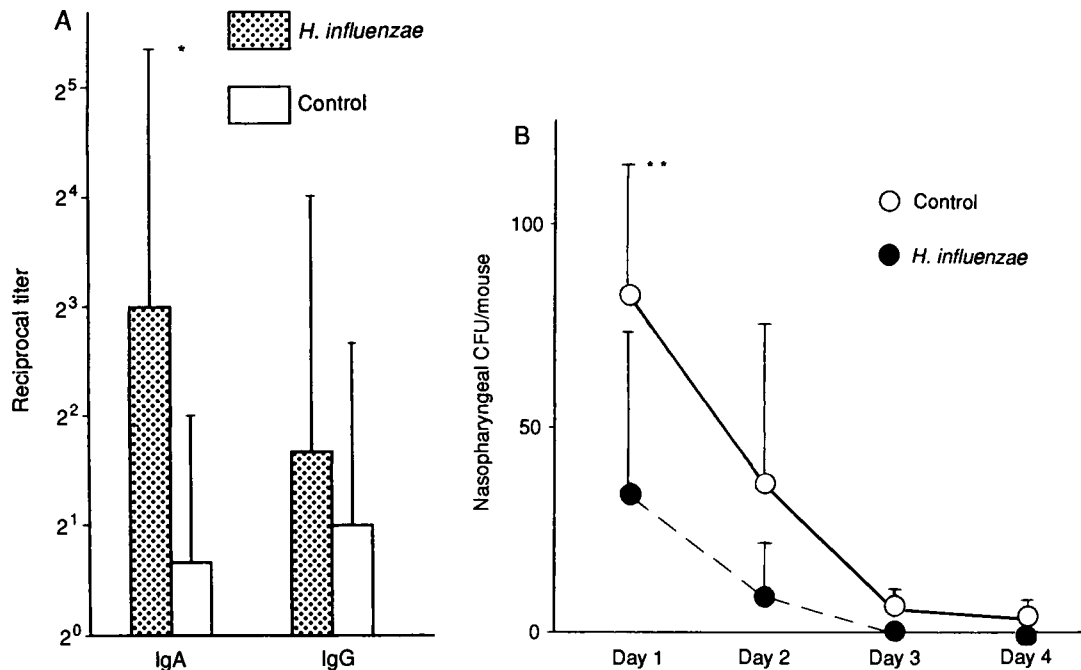

## IX. ROLE OF SECRETORY IgA IN BACTERIAL ADHERENCE

Colonization of pathogenic bacteria in the nasopharynx is an important etiological factor of middle ear infection (Kurono *et al.*, 1988; Stenfors and Raisanen 1990). Nasopharyngeal bacterial adherence is known to be of crucial importance in the pathogenesis of otitis media. The adherence of both nontypable *H. influenzae* and *S. pneumoniae* to nasopharyngeal epithelial cells *in vitro* was reported to be significantly greater in children with OME than in normal control children (Mogi, 1988). Shimamura *et al.* (1990) detected secretory IgA antibody activities in nasopharyngeal secretions against nontypable *H. influenzae* and *S. pneumoniae*, and reported that adherence of both bacteria is significantly less in the group of patients with secretory IgA antibody activity than in the group of patients with no activity. Kurono *et al.* (1991) further investigated bacterial adherence to nasopharyngeal epithelial cells *in vitro* and found that adherence is reduced remarkably by treating bacteria (*H. influenzae* or *S. pneumoniae*) with nasopharyngeal secretions and that the adhesion-blocking activity is significantly greater in nasopharyngeal secretions with secretory IgA antibody activity against bacteria than in those with no activity. These findings suggest that secretory IgA in nasopharyngeal secretions may inhibit bacterial adherence, thus significantly reducing nasopharyngeal bacterial colonization, a first important step in the process of otitis media. Results of an animal study support this concept (Y. Kurono, K. Shimamura, and G. Mogi, unpublished results). When nontypable *H. influenzae* was inoculated into the nasopharynx of BALB/c mice immunized by oral administration of formalin-killed bacteria, salivary IgA antibody titers against *H. influenzae* were increased significantly by oral immunization but salivary IgG antibody titers were not. The bacteria inoculated to the nasopharynx were eliminated more rapidly in immunized mice than in control mice (Figure 4). Further, systemic immunization of mice with *H. influenzae* was found to raise serum IgG antibody titer, but nasopharyngeal colonization of the bacteria was not inhibited (G. Mogi *et al.* unpublished data). Oral immunization that enhances mucosal immunity may be useful in preventing

otitis media by inhibiting the colonization of pathogenic bacteria in the nasopharynx.

## X. SOURCE OF IgA PRECURSORS IN MIDDLE EAR

The presence of secretory IgA in MEE and the existence of IgA immunocytes in the inflamed middle ear mucosa (rarely in normal mucosa) indicate that mucosal immunity is activated in the tubotympanic cavity under inflammatory conditions. In humans, the tonsils and adenoids were proposed to be possible sources of antibody-producing cells in the tubotympanum (Sorensen, 1983; Brandtzarg, 1984). Watanabe *et al.* (1988) induced antigen-specific IgA-forming cells in the middle ear mucosa of guinea pigs by immunizing the animals intraduodenally or intratracheally with protein antigen after systemic priming. Antigen-specific IgA-forming cells were detected in the inflamed middle ear mucosa, whereas these cells could not be found in animals that received only intratympanic inoculation after systemic priming (Figure 5). However, the number of IgA-forming cells in the inflamed middle ear mucosa was apparently smaller than that of cells induced in the mucosa of the alimentary tract and other sites of the respiratory tracts. These findings show that gut-associated lymphoid tissues (GALT) and bronchus-associated lymphoid tissues (BALT) are two of the sources of IgA precursors for inflamed tubotympanic mucosa and that the tubotympanum shares common mucosal immunity. The selective recruitment of precursors of IgA-forming cells to mucosal sites is thought to be influenced by factors such as hormones and organ-specific endothelial-cell determinants of high endothelial venules (Butcher and Scollary, 1980). Although the number of determinants is extremely small compared with that in the small intestine and spleen (Mogi *et al.*, 1990), a further study suggested that the inflamed mucous membrane of the middle ear possesses determinants to which lymphocytes bind. Normal middle ear mucosa does not express such determinants. Ryan *et al.* (1990) investigated the homing mechanism of middle ear lymphocytes and found that they do not appear to have specialized ligands or receptors that can recruit mucosal lymphocytes selectively to the middle ear sites, since lymphocytes of difference origin show no preferential homing during active recruitment of lymphocytes to the middle ear cavity.

**Figure 4** Secretory antibody production by oral immunization and effects of oral immunization on nasopharyngeal colonization of *Haemophilus influenzae*. (A) Salivary antibody activities against *H. influenzae* after oral immunization. Mice immunized orally with GM 53 (adjuvant) only, ○; mice immunized orally with liposomes containing *H. influenzae* and GM 53 (●). (B) Numbers of *H. influenzae* detected from the nasopharynx after nasopharyngeal inoculation of bacteria. Mice immunized with *H. influenzae*, shaded bars; mice immunized with adjuvant only, open bars.

## XI. PREVENTION OF IMMUNE-MEDIATED OTITIS MEDIA BY ORAL IMMUNIZATION

Antigen loading onto the duodenal mucosa enhances the mucosal immunity of various mucosal sites, including the

nasopharynx and tubotympanum (Watanabe *et al.*, 1988, 1989). Moreover, the mucosal immunization that stimulates GALT prevents the occurrence of immune-mediated otitis media (Watanabe *et al.*, 1988), Yoshimura *et al.* (1991) investigated the efficacy of oral immunization of killed bacte-

**Figure 5** Localization of antigen-specific IgA-forming cells in middle ear mucosa of guinea pigs immunized intraduodenally with protein antigen after systemic priming. Same section was treated with fluoresceinated isothiocyanate conjugates for antigen-specific antibody-forming cells (A) and consequently stained with rhodamine conjugates for IgA-forming cells (B).

ria on the prevention of bacterial otitis media in guinea pigs. With intratympanic inoculation of  $10^5$  and  $10^6$  live *S. pneumoniae*, the occurrence of pneumococcal otitis media significantly decreased in guinea pigs that received intraduodenal or intragastric immunization by enteric capsules containing killed bacteria of the same strain. In these guinea pigs, the values of salivary IgA antibody titers against *S. pneumoniae* were increased significantly. These findings indicate that oral vaccination by enteric capsules elicits mucosal IgA responses, presenting an opportunity for clinical application of oral vaccination by enteric capsules for the prevention of middle ear infection.

## XII. SUMMARY

The middle ear is anatomically and immunologically unique. Because the normally functioning eustachian tube protects the tympanic cavity, antrum, and mastoid cavities from bacterial invasion, these compartments are aseptically and only a few immunocompetent cells are present in the normal healthy middle ear. Tubotympanic encounters of antigens (bacteria/viruses) stimulate the development of local and systemic immune systems in an age-dependent manner, thus contributing to the protection of the tubotympanum from pathogenic bacteria. Whereas IgG (to a lesser extent IgM) is the main immunoglobulin affording protection, some evidence suggests that IgG-mediated immune reactions in the tympanic cavity also may contribute to the chronicity of MEEs. The role of IgA in protection against otitis media is not well defined. Evidence suggests that the secretory IgA response is beneficial in reducing bacterial adherence in the nasopharynx and in recovery from otitis media.

# Immunology of Diseases of the Oral Cavity

S. J. Challacombe · P. J. Shirlaw

## I. INTRODUCTION

Oral health is dependent on the integrity of the oral mucosa which normally prevents the penetration of microorganisms and macromolecules that might be antigenic. The mucosa is protected by both nonspecific and specific defense mechanisms. The former include mucins, lysozyme, lactoferrin, and lactoperoxidase; specific immunity includes the systemic immune system and the secretory immune system, both of which play a role in local immune defense in the oral cavity.

The mouth is part of the mucosal lining of the body, and structurally shows similarities with those tissues of the gut and lungs, among others. The most striking difference between the mouth and the tissue lining the remainder of the gastrointestinal tract is the presence of teeth. The junction between the teeth and mucosa not only allows a greater access of serum proteins to the mucosal surface than is found in other mucosae, but also results in exposure of a unique epithelium, the junctional epithelium, to microbial challenge. This epithelium is affected in periodontal diseases. As are other parts of the mucosal system, oral mucosa is exposed to both the systemic and the secretory immune systems but some immune mechanisms are found there that differ from those found elsewhere. Local immune responses include those that are part of the secretory immune system, emanating from major and minor salivary glands, and those of the systemic immune system, emanating from crevicular fluid or within the gingival and mucosal tissues.

The oral mucosa is bathed constantly in antigens; any deficiency in the surface mucosal systems may result in increased antigen access, as does trauma or inflammation. Such antigens and microorganisms may contain B-cell mitogens, for example, the polysaccharide capsules or antigens of some fungi and bacteria in plaque. If antigen is not cleared from the mucosal site or if additional antigen gains access, locally activated T and B cells may release various cytokines and interact with associated macrophages and neutrophils, resulting in localized inflammatory reactions that cause damage to the host as a by-product of an attempt to clear antigen from the area. The pathogenesis of some mucosal diseases may be related to cross reaction of some microbial components with host antigens, resulting in host damage subsequent to a normal immune response.

The main salivary immunoglobulin is secretory IgA (SIgA). Whole saliva is made of the secretions of the parotid glands (40%), the submandibular glands (40%), the sublingual glands

(10%), and the minor salivary glands (10%) of which many dozens occur around the oral mucosa, especially in the labial and buccal mucosae. A small but significant contribution to whole saliva is made by crevicular fluid (see subsequent text). The total volume of saliva produced per day is probably between 750 and 1000 ml. The majority of the IgA in saliva is dimeric, but 5–10% is monomeric. The IgA1:IgA2 ratio is about 55:45. The concentration of SIgA differs in various secretions but is always greater than that of IgG. In whole saliva, the contributions of SIgA, IgG, and IgM are approximately 200, 1, and 1 mg per 1000 ml, respectively.

### A. Induction of Salivary IgA Antibodies

Antibodies in saliva can be stimulated at remote sites (centrally) or locally. Locally, direct application of antigen to the mucosa may lead to the induction of antibodies in minor salivary glands (Krasse *et al.*, 1988) whereas injection of antigen submucosally or instillation into the ducts of the glands (Emmings *et al.*, 1975) may lead to antibodies in the saliva from major salivary glands. Centrally, the most effective method of inducing antibodies in saliva seems to be by intragastric or intraduodenal immunization (reviewed by Challacombe, 1987). Salivary antibody induction has been used widely as a model to study secretory responses, primarily because saliva is an easy secretion to collect and analyze. The induction of salivary antibodies after intragastric immunization has been demonstrated in a variety of species including humans (Mestecky *et al.*, 1978), rhesus monkeys (Challacombe and Lehner, 1980), rabbits (Montgomery *et al.*, 1978), rats (Michalek *et al.*, 1977), and mice (Challacombe and Tomasi, 1980). Most of these studies have used particulate antigens. Scientists now generally accept that, in the absence of adjuvants, antigen in particulate form is more effective than antigen in soluble form in the induction of salivary antibodies by remote site stimulation. However, salivary antibodies after intragastric immunization with soluble antigens have been reported in rabbits with bovine gamma globulin (Montgomery *et al.*, 1978) and in mice with ovalbumin (Challacombe and Tomasi, 1980) and streptococcal antigen I/II (Challacombe, 1983).

A feature of salivary antibodies shared with secretory antibodies elsewhere in the mucosal immune system is that antibodies are generally short lived and of low titer (Mestecky *et al.*, 1978). In humans (Mestecky *et al.*, 1978) and in monkeys

(Challacombe and Lehner, 1980), even secondary immunizations only lead to a salivary response slightly greater than that after the primary immunization. These studies suggest that either large doses of antigen or more persistent antigen presentation are needed to mount longer lasting salivary responses to central immunization. Several groups have examined the potential of biodegradable microparticles containing antigen to induce longer lasting secretory antibody responses using saliva as the mucosal model (Eldridge *et al.*, 1991; O'Hagan *et al.*, 1991; Challacombe *et al.*, 1992). These studies suggest that intragastric immunization with antigen incorporated in biodegradable particles not only gives rise to enhanced salivary antibodies, but also induces serum IgG, IgA, and IgM responses. Thus, oral immunization of this type would seem to lead to antibodies in serum and saliva as well as in other secretions and to have great potential in the development of vaccines against mucosal pathogens.

### **B. Major and Minor Salivary Glands**

Salivary gland lymphoid tissue, particularly that surrounding minor salivary glands (DALT), is thought to play a role in local production to secretory antibody (Nair and Schroeder, 1986). Minor salivary glands contribute only about 10% to the total volume of saliva (Dawes and Wood, 1973) but, since the secretory IgA content is much greater than in the main salivary glands (Crawford *et al.*, 1975), the contribution to the total salivary IgA could be as great as 25%. Bacteria have been observed in DALT (Nair and Schroeder, 1986) and direct access of antigens in the oral cavity to lymphoid aggregates may occur via the short ducts of the minor salivary glands.

### **C. Mechanisms of Action of Salivary IgA**

SIgA does not rely on opsonization or complement fixation for its biological activity since neither complement components nor phagocytes normally are found in abundance in secretions such as saliva. The main actions of SIgA in saliva are thought to be:

1. virus neutralization (e.g., polio virus)
2. neutralization of toxins or enzymes (e.g., streptococcal glucosyltransferase); note that the interaction of SIgA antibody and enzymes may, on occasion, lead to enhanced rather than inhibited enzyme activity (Russell and Challacombe, 1976)
3. inhibition of adherence (or growth) of microorganisms on epithelial cells or on teeth
4. antigen trapping and antigen exclusion by preventing the access of antigen to the systemic immune system; antigens are removed from the oral cavity by swallowing of saliva and mucins
5. interaction of IgA with nonspecific defense mechanisms

### **1. Salivary IgA and Mucin**

Secretory IgA will bind to mucins through cysteine residues. Salivary IgA can be found in a complex of very high molecular weight that has agglutinin activity and presumably reflects an IgA–mucin complex. In the intestinal mucosa, *in vivo* challenge of orally immunized rats has been shown to lead to intestinal goblet cell release of mucins. In addition, antigen–antibody complexes or IgE–mast cell reactions can lead to the release of mucins, which may contribute to inhibition of adherence of bacteria or viruses and to immune exclusions of antigens and of toxic substances. Although no such release of mucins by antigen complexes has been demonstrated within the oral cavity, the association of salivary IgA and mucins and the observation that salivary glycoproteins may inhibit the adherence of bacteria strongly suggest that a similar mechanism is operative (Biesbrock *et al.*, 1991).

### **2. Salivary IgA and Lactoferrin**

Lactoferrin is an iron binding protein that has bacteriostatic activity. This activity can be enhanced or, under some circumstances, reduced by SIgA antibodies. Experiments have used purified colostrum IgA; investigators assume that IgA from saliva acts in a similar manner. Presumably, when enhancement of lactoferrin activity is found, the synthesis of iron binding proteins (or their release) is prevented by the antibodies and, as a result, the lactoferrin binds the iron that is required as a growth factor for the bacteria.

### **3. Salivary IgA and Lysozyme**

Purified SIgA from colostrum has been shown to inhibit *Escherichia coli* in the presence of complement and lysozyme, whereas either component on its own was ineffective (Hill and Porter, 1974). These observations suggest that a similar mechanism might be operative within the oral cavity, although the concentrations of complement in whole saliva would seem too small for this to be a major defense mechanism unless inflammation is present. Also, salivary mucins may inhibit lysozyme activity; thus, the effectiveness of lysozyme as an antibacterial mechanism in the oral cavity is in some doubt.

### **4. Salivary IgA and Lactoperoxidase**

Salivary IgA can enhance the antimicrobial effect of lactoperoxidase (LPO; Crawford *et al.*, 1975). Interestingly, either IgA1 or IgA2 is effective but serum IgG or IgM has no effect, suggesting a specific relationship between IgA and LPO that might be of great importance at mucosal surfaces.

### **D. Gingival Crevicular Fluid**

Components of blood can reach the tooth surface through the junctional epithelium of the gingiva and is referred to subsequently as the crevicular fluid. This fluid contains both the humoral and cellular elements of blood, although in lower amounts and in different proportions (Shillitoe and Lehner,

1972). Much of the flow is likely to be secondary to the local inflammation in response to bacterial plaque that accumulates continuously, even within minutes of its removal, and causes a physiological inflammatory response in the gingiva. Even in subjects with no clinically detectable inflammation, a crevicular fluid flow rate of about 1–2  $\mu$ l per tooth per hour has been calculated (Challacombe, 1980b). Crevicular flow increases greatly with the inflammatory changes caused by gingivitis and periodontitis. The total surface area of crevicular epithelium around 28 teeth is approximately 760 mm<sup>2</sup> and can increase 10-fold with periodontal disease.

Many experiments have shown that both humoral (e.g., immunoglobulins) and cellular (e.g., lymphocytes and macrophages) components from blood can reach the tooth surface (Challacombe *et al.*, 1978). The immunological reactions of blood are, therefore, directly relevant to those found in crevicular fluid and may affect the health of the tooth and gingiva, and perhaps other mucosa. Crevicular fluid passes from the gingival crevice into the mouth, where it is mixed with saliva from the major and minor glands at a dilution of 1:500 to 1:1000. Thus, in addition to salivary IgA derived from the major and minor salivary glands, IgG derived from serum via crevicular fluid also could play a role in defense at mucosal surfaces.

## II. ORAL MUCOSAL DISEASES

### A. Recurrent Aphthous Stomatitis

#### 1. Characterization

Recurrent aphthous stomatitis (RAS; or recurrent oral ulceration, ROU) is one of the most common oral mucosal diseases and is characterized by oral ulcers, occurring singly or in crops, that usually persist for 7–21 days before healing spontaneously. These ulcers recur after a variable period of time, which may be a few days or several weeks. RAS can be separated clinically into three types: minor aphthous ulcers (MiAU), major aphthous ulcers (MjAU; Figure 1), and herpetiform ulcers (HU; Table I). Clinicians have shown a tendency to describe any ulcer occurring in the mouth as aphthous. However, aphthous ulcers have been defined carefully to allow differentiation from the many other types of ulcers occurring in the oral cavity (Table II) (Challacombe and Shirlaw, 1991).

The prevalence of RAS is on the order of 10% of the population, with a wide range reported in the literature. The peak age of onset of MiAU is in the second decade of life, MjAU in the first decade of life, and HU in the third decade

**Figure 1** Major aphthous ulcer showing periulcer erythema.

**Table I** Characteristics of Recurrent Aphthae

	Size	Shape	Color	Duration	Site	Ulcers/crop	Age of onset
Major	>0.5 cm	irregular/oval	gray base with indurated edges that may resemble a carcinoma	2/52–3/12; heal with scarring	most oral mucosa, but particularly fauces and soft palate	1–0	5–20 years
Herpetiform	0.5–3 mm	round/may coalesce to form irregular shape	yellow with marked periulcer erythema	1/52–2/52; heal without scarring	nonkeratinized oral mucosa, but particularly ventral surface of tongue, anterior labial sulci, and soft palate	5–20	20–35 years
Minor	2–7.5 mm	oval	yellow/gray base with thin erythematous border	1/52–2/52; heal without scarring	most nonkeratinizing oral mucosa, but particularly labial and buccal mucosa	1–5	5–45 years

of life. Thus some 85% of patients have developed RAS in the first three decades of life.

## 2. Genetic Aspects

A family history of ulcers is found in approximately 40% of patients. The highest incidence is found in sibling offspring of parents both of whom have RAS (Ship, 1965). Identical twins show a 90% concordance, implicating a genetic component (Miller *et al.*, 1977). The prevalence of HLA-A2 and B12 (B44) was shown to be higher in 100 patients with RAS than in 100 controls, suggesting that Class I gene products may be associated with the condition (Challacombe *et al.*, 1977b).

## 3. Etiology of Aphthous Ulceration

An impressive array of factors has been implicated as potentially causative in RAS, although many factors are likely to influence the nature of the disease rather than cause it (Table III). These factors include hereditary factors, hypersensitivity predisposition, socioeconomic status, psychological factors, endocrine factors, microbial agents, and chemical factors in foods (Wilson, 1980). No evidence exists that food allergy is causative in the majority of cases of aphthous ulceration although food allergy or intolerance is likely to initiate some cases of oral ulceration. Whether these cases can be distinguished clinically from the majority of cases of RAS is not clear.

Hematological deficiencies (Wray *et al.*, 1975; Challacombe 1977a); may not only cause some types of oral ulceration but also may influence susceptibility to other types of ulceration. In addition, lesions clinically consistent with RAS are found in association with some systemic or multisystem illnesses such as Behcet's syndrome, clinical neutropenia, vitamin B<sub>12</sub> deficiency, and celiac disease.

Little evidence exists to support a viral etiology for RAS. Typical RAS lesions fail to show any significant relationship to herpes virus on the basis of histopathology, culture, or serological investigations (Lehner, 1978). However, deoxyri-

bonucleic acid (DNA) hybridization experiments have indicated some homology between DNA of herpes type 1 virus and the DNA in mitogen-transformed lymphocytes from some cases of Behcet's syndrome and MiAU (Eglin *et al.*, 1982). Adenovirus has been identified in some aphthous lesions by immunofluorescence techniques, but no causative role has been determined (Sallay *et al.*, 1973).

## 4. Theory of Pathogenesis of RAS

Although no definitive infective microorganism has been identified, a currently accepted hypothesis for the etiology of RAS is that patients are exposed to an unidentified infective agent that, in susceptible patients, triggers an autoimmune response against oral mucosa (Donatsky, 1976). Therefore, the agent either is in or cross-reacts with oral mucosa in these patients. Autoantibodies, cytotoxic lymphocytes, and circulating sensitized lymphocytes to oral mucosa can be demonstrated in RAS patients (Lehner, 1978). In the majority of RAS patients, anti-epithelial antibodies that are cytotoxic to oral epithelial cells can be found (Thomas *et al.*, 1990).

## 5. Behcet's Syndrome

ROU, genital ulcers, and uveitis are the major features of Behcet's syndrome (BS; Behcet, 1937). Cutaneous, vascular, arthritic, neurological, and gastrointestinal manifestations may occur also (Lehner and Barnes, 1979). BS is an uncommon condition in the United Kingdom and the United States but is probably underdiagnosed. A high prevalence has been reported in Japan and in Eastern Mediterranean countries. Patients may suffer a variety of manifestations and, since only some may have the classical triad of ROU, genital ulcers, and iridocyclitis, involvement of a minimum of two of the major sites is sufficient for diagnosis. BS can be separated on clinical and prognostic bases into four types (Lehner and Barnes, 1979):

1. mucocutaneous type, in which the mouth, genitals, skin, and conjunctiva may be involved

**Table II** Classification of Oral Ulcers Related to Cause

Recurrent ulceration
Recurrent aphthous ulcers
Minor
Major
Herpetiform
Recurrent aphthous ulcers associated with Behcet's disease
Smoking-related aphthous ulcers
Atypical recurrent oral ulceration
Recurrent erythema multiforme
Recurrent/persistent oral ulceration
Secondary to haematological deficiency state/anemia
B <sub>12</sub> /Folate/Iron
Secondary to a gastrointestinal enteropathy
Ulcerative colitis
Crohn's disease
Celiac disease
Secondary to a dermatological condition
Benign mucous membrane/bullous pemphigoid
Pemphigus
Erosive lichen planus
Dermatitis herpetiformis and linear IgA disease
Secondary to connective tissue disease
Systemic/discoid lupus erythematosus
Oral ulcers as part of Reiter's syndrome
Single episode of ulceration
Infective
Viral (may also be recurrent)
Syphilitic
Tuberculous
Traumatic
Physical/mechanical
Chemical
Drug reaction
Single persistent ulcer
Neoplastic

2. arthritic type, in which one or more of the large joints is involved in addition to one or more of the mucocutaneous manifestations
3. neurological type, in which neurological involvement exists without ocular lesions
4. ocular type, which shows ocular involvement in addition to any of the mucocutaneous or arthritic features; of those with neurological manifestations, 92% show ocular involvement

Behcet (1937) proposed a viral etiology, but attempts to isolate viruses have been largely unsuccessful. However, several studies using DNA hybridization again have suggested a viral involvement (Denman *et al.*, 1986). Histopathological examination shows an early intense mononuclear cell infiltration, prominent vascular lesions, endarteritis obliterans, fibrinoid necrosis, and thromboses. The basic underlying histopathological lesion, therefore, is consistent with a vasculitis (Chajek and Fainaru, 1975).

## 6. Immunological Findings

No obvious association with classical autoimmune diseases has been demonstrated. Cellular immunity and hemagglutinating antibodies to fetal oral mucosa homogenates can be found in the majority of patients (Lehner, 1978). Antibodies against polymorphonuclear leukocytes and increased leukocyte chemotaxis (Matsumura and Mizushima, 1975) have been reported as well. Serum C9 levels may be increased (Adinolfi and Lehner, 1976) and C3 and C4 levels may be depressed before an attack of uveitis (Shimada *et al.*, 1974). Since C2 is reduced also, the classical pathway of complement may be activated. Immune complexes have been detected in the serum of 60% of patients, especially in those with the active form of neuroocular and arthritic types of BS (Williams and Lehner, 1977).

The abnormalities in the complement components and the clinical manifestations of uveitis, arthritis, and erythema nodosum suggest that such immune complexes may play a role in the pathogenesis of BS. The size and nature of the immune complexes may differ in the different types of BS. Recently an association between antibodies to a bacterial 65 kDa heat shock protein and Behcet's syndrome has been described (Lehner *et al.*, 1991).

BS has a well-established association with the major histocompatibility complex (MHC). The Class I gene product HLA-B51 (B5) is raised in all ethnic groups with BS studied to date (Spitler *et al.*, 1974; Lehner *et al.*, 1982). The Class II products DRw52 and DR7 also have raised prevalences, although this might be because of linkage disequilibrium with the Class I genes (Sun *et al.*, 1991).

### B. Lichen Planus

Lichen planus is a common and distinctive mucocutaneous disease that usually presents in the mouth as bilateral symmetrical white patches or striae on the mucosa, but may present as a bullous, ulcerative, or erosive condition, or even as desquamation of the gingivae. The most common form is a reticular pattern with a network of white striae, principally on the buccal mucosa (Wickham's striae: Figure 2). The lesions sometimes appear as white plaques on mucosa or

Hormones

**Figure 2** Classical reticular white striae in the buccal mucosa in lichen planus. Note also the erosive lesions medially in the buccal mucosa.

tongue, but often are associated with radiating peripheral white striae. Desquamative gingivitis is essentially an atrophic form of lichen planus. About 10% of patients presenting with oral lesions have cutaneous manifestations that appear as a papular rash, predominantly affecting the flexor surfaces of the arms. This condition is common and has a peak incidence in middle age. The lesions of the mucosa may persist for several years.

Lichenoid drug eruptions, which closely resemble lichen planus, can be precipitated by a number of drugs including methyl-DOPA,  $\beta$  blockers, and nonsteroidal anti-inflammatories and some antimalarials. Clinically, the lesions are often asymmetrical and histologically they may have a greater plasma cell or eosinophilic component, but distinguishing between true lichen planus and such lichenoid reactions often has been difficult.

### 1. Histopathological Features

Histologically, lichen planus is characterized by a dense, often band-like connective tissue infiltrate of lymphocytes that hugs the epithelium. This tissue formation is associated with widening of the basement membrane zone and loss of the basal cell layer, a phenomenon referred to as liquefaction degeneration. Also hyperparakeratosis, acanthosis, and,

classically, a saw-tooth configuration of the rete pegs occur. In the lower epithelial layers, circular eosinophilic Civatte bodies, which are probably degenerating epithelial cells, may be found. Alternating with acanthosis, epithelial atrophy may be found and, in some cases, is the predominant feature (Barnett, 1976).

### 2. Immunological Findings

Little evidence suggests that lichen planus is a classical autoimmune disease, but the finding of an intense lymphocytic infiltrate in addition to degeneration of the basal cell layer clearly suggests that immunological mechanisms may be of major importance in the pathogenesis. An early increase in the number of Langerhans cells in the epithelium (Ragaz and Ackerman, 1981) suggests that these cells may be functioning as antigen-presenting cells interacting with the lymphocytes. Contact between the Langerhans cells and mononuclear cells in lichen planus has been reported (Medenica and Lorincz, 1977). The antigen that might be responsible is unknown, but some studies have reported a lichen planus-specific epidermal antigen in the granular and deep-prickle epithelial cells in cutaneous lichen planus (Olson *et al.*, 1983).

Another early change in lichen planus is the expression of HLA-DR by keratinocytes. This expression by keratinocytes

also provides a possible mechanism by which epithelium-associated antigen could be presented to the lymphocytic infiltrate. However, this expression of HLA-DR by keratinocytes might be secondary to inflammation and switched on by interferon  $\gamma$  (IFN $\gamma$ ) produced by infiltrating lymphocytes rather than being a primary event.

The lymphocytic infiltrate is almost entirely composed of T cells (Dockrell and Greenspan, 1979). These T cells in the infiltrate are Ia antigen positive, suggesting they are activated T lymphocytes (DePanfilis *et al.*, 1983). The phenotype of the lymphocytes in established oral lichen planus appears to be predominantly CD8<sup>+</sup> or suppressor cytotoxic (Matthews *et al.*, 1984), although early lichen planus lymphocytes may be mainly CD4<sup>+</sup>. Predominantly helper-inducer CD4<sup>+</sup> T cells have been reported in cutaneous lesions (Bhan *et al.*, 1981). An antigen in the epithelium, possibly associated with local virus infection or induced by drugs, may be presented to lymphocytes in the connective tissue by Langerhans cells migrating from the epithelium. Reacting helper-inducer T cells then lead to the accumulation and retention of cytotoxic T cells that effect the keratinocyte damage. HLA-DR expression by keratinocytes is induced by IFN $\gamma$  and allows the keratinocytes to become involved in the persistence of the lesion by further presentation of antigen.

### C. Oral Candida Infections

Species of *Candida* can be found in the mouths of some 40% of normal subjects in amounts up to approximately 800 per ml. However, in patients with the various forms of candidiasis, these amounts are increased greatly; counts of more than 10<sup>4</sup> may be found. A classification of *Candida* infections is shown in Table IV.

1. Acute pseudomembranous candidiasis (thrush) is a common infection in the young, elderly, or debilitated. The white plaques are easily removable and contain candidal hyphae, spores, epithelial cells, and polymorphs.
2. Acute atrophic candidiasis also is known as antibiotic sore mouth because it frequently occurs during antibiotic therapy. This condition is a response to the suppression of the normal bacterial flora and is characterized by widespread erythematous stomatitis with accompanying depapillation of the tongue.
3. Chronic atrophic candidiasis (Figure 3A) also is known as denture sore mouth and presents as a relatively

asymptomatic confluent erythema and inflammation of the entire denture-bearing mucosa of the palate. This condition results from candidal colonization of the surface of the denture, usually in patients who wear their prosthesis continuously day and night.

4. Chronic hyperplastic candidiasis (candidal leukoplakia; Figure 3B) is a speckled or nodular chronic leukoplakia usually found in middle-aged or elderly patients. This invasive form of candidiasis shows hyphae present often throughout the depth of the epithelium, and carries a significant risk of malignant transformation.

Infection with *Candida albicans* is an almost universal finding in patients with severe immunodeficiency of the T-cell type. However, this condition is not seen in patients with B-cell defects in the absence of concomitant T-cell defects. *Candida* infections are found in about 40% of human immunodeficiency virus (HIV)-infected individuals and in over 75% of patients who suffer from acquired immunodeficiency syndrome (AIDS). Acute pseudomembranous candidiasis is found particularly in association with low CD4 counts, but a newly recognized entity, erythematous candidiasis, is found often. This condition presents as areas of erythema, usually of the palate or tongue, in the absence of white plaques (Challacombe, 1991).

Theoretically, IgA and cellular immunity might be expected to play a role in the protection of mucosal surfaces against candidal infections. Certainly in IgA-deficient individuals, a markedly increased prevalence of *Candida* infection is apparent. Animal studies using the rhesus monkey have emphasized the role of cellular immunity in chronic *Candida* infections (Budtz-Jorgensen, 1973). In this model, azathioprine-treated monkeys showed a depression of cellular immunity to *Candida* but a normal humoral antibody response. These animals had a prolonged and severe *Candida* infection, suggesting that cellular immunity to *Candida*, not serum antibody titer, is of primary importance in host resistance. *Candida* infection is not a noted feature of selected IgA deficiency although, in patients with chronic mucocutaneous candidiasis, over 50% appear to have reduced salivary IgA antibodies (Lehner *et al.*, 1972). Although serum IgG antibodies against *Candida* can be detected readily in humans, serodiagnosis of candidal infections is inconsistent.

In chronic mucocutaneous candidiasis (CMCC), a wide spectrum of immune abnormalities has been reported that ranges from lowered serum IgM and IgG antibodies to defects

**Table IV** Classification of Oral Candidiasis

Acute	Acute/chronic	Chronic
Pseudomembranous candidiasis Thrush	Erythematous candidiasis (HIV associated)	Hyperplastic candidiasis Candidal leukoplakia Median rhomboid glossitis
Atrophic candidiasis Antibiotic sore mouth	Angular cheilitis Mucocutaneous candidiasis	Atrophic candidiasis Denture induced stomatitis (Denture sore mouth)

**Figure 3** (A) Chronic atrophic candidiasis (denture-induced stomatitis) with marked erythema of palate corresponding to the denture outline. (B) Adherent nodular white patch at angle of mouth—histologically hyperplastic candidiasis.

in lymphocyte transformation and mitogen stimulation in the most severe types of CMCC (Lehner *et al.*, 1972). However, whether these immune defects are primary to the disease or a consequence of it is not clear. Several studies have shown restoration of immune functions once *Candida* has been cleared by antifungal therapy (Valdimarrson *et al.*, 1973).

#### D. Immunology of Dental Caries

Dental caries is one of the most prevalent diseases of humans. Despite reductions in the rate of decay in Western societies, the prevalence of caries in developed countries remains at greater than 95% of the population. Caries is still increasing in the developing countries. Thus, for practical purposes, the condition can be considered ubiquitous in developed countries. The cost of treatment of dental disease is probably the highest among bacterial infections and also results in considerable loss of time and productivity.

Dental caries may be defined as the localized destruction of tooth tissue by bacterial action. Dissolution of the hydroxyapatite crystals seems to precede the loss of organic components of both enamel and dentine. Demineralization is thought to be caused by acids resulting from the bacterial fermentation of dietary carbohydrates. Not all surfaces of the tooth are afflicted equally; areas that are protected from cleansing, for example, the fissures and areas between the teeth, are much more susceptible to decay.

##### 1. Immunity to Caries

The concept of immunity to caries depends on the demonstration that caries is a bacterial infection. Although vaccination against dental caries was attempted in the 1930s, the real impetus for development of vaccination came with the demonstration, using germ-free animals, that caries could not occur in the absence of bacteria regardless of diet and that specific bacteria were needed.

The tooth sits in a unique position between the secretory and systemic immune systems. The majority of the tooth surface would seem to be accessible to saliva, although the most caries-susceptible sites around the gingival margin and between the teeth are bathed in crevicular fluid (Figure 4). (Shillitoe and Lehner, 1972). Antibodies in crevicular fluid are derived largely from serum, although the local contribution, particularly of IgG, is up to  $\approx 20\%$  of the total antibody content (Brandtzaeg, 1972).

Both serum and secretory systems have been examined for natural immunity in humans, and for the protective effects in vaccination experiments in animal models. Induction of antibodies in both immune systems might be necessary to achieve effective protection by immunological methods.

##### 2. Causative Bacteria

Streptococci, lactobacilli, and *Actinomyces* species all have been shown to be able to cause caries in animal models. In humans, by far the strongest association is with *Streptococcus mutans*. This organism can produce copious amounts of extra polysaccharide from sucrose, much of which is insoluble in water (or saliva). *Streptococcus mutans* is also very

**Figure 4** Source of immunoglobulins bathing the teeth. Modified from Lehner, T. (1992). *Immunology of Oral Diseases*, 3rd ed. p. 12. Blackwell Scientific Publications, Oxford.

to date, including rats, hamsters, monkeys, and gerbils.

In the absence of detectable caries, the number of *S. mutans* in plaque is very low, but in carious lesions the numbers are raised substantially in nearly all subjects (Huis in't Veld *et al.*, 1979). However, some lesions apparently can develop in the absence of *S. mutans*, particularly in fissures. In addition, large numbers of *S. mutans* in plaque do not necessarily lead to the initiation of caries.

##### 3. Natural Immunity to Caries in Humans

The question of natural immunity requires the comparison of subjects with low caries experience with those with high caries experience in the absence of carious lesions. Several studies have compared low caries with rampant caries, but these studies confuse the question of natural immunity with that of an immune response to the caries process.

Subjects with low caries experience have significantly raised serum IgG antibody titers against whole cells of *S. mutans* compared with subjects with high caries experience (Figure 5; Challacombe and Lehner, 1976). This relationship seems to be specific to *S. mutans* and has not been found with strains of *Streptococcus sanguis*, *Streptococcus salivarius*, *Lactobacillus casei*, *Lactobacillus acidophilus*, or *Actinomyces viscosus* (Challacombe and Lehner, 1976). Serum IgG antibodies against the surface protein antigen I/II also are raised in subjects with low caries experience (Challacombe *et al.*, 1984). This protein has been used in immunization experiments in animals; inhibition studies indicate that antigen I/II is a major antigenic component of the *S. mutans* cell wall. (Czerkinsky *et al.*, 1983). IgG antibodies against antigen

I/II are mainly of the IgG1 subclass, whereas those against whole cells of *S. mutans* are mainly IgG1 and IgG2 (Challacombe *et al.*, 1986). These studies are consistent with the interpretation that serum IgG antibody contributes to protection against caries in humans.

#### 4. Immune Responses That Follow Dental Caries

Raised serum IgG antibody titers against *S. mutans* are found in subjects with carious lesions (Figure 5) compared with those without. This raised antibody titer seems to be specific to *S. mutans*, thus further implicating this bacterium in the pathogenesis of caries (Challacombe and Lehner, 1976; Challacombe, 1980). These findings are consistent with the view that infection with *S. mutans* and the development of carious lesions is associated with a rise in specific antibodies against *S. mutans*, as was confirmed in longitudinal studies (Challacombe, 1980), and are similar to findings in most infective diseases in which a rise in antibodies after infection is common.

Salivary antibody levels appear to be more variable than serum antibodies. The secretion rate of antibodies has been considered in few studies, although the great variation in salivary secretion rates is well known. No consistent patterns have emerged; raised levels of salivary IgA antibodies against *S. mutans* have not been found in subjects with low caries

**Figure 5** Serum and salivary antibodies in relation to dental caries. ■, antibodies to *S. mutans*; □, antibodies to *S. sanguis*; low, low DMF group; high, high DMF group; caries, group with carious lesions.

experience, and may reflect cumulative caries experience rather than protection (Challacombe and Lehner, 1976).

#### 5. Genetic Factors

Genetic factors long have been thought to play a role in caries resistance. Evidence has been found of genetically related immune factors in association with caries. In a study of caries-prone and low caries subjects using streptococcal antigen I/II, specific helper factor was found to be released optimally by a dosage between 1 and 10 ng antigen I/II from lymphocytes of low caries subjects, but the optimal dosage for caries-prone subjects was 1000 ng (Lehner, 1982). This marked difference in responses supports the suggestion that caries-resistant and caries-prone subjects differ in their ability to mount and maintain serum antibody responses to *S. mutans*. The response to antigenic stimulation using antigen I/II was related to the HLA status of the subjects (Figure 6). HLA-DRw6-positive subjects generally showed an optimal response at a low dose, whereas subjects who showed an optimal response at the high antigen dose were found to be HLA-DRw6 negative. These findings suggest that the ability to respond to very small amounts of streptococcal antigen may be the reason for the high levels of antibody against *S. mutans* in low-caries subjects. However, the immunoregulation of such responses is complex, and this area requires further study.

#### 6. Immunization against Dental Caries

Theoretically, local or systemic immunization might lead to protection against dental caries. With respect to local immunization, the rat has been used extensively as a model. Several groups have shown that the induction of salivary antibodies may be related to a reduction in caries (Smith *et al.*, 1979; McGhee and Michalek, 1981). Salivary IgA antibodies in humans may be induced by ingestion of capsules filled with *S. mutans* organisms (Mestecky *et al.*, 1978). No extended studies have been performed to see the effect of such antibody on caries. At present, longterm immunization seems

**Figure 6** T-cell helper function in relation to streptococcal antigen I/II concentration.

**Figure 7** Reduction in caries by immunization with *Streptococcus mutans* antigens. Weeks 0–24 oral immunization; subcutaneous immunization at week 0.

to be necessary since the salivary antibody response is short lived. Salivary antibodies may prove to be effective since a reduction in *S. mutans* numbers has been reported in such immunized subjects (Cole *et al.*, 1984).

Successful systemic immunization against dental caries in monkeys was reported first in 1969. Since then, Lehner and colleagues (1976, 1980) have described many experiments in the rhesus monkey model, and have demonstrated unequivocally that caries can be reduced by immunization. In early experiments, animals were immunized subcutaneously with whole cells of *S. mutans* in Freund's incomplete adjuvant; reduction in caries on the order of 75–80% was seen. Antibodies were detected in both serum and saliva, but the reduction in caries correlated best with serum antibodies against *S. mutans*. Passive transfer experiments in the monkey (Lehner *et al.*, 1978) have confirmed that serum IgG antibodies may be effective in reducing caries.

Subsequently, purified antigens from *S. mutans* also have been shown to be effective in reducing caries in the monkey (Figure 7). These antigens include glucosyltransferase and antigen I/II (Lehner *et al.*, 1980), as well as other protein antigens. Immunization with antigen I/II elicits serum IgG antibodies, skin delayed hypersensitivity, and a reduction of caries equivalent to that seen with immunization with whole cells of *S. mutans* (Lehner *et al.*, 1980). These studies suggest that vaccination of humans is a very real possibility.

An additional exciting possibility in caries prevention is passive immunization. Lehner and colleagues have shown that a monoclonal antibody against antigen I/II may inhibit the colonization of *S. mutans* in the oral cavity of humans and monkeys (Ma and Lehner, 1990). Given a suitable delivery system for monoclonal antibodies into humans, this method could be useful in reducing caries, and overcomes some of the objections to systemic therapy.

## E. Immunology of Periodontal Diseases

### 1. Classification

Periodontal diseases can be divided into at least four clinical entities (Table V). Gingivitis is a reversible inflammation

of the gingivae and can be considered an inflammatory reaction to the presence of plaque. Plaque contains many bacterial species; currently, the consensus is that gingivitis represents a nonspecific response to bacterial toxins and antigens.

Marked advances have been made in the past two decades in understanding the host responses that play a critical role in determining the course of periodontal infections. These advances have been facilitated greatly by additional knowledge of the microflora associated with different periodontal diseases. *Porphyromonas (Bacteroides) gingivalis* appears to be the major etiological organism associated with adult periodontitis, *Actinobacillus actinomycetemcomitans* is associated with localized juvenile periodontitis, and *Prevotella (Bacteroides) intermedia* and spirochaetes are associated with acute necrotizing ulcerative gingivitis. In addition, *Capnocytophaga* species have been associated with periodontal disease in immunocompromised hosts (Genco and Slots, 1984). Long-term epidemiological studies (Loe *et al.*, 1986) suggest that, even in subjects with gingivitis, only 10–15% eventually develop severe periodontal disease, clearly suggesting a role for host factors in the progression of periodontal diseases.

### 2. Adult Periodontitis

Not all cases of gingivitis ultimately develop periodontitis (Figure 8), but gingivitis always seems to precede periodontal disease. The hypothesis of four stages in the development of periodontal lesions (Page and Schroeder, 1982) was based primarily on histopathological findings and generally has been accepted (Figure 9).

1. The initial lesion is essentially gingivitis, localized to the gingival sulcus, and is reversible. Histologically, this condition is characterized by a polymorphonuclear leukocyte infiltration in response to plaque. This infiltrate has been shown in experimental gingivitis to develop within 2–4 days of plaque accumulation. Since serum antibodies against a variety of plaque bacteria can be detected (Genco and Slots, 1984), this initial lesion could be caused by activation of complement by the alternative pathway by plaque components or by the classical pathway by antibodies.

2. The early lesion is still essentially reversible and is characterized by a replacement of the polymorphonuclear infiltrate with lymphocytes, which may constitute some 75% of the cellular infiltration. At this stage, few plasma cells are seen. Most of the lymphocytes are T cells, with a small proportion of B cells, depending on the site examined.

3. The established lesion exists 2–3 wk after plaque accumulation. The distinguishing histopathological feature is the predominant plasma cell infiltrate. Many of the B cells seen in the early lesion are assumed to have been transformed by plaque antigens. Most of the plasma cells are IgG isotype. At this stage, the junctional epithelium may extend apically into the connective tissue, with an associated loss of collagen. Pocket formation occurs by a deepening of the gingival sulcus. Circulating systemic lympho-

**Table V** Classification of Periodontal Diseases<sup>a</sup>

Gingivitis		Periodontal diseases	
Acute	Chronic	Adult periodontitis	Periodontitis with systemic disease
Acute necrotizing gingivitis (ANUG)	Chronic marginal gingivitis	Early onset periodontitis	Down's syndrome, diabetes, cyclical neutropenia, Papillon-Lefevre syndrome, HIV infection
Acute herpetic gingivostomatitis	Plasma cell gingivitis	Prepubertal periodontitis	
Traumatic gingivitis	Desquamative gingivitis (Dermatoses)	Generalized	
Physical (Toothbrushing)	HIV-associated gingivitis	Localized	
Chemical (Aspirin burn)	Drug-induced gingivitis (e.g., Phenytoin)	Juvenile periodontitis	Necrotizing ulcerative periodontitis
Leukemia		Generalized	Refractory periodontitis
		Localized	
		Rapidly progressing periodontitis

cytes sensitized to plaque bacteria can be detected (Ivanyi and Lehner, 1970).

4. The advanced lesion marks the transition from a chronic established lesion to a destructive state. The host factors responsible for this transition have not been established fully, but evidence suggests that this stage of the disease is specific. *Porphyromonas (Bacteroides) gingivalis* has been associated strongly with this condition. Undoubtedly, the host immune responses play a critical role also. Histopathological features include pocket formation, ulceration of the pocket epithelium, destruction of the collagenous periodontal ligament, and, significantly, resorption of bone. These features eventually lead to mobility and loss of the teeth. The dense infiltration of plasma cells, lymphocytes, and macrophages now extends apically and is progressive.

### 3. Mechanisms of Damage in Periodontal Diseases

**a. Bacterial invasion.** Bacteria have been reported to invade the gingivae in gingivitis, in adult periodontitis (Saglie *et al.*, 1982), in acute ulcerative gingivitis (Listgarten, 1965), and in juvenile periodontitis (Gillett and Johnson, 1982). Bacterial invasion of the periodontal tissues could be an important component of the pathogenesis of periodontal disease, although bacterial toxins or the immune reaction to toxins could account equally for most of the damage seen.

**b. Tissue destruction.** Extensive studies have been made of the capabilities of periodontopathic bacteria to produce tissue damaging factors. *Porphyromonas gingivalis* shows an impressive ability to produce toxins or enzymes that are active against many substrates, including collagen, epithelial cells, and fibroblasts, and can stimulate bone resorption (Genco and Slots, 1984). No doubt, therefore, these organisms could inhibit most host responses marshalled against them.

**c. Healing and fibrosis.** An attractive hypothesis for the destructive phase of periodontal disease is that bacterial toxins or the reactions to them inhibit normal healing and repair, and that this inhibition leads to progressive damage to the

periodontium (Figure 9). The role of macrophages, for example, in fibrosis and repair, has received little attention although they are important cells in tissue repair. Activated macrophages produce fibroblast activating factors that stimulate the fibroblasts into active proliferation (Wahl and Wahl,

**Figure 8** Anterior teeth showing loss of soft tissue attachment and underlying bone, with heavy plaque, and calculus deposits in adult periodontitis.

**Figure 9** Hypothesis of periodontal aetiology. Reprinted with permission from Linde (1989).

1981). Fibroblast function also is affected by lymphocytes in inflammatory lesions, since the latter produce a chemotactic factor for fibroblasts (Postlethwaite *et al.*, 1976). Macrophages and lymphocytes therefore produce factors that recruit fibroblasts to the area of inflammation, stimulate their proliferation, and, thus, indirectly stimulate collagen production with replacement of lost collagen. Bacterial factors that interfere with this normal repair could have a profound effect on disease activity.

#### 4. Serum Antibodies to Periodontal Bacteria

**a. Adult periodontitis.** Many studies have examined the presence of antibodies against periodontopathic bacteria in the serum of patients with periodontal disease (Genco and Slots, 1984). Most of these studies have found raised antibodies against *P. gingivalis* in patients with adult periodontitis in comparison with controls (Mouton *et al.*, 1981; Taubman *et al.*, 1982). *Prevotella intermedia* has not been associated immunologically with adult periodontitis, but has been implicated in acute necrotizing gingivitis (Dzink *et al.*, 1985). Overall, the immunological findings confirm bacteriological findings and support the association of *P. gingivalis* with adult periodontitis.

**b. Juvenile periodontitis.** This disease is associated strongly with the bacterium, *A. actinomycetemcomitans* (Genco and Slots, 1984). In addition, antibodies against *A. actinomycetemcomitans* have been found in all patients with juvenile periodontitis at levels significantly greater than in

controls (Genco *et al.*, 1980). This *Actinobacillus* species produces a powerful leukotoxin (Taichman *et al.*, 1982); neutralizing activity against this toxin is present in the serum of patients with juvenile periodontitis (Tsai *et al.*, 1981). An interesting finding in this disease is the demonstration that many patients have depressed neutrophil chemotaxis and phagocytosis. Some 75% of patients with the classical localized disorder appear to suffer from a peripheral blood neutrophil chemotactic abnormality (Cianciola *et al.*, 1977). Neutrophil migration through the gingival crevice appears to be abnormal. These findings suggest a role for neutrophils in normal protection and suggest that, in juvenile periodontitis, this function is depressed, allowing for the overgrowth of organisms, particularly those such as *A. actinomycetemcomitans* that produce leukotoxic factors.

#### F. Immunology of Salivary Gland Diseases: Sjögren's Syndrome

Sjögren's syndrome (SS) is by far the most common immunologically based disease affecting the salivary glands. This condition is probably the second most prevalent collagen disease after rheumatoid arthritis (RA). SS is a chronic inflammatory disease with involvement of many systems and is characterized by a triad of dry eyes (keratoconjunctivitis sicca), dry mouth (xerostomia), and a connective tissue or collagen disease. The association of dry eyes and dry mouth, in the absence of a connective tissue disease, is known as the sicca syndrome. In secondary SS, the most commonly associated connective tissue disease is RA, but systemic lupus erythematosus, scleroderma, dermatomyositis, polyarteritis, primary biliary cirrhosis, and idiopathic thrombocytopenic purpura may be associated. SS affects females nine times more frequently than males, and is seen especially in the elderly. A dry mouth is the presenting symptom in the majority of patients.

A subdivision of Sjögren's syndrome has been described in which patients suffer from xerostomia and primary generalized nodal osteoarthritis; the salivary glands of these individuals show nonspecific sialadenitis, in contrast to the focal lymphocytic infiltrate of primary Sjögren's syndrome. This condition has been called SOX syndrome (Challacombe *et al.*, 1991). Whether it is a genetically homogeneous group is not clear. Nonspecific chronic sialadenitis in the absence of osteoarthritis is a common cause of xerostomia.

##### 1. Pathogenesis of SS

SS has many of the characteristics of a cell-mediated autoimmune disease. Histopathology shows a mononuclear cell infiltration of the salivary glands, with acinar destruction but sparing of the ducts. The lymphocytes appear to originate from an extrasalivary source. T-cell sensitization to salivary tissue may occur (Berry *et al.*, 1972). Lymphocytes and plasma cells occur in a perivascular distribution and the proportion of T lymphocytes increases as the lesions progress (Talal *et al.*, 1974). Intraductal cell proliferation forms compact epimyoepithelial islands. Patients with primary SS show an increased association with HLA-DwA3 (84%) and HLA-B8 (Chused *et al.*, 1977). IgG, IgA, or IgM autoantibodies

against ductal cell ribonucleoproteins called SSA(Ro) and SSB(La), which appear to be dimers of 52 and 65 kDa, are found in Sjögrens syndrome but do not appear to be responsible for tissue destruction (Moutsopoulos and Zerva, 1990) and do not correlate with focal lymphocytic sialadenitis. A possible association with Epstein-Barr virus infection has been claimed (Gaston *et al.*, 1990; Syrjanen *et al.*, 1990), Talal *et al.* (1990) have found that sera from many cases of primary Sjögrens syndrome react with the retroviral p24 antigen. The significance of these findings remains to be determined.

Rheumatoid factor occurs in 52–100% of patients, even in the absence of RA, and antinuclear antibody is found in 60% of patients (Beck, 1961). Other autoantibodies, for example, to thyroglobulin gastric parietal cells and mitochondria, are seen often. B cells in some patients bear multiple classes of heavy chains, an abnormality that may be significant since, in a small proportion of patients, SS progresses to lymphoma.

### III. ORAL MUCOSAL MANIFESTATIONS OF DISTANT IMMUNOLOGICAL DISEASES

#### A. Gastrointestinal Diseases

Celiac disease, ulcerative colitis, and Crohn's disease all can appear in the oral cavity. Frequently, the oral cavity can be the presenting site, although Crohn's disease can be limited to the oral cavity. Each of these gastroenteropathies can give rise to oral ulceration.

#### 1. Celiac Disease

Some 25% of patients with celiac disease may give a history of oral ulceration. However, the converse is not true. Studies of the incidence of celiac disease in patients presenting with recurrent aphthous stomatitis found 2–4% on the basis of jejunal biopsy (Ferguson *et al.*, 1980). The oral ulcers of those patients with celiac disease often respond extremely well to correction of underlying hematological deficiencies, particularly folate and iron. The oral ulceration seems to be the result of the associated deficiencies rather than a direct response of the oral mucosa to the allergen. Cooper *et al.* (1980) have described adult female patients suffering from abdominal pain and chronic diarrhea who responded immediately to a gluten-free diet and in whom symptoms returned on gluten challenge. Oral ulceration and macroglossia were described in several of these patients, but jejunal biopsies were normal, suggesting that oral signs and symptoms can be associated with gluten in the absence of celiac disease and that such oral symptoms are accompanied by varying abdominal problems.

#### 2. Crohn's Disease

Many cases of oral Crohn's disease have been reported over recent years, with or without accompanying gastrointestinal Crohn's. Crohn's disease in the mouth may present

either as thickened rubbery lips and cheeks with deep fissures and enlarged gingiva or as ulcers and epithelial tags in the buccal sulcus (Figure 10). In both these clinical manifestations, biopsy of the affected areas will show granulomata. A number of cases of swollen lips without any intraoral signs have been reported that also have been classified as oral Crohn's by some workers, although the term "cheilitis granulomatosa" would be more appropriate. The role of allergy to food or other substances has not been investigated fully, although some patients have been reported to be sensitive to cinnamon or sodium benzoate.

#### 3. Ulcerative Colitis

Oral ulceration frequently is associated with ulcerative colitis and may be one of at least four types: (1) aphthous, (2) pyostomatitis necrotica, (3) pyostomatitis vegetans, or (4) hemorrhagic. The incidence of oral lesions in patients with ulcerative colitis is approximately 20%. The oral ulcers of groups 2, 3, and 4 are readily distinguishable from the more common types of aphthous ulceration. Unlike Crohn's disease, these lesions do not appear to occur in the oral cavity in the absence of any bowel symptoms.

#### 4. Food Allergy and Oral Disease

Allergies to foods certainly may be manifest in the oral cavity. These sensitivities may present with a variety of oral signs and symptoms, including a perioral rash, swelling of the lips, oral pruritis, fissuring of the tongue, or oral ulceration (Challacombe, 1986). Aphthous ulceration affects approximately 10% of the population but food allergy or intolerance is unlikely to be responsible for more than a very small proportion of total cases, perhaps less than 1%. Overall, oral symptoms are most likely to be found in the atopic patient; in these subjects, allergy to foods should be entertained as a possible diagnosis in the absence of disease elsewhere.

**Figure 10** Ulceration in lower buccal sulcus associated with oral Crohn's disease. Note also folded appearance of buccal mucosa.

## B. Dermatoses

### 1. Discoid Lupus Erythematosus

Traditionally, lupus erythematosus is classified into a chronic discoid type (DLE) and a systemic type (SLE). Both types may give rise to lesions within the oral mucosa. The buccal mucosa is involved most frequently and bilateral lesions are common. Classically, the lesions appear as atrophic erythematous areas surrounded by a keratotic border. Sometimes the lesions are more plaque like and may resemble lichen planus or leucoplakias. Skin lesions are found in approximately half the patients. Histologically, the epithelium always shows orthokeratosis and parakeratosis, and areas of moderate epithelial hyperplasia alternate with areas of epithelial atrophy. A rather deeply seated focal or perivascular accumulation of lymphocytes is seen. Although a genetic susceptibility exists in SLE, with an increased frequency of HLA-DR2 and DR3 in Caucasian populations, no such relationship has been established for DLE (Woodrow, 1988).

### 2. Pemphigus

Pemphigus is a potentially lethal chronic bullous disease of the stratified squamous mucosa and skin, occurring mainly in adults over the age of 60 but sometimes in young adults (Zegarelli and Zegarelli, 1977). This condition commonly affects the oral mucosa and may present orally. Histologically, acantholysis with intraepithelial bulla formation is present. Serum IgG, IgM, or sometimes IgA autoantibodies against intercellular substances of the suprabasilar epithelium of skin and mucosa are found in 95% of cases of pemphigus (Beutner *et al.*, 1968). The autoantibody titer is correlated with the severity of pemphigus, and antibody disappears as the lesions heal (Weissman *et al.*, 1978).

Serum from patients can produce the characteristic histological lesion in organ culture of the skin. Antibody can be demonstrated to be bound to the epidermal cells prior to the onset of acantholysis. Acantholysis may be caused by an autoantibody-induced release of autolytic enzymes from the damaged epithelial cells (Schiltz *et al.*, 1978). Using direct immunofluorescence, IgG antibodies bound to intercellular areas of epithelium in patients with pemphigus can be demonstrated (Beutner *et al.*, 1968). These autoantibodies are, therefore, likely to be the cause of the lesions. HLA associations have been reported, particularly in Jewish and Japanese populations. An increased incidence of HLA-A10 and HLA-DR4 is seen in pemphigus. An interesting finding is the association of pemphigus with an HLA-DQw1B allele (Sinha *et al.*, 1988).

### 3. Benign Mucous Membrane Pemphigoid

Benign mucous membrane pemphigoid (BMMP; cicatricial or ocular pemphigoid) is a disease giving rise to bullous lesions predominantly involving the mucous membranes rather than the skin. Most cases are detected in the fourth decade; the disease is much more frequent in females than in males (McCarthy, 1972). As in bullous pemphigoid, histopathological examination of the lesion shows subepithelial vesiculation

and deposition of IgG, IgA, C<sub>3</sub>, and C<sub>4</sub> in the basement membrane area. In contrast to bullous pemphigoid, serum autoantibodies against epithelial basement membrane are detected infrequently and are in low titer (Rogers *et al.*, 1982).

Intraorally, two variants of BMMP are seen. The most common consists of bullous lesions involving much of the nonkeratinized and occasionally the keratinized mucosa. The other type is a form of desquamating gingivitis and involves only the gingivae around the teeth. The gingivae are very erythematous and hyperemic. Small bullae may be formed in protected areas around the teeth.

### 4. Erythema Multiforme

Erythema multiforme is a mucocutaneous disease characterized by typical target skin lesions, with oral or ocular involvement in some cases and a marked tendency to recur. The condition mainly affects young adult males and has a seasonal incidence, being seen mainly in the spring or autumn.

The etiology of oral erythema multiforme has not been established, but many agents have been implicated. A wide range of drugs may be responsible, especially the barbiturates, phenylbutazone, sulfonamides, carbamazepine, and penicillin. The anticonvulsant drugs of the hydantoin and succinimide groups may cause a severe bullous form of erythema multiforme (Levantine and Almeyda, 1972). Certain infections such as herpes simplex, Mycoplasma, Histoplasma, and Trichomonas also may be associated with erythema multiforme (Shelley, 1967). The most common identifiable factor associated is a preceding herpes simplex virus infection, and this relationship is found in about 15% of patients (Lozada and Silverman, 1978). Herpes simplex virus usually is not isolated from the lesions nor is it demonstrable in biopsy specimens, but erythema multiforme can be induced by challenge with a vaccine of herpes simplex virus (Shelley, 1967). In the majority of instances, however, no causal factor is found; little evidence exists for an allergic cause. No abnormalities of immunoglobulin levels, lymphocyte transformation, or skin testing have been reported, but increased macrophage aggregation is seen (Krueger *et al.*, 1973). Immune complexes may activate the classical pathway of complement to initiate bulla formation (Safai *et al.*, 1977). Histologically, degenerative changes occur at the dermo-epidermal junction. Acanthosis occurs, with bullae either sub- or intraepithelially. The degenerating oral epithelium is strikingly eosinophilic and a lymphohistiocytic infiltration in the lamina propria is common (Lozada and Silverman, 1978).

# Immunobiology of the Tonsils and Adenoids

Joel M. Bernstein • Noboru Yamanaka • David Nadal

## I. INTRODUCTION

The palatine tonsils and the nasopharyngeal tonsil (adenoid) are lymphoepithelial tissues located in strategic areas of the oral pharynx and nasopharynx, respectively. These immunocompetent tissues represent the first line of defense against ingested or inhaled foreign proteins such as bacteria, viruses, or food antigens. Tonsillectomy and adenoidectomy are the most common major operations performed on children under general anesthesia in the United States (Paradise and Bluestone, 1976). However, the indications for tonsillectomy and adenoidectomy have been complicated by the controversy over the benefits of extracting a chronically infected tissue and the possible harm this operation may cause by eliminating an important source of local mucosal defense in the host. The information necessary to make a rational decision in resolving this controversy can be obtained by understanding the immunological potential of the normal tonsils and adenoids and by comparing these functions with the changes that occur in the chronically diseased tonsil and adenoid. This chapter reviews the distribution of immunocompetent cells in various locations of the palatine tonsil and nasopharyngeal tonsil, and compares their numbers and function in aging and chronic infection. Further, the role of the tonsils and adenoids as part of the common mucosal immune system is reviewed. Finally, the palatine tonsil as a potential source of autoimmunity in other parts of the body is discussed briefly.

## II. IMMUNOLOGICAL CYTOARCHITECTURE OF THE TONSILS AND ADENOIDS

The palatine tonsil and nasopharyngeal tonsil have a characteristic lymphoid architecture that includes a reticular epithelium, a follicular region or primary and secondary germinal centers that are covered with mantle zones, and extrafollicular regions. The immunocompetent cells that are present in these various regions of the tonsil have been studied thoroughly by many investigators using specific polyclonal and monoclonal antibodies directed against specific epitopes of lymphocytes (Brandtzaeg *et al.*, 1979; Surjan *et al.*, 1978; Stein *et al.*, 1980; Surjan, 1980; Yamanaka *et al.*, 1983b, 1992; Brandtzaeg, 1984, 1987; Harabuchi *et al.*, 1985; Bernstein *et al.*, 1988).

Figure 1 summarizes the immunological cytoarchitecture of the palatine tonsil. The principal route of antigen uptake occurs in palatine tonsils in their crypts and in the nasopharyngeal tonsils in their furrows. In the human palatine tonsil, 10–20 crypts markedly increase the surface exposure for antigen uptake (Junqueira and Carneiro, 1980). Cells that may be important in antigen uptake, microfold (M) cells, are present that are also present in Peyer's patches of the small bowel (Owen and Nemanic, 1978). In addition, many HLA-DR-positive cells exist deep in the crypt that also may be important in antigen uptake (Brandtzaeg, 1984, 1987). Other important cells involved in antigen transport are macrophages, interdigitating cells (ICs) that are present in the extrafollicular areas (Tew *et al.*, 1982), and follicular dendritic cells (FDCs) that are primarily present in the germinal centers (Heinen *et al.*, 1984; Tew *et al.*, 1989).

Using specific monoclonal antibodies directed against receptors on the surface of antigen-presenting cells (APCs), our laboratory has demonstrated the distribution and location of APCs in the nasopharyngeal tonsil (Bernstein *et al.*, 1991). MAC387 and CD68 were used to identify cells of the monocyte-macrophage series, S-100 antibody was used to identify interdigitating cells, and antibody directed against the C3b receptor defined antigen-retaining reticulum in germinal centers. Quantification of the cells was done in the four compartments of the nasopharyngeal tonsils, namely, the crypt epithelium, the extrafollicular zones, the mantle zone, and the germinal center. Table I summarizes the average percentage of PCAs in the compartments of the nasopharyngeal tonsil. Figure 2(a–g) demonstrates different types of APCs in the nasopharyngeal tonsil compartments.

Thymus-derived (T) cells characteristically occupy the extrafollicular zones, but the helper-inducer T lymphocytes are also present in the germinal centers (Yamanaka *et al.*, 1983b). B cells are primarily present in the germinal center and mantle zone, but also may be found in the reticular epithelium. Using the fluorescence activated cell sorter (FACS), we measured the percentages of various T-cell subsets and different types of B cells in the palatine tonsil and adenoid. These data are summarized in Table II and are compared with the lymphocyte subpopulations in the autologous peripheral blood. The average percentage of T and B cells in the palatine tonsils, respectively, is 42% and 52%. In the peripheral blood, 67% of lymphocytes are T cells and 14% are B cells. CD4<sup>+</sup>Leu8<sup>+</sup> cells represent suppressor-inducer cells, whereas CD4<sup>+</sup>Leu8<sup>-</sup> cells represent helper-

**Figure 1** High power photomicrograph of the morphology of the tonsil surrounding a crypt (C). Antigen (Ag) enters the crypt and is taken up by cells of the reticular epithelium (RE). Antigen-presenting cells in this region consist of Langerhans cells, macrophages, and perhaps M cells. These cells then transport antigen to T cells in the extrafollicular zone (EF). In addition, antigen presentation to cells in the mantle zone (MZ) may stimulate memory cells with surface IgD and IgM to switch to more mature clones of B cells possessing IgA and IgG. Finally, specific dendritic cells in the germinal center (GC) may be responsible for antigen presentation to B cells in this area.

inducer cells (Lanier *et al.*, 1983). The helper-inducer cells represent the majority of cells found in the palatine tonsil, whereas the suppressor-inducer T cells are more abundant in the peripheral blood.

Using immunohistological localization of immunoglobulins, various investigators have studied the distribution of immunoglobulin-bearing cells in the palatine tonsils (Surjan *et al.*, 1978; Brandtzaeg *et al.*, 1978, 1979; Brandtzaeg, 1984, 1987, 1991; Bernstein 1990; Nadal *et al.*, 1992). Actively Ig-secreting cells, or plasma cells, constitute no more than 2% of the total cells in the palatine tonsil and nasopharyngeal tonsils (Nadal *et al.*, 1992). IgG appears to be the predominant immunoglobulin. The ratio of IgA to IgM differs according to the methods of study used. Studying the cytoplasmic staining of immunocytes, Brandtzaeg and his colleagues have suggested that the number of IgA immunocytes is significantly greater than that of IgM immunocytes (Brandtzaeg, 1984, 1987). However, using the ELISPOT technique, which specifically identifies cells that are secreting immunoglobulins actively, our laboratory has found that the numbers for IgA- and IgM-secreting cells are similar (Nadal *et al.*, 1992). However, IgA secretion in the palatine tonsils is significantly greater than in the lymph node (Woloschak *et al.*, 1986), suggesting that the palatine tonsil has characteristics of a mucosal immune system.

**Table I** Average Percentage of Antigen Presenting Cells in Compartments of Nasopharyngeal Tonsil<sup>a</sup>

	Antibody			
	MAC387	CD68	S-100	C3b
Crypt epithelium	6.1 ± 5.7 ↔ 0.39 ± 1.13 <sup>b</sup>		0.47 ± 0.86	0.01 ± 0.01
Extrafollicular zone	5.4 ± 2.3	4.4 ± 3.6	2.4 ± 1.5	0.01 ± 0.02
Mantle zone	0.17 ± 0.19	0.99 ± 2.4	0.05 ± 0.08	11.0 ± 7.8
Germinal center	0.66 ± 1.2 ↔ 2.5 ± 1.3 <sup>c</sup>		0.09 ± 0.24	42.0 ± 6.1

<sup>a</sup> MAC387 and CD68 are monoclonal antibodies that stain for macrophage cells. However, the distribution of CD68 is significantly different than that of MAC387 in the crypt epithelium and in the germinal center. CD68 in the germinal centers is believed to represent tingible macrophages.

<sup>b</sup>  $p < 0.01$

<sup>c</sup>  $p < 0.01$

**Figure 2** (A) Immunohistochemical staining with MAC387 shows staining of macrophages (arrow) in the crypt of the nasopharyngeal tonsil (APAAP × 25, alkaline phosphatase-antialkaline phosphatase). C, Crypt. (B) Immunohistochemical staining with MAC387 in the extrafollicular zone of the nasopharyngeal tonsil (APAAP × 10). gc, germinal center. These cells appear to be confined to the extrafollicular area and are not found in the germinal center. They most likely represent macrophages, although they also may represent interdigitating cells. (C) Immunohistochemical localization of CD68 cells in the extrafollicular zone of the nasopharyngeal tonsil. These cells are few in the crypt epithelium, but the cells are found mainly in the extrafollicular zone (APAAP × 10). (D) Immunohistochemical localization of CD68 cells in the germinal center of the nasopharyngeal tonsil (APAAP × 10). mz, Mantle zone. Many cells are found in the follicle of the nasopharyngeal tonsil. These cells represent tingible macrophages. (E) Immunohistochemical localization of cells staining with S100 in the extrafollicular zone of the nasopharyngeal tonsil (APAAP × 10). These cells most likely represent interdigitating cells and are found mainly in the extrafollicular zone and not in the germinal center. (F) Immunohistochemical localization of C3b receptor on the follicular dendritic cells (FDC) of the nasopharyngeal germinal center (APAAP × 10). These cells stain for the complement receptor in the germinal center. (G) High powered photomicrograph of C3b labeling (arrow) of the dendritic processes of FDCs showing the antigen retaining reticulum (ARR) (APAAP × 49).

**Table II** Lymphocyte Subsets in Palatine Tonsils and Peripheral Blood<sup>a</sup>

	Peripheral blood		Palatine tonsils	
	Total lymphocytes (%)	B cells (%)	Total lymphocytes (%)	B cells (%)
IgD	2.5	22	1.2	8
IgG	2.1	18	31.0	73
IgA	0.318	5	7.3	20
IgM	9.7	88	19.9	43
CD19 (Total B)	14		52	
CD3 (Total T)	67		42	
CD4	35		32	
CD8	29		9	
CD3 <sup>+</sup> Leu 8 <sup>+</sup>	30		10	
CD3 <sup>+</sup> Leu 8 <sup>-</sup>	7		21	

<sup>a</sup> Samples were from 46 patients undergoing tonsillectomy. The predominant immunoglobulin in the palatine tonsils is IgG and represents 73% of the B cells, whereas the predominant immunoglobulin in B cells in the peripheral blood is IgM. The peripheral blood possesses a majority of T lymphocytes, whereas the average number of B cells in the tonsil is 52%. The ratio of T helper to T suppressor cells in the palatine tonsil is significantly greater than the ratio in the peripheral blood. CD3<sup>+</sup>Leu8<sup>+</sup> cells, which represent suppressor inducer cells, are greater in the peripheral blood, whereas CD3<sup>+</sup>Leu8<sup>-</sup> cells, which represent helper inducer cells, are greater in the palatine tonsils.

The mantle zones of the tonsils appear to be very specific for early clones of B cells possessing both IgM and IgD on their surfaces (Yamanaka *et al.*, 1992). On the other hand, in the germinal center, IgD is found rarely whereas IgG and IgM are frequent, suggesting that significant switching of early clones of B cells to more mature B cells occurs in the germinal center (Brandtzaeg, 1987). Further, IgA and IgG immunocytes also are located in the crypt epithelium and in the extrafollicular zones (Figure 3A,B). A summary of the distribution of the cellular immunoglobulin isotypes in the human palatine tonsil is presented in Figure 4.

The production of J chain by different types of B cells in the palatine tonsil was studied by the Brandtzaeg laboratory and was shown to represent a very important concept with respect to the relationship between normal and diseased tonsils (Brandtzaeg *et al.*, 1979). A summary of J-chain expression by tonsillar immunoglobulin-producing cells in health and disease is shown in Figure 5.

This brief summary of the immunological cytoarchitecture of the palatine and nasopharyngeal tonsil suggests that these structures possess all the elements required of a mucosal immune system. Bacterial, viral, or food antigen can be adsorbed selectively by macrophages, HLA-positive cells, and M cells in the crypts of these lymphoepithelial tissues. Further, the antigens can be transported to T cells in the extrafollicular area by ICs and to B cells in the germinal centers by FDCs. Early clones of B cells in the mantle zone, which have surface IgM and IgD, may be memory cells that can be stimulated to switch into more mature clones of B cells, including IgG- and IgA-secreting cells. With proper stimulation by interleukins from T-helper cells in the follicular zone, B cells may mature into memory cells or into immunoglobulin-synthesizing plasma cells (Tew *et al.*, 1989).

These plasma cells then are distributed in the extrafollicular zone and in the crypt epithelium, and the immunoglobulins are secreted into the crypt. Therefore, the tonsil plays an important role in maintaining the normal microbiological flora in the crypts of the tonsils and in the furrows of the adenoids, at least in the healthy person. Finally, B cells that possess J chain may mature into IgM and IgA plasma cells that secrete J-chain-bearing immunoglobulins. The nasopharyngeal tonsil, which possesses secretory component (SC), will function as a true secretory immune system. In contrast, the palatine tonsil, which possesses either stratified squamous epithelium or simple cuboidal epithelium as in the crypt, will secrete IgA into the crypt lumen but also may be the source of dimeric J-chain-positive IgA B cells for other areas of the upper respiratory system, such as the parotid gland, the lacrimal gland, the nasal mucosa, and the middle ear mucosa in otitis media (Brandtzaeg, 1984,1987).

Cell-cell interaction in the palatine tonsil has been studied by a number of investigators (Perry *et al.*, 1991; Tsubota *et al.*, 1991). For example, a series of molecules that play a crucial role in adhesion and signal transduction have been reported. These molecules are designated, in general, adhesion molecules. Immunohistochemical analysis showed vitronectin, fibronectin, and laminin, as well as other surface-associated adhesions, to be present on tonsillar lymphocytes. Further, interleukin 6 (IL-6), an important mediator of B-cell maturation, has been demonstrated in palatine tonsils and seems to be associated with the macrophage in the palatine tonsil (Sugiyama, 1991). Moreover, B cells with IL-6 receptors have been demonstrated in the tonsil. In addition, this cytokine may induce the proliferation and differentiation of cytotoxic T cells.

The microvasculature of the human palatine tonsil and its

**Figure 3** (A) Immunohistological localization of IgA using FITC conjugated anti-immunoglobulin A antibody. cr, Crypt. IgA plasma cells are found in the lamina propria underlying the crypt epithelium and in the interfollicular areas (APAAP × 25). (b) Immunohistological localization of IgG immunocytes in the tonsillar tissue. mz, Mantle zone; gc, germinal center; ce, crypt epithelium. Multiple immunocytes possessing IgG are seen in the interfollicular area. Virtually no IgG is seen in the mantle zone, and lacy staining between the cells is seen in the germinal center (APAAP × 16).

role in homing of lymphocytes has been studied by investigators at the University of London (Perry *et al.*, 1991). This selective process is thought to be mediated in part by the lymphocyte function-associated antigen 1 (LFA-1) that is

**Figure 4** Diagram of the distribution of immunocytes found in the human palatine tonsil in 46 cases. IgM and IgG immunocytes are found in the germinal centers. A few IgM positive immunocytes are found in the mantle zone. IgG and IgA immunocytes are found primarily in the extrafollicular zones and in the crypt epithelium. expressed on the surface of lymphocytes and by its ligand, the intercellular adhesion molecule-1 (ICAM-1), that is expressed on the endothelium. Localization of ICAM-1 was confined predominantly to the endothelium, with greatest expression seen on the high endothelial venules (HEV) in both the extrafollicular and the intraepithelial locations of the human palatine tonsil. LFA-1-expressing lymphocytes were seen in both intra- and extravascular locations, especially in the extrafollicular T-cell region close to the HEV. The increased expression of LFA-1 on the large number of tonsillar lymphocytes, in conjunction with the up-regulated expression of ICAM-1 on the HEV, suggests that the latter functions as a promoter of lymphocyte extravasation into tonsillar tissue.

**Figure 5** Schematic representation of average J-chain positivity shown by intra- and extrafollicular Ig-producing immunocytes of various isotypes, as indicated. A significant decrease in the J-chain positive IgA cells is seen in the follicle and in the extrafollicular area in recurrent tonsillitis. Reprinted with permission from Brandtzaeg (1987).

In summary, the palatine and nasopharyngeal tonsils represent strategically located lymphoepithelial tissues that harbor all the immunocompetent cells and molecules necessary for the exhibition of a local immune response. Inasmuch as normal human lungs lack organized bronchus-associated lymphoid tissue (BALT; Brandtzaeg, 1991), which is prominent in certain animal species (Scicchitano *et al.*, 1987), the major source of B-cell precursors in the upper respiratory tract of humans appears to be the lymphoid tissue of Waldeyer's ring, dominated by the palatine tonsil.

### III. PALATINE TONSILS AND NASOPHARYNGEAL TONSIL AS LOCAL IMMUNE SYSTEMS

Tonsillar lymphocytes have the capacity to produce specific antibodies against a number of pathogens and other foreign proteins (Rynell-Dagoo, 1976; Harabuchi *et al.*, 1989; J. M. Bernstein and G. Rich, unpublished data). The predominant antibody isotype synthesized and released by both tonsillar lymphocytes and adenoidal lymphocytes is IgG. The observations of considerable interest, however, are that tonsillar and adenoidal lymphocytes exhibit specific activity against respiratory syncytial virus (RSV), an agent associated with upper airway disease, as well as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and beta hemolytic *Streptococcus* Group A. Various cow milk antigens, including casein and  $\beta$ -lactoglobulin, induce specific T-cell responses in tonsillar lymphocytes (J. M. Bernstein and G. Rich, unpublished data). Further, adenoidal lymphocytes are capable of synthesizing specific IgG, IgA, and IgM antibody against RSV virus, both spontaneously and when stimulated with the virus (Soh *et al.*, 1991). In contrast, adenoidal lymphocytes exposed to the polyclonal B-cell mitogens, the lipopolysaccharide (LPS) from *Escherichia coli*, and purified protein derivative (PPD) demonstrate only a poor response (Rynell-Dagoo, 1978; Meistrup-Larsen *et al.*, 1980). Exposure of adenoid lymphocytes to *H. influenzae in vitro* has been demonstrated to elicit higher responses when the cells are obtained from subjects apparently free from immediately preceding nasopharyngeal exposure to the same pathogen than when the cells are derived from individuals currently colonized with this bacterium (Harabuchi *et al.*, 1989). In our studies using RSV, the predominant immunoglobulin secreted was IgG (So *et al.*, 1991).

The results of these functional studies provide evidence that both the tonsils and adenoids are engaged continuously in local immune responses to viral and bacterial pathogens that have a tropism to the nasopharynx, oropharynx, and respiratory mucosa. In this regard, the clinical otolaryngologist must consider that tonsillectomy and adenoidectomy may result in the reduction of local immune competence against various pathogens and allergens, as suggested in a previous study detecting the fall of specific antibody titers against polio virus in nasopharyngeal washings (Ogra, 1971).

### IV. TONSILS AS A SOURCE OF IMMUNOCOMPETENT CELLS FOR OTHER AREAS OF THE UPPER RESPIRATORY TRACT

The existence of a protective local immune system that functions fairly independently of systemic immunity was proposed by Besredka (1919) when he demonstrated that, after oral immunization with killed Shiga bacillus, rabbits were protected against fatal dysentery irrespective of a serum antibody titer (Besredka, 1919). The interest in local immunity was revived significantly in the 1960s when Tomasi *et al.* (1963) reported that the predominant immunoglobulin in external body fluids was IgA. In 1974, a common epithelial transport model was proposed for dimeric IgA and pentameric IgM by Brandtzaeg (1974). The joining J chain had been identified a few years earlier as a unique polypeptide shared by these two immunoglobulin polymers (Mestecky *et al.*, 1971).

All secretory sites of adults normally contain a remarkable predominance of IgA-producing immunocytes, including plasma cells and their immediate precursors. Although these immunocytes are particularly common in the intestinal mucosa, they also exist in the lacrimal gland, nasal mucosa, parotid gland, mammary gland, and the middle ear mucosa in otitis media and chronic otitis media with effusion. A relatively large proportion of the IgA2 subclass has been reported for the IgA immunocytes present in secretory sites in the colon (Conley and Bartelt, 1984), whereas the tonsils possess primarily IgA1 immunocytes, suggesting that the source of the IgA B cells may be different for these two mucosal systems (Kett *et al.*, 1986). The source of the B cells that reach the nasal mucosa, middle ear, or parotid gland could be chiefly the lymphoid tissue of Waldeyer's ring. Therefore, tonsils and adenoids have been suggested as sources of dimeric J-chain-positive IgA B cells. Therefore the tonsils would, indeed, play a role as a "Peyer's patch" of the upper respiratory tract and seed the upper respiratory mucosa with J-chain-positive IgA B cells. This concept has been demonstrated by Brandtzaeg (1987). Data from our laboratory support the concept that the tonsil may play such a role (Bernstein *et al.*, 1988). *Streptococcus mutans*, a common bacterial organism associated with dental caries, is never found in the mucosa of the middle ear or the nose. However, B cells with specific surface antibody against this organism can be found at these sites (Figure 6A,B). The tonsils and/or adenoids have been suggested to be the source of B cells with specific surface immunoglobulin directed against an organism that is not present in the middle ear or nasal mucosa. Thus, a specific B cell arising from the tonsil or adenoid lymphoid tissue may migrate to an adjacent site in the upper respiratory mucosa.

The IgD-expressing lymphocytes present in the mantle zone of tonsillar lymph follicles, for the most part, bear IgM on their surface. These cells are considered to be memory cells that follow antigen-driven proliferation. Retained surface IgD is apparently a marker of early memory clones, whereas persistent secondary stimulation seems to result in

**Figure 6** (A) Immunocytes in the extrafollicular zone of the tonsil staining positive for antibody specific for *Streptococcus mutans* (APAAP  $\times$  25). (B) Immunohistological localization of *S. mutans* in the middle ear mucosa using fluorescent conjugated antiserum specific for *S. mutans*. Multiple immunocytes are present in the middle ear mucosa. *Streptococcus mutans* is virtually never found in the middle ear. This result is an example of seeding of specific tonsillar B cells that have been stimulated with *S. mutans* and have migrated to a distant area of the upper respiratory tract mucosa (APAAP  $\times$  25).

IgD-negative mature memory clones with the potential to produce antibody of higher affinity such as IgG and IgA (Brandtzaeg *et al.*, 1979). As previously mentioned, cells with concomitant production of IgA and J chain are common in the extrafollicular area, but less common in the germinal center. This observation indicates that extensive isotype switching takes place in the early phase of clonal proliferation and differentiation of tonsillar B cells.

Such a clonal development of tonsillar IgA would strengthen the potential of palatine tonsil to act as a putative precursor source for the secretory IgA system similar to BALT and gut-associated lymphoid tissue (GALT). Since a substantial number of B cells terminate in the extrafollicular region with concomitant production of IgA and J chain, precursors committed to this phenotype are likely to evade the tonsils and migrate to mucosal glandular tissue. The observation that *in vitro* stimulation of tonsillar lymphocytes with

an alimentary antigen ( $\beta$ -lactoglobulin) results mainly in generation of IgA immunocytes from tonsillar lymphoid cells supports the idea that these cells are integrated with the secretory immune system (Paganelli and Levinsky, 1981).

Circumstantial evidence indicates that tonsillar B cells with a potential for J-chain expression may contribute to the secretory immune system in glandular tissue of the upper respiratory tract. Moreover, the fact that nasal IgA antibodies show relatively broad specificity supports the theory that they are products of B-cell clones at an early phase of maturation (Brandtzaeg, 1984). Therefore, the normal tonsil and adenoid, in addition to playing an important role in immune exclusion, also appear to be a source of dimeric J-chain-positive IgA, which is the critical secretory antibody for the mucosa of the upper respiratory tract.

Most important for clinicians is an understanding of events during the disease state. If alterations in the normal immunoglobulin function appear in diseased states of the tonsil, and immune exclusion and immune regulation are dysfunctional, the tonsil will not serve adequately as a first line of defense. As is suggested in subsequent discussion, the tonsil actually may be harmful to the organism, as in the case of autoimmunity associated with focal tonsillitis.

## V. IMMUNOLOGICAL CYTOARCHITECTURE OF THE PALATINE AND NASOPHARYNGEAL TONSIL WITH AGE AND INFLAMMATORY DISEASE

Using the technique of image analysis, a quantitative study of the distribution of lymphoid cells in the tonsillar compartments in relation to infection and age has been undertaken (Yamanaka *et al.*, 1992). The distribution of lymphoid cells in the mantle zone, germinal center, extrafollicular area, and subepithelial area of the tonsil was evaluated quantitatively by image analysis in 90 subjects, aged 3 to 66 years. The number of immunoglobulin-positive cells in the tonsil decreased with advancing age in all compartments. This inverse correlation with age was statistically significant for IgD-, IgM-, and IgG-positive cells (Figure 7). The overall change of each T-cell subset with age was smaller than that of immunoglobulin-positive cells. An age-related marked decline was seen for CD4<sup>+</sup> cells only in the subepithelial area. KI-67-positive cells, which represent cells undergoing active division, were found mainly in the germinal centers. These cells also diminished in numbers with advancing age. Patients with frequent episodes of tonsillitis demonstrated a significant increase of IgD-positive cells and IgG-positive cells in extrafollicular and subepithelial compartments, and a decrease of CD4<sup>+</sup> cells in the germinal center and subepithelial areas. These results suggest that tonsillar involution with age is associated immunologically in all compartments with a decrease in immunoglobulin cells and cells undergoing active division, as demonstrated by KI-67-positive cells (Goding and Burn, 1981).

**Figure 7** Using the technique of image analysis, a quantitative study of the distribution of lymphoid cells in relation to age is shown. IgM ( $\blacktriangle$ ), IgG ( $\square$ ), and IgD ( $\nabla$ ) are decreased significantly with advancing age of the tonsil. IgA ( $\circ$ ) and IgE ( $\triangle$ ) remain about the same with increased age, as do CD4 ( $\blacksquare$ ) and CD8 ( $\bullet$ ) T cells.

On the basis of many other investigations, researchers generally agree that an altered immunological function occurs in the palatine tonsils with age and infection (Bernstein *et al.*, 1988; Brandtzaeg, 1984, 1987; Siegel, 1978; Siegel *et al.*, 1982; Surjan *et al.*, 1978; Surjan, 1980). Using FACS analysis with the monoclonal antibody against CD19, a statistically significant decrease of B cells with age was demonstrated (Figure 8). In addition, a decrease in the number of M cells, which are important APCs in the crypt epithelium, has been suggested (Brandtzaeg, 1987). The most extensive treatise on the immunopathology of tonsillar tissue has been presented by Brandtzaeg (1984, 1987). Altered antigen uptake and altered B-cell activity are major problems that may occur in chronic tonsillitis and in the aging tonsil. This altered immunological function may contribute to recurrence of tonsillitis and thereby lead to a vicious cycle. The microenvironmental conditions that best enhance tonsillar proliferation of J-chain-positive IgA B cells may depend on appropriate antigen presentation by M cells found in the reticular crypt epithelium and on particular subsets of regulatory T cells. The putative role of tonsils as precursor sources for the secretory immune system thus is jeopardized by tonsillar disease. Our laboratory has demonstrated that IgD expression in the mantle zone decreases with increased episodes of tonsillitis (Bernstein *et al.*, 1988). Further, marked reduction in IgG immunocytes occurs with many episodes of recurrent tonsillitis. Moreover, HLA-DR-positive cells decrease significantly in

**Figure 8** Regression analysis of CD19 (B cells) in the tonsil with increasing age. A highly significant inverse correlation ( $R^2 = 0.45582$ ) is seen between the number of B cells in the tonsil and age.

the mantle zone; a similar trend is observed in the other compartments. As demonstrated in Figure 3, a significant decrease in J-chain expression by IgA-positive cells occurs in both the follicle and the extrafollicular regions in the tonsils of patients with recurrent tonsillitis, particularly in the germinal center (Brandtzaeg, 1984, 1987).

## VI. DISTRIBUTION AND ENGRAFTMENT PATTERNS OF HUMAN TONSILLAR MONONUCLEAR CELLS AND IMMUNOGLOBULIN-SECRETING CELLS IN MICE WITH SEVERE COMBINED IMMUNODEFICIENCY: THE ROLE OF EPSTEIN-BARR VIRUS

As mentioned already, the tonsils and adenoids seem the ideal source for lymphocytes seeding into the mucosa of the respiratory tract. The distribution and engraftment of human lymphocytes injected into mice with severe combined immunodeficiency (SCID) are not well understood. In our laboratory, human tonsillar mononuclear cells (hu-TMC) were injected intraperitoneally into SCID mice (Nadal *et al.*, 1991c). The hu-TMC-SCID mouse "chimeras" subsequently were tested for the appearance and distribution of human lymphocytes tagged with H33342 and of immunoglobulin-secreting cells in various systemic and mucosal immunocompetent tissues. This testing was performed by fluorescence microscopy of tissue sections for cells supravivally stained before transfer and by an ELISPOT assay using cells isolated from murine organs. Most importantly, engraftment of hu-TMCs proved to be dependent on the presence of anti-Epstein-Barr virus (EBV) antibody in the donor. hu-TMCs engrafted in decreas-

**Table III** Human Immunoglobulin-Secreting Cells in Donors and in SCID Mice Showing Engraftment of Human Tonsillar Mononuclear Cells<sup>a,b,c</sup>

	Donors anti-EBV positive			Donors anti-EBV negative		
	IgG	IgA	IgM	IgG	IgA	IgM
Donors	716.8 ± 261.5	126.9 ± 27.8	163.3 ± 24.5	946.5 ± 253.4	131.4 ± 26.1	167.5 ± 53.7
Murine tissue <sup>d</sup>						
Peritoneum	375.9 ± 187.5	64.1 ± 50.2	1403.5 ± 584.0	5.7 ± 5.7	0.3 ± 0.3	0
Liver	238.1 ± 115.8	67.4 ± 29.1	818.4 ± 348.4	1.3 ± 0.9	3.3 ± 3.3	0.1 ± 0.1
Spleen	43.8 ± 19.8	13.9 ± 6.9	197.6 ± 69.3	1.3 ± 0.6	0.1 ± 0.1	0
Bone marrow	10.9 ± 3.6	2.2 ± 0.9	45.4 ± 17.9	1.3 ± 0.5	0.1 ± 0.1	0.7 ± 0.7
Lung	155.2 ± 58.0	32.1 ± 12.2	448.6 ± 219.8	1.4 ± 1.1	1.0 ± 0.5	0.3 ± 0.3
Intestine	0	0	0	0	0	0

<sup>a</sup> IgM-positive cells are predominant in all the murine tissues studied. Also, only donors who were anti-EBV positive had cells that could be engrafted in the SCID mouse. A predilection exists for engraftment in the respiratory tract mucosa, whereas no engraftment occurs in the intestinal mucosa.

<sup>b</sup> SCID mice were injected and sacrificed as described elsewhere. Enumeration of human immunoglobulin-secreting cells (hu-ISC) was done by ELISPOT.

<sup>c</sup> Values are given as mean ± SEM of isotype specific hu-ISC per 10<sup>5</sup> mononuclear cells.

<sup>d</sup> Cell suspensions from murine tissue were enriched for human cells.

ing numbers in the following systemic organs: peritoneum liver, spleen, and bone marrow. Among mucosal tissues tested, hu-TMCs were seen in the lungs but not in the intestines. The engraftment of hu-TMCs in the lung was more extensive than that in the spleen. These studies demonstrate that hu-TMCs engrafted in a variety of murine tissues. The striking presence of hu-TMCs in the lungs compared with the intestines suggests selective engraftment among distinct mucosal tissues (Table III). Further, note that not only are these transferred cells in SCID mice viable and produce immunoglobulin, but they also produce specific antibody against RSV (Nadal *et al.*, 1991a) after intraperitoneal immunization with an activated RSV. These data demonstrate for the first time that hu-TMC-SCID mice will respond to immunization with a viral antigen (Table IV). In other experiments, 5–11

weeks later, 29.4% (10/34) of mice injected with hu-TMCs from EBV-seropositive donors, but none of 34 animals receiving hu-TMCs from EBV-seronegative donors, developed intraabdominal or intraperitoneal tumors ( $p = 0.002$ ) (Nadal *et al.*, 1991b). By *in situ* hybridization using  $\alpha$  satellite DNA from human chromosome 17, all tumors resulting after cell transfer from EBV-seropositive donors were identified to be of human origin. Histologically, the tumors resembled large cell lymphomas. EBV genome was detected by *in situ* hybridization and EBV nuclear antigen by immunofluorescence in these tumors. The tumors were poly- or oligoclonal and stained for human IgG, IgM, and, less frequently, IgA and IgD. Human IL-6 was detected in the serum of most of the animals with human lymphomas, but not in any animals without human lymphoma.

**Table IV** Human Immunoglobulin-Secreting Cells Recovered from Human Tonsillar Mononuclear Cell-SCID Mice Immunized with Respiratory Syncytial Virus<sup>a</sup>

Tissue	Positive for RSV-specific hu-ASC <sup>b</sup>			Negative for RSV-specific hu-ASC <sup>c</sup>		
	IgG	IgA	IgM	IgG	IgA	IgM

Intestine	0	0	0	0	0	0

<sup>a</sup> A predilection exists for IgM cells to engraft in the murine tissue. Further, engraftment only occurs in the mucosa of the lung, suggesting the tonsils preferentially engraft to respiratory mucosa rather than to intestinal mucosa.

<sup>b</sup> RSV, Respiratory syncytial virus; hu-ASC, human antibody-secreting cells;  $n = 13$ .

<sup>c</sup>  $n = 4$ .

In summary, these observations suggest that a distinct distribution pattern of lymphocytes from human tonsils exists for the respiratory tract. Tonsillar lymphocytes can engraft efficiently into these immunodeficient mice. Further, an immunospot assay to detect human immunoglobulin-secreting cells in cell preparations from various murine organs enriched for human cells strongly indicated that, after engraftment, the cells are not only viable but also functional. Interestingly the relative isotype distribution of human immunoglobulin-secreting cells in engrafted animals shows significant differences from the isotype distribution in the donor-cell suspensions (Table III). Engraftment of hu-TMCs shows an increase of the IgM human immunoglobulin-secreting cell population and a significant decrease in the IgG immunoglobulin population. Analysis of cells isolated from human tonsils also has demonstrated a high death rate of germinal center-derived B cells, which have a high percentage of IgG isotype. The results observed in the SCID mouse experiments may reflect a fast death rate of IgG B cells derived from tonsillar germinal centers. The observations summarized from these experiments also suggest that human tonsillar lymphocytes from EBV-positive children and young adults give rise to large cell lymphomas of human origin when transferred into SCID mice.

## VII. TONSIL AS A SOURCE OF AUTOANTIBODY

The concept that altered antigens in the squamous epithelium of the palatine tonsil may serve as a source of autoantibody for diseases of the palms and soles long has been considered (Andrew *et al.*, 1935). Further, several renal diseases, including IgA nephropathy and glomerulonephritis, have been associated with inflammatory diseases of the upper respiratory tract (Miura *et al.*, 1984). In light of modern immunology, secondary disorders caused by focal infection of the tonsils may be considered in the category of autoimmune diseases. The final section of this chapter addresses the rela-

tionship between the palatine tonsils and autoimmunity as it may affect the skin.

Pustulosis palmaris et plantaris (PPP) is a chronic recurring disorder of the palms and soles characterized by sterile intra-epidermal pustules (Ofuji *et al.*, 1958; Thomsen and Osterbye, 1973; Noda and Ura, 1983). PPP affects women slightly more frequently than men, between the ages of 30 and 60 years. The disease is characterized by numerous pustules and erythematous patches on the palmo-plantar skin (Figure 9; Uehara, 1983; Undeutsch, 1972; Uehara and Ofuji, 1974). The disease tends to have unpredictable exacerbations that often occur during periods of acute aggravation of infected foci in the tonsil. The most popular pathogenic theory for PPP is focal infection of the tonsil (Andrew *et al.*, 1935; Thomsen and Osterbye, 1973). Further, several investigators have shown that PPP clears after tonsillectomy (Yamanaka *et al.*, 1983a, 1989).

The primary histological change in PPP is a spongiotic vesicle located deep within the epidermis (Figure 10a-d). Mononuclear cells are observed mostly in the involved epidermis and adjacent dermis. As the upper pole of the vesicle comes into contact with the stratum corneum, neutrophils begin to invade the epidermis and gather at the roof of the vesicle. When the vesicle moves upward, neutrophils further accumulate in the vesicle and the eruption becomes completely pustular. The deposition of all major immunoglobulin classes—IgG, IgM, and IgA—or complement fraction C3 in the pustules and intercellular spaces around pustules in patients with PPP has been demonstrated (Husby *et al.*, 1973). These findings, in addition to the fact that the pustulation of PPP takes place only when direct contact between the blister and the stratum corneum occurs, suggests that *in vivo* formation of antigen-antibody complexes in the stratum corneum of lesions of PPP may activate complement via the classical pathway and release chemical mediators such as chemotactic factors, which then trigger the migration of neutrophils at the subcorneal areas of the blisters (Krogh and Tonder, 1970; Tagami and Ofuji, 1978). The proteolytic enzymes thus are released from neutrophils and may cause destruction of the stratum corneum, resulting in the formation of pustules.

**Figure 9** Typical skin lesions of pustulosis palmaris et plantaris (PPP). The disease is characterized by numerous pustules and erythematous patches on palmo-plantar skin.

**Figure 10** Histopathogenesis of PPP. (A) A spongionic vesicle; (B) mononuclear cells in the involved epidermis and adjacent dermis; (C) neutrophils gather at the center of the roof of the vesicle; (D) the eruption becomes pustular.

The immunopathological hypothesis relating the tonsils to PPP may be related to the structure of the crypt epithelium of the tonsil. The structure of the palatine tonsil, as mentioned earlier, is characterized by numerous crypts and lymphoid follicles. The tonsillar crypts have primary and secondary branches that markedly increase the surface of the tonsil and appear to be the entrance for foreign antigens such as bacteria and viruses that invade the tonsil and provoke an immune response in the tonsil (Maeda and Mogi, 1982). Ono and co-workers (1983b) have demonstrated the presence of a substance resembling the epidermal keratinous layer in the crypt epithelium of tonsil by light and electron microscopic examination. Ultrastructurally, the crypt epithelium contains tonofibrils, and even a structure with a keratin pattern in the upper layer, mixed with parakeratosis. Macrophage-like cells can phagocytose this horny cell-like substance. As shown in Figure 11, keratin-like cells and substances are observed diffusely in the lymphoepithelial symbiosis (LES) and intermingle with mononuclear cells. Therefore, an immune reaction against keratinous substances is very likely to take place in the deep crypt of the tonsil. Yamanaka and co-workers (1983a) demonstrated the presence of considerable numbers of helper T cells in LES; Harabuchi and co-workers (1985) reported the majority of the cells in the site to have membrane or cytoplasmic staining with anti-OKT9 antibody (Figure 12), which recognizes the transferrin receptor on the proliferating cells (Goding and Burn, 1981). These findings, in addition to the presence of a T-dependent response to skin antigen in the tonsils and blast formation of tonsillar lymphocytes but

not in peripheral lymphocytes in response to skin extract (Tanaka *et al.*, 1983) strongly support the possibility of naturally occurring immune reactions of tonsillar lymphocytes against keratinous antigens common to both skin and crypt epithelium.

Advances in immunological techniques have made it possible to analyze soluble immune complexes and have brought new insight to the pathogenesis of many disorders with unknown etiology. Attempts to understand the pathophysiological relationship between PPP and the tonsil have been made by investigating immune complexes in the sera of patients with PPP. Yamanaka and co-workers (1983a) reported the presence of circulating immune complexes in the sera of patients with PPP using the C1<sub>q</sub>-binding assay. Patients in whom a high serum level of immune complexes decreased after tonsillectomy had a remarkable subsequent improvement in their skin lesions.

Using anti-C3 solid-phase enzyme-linked immunosorbent assay (ELISA), soluble immune complexes in the sera of 60 patients with PPP and 20 healthy controls were analyzed. The immune complex level in healthy controls was  $1.35 \pm 0.2$  (S.E.M.)  $\mu\text{g}$  aggregated human gammaglobulin equivalent (AHGeq)/ml and  $7.12 \pm 1.36$  (S.E.M.)  $\mu\text{g}$  AHGeq/ml in patients with PPP ( $p < 0.05$ ). In this study, 35% of patients with PPP were positive for immune complexes. The patient population was classified into four groups according to the outcome of skin lesions more than 6 months after tonsillectomy—healed group, markedly improved group, moderately improved group, and unchanged group. The positive rate of

**Figure 11** The structure of the lympho-epithelial symbiosis (LES) of the crypt of the tonsil. At the tip of crypt, the epithelium becomes sparse and mixes with mononuclear cells (arrow). C, Crypt.

immune complexes in each group is shown in Figure 13. In a longitudinal study, 62% of patients with PPP had a decrease of immune complex levels to less than  $5 \mu\text{g AHGeq/ml}$  within 6 months of tonsillectomy. Since the immune complex levels in those patients with PPP who showed marked or moderate improvements in skin lesions after tonsillectomy fell to the almost normal range following this procedure, the tonsils may play an important role as a pathogenic focus that releases certain components of immune complexes or even whole immune complexes.

Antikeratin antibodies of the IgG and IgM classes are a constant feature in the sera of patients with PPP (Okamoto *et al.*, 1980; Yamanaka *et al.*, 1989). To clarify the role of antikeratin antibody in the pathogenesis of PPP as well as the relationship between tonsil and the formation of antikeratin antibody, a longitudinal study of antikeratin antibody level after tonsillectomy was performed and compared with the antibody level in individuals who showed no improvement after tonsillectomy.

Solid-phase ELISA on serum samples from 50 patients with PPP and 20 healthy volunteers was used to evaluate antikeratin antibodies. The periods of follow-up for the patients with PPP after tonsillectomy ranged from 6 to 24 months. As shown in Figure 14, the IgM antikeratin antibody level was significantly higher in the healed group and in the markedly improved group, as well as in the moderately improved group, than in the healthy control group. In addition, patients in the healed group and the markedly improved group showed significantly higher IgM antikeratin antibody levels than did those in the unchanged group ( $p < 0.05$ ). With respect to IgG antikeratin antibody, only the moderately improved group showed a significantly higher level than the healthy control group ( $p < 0.01$ ) (Figure 15). These results strongly suggest that IgM antikeratin antibody may play a

**Figure 13** The positive rate of soluble immune complexes in the sera of patients with PPP. Immune complex levels more than 3.0  $\mu\text{g}$  AHG eq/ml is set as positive.

**Figure 14** Anti-keratin antibody level in each group classified by the improvement of skin lesions after tonsillectomy. (A) IgM anti-keratin antibody. (B) IgG anti-keratin antibody.

more important role in the formation of pustules in patients who are free of skin lesions or show marked improvement in skin lesions after tonsillectomy, and support the concept that PPP is a tonsil-related immunological disorder.

EBV infects and transforms only human B cells. The tonsil is well known to be a B-cell dominant lymphoid organ (Yamanaka *et al.*, 1992). Further, some investigators have reported that EBV is associated with recurrent tonsillitis (Veltri *et al.*, 1976). In addition, EBV-transformed lymphocytes derived from peripheral blood or bone marrow secrete autoantibodies against various cellular components (Fong *et al.*, 1982; Robinson and Stevens, 1984). The possibility of autoantibody production by tonsillar lymphocytes infected with EBV has been analyzed. Tonsillar lymphocytes obtained from 15 patients with PPP were infected with EBV. Subsequently, transformed cell lines were obtained after incubation for 2–4 wk. Antibody activity against cultured cell line (Hep2)-derived human squamous cell carcinoma was evaluated by indirect immunofluorescence. Culture supernatant reacted with various cellular antigens of Hep2 cells in 4 of 15 patients with PPP. The immunofluorescence patterns were positive for nuclear envelope and cytoskeletal filaments, speckled nuclei, and nucleoli (Figure 14). Note that these autoantibodies were secreted only after EBV transformation. Other investigators (Garzelli *et al.*, 1984; Uhlig *et al.*, 1985) have reported that EBV-transformed lymphocytes produce autoantibodies reactive with various cellular antigens and with antigens in multiple organs, which may play an important role in the pathogenesis of autoimmune diseases. Thus, EBV may even be a trigger in the development of autoantibodies directed against squamous epithelium. The data described in this section, in addition to the anatomical location of the tonsil, show that the palatine tonsil is susceptible to viral and bacterial infections and strongly suggest the tonsil as a source of autoantibody against a number of organ systems.

In conclusion, focal tonsillitis caused by viruses or bacteria may produce altered antigens in the crypts of the tonsil. Both cell-mediated and humoral immunity directed against these altered antigens may produce immune complex disease directed against similar antigens in other parts of the body such as the skin, mesangium of the kidney, and perhaps the costoclavicular joints. Tonsillectomy is a surgical procedure that may reduce the severity of these diseases markedly and, in some cases, abrogate the disease completely (Ono, 1977; and Ono *et al.*, 1983a).

## VIII. SUMMARY

This chapter has summarized the immunological characteristics of the lymphoid tissue of the tonsils and adenoids. The mucosa of the upper respiratory tract is protected by a secretory immune system that is under complex immunoregulatory control. B cells with the potential for J-chain expression are stimulated initially in organized mucosa-associated lymphoid tissue in the nasopharyngeal and palatine tonsil. Thereafter they migrate through lymph and blood to glandular sites, such as the paranasal sinuses and other mucosa of the

**Figure 15** Autoantibodies to various cellular antigens secreted from Epstein-Barr virus (EBV)-transformed tonsillar lymphocytes. Cultures from EBV-transformed tonsillar lymphocytes originated from patients with PPP show positive reaction (A) with nuclear envelope and cytoskeletal filaments, (B) with speckled nuclei and nucleoli, (C) with nucleoli and with speckled nuclei, and (D) with cytoskeletal filaments.

upper respiratory tract, where they differentiate into plasma cells. Normal human lungs lack BALT, which is prominent in certain animal species. Therefore, the major source of B-cell precursors in the upper respiratory tract in humans appears to be the lymphoid tissue of Waldeyer's ring, dominated by the palatine tonsil. The reticular tonsillar crypt epithelium contains macrophages and dendritic cells that may transport antigen to the extrafollicular T-cell areas and the B-cell follicles. Interdigitating APCs are present in the extrafollicular zone and often are surrounded by T lymphocytes that are mainly of the CD4<sup>+</sup> (helper) phenotype. Tonsils, therefore, appear to be able to mount both primary and secondary T-cell responses. The preferential production of IgA1 in the upper respiratory tract suggests that the nasopharyngeal and palatine tonsil are responsible for the B cells that colonize the upper respiratory tract.

The capacity of palatine tonsils to generate J-chain-expressing B cells is significantly reduced in children afflicted with recurrent tonsillitis. A consequence of this reduction may be reduced maintenance of early memory B-cell clones that contribute to secretory immunity of the upper respiratory and digestive tract. Aging and chronic inflammation appear to effect APCs as well as B cells in the palatine and nasopharyngeal tonsil. These facts are not necessarily indications for removal of tonsils and adenoids, although chronically infected and aging tonsils may not be able to perform their immunological function in many cases. Work from our laboratory has been reviewed that demonstrates that human ton-

sillar lymphocytes can engraft SCID mice and produce viable cells that may release specific immunoglobulin against viruses. Finally, the tonsils may play a role in certain autoimmune diseases of the skin and kidney. For the clinician who removes these organs, an understanding of the immunological potential of the tonsils and adenoids is imperative so a wise decision can be made for the maintenance of maximum health of the child or adult.

# Immunological Components of Milk: Formation and Function

Randall M. Goldblum • Armond S. Goldman

## I. INTRODUCTION

Among the external secretions, milk is unique in its complexity and high concentrations of mucosal immune products. This chapter explores the nature of that uniqueness and attempts to explain its basis. Throughout the chapter, we emphasize human milk since it differs significantly from that of other nonprimate species. However, because bovine milk commonly is consumed by humans, particularly infants and children, we contrast human and bovine milk when major differences are known. The immunological outcomes of breast-feeding in the infant are discussed in Chapter 52.

The high degree of complexity of human milk, relative to the other external secretions, apparently has evolved to provide key factors for the nutritional, metabolic, and immunological needs of the infant. If the lactating woman is nourished adequately, her milk will contain essentially all the nutrients required by the infant for at least the first 6 months of life. In addition, many immunological factors are present in human milk, presumably to protect the lactating mammary gland and the nursing infant from pathogenic microorganisms. The immunological constituents of milk must enhance the probability that maternally derived nutrients will be transferred to the infant without contamination or degradation, so they can be used optimally for the growth and development of the infant.

Another source of complexity of human milk is the dynamic change in composition that occurs during lactation. In this sense, milk is really a series of secretions that is produced as lactation progresses and the infant matures. An interesting speculation is that the changes in milk composition are timed to respond to changing needs of the infant, whose own mucosal immune system is developing rapidly.

In trying to understand the function of the immunological factors in milk, we must recognize that the *in vivo* fate and functions have been demonstrated to date for a limited number of the factors. In particular, limited information exists concerning the distribution, survival, and function of immunological factors within the infant.

Finally, evidence suggests that the immunological impact on the infant of the feeding of human milk may not be totally passive in nature. Some milk factors may interact with factors produced by the infant, whereas others may act as stimuli for the development of the infant's own mucosal immune

system. Thus, milk may be part of a dynamic mother–infant interaction that supports the newborn infant's growth and immunological development to a level that enhances the chances of survival in the extrauterine environment.

## II. ANATOMY, CELL BIOLOGY, AND PHYSIOLOGY OF MILK PRODUCTION

### A. General Features

The human mammary gland is a compound tubuloalveolar organ. The glandular secretions empty into ducts that coalesce as they course through the stroma of the breast toward the nipple. During pregnancy, the number and size of the alveolar clusters increase until, at parturition, 70% of the gland is composed of parenchymal tissue. The process of lactation is modulated by hormones including prolactin, insulin, and growth hormone. The release of some of these hormones, particularly prolactin, is triggered by a neurosensory–endocrine pathway that is initiated by nursing. The autocrine and paracrine events that control lactation remain poorly defined.

### B. Secretory Pathways

Four pathways exist for the secretion of milk components. The first one is responsible for secretion of many of the aqueous components of milk including casein,  $\alpha$ -lactalbumin, and lactose. Caseins, after translation, are transferred to the Golgi apparatus, where they are phosphorylated or glycosylated. As these proteins pass from the terminal cisternae of the Golgi compartment into secretory vesicles, their concentration increases to the millimolar range, causing aggregation of the casein molecules into micelles (Morr *et al.*, 1971). The secretory vesicles migrate to the apical membrane, fuse with it, and release their contents by exocytosis. One prominent milk protein,  $\alpha$ -lactalbumin, forms a complex with the enzyme galactosyltransferase in the Golgi, where the complex catalyzes the synthesis of lactose. The osmotic activity of this disaccharide draws water and presumably ions into the Golgi, providing the driving force for fluid secretion.

The second or apocrine pathway is responsible for secre-

tion of milk fat. The substrate for milk fat synthesis derives from two sources. Fatty acids are synthesized from glucose by mammary alveolar cells that contain fatty acid synthetase. These fatty acids have somewhat shorter chain lengths (10–16 carbons) than those synthesized in adipose tissue because of the presence of a mammary gland-specific enzyme called thioesterase II. In addition, plasma triacylglycerols are cleaved within the mammary gland by the enzyme lipoprotein lipase. The resulting fatty acids are transported into the mammary alveolar cells, where they are reesterified with glycol to make the neutral fat molecules that coalesce to form milk fat globules. Alveolar cells have a columnar shape with copious endoplasmic reticulum surrounding the nucleus in the basal region. During milk secretion, the Golgi apparatus and secretory vesicles become more numerous toward the apical pole. Abundant cytoplasmic lipid droplets enlarge as they move toward the luminal end of the cell. As they press into the apical plasma membrane, the droplets are released into the milk as membrane-bound milk fat globules (Moyer-Mileur and Chan, 1989). Other globules that are formed during this process contain fewer lipids but larger amounts of other cytoplasmic constituents (Patton and Huston, 1985).

The third pathway transports certain small molecules including sodium, potassium, chloride, and glucose across the apical membrane of the cell. The secretion of the monovalent ions is effected by the electrical gradient across this membrane.

The fourth pathway transfers proteins and possible other substances from the interstitial space to the lumen using receptors and intracellular vesicles. This mechanism will be considered in the description of the formation of secretory IgA (SIgA) in milk via polymeric immunoglobulin receptors.

Finally, in addition to soluble components, certain cells and cellular membranes enter human colostrum and milk. Epithelial cells or their membranes are shed directly into milk. Most B cells that home to the mammary gland remain sessile, whereas many T cells, macrophages, and neutrophils that have entered the lamina propria pass through the intercellular junctions of alveolar cells into the milk (Brandtzaeg, 1983). The mechanisms that attract the leukocytes to the mammary gland and trigger the migration of those cells into the milk are considered in a subsequent section.

### C. Milk Ejection

Milk secretions are stored in the alveoli and small ducts until they are ejected during nursing. Epithelial cells of the alveoli and ductules are surrounded by contractile basket-

like epithelial cells. The ejection of milk from the breast is mediated by neuroendocrine events that culminate in the contraction of those myoepithelial cells. As a result of stimulation of sensory nerves at the nipple and areola during nursing, oxytocin is released from the hypothalamus into the posterior lobe of the pituitary gland and then into the peripheral circulation. Oxytocin triggers myoepithelial cells to contract, forcing milk into the larger ducts and finally through the orifice of the nipple.

## III. COMPOSITION OF MILK

### A. Cellular Elements in Milk

Human milk from early in lactation differs from most other external secretions because it contains viable leukocytes. The concentration of leukocytes is highest in colostrum and declines rapidly during the first months of lactation. Table I displays estimates of the numbers of neutrophils, macrophages, and lymphocytes in human milk during the first months of lactation. These numbers are based on morphological characteristics. However, distinguishing neutrophils from macrophages in human milk is difficult because the morphology of both cells is dominated by the large amount of lipid-containing vesicles in the cytoplasm (Smith and Goldman, 1968). The mechanism by which maternal leukocytes enter the milk is poorly understood. However, one potentially important clue to this process is the finding that essentially all these cells have surface markers or physiological features of activated cells. Since most of the surface markers of activation on milk leukocytes are also present on leukocytes found in sites of inflammation, and are known to be important in homing and egress of leukocytes from the vascular compartment, the mechanism of migration of leukocytes into the milk may be similar to that involved in inflammation. Although the array and mechanisms of production of inflammatory mediators in the lactating mammary gland are not well understood, several cytokines that may be involved in leukocyte migration have been detected in human milk, as described in later sections of this chapter. The following sections discuss our current knowledge of the morphology and *in vitro* function of the milk leukocytes.

#### 1. Macrophages

Macrophages may have been first photographed in human milk by the French microscopist Alfred Donné (1844). How-

**Table I** Estimated Mean (std) Concentration ( $\times 10^9$ /ml) of Leukocytes in Human Milk by Phase of Lactation<sup>a</sup>

	2–3 days	4 wk	24 wk	52 wk
Macrophages/neutrophils	3.6 (2.7)	0.06 (0.12)	0.04 (0.09)	<0.01
Lymphocytes	0.2 (0.1)	0.02 (0.03)	0.01 (0.02)	<0.01

<sup>a</sup> Adapted with permission from Goldman *et al.* (1982).

ever, little attention was paid to the cells in milk until Smith and Goldman (1968) described milk cells with the morphology and phagocytic activity consistent with activated macrophages. The concentration of macrophages in early milk is usually greater than that of their counterparts in peripheral blood, the monocytes.

More recent studies have demonstrated that the milk macrophages are more motile than their counterparts in blood (Özkaragöz *et al.*, 1988; Mushtaha *et al.*, 1989) and display a pattern of surface markers associated with activation (Keeney *et al.*, 1993). These cells also actively produce toxic oxygen radicals (Tsuda *et al.*, 1984). Attributing other activities to the milk macrophages is difficult since most studies of milk leukocytes have used unseparated cells. The role of the milk macrophage *in vivo* has not been established.

## 2. Polymorphonuclear Leukocytes

Early in lactation, the concentration of neutrophils in milk approaches that in peripheral blood (Table I). Neutrophils in human milk have been demonstrated to be phagocytic (Smith and Goldman, 1968). However, the adherence, response to chemotactic factors, and motility of these cells are less than those of neutrophils from peripheral blood (Thorpe *et al.*, 1986; Özkaragöz *et al.*, 1988). Studies of surface markers suggest that some of these functional features may be the result of prior activation of the neutrophils (Keeney *et al.*, 1993). Activation of neutrophils may occur during the process of egression from the vascular space, may relate to the process by which large numbers of milk globules are engulfed by neutrophils in milk, or may be the result of exposure to cytokines demonstrated to exist in milk (see subsequent text).

## 3. Lymphocytes

Although the concentration of lymphocytes in human milk is small relative to that in peripheral blood, these cells are consistently present in milk obtained during the first few months of lactation. Approximately 80% of milk lymphocytes are T cells (Wirt *et al.*, 1992). The precise distribution of T-cell subpopulations in milk lymphocytes is controversial, since different investigators have reported numbers of CD4<sup>+</sup> and CD8<sup>+</sup> cells similar to those in peripheral blood (Keller *et al.*, 1986), a CD8<sup>+</sup>-cell predominance (Richie *et al.*, 1982), or moderate increase in the proportion of CD8<sup>+</sup> cells relative to peripheral blood (Wirt *et al.*, 1992). These differences may be the result of selection of certain subsets during the fractionation of milk or of the analytic limitations of direct fluorescent microscopy. These problems were avoided in the last study by using flow cytometry of unfractionated milk (Wirt *et al.*, 1992). As in the case for other milk leukocytes, the increased display of certain surface phenotypic markers, including CD45RO, CD25 (IL-2R), and HLA-DR, suggests that the T lymphocytes are activated memory cells (Wirt *et al.*, 1992).

Milk lymphocytes can be activated to proliferate using mitogens, but their responses are weaker than those of peripheral blood T cells (Parmely *et al.*, 1976; Goldblum *et al.*, 1981). The spectrum of antigen-specific responses, as measured by proliferation, is thought to differ from that of

peripheral blood lymphocytes from the same donor (Parmely *et al.*, 1976), but the T-cell receptor repertoire of milk T lymphocytes has not been investigated. Although evidence exists for the production of interferon (Emodi and Just, 1974; Keller *et al.*, 1981; Bertotto *et al.*, 1990) and monocyte chemotactic factor (Keller *et al.*, 1981), the full array of cytokines produced by milk cells has not been determined.

## B. Particulate Structure of Milk

In addition to viable cells, several different types of particles are suspended in human milk, including casein micelles, globules packed with lipid, and globular structures containing less lipid but more cytoplasmic structures (Patton and Huston, 1985). With low speed centrifugation, some of these particles sediment with the cells whereas many of the membrane-bound lipid-filled particles rise to the surface and coalesce. Understanding this particulate structure of milk may be important, since several studies suggest that some host defense factors are compartmentalized within these structures. For instance, centrifugation of human milk causes the concentration of lysozyme to increase approximately fivefold over the value obtained by sampling milk prior to centrifugation (Goldblum *et al.*, 1975). Crago *et al.* (1979) demonstrated that some of the SIgA antibodies in human milk are contained in lipid-filled particles. Little is known about the direct effects on host defenses of the particles suspended in human milk, although some of them may be neutrophil activators (Keeney *et al.*, 1992) or may interfere with the attachment of enterobacteria to epithelial cells (Schroten *et al.*, 1992).

## C. Soluble Factors in Milk

### 1. Proteins and Peptides

**a. Immunoglobulins and Ig transport fragments.** The major class of immunoglobulins in human milk is IgA. In contrast, mature cow's milk contains predominantly IgG. The structure and function of SIgA, which makes up at least 80% of the milk IgA, is discussed in Chapters 7 and 11, respectively. Chapter 21 considers the distribution and characteristics of the cells that produce immunoglobulins within the mammary gland. The demonstration of a very high density of IgA1- and IgA2-producing cells in the lactating mammary gland (Brandtzaeg, 1983) helps explain why human colostrum and milk contain the highest concentrations of SIgA of any secretions. The high proportion of SIgA in human milk of the IgA2 isotype (~40%) relative to plasma (10%) also must be related to the isotype distribution of these cells in the mammary gland. These findings also provide evidence that most of the IgA secreted into the milk is produced locally within the breast, rather than transported from the plasma.

The mechanism of antigenic sensitization and migration of IgA-committed B cells into the mammary gland is considered in several earlier chapters. Briefly, current evidence indicates that many of the IgA antibody responses detected in human milk originate from antigenic stimulation at specialized mucosal sites in the intestinal and respiratory tracts

(Goldblum *et al.*, 1975; Roux *et al.*, 1977). IgA-committed B cells emerging from mucosal sites, such as Peyer's patches in the small intestine, migrate preferentially to other mucosal sites, including the lactating mammary gland. Migration to the mammary gland is under hormonal regulation (Weisz-Carrington *et al.*, 1978). The wide array of specific antibodies found in human milk suggests that some of these cells are derived from memory B cells rather than from recent antigenic exposure. In the breast, B cells mature into plasma cells, the predominant product of which is polymeric IgA.

As in other secretory mucosae, transport of immunoglobulins into colostrum and milk is accomplished predominantly by the polymeric immunoglobulin receptor (PIgR). Chapter 10 describes in detail the mechanism by which PIgR mediates specific binding, endocytosis, and transcellular transport of immunoglobulins. Proteolytic cleavage of PIgR at the apical membrane of the mammary alveolar cell releases the polymeric IgA molecule, covalently complexed to a fragment of PIgR termed secretory component (SC). This complex is called SIgA.

Some of the PIgR molecules are transported and cleaved by the epithelial cells without any attached immunoglobulin. The resulting proteolytic fragment, free SC, is also present in high concentrations in human milk. The function of free secretory component has not been established clearly. One study (Wilson and Christi, 1991) suggests that these molecules may be able to inhibit the enzyme phospholipase A<sub>2</sub>, a function that could reduce inflammatory reactions along mucosal surfaces as well as, perhaps, the fluid accumulation produced by some intestinal pathogens (Peterson and Ochoa, 1989).

From this brief outline of the immunogenesis of SIgA, we can deduce that this system is well adapted for the production, and secretion into milk, of specific antibodies against pathogenic microorganisms to which the mother's mucosal immune system has been exposed. Since the mother-infant pair normally shares many environmental exposures, this system may be ideal for protecting the infant from potential pathogens entering the environment. As indicated in Chapter 52, several epidemiological studies have shown that the presence in milk of specific SIgA antibodies against enteric pathogens diminishes the incidence or severity of diarrhea caused by bacterial and viral organisms.

Immunoglobulins of the other major isotypes also are found in human milk, although at lower concentrations than in plasma. IgM in milk is in its typical pentameric form, although some of the molecules have noncovalently attached SC, suggesting that IgM is transported into the milk via the PIgR. However, the binding of free SC in milk could generate the same complexes. The antibody specificity of IgM in milk has not been tested extensively, but seems to parallel that of IgA when examined. The presence of IgM antibodies with attached SC should be considered when designing studies of SIgA in human milk, since detection systems based on anti-SC antibodies also may detect secretory IgM (Mellander *et al.*, 1985).

In cow milk, IgG is the major isotype. However, only small amounts of each of the subclasses of IgG have been detected in human milk. The relative proportion of IgG4 is greater in milk than in serum, suggesting that more of this isotype may be produced locally or selectively transported by the interstitium (Keller *et al.*, 1983). This hypothesis has not been borne out in a more recent investigation (Mehta *et al.*, 1991). Nonetheless, the total amount of IgG4 is so low that attributing biological functions to this or the other IgG isotypes will be difficult.

The concentration of IgD in human milk is very low, even relative to serum concentrations (Keller *et al.*, 1984). IgE is essentially absent from human milk (Underdown *et al.*, 1976).

Antibodies against a large number of microbes and specific antigens have been detected in human milk. Table II provides a summary of some of these specificities. This list should not be considered complete or thought to imply functional significance of the presence of antibodies of particular specificity, since it represents a summary of studies from groups with particular interest in the antigens tested.

The stability of the immunoglobulins in human milk has been the subject of a number of studies, most of which have concentrated on SIgA. The majority of the IgA molecules in postnatal milk seems to be intact, based on Western blots using anti- $\alpha$  chain antibodies as developing reagents (Cleveland *et al.*, 1991). Thus, during active lactation, little degradation must occur within the mammary gland. Following the fate of the SIgA within the infant is difficult. Fecal excretion of SIgA has been examined in low birth weight and full-term infants (Schanler *et al.*, 1986; Prentice *et al.*, 1987; Davidson and Lönnerdal, 1987). The finding that SIgA excretion in the

feces was 30 times higher in low birth weight infants receiving human milk than in similar infants fed cow milk formulas strongly suggested that a portion of the ingested milk survived the whole gastrointestinal tract. However, when expressed as a proportion of the SIgA fed, approximately 9% of the SIgA was recovered as SIgA (Schanler *et al.*, 1986).

The function of mucosal immunoglobulins is discussed in detail in Chapter 11. Of potential importance for milk immunoglobulins is the amplification of the effect of other milk defense factors by IgA. For instance, some of the lactoferrin in milk is found complexed with IgA (Arnold *et al.*, 1977). These complexes may have enhanced activity since they can be targeted to surfaces of pathogenic microorganisms where lactoferrin could function to chelate selectively the iron needed by the microorganism for growth. Microorganisms that are resistant to the lytic action of lysozyme may become more susceptible in the presence of SIgA and complement (Adinolfi *et al.*, 1966). Galactosyltransferase enzyme also complexes tightly with IgA, although the functional significance of these complexes is not known (McGuire *et al.*, 1989).

**b. Lysozyme.** Lysozyme, a 12-kDa single polypeptide, catalyzes the hydrolysis of  $\beta$ 1-4 linkages between *N*-acetylmuramic acid and 2-acetylamino-2-deoxy-D-glucose groups in bacterial cell walls, leading to direct lysis of susceptible bacteria, predominantly those without an extensive cell wall. As indicated earlier, interaction with IgA and complement may expand the antimicrobial range of activity of this secretory enzyme.

The quantity of lysozyme supplied to the infant each day are presented in Table III. Although the concentration varies during lactation the amount delivered appears to remain relatively constant for at least the first 4 months (Butte *et al.*, 1984). These concentrations are among the highest of any secretion (Jolles and Jolles, 1967).

The relative stability of lysozyme against acid denaturation and tryptic digestion makes it well suited to function in the gastrointestinal tract of the recipient infant. However, the fate of the ingested lysozyme is not clear. Low birth weight infants who are fed human milk excrete about eight times more lysozyme in their stool than do cow milk-fed infants (Schanler *et al.*, 1986).

**c. Lactoferrin.** Lactoferrin is the whey protein with the highest concentration in human milk. The daily amount of lactoferrin ingested by the infant at various stages of lactation are shown in Table III. A gradual decline is seen in the amount transferred to the infant, beginning soon after initiation of lactation.

A single chain glycoprotein of 79 kDa, lactoferrin consists of two globular lobes, each with two domains surrounding a binding cleft for an atom of ferric iron and a bicarbonate ion. The major function of lactoferrin is the chelation of iron. In that respect, apolactoferrin robs the siderophilins of microorganisms of iron that is essential for their growth (Spik *et al.*, 1978). The lactoferrin in human milk is well suited for this role, since 90% of the molecules are devoid of iron (Fransson and Lönnerdal, 1980). Several other functions have been suggested for lactoferrin. The finding of a specific receptor for lactoferrin on the mucosa of the upper bowel suggested that lactoferrin might enhance the uptake of milk iron by the infant (Davidson and Lönnerdal, 1988). The low degree of iron saturation in milk lactoferrin makes this function seem unlikely, unless iron was transferred from other compartments during the digestion process. Some evidence also suggests that lactoferrin has trophic effects on enterocytes (Nichols *et al.*, 1987) and may inhibit complement activity (Kijlstra and Jeurissen, 1982).

Few studies have been done on the disposition of milk lactoferrin in the infant. One study was carried out on infants with enterostomies, which allowed the gut contents to be recovered before entering the colon (Hambreus *et al.*, 1989). The results indicated that 9-32% of the ingested lactoferrin could be recovered from this site. Low birth weight infants fed a human milk preparation excreted almost 200 times more lactoferrin in their stool than similar infants fed a cow milk-based formula (Schanler *et al.*, 1986). However, only 3% of the ingested lactoferrin was recovered in the fecal sample. In addition, a major portion of the excreted lactoferrin was partially digested, resulting in molecules of unknown activity (Goldman *et al.*, 1990). Infants fed human milk also had a larger amount of lactoferrin and lactoferrin fragments in their urine (Goldblum *et al.*, 1989); the molecular sizes of those fragments were similar to those in the stools (Goldman *et al.*, 1990). Another study using stable isotope methods also suggested that some lactoferrin derived from the milk may

**Table III** Quantity (mg/kg/D) of Immune Factors [mean (Std)] Provided by Human Milk<sup>a</sup>

Factor	Phase of lactation (age of infants in months)			
	1	2	3	4

SIgA	130 (50)	105 (40)	88 (3)	77 (35)
Lysozyme	4 (3)	5 (3)	4.9 (1.5)	6 (2)

<sup>a</sup> Data modified from Butte *et al.* (1984).

be absorbed intact from the intestinal tract and then excreted into the urinary tract (Hutchens *et al.*, 1991). If this occurs, the absorbed lactoferrin must be cleared rapidly since human milk ingestion does not increase the serum concentration of lactoferrin (Schanler *et al.*, 1986).

**d. Complement components.** Many of the components of the classical and alternative complement pathway have been detected in human milk (Ballow *et al.*, 1974; Nakajima *et al.*, 1977). However, with the exception of C3, the concentrations of these factors are very low. The activity of the complement system in human milk is not likely to be great, although interactions with other milk constituents may allow some function (Adinolfi *et al.*, 1966).

**e. Bioactive peptides.** Several cytokines have been quantified by immunoassays in human milk, including interleukin-1 $\beta$  (IL-1 $\beta$ ; Munoz *et al.*, 1990), tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ; Mushtaha *et al.*, 1989; Rudloff *et al.*, 1992a) and IL-6 (Saito *et al.*, 1991; Rudloff *et al.*, 1992b). The functions of these factors in the infant remain to be elucidated. However, studies of the leukocytes in the milk suggest that some of these cytokines may be active (Söder, 1987; Mushtaha *et al.*, 1989). Of special interest is the finding that incubation of peripheral blood leukocytes with human milk causes monocytes and neutrophils to become activated. Further, addition of neutralizing antibodies against human TNF $\alpha$  abrogated the activating effects of milk on monocytes (Mushtaha *et al.*, 1989).

Some fragments of casein, the  $\beta$ -casomorphines, which are created during proteolysis of casein in the gastrointestinal tract, are biologically active (Teschenmacher, 1987).  $\beta$ -Casomorphines not only have endorphin effects but may be immunoregulatory as well (Parker *et al.*, 1984).

Several different isoforms of prolactin have been demonstrated in human milk that apparently are produced by post-translational modifications in the mammary gland. Although the function of each of these isoforms is not delineated, the basic protein molecule has been found to influence the development of T cells in animal model systems (Chikanza and Panay, 1991; Gala, 1991; Rovinsky *et al.*, 1991) and to enhance the formation of specific antibodies in serum and milk (Ijaz *et al.*, 1990).

The array of growth factors in human milk includes epidermal growth factor (EGF), insulin, transforming growth factor  $\beta$  (TGF- $\beta$ ; Hooton *et al.*, 1991), and mammary gland derived growth factor (Kidwell *et al.*, 1987). Some of these factors have been postulated to aid in the postnatal development of the mucosal barriers of the intestinal and respiratory tracts. However, the *in vivo* effects of these factors are not well characterized.

## 2. Carbohydrates and Glycoconjugates

**a. Lactobacillus growth factors.** Human milk contains high levels of a growth-promoting activity for *Lactobacillus bifidus* var. *Pennsylvania* (György *et al.*, 1974). This activity, which is essentially absent from cow milk, is generated by oligosaccharides (György *et al.*, 1974), glycopeptides, and proteins (Nichols *et al.*, 1975; Bezkorovainy *et al.*, 1979).

Similar activity associated with caseins also may be the result of oligosaccharide moieties on that protein (Bezkorovainy and Topouzian, 1981). The role of these factors in host defense may be related to the predominance of *Lactobacillus* in the bacterial flora in the colon of infants fed human milk. The large amount of acetic acid produced by these organisms suppresses the growth of enteropathogens.

**b. Oligosaccharides and glycoconjugates.** Human milk is rich in oligosaccharides that appear to be formed in the mammary epithelium by the same galactosyltransferases that glycosylate proteins and peptides, using lactose as the acceptor molecule. Various biological activities have been attributed to the whole group of oligosaccharides (Holmgren *et al.*, 1981) and, more recently, to individually characterized moieties, including fucosylated oligosaccharides that inhibit the hemagglutinin activity of the classical strain of *Vibrio cholerae* (Holmgren *et al.*, 1983) and protect against the heat-stable toxin of *Escherichia coli* (Newburg *et al.*, 1990). Mannose-containing glycoproteins and glycolipids interfere with the fimbria-mediated binding of *E. coli* (Holmgren *et al.*, 1987; Wold *et al.*, 1990). The attachment of *Haemophilus influenzae* and *Streptococcus pneumoniae* to epithelial cells is inhibited by saccharides containing the disaccharide subunit *N*-acetylglucosamine (1-3)- $\beta$ -galactose (Andersson *et al.*, 1986). These units may exist as free oligosaccharide or in glycoproteins or peptides. In any case, molecules with these structures may act as false receptors for the lectin-like adherence structures on the microorganism and thereby protect the infant from colonization or infection with these pathogens. Although an *in vivo* role for these oligosaccharides is suggested by animal models (Otnaess and Svennerholm, 1982; Cleary *et al.*, 1983; Ashkanazi *et al.*, 1992) few human studies have been done that pertain to this question.

## 3. Lipids

**a. Unsaturated fatty acids and monoglycerides.** Free fatty acids and monoglycerides are produced by the digestion of milk triglycerides by bile salt-stimulated lipases or lipoprotein lipases in human milk. In addition, the lingual and gastric lipase activities of the recipient infant are active on the milk triglycerides (Hosmoh, 1990). The lipid products have several host defense activities including disruption of enveloped viruses (Stock and Frances, 1940; Welch *et al.*, 1979; Issacs *et al.*, 1986; Thromar *et al.*, 1987), which may prevent coronavirus infection in the intestinal tract (Resta *et al.*, 1985). The fatty acids and monoglycerides also may provide some defense against intestinal parasites such as *Giardia lamblia* (Gillin *et al.*, 1983, 1985; Hernell *et al.*, 1987).

**b.  $\alpha$ -Tocopherol and  $\beta$ -carotene.** Two vitamins found in human milk (Chapell *et al.*, 1985) also may have host defense activity. High levels of  $\alpha$ -tocopherol in milk may serve as an antioxidant, but additionally this vitamin is known to stimulate the development of immunity (Tengerdy *et al.*, 1981; Bendich *et al.*, 1986).  $\beta$ -Carotene, another potent antioxidant, is present in high concentrations in the mammary gland at parturition. This agent is released from the tissue into milk

during the first few days of lactation (Chapell *et al.*, 1985). As a result of the ingestion of  $\alpha$ -tocopherol and  $\beta$ -carotene in human milk, the blood levels of these two agents rise substantially in the recipient infant (Chapell *et al.*, 1985; Ostrea *et al.*, 1986). These and other agents in human milk may regulate inflammatory responses and immune functions of the infant.

#### IV. OVERVIEW OF THE FUNCTION OF HUMAN MILK IN HOST PROTECTION AND CONCLUSIONS

Despite the identification and quantification in human milk of many factors that have the potential to protect the lactating breast and the recipient infant, little currently is known about how these factors function *in vivo*. Progress in this area has been limited by the types of studies that can be carried out in human infants and by the large species differences in milk composition and function that make experimental animal studies difficult to apply to humans. However, certain patterns of factors may provide clues to unique *in vivo* function of human milk.

##### A. Production of Immune Factors by the Breast Is Regulated

In contrast to many mucosal glands, which function on a continuous basis, the mammary gland secretion of immune factors is restricted largely to periods of lactation. The factors that regulate the onset, quality, and quantity of the human milk are only partially understood. Prolactin and other lactogenic hormones are essential for the onset and maintenance of lactation. An array of growth factors including EGF, insulin, and mammary gland derived growth factors that are concentrated in human milk (Kidwell *et al.*, 1987) also may play a role in these processes.

##### B. Immune Factors in Milk May Prevent Infection without Causing Inflammation

The same proximity of the mucosal surfaces to the external environment that leads to extensive exposure to microorganisms and other antigens allows the mucosal immune system to defend against infections without the need for the extensive inflammatory and phagocytic responses that are typical of the systemic defenses. Thus, if factors in milk can reduce the adherence, colonization, or growth of microorganisms in the infant's respiratory or intestinal tract, the incidence or severity of infection would decrease correspondingly without producing much physiological abnormality in the infant. We have hypothesized previously that a characteristic of the immune system in human milk is the absence of phlogistic factors and the presence of agents with anti-inflammatory activity (Goldman *et al.*, 1986). Demonstrations that infants who receive mother's milk that contains specific antibodies against an enteric pathogen still have culture-proven infections but less diarrhea than those receiving milk without those

antibodies (Glass *et al.*, 1983; also see Chapter 52) are in keeping with this hypothesis. In that respect, the lower morbidity of breast-fed infants infected with rotavirus was not found to be related to the levels of specific antibodies in the milk (Duffy *et al.*, 1986). This result suggests that other agents, including anti-inflammatory factors, may be responsible for some of the protection against certain pathogens.

##### C. Long-Term Effects of Breast Feeding

Several studies suggest that breast feeding may have effects that last much longer than the breast-feeding period. For instance, breast-fed infants have a lower incidence of juvenile diabetes mellitus (Mayer *et al.*, 1988; Hamman *et al.*, 1988) and Crohn's disease (Koletzko *et al.*, 1989) than those fed formulas. Retrospective analysis also suggests a diminished risk of lymphomas after breast-feeding (Davis *et al.*, 1988). Whether these long-term effects are the result of mucosal immune factors in human milk is unclear. However, speculating that breast-feeding alters the development of the infant's immune system or protects against certain infections during a critical developmental period, thereby preventing illnesses that become manifest later in life, is interesting.

# Immunologic Effects of Breast-Feeding on the Infant

B. Carlsson · L. Å. Hanson

## I. BREAST-FEEDING AND OTHER MODES OF FEEDING OF THE INFANT

No one would deny that breast-feeding is the natural mode of feeding of the human offspring. Most of us believe that it is only in modern times that neonates and young infants have been fed with foods and fluids other than human milk. However, this is not so. King Ashurbanipal (7th century B.C.) may have been the first artificially fed infant to have been recorded in history. Writings from ancient India (B.C. 1500–A.D. 700) prescribed delayed onset of breastfeeding and so did the Greek physician Soranus (approximately A.D. 100) who claimed that the maternal milk was unwholesome for the first 20 days of lactation (Fildes, 1986).

Before describing the immunological consequences of breast-feeding for the infant it is necessary to define breast-feeding and to indicate to what extent infants really are breastfed.

*Exclusive or complete breastfeeding* will be used when nothing but maternal milk is given, not even water, which may be contaminated. *Partial breast-feeding* will include those who receive any other fluid or food in addition to the human milk.

### A. The Time of Onset of Breast-Feeding

It is remarkable that the prescription of the ancient authors still seems to be in effect. Thus, in traditional societies (e.g., in Pakistan) the onset of breast-feeding is still delayed, with less than 50% of the infants being breast-fed at 48 hours of life (Hanson *et al.*, 1986; Ashraf *et al.*, 1992). Instead they are given various other foods and fluids, such as ghutti (cleared butter) and honey and herb extracts advised more than a thousand years ago (Fildes, 1986).

### B. Prevalence and Duration of Breast-Feeding

The prevalence of breast-feeding decreased in industrialized countries to very low levels in the 1950s and 1960s, in parallel with the development of commercial formulas and the concept that the antibodies of human milk were of no importance since they were not resorbed by the breast-fed infant (Vahlqvist, 1958). With the increased understanding

of the many nutritional and immunological advantages of breast-feeding a change in attitude has occurred that has resulted in a continuous increase both of direct onset of breast-feeding at birth and of the prevalence and duration of breast-feeding in some Western societies.

Breast-feeding is believed to be very common in traditional societies in the Third World. However, all infants in a large study in Lahore, Pakistan, received the initial traditional foods and fluids before breast-feeding started (Ashraf *et al.*, 1992). After that, only 9% were breast-fed exclusively after the first few days of life. About 70% were breast-feeding partially at 12 months of age (Ashraf *et al.*, 1992). Those infants not breast-feeding were found mainly in the upper middle class, in which commercial formulas were used widely. In contrast, such formulas were rarely given among the poor mothers, almost 100% of whom gave their infants water or buffalo milk in a bottle instead, usually in addition to breast-feeding. During the hot season, the infants were given more water under the misconception that breast-fed infants then require extra fluid. As a consequence, almost no exclusively breast-fed infants are found during this period, when diarrheal diseases are most common, the defense provided by the maternal milk is most needed, and other fluids more often may be contaminated (Ashraf *et al.*, 1992). Several studies have shown that no extra fluid is required for a breast-fed infant, even in a hot and dry climate (Ashraf *et al.*, 1992).

### C. Effects of the Mode of Feeding on the Microbial Flora of the Infant

At birth, the newborn is exposed immediately to numerous microorganisms of different species, among which potential pathogens also may be included. Already in the first few days after parturition, many anaerobic as well as aerobic bacteria have colonized the gut.

The intestinal flora has been shown to differ in breast-fed and non-breast-fed infants (Ørskov and Biering-Sørensen, 1975; Raibaud, 1988; Balmer and Wharton, 1989). Pakistani infants, delivered both vaginally and by caesarian section, were colonized already from the first day of life, whereas some Swedish infants still had no demonstrable enterobacterial strains on the fifth day of life. The Swedish infants were colonized mainly only by one type of aerobic gram-negative

bacterium whereas the Pakistani infants frequently carried strains of several types. In Pakistani infants, *Proteus*, *Klebsiella*, *Enterobacter*, and *Citrobacter* were significantly more common in non-breast-fed than in breast-fed babies; *Escherichia coli* was found significantly earlier in breast-fed than in non-breast-fed infants (Hanson *et al.*, 1989a; Adlerberth *et al.*, 1991).

Aerobic gram-negative bacteria from the intestine of breast-fed infants also have been demonstrated to be more sensitive to the bactericidal effects of antibodies than bacteria from formula-fed infants (Gothefors *et al.*, 1975), suggesting a decrease of virulence of the bacteria. Similar conclusions might be drawn from observations of the effect of breast-feeding on newborns colonized artificially by a harmless *E. coli* 083 strain during the first week of life (Lódinova-Zadnikóva *et al.*, 1991). The *E. coli* 083 strains from breast-fed infants more often carried type 1 fimbriae, which do not seem to be virulence factors (Wold *et al.*, 1990). Breast-feeding favored colonization by the type 1 fimbriated 083 strain (Lódinova-Zadnikóva *et al.*, 1991).

## II. EFFECTS OF BREAST-FEEDING ON HOST DEFENSE COMPONENTS OF THE INFANT

### A. Immunoglobulins

We have found that the newborn, already at birth, has secretory IgA and IgM (SIgA and SIgM) antibodies in saliva, against both *E. coli* and poliovirus antigens (Mellander *et al.*, 1984, 1986). Such antibodies are present in newborns of healthy mothers as well as of mothers with hypogammaglobulinemia and IgA deficiency who lack IgA or IgM, supporting the idea that these antibodies are produced by the fetus (Mellander *et al.*, 1986; Hahn-Zoric *et al.*, 1992). We have proposed that the antigenic stimulus for the fetus could be anti-idiotypic antibodies that come from the mother (Mellander *et al.*, 1986). We were able to demonstrate such anti-anti-poliovirus antibodies in the immunoglobulin preparations given to the immunodeficient mothers, as well as in human milk (Hanson *et al.*, 1989b; M. Hahn-Zoric, 1993). If our assumption is correct, antibodies passively received by the fetus from the mother before birth via placenta or after birth via the milk can prime the immune system of the offspring actively in addition to conferring passive protection on the baby. In animal experiments, such an effect of anti-idiotypic antibodies has been demonstrated against bacterial as well as viral antigens when anti-antibodies were given directly to the newborn mouse or, via the mother animal, reached the offspring through the milk (Stein and Söderström, 1984; Okamoto *et al.*, 1989). The exposure of the mother to microbes is likely to direct her immune response and influence her levels of corresponding idiotypes and anti-idiotypes, which will be transferred to the fetus and infant, presumably both by serum and by milk. Presently, however, little is known about the factors that determine whether stimulation or inhibition of the immune response will result.

In preterm infants, serum immunoglobulin levels were higher in formula-fed infants than in breast-fed infants. For IgA, this difference was demonstrated from 7 weeks of age and for IgG, from 11 weeks (Savilahti *et al.*, 1983). Full-term infants showed similar patterns (Saarinen *et al.*, 1979; Savilahti *et al.*, 1987). In saliva, SIgA levels have been demonstrated to be higher in breast-fed than in formula-fed infants, although possible contamination from the milk was not excluded (Roberts and Freed, 1977). Other studies have shown no influence on serum IgA by the mode of feeding, but an increase of SIgA was seen in the stool and urine of breast-fed infants compared with formula-fed controls (Schanler *et al.*, 1986).

Human milk also contains considerable numbers of lymphocytes, granulocytes, and macrophages, especially during early lactation. Most of the milk lymphocytes are T cells, many of which carry the CDw29 marker of memory T cells (Bertotto *et al.*, 1990, 1991). Such memory T cells could support the production of the wide diversity of milk SIgA antibodies, but also might have an effect on the breast-fed offspring. A positive tuberculin reaction has been observed temporarily in breast-fed infants of tuberculin-positive mothers (Mohr 1973; Ogra *et al.*, 1977; Schlesinger and Covelli, 1977).

Some, but not all, studies show no impairment of titers of milk IgA antibodies against various microbes by undernutrition (Cruz *et al.*, 1982, 1985; Miranda *et al.*, 1983). However, a study by Herías *et al.* 1993 demonstrated a decreased milk SIgA concentration as well as decreased antibody affinity as a result of undernutrition, which could be an effect of undernutrition on T cells (Chandra, 1979a).

### B. Vaccine Responses

In another study, we noticed that breast-fed infants had significantly higher serum and saliva antibodies against diphtheria and tetanus toxoids and poliovirus than did formula-fed infants after the first two vaccine doses (Hahn-Zoric *et al.*, 1990). The SIgA responses in saliva and IgM in stool samples were significantly higher at 3–4 months of age, whereas the serum IgG antibody response to diphtheria toxoid and the neutralizing antibodies against poliovirus were higher at 20–40 months of age. Similar results were found after immunization of infants using a *Haemophilus influenzae* type b conjugate vaccine; breast-fed babies were shown to have significantly higher serum antibody levels than formula-fed infants (Pabst and Spady, 1990). The purified protein derivative (PPD) reaction was stronger after immunization with *Bacillus Calmette-Guérin* (BCG) in breast-fed than in formula-fed infants (Pabst *et al.*, 1989). The possibility that the mother's milk enhances vaccine response might be of clinical relevance and suggests that the immunoglobulins in human milk may not merely provide the neonate with passive immunity but also may actively stimulate the lymphoid system of the breast-fed infants. Experimental data indicate that human milk contains anti-idiotypic antibodies (Hanson *et al.*, 1989b; M. Hahn-Zoric, 1993).

### C. Other Components

Several molecules that are known to be responsible for inducing inflammation, for example, IgM and IgG antibodies, complement, and coagulation factors, are found at low levels in, or are almost absent from, human milk. In contrast, milk seems to be a rich source of other factors that block inflammation (Goldman *et al.*, 1986). The SIgA antibodies, present in high concentration in milk, as well as the milk oligosaccharides or glycoconjugates, which may be structurally similar to epithelial receptors for microbes, have the capacity to block the binding of microbes to mucosal epithelia, thus preventing infection in the newborn (Holmgren *et al.*, 1981; Andersson *et al.*, 1983,1986; Lagreid *et al.*, 1986; Lagreid and Kolstø Otnaess, 1987).

We have explored whether human milk components have the capacity to prevent the release of cytokines from various cells induced by exposure to lipopolysaccharides (LPS). This ability is of interest since these molecules are known to have striking effects, for example, on epithelial cells, making them produce cytokines such as interleukin 1 (IL-1), IL-6, and tumor necrosis factor  $\alpha$  (TNF $\alpha$ ). We have found that lactoferrin isolated from human milk can block LPS-induced IL-6 release from a human macrophage and a human colonic epithelium cell line (Hanson *et al.*, 1991b; I. Mattsby Baltzer, A. Roseanu, I. Engberg, C. Motas, and L. Å. Hanson, unpublished data). Such activities of human milk components may help prevent the release of IL-6 or other cytokines in the newborn being colonized with gram-negative bacteria. Such a release might induce symptoms and catabolic effects, for instance, possibly explaining some of the early weight loss of neonates. Whether the prevention of cytokine release in mucosal membranes can have consequences for the immune response of the infant still must be explored. However, TNF $\alpha$  has been demonstrated in milk (Goldman *et al.*, 1991; Rudloff *et al.*, 1992). Breast-feeding has been suggested to stimulate the maturation of the immune system in the newborn; part of this stimulation may be caused by TNF $\alpha$  in human milk, which might up-regulate the expression of secretory component on epithelial cells or of Class I and II major histocompatibility complex (MHC) molecules on macrophages, or perhaps enhance maturation of monocytes or T lymphocytes (Goldman *et al.*, 1991).

Human milk also contains numerous components such as lysozyme, lipids, and antioxidants that prevent neutrophil chemotaxis, granular release, and production of free radicals (Goldman *et al.*, 1986). Such activities are likely to add to the well-being of the infant by depressing or preventing inflammatory reactivity. Epidermal growth factor (EGF), which is present in considerable amounts in milk, probably plays a role in the regulation of the development of the gastrointestinal tract of the newborn (Bines and Walker, 1991; Koldovsky *et al.*, 1991). The existence of analogous inhibitors of virus receptors also may be important in infections by viruses such as the human immunodeficiency virus (HIV). A factor in the macromolecular fraction of human milk has been demonstrated that inhibits binding of HIV epitope-specific monoclonal antibodies and HIV envelope glycopro-

tein gp120 to recombinant CD4 receptor molecules. The role this factor plays in HIV infection, as well as its chemical character, remains to be investigated (Newburg *et al.*, 1992).

## III. EFFECTS OF BREAST-FEEDING ON INFECTIONS IN THE INFANT

### A. Gastroenteritis

Extensive studies support the notion that breast-feeding is of importance in minimizing infant mortality and morbidity from diarrhea. In the 18th and 19th centuries, observers in Sweden noted that infant mortality due to diarrhea was strikingly increased during the summer months when mothers were not breast-feeding (Brändström, 1984). Feachem and Koblinsky (1984) reviewed the literature and concluded that the risk of dying from diarrhea was increased 25-fold in non-breast-fed infants compared with exclusively breast-fed infants. Infants who are breast-fed also suffer from fewer episodes of diarrhea than those who are not breast-fed (Feachem and Koblinsky, 1984; Cunningham *et al.*, 1991; F. Jalil, A. Mahmud, R. N. Ashraf, S. Zaman, J. Karlberg, L. Å. Hanson, and B. S. Lindblad, unpublished data). Clinical studies that are meant to demonstrate protection by breast-feeding often are disrupted by several confounding factors that influence the outcome (Victora, 1990). The late start of breast-feeding and the often unrecognized extra food or water given to the breast-fed infant in traditional societies often have not been considered. This oversight may have led to an underestimation of the protective value of breast-feeding (Hanson *et al.*, 1986). However, in Brazil, breast-feeding clearly was shown to protect against death in diarrhea, especially in the first few months of life (Victora *et al.*, 1987). Partial weaning was followed by an increased risk, and infants who were weaned completely were at the greatest risk.

In a field study in Lahore, Pakistan, significant protection against diarrhea by breast-feeding was demonstrated during the first 3 months for the upper middle class, for 6 months in the urban slum, and for 12–24 months for village and periurban slum inhabitants (F. Jalil, A. Mahmud, R. N. Ashraf, S. Zaman, J. Karlberg, L. Å. Hanson, and B. S. Lindblad, unpublished results). The protection was seen especially during the hot season, when diarrhea is more prevalent and the infectious dose presumably is higher. The efficacy of the protection was, in early life, as high as 70–80% in the two poorest groups (village and periurban slum) and ~40% in the upper middle class (Ashraf *et al.*, 1992). Even partial breast-feeding, which is the predominant mode of feeding in this area, can protect infants to a surprisingly high degree.

Few studies have been able to define the protective role and the importance of specific host defense components in maternal milk. However, the protection against diarrhea caused by *Vibrio cholerae*, enterotoxigenic *E. coli*, and *Campylobacter* in breast-fed infants has been shown to relate to the presence of special milk IgA antibodies against each of these pathogens in mother's milk (Glass *et al.*, 1983; Cruz *et al.*, 1988; Ruiz-Palacios *et al.*, 1990). Other milk compo-

nents such as lactoferrin and receptor analogs could be important as well, but this has not been demonstrated.

### **B. Septicemia and Other Infections**

Breast-feeding does not only seem to protect against gastroenteritis, but evidence also exists of protection against septicemia during early infancy (Winberg and Wessner, 1971; Narayanan *et al.*, 1981). In a study of neonatal septicemia in Lahore, Pakistan, an odds ratio of 18 was found for protection even by partial breast-feeding compared with feeding with animal milk (Ashraf *et al.*, 1991). Finding evidence for protection against lower respiratory tract infections has been more difficult but some positive studies have been presented (Victora *et al.*, 1987; Wright *et al.*, 1989; Howie *et al.*, 1990). Protection has not been demonstrated in all investigations, and a preliminary analysis of the prevalence of respiratory infections in our study in Pakistan to date has not shown a correlation to the mode of feeding (F. Jalil, *et al.*, unpublished data).

Certain investigations have indicated that breast-feeding protects against otitis media (Saarinen, 1982; Aniansson *et al.*, 1990) and necrotizing enterocolitis (Lucas and Cole, 1990). The latter authors estimate that breast-feeding could prevent as many as 500 cases of necrotizing enterocolitis a year in the United Kingdom, of which about 100 infants otherwise would die.

## **IV. EFFECTS OF BREAST-FEEDING ON ALLERGY IN THE INFANT AND CHILD**

Atopic allergies are becoming increasingly common. Allergies to foods are especially prevalent in infancy and early childhood. Much interest has been directed toward breast-feeding as a possible way to prevent allergy.

### **A. Breast-Feeding and the Serum and Secretory Antibody Response to Food Proteins in the Infant**

Salivary SIgA antibodies previously have been shown to be found in the neonate and increase rapidly on antigenic exposure (Mellander *et al.*, 1984, 1985). Even the premature infant can respond with SIgA antibodies against cow's milk proteins in saliva (Robertson *et al.*, 1986). Breast-fed infants show significantly lower salivary SIgA anti-bovine casein than cow's milk-fed infants (Renz *et al.*, 1989). Infants without any risk factors for atopic allergy have significantly higher levels of such salivary SIgA antibodies after being fed cow's milk than do those with risk factors who were fed similarly.

Prolonged breast-feeding leaves infants with significantly lower serum IgG, IgM, and IgA levels than non-breast-fed infants (Savilahti *et al.*, 1987). Serum IgG antibodies against cow's milk proteins increased most in those infants given cow's milk formula before the age of 1 month. Fully weaned and partially breast-fed infants had similar increased levels

(Tainio *et al.*, 1988). Exclusively breast-fed infants also produced antibodies against cow's milk, perhaps because of the presence of cow's milk proteins in the maternal milk (e.g., Machtinger and Moss, 1986) or because of the exposure to anti-idiotypic antibodies via the placenta or the maternal milk (Mellander *et al.*, 1986; Hanson *et al.*, 1989b; Hahn-Zoric *et al.*, 1990, 1992, 1993).

The appearance of anti-food antibodies was analyzed in infants breast-fed by mothers on a normal diet, on a diet free of the allergens of egg and cow's milk, or restricted with respect to the intake of these foods from week 28 of pregnancy to delivery. The babies of the mothers on the allergen-free diet curiously had significantly higher IgG, IgA, and IgM antibodies against ovalbumin and gluten, but not against  $\beta$ -lactoglobulin (Fälth-Magnusson *et al.*, 1988). In another similar study in which the diet restriction for one group of mothers included egg, cow's milk, and fish during the first 3 months of lactation, the only significant difference among the breast-fed infants from the two groups was that fewer infants in the diet group than the non-diet group had IgE antibodies against eggwhite and cow's milk proteins. IgE antibodies also appeared during exclusive breast-feeding (Hattevig *et al.*, 1990).

### **B. Antibodies in Human Milk in Relation to the Maternal Diet**

Enteric exposure of the mother to foods may, via the enteromammary pathway, result in SIgA antibodies against these foods in her milk. Mothers with cow's milk as a regular component of the diet had higher levels of SIgA antibodies against cow's milk proteins in their milk than did those who did not regularly drink cow's milk (Cruz *et al.*, 1981). Oral exposure to a cowpea protein induced a milk SIgA antibody response in lactating mothers who did not have any prevaccination titer. However, in the few individuals who had such titers, a decrease was seen instead after eating the cowpeas (Cruz and Hanson, 1986). In another study, no differences were seen in milk IgG and IgA antibody levels against  $\beta$ -lactoglobulin, ovalbumin, and gliadin between atopic and nonatopic mothers at 1 week of lactation. Also no differences were seen in antibody levels between mothers on a cow's milk- and egg-free diet and mothers on a normal diet during pregnancy (Fälth-Magnusson, 1989).

Obviously, we currently do not know how oral exposure to a food protein may affect the milk antibody level. Perhaps antibody responses in the milk partly originate from the influx of memory cells into the lactating gland. One finding to support such a view is the presence of such a wide array of different antibody specificities at one time in the maternal milk, many more than the mother is likely to produce against antigens to which she has been exposed recently (Hanson and Brandtzaeg, 1989). Further, the relative affinities of these milk antibodies are often high and do not increase by vaccination, suggesting the presence of already mature antibody responses (Robertson *et al.*, 1988; Dahlgren *et al.*, 1989).

### C. Breast-Feeding and the Prevention of Allergy

Several studies have investigated the possibility that breast-feeding can prevent the development of atopic disease in the infant. Some of these studies have concerned risk families with a heredity predisposition to atopic diseases. In some investigations, the role of maternal avoidance diets has been analyzed.

Chandra and Hamed (1991) compared the incidence of atopic allergy in high risk children at 12 and 18 months of age; the infants were given a whey hydrolysate, conventional cow's milk formula, soy-based formula, or exclusively human milk. Atopic dermatitis and other allergic symptoms were significantly less common among those breast-fed or given the hydrolysate than among those given soy or cow's milk formula.

In an interesting study, Machtiger and Moss (1986) presented data that suggested that the risk of developing cow's milk allergy for the breast-fed infant may relate to the antibody content of the maternal milk. The milk of the mothers of children developing allergy had significantly lower total IgA and IgG antibodies against casein and whole cow's milk than did the milk of mothers whose children did not become allergic. These observations agree with those of Casimir *et al.* (1989) who studied IgG antibodies against  $\beta$ -lactoglobulin in maternal milk.

Some studies have noted that a maternal avoidance diet during late pregnancy has decreased atopic manifestations during infancy in high risk families (Chandra, 1979b; Zieger *et al.*, 1989). However, no difference in occurrence of allergy in breast-fed infants was found in a study of mothers on or off a diet of cow's milk and egg avoidance from week 28 of pregnancy to delivery (Fälth-Magnusson and Kjellman, 1987). Even at the 5-yr follow-up including 95% of the 209 initial children, no difference was found between the infants breast-fed by mothers in the diet and non-diet groups (Fälth-Magnusson and Kjellman, 1992). In another prospective study with maternal avoidance of egg, cow's milk, and fish during the first 3 months of lactation, a significantly lower incidence of atopic dermatitis was noted (Hattevig *et al.*, 1989). Reinvestigating the children at the age of 4 years showed that those in the diet group still had a cumulative incidence and a current prevalence of atopic dermatitis that was significantly lower than that of the non-diet group (Sigurs *et al.*, 1992). Other allergic manifestations did not differ, but the numbers of positive skin prick tests and specific serum IgE antibody reactions were significantly lower among the children in the diet group. A third study tried a low and a high intake of eggs and cow's milk for 171 atopic mothers during the last 3 months of pregnancy. All infants were breast-fed for at least 3 months. Investigating the infants at 18 months of age showed no difference between the diet groups with respect to occurrence of atopic disease (Lilja *et al.*, 1989). These authors assumed that genetic factors rather than allergen exposure were important in the development of allergy.

The question of the role of early introduction of cow's milk to breast-fed infants in the risk of developing allergy

also has been analyzed. In a study assigning 250 infants to be given either cow's milk or a whey hydrolysate for 1–4 days before the onset of breast-feeding, IgG antibodies showed priming by the cow's milk exposure and IgE antibodies increased significantly (Schmitz *et al.*, 1991). Going back to detailed feeding records, Gustafsson *et al.* (D. Gustafsson, T. Löwhagen, and K. Andersson, unpublished data) could show that whether or not the neonates had been given early cow's milk formula supplementation before breast-feeding started did not affect the prevalence of atopic disease in the early teens.

The risk of developing food allergy does not seem to be higher in premature infants than full-term infants, even if the premature infants were breast-fed for a shorter period of time than the full-term infants (de Martino *et al.*, 1989).

## V. CONCLUSIONS

The time of onset, the duration, and the rate of breast-feeding vary widely in different cultural settings. This variation has striking consequences for the infants, since the maternal milk is so important for the host defense of the newborn. The immunodeficiency that is secondary to lack of breast-feeding may be the most common in the world.

Breast-feeding influences the bacterial colonization, since it delays the appearance and decreases the virulence and number of the types of microbes that colonize the gut of the neonate. Human milk also contains several components that seem to counteract inflammatory activities. The protective effects of breast-feeding have been demonstrated against infections such as diarrhea, septicemia, and respiratory tract infections. Breast-feeding seems to enhance vaccine responses, possibly because of the effect of anti-idiotypic antibodies present in the milk. Breast-feeding also may decrease the risk of development of allergy in the infant.

### Acknowledgments

We thank Ms. A.-C. Malmefeldt for typing the manuscript. Our own studies referred to in this chapter were supported by the Swedish Agency for Research Cooperation with Developing Countries, the Swedish Medical Research Council (No. 215), and the Ellen, Walter, and Lennart Hesselman Foundation.

# IgA Nephropathy and Related Diseases

Steven N. Emancipator • Michael E. Lamm

IgA nephropathy (IgAN) is defined as a form of glomerulonephritis in which immunoglobulins of the IgA isotype predominate or codominate in the glomerular deposits. The clinical and pathological features of both primary and secondary forms are well documented in several comprehensive reviews (Clarkson *et al.*, 1977; D'Amico *et al.*, 1985; Clarkson, 1987; D'Amico, 1987; Julian, 1988; Emancipator and Lamm, 1989; Sakai *et al.*, 1990; Emancipator, 1992; Schena, 1990) and will be presented here only briefly. We consider, in some detail, evidence for increased production of IgA, increased entry of antigen into the systemic circulation, and impaired clearance of aggregates containing IgA, whether immune or nonimmune in nature. In each of these categories of pathogenesis, we consider the potential contribution of the mucosal immune system. We conclude that, although several distinct mechanisms may underlie the pathogenesis of IgAN, the mucosal immune system is likely to figure prominently in each. Hence, we consider IgAN a consequence of a defective or inadequate mucosal immune system. Particularly, dysregulated specific responses to a variety of antigens, possibly multiple in an individual patient, are thought to lead to a set of conditions that favors glomerular deposition of immune complexes that contain IgA.

## I. DISEASE PRESENTATION

### A. Clinical Features

Although variable, the signs and symptoms of IgAN allow the grouping of cases into three syndromes that incorporate hematuria, proteinuria, hypertension, and renal insufficiency to varying degrees (reviewed in Emancipator, 1992). Hematuria may be evident to the naked eye (gross) or microscopic, and episodic or continuous. Proteinuria, ranging from a few hundred milligrams per day to frank nephrosis, is usually but not inevitably present. Acute or chronic renal failure may be observed, but is not common. Overall, the disease usually first becomes manifest during the second or third decade of life and is more prevalent in males by a factor of two or three. The most common syndrome is episodic macrohematuria associated with low-level (<1 g/24 hr) proteinuria (Clarkson *et al.*, 1977; D'Amico *et al.*, 1985). This pattern, typically observed in young males, also may feature bouts of acute hypertension or acute renal failure, and most often accompa-

nies acute respiratory or gastrointestinal infections. The tendency for progression to glomerulosclerosis and chronic renal failure in this group, accounting for approximately 60% of all patients worldwide, is low (10%) over a sustained follow-up period (10–20 yr).

Microscopic hematuria, usually persistent but sometimes intermittent, is a somewhat less common presentation (Clarkson *et al.*, 1977; D'Amico *et al.*, 1985). Among these patients, many also have proteinuria in excess of 1 g/day. The proportion of all IgAN patients represented by such proteinuric patients varies geographically. In regions in which "major" signs or symptoms such as acute renal failure, gross hematuria, or substantial proteinuria are required before a renal biopsy is done, virtually all microhematuric patients have moderate or heavy proteinuria. Where persistent microhematuria is itself an indication for renal biopsy, roughly 30% of microhematuria patients have proteinuria exceeding 1 g/day.

Chronic renal insufficiency, frequently with hypertension, is the third syndrome. These patients, presumably with an earlier occult onset of disease, form the smallest group (10% of all patients) and often manifest proteinuria or hematuria on diagnosis as well.

### B. Pathologic Features

In some 60% of cases, mesangial proliferation is observed in the biopsy of a patient with IgAN (reviewed by Emancipator and Lamm, 1989; Emancipator, 1992). This condition is defined as some combination of matrix expansion and cell proliferation confined to the mesangial compartment of the glomerulus, without compromise of capillary lumina. Mild or minimal mesangial change or focal endocapillary proliferation and matrix expansion, that is, lesions causing narrowing of some capillaries superimposed on an established mesangial proliferative pattern, occurs in roughly 15% of patients. The spectrum from mild mesangial to focal proliferative change to diffuse endocapillary proliferation (in which most capillaries are occluded by lesions) occurs in association with endogenous or foreign antigens complexed with specific antibody; such circulating immune complexes are implicated etiologically for glomerulonephritis in general (reviewed by Germuth and Rodriguez, 1973; McCluskey, 1992). In experimental animal models, the extent of the histological lesions is related to the amount and duration of circulating immune complexes, as well as to their character. Moreover, a correlation exists

in patients between the histological pattern of injury and the level and frequency of detection of circulating immune complexes (reviewed by Germuth and Rodriguez, 1973; Hill, 1992; Silva, 1992). Therefore, the degree of proliferation and matrix expansion in immune complex glomerulonephritis may be viewed as an expression of the integral of immune complex load over time. In this context, note that immunoglobulins aggregated on a nonimmune basis and rheumatoid factor complexes share most of the biological properties of antigen-antibody complexes. "Immune complex glomerulonephritis" is a term that embraces these alternative immune aggregates. In any case, immune aggregates are likely to be related to the pathogenesis of glomerulonephritis; injection of aggregates into animals evokes disease (reviewed in Clarkson, 1987; Rifai, 1987; Emancipator, 1992).

Immunofluorescence detects the accumulation of Ig and activated complement components within diseased glomeruli in IgAN (reviewed by Emancipator, 1992). These deposits, electron dense by traditional transmission electron microscopy, also can be identified by immunoelectron microscopy (Dysart *et al.*, 1983; Doi *et al.*, 1984; Mathews *et al.*, 1985; Tanaka, 1986; Nakajima *et al.*, 1987). The complexes contain IgA as the predominant Ig, by definition, with IgG or IgM associated in most cases. Alternative pathway (B, D, H, C3, C5-9, and properdin) but not classical pathway (C1, C4, C2) complement components are almost invariably present in the mesangium (reviewed by Emancipator, 1992), another indication of the primacy of IgA, which does not activate the classical pathway. The deposits tend to be associated with reactive changes in the contractile mesangial cells, as predicted by the mesangial cell hypertrophy and hyperplasia seen by light microscopy. A significant proportion of cases also reveals deposits in the glomerular capillary walls, subendothelial or subepithelial; these patients typically exhibit segmental endocapillary proliferation by light microscopy. Overall, the correlation among light, electron, and immunofluorescence microscopy is excellent in IgAN.

Glomeruli in individual patients with IgAN may vary widely in appearance. The severity of morphological changes may differ from glomerulus to glomerulus and among the several segments in a particular glomerulus. Moreover, the elements of these changes—cellular hyperplasia, cellular hypertrophy, and expansion of extracellular matrix—occur independently. Hence, glomeruli with proliferation may be interposed with glomeruli with matrix expansion or both within one biopsy. This variation is consistent with the episodic clinical pattern, in which the severity may vary from time to time. A sample at a static time point, such as a biopsy, reveals lesions with different chronicity, presumably evoked by distinct "showers" of immune aggregates. Variation in immunohistology, for example, the extent of IgG or IgM co-deposits, classical complement components, and the extent and site of capillary wall deposits, are likely to be explained on a similar basis: the deposits represent a time-averaged view of the isotype repertoire, antigen load, and complement-activation capacity of the immune complexes generated.

The remaining 10% of IgAN patients reveal glomerular

abnormalities that run the gamut of glomerular disease, including membranoproliferative, membranous, crescentic, and sclerotic. In some cases, overlap of two independent glomerular diseases has been invoked to explain the findings. Because IgAN is defined on the basis of the predominant Ig isotype deposited, IgAN can be expected to represent a microcosm of glomerular disease in general. Finally, note that tubulointerstitial nephritis and arteriolar changes also are observed frequently in IgAN patients (reviewed by Emancipator, 1992). These lesions may not derive from the glomerular injury, are of uncertain pathogenic significance, and often are observed in other forms of proliferative glomerulonephritis. They will not be considered further since no clear relation to a mucosal immune response is recognized.

## II. PRIMARY IMMUNOLOGICAL ALTERATIONS IN IgA NEPHROPATHY

### A. General Observations

The concentration of IgA in the serum of patients with IgAN is frequently (50%) increased relative to age-matched normal controls or patients with other glomerulonephritides, often 2- or 3-fold (Lopez-Trascasa *et al.*, 1980; Egido *et al.*, 1982a,1987a; Schena *et al.*, 1986; Williams *et al.*, 1987; van Es *et al.*, 1988; Peterman *et al.*, 1991). The IgA is polyclonal, but several investigators have reported that the percentage of J-chain-linked oligomers is elevated markedly in patients over controls (Kupor *et al.*, 1975; Lopez-Trascasa *et al.*, 1979; Woodroffe *et al.*, 1980; Stachura *et al.*, 1981; Lesavre *et al.*, 1982; Endoh *et al.*, 1984; Czerkinsky *et al.*, 1986; Hernando *et al.*, 1986; van Es *et al.*, 1988; Nagura, 1989; Jones *et al.*, 1990; Waldo, 1990; Chen *et al.*, 1991; Peterman *et al.*, 1991). Congruent with the renal deposits, IgA1 predominates over IgA2 in patient serum, as it does normally. The increased IgA may be immunologically specific because marked increases in the levels of circulating immune complexes containing IgA frequently are present and these complexes contain different antigens (Kupor *et al.*, 1975; Tung *et al.*, 1978; Lopez-Trascasa *et al.*, 1979; McKenzie *et al.*, 1980; Woodroffe *et al.*, 1980; Cairns *et al.*, 1981; Kauffmann *et al.*, 1981; Mustonen *et al.*, 1981; Stachura *et al.*, 1981; Coppo *et al.*, 1982a,1984; Lesavre *et al.*, 1982; Tomino *et al.*, 1982a,b,c; Hall *et al.*, 1983; Sancho *et al.*, 1983; van der Woude *et al.*, 1983; Endoh *et al.*, 1984; Nagy *et al.*, 1984,1988; Czerkinsky *et al.*, 1986; Hale *et al.*, 1986; Hernando *et al.*, 1986; Russell *et al.*, 1986; Schena *et al.*, 1986; Drew *et al.*, 1987; Fornasieri *et al.*, 1987; Laurent *et al.*, 1987; Yap *et al.*, 1987; Rostoker *et al.*, 1989a,1991). IgG synthesis and immune aggregate content are heightened during disease exacerbation as well (Russell *et al.*, 1986; Schena *et al.*, 1986). Moreover, IgG1 and IgG3 are represented disproportionately in the circulating complexes and renal deposits, whereas serum IgG2 and IgM levels are decreased in patients with IgAN

(Aucouturier *et al.*, 1989; Rostoker *et al.*, 1989b). These observations also are consistent with an immune abnormality.

Studies *in vitro* suggest that at least part of the increment in circulating IgA results from increased production. Although not all observers agree, peripheral blood lymphocytes from patients with IgAN produce significantly more IgA during culture than do lymphocytes from control groups, whether resting or after mitogen stimulation. The frequency of B cells bearing surface IgA in the circulation and in culture, resting or mitogen stimulated, is also higher in patients relative to controls (Nomoto *et al.*, 1979; Sakai *et al.*, 1979b; Cosio *et al.*, 1982; Egido *et al.*, 1982b,1983a,c; Fornasieri *et al.*, 1982; Cagnoli *et al.*, 1985; Linné and Wasserman, 1985; Feehally *et al.*, 1986; Hale *et al.*, 1986; Schena *et al.*, 1986; Waldo *et al.*, 1986; Lai *et al.*, 1987; Chen *et al.*, 1991). Parallel alterations of B-cell function, *in vivo* and *in vitro*, have been reported in first-degree relatives of patients with IgAN, consonant with recognition of multiply affected individuals within several pedigrees of familial IgAN (Sakai *et al.*, 1979b; Egido *et al.*, 1985,1987a,b; Julian *et al.*, 1985; Waldo *et al.*, 1986; Waldo and Cochran, 1987; Waldo, 1992).

Some evidence suggests that IgAN patients' T cells are the site of the primary defect and that the B-cell dysfunction is largely secondary (Sakai, 1987,1988). Perhaps the most compelling support for a primary defect in T cells arises from *in vitro* experiments by the Sakai group. This group reported that B cells from patients function normally when cultured with histocompatible normal T cells, but that normal B cells reveal derangements similar to those just described when cultured with IgAN patient T cells (Sakai *et al.*, 1979a,b; Sakai, 1987). Defects in T-cell function and in the distribution of T-cell subsets have been described by a number of laboratories (Sakai *et al.*, 1979a,1982; Chatenoud and Bach, 1981; Cosio *et al.*, 1982; Egido *et al.*, 1982a,b,1983a,b,c; Woo *et al.*, 1982; Adachi *et al.*, 1983; Cagnoli *et al.*, 1985; Feehally *et al.*, 1986; Hale *et al.*, 1986; Waldo *et al.*, 1986). This concept also might explain discrepancies in some of the *in vitro* studies; use of IgAN patient unfractionated peripheral blood lymphocytes, which include T cells, or use of mitogens that are T-cell directed would favor observations of abnormal Ig production by patient B cells if the primary defect were in the T-cell population. Indeed, T cells from patients and first-degree relatives do respond aberrantly to a variety of stimuli, whereas lipopolysaccharide (LPS) stimulation of patient B cells appears normal.

Although a primary derangement in T-cell function seems plausible in IgAN, the evidence is limited and circumstantial. In fact, until a specific sequence of events leading to IgAN can be identified, even the concept of IgAN as an immunological disease remains somewhat speculative. More cogently, no confidence exists that all IgAN patients share the same pathogenic mechanism; IgAN may be a syndrome that develops via several distinct mechanisms, not all of which are necessarily immunological in nature. Notwithstanding these cautions, concluding that at least a percentage of IgAN patients suffers from an immunological disease does seem reasonable. Elucidation of the nature and character of the disease remains a priority.

### **B. The Mucosal Immune System and the Genesis of IgA Nephropathy**

Focus on the mucosal immune system as an element in the genesis of IgAN began almost simultaneously with the recognition of IgAN as a clinicopathological entity some 25 years ago. Collectively, mucosal sites are rich in IgA-producing cells because of a high density of plasma cells and a disproportionately high fraction of IgA-producing plasma cells (Lamm, 1976; Underdown and Schiff, 1986; Mestecky and McGhee, 1987). Indeed, the gut and upper airways account for most of the total body content of IgA (Vaerman and Heremans, 1970; Craig and Cebra, 1975; Rothberg *et al.*, 1978). Moreover, the body's synthetic rate of IgA well exceeds that of all other Ig classes combined (Mestecky, 1988). Although the marrow and spleen are significant sources of IgA as well, and this IgA contributes significantly to the pool of IgA in serum, evidence exists that mucosally derived T cells can exert major regulatory influences on these sites (Pabst and Binns, 1981; Alley *et al.*, 1986; Pabst *et al.*, 1987). Hence, even IgA produced in extramucosal regions may, broadly speaking, be "mucosal."

In an attempt to identify the source of IgA in the glomerular deposits, some investigators have studied the properties of the IgA in glomeruli or in the circulating immune complexes. Initially, the presence of J chain within glomerular deposits in association with IgA was offered as evidence of a mucosal origin (Dobrin *et al.*, 1975; Lopez-Trascasa *et al.*, 1979; André *et al.*, 1980; Egido *et al.*, 1980; Béné *et al.*, 1982; Coppo *et al.*, 1982b; Donini *et al.*, 1982; Tomino *et al.*, 1982c; Komatsu *et al.*, 1983; Lomax-Smith *et al.*, 1983; Monteiro *et al.*, 1984; Waldherr *et al.*, 1983). Although Monteiro *et al.* (1984) eluted 300-kDa IgA-containing J chain from renal deposits, thereby demonstrating that at least some deposited IgA is a J-chain-linked dimer, the source of the IgA was not elucidated because both mucosal and extramucosal plasma cells produce J-chain-containing IgA oligomers. Moreover, IgM, which also contains J chain, frequently is co-deposited in glomeruli in patients with IgAN.

The subclass distribution of the deposited IgA also has been considered. Serum IgA, thought to be derived largely from marrow and other nonmucosal sites, is mostly IgA1, whereas secretory IgA derived from mucosal plasma cells contains considerable IgA2. Recognition that, in IgAN the renal deposits, elevations in serum IgA (oligomeric or not) and circulating immune complexes all are associated with IgA1 rather than IgA2 was cited by several groups as testimony to an extramucosal source of the renal IgA (Shigematsu *et al.*, 1980; Tomino *et al.*, 1981; Rambašek *et al.*, 1982; Hall *et al.*, 1983; Lomax-Smith *et al.*, 1983; Czerkinsky *et al.*, 1986; Conley and Delacroix, 1987; Béné and Faure, 1988; van den Wall Bake *et al.*, 1988). However, a substantial proportion of mucosal IgA is in fact IgA1, even predominating over IgA2 in some mucosal locations, particularly in the airways and small bowel. Moreover, certain categories of antigens may induce IgA1 (or IgA2) antibodies preferentially. Therefore, the source of the IgA cannot be identified reliably from its subclass distribution (Lamm, 1976; Underdown and

Schiff, 1986; Mestecky and McGhee, 1987; Rifai, 1987; Mestecky, 1988). The predominance of  $\lambda$  light chains in both renal deposits and IgA from mucosal versus nonmucosal sources was cited to support a mucosal origin for the IgA (Béné and Faure, 1988; Faure *et al.*, 1990; Chen *et al.*, 1991). Again, this argument is circumstantial and subject to reinterpretation if  $\kappa/\lambda$  ratios in mucosal sites other than tonsil and small bowel should resemble the marrow, where  $\kappa$  chains predominate, more closely.

A second line of evidence implicating the mucosal immune system in the genesis of IgAN derives from the antigens identified within the glomerular deposits and circulating immune complexes. The constellation of such antigens is large, ranging from "inert" proteins, glycoproteins, saccharides, and nucleic acids to infectious microorganisms and autoantigens. The inert antigens identified are nearly all dietary components; the infectious organisms identified to date are all trophic for mucosal sites since they invade the body via the airways or intestinal tract (Kupor *et al.*, 1975; Tung *et al.*, 1978; Lopez-Trascasa *et al.*, 1979; McKenzie *et al.*, 1980; Woodroffe *et al.*, 1980; Cairns *et al.*, 1981; Kauffmann *et al.*, 1981; Mustonen *et al.*, 1981; Stachura *et al.*, 1981; Coppo *et al.*, 1982a, 1984; Lesavre *et al.*, 1982; Tomino *et al.*, 1982a, b, c, 1987; Hall *et al.*, 1983; Sancho *et al.*, 1983; van der Woude *et al.*, 1983; Endoh *et al.*, 1984; Nagy *et al.*, 1984, 1988, 1989; Czerkinsky *et al.*, 1986; Hale *et al.*, 1986; Russell *et al.*, 1986; Schena *et al.*, 1986; Drew *et al.*, 1987; Fornasieri *et al.*, 1987; Laurent *et al.*, 1987; Sato *et al.*, 1987; Yap *et al.*, 1987; Nagura, 1989; Rostoker *et al.*, 1989a, 1991).

A third and probably significant line of evidence derives from the close temporal relationship between acute "viral" syndromes, usually respiratory, and the onset or exacerbation of IgAN, particularly among macrohematuric patients (reviewed by Emancipator *et al.*, 1985; van Es *et al.*, 1988). Temporal associations also are recognized between dietary intake of gluten and the frequency and severity of hematuric episodes in IgAN (Coppo *et al.*, 1986; DelPrato *et al.*, 1988; Rostoker *et al.*, 1990a).

In a fourth line of evidence, Béné *et al.* (1984, 1986, 1991b) and Westberg *et al.* (1983) have studied tonsillar and, to a more limited degree, gut and scleral plasma cells in patients with nephritis and in controls. Although the tonsils are not a purely mucosal lymphoid tissue, tonsils and gut from IgAN patients reveal similar changes in the ratio of IgG : IgA plasma cells and similar abnormalities in Ig secretion by isolated cells in culture relative to normal controls and glomerulonephritic patients without IgA deposits. Yasumori (1990) reported that patients with IgAN have an increase in serum IgA associated with an increase in salivary secretory IgA levels relative to controls. The increase in salivary IgA is seen in all forms of glomerulonephritis, suggesting that polyclonal B-cell activation leads to increased IgA in general (Rostoker *et al.*, 1990b; Yasumori, 1990). However, patients with IgAN have a low ratio of salivary to serum IgA relative to individuals with non-IgA glomerulonephritis. Some patients with IgAN also have abnormally low secretory IgA in jejunal secretions. In addition, serum levels of secretory IgA are elevated in IgAN patients with hematuria (Yasumori, 1990). Therefore, perturbations in the mucosal immune system may exist in patients

with IgAN with respect to transepithelial transport. A newly recognized deficiency in the production of J chain by lamina propria plasmacytes in intestinal biopsies of patients with IgAN relative to healthy individuals (J. Feehally, personal communication) predicts such diminished transepithelial transport, and may prove important in the genesis of IgAN.

Some of the most compelling evidence considers specific immune responses to mucosal immunization with tetanus toxoid in patients with IgAN. Waldo (1992) reported that patients with IgAN develop higher serum IgG antibody levels after mucosal immunization and a greater increase in specific IgG after boosting, relative to controls. These patients had lower levels of specific serum IgA than controls and did not increase specific IgA titers after boosting, despite increased IgA responses of peripheral blood mononuclear cells after mitogen stimulation. Indeed, patients with IgAN who had elevated IgA anti-poliovirus titers in serum manifested suppression of specific IgA after oral poliovirus challenge; parallel abnormalities were observed in cells from these patients *in vitro* (Waldo and Cochran, 1987). Patients also had increased total serum IgA not specific for poliovirus relative to controls, further supporting a dysregulation of IgA synthesis. Other vaccination studies also support a more vigorous immune response, particularly of the mucosal immune system, in patients with IgAN (Endoh *et al.*, 1984; Leinikki *et al.*, 1987; van Es *et al.*, 1988), as well as in first-degree relatives (Waldo and Cochran, 1987; Waldo, 1992). Abnormalities in serum IgA levels, particularly polymeric IgA1 and IgA associated with complement (i.e., conglutinin-binding IgA), are accentuated in IgAN patients during mucosal infections (van Es *et al.*, 1988; Jones *et al.*, 1990). Although these data further emphasize the contribution of mucosal immune responses to alterations in circulating IgA, they again do not pinpoint these alterations as the source of the glomerular deposits.

When all the evidence is considered, we believe it favors a mucosal source of the IgA aggregates in the kidney and in the circulation. Admittedly, however, despite the abundant data implicating the mucosal immune system in the pathogenesis of IgAN, little direct evidence supports such a link.

### III. ENHANCED MUCOSAL PENETRABILITY BY ANTIGEN

The aforementioned increases in polyclonal IgA, and perhaps IgG, production have been viewed as the result of a dysregulated immune system, systemic or mucosal. However, an equally plausible scenario posits increased penetration of mucosal surfaces by antigen, perhaps in the face of a normally regulated immune response. The enhanced exposure of mucosa-associated lymphoid tissue (MALT) to antigen would evoke a heightened immune response, and would favor elevated levels of immune complexes within the body proper, including the mucosae. Such immune complexes could gain access to the circulation and ultimately could lodge in the kidney.

Data in support of specific mechanisms by which increased antigen penetration could occur are limited. As already men-

tioned, various dietary and airway antigens, complexes of those antigens with specific antibody, or specific antibodies are present in the blood of patients with IgAN in excess of the levels found in normals (Kupor *et al.*, 1975; Tung *et al.*, 1978; Lopez-Trascasa *et al.*, 1979; McKenzie *et al.*, 1980; Woodroffe *et al.*, 1980; Cairns *et al.*, 1981; Kauffmann *et al.*, 1981; Mustonen *et al.*, 1981; Stachura *et al.*, 1981; Coppo *et al.*, 1982a,1984; Lesavre *et al.*, 1982; Tomino *et al.*, 1982a,b,c,1987; Hall *et al.*,1983; Sancho *et al.*, 1983; van der Woude *et al.*, 1983; Endoh *et al.*, 1984; Nagy *et al.*, 1984, 1988; Czerkinsky *et al.*, 1986; Hale *et al.*, 1986; Russell *et al.*, 1986; Schena *et al.*, 1986; Drew *et al.*, 1987; Fornasieri *et al.*, 1987; Laurent *et al.*, 1987; Sato *et al.*, 1987; Yap *et al.*, 1987; Rostoker *et al.*, 1989a,1991). Although increased titers of antibodies specific for a variety of "mucosal" antigens also are seen in glomerulonephritides other than IgAN (Rostoker *et al.*, 1991), the presence of dietary antigens appears limited to IgAN patients, as are titers for some specific antibodies.

Increased antigen penetration consequent to a general failure of the mucosal barrier is encountered infrequently in IgAN patients, even during exacerbations of hematuria associated with increased dietary antigens in serum (Davin *et al.*, 1988; Jenkins *et al.*, 1988; Rostoker *et al.*, 1989a,1990a; Davin and Mahieu, 1992). The majority (75%) of patients with IgAN have normal or borderline high degrees of intestinal absorption of materials such as cellobiose and <sup>51</sup>Cr-labeled EDTA. These observations argue against a general intrinsic defect in mucosal surfaces. Moreover, these data also render two other hypotheses less likely: infectious injury to mucosal epithelium and immune-mediated injury to the mucosa (Emancipator and Lamm, 1989).

The increase in circulating dietary antigens without a general increase in gut permeability could be the result of a defect in immune inhibition of the uptake of macromolecules by the gut. Since specific secretory antibody in the lumen can interfere with the transport of macromolecules across the lining, defects in the secretion of specific antibodies could increase such transit (Cunningham-Rundles *et al.*, 1978; Walker and Bloch, 1983; Cunningham-Rundles, 1990,1991). Such defects would, in principle, include IgA deficiency, specific immune tolerance for penetrating antigens, inappropriate or inadequate differentiation or distribution of stimulated MALT B lymphocytes, impaired IgA transport across mucosal epithelium, or accelerated degradation of IgA within mucosal lumina. IgA deficiency is not likely in IgAN, since heightened or normal IgA production is characteristic *in vitro* and *in vivo*. Specific tolerance for selected antigens could occur; however, since a causal antigen is not known in any patient and may be multiple in a given patient, this issue cannot be evaluated. Dichotomy between secreted and systemic IgA levels is recognized (Cunningham-Rundles, 1990,1991). However, a defect in the secretion of selected specific IgA antibodies with a coexisting generation of systemic antibody of the same specificity, required to generate pathogenic immune complexes, seems improbable. Impaired differentiation or homing of MALT lymphocytes in general is also doubtful, since none of a significant sample of patients with IgAN had decrements in mucosal IgA plasma cells (Westberg *et al.*, 1983; Béné *et al.*, 1984,1986,1991b). None-

theless, all these possibilities remain because small differences beyond the resolution of currently available assays could, over a long period of time and a large surface area as manifested in the mucosae, result in significant differences in the proportion and amounts of antigen and antibody in various parts of the body.

Perhaps more intriguing and plausible, impaired polymeric Ig receptor-mediated transport of IgA across the mucosa merits discussion. Salivary IgA is increased relative to other proteins in all glomerulonephritides, but the salivary content of secretory IgA is decreased selectively in patients with IgAN (Rostoker *et al.*, 1990b; Yasumori, 1990). Hematuric IgAN patients have increased secretory IgA in serum. During normal transport of IgA across exocrine epithelium, dimeric IgA is attached to the external domain of the polymeric Ig receptor; the receptor, in turn, is cleaved proteolytically at the junction of its external and transmembrane domains at the apical surface of the cell. Increased secretory IgA in serum, with decreased secretory IgA in secretions, could result from proteolytic release of secretory component at the basolateral surface of mucosal epithelium, related either to misdirection of IgA within the epithelial cell or to altered localization of the relevant plasma membrane endopeptidase. Although glomerular deposits do not contain appreciable secretory IgA in patients with primary IgAN (reviewed by Emancipator *et al.*, 1985), increased mucosal penetration by antigen favored by relatively small shifts in polymeric Ig receptor-mediated IgA transport could lead to increased antigen-specific antibody responses of mixed isotype in both mucosal and extramucosal sites. In this scenario, even if the IgA deposited in glomeruli were derived from marrow or splenic plasma cells, disease could be related to defective mucosal immunity. On the other hand, permeation of the mucosal defenses by antigen need not represent an actual defect in mucosal immunity. Rather, an antigen load could increase suddenly, generating a transient period of antigen excess that could overwhelm local immunity for a time. Although this sequence of events would, in a sense, represent a failure of the mucosal immune system, it would nonetheless be physiological. Moreover, repetition of such a scenario with differing "novel" antigens over a period of time might prove noxious, particularly in individuals such as patients with IgAN, with a tendency toward an especially robust immune response (Endoh *et al.*, 1984; Leinikki *et al.*, 1987; Waldo and Cochran, 1987; van Es *et al.*, 1988; Waldo, 1992). Finally, defective trans-mucosal transport of IgA antibody consequent to the diminished synthesis of J chain observed in the gut lamina propria of patients with IgAN (J. Feehally, personal communication) could favor increased penetration of the gut wall by antigen.

Of interest is the recognition that intraepithelial neutralization of mucosal pathogens by specific IgA antibody can occur, for example, if the transcytotic pathway of IgA intersects the cellular pathway followed by the synthesis and assembly of viral components (Mazanec *et al.*, 1992). Misdirection of IgA-containing vesicles might allow greater mucosal penetration by virus, viral antigens, or IgA immune complexes. Indeed, a parallel mechanism could be operative for inert macromolecules, if pinocytotic vesicles containing lumenally

derived antigens normally intersect with transcytotic vesicles containing specific IgA. Subversion of this system provides another mechanism by which mucosal penetration by antigen might occur.

#### IV. DEFECTIVE CLEARANCE OF IMMUNE COMPLEXES

##### A. Mononuclear Phagocyte System

Immune complexes in the circulation typically are taken up by cells of the mononuclear phagocyte (reticuloendothelial) system (Arend and Mannik, 1971; Mannik and Arend, 1971; Haakenstad and Mannik, 1974; Mannik and Jimenez, 1979), primarily in the liver and spleen (Mannik *et al.*, 1971). Fixed phagocytes can remove particles nonspecifically (Biozzi *et al.*, 1953; Normann, 1974). In addition, these cells bear a high density of receptors for immunoglobulin Fc regions and for complement components (reviewed by Cornacoff *et al.*, 1983; Medof *et al.*, 1983). Thus, uptake of particulates coated with antibody or complement (opsonized) is more efficient (Mannik *et al.*, 1971; Mannik and Jimenez, 1979). Impaired phagocyte function is, therefore, a potential contributor to immune complex disease, including glomerulonephritis (Haakenstad and Mannik, 1976; Germuth *et al.*, 1977, 1982). With respect to this possibility, many variables must be considered that are related to the nature of the antigen and the host immune response.

Factors such as the chemical nature of the antigen, its electrostatic charge and catabolic rate, and the quantity and quality of the responding antibody (including isotype distribution and avidity) influence the molecular weight, electrostatic charge, and tissue distribution of the resultant complexes and, therefore, their rate of clearance (Haakenstad and Mannik, 1976; Germuth *et al.*, 1977, 1982; Finbloom *et al.*, 1981; Gauthier *et al.*, 1982; Isaacs and Miller, 1982; Gallo *et al.*, 1983; Mannik *et al.*, 1983). In human glomerulonephritis, however, these factors cannot be evaluated completely since the causal antigens have not been identified.

The study of immune complexes containing IgA involves its own distinct factors (Rifai and Mannik, 1983, 1984). The presence of IgA within an immune lattice can influence its clearance kinetics in relation to mechanisms that depend on cellular immune adherence receptors (Waxman *et al.*, 1986). These receptors bind to activation fragments of the third component of complement with a higher affinity than Fc receptors have for Ig, and they promote uptake of immune complexes containing appropriate C3 polypeptides. Also, when inserted into immune complexes, C3b promotes binding to erythrocytes via one of these receptors (CR1). The erythrocyte then can transport such complexes efficiently to phagocytes in the spleen and liver without allowing the complexes to circulate freely in the interval (Cornacoff *et al.*, 1983; Medof *et al.*, 1983). Interestingly, when IgA is present, it seems to inhibit complement fixation by IgG in the same immune lattice (Waldo and Cochran, 1989). Hence, the presence of IgA in an immune complex may subvert immune adherence receptor-dependent mechanisms, and may impair

the clearance of the complexes by phagocytes. For example, in baboons, immune complexes containing IgA do not bind erythrocytes as well as immune complexes containing only IgG antibody; IgG complexes contain relatively more complement (Waxman *et al.*, 1986). The IgA immune complexes are, nevertheless, taken out of circulation more quickly, presumably because they are free in solution rather than bound to erythrocytes and are distributed more widely, with relatively higher concentrations in organs other than liver and spleen, for example, the kidney and lungs. Hence, intercalation of IgA into an immune lattice may increase renal deposition. Deficient selective CR1 uptake of IgA-containing complexes cannot be ascribed to increased alternative versus classical pathway complement activation, since particles opsonized via alternative pathway activation by zymosan bind readily to primate erythrocytes (Cornacoff *et al.*, 1983; Medof *et al.*, 1983).

##### B. Other Mechanisms

In rodents, immune complexes containing polymeric IgA can be transported actively across hepatocytes by the same polymeric Ig receptor-dependent mechanism that normally applies to free polymeric IgA (Nagura *et al.*, 1981; Peppard *et al.*, 1981; Socken *et al.*, 1981; Brown *et al.*, 1982; Delacroix *et al.*, 1982; Mestecky *et al.*, 1989). In humans, biliary epithelial cells rather than hepatocytes support this function, but this process is relatively inefficient (Mestecky *et al.*, 1989; Rifai *et al.*, 1989). When radiolabeled model IgA immune complexes are injected into primates, the liver and, secondarily, the spleen manifest the most uptake in scintillographic studies in humans (Rifai *et al.*, 1989; Roccatello *et al.*, 1989, 1992) and in direct  $\gamma$  counting of tissue samples in baboons (Waxman *et al.*, 1986). Fixed phagocytes appear to account for clearance of the aggregates, as outlined earlier, with little radiolabeled IgA excreted into bile. However, the observation that epithelial cells can transport immune complexes containing oligomeric IgA efficiently from the basolateral (lamina propria) surface to the apical (luminal) surface may be germane to elucidating the mechanism of clearance (Kaetzel *et al.*, 1991). The vast number and incessant activity of secretory epithelial cells may represent a critical, topographically diffuse mechanism for ridding the body of locally formed IgA immune complexes. A defect in this transport system, such as the deficient production of J chain reported in IgAN patients by Feehally and associates (J. Feehally, personal communication), would promote systemic accumulation of IgA immune complexes and, perhaps, mesangial IgA deposits.

Three clinical investigations from two separate laboratories failed to observe significant intestinal or bronchial uptake of model IgA immune complexes from the circulation (Rifai *et al.*, 1989; Roccatello *et al.*, 1989, 1992). However, because a given cell would take up only a small amount of complexes, a widely disseminated mass of involved cells might not be recognized by the scintillographic imaging techniques employed. Moreover, traditional methods of measuring removal of radioactivity from the circulation over many hours cannot resolve the contribution by a particular organ.

The relative mass of the liver versus spleen makes hepatic clearance more significant than splenic clearance of IgA immune complexes, despite a greater amount of IgA binding per unit tissue in spleen. Similarly, in humans, the relative number of erythrocytes favors greater cumulative binding of C3b-containing immune complexes to erythrocytes than to circulating phagocytes, despite a lower number of CR1 receptors per red cell (Cornacoff *et al.*, 1983; Medof *et al.*, 1983). In analogous fashion, fewer immune complexes per cell may be cleared from the lamina propria by enterocytes and bronchial epithelial cells but this clearance, nevertheless, translates into more total transport when the aggregate number of cells in the body is considered. Evaluation of the potential excretion of IgA-containing immune complexes, particularly locally and perhaps from the circulation, by secretory epithelium *in vivo* is warranted in terms of our need to comprehend both normal "excretory" immune function and the pathogenesis of IgAN.

Although secretory component-mediated hepatobiliary transport of polymeric IgA is inefficient in humans relative to rodents (Mestecky *et al.*, 1989; Rifai *et al.*, 1989), hepatocytes may take up and catabolize IgA via the asialoglycoprotein receptor (Mestecky *et al.*, 1989). Although the extent to which hepatobiliary transport applies to circulating IgA immune complexes is not clear, indications are that this mechanism does operate in human liver (Mestecky *et al.*, 1989; Rifai *et al.*, 1989). Another potential mechanism for removal of IgA relates to erythrocyte binding independent of CR1. Approximately 40% of patients with IgAN exhibit an increase in such binding. The mechanism by which this binding occurs and its biological significance are uncertain (Matsuda *et al.*, 1988).

### C. Role of Defective Clearance and Relation to the Mucosal Immune System

Studies addressing the issues just described for IgA immune complexes do not answer the specific question of a possible defect in clearance in patients with IgAN. Logically, a difference between controls and patients with IgAN in the rates of clearance of soluble macromolecular aggregates that contain IgA is more relevant to the pathogenesis of the disease than the previously reported defective clearance of IgG-coated erythrocytes (Lawrence *et al.*, 1983; Nicholls and Kincaid-Smith, 1984; Solomon *et al.*, 1984; Roccatello *et al.*, 1985). The relative clearance rates of complexes that contain only IgG compared with those with pure or admixed IgA might not relate to the pathogenesis of IgAN, given the central role of the IgA component in the immune complexes in this disease. The fate of IgA-containing complexes emerges as a potentially critical factor in the genesis of IgAN (Nagura, 1989), but results of studies in patients with human IgAN conflict (Rifai *et al.*, 1989; Roccatello *et al.*, 1989, 1992). The discrepancy between the two laboratories that have addressed this issue directly could result from differences in the preparation, and therefore the character, of the model IgA aggregates. Alternatively, the discrepancy might reflect the fact that the differences between patients and controls, although statistically significant in one laboratory, are small

and close to the limit of detection by current methods. Small differences, even if not statistically significant or measurable at present, nonetheless might prove critical in the chronic time-frame operative in IgAN. Particularly, the extensive mass and continuous activity of the intestinal epithelium might translate into a significant difference in the total excretion of local IgA immune complexes between IgAN patients and controls. Defects in polymeric Ig receptor-mediated excretion of mucosal immune complexes (Kaetzel *et al.*, 1991), perhaps in concert with defects in polymeric Ig receptor-mediated transport of free oligomeric IgA antibody, would favor accumulation of IgA immune complexes in the circulation and ultimately in the kidney.

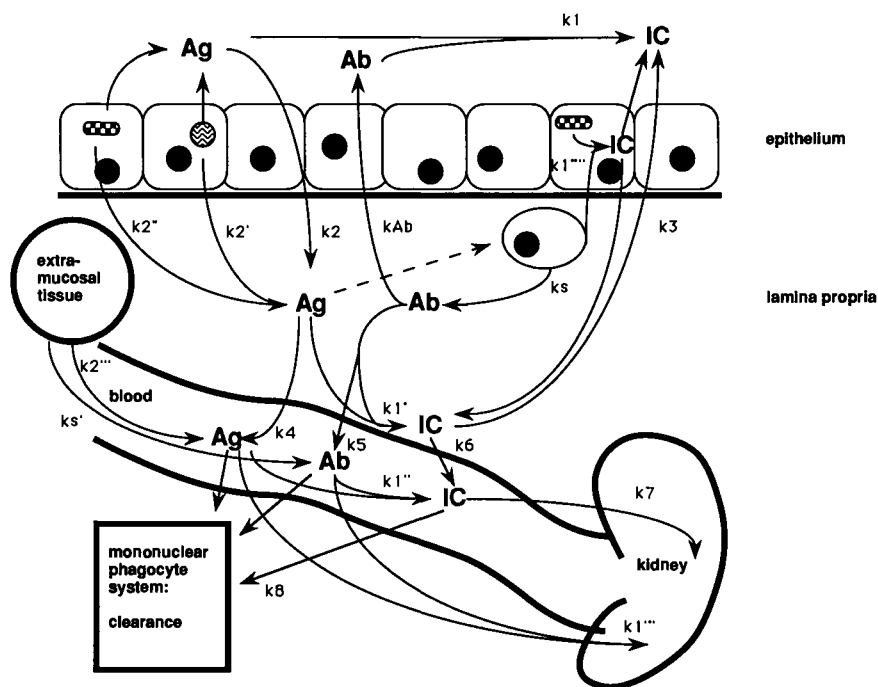

As already discussed, under physiological circumstances an abrupt increase in the concentration of antigen intraluminally or intraepithelially could lead to transiently increased permeability of that antigen, whether it is a novel environmental or infectious agent or an antigen to which the host is already immune through prior exposure. Under these circumstances, small soluble immune complexes in response to antigen excess would form with the first available antibody. Locally formed IgA complexes with oligomeric IgA should be cleared efficiently by the overlying epithelium (Kaetzel *et al.*, 1991). However, complexes with monomeric IgA or IgG would be removed by this mechanism only if they also contained oligomeric IgA (C. Kaetzel, J. Robinson, and M. Lamm, unpublished observations). Small immune complexes formed under extreme antigen excess are less likely to contain both oligomeric and monomeric antibody in the same complex, since only one or two antibody molecules would be present. Small complexes of antigen with IgG or monomeric IgA but without oligomeric IgA would escape clearance by the mucosal epithelium and therefore would become concentrated within the lamina propria. Alternately, complexes that contain oligomeric IgA with relatively less J chain could develop in patients with IgAN (J. Feehally, personal communication), similarly less susceptible to clearance by the mucosal epithelium. These complexes could gain access to the circulation and deposit in glomeruli. As the mucosal immune response adapted to the new level of antigen exposure by making more antibody, free antibody (predominantly IgA) also would gain access to the circulation. At this point, the free IgA could deposit on top of the previously deposited glomerular immune complexes, adding appreciably more IgA. This sequence of events explains well the generation within the kidney of the mixed IgA and IgG isotypes considered particularly pathogenic in IgAN (reviewed by Emancipator and Lamm, 1989; Emancipator, 1990, 1992). If this sequence of events actually occurs, it clearly relates the mucosal immune system to the pathogenesis of IgAN.

## V. CONCLUDING PERSPECTIVES

The preceding discussion clearly shows that the source (mucosal or extramucosal) and the nature (immune complexes or nonimmune aggregates) of the IgA deposited in the mesangium in IgAN are still controversial. We favor a view of IgAN as a form of serum sickness in which mucosally

derived antigens elicit local mucosal antibody synthesis, thereby generating pathogenic immune complexes. Although much of the evidence for either perspective is circumstantial, the unambiguous facets all support this view; some of the arguments advanced in favor of a mucosal source render extramucosal sources less likely (Béné and Faure, 1988). Moreover, the evidence cited to favor a bone marrow origin of the IgA deposits, that is, predominance of IgA1 not exclusively found as oligomers linked by J chain (van den Wall Bake *et al.*, 1988), does not necessarily argue against a mucosal source. Although dietary antigens and infectious agents interacting with mucosal epithelium certainly can gain access to extramucosal lymphoid tissue, mucosal lymphocytes would be exposed initially. Moreover, extramucosal sites of Ig synthesis, including the marrow, tend to produce more IgG and IgM relative to IgA than do mucosal sites.

Similar reasoning favors the concept that IgA aggregates are immune complexes. The renal deposits and the circulating IgA aggregates are acid dissociable. The eluted IgA, once fractionated, does not self-aggregate (Monteiro *et al.*, 1984). Although anti-Ig antibodies, including IgA rheumatoid factors and IgG specific for the constant domain of Fab fragments of IgA, have been invoked, no predictive value for diagnosis or severity of IgAN is associated with such antibodies (Czerkinsky *et al.*, 1986; Sinico *et al.*, 1986, 1988; Jackson *et al.*, 1987; Jackson, 1988; Schena *et al.*, 1988; van Es *et al.*, 1988). Presumably, therefore, at least one non-Ig component is required for IgA or mixed-isotype dissociable immune aggregate formation. Although Ig-binding proteins such as lectins, which can bind glycosyl side chains of Ig (DelPrato *et al.*, 1988; Emancipator *et al.*, 1992), and extracellular matrix proteins such as collagen or fibronectin (reviewed in Jennette

**Figure 1** Some of the theoretically possible events related to the genesis of IgAN are schematized. Antigen (Ag) may combine with antibody (Ab) to generate immune complexes (IC) in the lumen, in the extracellular fluid in the mucosal lamina propria, in the circulation, or *in situ* in the glomeruli; these rate constants are denoted  $k_1, k_1', k_1'',$  and  $k_1'''$ , respectively, since the formation rates vary in differing environments. Although mucosal immune responses to local antigens are emphasized, the scheme also can apply to antigen, antibody, and IC that enter the blood and tissues from other sites. Entry of antigen via the rate constants  $k_2, k_2', k_2'',$  and  $k_2'''$  consider penetration of mucosa by antigen ( $k_2$ ), production of antigens within the mucosa such as autoantigens or products of microorganisms ( $k_2', k_2''$ ), and entry into the blood from an extramucosal source ( $k_2'''$ ). Free antigen in the lamina propria also may enter the general circulation ( $k_4$ ). Antibody synthesized by mucosal ( $k_s$ ) or extramucosal ( $k_{Ab}$ ) plasma cells is subject to transport by the polymeric Ig receptor ( $k_{Ab}$ ) if the antibody is a J-chain-containing oligomer; combination with antigen to form IC in various sites ( $k_1-k_1'''$ ); or entry into the blood ( $k_5$ ). ICs formed in the lamina propria may enter the blood ( $k_6$ ), or, if they contain at least some J chain-linked oligomeric Ig, may be excreted actively by the overlying epithelium ( $k_3$ ). Circulating ICs can be removed by the mononuclear phagocyte system or by other clearance mechanisms ( $k_8$ ) or be deposited in glomeruli ( $k_7$ ). Of course, free antigen and antibody in the circulation also are subject to catabolic removal (constants not shown). Within this complicated scheme, a number of possibilities for the genesis of IgAN can be accommodated. Within an individual patient, one or perhaps a few of these mechanisms might apply, but different patients could incorporate features in distinct portions of the scheme. For reasons explained in the text, we favor the dominance of mucosally related antigen ( $k_2, k_2', k_2''$ ) combining with local antibody to generate ICs ( $k_1$ ). Whatever the specific mechanisms, virtually all the possible pathways relate to mucosal function in some way.

*et al.*, 1991) theoretically could promote aggregation of immunologically nonspecific Ig, innumerable antigens could elicit formation of complexes with specific antibodies. Many diverse mucosally related antigens have been implicated (Kupor *et al.*, 1975; Tung *et al.*, 1978; Lopez-Trascasa *et al.*, 1979; McKenzie *et al.*, 1980; Woodroffe *et al.*, 1980; Cairns *et al.*, 1981; Kauffmann *et al.*, 1981; Mustonen *et al.*, 1981; Stachura *et al.*, 1981; Coppo *et al.*, 1982a,1984; Lesavre *et al.*, 1982; Tomino *et al.*, 1982a,b,c; Hall *et al.*, 1983; Sancho *et al.*, 1983; van der Woude *et al.*, 1983; Endoh *et al.*, 1984; Nagy *et al.*, 1984,1988; Czerkinsky *et al.*, 1986; Hale *et al.*, 1986; Russell *et al.*, 1986; Schena *et al.*, 1986; Drew *et al.*, 1987; Fornasieri *et al.*, 1987; Laurent *et al.*, 1987; Yap *et al.*, 1987; Rostoker *et al.*, 1989a). Moreover, in the broad sense, dietary lectins or mucosal pathogen- or commensal-derived Ig-binding proteins or lectins are, themselves, potential immunogens. Aside from the issue of whether the glomerular aggregates represent immune complexes, several distinct mechanisms promoting renal deposition can be envisioned. Possibilities are summarized in Figure 1.

Several investigators, noting the diversity of features among patients with IgAN, have proposed that IgAN is a syndrome rather than a disease. This argument presupposes that different patient groups have distinct defects and pathogeneses and, therefore, distinct diseases. Perhaps several individual diseases, all with the common syndrome of IgAN, signal a primary defect in one of the pathways in Figure 1. Perusal of this scheme, however, reveals that mucosal function impacts a majority of the mechanisms considered. Therefore, various insufficiencies of mucosal defense could promote the development of IgAN.

A body of literature focusing on genetic risk has prompted speculation that IgAN is a polygenic disease (reviewed by Emancipator, 1992). In this context, immunoregulatory, transport, and cytokine genes all could impact upon elements of Figure 1. Except for aberrant regulation of Ig synthesis, data exist that contradict proposed defects in many of the pathways considered. Reports affirming defects often have borderline statistical significance or modest biological differences. We already have discussed the possibility that small quantitative differences over protracted time in a chronic disease such as IgAN could result in large differences in the accumulation of IgA deposits. Similarly, small shifts in the rate constants of multiple pathways in the overall scheme of Figure 1 could synergize to give a large shift in the overall rate of deposition versus clearance. Does this represent the polygenic origin postulated for IgAN?

A simple imbalance between production and clearance of immune complexes probably cannot account entirely for the development of IgAN (van Es *et al.*, 1988; Waldo, 1990; Julian *et al.*, 1991). Despite high levels of circulating IgA immune complexes, comparable to or in excess of levels seen in IgAN, patients with human immunodeficiency virus (HIV) infections rarely have glomerular deposits of IgA (Kenouch *et al.*, 1990; Béné *et al.*, 1991a; Schoeneman *et al.*, 1992). Indeed, IgAN associated with HIV has been recognized only recently, despite many renal biopsies of HIV-infected patients over several years. What factors, beyond the relative rates of production and clearance of IgA immune complexes,

might apply to the development of this syndrome? Is the IgA produced by plasma cells from IgAN patients somehow different? Does the antigen component target IgA immune complexes to the mesangium in individuals at risk for IgAN (Emancipator *et al.*, 1992)? Is the mesangium of IgAN patients somehow different (Nagura, 1989)? Although such questions are emerging, their importance and relationship to the more established issues discussed earlier are speculative.

In conclusion, the pathogenesis of IgAN and the role of the mucosal immune system in the process are not yet clear. Nevertheless, we strongly favor the view that the glomerular IgA deposits represent complexes of mucosal antigens combined with antibodies synthesized by mucosal plasma cells that reached the circulation and were not cleared by the mononuclear phagocyte system or other mechanisms for elimination. This hypothesis, therefore, ascribes a major and central role in the genesis of IgAN to the mucosal immune system.

# Mucosal Immunity in the Female and Male Reproductive Tracts

Margaret B. Parr · Earl L. Parr

## I. INTRODUCTION

Mucosal immunity in the female and male reproductive tracts is uniquely adapted to serve the particular requirements of reproduction. This immune system reacts against microorganisms and helps maintain an aseptic environment in the genital tracts during most stages of the reproductive process. At the same time, the system fails to react against the antigens of sperm, the zona pellucida, and the early embryo, and thereby avoids inhibiting reproduction. A consequence of this adaptation is that mucosal immunity in the genital tracts differs in significant ways from that in the intestine. In particular, several basic characteristics of mucosal immunity in the intestine are absent or inconspicuous in the genital tracts, including antigen-transporting epithelial cells, mucosal lymphoid nodules, homing, and a preponderance of IgA in secretions. A consideration of these differences is a major focus of this chapter.

Progress in several important clinical and public health issues cannot be made without a better understanding of mucosal immunology in the genital tracts. For example, effective vaccination to protect the genital tracts against sexually transmitted diseases, including acquired immunodeficiency syndrome (AIDS), probably will require activation of local immune mechanisms in the mucosa (Archibald *et al.*, 1987; Forrest, 1991; Ward, 1993). Similarly, considerable interest has arisen in the development of vaccines that stimulate local secretory immunity against sperm for short- or intermediate-term immunocontraception (E. L. Parr and M. B. Parr, 1993). A need to understand better the immunologically mediated infertility that occurs in a few individuals of both sexes as a result of IgA antisperm antibody in the genital tracts also exists (Bronson *et al.*, 1984).

Finally, we would like to emphasize, as did Schumacher (1980), that remarkable variation in the structure and function of the mammalian reproductive system occurs from one stage of the reproductive process to another, as well as among species. Caution, therefore, is necessary when correlating immunological results with reproductive function and when extending results from one species to another.

## II. FEMALE REPRODUCTIVE TRACT

### A. Efferent Limb of Mucosal Immunity

The main elements of secretory immunity in the genital tract appear to be secretory component (SC) in epithelial cells, IgA plasma cells in the underlying stroma, and immunoglobulins (SIgA and IgG) in luminal fluids. In the following sections, we summarize available information concerning these immune elements in the oviduct, uterus, and vagina of several species. We also discuss the pathways of immunoglobulin movement across the mucosa of those organs.

#### 1. Secretory Component, Plasma Cells, and Immunoglobulins

In humans, SC and IgA plasma cells in the female genital tract have been the subject of numerous investigations. These studies have shown that the isthmus and ampulla of the oviduct contain SC on the luminal epithelium and IgA plasma cells in the stroma, suggesting that the oviduct is a potential site for mucosal immunity in the genital tracts of women (Tourville *et al.*, 1970; Kutteh *et al.*, 1988, 1990). Specific observations are not available for the preampulla of the oviduct, in which plasma cells and interstitial immunoglobulins are most concentrated in the mouse oviduct (E. L. Parr and M. B. Parr, 1985). The body and fundus of the uterus contain SC and IgA in glandular epithelia and IgA in the glandular lumina (Tourville *et al.*, 1970; Vaerman and Ferin, 1974; Rebello *et al.*, 1975; Kelly and Fox, 1979; Kutteh *et al.*, 1988). However, IgA plasma cells are rare or absent, suggesting that serum may be an important source of IgA for secretion in this part of the uterus. The endocervix, which in humans is lined by columnar epithelium and contains numerous glands, exhibits SC on the luminal and glandular epithelia and contains many IgA plasma cells (Rebello *et al.*, 1975; Kutteh *et al.*, 1988). These observations suggest that the endocervix is likely to be a focal point for mucosal immunity in the genital tract of women (Ingerslev, 1981). The ectocervix, on the other hand, is similar to the vagina; it is lined by stratified

squamous epithelium, lacks glands and SC, and shows few subepithelial IgA plasma cells.

Several studies have shown that both IgA and IgG are present in cervicovaginal fluids and that IgG appears to be the predominant immunoglobulin, but the reported ratios of IgG to IgA vary from approximately 2:1 to 10:1 (Chordirker and Tomasi, 1963; Masson *et al.*, 1969; Schumacher, 1973, 1980; Tjokronegoro and Sirisinha, 1975; Coughlan and Skinner, 1977; Jalanti and Isliker, 1977; Usala *et al.*, 1989). One report indicates that the predominant immunoglobulin in these secretions is IgA with characteristics of secretory IgA (Waldman *et al.*, 1972a). The reasons for these differences are not entirely clear, but note that many technical problems are involved in obtaining accurate measurements of immunoglobulins in genital tract secretions. The recovery of sufficient quantities of secretions uncontaminated by serum or tissue fluids is difficult, and methods for extraction of immunoglobulins from mucus have not been standardized and may be ineffective (Schumacher, 1980; Ingerslev, 1981). Other problems include the use of 7 SIgA standards for measurement of 11 SIgA (Schumacher, 1980), as well as the variability of immunoglobulin concentrations in cervicovaginal mucus during the menstrual cycle (Schumacher, 1980; Sullivan *et al.*, 1984; Suzuki *et al.*, 1984).

Measurements of immunoglobulins in human uterine fluid also indicate that IgG is the predominant immunoglobulin present (Schumacher *et al.*, 1979). Nevertheless, the uterus may be the primary source of IgA in cervicovaginal fluids, since the concentration of IgA in vaginal fluid from hysterectomized women was only about 10% of normal (Jalanti and Isliker, 1977). Also, SC has not been detected in human vaginal epithelium. On the other hand, the concentration of IgA in vaginal fluid of three hysterectomized women appeared to be normal (Waldman *et al.*, 1972a). The IgG in vaginal fluid appears to be derived locally from the vaginal mucosa, since its concentration in intact and hysterectomized women is the same (Waldman *et al.*, 1972a; Jalanti and Isliker, 1977).

In mice, the preampulla of the oviduct, which is the short initial segment composed of the fimbria and infundibulum, contains some IgA plasma cells in the stroma. IgA and IgG are present in the luminal epithelium and interstitial space (M. B. Parr and E. L. Parr, 1985; E. L. Parr and M. B. Parr, 1986; Parr *et al.*, 1988b). These immune features are not observed in the remainder of the oviduct. Many IgA plasma cells are found in the uterine horns and body, where they are concentrated around the endometrial glands (Bernard *et al.*, 1981; Rachman *et al.*, 1983, 1984; M. B. Parr and E. L. Parr, 1985). SC is also present on the glandular epithelium and, to a lesser extent, on the luminal epithelium (E. L. Parr and M. B. Parr, unpublished data). These observations suggest that the preampulla of the oviduct and the horns and body of the uterus are important sites of IgA secretion into luminal fluids of the genital tract. The mouse cervix and vagina are similar because both are lined by stratified squamous epithelium, lack glands, and contain few IgA plasma cells (M. B. Parr and E. L. Parr, 1985). The mouse cervix is, thus, quite different from the human endocervix. The uterine horns and body in mice and the endocervix in women

appear to be the main regions of the genital tract involved in IgA secretion in these species.

Both IgA and IgG have been detected in murine uterine and vaginal fluids that were uncontaminated by serum or tissue fluids (E. L. Parr and M. B. Parr, 1990; Thapar *et al.*, 1990a). Neither the antibody concentrations nor the IgA:IgG ratios in these fluids have been reported. Most of the IgA in vaginal fluid appears to come from the uterus, since specific IgA titers in vaginal fluids of hysterectomized mice were only about 5% of those in controls. Titers of IgG, on the other hand, increased to some extent in vaginal fluids of hysterectomized mice, indicating that IgG readily crosses the vaginal mucosa (E. L. Parr and M. B. Parr, 1990).

The number of IgA plasma cells in the murine genital tract changes during the estrous cycle. These cells are most numerous at proestrus and estrus (Rachman *et al.*, 1983), and their numbers increase further between days 1 and 5 of pregnancy (Bernard *et al.*, 1981; M. B. Parr and E. L. Parr, 1985; Rachman *et al.*, 1986). The increased number of plasma cells at estrus may be caused by the action of estradiol (Canning and Billington, 1983), whereas the additional rise that occurs during early pregnancy may be caused, at least in part, by the action of progesterone on an estrogen-primed uterus (M. B. Parr and E. L. Parr, 1986a). Also, migration of radiolabeled lymphoblasts from the mesenteric lymph node to the genital tract is maximal during proestrus and estrus (McDermott *et al.*, 1980).

In rats, the luminal and glandular epithelial cells of uterine horns contain IgA (Mitchell, 1986) and SC (Parr and Parr, 1989a), but the occurrence of IgA plasma cells in the endometrium is controversial. These cells were reported by Wira and colleagues (Wira *et al.*, 1980), but were not detected in other studies (Mitchell, 1986; Parr and Parr, 1989a). No studies have been done on SC or IgA in the oviduct, but SC is present in the mucous epithelial cells lining the cervix and vagina at diestrus and proestrus (Parr and Parr, 1989a). Uterine and vaginal fluids contain SC, IgA, and IgG (Wira and Sandoe, 1977; Sullivan and Wira, 1981; Wira and Sullivan, 1985).

Less is known about secretory immunity in the genital tracts of other species. Plasma cells containing IgA or IgG have been reported in the genital tracts of the monkey (Miller *et al.*, 1992), pig (Hussein *et al.*, 1981, 1983a,b), horse (Kenney and Khaleel, 1975; Mitchell *et al.*, 1982; Widders *et al.*, 1985b; Waelchli and Winder, 1987), and hamster (Roig de Vargas-Linares, 1968). Immunoglobulins A and G have been detected in reproductive tract secretions in the monkey (Yang and Schumacher, 1979; Miller *et al.*, 1992), cow (Wilkie *et al.*, 1972), horse (Widders *et al.*, 1985a), and rabbit (Symons and Herbert, 1971; McAnulty and Morton, 1978), and SC is present in equine endometrial glands (Widders *et al.*, 1985b).

## 2. Transfer of Immunoglobulins into the Lumen of the Genital Tract

The vaginal fluids of all species studied contain IgA and IgG. The pathways followed by these immunoglobulins to reach the vaginal lumen may be of some relevance to mucosal immunity. Studies of hysterectomized humans and mice sug-

gest that much of the IgA in vaginal fluid is derived from the uterus (Jalanti and Isliker, 1977; E. L. Parr and M. B. Parr, 1990). SC has been demonstrated in the mucous layer of the vaginal epithelium at diestrus and proestrus in rats (Parr and Parr, 1989a) and mice (E. L. Parr and M. B. Parr, unpublished data), but the possibility that it might mediate direct transport of IgA across vaginal epithelium at these stages has not been evaluated. The hysterectomy studies cited earlier also suggest that IgG passes directly across the vaginal mucosa, since its concentration in vaginal fluid is the same in hysterectomized and intact individuals. However, the pathway of IgG movement across the vaginal epithelium is not entirely understood. Tracer studies indicate that proteins can enter the intercellular channels in the basal layers of the monkey vaginal epithelium, but are blocked at the granular layer in the superficial part of the epithelium (King, 1983, 1985). Similarly, IgG has been localized in the intercellular spaces of the mouse vaginal epithelium at diestrus, but whether the immunoglobulin penetrates the tight junctions joining the superficial mucous cells is not clear (E. L. Parr and M. B. Parr, unpublished data). Therefore, whether IgG reaches vaginal fluid by slow leakage through the intercellular permeability barrier or by an intracellular transport pathway is currently unknown. In either case, the stage of the reproductive cycle, through its effect on the structure of the epithelial layer, is likely to influence the rate of IgG movement across the epithelium.

Immunoglobulins A and G are also present in the luminal fluids of the oviduct and uterus in several species. In rats and mice, and probably in other species as well, these organs are lined by simple columnar epithelial cells that are joined by functional tight junctions (Parr, 1980b; Parr *et al.*, 1988b; Tung *et al.*, 1988), suggesting that immunoglobulins are transported from the stroma into the lumen of these organs primarily by an intracellular route. In the mouse, IgA, IgG, and intravenously administered protein tracers have been demonstrated in the luminal epithelium covering the villi in the preampulla of the oviduct and in luminal and glandular epithelial cells in the uterine horns (Parr, 1980ab; E. L. Parr and M. B. Parr, 1986; Parr *et al.*, 1988b; Tung *et al.*, 1988). IgA presumably is taken into the epithelial cells by receptor-mediated endocytosis, the receptor being SC, whereas IgG may be present in these or other vesicles in proportion to its concentration in the interstitial fluid.

## B. Afferent Limb of Mucosal Immunity

### 1. Langerhans Cells and Lymphocytes in the Epithelium

Infection or local immunization in the genital tract can elicit immune responses (Strauss, 1961; Omran and Hulka, 1971; Waldman *et al.*, 1972b; Wilkie *et al.*, 1972; Ogra and Ogra, 1973; Yang and Schumacher, 1979; Widders *et al.*, 1986; Parr *et al.*, 1988a), but the pathways of antigen uptake and the sites of antigen recognition remain to be clarified. A major advance in our understanding of antigen recognition in the lower part of the female genital tract has come with reports that Langerhans cells (LCs) are present in the stratified epithelium of the murine vagina and cervix

(Young, 1985; Young *et al.*, 1985; Young and Hosking, 1986; Lin *et al.*, 1988; Parr and Parr, 1991; Parr *et al.*, 1991a,b). LCs have been studied extensively in the epidermis, where they function as antigen-presenting cells for T lymphocytes in conjunction with major histocompatibility complex (MHC) molecules (Stingl *et al.*, 1989). Results of *in vivo* and *in vitro* studies suggest that LCs capture antigen within the epidermis and carry it to the draining lymph nodes, where T lymphocytes become activated, multiply, and differentiate into immune helpers or effectors (Stingl *et al.*, 1989).

LCs in the mouse vagina and cervix are immunophenotypically similar to epidermal LCs; they exhibit NLDC-145, Ia, F4/80, and CD45 surface antigens and contain ATPase and LC granules (Parr and Parr, 1991; Parr *et al.*, 1991b). Moreover, LCs take up luminal proteins by endocytosis during late metestrus and diestrus when the vaginal epithelium is most permeable (Figures 1 and 2; M. B. Parr and E. L. Parr, 1990; Parr *et al.*, 1991a). The presence of LCs in the vaginal and cervical epithelia, close to the lumen, indicates a significant potential for local antigen processing in the lower part of the female genital tract.

Interestingly, LCs in the vagina and cervix also have been shown to phagocytose epithelial cells undergoing apoptosis or programmed cell death (Young *et al.*, 1985; Parr *et al.*, 1991b). This activity may be unique to LCs in the genital tract because epidermal LCs are considered to be nonphagocytotic and only weakly pinocytotic (Stingl *et al.*, 1989). Death of

**Figure 1** Mouse vagina at early metestrus, 2 hr after intravaginal administration of horseradish peroxidase. The tracer is located between epithelial cells, in three dendritic LCs (arrows) in the epithelium, and in the stroma.  $\times 500$ . (Reproduced with permission from Parr *et al.*, 1991a.)

**Figure 2** Fluorescent labeling of Ia antigen on dendritic LCs (arrows) in an isolated sheet of epithelium from the mouse vagina.  $\times 200$ .

vaginal epithelial cells and phagocytosis of the dead cells by LCs may play a role in the extensive tissue remodeling that occurs in the vagina and cervix during the estrous cycle.

Intraepithelial T lymphocytes (IELs) are also present in the stratified epithelium of the mouse vagina and cervix (Parr and Parr, 1991). Whether these cells are involved in the afferent or efferent limb of mucosal immunity, or both, is not known. The cells are Thy1 positive (Figure 3) and either CD4 or CD8 positive, and are more numerous at diestrus than at any other stage in the estrous cycle (Parr and Parr, 1991). The latter observation suggests an influx of T cells into the vaginal epithelium during each estrous cycle when the epithelium is thinnest and most permeable to protein tracers. The IELs occasionally are seen in contact with LCs, although the functional significance of this association remains speculative (Parr and Parr, 1991; Parr *et al.*, 1991b). Knowing whether IELs in the genital tract are involved in the cell-mediated protective effects that have been reported in chlamydial and herpesvirus infections would be most interesting (McDermott and Svedsmith, 1989; Ramsey and Rank, 1991).

As in the mouse, LCs and IELs are present in the human vagina and cervix (Figuroa and Carosi, 1981; Becker *et al.*, 1985; Hawthorn *et al.*, 1988). Moreover, the cells are most concentrated in the transformation zone of the cervix, where they are ideally situated to guard the entrance to the uterus (Morris *et al.*, 1983; Edwards and Morris, 1985; Roncalli *et al.*, 1988). In the cervix, cell contacts are observed between LCs and several other cell types, including IELs, capillary endothelium in the subepithelial connective tissue, and "hugging cells" (possibly macrophages) that are applied closely to the stromal side of the basement membrane. The uterus

and oviduct also contain IELs that are mainly of the T cytotoxic/suppressor subtype (Morris *et al.*, 1986; Kamat and Issacson, 1987; Otsuki, 1989). Additionally, IELs have been identified in the uterine epithelium of the rat (Sawicki *et al.*, 1988), cow (Vander-Wielen and King, 1984), sheep (Lee *et al.*, 1988), and pig (King, 1988).

## 2. Antigen Uptake

One of the most important aspects of the afferent limb of the immune system in the genital tract is the movement of antigen from the lumen into the mucosa. Early studies suggested that the vaginal stratified epithelium was permeable to various proteins (see M. B. Parr and E. L. Parr, 1990, for references). Studies have demonstrated that proteins can cross the epithelium of the murine cervix and vagina during diestrus and early pregnancy and, to a lesser extent, at proestrus and metestrus; however, proteins do not cross the epithelium at estrus (M. B. Parr and E. L. Parr, 1990). When proteins cross the cervicovaginal epithelium, they are taken up by epithelial LCs and by stromal cells that resemble dendritic cells, fibroblasts, or macrophages. The observations suggest that the mouse vagina and cervix sample antigens from the external environment during certain stages of the reproductive cycle and early pregnancy. This sampling may lead to immune responses. In contrast, the block against antigen uptake at estrus would minimize sensitization to sperm and seminal fluid proteins at the time of mating.

Proteins do not appear to cross the uterine epithelium from the lumen to the endometrial stroma. Specialized antigen-transporting epithelial cells have not been reported in the

**Figure 3** Fluorescent labeling of Thy1 on IELs (arrow) in the mouse vagina. L, Lumen.  $\times 200$ .

uterus or in any other part of the female reproductive tract. Proteins in the luminal fluid can be taken into uterine epithelial cells by endocytosis at certain stages, but such proteins are channeled into the lysosome system for digestion and do not appear to be released into the stroma (Parr and Parr, 1978; Parr, 1980b; M. B. Parr and E. L. Parr, 1986b; Tung *et al.*, 1988). Some investigators have reported that proteins injected into the uterine lumen were detected later in the stroma, but these results seem likely to be due to epithelial damage caused by the use of sutures to prolong retention of tracers or to other nonphysiological conditions in the uterine lumen (Parr, 1980b).

### 3. Stromal Lymphoid Cells and Nodules

The precursors of IgA plasma cells in the intestine and respiratory tract are believed to originate mainly in the mucosal lymphoid nodules of those organs (Mestecky, 1987; Scicchitano *et al.*, 1988). Thus, another important aspect of the afferent limb of mucosal immunity in the female genital tract is that mucosal lymphoid nodules containing B lymphocytes are far less abundant in the genital tract than in the intestinal and respiratory mucosae. Extensive histological examinations of mouse oviduct, uterus, and vagina have never revealed mucosal lymphoid nodules (M. B. Parr and E. L. Parr, 1985; Parr *et al.*, 1988a; E. L. Parr and M. B. Parr, unpublished observations). In humans, lymphoid nodules are rare in the endometrium (Schumacher, 1980): those that have been reported were mainly aggregates of T lymphocytes; germinal centers and mantle zones containing B lymphocytes were present only in a few specimens (Morris *et al.*, 1985; Bulmer *et al.*, 1988). The low numbers of B cells in human endometrial lymphoid nodules may be related to lack of antigen stimulation, since the Peyer's patches of neonatal animals also contain mainly T lymphocytes (Morris *et al.*, 1985). A few lymphoid nodules have been reported in the human oviduct and cervix, but not in the vagina (Edwards and Morris, 1985; Otsuki, 1989). Since B cells are rare in the mouse and human female genital tracts, IgA plasma cells in those tracts are likely to be derived mainly from other sources, such as genital lymph nodes or other mucosal tissues. The significance of mucosal lymphoid nodules for local immunity in the human female tract requires clarification, but the few that are present may be the residue of previous responses to invasive microorganisms. In sheep, lymphoid nodules were observed in 3 of the 24 uteri examined (Lee *et al.*, 1988).

In addition to lacking lymphoid nodules, the stroma of the normal murine vagina and cervix contains few individual T lymphocytes and no B lymphocytes (Parr and Parr, 1991). Information concerning the occurrence of T lymphocytes in the stroma of murine uterine horns and oviducts is not available, but a few stromal T cells have been observed in the rat uterus (Head and Gaede, 1986). The stroma of the human cervix contains numerous T cells, but such cells are infrequent in vaginal stroma (Edwards and Morris, 1985). The endometrial stroma contains T cells that are mainly of the CD8<sup>+</sup> phenotype, both individually and in occasional aggregates (Morris *et al.*, 1985; Kamat and Issacson, 1987; Bulmer *et al.*, 1988); B cells are relatively common in the stroma of the oviduct (Morris *et al.*, 1986).

## 4. Biological Significance

The biological function of the female reproductive tract requires that the mucosal surface of the tract be exposed to sperm and seminal fluid proteins. These substances stimulate immune responses if they are administered parenterally in females. Antisperm antibodies in luminal fluids of the female genital tract cause reduced fertility (Bronson *et al.*, 1984). Thus, an effective mechanism is needed to prevent sperm and seminal fluid proteins in the luminal compartment of the female tract from stimulating the immune system. The evidence reviewed earlier indicates that, at the time of mating, the luminal epithelium of the genital tract functions as a barrier that prevents luminal proteins from reaching immune cells or lymphatic vessels in the tissues. Although other immune suppressive mechanisms may be involved as well, this barrier function of the luminal epithelium is likely to be fundamentally important to reproduction. In mice and rats, the epithelium of the oviduct and uterus constitutes a barrier to protein movement at all stages of the reproductive cycle and early pregnancy, whereas the vaginal epithelium is a barrier mainly at the time of mating. Thus, in the absence of damage to the epithelial layer, the available evidence indicates that local mucosal immunization in the female genital tract with noninvasive antigens would stimulate immune responses mainly when the antigens are applied to the vaginal mucosa at nonestrous stages. Invasive microorganisms, of course, may trigger immune responses whenever they penetrate the epithelial barrier.

### C. Role of Mucosal Immunity in Protection against Infections

#### 1. Antibodies to Microorganisms

Local secretory immunity generally is considered to be important in protecting mucosal surfaces against invading microorganisms (Waldman and Ganguly, 1974), but few reports demonstrate this characteristic in the genital tract. In women, cervicovaginal fluids contain antibodies against microorganisms (Schumacher, 1980). Studies of women with genital tract infections involving herpes simplex virus 2 (HSV-2) or *Chlamydia trachomatis* have revealed inverse relationships between specific SIgA antibody titers in cervicovaginal secretions and the number of disease organisms present (Brunham *et al.*, 1983; Merriman *et al.*, 1984). Similarly, the susceptibility of women to *Escherichia coli* urinary tract infections is correlated inversely with the titers of specific IgA antibodies against *E. coli* in their vaginal fluids (Stamey *et al.*, 1978). Data on the local immune response to genital papillomaviruses have been reviewed by Roche and Crum (1991).

In mice, one of the many mammalian species in which insemination occurs directly into the uterine lumen, bacteria are introduced into the uterine horns at the time of mating. These bacteria are cleared from the uterus during the next 2–3 days, before embryos arrive for implantation (E. L. Parr and M. B. Parr, 1985). We have observed IgA and IgG bound to many bacteria in the uterine lumen on the morning after

mating, as well as IgA bound to bacteria in the vagina of normal mice (E. L. Parr and M. B. Parr, 1985; M. B. Parr and E. L. Parr, 1985). The uterine fluid of normal mice also contains antibodies against most of the bacterial species that were cultured from the vagina (E. L. Parr and M. B. Parr, 1988b).

Specific antibodies in luminal fluids of the reproductive tract may protect against infections by several mechanisms. For example, immunoglobulins may inhibit binding of microorganisms to the endometrial epithelium, a step that is thought to be required for infection of mucosal surfaces (Williams and Gibbons, 1972; Fubara and Freter, 1973; Abraham and Beachey, 1985). These antibodies may cause agglutination and thus reduce the number of organisms available to bind to the epithelium (Bellamy *et al.*, 1975; Steele *et al.*, 1975), and may opsonize organisms for phagocytosis. Opsonization is mediated by IgG and perhaps also by IgA when the latter is combined with small amounts of IgG (Goldstein *et al.*, 1983). Opsonization would be augmented by C3, which is bound to some of the uterine bacteria in mice (E. L. Parr and M. B. Parr, 1988) and is secreted by luminal epithelial cells (Sundstrom *et al.*, 1990). Since we have observed phagocytosis of bacteria by neutrophils in the mouse uterine lumen after mating (E. L. Parr and M. B. Parr, 1985b), evidently this process plays a role in returning the uterine lumen to an aseptic state after mating. Finally, secretory IgA may mediate local killing of bacteria by antibody-dependent cellular cytotoxicity (Tagliabue *et al.*, 1984).

## 2. Importance of IgA Relative to IgG

Whether IgA is more important than IgG in protecting the female genital tract against bacterial and viral infections is not yet clear. On the one hand, IgA may be intrinsically more effective than an equivalent amount of IgG against certain infections in the intestine and respiratory tract (Fubara and Freter, 1973; Taylor and Dimmock, 1985; Bessen and Fischetti, 1988), and IgA antibody against sperm has a greater contraceptive effect than an equivalent amount of IgG anti-sperm antibody in human immunological infertility (Parr and Parr, 1993). On the other hand, available data indicate that the concentration of IgG in human cervicovaginal mucus may be higher than that of IgA (Schumacher, 1980). IgG appears to be protective against vaginal HSV-2 infection, since parenteral immunization with glycoprotein D of HSV-2 or with mixtures of membrane glycoproteins from HSV-1 and HSV-2, which presumably generates mainly IgG antibody in the genital tract, protects guinea pigs against vaginal challenge with HSV-2 (Berman *et al.*, 1984; Meignier *et al.*, 1987; Sanchez-Pescador *et al.*, 1988; Mishkin *et al.*, 1991). Given the diversity of organisms that can infect the female reproductive tract, the issue of which immunoglobulin class is more protective, or whether humoral immunity is more important than cellular immunity, may depend as much on the specific pathogen involved as on any fundamental immunological considerations. Thus, the development of immunization strategies that protect the human female tract from its diverse pathogens probably will require an integrated understanding of both mucosal immunology in the female tract and the infectious processes of the organisms.

## D. Immunization to Elicit Mucosal Immunity

Immunization that produces secretory immunity in the female reproductive tract against sperm or sexually transmitted disease organisms could have important practical applications, but methods to stimulate vigorous sustained IgA responses at this site are not yet well established. Investigators have attempted to elicit secretory immunity in the genital tract using three routes of immunization: local mucosal immunization in the genital tract, remote mucosal immunization in the intestine, and local parenteral immunization in the pelvis.

### 1. Local Mucosal Immunization

Local mucosal immunization in the intestine or respiratory tract can be an effective way to stimulate secretory immune responses at those sites, but local immunization in the female reproductive tract under physiological conditions elicits little or no specific antibody generation in genital tract secretions. An early indication of this is the observation that intravaginal (ivag) immunization of mice with spermatozoa had no effect on fertility, whereas parenteral immunization with sperm significantly reduced fertility (Bell, 1969). Subsequent studies of immunization in the human and rabbit uterine lumen with horse ferritin, sperm, or horseradish peroxidase failed to detect immune responses in the reproductive tract (Vaerman and Ferin, 1974; McAnulty and Morton, 1978; Moretti-Rojas *et al.*, 1990), although specific antibody was detected in the human tract after intrauterine immunization with killed influenza virus (Ogra and Ogra, 1973). Other reports indicating that immune responses are detectable in the reproductive tract after intrauterine immunization have involved nonphysiological conditions, such as the use of ligatures to close the cervical end of the uterus after immunization or the mixture of antigen with an adjuvant (Menge and Lieberman, 1974; Lande *et al.*, 1981; Lande, 1986; Wira and Sandoe, 1989). The sutures and adjuvants are likely to damage the uterine epithelium, thus allowing antigen to reach lymphoid cells and lymphatic vessels in the stroma. Comparative studies have demonstrated that antibody titers in luminal fluids of the monkey and mouse female tract after ivag immunization are low in comparison with titers produced by systemic immunization (Yang and Schumacher, 1979; Parr *et al.*, 1988a; Thapar *et al.*, 1990b, 1991). Adjuvants, including aluminum hydroxide and lipid A, increased local immune responses to ivag immunization with large doses of horse ferritin in mice, but the specific IgA titers observed in vaginal fluid were only slightly higher than those obtained by parenteral immunization with single small doses of ferritin; the IgG titers were lower (Thapar *et al.*, 1990a).

The relatively weak immune responses after local immunization in the uterus or vagina with noninvasive antigens are probably caused by the inability of the antigen to penetrate the luminal epithelium and by the rapid loss of antigen from the genital tract. Immune responses to ivag immunization in mice might be higher if the animals were immunized at diestrus or during early pregnancy, when penetration of proteins across the vaginal epithelium was maximal (M. B. Parr

and E. L. Parr, 1990). Edwards (1960) reported that vaginal immunization of rabbits with sperm during early pregnancy gave stronger immune responses than similar immunization at estrus. Responses also might be increased by the use of bioadhesive microspheres and absorption enhancing agents, which promote the retention and absorption of proteins on mucosal surfaces (Illum *et al.*, 1990).

In contrast to protein antigens, invasive microorganisms may penetrate the epithelium of the reproductive tract. McDermott and colleagues (McDermott *et al.*, 1984, 1987, 1990; McDermott and Svedsmith, 1989) have studied vaginal HSV-2 infection in mice, using a viral strain isolated from humans and adapted to mice. The virus causes lethal neurological illness in mice after ivag inoculation, but an attenuated strain causes only a transient vaginal infection and is incapable of lethal neurological spread. Importantly, ivag inoculation with the attenuated virus induces protective immunity to subsequent lethal challenge with wild-type virus (McDermott *et al.*, 1984). The basis of this immunity has been investigated and appears to involve T lymphocytes (McDermott and Svedsmith, 1989); the possible protective role of specific antiviral IgA and IgG antibodies in genital tract secretions is not yet clear. Note that infection of the female genital tract can be markedly dependent on the stage of the reproductive process. For example, ivag infection with HSV-2 is increased in pregnant or progesterone-treated adult mice (Baker and Plotkin, 1978), and genital infection of mice with *C. trachomatis* requires pre-treatment with a progestagen (Tuffrey *et al.*, 1986).

## 2. Remote Mucosal Immunization

The hypothesis of a common mucosal immune system predicts that presentation of antigen in the intestine will stimulate local B lymphocytes that ultimately will migrate as IgA plasmablasts to other mucosal sites (Scicchitano *et al.*, 1988). Migration of lymphoblasts from the mesenteric lymph node to the mouse female genital tract has been demonstrated by McDermott *et al.* (1980), suggesting that immunization in the intestine, which has specialized antigen-transporting epithelial cells and abundant mucosal lymphoid tissue, effectively might generate immune responses in the genital tract. This relationship has been illustrated by several studies. Specific IgA antibodies in mouse uterine washings were produced by two oral immunizations with a live influenza vaccine (Briese *et al.*, 1987). Oral vaccination of guinea pigs with HSV-1 developed protection against intravaginal challenge with HSV-2, presumably because of the antigenic similarity of the two viruses (Sturn and Schneeweis, 1978). A live oral chlamydial vaccine proved to be effective against both ocular and vaginal challenge with the homologous organism in guinea-pigs (Nichols *et al.*, 1978), and against pulmonary and vaginal challenge in mice (La Scolea *et al.*, 1991). Oral immunization of rats with spermatozoa caused reduced fecundity (Allardyce, 1984). However, oral immunization of mice with a large dose of horse ferritin (5 mg) without adjuvant caused no detectable IgA response in vaginal washings, although it did prime the mice for vaginal boosting (Parr *et al.*, 1988a). The IgA titer in mouse vaginal fluid after oral-vaginal immunization was approximately equal to that produced by a single parenteral immunization with ferritin in Freund's

complete adjuvant. Oral immunization with a large dose of horse ferritin also caused a detectable IgA, but not IgG, response in uterine fluid (E. L. Parr and M. B. Parr, 1990). The magnitude of this IgA response was not greater than that produced by several other routes of immunization.

In general, secretory immune responses in the intestine are developed most effectively by replicating microorganisms (Mestecky, 1987). Most nonreplicating antigens do not stimulate vigorous immune responses in the intestine (Waldman and Ganguly, 1974; Fuhrman and Cebra, 1981; Nicklin and Miller, 1983; Elson and Ealding, 1984; Dahlgren *et al.*, 1986), perhaps because of digestion of antigens in the intestine, complexing with pre-existing antibodies, or failure to penetrate the mucus layer covering the epithelium (Mestecky, 1987). Despite these limitations, the advantages of oral vaccination to generate IgA immune responses in the genital tract are obvious. Further investigation of this procedure is warranted. One approach to improving immunization in the intestine involves the use of antigen-containing microparticles, which are transported across M cells into Peyer's patches (Eldridge *et al.*, 1990). Another approach uses an antigen-expressing organism that can colonize the intestine, for example, a genetically engineered *Salmonella* strain (Curtiss, 1993).

## 3. Local Nonmucosal Immunization

Parenteral immunization generally is associated with serum IgG responses and little secretory IgA. However, a few reports have suggested that parenteral immunization in the vicinity of a mucosal organ can elicit significant IgA secretion by that mucosa (reviewed by Thapar *et al.*, 1990b). We immunized female mice at two parenteral sites in the pelvis: the subserous space and the presacral space. Immunization at these pelvic sites, either with horse ferritin adsorbed to aluminum hydroxide or with a Quil A immunostimulating complex (ISCOM) containing sheep erythrocyte membrane proteins, caused higher and better sustained IgA titers in vaginal fluid than parenteral immunization at nonpelvic sites. All parenteral immunizations, both in the pelvis and elsewhere, generated similar IgG titers in vaginal fluid (Thapar *et al.*, 1990b, 1991).

The immunological basis of IgA responses in the female reproductive tract after parenteral immunization in the pelvis is not well understood, but such responses are most likely to be generated in the iliac or para-aortic lymph nodes that drain the reproductive tract (Thapar *et al.*, 1990b). Lymph nodes that drain large mucosal tissues such as the lungs and female genital tract may differ from peripheral lymph nodes that drain nonmucosal tissues. Such differences could arise because of unique antigen-presenting cells or cytokines entering mucosa-associated nodes from the mucosae. A striking difference between peripheral and mucosa-associated lymph nodes has been demonstrated (Daynes *et al.*, 1990). T helper cells from mouse peripheral lymph nodes produced interleukin 2 (IL-2) almost exclusively, whereas those from mucosa-associated nodes produced mainly IL-4. Interestingly, IL-4 has been shown to induce IgM-positive B cells to express IgA *in vitro* (Kunimoto *et al.*, 1988; Harriman *et al.*, 1989).

### III. MALE REPRODUCTIVE TRACT

#### A. Efferent Limb of Mucosal Immunity

The mucosal immune system in the male urogenital tract has been studied in the rat, mouse, and human. Both IgA and IgG are found in seminal fluids of normal men (Chordirker and Tomasi, 1963; Hermann and Hermann, 1969; Uehling, 1971; Tauber *et al.*, 1975). IgA or SIgA sperm agglutinins are present in seminal fluids of men with autoimmunity to spermatozoa. SIgA with antisperm activity also has been found in the genital tracts of some vasectomized men (see Parr and Parr, 1987b, for references). The origin of secretory immunoglobulins in seminal fluids is not precisely known. Prostatic fluids contain IgA; studies of split human ejaculates have suggested that seminal fluid immunoglobulins may originate either in the prostate (Rumke, 1974; Hekman and Rumke, 1976) or in the seminal vesicles (Uehling, 1971). The human prostate contains a few IgA plasma cells (Ablin *et al.*, 1972; Doble *et al.*, 1990), IgG in the basal part of the epithelial cells, and both IgA and IgG in secretory granules in the lumen of the prostatic ducts (Ablin *et al.*, 1972). These studies suggest that secretory epithelial cells in the prostate contribute at least some of the immunoglobulins in human seminal fluid.

In rats, SC has been demonstrated by immunolabeling at several sites in the male urogenital tract, including the

**Figure 4** Fluorescent labeling of SC in the excretory ducts of the dorso-lateral prostate glands in the rat male genital tract. SC is localized at the basolateral borders of the epithelial cells and in the apical portions of many cells.  $\times 170$ . (Reproduced with permission from Parr and Parr, 1989b.)

ejaculatory ducts, excretory ducts of several accessory glands, and urethral glands in the pelvic and bulbous portions of the urethra (Figures 4 and 5; Parr and Parr, 1989b). Pale staining of SC also was detected in epithelial cells of the ventral prostate gland. Plasma cells containing IgA were observed only in the urethral glands in the wall of the bulbous urethra. These results suggest that IgA may be transported into the urogenital tract from the ventral prostate as well as at several sites distal to the production of seminal fluid and spermatozoa. Locally synthesized IgA may be available in the urethral glands, but serum appears to be the main source of IgA for transport into the rat urogenital tract at other sites where SC was demonstrated (Parr and Parr, 1989b). Similarly, immunolabeling in the urogenital tract of the male mouse showed SC in the excretory ducts of the ventral prostate and in the urethral glands in the pelvic and bulbous urethrae (E. L. Parr and M. B. Parr, unpublished observations), as well as IgA in plasma cells in the urethral glands (Parr and Parr, 1989b).

#### B. Afferent Limb of Mucosal Immunity

The afferent limb of mucosal immunity in the male genital tract remains unexplored. Data are not available concerning local immunization at the mucosal surface, presumably because the mucosa of the male genital tract is relatively inaccessible and parts of it are washed frequently by urine. Similarly, no direct studies of antigen transport across the epithelium of the male tract have been reported, but the epithelium is likely normally to be an effective barrier to noninvasive antigens because sperm are antigenic and anti-sperm immunity in males causes infertility (Bronson *et al.*, 1984). Studies of the fate of invasive microorganisms, such as human immunodeficiency virus (HIV), in the male urogenital tract would be of great interest.

Mucosal lymphoid nodules appear to be rare in the human male genital tract (El-Demiry and James, 1988). During our immunohistological studies of the male tract in mice and rats, we only rarely observed aggregates of lymphoid cells (E. L. Parr and M. B. Parr, unpublished observations). However, IELs have been reported in the human epididymis (Wang and Holstein, 1983; Ritchie *et al.*, 1984), and ductus deferens (El-Demiry and James, 1988), and from the tubuli recti of the testes to the ductus deferens in monkeys and rats (Dym and Romrell, 1975). The role of these cells in mucosal defense is unknown. Lymphoid cells, including macrophages, neutrophils, and lymphocytes, are normally present in seminal fluids of fertile men (El-Demiry *et al.*, 1986; Wolff and Anderson, 1988; Harrison *et al.*, 1991).

#### C. Role of Mucosal Immunity in Protection against Infections

The functions of mucosal immunity in the male genital tract are poorly documented. Bacteria isolated from prostatic fluid of patients with prostatitis were coated with IgA and IgG antibodies (Drach and Kohlen, 1977). Prostatitis and nonspecific urethritis may be accompanied by abnormally

**Figure 5** Fluorescent labeling of SC in the acini and ducts of the urethral glands in the bulbous portion of the urethra in the male rat genital tract.  $\times 190$ . (Reproduced with permission from Parr and Parr, 1989b.)

high local levels of IgA. Seminal fluid immunoglobulins normally may prevent harmful effects of vaginal bacteria on spermatozoa (Uehling, 1971). Plasma cells containing IgA or IgM were observed in the human prostate and were most numerous in patients with previous prostatitis, suggesting local response to bacterial stimuli (Bene *et al.*, 1988). Also of interest is that sperm-agglutinating antibodies in seminal fluid are mainly of the IgA class (Friberg, 1974). These antibodies cause infertility and thus have clinical significance (Bronson *et al.*, 1984). Collectively, these observations suggest that IgA in seminal fluid may play a role in protecting the male urogenital tract against infection, and that it occasionally may be involved in immunologically mediated infertility.

# Immunologically Mediated Male and Female Reproductive Failure

R. A. Bronson • F. M. Fusi

## I. INTRODUCTION

Spermatozoa possess a variety of unique tissue-specific antigens not present in the individual during fetal life, when immune self-recognition takes place and tolerance toward self occurs. Since spermatogenesis is not initiated until puberty, antigens unique to spermatozoa are not included in that recognition process; their physiological development must proceed in a milieu that limits their exposure to the male immune system to avoid generating an immune response.

Spermatozoa also have an unusual relationship with the immune system of women, whose bodies they periodically invade, as foreigners, after coitus. However, after their intravaginal deposition, spermatozoa may pass through various compartments of the female reproductive tract that are capable of mounting an immune response without eliciting the formation of sperm-directed antibodies. That the mechanisms that prevent these pathological immune responses can be impaired is attested to by the long-standing clinical association of infertility in men and women with the presence of humoral antisperm antibodies.

In this chapter, we review the mechanisms that normally prevent the development of immunity to spermatozoa and describe conditions that may abrogate those defenses. Evidence is presented that the local immune system of the reproductive tracts of both men and women can participate in immunologically mediated infertility. Increasing evidence also has been accumulated that antisperm antibodies alter sperm function, both in terms of their ability to populate the female reproductive tract and in terms of gamete interactions.

## II. MECHANISMS THAT PREVENT IMMUNITIES TO SPERMATOZOA

The first line of defense against the development of a sperm-specific autoimmune response in men is the blood-testis barrier between Sertoli cells (Table I). The tight junctions between Sertoli cells divide the seminiferous tubules into adluminal and basal compartments, excluding the passage of lymphocytes and high molecular weight proteins such as immunoglobulins and complement (Hamilton, 1975; Gilula *et al.*, 1976). In addition, the Sertoli cells form an

immunological barrier by actively phagocytosing and degrading sperm and residual products of spermatogenesis that would be a major source of antigenic stimulation if absorbed. Only approximately one-fifth of sperm produced leave the testis; the remaining four-fifths are resorbed (Johnson *et al.*, 1983). Additionally, Sertoli cells probably produce immunoregulatory factors since they secrete transferrin, which has been shown to inhibit lymphocyte blastogenesis and complement-mediated cell lysis (Skinner *et al.*, 1984). The barrier between the reproductive system and the immune system is less effective in the rete testis and the ductus efferentes so these sites are more accessible to cellular immune components, as demonstrated in mice by the ability of sperm-sensitized activated T lymphocytes, transferred to recipient males, to react with autoantigens in this region as well as in the vas deferens (Tung *et al.*, 1987). Conversely, dilution of sperm antigens in the rete testis (Jones, 1977) and its poor vascularization (Kormana and Reijonen, 1976) may limit the interchange between intraluminal and intravascular compartments.

In females, the absence of an immune response to spermatozoa after coitus has been ascribed to several factors. First, except when ovulatory cervical mucus is present, spermatozoa are confined to the vagina; even when cervical mucus allows the passage of spermatozoa, the majority of sperm-containing semen is expelled. The human vagina is lined with a thick stratified squamous epithelium that retards the passage of spermatozoa into the vascular system (Shearer and Rabson, 1984) and has only a limited number of plasma cells beneath its epithelial surface (Haas and Beer, 1986). However, this area is not an immunologically privileged site, as suggested by the study of Ogra and Ogra (1973), who observed that intravaginal as well as intrauterine immunization with poliovirus type I resulted in the appearance of secretory IgA antibody against poliovirus in the genital tract.

In addition to the barrier mechanisms that limit the contact of sperm antigens with both male and female immune systems, an active semen-related immunosuppression appears to exist. Several lines of evidence have been presented for the existence of immunosuppressive factors within the seminal fluid. Seminal plasma inhibits the ability of T and B lymphocytes to proliferate in response to mitogen or antigen challenge (Lord *et al.*, 1977; Marcus *et al.*, 1978), impairs antibody-dependent cell-mediated cytotoxicity (James and

**Table I** Factors Limiting an Antisperm Immune Response in the Male

---

Tight junctions between Sertoli cells
T suppressor/T helper ratio
Immunoregulatory factors
Effects of seminal plasma
Inhibition of T and B lymphocyte proliferation by mitogens and target antigens
Block of antibody-dependent cell-mediated cytotoxicity
Inhibition of NK and T cytotoxic lymphocyte recognition of tumors and polymorphonuclear leukocytes (PMNs)
Inhibition of macrophage and PMN phagocytosis
Inhibition of the action of complement
Block of the Fc portion of IgG ?
Effects of spermatozoa
Immunosuppression
Inhibition of B lymphocyte antibody production through activation of C3a

---

Szymaniec, 1985), and blocks the recognition of tumor cells or virally infected cells by natural killer (NK) and cytotoxic T lymphocytes (Marcus *et al.*, 1984; Witkin, 1984). In addition, seminal fluid inhibits phagocytosis by macrophages and polymorphonuclear leukocytes (PMNs; Witkin, 1986) and the action of complement (Tarter and Alexander, 1984). Soluble receptors for IgG (Fc $\gamma$ RIII) have been detected in human seminal plasma (Thaler *et al.*, 1989), raising the possibility of their role in blocking antibody-mediated sperm damage by binding to the Fc portion of the immunoglobulin molecule. Spermatozoa also have been demonstrated to be immunosuppressive, as judged by their ability to induce tolerance *in vitro* in an autologous system (Hurtenbach *et al.*, 1980). Since they are able to induce the activation of complement by the alternative pathway (Witkin *et al.*, 1983), spermatozoa may modulate the immune response via C3a, which suppresses antibody production by B lymphocytes *in vitro* (Morgan, 1987).

Evidence also exists for active cellular immunosuppressive activity in the male reproductive system and in semen. T suppressor lymphocytes have been detected in the interstitium of the testis and in the submucosal regions of epididymis (El-Demiry and James, 1988). The ratio of T suppressor to T helper lymphocytes in semen indicates the prevalence of suppressing activity (Witkin, 1988). In the female, a dominance in the activity of T suppressor lymphocytes may exist. In mice, after their intravaginal exposure to sperm, an increase in the weight of the draining lymph nodes occurs that is not followed by antibody production, suggesting that a suppressive response may be stimulated in the lymph nodes (Beer and Billingham, 1978). Hill *et al.* (1987a) observed, in clear follicular fluid aspirated from follicles of women undergoing oocyte retrieval for *in vitro* fertilization, that the CD4<sup>+</sup>:CD8<sup>+</sup> T lymphocyte ratio, which is usually 2:1 in peripheral blood, is decreased dramatically in follicular fluid to 1:25, with a clear predominance of suppressor cells. T suppressor (CD8<sup>+</sup>) cells, which may function in the induction

of immune tolerance, also were found in the intraepithelial spaces of fallopian mucosa (Kutteh *et al.*, 1990).

### III. PATHOPHYSIOLOGY OF THE PRODUCTION OF ANTISPERM ANTIBODIES

Evidence exists in humans, as well as in other species, that both the male and the female reproductive tracts are able to participate in mucosal immunity and to secrete antibodies, primarily secretory IgA, locally (Ogra and Ogra, 1973; Mestecky and McGhee, 1987; Parr and Parr, 1990; Wira and Stern, 1990).

In women, subepithelial plasma cells have been identified in the fallopian tube, endocervix, ectocervix, and vagina (Kutteh *et al.*, 1988,1990). Approximately two-thirds of the immunoglobulin-positive cells contained IgA and J chain, indicating that they produce polymeric IgA. Secretory component (SC)-producing epithelial cells were found in the fallopian tube and endocervix. In addition, although the IgA1-containing plasma cells predominated in all tissues examined (except vagina), the relative proportion of IgA2 plasma cells was found to be increased compared with tissues such as bone marrow and spleen (Kutteh *et al.*, 1988). The number of plasma cells of all classes, including IgG and IgM, also was found to be 6- to 10-fold higher in infected fallopian tubes than in normal tubes, suggesting that a local immune system is functioning in the female genital tract (Kutteh *et al.*, 1990).

In addition, the local immune response may not be restricted geographically, since migration of lymphocytes between different mucosae can occur (McGhee and Mestecky, 1990). IgA precursor cells may populate remote secretory sites, including the uterus and the cervix, that differ from the initial site of immunization. Heremans and Bazin (1971) found plasma cells producing secretory IgA directed against specific antigens in nonlymphatic organs after oral immunization of mice with sheep red blood cells.

Evidence of lymphocyte trafficking in humans is suggested by the presence of specific secretory IgA antibodies against *Streptococcus mutans* in saliva and tears after their ingestion in gelatin capsules (Arnold *et al.*, 1976). The intragastric immunization of women with polio vaccine also results in the presence of antiviral IgA antibodies in both uterine and vaginal secretions (Ogra and Ogra, 1973).

Evidence also has been presented that an IgE-mediated allergic response to seminal plasma proteins may occur in vagina, leading to a chronic vulvovaginitis (Chang, 1976; Witkin, 1987) and perhaps to anaphylaxis (Halpern *et al.*, 1967). Skin testing with antigens indicated that this allergy is caused by hypersensitization to seminal plasma proteins, not by sperm cells (Halpern *et al.*, 1967). Although increased levels of IgE have been associated with infertility (Mathur *et al.*, 1981), no evidence has been presented for immunological infertility caused by specific antisperm IgE antibodies. The production of secretory IgA appears to be the most important local immune response to spermatozoa.

That the male reproductive tract can participate in a local

immune response to infections has been suggested by the finding that total IgA concentration is greater in the prostatic secretions than that of IgG or IgM. Total IgA in the presence of prostatitis has been found to be greater than total IgA in men with urinary tract infection. More than 50% of the total prostatic fluid IgA contains SC, suggesting local production or active transport from serum by prostatic epithelium. In prostatitis caused by *E. coli*, 90% of total IgA and IgG is *E. coli* specific. *Escherichia coli*-specific IgA concentration is 40 times higher in prostatic fluid than in serum, providing further circumstantial evidence that active IgA transport occurs in the prostate (Fowler and Mariano, 1982).

A mixture of IgA and IgG antisperm antibodies is observed in ejaculates of men with autoimmunity to sperm. Antisperm IgG is derived primarily as a transudate from serum, and its presence in the ejaculate correlates with the titer of circulating antisperm antibodies (Rumke, 1974). The local production of antisperm IgA in the male genital tract has been suggested both by its detection in semen although absent from serum and by the presence of antisperm antibodies with unique regional binding specificities on the spermatozoan surface that differ from those present in serum. In a study of 856 matched serum and semen samples, immunoglobulins primarily of the IgA class were detected on the sperm surface in 15% of cases (Pavia *et al.*, 1987). Hellstrom *et al.* (1988) also have demonstrated the presence of IgA on sperm despite its absence in serum, as detected by immunobead binding.

Since IgA is transported locally across mucosal surfaces through its association with SC, which is produced by epithelial cells, the finding of SC in association with IgA on the sperm surface is presumptive evidence for its local secretion, although not necessarily its local production (Parslow *et al.*, 1985; Meinertz *et al.*, 1990). Meinertz *et al.* (1990, 1991) have detected SC, utilizing a mixed agglutination reaction (MAR) test, on the surface of spermatozoa in men with autoimmunity to sperm.

Additional evidence for the involvement of local mucosal immunity in the production of antisperm antibodies comes from an analysis of IgA subclasses. Whereas monomeric IgA1 predominates in serum, immunoglobulins of the IgA2 class, in addition to IgA1, are present in mucosal secretions such as tears, saliva, and colostrum (Crago *et al.*, 1983; Delacroix *et al.*, 1983).

Using mouse monoclonal antibodies directed against the two different subclasses of human IgA (IgA1 and IgA2), and subsequently using immunobeads coated with anti-mouse immunoglobulins, Bronson and Cooper (1988) showed that a preponderance of IgA1 exists in the ejaculates of men with antisperm autoimmunity, although a wide variation was noted in the ratio of IgA1 to IgA2 among different patients. The varying proportion of antisperm IgA subclasses in different men might be a reflection of varying etiologies or different routes of immunization.

Conditions that result in an alteration in the balance between the exposure of the male or female immune system to sperm antigen and immunosuppressive factors may lead to antisperm antibody production (Table II).

Vasectomy is associated with autoimmunity to spermato-

**Table II** Summary of the Conditions Associated with the Production of Antisperm Antibodies

Men	Women
Disruptions of the blood-testis barrier	Factors depending on spermatozoa or seminal plasma
Vasectomy

Obstructions	
Cystic fibrosis	
Failure of the mechanisms of immunosuppression	
Decrease of T suppressor lymphocyte activity	
Lack of immunosuppressive factors in the seminal plasma?	
Abnormal expression of antigens on the sperm surface?	
Gastrointestinal exposure to spermatozoa (homosexuals)	

zoa in 60–70% of men (Alexander and Anderson, 1979), perhaps mediated by the absorption of an increased amount of sperm antigens that cannot be balanced by immunosuppressive factors. Testicular trauma (Haensch, 1973), torsion (Mastrogiacono *et al.*, 1982), biopsy (Hjort *et al.*, 1974), and tumors (Guazziero *et al.*, 1985) also have been associated with the production of antisperm antibodies. Witkin and Toth (1983) have presented evidence that genital tract infections, which can act as adjuvants for immune activation, are associated with antisperm antibody production. Nongonococcal urethritis, particularly urethritis resulting from *Chlamydia*, has been associated with antisperm autoantibodies (Shamanesh *et al.*, 1986). Even unilateral obstruction of the vas deferens may be responsible for antisperm antibody production (Hendry *et al.*, 1982). In addition, congenital obstruction of the vas deferens, seen in cystic fibrosis, has been associated with the appearance of antisperm antibodies (D'Cruz *et al.*, 1991).

Other possible causes of sperm antibody formation are related to the failure of immunosuppressive mechanisms. A decrease in the number or activity of T suppressor cells in the male genital tract or in semen has been postulated to play a role in the production of antisperm antibodies by B lymphocytes and plasma cells. In fact, men who underwent a vasectomy and whose semen contained antibody-labeled spermatozoa showed predominantly helper cells in their ejaculates (Witkin, 1988). In addition, the lack of immunosuppressive factors in the seminal plasma or the diminution of Fcγ receptors or their inactivity might induce an immune response in both men and women. Abnormal expression of antigens by spermatozoa or display of certain immunodomi-

nant antigens also has been proposed to cause lymphocyte activation (Mathur *et al.*, 1983,1988). An abnormal decrease in number or activity of T suppressor lymphocytes or an adjuvant action by bacteria in the female reproductive tract could, in theory, play a role in antisperm antibody production. Studies performed using immunoblot analysis of sperm antigen extracts showed that upper genital tract infections in women appear to be associated with the production of antisperm antibodies directed against antigens different from those involved in idiopathic immune infertility (Cunningham *et al.*, 1991).

A different pathogenesis of autoimmunity to spermatozoa has been suggested for homosexual men and for women who engage in oral and anal intercourse. Under experimental conditions, the rectal introduction of spermatozoa in rabbits elicits a systemic immune response (Richards *et al.*, 1984); gastric administration to rats of homologous spermatozoa results in an antisperm antibody production associated with decreased fertility (Allardyce, 1984). In humans, a higher prevalence of antisperm antibodies has been described in homosexual men than in heterosexual men from infertile couples (Witkin and Sonnabend, 1983, Bronson *et al.*, 1983; Table III). In 40–50% of homosexual men, antisperm antibodies can be detected in serum (Wolff and Schill, 1985). Bronson *et al.* (1983) observed a higher prevalence of antisperm antibodies of the IgM class relative to IgG and IgA in sera of homosexual men than in sera of autoimmune men from infertile couples. These researchers proposed that these differences might reflect differences in the etiology of autoimmunity to sperm in the two groups. Intrarectal ejaculation in cases of sodomy may lead to altered processing of antigens, since the single layer columnar epithelium of the rectum is much more permeable than the thick epithelium of the vagina. In addition, the population of B lymphocytes and plasma cells in the gastrointestinal tract is different from that present in the reproductive tract (Mestecky and McGhee, 1987), and the reactivity of these cells with sperm antigens might be different. Several lines of evidence have been presented that the large intestine is an organ in which plasma cells producing the IgA2 subclass of antibodies prevail (Kett *et al.*, 1986; Crago *et al.*, 1984). Intrarectal deposition of spermatozoa has been postulated to result in the stimulation of IgM- or IgA2-producing cells, which might then home to the genital tract, leading to the production of antisperm antibodies of this isotype and subclass within semen rather than to the

production of those present in immune infertile men (e.g., IgA1 and IgG).

#### IV. PATHOGENESIS OF INFERTILITY DUE TO ANTISPERM ANTIBODIES

Immunity to spermatozoa is not an all-or-nothing phenomenon, that is, the effects of antibodies on fertility depend on their titer, the class of immunoglobulin produced, the affinity for specific epitopes displayed by spermatozoa, the nature of the antigens involved, and other associated phenomena, such as the time between ejaculations.

Antisperm antibodies can affect the mechanisms of transport of spermatozoa within the female genital tract, can alter sperm capacitation or the acrosome reaction, can interfere with egg fertilization, or can have postfertilization effects on the zygote and pre-implantation early embryo.

##### A. Sperm Transport

As a first step in their passage through the human female genital tract, spermatozoa must penetrate and progress through cervical mucus to gain entry into the uterus and fallopian tubes. The association between abnormal or inhibited mucus penetration and the presence of antisperm antibodies was reported first when Fjallbrant (1969) demonstrated that antisperm antibodies, obtained from infertile patients or from immunized rabbits, are able to inhibit *in vitro* penetration of human cervical mucus by human spermatozoa.

Sperm penetration through cervical mucus *in situ* is evaluated clinically by means of the postcoital test, which in summary consists of the evaluation of number and motility of spermatozoa present in the cervical mucus 8–12 hr after intercourse at the time of ovulation. The results of a postcoital test depend on mucus quality, particularly sialic acid biochemistry (Lutjen *et al.*, 1984); sperm concentration in semen (Jette and Glass, 1972); the pattern of sperm motility (Mortimer *et al.*, 1986); and the proportion of spermatozoa labeled with antibodies (Bronson *et al.*, 1984a).

Many studies have demonstrated that antisperm antibodies affect sperm penetration into and motility within cervical mucus (Alexander, 1984; Bronson *et al.*, 1984a; Haas, 1986). The greater the proportion of antibody-bound sperm, the

**Table III** Comparison of Incidence of Antisperm Antibodies in Sera of Homosexual Men and Men from Infertile Couples Suspected of Immunological Infertility

	Number of serum samples	Antibody-negative sera (%)	Antibody-positive sera (%)	
			High levels <sup>a</sup>	Low levels
Homosexual males	60	21.7	50	28.3
Heterosexual infertile males	180	45.6	25.3	31.1

<sup>a</sup> More than 40% of spermatozoa bind immunobeads following preincubation with sera diluted at 1:4.

fewer sperm are able to enter and pass through cervical mucus; when all spermatozoa are coated with antibodies, seeing motile spermatozoa in the mucus is uncommon (Bronson *et al.*, 1984a). Hence, these men should be considered functionally oligospermic, despite normal sperm concentration in semen. Antisperm IgG and IgA have been found in the cervical mucus after its liquefaction with bromelain (Clarke *et al.*, 1984a). Kremer and Jager (1980) suggested that antibodies of the IgA class were responsible for the shaking of antibody-labeled spermatozoa within cervical mucus. These investigators postulated that IgA was attached via SC to glycoproteins of the cervical mucus. Later, Jager *et al.* (1981a) showed that IgG also induces a shaking phenomenon, suggesting that other mechanisms are involved, and implicated the Fc region of the immunoglobulin molecule. Disulfide exchanges between sulfhydryl residues of sperm-bound immunoglobulins and glycoprotein molecules of mucin have been suggested to lead to impairment of motility of antibody-labeled sperm within cervical mucus (Bronson *et al.*, 1984a). The fact that monoclonal antibodies raised in mice (Bronson and Cooper, 1987) and polyclonal antibodies raised in rabbits (Fjallbrant, 1969) impair the ability of human spermatozoa to penetrate cervical mucus suggests that this effect is not species specific. Studies performed using an IgA 1 protease derived from *Neisseria gonorrhoeae* demonstrated that the pretreatment of IgA-coated spermatozoa with this protease improved their mucus-penetrating ability (Bronson and Cooper, 1988). This protease cleaves a single peptide bond of the heavy chain of IgA1, liberating the Fc portion of the molecule (Plaut, 1983). The fact that IgA-labeled (but not IgG-labeled) spermatozoa treated with this protease show an improved ability to penetrate into and sustain motility within cervical mucus, although they remain coated with IgA Fab (Bronson *et al.*, 1987a; Table IV), suggests that the failure of cervical mucus penetra-

tion might not be related to the Fab portion of antibodies, nor to sperm surface antigens, but to the Fc portion. Alternatively, the effect might be caused by a different activity of univalent rather than multivalent IgA. However, these findings confirmed the earlier data presented by Jager *et al.* (1981b), which demonstrated that spermatozoa exposed to Fab preparations of antisperm IgA are able to penetrate cervical mucus, in contrast to those exposed to the intact immunoglobulins. On this basis, we can postulate that human cervical mucus possesses a receptor for the Fc portion of the immunoglobulin molecule. Monoclonal antibodies raised against spermatozoa from several species including humans (Anderson *et al.*, 1987), directed against epitopes present on the surface of live sperm, impaired human sperm penetration through a column of bovine cervical mucus whereas monoclonal antibodies directed against subsurface epitopes did not (Bronson and Cooper, 1987).

A correlation also has been observed between the regional specificity of antisperm antibodies to the spermatozoan surface and their ability to impair penetration of cervical mucus. Binding of IgG and IgA immunoglobulins to the tail tip of spermatozoa is not associated with an alteration of their mucus-penetrating ability (Bronson *et al.*, 1984b). In contrast, sperm-head directed antibodies, mainly those of the IgA class, as well as antibodies of both IgA and IgG classes directed against antigens on the principal piece of the sperm tail severely impair the ability of spermatozoa to penetrate mucus (Wang *et al.*, 1985).

Both the immunoglobulin class and the regional specificity of antibodies are important for the second mechanism of sperm transport impairment, that is, complement-mediated immobilization. IgG and IgM immunoglobulins are able to activate the complement cascade, which results in target cell lysis. Whereas a single molecule of IgM is necessary to lyse

<sup>b</sup> ND, None detected.

a red blood cell, approximately 1000 molecules of IgG are required (Humphrey and Dourmashkin, 1965). IgA does not activate the classical complement pathway. Complement proteins have been found in several secretions of the female genital tract, for example, those of the cervix (Price and Boettcher, 1979), uterus (Lint, 1980), fallopian tubes (Yang *et al.*, 1983), and ovarian follicle (Schumacher, 1980; Clarke *et al.*, 1984b; D'Cruz *et al.*, 1990). Price and Boettcher (1979), using hemolysis of red blood cells exposed to anti-red blood cell antibodies, showed that the complement activity in cervical mucus is much lower than that in serum (10%). This observation may explain why complement-mediated sperm immobilization within cervical mucus does not take place immediately after sperm penetration into the cervical mucus, but requires 4–8 hr. The regional specificity of antibody binding to the spermatozoan surface is also an important factor in complement-mediated immobilization. IgG antibodies directed against the head, the distal one-fifth of the sperm tail principal piece, or the tail end piece were found to be ineffective in promoting complement-mediated loss of sperm motility, whereas a high degree of sperm immobilization was observed when IgG binding occurred on a majority of the principal piece of the sperm tail or when IgM labeled the tail end piece (Bronson *et al.*, 1982b). Hence, the amount of antibody, its location, and its isotype all play a role in sperm immobilization.

An accessory mechanism of interference with fertilization by antisperm antibodies may be antibody-dependent cell-mediated cytotoxicity (ADCC). Macrophages that populate the female genital tract may interact with the Fc portion of immunoglobulins or with C3 fixed by IgG and IgM antibodies and phagocytosis may be promoted, as demonstrated by the lysis of <sup>111</sup>In-labeled spermatozoa by peritoneal macrophages when spermatozoa were covered with specific antibodies (London *et al.*, 1985).

### B. Sperm Capacitation and Acrosome Reaction

Fresh ejaculated spermatozoa are not able to penetrate oocytes and must undergo a series of calcium-dependent biochemical and structural changes before they become capable of fusing with the egg plasma membrane. First, spermatozoa must undergo plasma membrane modifications termed capacitation, which render them able to undergo the acrosome reaction. This latter process consists of loss of the plasma membrane of the rostral portion of the spermatozoan head, shedding of the acrosomal cap (a modified secretory granule situated over this region of the sperm head), and exposure of the inner acrosomal membrane (Yanagimachi, 1988). Only acrosome-reacted sperm can penetrate the zona pellucida and fuse with the egg plasma membrane. The release of the acrosomal contents—which consist of the enzymes acrosin, a trypsin-like protease, and hyaluronidase—plays a role in spermatozoan passage through the cumulus oophorus and the zona pellucida, allowing its contact with the oolemma, the egg plasma membrane. Evidence has been presented that antisperm antibodies may induce a premature acrosome reaction (Lansford *et al.*, 1988) which

may alter the ability of sperm to penetrate the zona, so their fertilizing life-span may be shortened (Wolf, 1989). Bronson *et al.* (1987b), demonstrated that antisperm antibodies of the IgG class directed against the rostral portion of the head, in the presence of complement, are able to increase the number of acrosome-reacted spermatozoa, as detected by ultrastructural studies. Other antibodies might have an opposite effect on the acrosome reaction, since a monoclonal antisperm antibody has been reported to block the calcium ionophore-induced acrosome reaction (Wolf, 1989).

### C. Sperm–Egg Interaction

Antisperm antibodies directed against antigens involved in the interaction between the male and the female gametes may alter fertilization by affecting the ability of spermatozoa to bind to the zona pellucida as well as the fusion between the spermatozoan and egg plasma membranes.

Several lines of evidence have been presented that indicate that antisperm antibodies may interfere with sperm recognition of the zona pellucida, in other mammals and in humans. During the process of fertilization, spermatozoa bind to species-specific receptors on the zona pellucida. In mice, several monoclonal antibodies are able to inhibit the binding of spermatozoa to zona pellucida (Saling and Lakosky, 1985). In guinea pigs, autoantibodies induced by vasectomy block zona binding and *in vitro* fertilization (Huang *et al.*, 1981). A specific autoantigen, RSA-1, was demonstrated in the rabbit to be involved in zona recognition by the ability of specific antisera to block fertilization (O'Rand, 1981). In a series of experiments performed with donor spermatozoa exposed to sera containing antisperm antibodies, Bronson *et al.* (1982a) showed that the presence of these antibodies on the sperm surface interferes with their recognition of salt-stored zonae pellucidae of oocytes obtained from human ovaries that had been removed surgically. When the titer of antisperm antibodies was lowered by absorption of these sera with spermatozoa before their exposure to test sperm, a partial recovery of zona binding ability could be observed. These experiments also suggested that the isotype of antisperm antibody bound to the head may be important in determining the degree of impairment of sperm zona binding, since IgA was more inhibitory than IgG. In addition, the total immunoglobulin labeling of the sperm surface appeared to be an important prognostic factor: when 100% of spermatozoa were antibody labeled, the impairment of zona binding was more evident. A similar experiment using live oocytes obtained by follicular aspiration for *in vitro* fertilization confirmed these findings for the effect of antisperm antibodies (Tsukui *et al.*, 1986). Further studies, performed using salt-stored human zonae pellucidae (Yanagimachi *et al.*, 1979) that were bisected to allow each egg to act as its own control, have demonstrated that antibodies directed against the sperm head can affect zona binding (Mahoney *et al.*, 1990), but not in every case. This result suggests that the zona binding impairment depends on the antigens against which antibodies are directed, that is, whether these antigens are the functional epitopes of a zona receptor ligand.

Many studies also have been performed on the effect of antisperm antibodies on sperm–oolemmal fusion, using the ability of zona-free hamster oocytes to be penetrated by capacitated human spermatozoa. Yanagimachi *et al.* (1976) reported that hamster eggs removed from their vestments (the cumulus oophorus and the zona pellucida) could be penetrated by acrosome-reacted sperm of several species, including humans. Several investigators have shown that homologous antibodies can affect the penetration of hamster oocytes by human spermatozoa (Alexander, 1984; Dor *et al.*, 1981; Requena *et al.*, 1983; Haas *et al.*, 1985; Abdel-Latif *et al.*, 1986). In some studies, the inhibitory properties were found to be retained by IgG fractions of antisera (Haas *et al.*, 1980; Alexander, 1984). In one study, the Fab fractions from three antisera also were found to be inhibitory (Menge *et al.*, 1984). In apparent contrast with these findings, Bronson *et al.* (1981) found that some sera containing antisperm antibodies promote the penetration of zona-free hamster eggs by human spermatozoa after enhancing their oolemmal adhesion. These observations were confirmed by Aitken *et al.* (1987,1988), who showed that purified IgG from sera of patients containing antisperm antibodies can promote human sperm penetration of zona-free hamster eggs, inhibit penetration, or be inactive. Bronson *et al.* (1990a) observed that, when antisperm antibodies promoted penetration, the number of oolemmal-adherent antibody-labeled sperm was increased greatly (Table V). However, once these antibody-labeled sperm adhered to the oolemma, their chance of penetrating the egg was the same as that of antibody-free spermatozoa from the same ejaculate. This finding suggests that the promotion of egg penetration by antisperm antibodies is caused solely by their promotion of sperm–oolemmal binding. Evidence has been presented that Fc $\gamma$  receptors, present on the oolemma of both hamster (Bronson *et al.*, 1990b) and human (Bronson *et al.*, 1991) oocytes, may account for the increased adherence of antibody-labeled sperm to eggs. Zona-free hamster eggs, preincubated with IgG Fc to occupy oolemmal Fc $\gamma$  receptors, bound fewer IgG-labeled spermatozoa than unexposed eggs. Via Fab preparations of monoclonal antibodies directed against Fc $\gamma$ RI, Fc $\gamma$ RII, and Fc $\gamma$ RIII, all three receptors were demonstrated to be present on the oolemma of unfertilized human eggs; their ability to bind human and mu-

rine IgG-Fc was shown also (Bronson *et al.*, 1991). The promotion of oolemmal binding of spermatozoa coated with anti-sperm antibodies via the interaction of oolemmal Fc receptors and the Fc portion of immunoglobulins could lead to a higher number of sperm penetrations. This mechanism could result *in vivo* in polyspermic fertilization of oocytes, diminishing the chances of reproductive success, since polyploid embryos exhibit diminished preimplantation growth potential and a higher rate of spontaneous abortion (Hassold *et al.*, 1980).

Conversely, in cases in which the penetration of oocytes is inhibited by antisperm antibodies, these antibodies are likely to be directed against fertilization antigens that play a role in sperm–egg plasma membrane fusion. Antibodies directed against the rabbit antigens RSA-1, 2, and 3, which also cross-react with human spermatozoa, block penetration of zona-free hamster oocytes by these spermatozoa (O'Rand and Irons, 1984). Naz *et al.* (1984) have identified a 23-kDa sperm membrane glycoprotein (FA-1) and have demonstrated that a monoclonal antibody directed against FA-1 completely blocks the fertilization of zona-free hamster oocytes by human spermatozoa. The monoclonal antibody MH61, raised against human spermatozoa and reacting mainly with capacitated and acrosome-reacted sperm (being barely reactive with fresh sperm), was found to inhibit the penetration of hamster eggs by human spermatozoa almost completely (Okabe *et al.*, 1990).

Evidence that peptides containing the Arg–Gly–Asp sequence (RGD), a recognition sequence involved in many cell–cell adhesion mechanisms (Ruoslahti and Piershbacher, 1986), interfere with oolemmal adhesion and sperm penetration of hamster oocytes (Bronson and Fusi, 1990a,b), suggests that this sequence also is involved in the binding of spermatozoa by the oolemma. The presence of RGD-binding moieties on the oolemma of hamster (Bronson and Fusi, 1990a) and human (Fusi *et al.*, 1991) oocytes, and the detection of RGD-containing proteins such as fibronectin, vitronectin, and laminin on the surface of capacitated human spermatozoa (Fusi *et al.*, 1992a,c), might indicate that these molecules are involved in sperm–oolemmal interaction. Anti-sperm antibodies directed against these glycoproteins, either from infertile couples or produced experimentally, could inhibit penetration of hamster and human eggs by spermatozoa.

**Table V** Effects of Different Antisperm IgG, Directed against the Sperm Head, on the Ability of Human Spermatozoa to Adhere to and Penetrate Zona-Free Hamster Eggs

Serum number	Number of eggs	Mean oolemmal adherent sperm (range)	Eggs penetrated (%)	Penetrating sperm per egg
1	15	33 (12–64)	67	1.4
2	29	55 (27–85)	93	2.9
3	27	71 (43–121)	100	8.2
4	28	78 (49–112)	100	5.2
5	27	110 (68–152)	100	6.5
6	29	140 (92–184)	100	8.2
Control	29	25 (13–41)	78	1.7

Preliminary evidence for this idea comes from experiments in which *in vitro* exposure of human spermatozoa to monoclonal and polyclonal antifibronectin antibodies partially inhibits their binding to and penetration of hamster oocytes (Fusi and Bronson, 1991; Table VI).

Retrospective and prospective analysis of fertilization data from programs performing *in vitro* fertilization provide another means of assessing the possible effects of anti-sperm antibodies on fertilization. Clarke and associates (1985b, 1986) have shown that fertilization could be achieved at higher frequencies in women with humoral antisperm antibodies when culture medium was supplemented with nonimmune serum in place of the patient serum. These data suggest that the presence of antisperm antibodies in the *in vitro* fertilization culture medium results in an impairment of fertilization. Immunoglobulins of the IgA class appeared to be more effective in impairing fertilization than those of the IgG class. A more critical examination of the results of *in vitro* fertilization in women with immunities to sperm has revealed both a diminished fertilization rate and a diminished embryonic cleavage rate, resulting ultimately in a diminished chance of pregnancy (Vasquez-Levin *et al.*, 1991). In this study, bovine serum albumin was used in the culture medium in lieu of patient serum if significant levels of serum antisperm antibodies were present. In these women, 44% of eggs were fertilized in 50 cycles compared with 75% for the bovine serum albumin controls. The percentage of high-quality embryos was 49% in the immunologically infertile group compared with 75% for the control subjects. Clinical pregnancies occurred in 10 individuals of the former group, compared with 18 in the latter. Although the results are promising because they illustrate that significant pregnancy rates can be achieved in these couples despite the presence of antisperm antibodies, these results suggest that these antibodies cannot be eliminated from the egg by washing, hence impairing fertilization, or that the antibodies may be cytotoxic to the egg.

Clarke *et al.* (1985a) and De Almeida *et al.* (1989) studied the relationship between antisperm antibodies in the ejaculates of men with autoimmunity to sperm and human *in vitro* fertilization. Both groups found that, when more than 80% of spermatozoa were labeled with head-directed IgA or a combination of IgA and IgG, a low fertilization rate of human oocytes was seen. In another study, Junk *et al.* (1986) sug-

gested that fertilization rates were affected adversely if the autoimmunity against spermatozoa was caused by associated IgG and IgA antibodies, whereas impairment was less evident when only IgG or IgA was present. These researchers concluded that inhibition of fertilization may be caused by a synergistic effect of both classes of antibodies. Although these studies are suggestive, the analysis of the effects of antisperm antibodies on *in vitro* fertilization is quite difficult. In effect, the small number of patients makes a serious statistical analysis difficult because the association of nonimmunological factors relating to egg quality and sperm penetrating ability may bias the results in a group.

#### D. Effects of Antisperm Antibodies on Reproduction after Fertilization

Evidence that spermatozoa share antigenic specificities with fertilized ova and cleaving embryos has been demonstrated by several authors in several mammalian species. In guinea pigs (Behrman and Otani, 1963; Otani *et al.*, 1963; Kiddy and Rollins, 1973) and in rabbits (Sawada and Behrman, 1966), researchers have shown that immunization with spermatozoa had little effect on fertilization but resulted in a much greater incidence of postfertilization embryonic losses. Menge (1970), using rabbits, demonstrated that isoimmunization of females with sperm or testis, but not seminal plasma, resulted in an impaired chance of embryonic survival to term. In addition, a reduction in the survival of fertilized eggs transferred to immunized pseudo-pregnant females was observed in relation to those transferred to nonimmunized controls. Subsequently, the same authors (Menge and Lieberman, 1974; Menge *et al.*, 1974) found that antisperm IgA obtained from the uterus of rabbits immunized with homologous spermatozoa led to degenerative changes in morulas and blastocysts when cultured *in vitro* in its presence, whereas antisperm IgG did not. Menge and Naz (1988) suggested three mechanisms by which antisperm antibodies can affect embryo survival.

The first mechanism consists of the possibility that sperm surface antigens are incorporated into the zygotic membrane at fertilization. Fertilization involves the fusion of sperm and oolemma plasma membranes, leading to a mixture of anti-

**Table VI** Effects of Anti-Fibronectin Antibodies on the Adhesion and Penetration of Zona-Free Hamster Eggs by Human Spermatozoa

Antibody	Eggs penetrated (%)	Penetrating sperm per egg	Number of oolemmal adherent sperm
Mouse anti-FN Monoclonal Antibody	6.6	0.06 ( $p = 0.001^a$ )	26.2 ± 7.5 ( $p = 0.005^a$ )

<sup>b</sup> Control consisted of MOPC21, a mouse myeloma IgG protein.

gens. In rabbits, O'Rand (1977) presented evidence that sperm antigens were transferred to eggs after fertilization. Gaunt (1983) showed the same phenomenon in rats, using a monoclonal antibody directed against a single antigen, and demonstrated that the incorporated antigen was no longer present on the zygote plasma membrane after the first cleavage division. In humans, Wiley *et al.* (1987) demonstrated that some antisperm antibodies present in sera of infertile couples could react with hamster oocytes penetrated by human spermatozoa, as judged by complement-dependent lysis, but not with unpenetrated oocytes, suggesting that antigens could be transferred to the oolemma at the time of fertilization.

The second mechanism proposed is that similar epitopes are present on spermatozoa and embryos. Several common antigens have been found, including the nervous system antigens NS-4 and NS-7 (Solter and Schachner, 1976; Chaffee and Schachner, 1978). Oncofetal antigens also have been observed on both sperm and embryos, for example, teratocarcinoma antigen OTT6050 (Webb, 1980), PCCC4 (Gachelin *et al.*, 1977) PYS-2 (Artzt *et al.*, 1976), and F-9 (Artzt *et al.*, 1973). Antibodies raised against teratocarcinoma cells, mainly those directed against F-9 (Hamilton *et al.*, 1979; Johnson *et al.*, 1979), have been reported to induce both infertility and preimplantation loss (Hamilton *et al.*, 1979). Different antigens, such as the TLX antigen (Anderson *et al.*, 1989) commonly found on trophoblasts, also have been found on sperm surfaces after capacitation.

Another proposed mechanism to account for postfertilization reproductive loss mediated by antisperm antibodies is an indirect effect of antibodies on embryo development. The release of lymphokines, monokines, interleukins, and tumor necrosis factors from women sensitized to sperm after their exposure to semen could affect embryo development. Several studies, in fact, have demonstrated that those substances are cytotoxic to preimplanting embryos (Faikih *et al.*, 1987; Hill *et al.*, 1987b). However, despite laboratory data, no clear clinical evidence has been found in humans for an association between perinidatory early pregnancy loss and immunities to spermatozoa.

## V. SUMMARY

Antisperm antibodies are able to interfere, through several mechanisms, with all stages of human fertilization, and may exhibit postfertilization effects on embryonic growth as well. Antisperm antibodies of the IgA class appear to be particularly able to affect reproductive outcome of patients sensitized to spermatozoa, suggesting that the local immune response could be important in infertile couples. Several of the mechanisms responsible for these effects appear to involve specific antigens, whereas others (particularly those impairing sperm transport) may be related to the Fc portion of the immunoglobulin molecule. Hence, the determination of the epitopes specifically involved in binding of spermatozoa to the zona pellucida and in sperm-oolemmal interaction

appears to be a necessary step in the assessment of the reproductive prognosis of these individuals.

Spermatozoa must traverse the female reproductive tract, a part of the greater common mucosal immune system, to reach the oocyte. That the interaction of gametes occurs therein suggests that aberrant local immunological responses could play a significant role in human infertility. Increasing knowledge of the normal regulation of immunoglobulin production and secretion within the genital tracts of men and women, as well as of the response of the mucosal immune system of the reproductive tracts to microbial pathogens, will allow us to substantiate this thesis.

# Endocrine Regulation of Mucosal Immunity: Effect of Sex Hormones and Cytokines on the Afferent and Efferent Arms of the Immune System in the Female Reproductive Tract

Charles R. Wira • Jan Richardson • Rao Prabhala

## I. INTRODUCTION

Optimal immune protection at mucosal surfaces is dependent on the secretory immune system, which responds to both viral and bacterial pathogens (for reviews see Heremans, 1974; Mestecky and McGhee, 1987). Characterized by the presence of secretory IgA and IgG (Ogra *et al.*, 1981; Brandtzaeg and Prydz, 1984), immune protection is dependent on T and B lymphocytes, monocytes, and macrophages, as well as on other antigen-presenting cells that monitor the external environment and respond to antigenic challenge (McDermott and Bienenstock, 1979; Underdown and Schiff, 1986). After the recognition of antigen, immune protection is conferred through humoral and cell-mediated components of the mucosal immune system which respond by cytotoxic mechanisms (Shen and Fanger, 1981), the production of specific antibodies (Williams and Gibbons, 1972; Heremans, 1974), and phagocytosis (Fanger *et al.*, 1983) to destroy potential pathogens or exclude them from gaining access to the body.

Within the female reproductive tract, the mucosal immune system has evolved to protect against potential pathogens without compromising fetal survival (Harbour and Blalock, 1989; Wira and Stern, 1992). Periodically exposed to allogeneic sperm and to a fetal-placental unit that is immunologically distinct, the mucosal immune system within the uterus, cervix, and vagina is controlled precisely by the female sex hormones to optimize both maternal and fetal survival (Wira and Sandoe, 1977; Schumacher, 1980; Sullivan *et al.*, 1984). Depending on the site analyzed and the reproductive state (endocrine balance), immunocompetency of the female reproductive tract may be enhanced or suppressed to meet maternal and fetal needs (Wira and Stern, 1992).

Despite the effectiveness of immune protection, sexually transmitted diseases (STD) represent a major global health problem that threatens both adult and newborn (Cates, 1986; Piot *et al.*, 1988). The limited success achieved in controlling gonorrhea, herpes simplex virus 2, pelvic inflammatory disease, group B *Streptococcus*, *Chlamydia*, and human immunodeficiency virus (HIV), the causative agent of acquired immunodeficiency syndrome (AIDS) (Peterman and Curran,

1986; McDonough, 1987), demonstrates the need for a better understanding of the elements of the secretory immune system in the female reproductive tract and the ways in which the endocrine system regulates immune function at these sites.

Previous studies have shown that both oral and reproductive tract immunization can lead to the presence of specific antibodies in uterine and vaginal secretions. Ogra and Ogra (1973) demonstrated that inactivated poliovirus, given orally or deposited locally into the uterus or vagina of women, generated IgG antibodies in uterine and cervicovaginal secretions. In contrast, when horseradish peroxidase was placed in the uterus, no antibody response was detected (Vaerman and Ferin, 1974). Several studies focusing on vaginal and cervical deposition of antigen have demonstrated local antibody production in the lower genital tract (Kerr, 1955; Bell and Wolf, 1967; Yang and Schumacher, 1979; Parr *et al.*, 1988). That gastrointestinal, intrauterine, and pelvic immunization lead to the accumulation of antibodies in genital tract secretions (Wira and Sandoe, 1987, 1989; Wira and Prabhala, 1992) also shows that specific IgA and IgG antibodies in uterine, cervical, and vaginal secretions are derived from distal and local (genital tract) exposure to antigen. Despite this progress, much remains to be learned about the mechanisms by which immune protection is conferred within the reproductive tract and the ways in which sex hormones and selected cytokines regulate immune events at mucosal surfaces.

Implicit in the ability of the female reproductive tract to respond to local antigen exposure is the requirement that antigen-presenting cells recognize and present antigen to T lymphocytes (Ziegler and Unanue, 1981; Weinberger *et al.*, 1981). At other sites in the body, for example, macrophages (Rosenthal and Shevach, 1973) as well as B lymphocytes (Ashwell *et al.*, 1984), dendritic cells (Steinman and Nussenzweig, 1980), keratinocytes (Gaspari and Katz, 1988), Langerhans cells (Aiba and Katz, 1991), and epithelial cells have been shown to present antigen. Antigen presentation is characterized by the internalization and processing of exogenous antigen to immunogenic fragments, which then are presented

in combination with major histocompatibility complex (MHC) Class II molecules to T lymphocytes. These events, in turn, lead to the production of cytokines that mediate cellular and humoral immune responses (Balkwill and Burke, 1989). Despite the absence of aggregated follicles similar to Peyer's patches in the gastrointestinal tract, the reproductive tract contains B lymphocytes, macrophages, and dendritic cells as well as epithelial cells that are potentially capable of presenting antigen. Within the reproductive tract, endometrial cells of the uterus express MHC Class II molecules that are under estradiol and cytokine control (Head and Gaede, 1986; Tabibzadeh *et al.*, 1986a,b). The identification of interferon  $\gamma$  (IFN $\gamma$ ) receptors in the uterus (Tabibzadeh, 1990), interleukin 1 (IL-1) and IL-6 production by uterine cells (Takacs *et al.*, 1988; Tabibzadeh *et al.*, 1989), and the important observation that estradiol stimulates IFN $\gamma$  mRNA production by lymphocytes (Fox *et al.*, 1991) provide evidence for the complex interactions that exist between hormones and cytokines in the regulation of mucosal immunity in the female reproductive tract.

In this chapter, we present studies from our laboratory that define the roles of steroid hormones in regulating the efferent (response) arm of the mucosal immune system in the female reproductive tract. We include our most recent findings that demonstrate that the afferent (inductive) arm of the immune system exists in the female reproductive tract and is controlled by sex hormones and cytokines. Particular attention is paid to the mechanisms by which hormones and cytokines exert their effects, during the reproductive cycle as well as after exogenous hormone administration. The data presented in this chapter indicate that the regulation of reproductive tract mucosal immunity is the result of a precise interplay between sex hormones and cytokines. Further, they

indicate that sex hormones and cytokines, working together, are major contributors to the maintenance of immune function. Finally, these studies emphasize that immune function and its regulatory control within the fallopian tube, uterus, cervix, and vagina are separate and distinct, and that each site must be analyzed in the context of the unique contributions it makes to procreation and to maternal and fetal protection.

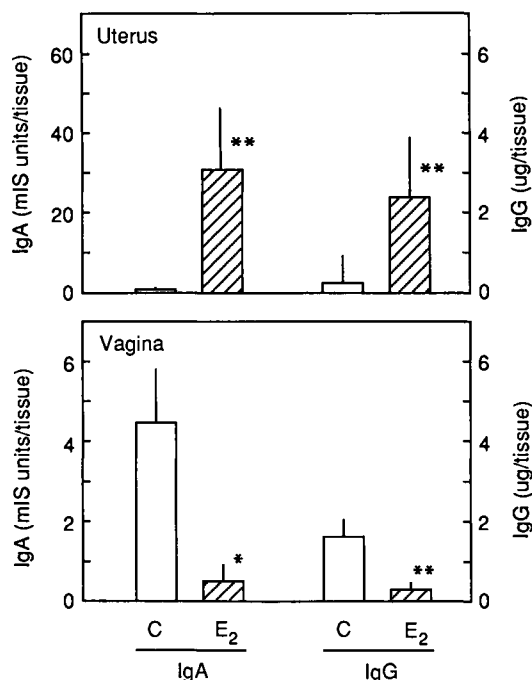

## II. SEX HORMONE AND GLUCOCORTICOID REGULATION OF MUCOSAL IMMUNITY

Figure 1 shows results from our laboratory in 1977 that demonstrated that IgA and IgG levels in uterine secretions change markedly in intact rats during the reproductive cycle; higher levels are measured at the time of ovulation than at any other stage of the cycle (Wira and Sandoe, 1977). These observations led to the conclusion that estradiol and progesterone are the principle hormones responsible for regulating IgA and IgG in uterine secretions. As seen in Figure 2, when ovariectomized rats were treated with estradiol, IgA and IgG levels in uterine secretions were elevated relative to saline controls (Wira and Sandoe, 1980). We unexpectedly found that IgA and IgG levels in cervicovaginal secretions were controlled hormonally. Unlike the uterus, however, levels here were lowered in response to hormone treatment (Wira and Sullivan, 1985). These responses are separate and distinct, since uterine ligation had no effect on the hormone response of IgA and IgG to estradiol treatment. We also found that the uterine response was specific for estradiol, that progesterone blocks estradiol-stimulated increases in uterine

**Figure 1** Immunoglobulin A and G levels in uterine secretions of adult female rats at various stages of the estrous cycle and following castration. Values represent the mean  $\pm$  SEM of 5–8 rats per group. IgG values (open bars) are expressed as  $\mu$ g per uterus, IgA results (hatched bars) as immunocytoma serum (IS) units, where 1.0 IS unit is defined as a concentration of 1 mg lyophilized immunocytoma serum in 1 ml distilled water. Values of IgA and IgG at proestrus and estrus are significantly different from those measured during diestrus and following castration ( $P < 0.01$ ). No significant differences were measured in serum samples. Adapted with permission from Wira and Sandoe (1977).

**Figure 2** The influence of estradiol on immunoglobulin A and G levels in uterine (*top*) and vaginal (*bottom*) secretions. Ovariectomized rats were injected with estradiol (E<sub>2</sub>; 1  $\mu$ g/day) or saline (C) for 3 days prior to sacrifice 24 hr after the third injection. Each bar represents the mean value of 5–7 animals per group. The vertical line on each bar represents the standard error (SE). \*, Significantly ( $P < 0.05$ ) different from control (saline); \*\*, significantly ( $P < 0.01$ ) different from control. Reprinted with permission from Wira and Sandoe (1987b).

IgA and IgG, and that progesterone either alone or with estradiol inhibits cervicovaginal levels of IgA and IgG.

Since IgA is transported into secretions at mucosal surfaces by secretory component (SC), the external domain of the polymeric IgA receptor (for review, see Mestecky and McGhee, 1987), studies were undertaken to determine whether SC is also under hormonal control. As seen in Figure 3, when estradiol was given to ovariectomized rats for 3 days, SC levels increased sharply, in parallel with IgA in uterine secretions (Sullivan *et al.*, 1983). In contrast, SC levels in cervicovaginal secretions were reduced markedly in response to estradiol treatment (Wira and Sullivan, 1985). Subsequent studies showed that, whereas IgA of blood origin enters uterine tissues within 2–4 hr of each injection of estradiol, IgA movement from tissue to lumen takes place only after uterine epithelial cells produce SC in response to estradiol or IFN $\gamma$  (Prabhala and Wira, 1991).

An apparent paradox involving the time required for estradiol to exert a stimulatory effect on uterine SC levels was resolved when animals were ovariectomized on day 2 of diestrus, just after estradiol had been released by the ovary. Under these conditions, uterine SC levels increased within 16 hr of hormone stimulation (Wira and Stern, 1985). Since the earliest response occurs approximately 3 days after estradiol is given to ovariectomized rats, these findings indicate

that, when uterine tissues are deprived hormonally by ovariectomy, more time is required for hormones to exert their actions on cell growth.

To examine the mechanisms by which estradiol exerts its effect on uterine SC, uteri from saline- and estradiol-treated rats were incubated with actinomycin D (Figure 4) and cycloheximide (not shown). SC accumulation in the incubation media was inhibited, suggesting that hormonal regulation of uterine SC is mediated through mRNA and protein synthesis (Wira *et al.*, 1984). We used the SC cDNA probe (Banting *et al.*, 1989) to measure rat uterine SC mRNA levels in the presence or absence of estradiol. As seen in Table I, when ovariectomized rats were treated with estradiol daily for 3 days, SC mRNA levels increased after the second and third injection of estradiol (Morganielli *et al.*, 1991). Although preliminary, these findings suggest that estradiol increases uterine SC levels by increasing SC mRNA levels in uterine tissues. In other studies (not shown), we have found that SC mRNA levels in vaginal tissues are lowered in response to hormone treatment. Studies are currently underway to deter-

**Figure 3** Time course of the effect of 1, 2, or 3 estradiol treatments on secretory component (SC) (*bottom*) and IgA (*top*) content in uterine secretions of ovariectomized rats. Animals were injected with either estradiol (E<sub>2</sub>; 2  $\mu$ g/day) or saline (controls; indicated as 0 time point). Each value equals the mean  $\pm$  SE of 4 (E<sub>2</sub>) or 12 (saline) determinations. The levels of IgA are reported as immunocytoma (IS) units, as previously described (Wira and Sandoe, 1980). Reprinted with permission from Sullivan *et al.* (1983).

**Figure 4** Antagonism by actinomycin D of the estradiol-induced increase in uterine secretory component (SC) *in vitro*. After 3 days of *in vivo* estradiol (1 µg/day) or saline treatment of ovariectomized rats (4 animals per group), uterine horns were divided and were placed either in incubation medium or in medium with actinomycin D (20 µg/ml). The curves shown are as follows: (A) estradiol; (B) estradiol/actinomycin D; (C) saline; (D) saline/actinomycin D. Numbers represent the mean  $\pm$  SE of samples taken at the indicated time point. \*\*, Significantly greater than the value from estradiol-treated uteri in actinomycin D-containing media. Reprinted with permission from Wira *et al.* (1984).

mine whether estradiol influences synthesis or stability of SC mRNA in reproductive tract tissues.

To examine the role of other steroid hormones in regulating SC and IgA levels in uterine secretions, ovariectomized animals were treated with estradiol, progesterone, or dexamethasone, a synthetic glucocorticoid. As seen in Figure 5, dexamethasone and progesterone, given with estradiol for 3 days, had pronounced inhibitory effects on uterine IgA levels. In contrast, dexamethasone, unlike progesterone, had no effect on SC levels (Sullivan *et al.*, 1983). These findings indicate that glucocorticoids influence mucosal immune responses to estradiol in the female reproductive tract in a different way than progesterone.

To examine more fully the role of glucocorticoids in influencing mucosal immune responses, dexamethasone was given to ovariectomized animals for 1, 2, and 3 days. As seen in Figure 6, IgA levels in serum were significantly higher in dexamethasone-treated rats than in saline-treated rats (Wira *et al.*, 1990). In contrast, IgA levels in salivary (and vaginal, not shown) secretions were lowered in animals treated with dexamethasone. In other studies (not shown), we found that dexamethasone raises specific IgA antibodies in serum and lowers antibody levels in secretions after Peyer's patch priming and uterine boosting with sheep red blood cell (SRBC) antigen. This result suggests that glucocorticoids cause a redistribution of IgA from mucosal surfaces to serum, possibly to enhance systemic immune protection. To determine whether glucocorticoids influence SC levels in serum, animals were treated with dexamethasone for 1, 2, or 3 days

(Wira and Rossoll, 1991). Under these conditions, SC levels in serum increased significantly with dexamethasone treatment. Our finding that SC in serum is associated with polymeric IgA suggests that, by increasing serum SC levels, dexamethasone may be decreasing SC-mediated clearance of IgA from blood into bile. In other studies, we found that dexamethasone stimulates SC production by rat hepatocytes (Wira and Colby, 1985), suggesting that serum SC, which has a molecular mass of 29 and 27 kDa, may be of liver origin. Additional studies are needed to identify the origins of serum SC and to determine whether IgA antibodies in serum after dexamethasone stimulation exert a protective effect against systemic antigenic challenge.

### III. ROUTES OF IMMUNIZATION AND HORMONALLY STIMULATED ANTIBODIES IN MUCOSAL SECRETIONS

To identify the origins of antibodies and the role of hormones in regulating their presence in reproductive tract secretions, adult female rats were immunized via Peyer's patches (pp), intraperitoneally (ip), and subcutaneously (sc), and boosted 6 days later with SRBC, a known T cell-dependent antigen. Uterine secretions were collected from uterine-ligated animals after each rat had gone through two normal estrous cycles. As seen in Figure 7, when animals were immunized pp or ip, specific anti-SRBC IgA antibodies were found in uterine and cervicovaginal secretions (Wira and Sandoe, 1987). IgG antibodies were found in uterine but not in cervicovaginal secretions. In contrast, sc immunization resulted in a weak uterine IgG antibody response but failed to elicit an IgA response.

The role of estradiol in the accumulation of specific antibodies in reproductive tract secretions is shown in Figure 8. After priming (pp) and boosting (pp) with SRBC, little antibody was found in ovariectomized animals that received saline. With estradiol treatment, IgA and IgG antibodies in-

**Table 1** Effect of Estradiol on Secretory Component mRNA Levels in Uterine Tissues of Ovariectomized Rats<sup>a</sup>

	Estradiol treatment on day			
	0	1	2	3
SC mRNA (area/slot)	$\pm$	+	+++	+++

<sup>a</sup> RNA was extracted from uteri of rats (7–12 animals/group) treated with estradiol (1 µg/day) for 1, 2, or 3 days prior to sacrifice 24 hr later. Control animals received saline for 3 days. RNA was extracted essentially by homogenization in RNA extraction buffer as described by Sambrook *et al.* (1989). Poly(A) + RNA was isolated on oligo(dT)-cellulose. Poly(A) + RNA (50 µg) was used for slot blot analysis and probed with <sup>32</sup>P-labeled secretory component (SC) cDNA, kindly provided by G. Banting. Hybridization signals for each group were quantified by densitometry. Amount of SC mRNA:  $\pm$ very low; + low; ++ medium; +++ high.

**Figure 5** Antagonism by dexamethasone and progesterone of the uterine secretory component (SC) (*bottom*) and IgA (*top*) responses to estradiol. Ovariectomized rats with uterine ligations received saline (NS), dexamethasone (DEX; 1 mg/day), or progesterone (P; 2 mg/day) approximately 30 min before an injection of saline or estradiol (E<sub>2</sub>; 1 µg/day). Animals were killed 24 hr after the third injection. Numbers represent the mean ± SE of 5–6 values. Reprinted with permission from Sullivan *et al.* (1983).

creased in uterine secretions relative to control animals. To study the effectiveness of the uterus in responding to antigenic challenge, ovariectomized rats were immunized by placing SRBC directly into the uterine lumen (Wira and Sandoe, 1989). As seen in Figure 8, uterine (ut/ut) immunization resulted in pronounced IgA and IgG antibody responses in the immunized horns that were 20- to 30-fold (IgA) and 2- to 5-fold (IgG) greater than those seen after pp/pp immunization. In contrast to pp/pp immunization, estradiol administered for 3 days had no effect on uterine antibody levels at the end of the immunization procedure. In other studies, we found that intraperitoneal immunization with SRBC leads to uterine antibody responses that, similar to those seen with pp immunization, are dependent on estradiol for genital tract antibody accumulation (Wira and Prabhala, 1992).

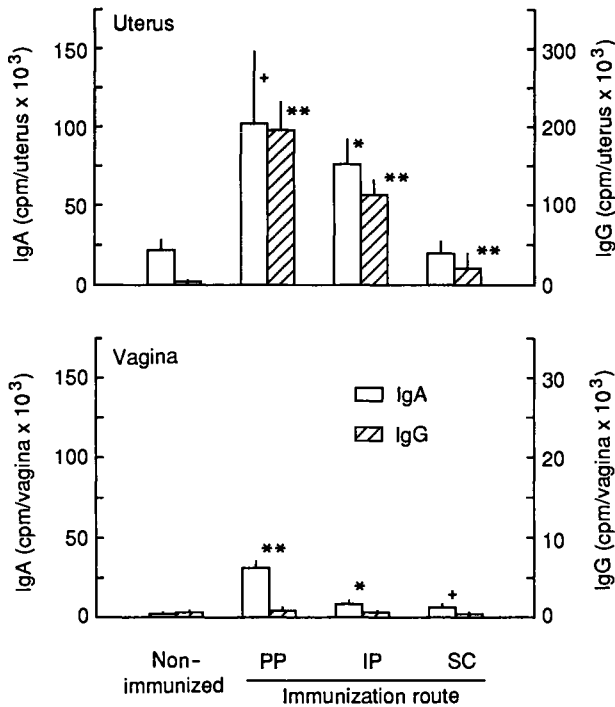

Of particular interest in our uterine immunization studies is that, as a consequence of placing SRBC in the uterine lumen, specific antibodies appear in the contralateral (nonimmunized) uterine horn, in vaginal secretions, in serum, and

in saliva. These studies demonstrate for the first time that, in addition to being an inductive site for humoral immune responses, the reproductive tract provides immunological information to other mucosal surfaces in the form of IgA and IgG antibodies that may be distributed systemically through the blood. The implication of these findings is that antigen challenge in the reproductive tract may result in immune protection at other sites of the body.

As part of our uterine immunization studies, we analyzed IgA in uterine secretions by high performance liquid chromatography (HPLC) and found that all IgA antibodies existed as dimers. We then examined the possibility that SC was responsible for the accumulation of IgA in uterine secretions. As seen in Figure 9, in the absence of estradiol, SC levels increased in uterine secretions in response to uterine immunization with SRBC. When analyzed by HPLC, SC consisted of free SC and SC bound to IgA anti-SRBC antibodies (Wira *et al.*, 1991). Western blot analysis demonstrated that SRBC-stimulated SC consists of two major bands (75 and 76 kDa) and a third minor band (30 kDa). The major bands are identical to those seen in bile and in uterine fluid from nonimmunized animals (Whittemore *et al.*, 1990). Our conclusion from these studies was that, in addition to stimulating a local anti-

**Figure 6** Time course of the effect of dexamethasone on the levels of IgA in serum (*top*) and saliva (*bottom*). Ovariectomized rats were treated with dexamethasone (1 mg/day; hatched bars) or saline (0.1 ml; open bars) for 1, 2, or 3 days. Then, 24 hr after the last injection, saliva and serum were collected and analyzed for IgA. Bars represent the mean ± SE of 7–8 animals/group. \*Significantly ( $P < 0.01$ ) different from control groups; \*\*significantly ( $P < 0.001$ ) different from control groups. body response, SRBC antigen also stimulates the production of SC, which may be responsible for the transport of polymeric IgA into uterine secretions.

#### IV. INFLUENCE OF CYTOKINES ON GENITAL TRACT HUMORAL IMMUNITY

To examine the possibility that  $IFN\gamma$  might be involved in regulating SC production in the rat uterus,  $IFN\gamma$  was placed in the uterine lumen of ovariectomized rats. As seen in Figure 10, increasing doses of  $IFN\gamma$  increased SC levels in uterine secretions. This response was specific for  $IFN\gamma$  because  $IFN\alpha/\beta$  at the same dose (5000 Units) had no effect on uterine SC levels (Prabhala and Wira, 1991). These studies build on the important observation by Sollid *et al.* (1987) that, when  $IFN\gamma$  was added to the incubation media of human colon carcinoma cells (HT29), SC expression increased. These results led to the proposal that epithelial cell-mediated SC IgA

transport might respond to cytokine stimulation (Kvale *et al.*, 1988). To test this hypothesis with normal cells, we ovariectomized rats and treated them with  $IFN\gamma$  or estradiol. As seen in Figure 11, when animals received  $IFN\gamma$  alone, SC but not IgA levels increased in the uterine lumen. Since tissue IgA levels are known to be low in the absence of estradiol (Sullivan and Wira, 1983), animals were treated with estradiol for 2 days prior to sacrifice 4 hr after the second injection. This time interval of estradiol exposure previously has been shown to increase tissue levels of monomeric and polymeric IgA without increasing either SC or IgA levels in uterine secretions (Sullivan and Wira, 1983,1984). In contrast, when estradiol was given to  $IFN\gamma$ -treated animals, IgA levels increased in uterine secretions relative to those in animals that

**Figure 8** Influence of estradiol and route of immunization on the presence of anti-SRBC-specific IgA (top) and IgG (bottom) antibodies in uterine secretions. Ovariectomized animals were immunized with SRBC injected into Peyer's patches (PP) or instilled intraluminally into one uterine horn (UT). Animals were immunized (primary, day 0) via the Peyer's patches and boosted (secondary, day 13) either via the Peyer's patches (PP/PP) or the uterus (PP/UT), or were immunized and boosted by placing SRBC directly into the uterine lumen (UT/UT). Nonimmunized animals were sham-operated at the time of primary and secondary immunization. Animals were injected with 0.1 ml saline (S) or estradiol ( $E_2$ ; 1.0  $\mu$ g/day) for 3 days prior to killing 24 hr after the last injection on day 26 after primary immunization. Bars represent the mean  $\pm$  SE values of samples taken from 5–6 animals/group. \*, Significantly ( $P < 0.05$ ) greater than saline-treated immunized controls, \*\*, significantly ( $P < 0.01$ ) greater than saline-treated immunized controls. Reprinted with permission from Wira and Sandoe (1989).

**Figure 9** Influence of uterine immunization and boost on the presence of secretory component (SC) in uterine secretions. Ovariectomized animals were immunized with SRBC (20  $\mu$ l/horn) instilled intraluminally into both uterine horns. Animals were immunized (primary, day 0), boosted (secondary, day 13) in the same uterine horn, and killed on day 26. Nonimmunized animals received 20  $\mu$ l of PBS in each uterine horn at the time of primary and secondary immunization. After injection of SRBC or PBS into the lumen, uteri were ligated at the uterocervical junction. On the day of boost, SRBC or PBS was injected into the oviductal ends of immunized horns and then ligated. Bars represent the mean  $\pm$  SE of 6 animals per group. \*\*, Significantly more than nonimmune or contralateral controls ( $P < 0.01$ ). Reprinted with permission from Wira *et al.* (1991).

received either estradiol or IFN $\gamma$  alone. These findings demonstrate that stimulation of uterine SC by IFN $\gamma$  increases the movement of IgA from tissue to lumen. These results also represent our most direct evidence to date that some IgA in uterine secretions is of serum origin.

In light of our finding that intrauterine-instilled IFN $\gamma$  (5000 Units) had a stimulatory effect on uterine SC levels, animals were treated with 10,000 Units of IFN $\gamma$ . Unexpectedly, we found that SC responses in the uterine lumen to 10,000 Units were significantly lower than those to 5000 Units of IFN $\gamma$  (Prabhala and Wira, 1991). To examine the possibility that IFN $\gamma$  might have effects beyond the uterus, spleen cells from rats that received 5000 or 10,000 Units of IFN $\gamma$ /uterus were analyzed for their responsiveness to B- and T-cell mitogens. As seen in Figure 12, IFN $\gamma$  (5000 Units) had a marked stimulatory effect on spleen cell mitogenesis in response to concanavalin A (ConA), phytohemagglutinin (PHA), and lipopolysaccharide (LPS). In contrast, when 10,000 Units were placed in the uterine lumina of ovariectomized rats, the response to mitogens was significantly lower than that seen in animals that received 5000 Units. In other studies (not shown), we found that 5000 Units given sc to ovariectomized rats had no effect on spleen cell mitogenesis. These findings indicate that intrauterine exposure to IFN $\gamma$  results in a signal that is sent from the genital tract to the spleen and influences both B- and T-cell mitogenesis. Further, we find that the magnitude of this response, similar to that seen in the reproductive tract, is dependent on the dose of IFN $\gamma$  administered as well as

the location (intrauterine vs subcutaneous) of IFN $\gamma$  administration.

In other studies, we examined the possibility that other cytokines may be involved in IgA movement into uterine secretions. Since IL-6 is synthesized by stromal cells in the uterine endometrium (Tabibzadeh *et al.*, 1989), we instilled IL-6 into the uteri of ovariectomized rats. As seen in Table II, IL-6 had a pronounced stimulatory effect on both SC and IgA accumulation within the uterine lumen. What remains unclear is whether IL-6 increased the movement of IgA from serum into uterine tissues and stimulated SC production, or whether IL-6 influenced the terminal differentiation of IgA-lymphoid cells in the reproductive tract into plasma cells, which then synthesized IgA for transport into uterine secretions.

## V. REGULATION OF CELL-MEDIATED IMMUNITY AND ANTIGEN PRESENTATION BY SEX HORMONES AND CYTOKINES

Several studies have shown that immune cells are present throughout the female reproductive tract. Bulmer *et al.* (1988, 1991), for example, reported that macrophages, B cells, and T cells are present in the human endometrium and that numbers vary during the menstrual cycle depending on the region of endometrium analyzed. Others have found that lymphocyte numbers remain unchanged whereas macrophage numbers increase during the latter part (secretory phase) of the cycle (Morris *et al.*, 1985; Kamat and Isaacson, 1987). In an attempt to determine whether T-cell numbers

**Figure 10** Effect of increasing doses of IFN $\gamma$  on uterine lumina secretory component (SC) levels. Ovariectomized rats received 20  $\mu$ l of IFN $\gamma$  (1000, 3000, or 5000 Units/uterus) in each uterine horn. Control animals were given PBS by the same route. Animals were sacrificed and uterine secretions collected for analysis of SC levels 7 days after intrauterine instillation of IFN $\gamma$ . Each bar represents the mean  $\pm$  SE of 6 animals per group. \*\*, Significantly ( $P < 0.01$ ) greater than the control group. Reprinted with permission from Prabhala and Wira (1991).

**Figure 11** The effect of IFN $\gamma$  and estradiol on secretory component (SC) (*top*) and IgA (*bottom*) levels in the uterine lumen of ovariectomized animals. PBS or IFN $\gamma$  (5000 Units/uterus) was placed in the uterine lumen. Animals were given, systemically, either saline (0.1 ml) or estradiol (2  $\mu$ g/day) daily for the last 2 days prior to sacrifice 4–6 hr after the second injection on day 7. Bars represent the mean  $\pm$  SE of 6 animals per group. \*\*, Significantly ( $P < 0.01$ ) greater than control values. Reprinted with permission from Prabhala and Wira (1991).

in the female reproductive tract vary with the stage of the reproductive cycle and are influenced by endocrine balance, studies were undertaken to measure T-cell numbers in the rat uterus. As seen in Table III, when analyzed by flow cytometry, significant numbers of total T lymphocytes (Ti) and T-helper lymphocytes (Th) were found in the uteri of intact rats at the proestrous stage of the reproductive cycle. In contrast, cell numbers were reduced at estrus and were either low or not detectable at diestrus. This information indicates that these cells, in addition to B lymphocytes and macrophages (not shown), are present in the uterus in greatest numbers when estradiol levels are known to be highest in serum (at proestrus).

To determine whether estradiol influences the presence of lymphocytes at intraepithelial sites in the uterus, ovariectomized animals were treated with hormone for 3 days prior to histological analysis. As seen in Figure 13A, very few intraepithelial lymphocytes and polymorphonuclear leukocytes ( $1 \pm 0.4$  cells/uterine section) were found in uterine tissues in the absence of estradiol (Prabhala and Wira, 1991). In response to estradiol (13B), increased numbers of lympho-

cytes ( $17 \pm 2$  cells/uterine section) and polymorphonuclear leukocytes ( $5.7 \pm 0.5$  cells/uterine section) were found adjacent to the basement membrane region of epithelial cells. When IFN $\gamma$  (5000 Units) was placed in the uterine lumen (13C), intraepithelial and subepithelial lymphocytes ( $37 \pm 6$  cells/uterine section) and polymorphonuclear leukocytes ( $23 \pm 7.5$  cells/uterine section) increased significantly beyond levels seen with estradiol. In contrast, IFN $\alpha/\beta$  administered at the same dose (13D) had no effect on either lymphocyte or polymorphonuclear leukocyte numbers. In other studies, Itohara *et al.* (1990) demonstrated that  $\gamma/\delta$  intraepithelial cells are present in the female reproductive tract. Haas *et al.* (1990) reported that  $\gamma/\delta$  intraepithelial lymphocytes are present in greatest numbers at the proestrous stage of the reproductive cycle. Our findings that estradiol and IFN $\gamma$  increase intraepithelial lymphocytes and polymorphonuclear leukocytes demonstrate that these cells are responsive to sex hormones and cytokines, and suggest that immune functions of  $\gamma/\delta$  cells, including immunosurveillance (Raulet, 1989), cytotoxicity (Ferrini *et al.*, 1987), and cytokine production (Christmas and Meager, 1990), may be regulated hormonally in the female reproductive tract. Additional studies are needed to identify the mechanisms through which estradiol and IFN $\gamma$  exert their stimulatory effects on immune cell migration into the female reproductive tract.

**Figure 12** Mitogenic response of isolated spleen cells from ovariectomized rats treated with varying doses of IFN $\gamma$ . Ovariectomized rats were given IFN $\gamma$  (5000 or 10000 Units/uterus) or PBS (20  $\mu$ l/horn) by intrauterine instillation. Seven days later, animals (6/group) were sacrificed and spleens were collected. Splenocytes were prepared from pooled spleens and incubated either with ConA (1  $\mu$ g/ml), PHA (5  $\mu$ g/ml), or LPS (10  $\mu$ g/ml) for 3 days. [<sup>3</sup>H]Thymidine was added to culture wells for the last 24 hr of each incubation. Each bar represents the mean  $\pm$  SE minus background (cpm/well in the absence of mitogen) of 6 animals per group. \*\*, Significantly ( $P < 0.01$ ) greater than control values; \*, significantly ( $P < 0.03$ ) greater than control values; +, significantly ( $P < 0.03$ ) lower than 5000 Unit IFN $\gamma$  values. <sup>b</sup> Significantly ( $p < 0.01$ ) greater than controls.

In preliminary studies, to determine whether cells in the female reproductive tract are able to present antigen, purified uterine epithelial cells were isolated from the uteri of rats at the proestrous stage of the reproductive cycle. Epithelial cells were prepared as described previously (McCormack and Glasser, 1980) and following preincubation to remove macrophages, cells were incubated with sensitized T lymphocytes prepared from the lymph nodes of animals immunized by footpad injections with ovalbumin (OVA) antigen. As seen in Figure 14, when epithelial cells were incubated with T lymphocytes in the presence of OVA, they were able to present antigen to sensitized T lymphocytes. Lymphocyte proliferation, measured as [<sup>3</sup>H]thymidine incorporation, was significantly greater than that seen when epithelial cells or lymphocytes were incubated with OVA or when epithelial cells and lymphocytes were incubated together in the absence of OVA. Studies are underway to verify that uterine epithelial cells used in antigen presentation studies are free of macrophages, which are known to enter uterine tissues in increasing numbers at proestrus (Head and Gaede, 1986b). In a parallel study (Figure 14), stromal cells were prepared from the uteri of proestrous rats. When incubated under the conditions described for epithelial cells, stromal cells were able to present antigen to sensitized T lymphocytes. Based on our preliminary findings of macrophages, B lymphocytes, and dendritic cells in the uterine stroma and the recognition that these cells present antigen at other sites in the body, these cells are likely to be responsible for antigen presentation in our studies. To the best of our knowledge, this demonstration is the first that uterine cells present antigen and thereby initiate an immune response in the reproductive tract.

In other studies, we undertook to determine whether antigen presentation varies with the stage of the reproductive cycle. When uterine cells from proestrous, estrous, and diestrous rats were incubated with sensitized T lymphocytes in the presence of OVA, cells from proestrous rats presented antigen more efficiently than did cells from either estrous or diestrous animals. We have treated ovariectomized rats with estradiol (1  $\mu$ g/day for 3 days) and found that antigen presen-

tation is increased markedly in response to hormone treatment relative to saline controls. As a part of these studies, we found that antigen presentation by uterine cells is MHC Class II restricted. Further, Class II expression on uterine cells is hormonally dependent, that is, expression is elevated at proestrus relative to estrus and diestrus in the reproductive cycle. In other studies (not shown), we have found that IFN $\gamma$  placed in the uterine lumen of ovariectomized rats increases MHC Class II expression on uterine luminal epithelial cells. Further, intrauterine instillation of IFN $\gamma$  or IL-6 enhanced antigen presentation by uterine cells. Studies are currently underway to define more clearly the mechanisms by which antigen presentation is regulated by sex hormones and cytokines.

## VI. CONCLUSIONS

The results presented indicate that the secretory immune system in the female reproductive tract is fully immunocompetent and able to respond to antigenic challenge. Moreover, our findings indicate that the recognition of antigen (afferent arm) and the response to antigenic challenge (efferent arm) of the immune system in the uterus are regulated precisely by sex hormones, cytokines, and glucocorticoids. Our present understanding of the multiple levels at which hormones and cytokines interact with the secretory immune system is presented schematically in Figure 15. In response to antigen, uterine cells are capable of presenting antigen to sensitized T cells. When estradiol is given systemically, or is present as a normal consequence of the reproductive cycle, antigen presentation that is Class II restricted is enhanced. An increase in antigen presentation also occurs when IFN $\gamma$  or IL-6 is placed in the uterus. In light of the findings that IL-6 and IFN $\gamma$  are produced by cells in the reproductive tract, our studies indicate that enhancement of the afferent arm of the immune system occurs in response to sex hormones and

**Table III** Presence of T Lymphocytes in Uterine Tissues at Various Stages of the Estrous Cycle<sup>a</sup>

	Estrous cycle stage

<sup>a</sup> T lymphocytes/gm tissue ( $\times 10^5$ ). Each value represents the mean  $\pm$  SE of 2–4 animals/group. Uterine cells were prepared by endometrial scraping and needle aspiration (16–22 g) to prepare isolated cells. Endometrial cells were incubated with W3/25 (T helper) and W3/13 (T total) monoclonal antibodies before analysis by flow cytometer. Number of T cells:  $\pm$ very low; +few; ++some; +++many.

**Figure 13** Light microscopic appearance of intraepithelial lymphocytes and epithelial cells in uteri from rats after treatment with interferons and/or estradiol. Ovariectomized rats were given a single dose of either  $\text{IFN}\gamma$  (5000 Units/uterus),  $\text{IFN}\alpha/\beta$  (5000 Units/uterus), or PBS ( $20\ \mu\text{l}/\text{horn}$ ) by intrauterine instillation 7 days prior to sacrifice. Rats were injected subcutaneously either with estradiol ( $2\ \mu\text{g}/0.1\ \text{ml}/\text{day}$ ) or saline ( $0.1\ \text{ml}/\text{day}$ ) for 3 days prior to sacrifice 24 hr after the third injection on day 7. Uteri were fixed to Bouin's solution, sectioned, and stained with hematoxylin and eosin. Uterine sections were prepared from rats as follows: (A) saline-treated controls; (B) estradiol treatment; (C) intrauterine instillation of  $\text{IFN}\gamma$ ; and (D) intrauterine  $\text{IFN}\alpha/\beta$ . Arrows indicate the locations of intra- and subepithelial lymphocytes.  $\times 1860$ . Reprinted with permission from Prabhala and Wira (1991).

cytokines, and that antigen presentation during the reproductive cycle may be a reflection of an interaction that exists between these two groups of immune regulators. From a physiological standpoint, differential control of the afferent arm might result in immune protection from antigenic challenge during the reproductive cycle that would be enhanced prior to and following ovulation to protect against potential pathogens, and would be suppressed at the time of fertilization when the female is exposed to allogeneic antigens of paternal origin.

Also shown in Figure 15 is the effect of estradiol on the movement of T cells, B cells, macrophages, and intraepithelial lymphocytes into reproductive tract tissues. This influx

of cells into the reproductive tract, in addition to eosinophils and neutrophils (not shown), is controlled precisely during the reproductive cycle and is under hormonal control. Movement of these cells and the mechanisms involved in their selective infiltration, however, remain to be established.

An unexpected finding in our study was that  $\text{IFN}\gamma$  placed in the uterine lumen had a stimulatory effect on spleen B- and T-cell responses to mitogens. Since an identical dose of  $\text{IFN}\gamma$  (5000 Units) given subcutaneously had no effect, we conclude that factors other than leakage of  $\text{IFN}\gamma$  from the uterine lumina are involved in spleen cell responses. These studies suggest that, in response to  $\text{IFN}\gamma$ , macrophages or dendritic cells (Head and Billingham, 1986) may move from

the reproductive tract into the spleen or lymph nodes to influence mitogenesis. This possibility is supported further by the finding that  $\text{IFN}\gamma$  enhances the activation and migration of dendritic cells from the heart and respiratory tract to the spleen (Larsen *et al.*, 1990). Studies are needed to determine whether immune cells in the reproductive tract migrate to distal sites and to define the role of sex hormones and cytokines in influencing this process.

Our earlier studies have demonstrated that the efferent arm of the immune system in the female reproductive tract is under hormonal control. As seen in Figure 15, estradiol and progesterone control the levels of IgA, IgG, and SC in uterine as well as in cervicovaginal secretions. These findings led us to the conclusion that endocrine balance during the reproductive cycle, at implantation and throughout pregnancy (Wira and Stern, 1992), results in separate and distinct changes in the mucosal immune system that are unique to the uterus, cervix, and vagina. In several studies, we focused on the origin(s) of specific IgA and IgG antibodies and determined that antibodies in reproductive tract secretions are derived from both the gastrointestinal and the reproductive

tracts. On examining the role of hormone balance in antibody levels in reproductive tract secretions, we found that estradiol stimulates the accumulation of gastrointestinally derived antibodies in uterine secretions. We also found that animals respond locally to uterine antigenic challenge. In addition to accumulating at the site of antigenic challenge, IgA and IgG antibodies accumulate in the nonimmunized uterine horn, in vaginal secretions, in serum, and in saliva. These studies demonstrate that, in addition to receiving antibodies from distal sites, the reproductive tract shares immunological information with other mucosal surfaces.

On further examination of the uterine immune response, we found that antigen,  $\text{IFN}\gamma$ , and IL-6 stimulate SC production by uterine epithelial cells. This study suggests that antigenic control of uterine SC may be mediated by  $\text{IFN}\gamma$  and IL-6, which act to stimulate SC production and IgA transport.

In conclusion, our studies demonstrate that the female reproductive tract is an inductive site for mucosal immune responses and that the mucosal immune system in the uterus, cervix, and vagina is regulated by estradiol, progesterone, and selected cytokines, including  $\text{IFN}\gamma$  and IL-6. By ob-

**Figure 14** Antigen presentation by uterine luminal epithelial cells (Ec; *top*) and stromal cells (STR; *bottom*) to antigen-primed lymph node T lymphocytes (Tln). Epithelial cells ( $10^5$ ) and/or primed T lymphocytes ( $5 \times 10^5$ ) were incubated with ovalbumin (OVA;  $1000 \mu\text{g}/\text{ml}$ ) for 18 hr. T lymphocytes were isolated on Ficoll–Hypaque and allowed to proliferate for 72 hr prior to incubation for 24 hr with [ $^3\text{H}$ ]thymidine ( $1 \mu\text{Ci}/\text{well}$ ). \*\*, Significantly greater ( $P < 0.01$ ) than controls. taining a clearer understanding of the interrelationships between sex hormones, cytokines, and glucocorticoids as they influence mucosal immunity in the female reproductive tract, valuable information should become available for the development of appropriate immunoprophylaxis to regulate fertility and control sexually transmitted diseases.

# Mucosal Immunopathophysiology of HIV Infection

Phillip D. Smith

## I. INTRODUCTION

Despite major advances in medical science and public health measures, the world has witnessed the emergence of a new and devastating infectious disease—the acquired immunodeficiency syndrome (AIDS). Indeed, as the 21st century approaches, this disease has reached pandemic proportions. In the United States alone, 315,390 persons have been reported to have AIDS, of whom 194,354 have died (Centers for Disease Control, 1993). Worldwide, up to 20 million persons are predicted to acquire asymptomatic infection with the causative agent of AIDS, human immunodeficiency virus (HIV), by the year 2000. Accentuating the magnitude of this global epidemic is the absence of an effective cure for HIV infection, which eventually leads to death in 100% of cases. Thus, AIDS is having an enormous impact on individuals and, consequently, on whole societies in developed and developing nations.

The magnitude of the AIDS epidemic and the absence of a curative antiviral agent underscore the need for an effective vaccine against HIV. Since most homosexual and heterosexual transmission of the virus involves passage across mucosal surfaces, such a vaccine will need to induce protective or neutralizing factors at mucosal membranes. Designing this vaccine will require a detailed understanding of the mucosal events that occur in HIV disease. Accordingly, the goal of this chapter is to integrate into a common hypothesis the known and presumed immunopathophysiological events that occur in the mucosa during HIV infection. Divided into early-, intermediate-, and late-phase events, this chapter describes how these events predispose the host to the mucosal manifestations of HIV disease.

## II. EARLY PHASE MUCOSAL EVENTS IN HIV INFECTION

### A. HIV Entry

The gastrointestinal tract plays a critical role in the pathogenesis of HIV disease. At the outset, the distal colon serves as the most likely portal of entry for HIV in homosexual men, who constitute the majority of persons infected with HIV in developed countries. Many homosexual men have trauma-induced (Sohn and Ribilotti, 1977) or infection-

associated (Quinn *et al.*, 1981; Surawicz *et al.*, 1986) erosions, breaks, and tears of the rectal mucosa. After inoculation, these lesions provide the virus direct access to the microcirculation of the rectal mucosa (Figure 1, Step 1).

In homosexual men without mucosal changes in the distal colon, however, HIV may enter the host through membranous microfold (M) cells (Figure 1, Step 2). Present throughout the intestinal tract, but with increased frequency in the distal colon (O'Leary and Sweeney, 1986), these specialized epithelial cells bind macromolecules and microorganisms, including viruses such as poliovirus and reovirus (Wolf *et al.*, 1981; Sicinski *et al.*, 1990), to their apical surface and transport them by a nondegradative process to their basal surface (Owen, 1977). The intact macromolecule or microorganism then is delivered by exocytosis to interdigitating mononuclear cells in the underlying lymphoid aggregate, where accessory cells take up, process, and present the antigens to lymphocytes within the aggregate. In this regard, studies in a mouse model of M-cell uptake indicate that murine M cells are capable of taking up and transporting HIV to underlying lymphoid aggregates (Amerongen *et al.*, 1991). Studies to determine the role of human M cells as a potential route of entry for HIV are currently in progress. The mucosa of the upper gastrointestinal tract, including tonsillar M cells, also could play a role in the postnatal transmission of HIV in colostrum and milk from mother to infant (Van de Perre *et al.*, 1991). In hemophiliacs and persons using illicit intravenous drugs, the virus is inoculated directly into the circulation (Figure 1, Step 3).

### B. HIV Infection of CD4<sup>+</sup> Cells

After entry into the host, the initial event in the interaction between HIV and lymphoid cells is binding of the envelope glycoprotein 120 (gp120) on the virus to the cell-surface CD4 molecule, which serves as receptor for the virus (Klatzman *et al.*, 1984a,b). The viral envelope then fuses to the cell plasma membrane, and the virus is internalized (Stein *et al.*, 1987). Alternatively, studies of HIV infection of cells *in vitro* (Homsy *et al.*, 1989) suggest that the virus also might enter monocytes and macrophages by a mechanism involving Fc $\gamma$ RIII (CD16) receptor-mediated uptake of HIV-antibody complexes. In this connection, the increased expression of Fc $\gamma$ RIII receptors on circulating monocytes and tissue macrophages in patients with AIDS could contribute to HIV

**Figure 1** Early phase immunopathophysiological events in the mucosa in HIV infection. Adapted with permission from Smith *et al.* (1992b).

infection of mononuclear phagocytes (Allen *et al.*, 1990). For virus entering the host through mucosal breaks, CD4-bearing cells could be infected in the microcirculation of the mucosa and then be distributed via the systemic circulation to tissues, including the gastrointestinal mucosa, throughout the body (Figure 1, Step 4).

For virus entering the host through M cells, however, mononuclear cells in the underlying lymphoid aggregate are likely to be potential targets for HIV infection. Lymphocytes leave the lymphoid aggregate, migrating via the lymphatics to the mesenteric lymph nodes and via the thoracic duct to the systemic circulation. A mechanism involving homing receptors on mucosa-derived lymphocytes and organ-specific molecules on lamina propria endothelial cells then directs these antigen-reactive lymphocytes to the mucosal lamina propria and epithelium (Jalkanen *et al.*, 1986). Thus, lymphocytes stimulated at one site in the gastrointestinal tract eventually are distributed to distant mucosal sites, thereby providing a potential mechanism by which mononuclear cells, at least lymphocytes, infected with HIV in the rectum could distribute to the lamina propria throughout the gastrointestinal tract (Figure 1, Step 4).

Several days to weeks after inoculation, sufficient quantities of virus trigger a humoral immune response and seroconversion. At the time of HIV seroconversion, the first manifestation of HIV infection is experienced as an acute mononucleosis-like illness (Cooper *et al.*, 1985). Varying degrees of this syndrome appear to occur in a majority of newly infected persons. Among the clinical features of the syndrome

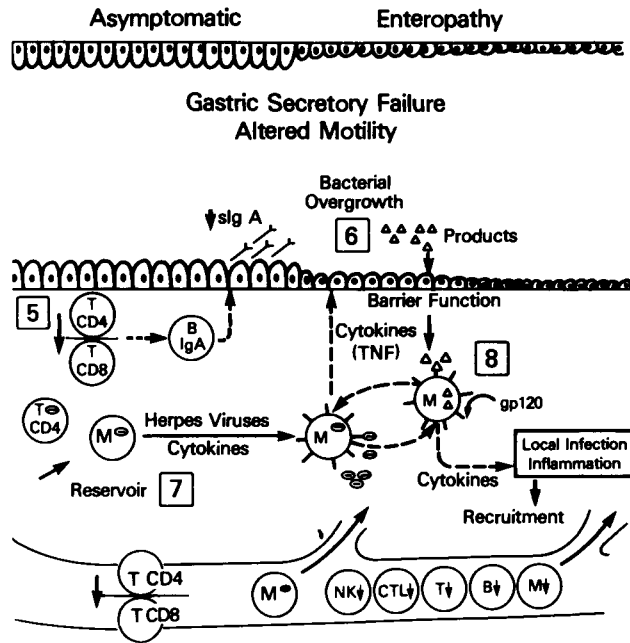

are the "early" gastrointestinal symptoms of HIV infection, including diarrhea, nausea, and anorexia. The pathophysiology of the syndrome is unknown but could involve the local or systemic release of cytokines such as interleukin 1 (IL-1) and tumor necrosis factor (TNF), which have important roles in mediating acute febrile responses. Although controversial, the increased levels of these cytokines in HIV-infected patients could be generated, in part, by the ability of HIV-1 and its envelope glycoprotein (gp120) to stimulate mononuclear cell production of IL-1 (Wahl *et al.*, 1989) and TNF- $\alpha$  (Wright *et al.*, 1988; Voth *et al.*, 1990; Riekmann *et al.*, 1991). Acute symptomatic HIV infection is associated with expression of high titers of cytopathic virus followed by a rapid and spontaneous decline in the viral burden (Clark *et al.*, 1990; Daar *et al.*, 1991). The mononucleosis-like syndrome associated with seroconversion is transient and the patient recovers, at least symptomatically.

### III. INTERMEDIATE PHASE MUCOSAL EVENTS IN HIV INFECTION

#### A. Reduction in Mucosal CD4<sup>+</sup> (Helper/Inducer) Lymphocytes

The migration of HIV-infected lymphocytes from the rectal mucosa to distant mucosal sites, either randomly or via a homing mechanism, provides one potential explanation for the presence of HIV-infected mononuclear cells throughout the gastrointestinal tract. Accordingly, HIV has been identified in mononuclear cells in the mucosa of the esophagus (Smith *et al.*, 1993) duodenum (Ulrich *et al.*, 1989; Jarry *et al.*, 1990), ileum (Harriman *et al.*, 1989), colon, and rectum (Fox *et al.*, 1989). Similar to the low level of HIV infection in mononuclear cells in the circulation ( $\leq 1/100$  CD4<sup>+</sup> cells) (Schnittman *et al.*, 1989), the frequency of HIV-infected cells in the gastrointestinal tract lamina propria is also low ( $\leq 1/100$  mononuclear cells; P. D. Smith, personal observations). Moreover, HIV-infected cells are detected in only one-third of intestinal biopsy specimens from HIV-infected persons (Fox *et al.*, 1989; Ulrich *et al.*, 1989; Jarry *et al.*, 1990). Although the frequency of HIV-infected CD4<sup>+</sup> cells is low in the circulation and the mucosa, these infected cells are likely to contribute to the progressive reduction in the total number of CD4<sup>+</sup> cells by a mechanism in which fusion of uninfected CD4<sup>+</sup> cells with viral components or budding virus expressed on HIV-infected CD4<sup>+</sup> cells causes the formation of multinucleated giant cells and lysis of the uninfected cells (Lifson *et al.*, 1986; Yolffe *et al.*, 1987).

The apparent removal of giant syncytia by the reticuloendothelial system and the lysis of CD4<sup>+</sup> cells fused to HIV-infected cells lead to a progressive decline in the number of CD4<sup>+</sup> lymphocytes. The decline in the number of CD4<sup>+</sup> T cells in comparison to the relatively constant number of CD8<sup>+</sup> (suppressor/cytotoxic) T cells is reflected in a progressive reduction in the ratio of CD4<sup>+</sup> to CD8<sup>+</sup> cells in the circulation. A corresponding reduction in the number of CD4<sup>+</sup> T cells also occurs in intestinal mucosa (Figure 2, Step 5) (Rodgers

**Figure 2** Intermediate phase immunopathophysiological events in the mucosa in HIV infection. Adapted with permission from Smith *et al.* (1992b).

*et al.*, 1986; Budhraj *et al.*, 1987; Ellakany *et al.*, 1987). Since CD4<sup>+</sup> T cells play a critical role in providing helper and inducer function for many immune responses, the reduction in the ratio of CD4<sup>+</sup> to CD8<sup>+</sup> cells in the gastrointestinal mucosa suggests that the immune function of the mucosa is impaired also.

In addition to causing the selective depletion of CD4<sup>+</sup> lymphocytes, HIV impairs certain functions of these cells. For example, CD4<sup>+</sup> T cells from AIDS patients have a reduced ability to respond to soluble antigens, such as tetanus toxoid and *Candida albicans* (Lane *et al.*, 1985a; Giorgi *et al.*, 1987). In light of the role of CD4<sup>+</sup> T cells in regulating IgA class-specific immunoglobulin production (Elson *et al.*, 1979; Richman *et al.*, 1981), the reduced number and function of CD4<sup>+</sup> T cells could affect the switch of IgM- to IgA-bearing B cells in the lymphoid aggregates of the intestinal mucosa (Kawanishi *et al.*, 1983a) as well as the terminal differentiation of IgA-bearing to IgA-secreting B cells (Kawanishi *et al.*, 1983b). From this perspective, the observations by Kotler *et al.* (1984b) that AIDS patients have a reduced number of IgA-bearing plasma cells in the intestinal mucosa are particularly relevant. Thus, a reduction in the number and function of mucosal CD4<sup>+</sup> cells ultimately could contribute to a dysregulation in the generation and function of IgA-secreting cells. In support of the latter result are observations of a reduced IgA class-specific antibody response to HIV, which we have detected in intestinal fluids (Janoff *et al.*, 1989) and others have detected in saliva (Jackson, 1990).

In addition to specific secretory antibody responses, non-specific host defense mechanisms such as gastric acid secretion and intestinal peristalsis play an important role in protecting intestinal mucosa against ingested organisms

(Giannella *et al.*, 1973; Vantrappon *et al.*, 1977). Several studies (Lake-Bakaar *et al.*, 1988a,b) have shown that some AIDS patients, however, have an impaired capacity to secrete gastric acid, resulting in an increase in fasting gastric pH and a reduction in stimulated gastric acid secretion. The presence of circulating antiparietal cell antibodies in approximately 50% of these patients suggests an autoimmune mechanism. In addition to dysfunction in acid secretion, preliminary studies (Reeves-Darby *et al.*, 1991) indicate that some HIV-infected patients also exhibit a dysfunction in intestinal motility, manifesting as markedly abnormal migrating motor complexes.

## B. Intestinal Bacteria

Colonization of the proximal small intestine by increased numbers of bacteria reflects an alteration in the delicate balance between host defense mechanisms and enteric microorganisms. In HIV-infected persons, impaired secretory antibody responses in conjunction with gastric secretory failure and intestinal dysmotility could predispose the host to increased numbers of intestinal bacteria (Figure 2, Step 6). In this regard, we (Smith *et al.*, 1988) and others (Budhraj *et al.*, 1987) have detected  $4.5 \times 10^4$ – $10^5$  bacteria/ml intestinal fluid in the proximal small intestine in AIDS patients with diarrhea. Although aerobes predominated or were equivalent in number to anaerobes, these levels of bacteria represent an increase over the number of bacteria ( $10^3$  bacteria/ml) generally accepted as the upper limit of normal in the proximal small intestine. Increased numbers of bacteria in the small intestine, particularly anaerobes, play an etiological role in some malabsorption syndromes. Accordingly, low-grade bacterial overgrowth could contribute to the malabsorption and diarrhea that is common in patients with AIDS before such patients manifest full-blown opportunistic viral and parasitic intestinal infections.

## C. HIV Reservoir

In addition to gut-associated lymphoid tissues as a site for immunosuppression, the gastrointestinal tract also may serve as a reservoir for HIV-infected mononuclear cells. The identification of a cellular DNA binding protein that represses HIV-1 transcription in *in vitro* studies (Kato *et al.*, 1991) raises the intriguing possibility that local production of this factor may play a role in promoting latent HIV infection in mononuclear cells in the mucosa. As previously discussed, approximately one-third of HIV-infected persons have detectable HIV in their intestinal mucosa. Our identification of HIV in biopsy specimens from the esophagus in 36% of HIV-infected patients with esophageal symptoms (Smith *et al.*, 1993) indicates that, in symptomatic persons, HIV infects the mucosa of the esophagus as often as it infects the mucosa of the intestine. Although the frequency of HIV-infected CD4<sup>+</sup> cells within the mucosa appears to be similar to that in the circulation, the large number of mononuclear cells within the mucosa (making it the largest lymphoid organ in

the body) would allow the alimentary canal to act as a major reservoir for HIV (Figure 2, Step 7).

In light of its potential role as a reservoir for HIV, the gastrointestinal tract is also likely to be a site for the expression of HIV from HIV-infected mononuclear cells. Two factors that stimulate expression of HIV *in vitro*, herpes-group viruses (Gendelman *et al.*, 1986) and certain cytokines (Rosenberg and Fauci, 1990 and Koyanagi *et al.*, 1988), may be present in the gastrointestinal mucosa of persons at risk for HIV infection or with AIDS (Figure 2, Step 7). Among the herpes-group viruses, herpes simplex virus is the most common cause of nongonococcal proctitis in sexually active homosexual males (Goodell *et al.*, 1983; Quinnan *et al.*, 1984) and is an important cause of esophagitis (Smith *et al.*, 1993) and proctitis (Siegal *et al.*, 1981) in patients with AIDS. Another herpes group virus, cytomegalovirus, causes subclinical infection in more than 90% of HIV-seronegative homosexual men (Drew *et al.*, 1981) and is a common cause of serious disease in virtually any organ of the gastrointestinal tract in patients with AIDS (Smith *et al.*, 1992a). The relevance of these pathogens to gastrointestinal tract HIV infection lies in their ability to activate transcription of latent HIV in HIV-infected cells. In the case of herpes simplex virus, this event probably occurs by a *trans*-acting factor encoded by the virus (Mosca *et al.*, 1987a,b); in the case of cytomegalovirus, the immediate-early gene region of the virus is likely to be responsible (Davis *et al.*, 1987). These factors stimulate HIV expression *in vitro* by activating the single promoter located within the 5'-long terminal repeat (LTR), which directs HIV transcription. Coincident with herpes-group virus stimulation of HIV expression, HIV stimulation of herpes-group virus (cytomegalovirus) expression has been demonstrated *in vitro* (Skolnik *et al.*, 1988), raising the possibility that bidirectional viral up-regulation may occur *in vivo* in tissues such as the gastrointestinal tract where mononuclear cells could be infected, albeit infrequently, by both viruses.

In addition to herpes-group viruses, cytokines also activate mononuclear cells, thereby stimulating the expression of HIV from cells that are infected latently or are producing low levels of HIV (Figure 2, Step 7). Granulocyte-macrophage colony-stimulating factor (Folks *et al.*, 1987; Perno *et al.*, 1989), interleukin 6 (Poli *et al.*, 1990a), and TNF (Poli *et al.*, 1990b; Mellors *et al.*, 1991) are capable of stimulating HIV expression in mononuclear cell lines and primary cells by a mechanism that is likely to involve the transcriptional regulation of HIV. TNF, for example, induces HIV expression from infected cells *in vitro* by an autocrine and paracrine mechanism (Rosenberg and Fauci, 1990), probably by induction of cellular factors that bind to the nuclear factor  $\kappa$ B, thereby stimulating the HIV enhancer that induces HIV expression (Osborn *et al.*, 1989).

Within the gastrointestinal mucosa, these cytokines could play a particularly important role in the regulation of HIV expression. Infectious processes such as cytomegalovirus colitis have been shown to be associated with the expression of TNF within the colonic mucosa (Smith *et al.*, 1992c). Thus, local production of TNF and other inflammatory cytokines capable of up-regulating HIV expression (Clouse *et al.*, 1989) could obviate the requirement that both viruses be present in the same cell to induce HIV transcription.

During the intermediate phase of mucosal events in HIV infection, the patient begins to re-experience gastrointestinal symptoms, most commonly diarrhea. The diarrhea may occur initially in the absence of detectable pathogens, a condition referred to as the "AIDS enteropathy" (Kotler *et al.*, 1984a). The intestinal mucosa in this setting has been reported to show structural and functional alterations, including low-grade small bowel atrophy, a maturational defect in enterocytes, and decreased mucosal enzyme activities. Small bowel atrophy and defects in enterocyte maturation could contribute to a reduction in normal mucosal surface area. Factors that may play an etiological role in these alterations include mucosal HIV, which has been identified in the lamina propria of patients with these changes (Ulrich *et al.*, 1989), and increased numbers of certain intestinal bacteria (Budhruja *et al.*, 1987; Smith *et al.*, 1988) or their products, such as deconjugated bile salts. In addition, cytokines currently are being investigated for their ability to alter electrolyte transport mechanisms in mucosal epithelium. In this respect, we showed that the increased levels of TNF produced by activated alveolar macrophages during endotoxin administration (P. D. Smith, A. F. Suffridini, J. B. Allen, J. E. Parillo, and S. M. Wahl, unpublished data) are associated with local changes in lung permeability (Suffridini *et al.*, 1992). Thus, HIV, luminal bacteria, and cytokines are potential factors that might contribute to changes in the structure and function of mucosal epithelium.

#### D. Macrophage Activation

The structural and functional changes in the intestinal mucosa described in this chapter are associated with increased mucosal permeability to luminal materials, including bacterial products (Lichtman *et al.*, 1991). Since cell wall turnover is a characteristic of many gram-negative microorganisms (Doyle *et al.*, 1988), one product of potential significance is the surface protein shed by such bacteria. We have used *Helicobacter pylori*, a noninvasive mucosal bacterial pathogen, to show that surface proteins from gram-negative bacteria can be absorbed across the mucosal epithelium and can serve as chemoattractants for monocytes and neutrophils (Mai *et al.*, 1992). These chemotactic products are also potent activators of monocytes and macrophages, causing the release of increased amounts of inflammatory cytokines, such as TNF and interleukin 1, and toxic products, such as oxygen radicals (Mai *et al.*, 1991). Interestingly, the single reported case of invasive *H. pylori* gastritis was in a patient with AIDS (Meiselman *et al.*, 1988). Although *H. pylori* actually may infect HIV-infected persons less frequently than seronegative persons (Francis *et al.*, 1990), products from other enteric bacteria could function as pro-inflammatory factors similar to *H. pylori* surface proteins. One such product, lipopolysaccharide (LPS), is a potent activator of macrophages and can stimulate HIV-infected cell-line monocytes to express HIV as well (Pomerantz *et al.*, 1990). However, LPS induction of HIV expression has not been reproduced in primary monocytes infected with the virus (Kornbluth *et al.*, 1989; Bernstein *et al.*, 1991) and, to date, has not been investigated in tissue macrophages. Viruses and their products also can

stimulate macrophages. For example, cytomegalovirus (Smith *et al.*, 1992c) is similar to influenza A (Gong *et al.*, 1991) in its ability to prime monocytes and macrophages for increased inducible TNF production. In addition, HIV is capable of activating monocytes (Allen *et al.*, 1990; Allen *et al.*, 1991), and HIV envelope gp120 is capable of stimulating monocytes and macrophages to produce increased amounts of inflammatory cytokines and prostaglandins (Wahl *et al.*, 1989) and B cells to produce TNF (Riekmann *et al.*, 1991). Thus, luminal bacteria and viruses or their products are potential activators of macrophages, leading to the production of increased amounts of cytokines and soluble inflammatory mediators (Figure 2, Step 8) that could, in turn, promote and perpetuate the chronic inflammation that characterizes mucosal histopathology in HIV-infected persons (Smith *et al.*, 1988).

#### IV. LATE PHASE MUCOSAL EVENTS IN HIV INFECTION

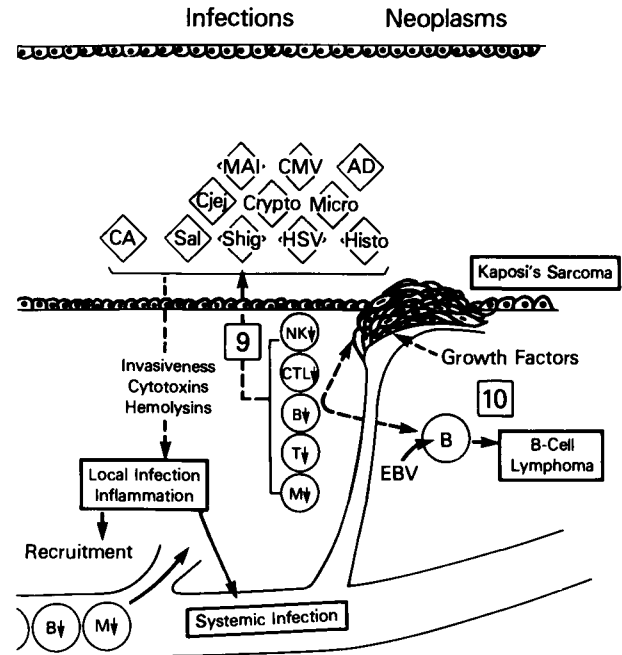

##### A. Lymphoid Cell Responses

After a period that may last from weeks to months or even years, the late phase of HIV infection emerges. By this point, increasing numbers of circulating natural killer cells, cytotoxic lymphocytes, T lymphocytes, B lymphocytes, and monocytes have impaired functions (Fauci, 1988; Meltzer *et al.*, 1990). Those functions that are impaired in circulating lymphoid cells have not been investigated yet in mucosal lymphoid cells. Nevertheless, mucosal lymphoid cell function probably becomes impaired as well (Figure 3, Step 9), since circulating lymphoid cells traffic through and populate the mucosa.

##### B. Opportunistic Infections

Impaired cellular immune responses, in conjunction with gastric secretory failure, altered intestinal motility, and impaired local IgA responses, predispose the gastrointestinal tract in HIV disease to a wide spectrum of opportunistic pathogens (Janoff and Smith, 1988). We define opportunistic gastrointestinal pathogens as those infectious agents that consistently cause severe, chronic, or frequent gastrointestinal disease in persons with compromised immune function (Smith and Janoff, 1988). Nonopportunistic pathogens are those that usually cause acute treatable gastrointestinal disease (Smith and Janoff, 1988) in immunocompromised as well as immunocompetent persons. The opportunistic and nonopportunistic pathogens that cause enteric infection in HIV-infected persons include the viral, fungal, bacterial, and protozoan agents listed in Table I.

Among the first pathogens that herald the late phase of the gastrointestinal manifestations of HIV disease is *C. albicans*. The presence of oral candidiasis in persons at risk for AIDS signals the likelihood of concomitant HIV infection, since 60% of such persons ultimately develop an AIDS-related infection or Kaposi's sarcoma within 2 yr (Klein *et al.*, 1984).

**Figure 3** Late phase immunopathophysiological events in the mucosa in HIV infection. Adapted with permission from Smith *et al.* (1992b).

*Candida albicans* is a typical opportunistic pathogen by virtue of the fact that, in immunosuppressed HIV-infected persons, it frequently causes severe chronic disease of the oral cavity and esophageal mucosa whereas, in immunocompetent persons, it is a common nonpathogenic commensal of the gastrointestinal tract. Further, the striking similarity among isolates of *C. albicans* that cause mucosal disease in AIDS patients and isolates present in healthy persons, which we reported (Whelan *et al.*, 1990), suggests that candidiasis in patients with AIDS is not caused by a unique or particularly virulent strain, but is the consequence of a defect in local cell-mediated host defense mechanisms.

The many enteric infections that may develop during late phase mucosal events in HIV infection have been reviewed (Kotler, 1989; Smith *et al.*, 1992a). One or more of these pathogens can be identified in the majority of AIDS patients with gastrointestinal symptoms (Smith *et al.*, 1988; Laughon *et al.*, 1988), in contrast to the previously held notion that the majority of HIV-infected persons with diarrhea had AIDS enteropathy. In fact, increasing numbers of persons diagnosed initially as having AIDS enteropathy have been found on further analysis to have one of the more recently appreciated enteric pathogens, such as *Enterocytozoon bienersi* (microsporidia; Kotler *et al.*, 1990) and adenovirus (Janoff *et al.*, 1991).

##### C. Mucosal Neoplasms

Malignant neoplasia of the gastrointestinal tract occurs in approximately 12% of patients with AIDS (Danzig *et al.*, 1991). Kaposi's sarcoma is the most common of such neoplasias, occurring in 60% of AIDS patients with gastrointestinal malignancies (Danzig *et al.*, 1991). Lesions begin as small

**Table 1** Enteric Pathogens in HIV Disease

Pathogen	Viral	Protozoal	Fungal	Bacterial
Opportunistic	Cytomegalovirus	<i>Cryptosporidia</i>	<i>Candida albicans</i>	<i>Mycobacterium avium-intracellulare</i>
	Herpes simplex	<i>Isospora belli</i>	Histoplasma capsulatum	<i>Salmonella</i> sp.
	Adenovirus	<i>Enterocytozoon bieneusi</i>		<i>Shigella flexneri</i> <i>Campylobacter jejuni</i>
Nonopportunistic	Rotavirus	<i>Giardia lamblia</i>		<i>Mycobacterium</i>
	Norwalk agent	<i>Entamoeba histolytica</i>		Spirochetes

papules that progress into multifocal vascular nodules because of the proliferation of a mixed cell population, in particular spindle-like cells with neovascularization. Gastrointestinal Kaposi's sarcoma is present in 40–50% of patients with skin involvement (Friedman *et al.*, 1985). Involvement of the small and large intestine is nearly always asymptomatic (Friedman *et al.*, 1985), whereas lesions in the esophagus that involve the sphincters or epiglottis may cause dysphagia (Eisner and Smith, 1990).

In contrast to the association between opportunistic infections and declining immune function (Lane *et al.*, 1985b; Smith *et al.*, 1988), Kaposi's sarcoma is not necessarily related to the degree of HIV-induced immunosuppression (Lane *et al.*, 1985b). *In vitro* studies (Nakamura *et al.*, 1988; Ensoli *et al.*, 1990) suggest that HIV-infected mononuclear cells release a transactivator of transcription (Tat) protein and certain cytokines (i.e., TNF) that stimulate proliferation of Kaposi's sarcoma-derived spindle cells (Figure 3, Step 10). Spindle cells produce, in turn, several growth factors (IL-1, IL-6, basic fibroblast growth factor) that stimulate their own growth as well as the growth of other cells, such as cells of vascular and lymphatic origin, within the Kaposi lesion (Salahuddin *et al.*, 1988; Ensoli *et al.*, 1989; Miles *et al.*, 1990). Oncostatin M, another growth factor produced by Kaposi's sarcoma cells and activated T cells (Nair *et al.*, 1992; Miles *et al.*, 1992), appears to be the most potent mitogen for spindle-cell growth, acting in an autocrine and paracrine loop. Thus, the presence of HIV-infected CD4<sup>+</sup> T cells and increased levels of cytokines in the gastrointestinal mucosa, as discussed earlier, could play an important role in the development of gastrointestinal Kaposi's sarcoma.

Lymphoma is the second most common malignancy of the gastrointestinal tract in patients with AIDS. Occurring in approximately 35% of AIDS patients with gastrointestinal malignancy (Danzig *et al.*, 1991), the lymphoma is usually non-Hodgkin's. In contrast to Kaposi's sarcoma, gastrointestinal lymphoma often produces obstruction or pain. Latent and replicating Epstein-Barr virus (EBV) DNA has been detected in lymphomas in patients with AIDS and other lymphoproliferative disorders (Katz *et al.*, 1989). Infection with EBV is common in AIDS patients (Quinnan *et al.*, 1984). The virus is capable of replicating in mucosal epithelial cells (Lemon *et al.*, 1977; Sixbey *et al.*, 1984); thus, in the setting of impaired EBV-specific cytotoxic T-cell responses (Ricksen, 1986; Figure 3, Step 9), lymphoproliferative lesions in the gastrointestinal tract could represent the outgrowth of EBV-transformed B cells (Figure 3, Step 10), similar to that

reported in severe combined immunodeficient (SCID) mice inoculated with peripheral blood leukocytes from EBV-seropositive donors (Rowe *et al.*, 1991).

In summary, a sequence of interrelated immunological events in the gastrointestinal mucosa is a major complication of HIV infection. Over time, these events lead to local immunosuppression, predisposing the gastrointestinal tract to the acquisition of opportunistic infections and the development of certain neoplasms. Understanding the immunopathophysiology of the mucosal events in HIV infection should facilitate the development of more effective therapies for the gastrointestinal complications of AIDS and, eventually, of an effective vaccine against HIV.

# Genital Tract Infection: Implications in the Prevention of Maternal and Fetal Disease

Debra A. Tristram • Pearay L. Ogra

## I. INTRODUCTION

The incidence of sexually transmitted diseases (STDs) has risen markedly worldwide in the past decade (Antal, 1987; Johnson *et al.*, 1989; Brunham and Plummer, 1990). The acquisition of the human immunodeficiency virus (HIV) and development of acquired immunodeficiency syndrome (AIDS), widespread drug abuse, and prostitution for drugs or money have resulted in the resurgence of many STDs once thought to be controlled in developed nations. Since most species of organisms responsible for STDs are not capable of survival outside the human host and must be transmitted by direct human contact, STDs characteristically are restricted to a sexually active population, with a peak incidence between the ages of 15 and 34, and to newborns of women in this population. Although the incidence of AIDS in the homosexual population has decreased largely because of alterations in high-risk behavior, AIDS has continued to rise at an alarming rate in the heterosexual and drug-abusing populations of many countries [Morbidity and Mortality Weekly Reports (MMWR), 1991a,b; World Health Organization (WHO), 1991]. Although these HIV-positive individuals are not the only reservoir for STDs, they have become a major source. Clearly current strategies for disease containment are insufficient; other modalities, including immunization, are needed desperately to prevent the widespread continued increase of STDs.

Sexually transmitted agents long have been recognized to be responsible for many acute genital infections, but only recently has a wider role been established for these agents in the epidemiology of prolonged maternal and infant morbidity and mortality. Although men can have long-term complications from STDs, they are often more symptomatic early in the infection cycle and, thus, may seek care before the infection becomes deeply established. Women, on the other hand, are more susceptible to infection and may be asymptomatic in the early stages of infection. Thus, they may be less likely to seek health care and more likely to transmit disease to other sexual partners. In addition to causing widespread infections, STDs have a major impact on reproductive health: infertility has been linked to some genital infections (e.g., *Chlamydia* and *Mycoplasma* species) and maternal-fetal transmission of genital organisms remains a common cause of fetal and infant morbidity and mortality. Since pregnant

women, regardless of their socioeconomic status, are likely to seek medical attention at or near the time of delivery, they constitute a reasonable target population for intervention. A significant decrease in infant morbidity (and possibly fetal and infant mortality) might be achieved if STDs could be controlled better in women of child-bearing age. The unique immune system of the pregnant and lactating female has been demonstrated in the past to provide temporary protection against a host of agents to which the mother has been exposed previously. Perhaps advantage could be taken of maternal immunity to provide additional protection for the infant at the time of delivery and for the mother during her subsequent years of sexual activity. The immunology of the male and female genital tracts (Chapter 54), lactation (Chapters 51 and 52), and mucosal response to viral and bacterial pathogens are discussed in detail elsewhere in this volume. Hence, this chapter provides a brief overview of the local female immune response to several common STDs and the possible impact of controlling these infections on maternal and child health.

## II. DEFENSE MECHANISMS OF THE FEMALE GENITAL TRACT

The entire mucosal surface of the female genital tract, including the vagina, cervix, endometrium, fallopian tubes, and oviduct, is bathed in protective secretions. Among the various sections of the genital tract, these secretions differ in their biochemical and biological functions. The vaginal secretions represent a mixture of contaminants from the secretory products of the fallopian tubes, cervix, and endometrium, as well as small amounts of secretions produced by the Skene's and Bartholin's glands. Although plasma cells of the IgG type have been observed infrequently in the vaginal mucosa (Blandau and Moghissi, 1983), neither IgA- nor IgM-containing cells have been detected in the subepithelial regions of the vaginal mucosa (Tourville *et al.*, 1970). Secretory component (SC), the nonimmunoglobulin portion associated with secretory IgA, has been found in vaginal secretions in a free form rather than associated with the superficial epithelial layers and apical glands typically found in the cervix and

other portions of the upper female genital tract. Free SC, as well as the IgA and IgM detected in vaginal secretions, has been suggested to be a contaminant from the upper genital tract, particularly from the cervical mucosa (Moghissi, 1970). However, Lai and colleagues were able to demonstrate that vaginal explants from the mucocutaneous regions of the vaginal epithelium were capable of producing IgA and SC (Lai *et al.*, 1973). Although hemolytic complement activity or fluorescent localization of the components of complement in the vagina has not been observed, the synthesis of C3 in the vaginal mucosa has been noted using labeled amino acids (Lai *et al.*, 1973). Clearly the presence of antibody and the ability to generate complement components in the lower tract in proximity to the entry of most pathogens would be advantageous, whether or not these components are produced locally or migrate from the upper genital tract.

In contrast to the vaginal secretions, the cervical secretions contain significant amounts of IgG and IgA; the ratio of IgA to IgG is greater than that observed in serum (Moghissi and Neuhaus, 1962). IgM, although present, is found in much smaller amounts (Moghissi and Neuhaus, 1962). During the menstrual cycle, these immunoglobulins undergo considerable variation in concentration; IgG and IgA are highest at the beginning and end of the cycle and decrease toward midcycle. Hence, midcycle has the least immunoglobulin and the most favorable (thinnest) cervical mucus to allow penetration of sperm. Unfortunately, microorganisms also can gain access to the upper genital tract at midcycle and may, in part, be responsible for the increased incidence of STDs in the second portion of the menstrual cycle. The content of IgA and IgG in the cervical mucus ranges from 0.05 to 1.4 mg/ml and 0.1 to 6 mg/ml, respectively, whereas IgM is present to a lesser degree. Immunoglobulin content is not altered by oral contraceptive agents, although hormones have been found to have other influences on pathogen growth and host immunity (Schumacher, 1973a,b). Most of this immunoglobulin appears to be produced by the IgA- and IgG-containing plasma cells (Blandau and Moghissi, 1983; Hulka and Omran, 1969; Lippes *et al.*, 1970; Rebello *et al.*, 1975; Tjokonegoro and Sirisinha, 1975), and cells staining positive for SC (Lippes *et al.*, 1970) in the human endocervix. Note that studies of cervical biopsy tissues from infertile women demonstrate significantly higher numbers of IgA-containing plasma cells than tissues from parous women; antispermatozoal antibodies of the three major immunoglobulin classes have been detected in cervical mucus (Clarke, 1984). Additionally, women with genital infections, compared with women without infection, exhibit increased numbers of IgA-positive cells in this region of the genital tract (Waldman *et al.*, 1972). However, the numbers of IgG- and IgM-containing plasma cells in the two groups are comparable (Hutcheson *et al.*, 1974). From these and other studies, we know that secretory IgA in the genital tract is produced in response to foreign antigens, both human sperm and infectious agents, and seems to function in the genital tract as it does on other mucosal surfaces (reviewed by Mestecky and McGhee, 1987; Tomasi, 1989).

All major immunoglobulin classes have been demonstrated

in human endometrial secretions. IgG-containing cells are slightly greater in number than IgA-containing cells, similar to the endocervical immunohistology (Lippes *et al.*, 1970). IgM is demonstrated infrequently in the human endometrium during the proliferative, secretory, and decidual phases (Lippes *et al.*, 1970). Most of the immunoglobulin appears to be distributed in the stroma between the glands and along the basement membranes of the glandular epithelium. During the early proliferative phase, IgA- and IgG-staining plasma cells have been located in the endometrium. SC has been identified in the apical glands during the secretory and proliferative phases (Tourville *et al.*, 1970).

Lymphoid tissues, although not as numerous as in other branches of the mucosa-associated lymphoid tissue (MALT), have been demonstrated in the female genital tract. Many segments of the female genital tract contain glandular epithelium and possess varying amounts of organized lymphoid tissue or lymphocytes diffusely scattered in the subepithelial regions. Although the uterus has not been demonstrated to possess organized lymphoid tissue, the endocervix has been reported to contain lymphoid aggregates that are analogous to the Peyer's patches of the small intestine (Blandau and Moghissi, 1983). As mentioned, the cervix contains numbers of lymphocytes and plasma cells, whereas the vagina has minimal to no collections of epithelial or subepithelial lymphoid tissue. Little published information is available regarding the presence of T cells, T-cell subpopulations, or possible *in vitro* correlates of cellular immunity in the female genital tract. However, sufficient data are available regarding the fate of allogeneic transplants in the uterus in several animal models (Beer and Billingham, 1971, 1975). Histoincompatible grafts are rejected uniformly, so the uterus appears to possess a significant degree of T cell-mediated immunocompetence. However, during pregnancy the fetus, despite the presence of incompatible antigens, is not rejected (reviewed by Scott, 1991). This response appears to be local, since pregnancy per se does not increase the survival of orthotopic skin grafts. Suppressor subpopulations of T lymphocytes have been suggested to predominate in the fetal environment and at the transplantation site of the embryo in the uterus. This possibility is supported by observations that fetal blood possesses a higher proportion of suppressor T lymphocytes (Olding and Oldstone, 1974). Another hypothesis is that effector lymphocytes may be inhibited by an increase in the level of a "blocking factor," as observed in the tumor immunity systems (Hellstrom and Hellstrom, 1971; Scott, 1991). Although clearly for the fetus to be undisturbed by the maternal immune response is a survival advantage, some systemic impairment of maternal immunity is evidenced by more severe primary varicella infection, occasionally resulting in death of the mother from severe pneumonia. Whether or not these phenomena are mediated by maternal or fetal suppressor T-cell activity is unknown. More recent studies (see subsequent discussion) have demonstrated that local lymphocytes are capable of proliferation in response to infectious agents, and that lymphocyte reactivity may be, in part, responsible for immunocompetence against some infectious agents in the genital tract.

### III. INFECTIOUS AGENTS AND THE MUCOSAL IMMUNE RESPONSE

Most STD organisms first contact the host mucosal surface in the genital tract. Attachment must take place here before a cycle of infection can occur; the host has the first encounter with the invading pathogen at this site as well. Maternal infection is correlated most often with subsequent fetal or newborn infection, but maternal colonization with STD organisms can affect the fetus or newborn even if maternal infection has not yet been established. A partial list of important sexually transmitted female genital tract pathogens associated with fetal and neonatal disease is presented in Table I.

Although each specific sexually transmitted organism elicits a unique host response, some common features are shared by the mucosal immune response in the genital tract and the mucosal immune responses at other mucosal surfaces (i.e., the respiratory tract and the gastrointestinal tract, collectively called the MALT). Unlike the other mucosal surfaces of the MALT, the female genital tract undergoes a series of continual and well-defined developmental changes from the onset of menarche to the appearance of menopause. In addition, these tissues are exquisitely sensitive to changes in the

hormonal milieu of the host during the menstrual cycle and pregnancy and lactation. A large number of nonspecific and specific factors plays an important role in providing a broad-range barrier to the penetration of environmental pathogens across the genital mucosa, in a manner similar to those of the respiratory and intestinal tracts (see Table II). Often, these cells and their products acting in concert are successful; often they are not. In the case of a pregnant female, the health and well-being of both the mother and the fetus are dependent on the maternal immune system to provide adequate protection against infection.

### IV. SPECIFIC PATHOGENS AND THE ROLE OF THE FEMALE IMMUNE RESPONSE

Microorganisms applied to the genital tract, either by natural infection or by experimental application, have been demonstrated to produce a local and systemic immune response in human and other mammalian species (see Table III). These and other studies clearly demonstrate immunological reactivity in the genital tract. The discussion that follows focuses on some specific pathogens that are transmitted by sexual contact, with emphasis on local or systemic immune re-

**Table I** Microorganisms Transmitted by Sexual Contact and Their Association with Neonatal Disease

Association with significant disease	Mode of acquisition
<b>Strong</b>	
<b>Bacteria</b>	
<i>Chlamydia trachomatis</i>	Passage through colonized or infected birth canal; ascending infection
<i>Neisseria gonorrhoeae</i>	Passage through colonized or infected birth canal; ascending infection
<i>Streptococcus</i> group B	Passage through colonized or infected birth canal; ascending infection
<i>Treponema pallidum</i> <sup>a</sup>	Transplacental
<b>Fungi</b>	
<i>Candida albicans</i>	Passage through birth canal
<b>Viruses</b>	
Cytomegalovirus <sup>a</sup>	Transplacental; maternal secretions
Hepatitis B	Infected secretions; aspirated maternal blood
Herpes simplex <sup>a</sup>	Infected secretions; ascending infection
Human immunodeficiency virus <sup>a</sup>	Transplacental infection; secretions and maternal blood; virus in breast milk
Human papilloma virus	Infected secretions
<b>Rare</b>	
<b>Protozoa</b>	
<i>Trichomonas vaginalis</i>	Passage through birth canal
<b>Possible</b>	
<b>Mycoplasma</b>	
<i>Mycoplasma hominis</i> <sup>a</sup>	Transplacental
<i>Ureaplasma urealyticum</i> <sup>a</sup>	Passage through birth canal

<sup>a</sup> Can also cause fetal infection, birth defects, abortion, and/or stillbirth.

**Table II** Factors with a Potential Role in the Local Defense Mechanisms of the Genital Tract

	Soluble	Mechanism of action	Cellular	Mechanism of action				
Nonspecific	Vaginal secretions	Natural barrier; inhibition of growth; nonspecific binding of organisms; impairment of organism motility; masking of receptors; digestion of organism glycoproteins or glycolipids	Intact skin and mucosa	Barrier; when damaged may release products involved in cell recruitment; antigen presentation by certain epithelial and endothelial cells possible				
	Cervical mucus							
	soluble proteins							
	mucin							
	Endometrial secretions							
	uteroglobulin							
Nonspecific	lactoferrin	Alteration of host cell receptor expression	Phagocytes macrophages PMNs	Nonspecific phagocytosis and intracellular lysis of invading organism; macrophages also participate in generation specific responses by antigen presentation Infected cell cytotoxicity				
	lysozyme							
	other proteins							
	Oviductal fluid							
	Follicular fluid							
	Hormones							
	Prostaglandins				Alterations in vascular permeability and coagulation	NK cells		
	Leukotrienes						Recruitment of cells to site of infection	
	Immunologically specific				Immunoglobulins	Inhibition of attachment of invading microorganisms	CTL	Direct lysis of infected cells
					mucosal antibody			
circulating antibody		Opsonization; ADCC; neutralization	ADCC	Lysis of cells coated with specific antibody				
Complement								
Soluble mediators of cellular immunity—interferon	Prevention of intracellular infections through uninfected neighboring cells							

sponses that are potentially capable of conferring protection to the mother and her offspring.

### A. *Neisseria gonorrhoeae*

*Neisseria gonorrhoeae* is a pathogen of the mucosal surface, causing the majority of its infections in the genitourinary tract. Humans are the primary reservoir. Many laboratory animals have some inherent resistance to infection; hence, studies of host-pathogen interactions have been hampered by lack of a suitable host and sample material. Uncomplicated gonococcal infections manifest as urethritis in males and endocervical infection in women. A pregnant woman with gonococcal disease can transmit the organism to her offspring, causing a spectrum of diseases from mild conjunctivitis to invasive gonococcal infection (Gutman and Holmes, 1990). Although local and systemic antibody responses, both IgG and IgA, are produced during infection, little is known about the ability of antibody to prevent or modify the course of disease in adults or in newborns.

Infection with *N. gonorrhoeae* occurs in two stages: attachment and invasion. The initial attachment brings the gonococcus and the host cell in close proximity and is thought to be mediated by nonspecific factors such as surface charge,

hydrophobic/hydrophilic interactions, and pH (Watt and Ward, 1980). This interaction allows the more specific attachment structures—pili and outer membrane proteins (OMP)—to interact with host receptors (McGee *et al.*, 1978). By studying human fallopian cell cultures, several investigators have demonstrated that gonococci adhere to nonciliated epithelial cells and subsequently are endocytosed (Ward *et al.*, 1974; McGee *et al.*, 1978). Intracellular replication and excretion of the organisms into the lamina propria sets up a submucosal infection. An OMP (PI) appears to facilitate entry into the host cell after the initial attachment is established (Blake, 1985).

Polymorphonuclear leukocytes are attracted locally in response to gonococcal infection, but their role in host immunity is currently in question. Gonococcal antibody is known to be opsonic, and facilitates the uptake of gonococci by polymorphonuclear leukocytes. However, evidence suggests that intracellular oxidative neutrophil systems may be relatively inefficient at lysis of *N. gonorrhoeae* (Casey *et al.*, 1979, 1980, 1983; Parsons *et al.*, 1981, 1982, 1985, 1986; Veale *et al.*, 1977, 1979) but that nonoxidative systems may contribute to the intraphagosomal lysis of gonococci (Casey *et al.*, 1986). Observations by Shafer *et al.* concur with the speculation that, although gonococci may be eliminated more effectively *in vivo* than in *in vitro* study systems, the relative

inefficiency of intracellular neutralization and killing of gonococci may contribute to the spread of disease, both within and outside the genital tract (Shafer and Rest, 1989).

As in most mucosal infections, the function of local antibody is thought to be prevention of attachment and subsequent infection of the host mucosa (Mestecky and McGhee, 1987). Urethral exudates from men with gonococcal infection have demonstrated that all three antibody classes are produced in response to infection (Kearns *et al.*, 1973a,b; McMillan *et al.*, 1979a). In women, vaginal washings after infection with gonococci have been shown to contain both IgG and IgA antibody against pili, lipopolysaccharide (LPS), and the OMPs implicated in attachment (Lammel *et al.*, 1985; Ison *et al.*, 1986). Although IgG and IgA specific for gonococci have been demonstrated, production of specific IgM has not been well documented (O'Reilly *et al.*, 1976; McMillan *et al.*, 1979b; Ison *et al.*, 1986). Despite the formation of these local antibodies, little is known about their functional activity. Antibody directed against pili and outer membrane complexes altered the ability of the gonococci to attach to epithelial cells *in vitro* (Tramont *et al.*, 1980), whereas mucosal antibody produced after vaccination of male volunteers could inhibit attachment, requiring larger inocula to achieve infection (Tramont *et al.*, 1980). This result suggests that local antibody can modify colonization.

Since antibody appears to be the most effective means for the prevention and control of gonococcal infections, immunization would be a reasonable means of stimulating host antibody production. Repeat infection with a homologous gonococcus strain is unusual, but infection with heterologous strains can and probably does occur frequently. Buchanan and colleagues (1980) demonstrated that women with salpingitis developed antibody and protection against the original infecting serotypes. Systemic antibody response seems to be much stronger than the mucosal response, according to data from several investigators (Lammel *et al.*, 1985; Ison *et al.*, 1986). Whether or not this result reflects less local antibody production or the formation of antibody-antigen immune complexes that prevent antibody detection by present methods, as suggested by Ison (1988), is unknown. Further characterization of the gonococcus-specific antibody responses has involved identification of the major antigens that stimulate a specific antibody response. These include pili, OMPs (PI, PII, and PIII), and LPS, all constituents of the gonococcal surface (Tramont *et al.*, 1980; Lammel *et al.*, 1985; Ison *et al.*, 1986). Although antibody directed against pili would be desirable to prevent attachment of the organism to the host epithelial surface, the remarkable strain variation in pili limits their usefulness as a sole agent in vaccine candidates. A similar problem has been encountered for LPS and protein II (PII). Studies also suggest that antibodies against PII may block the interactions of the gonococcus with host neutrophils (Elkins and Rest, 1990). PIII, although a highly conserved OMP, can induce a polyclonal antibody response to its antigenic determinants that has been demonstrated to inhibit the effects of PI-induced antibodies *in vitro* and in animal hosts (Buchanan and Arko, 1977; Rice *et al.*, 1985, 1986; Blake *et al.*, 1988). These blocking antibodies have been implicated in the earlier failure of OMP preparations to pro-

tect against subsequent infection. In fact, one such preparation administered to individuals with a history of previous gonococcal infection induced a quantitative decrease in opsonic antibody and bactericidal antibody after immunization that was below that of the preimmunization sera (Arminjon *et al.*, 1987).

To date, PI appears to have the most potential as a vaccine candidate, but must be purified from other outer membrane components. Fortunately, although some antigenic diversity exists among different *N. gonorrhoeae* strains producing PI, the differences fall into two major immunological and biological groups: PIA and PIB (Sandstrom *et al.*, 1982). Antibodies, both polyclonal and monoclonal, directed against PI are opsonic and bactericidal, and can prevent the *in vitro* invasion of gonococci into cell cultures (Joiner *et al.*, 1985; Virji *et al.*, 1986, 1987). However, the vehicle of antigen administration to animals has a marked effect on the *in vivo* development of antibody response. Wetzler and colleagues (1988) utilized a chromatographically prepared PI vaccine composed of PIA- and PIB-alum adjuvant and found minimal opsonic and bactericidal antibody production. However, the opposite was noted when PI was inserted into liposomes (Wetzler *et al.*, 1988). A small but significant quantity of PIII may have contaminated this vaccine preparation and generated antibodies against this immunogen. The clinical significance of these results remains unknown since this study did not employ subsequent challenge of the immunized animals with virulent organisms.

Currently, a suitable vaccine for the prevention or modification of gonococcal disease remains elusive. Studies focusing on outer membrane components show the most promise (Heckels *et al.*, 1989, 1990), but have not met with complete success yet. Meanwhile, the gonococcus itself has begun to develop considerable antibiotic resistance in certain parts of the world, making management of disease more difficult and development of a vaccine more critical. Although maternal and neonatal disease constitute only a small percentage of the total number of gonococcal infections reported yearly, effective maternal vaccination would help reduce the pool of infected and transmitting partners.

## B. Chlamydia

Chlamydial infections of the genital tract are a major health problem in both developed and developing countries (Schachter and Grossman, 1990). Infection rates can reach as high as 30% among sexually active teenagers in the United States. Urethritis and cervicitis are common and often can be asymptomatic in females, contributing to additional spread of infection prior to treatment. More serious infection of the upper genital tract in women can lead to involuntary sterility. In addition, a pregnant woman infected with *Chlamydia* can transmit the organism to her offspring, producing conjunctivitis and pneumonia. In Third World nations, where STDs are more common, serious infections such as trachoma and lymphogranuloma venereum can be transmitted by other chlamydial serovars. Hence, effective control strategies must target both the asymptomatic carrier and the symptomatic

patient. To date, a vaccine has not been developed, yet information regarding host response to infection through study of natural human infection and infection in animal models has led to several exciting prospects.

Nonspecific host defenses that can inactivate chlamydial elementary bodies *in vitro* have been identified, but the extent of their contribution to prevention or eradication of chlamydial infection *in vivo* is unknown. Biochemical inactivators are present in seminal plasma, and reduce the infectivity of several chlamydial serovars in cell culture (Mardh *et al.*, 1980; Hanna *et al.*, 1981). Spermine, cupric chloride, and zinc chloride inhibit the elementary bodies of serovar F. Although the specific mode of action for these compounds is unknown, they could be used in the future as adjuncts to preventive or therapeutic measures used to control *Chlamydia trachomatis* infection.

Hormones also affect the growth of *C. trachomatis* in cell culture. Cortisol has variable effects on *C. trachomatis* serovars: preincubation of tissue culture cells prior to inoculation with *Chlamydia* inhibits the growth of serovar L2 whereas postinoculation incubation with cortisol enhances the growth of L2 (Bushell and Hobson, 1978; Reed and Hann, 1980). Estrogens have no effect on the binding of elementary bodies to cell cultures; incubation of tissue culture with estrogens nearly doubles the numbers of infectious bodies recoverable from the tissue culture (Sugarman and Agbor, 1986). This estrogen effect has been exploited by researchers using animal models to increase the yield of infectious organisms and may also may explain, in part, the increased susceptibility of women using oral contraceptive agents to this organism. Progesterone, testosterone, and other hormones do not appear to have any effect on the growth of *C. trachomatis*.

*Chlamydia* can induce the production of interferon  $\gamma$  (IFN $\gamma$ ), most likely because, as an obligate intracellular parasite, this organism causes alterations in the cell surface membrane of the cell it has parasitized. In the mouse model, IFN $\gamma$  induction rapidly follows intravenous injection of elementary bodies. Infected cell cultures, HeLa cells, and L cells also produce IFN $\gamma$  in response to several chlamydial serovars. Both human and mouse IFN $\gamma$  can inhibit various stages of chlamydial intracellular growth in *in vitro* cell cultures (Hanna *et al.*, 1967; Kazar *et al.*, 1971; Rothermel *et al.*, 1983; de la Maza *et al.*, 1985, 1986; Shemer and Sarov, 1985). However, *in vivo* human correlates of tissue culture and animal models for *Chlamydia*-induced IFN $\gamma$  production are lacking.

In addition to these biochemical mechanisms capable of chlamydial inhibition, a number of cellular mechanisms can inhibit or destroy *Chlamydia* elementary bodies. However, whether these responses are completely nonspecific or require the participation of specific antisera is questionable. *In vitro* studies by Yong *et al.* (1982, 1986) and Zvillich and Sarov (1985) have shown that polymorphonuclear leukocytes (PMNs) rapidly take up elementary bodies and degrade them, but the role of specific or nonspecific human sera was not investigated in this phenomenon. Enhancement of chemiluminescent responses of PMNs to elementary bodies was noted with the addition of *Chlamydia* serovar-specific sera but not group-specific sera (Soderlund *et al.*, 1984), whereas

the same response using L2 elementary bodies is enhanced with human sera, regardless of whether or they contain serovar-specific antibody (Hammerschlag *et al.*, 1985). Clearly PMNs do interact with *Chlamydia*, but their role in disease control is not clarified.

Lymphocytes, monocytes, and macrophages also interact with *Chlamydia in vitro*. L2 elementary bodies, when incubated with peripheral blood lymphocytes, have decreased infectivity but can replicate in macrophages (Manor and Sarov, 1986). An increased production of nonspecific immunoglobulin is stimulated by cocultivation of *Chlamydia* L2 elementary bodies (live or formalin fixed) with human peripheral blood lymphocytes, regardless of the donor's previous exposure to *Chlamydia*, and probably represents nonimmune polyclonal responses to chlamydial antigen (Bard and Levitt, 1984). Further studies by Bard have revealed that about 50% of the B lymphocytes so exposed bind elementary bodies whereas less than 10% of the T cells do so (Bard and Levitt, 1986). However, although binding was not assessed, an increase in nonspecific T-cell proliferative response to concanavalin A (ConA) was noted by Rank *et al.* in the peripheral blood lymphocytes of guinea pigs immunized subcutaneously with live or UV-inactivated *C. trachomatis* (Rank *et al.*, 1990). However, this treatment appeared to have little effect on the resulting genital chlamydial infection when immunized guinea pigs were challenged subsequently.

Although several nonspecific host responses to *C. trachomatis* antigen exist, specific immune responses, both cell-mediated and specific antibody-dependent, are more likely to modify infection or to confer immunity against reinfection. Several groups of investigators have documented the production of serovar-specific antibody, particularly in women who experienced upper genital tract infection (salpingitis, endometritis). However, little correlation appears to exist between the intensity of the humoral immune response and resistance to reinfection. More important is the role of local antibody, particularly IgA, in resistance to or modification of infection of the genital tract.

The antibody response to *C. trachomatis* has been well documented (Rank *et al.*, 1979; Monnickendam and Pearce, 1983; Schachter *et al.*, 1983; Monnickendam, 1988). Although humoral antibodies are generated in *C. trachomatis* infection (IgG, IgM, IgA), their role in subsequent protection is partial or transitory, at best (Katz *et al.*, 1987; Rank *et al.*, 1988). However, in the mouse model, passive immunization with polyclonal and certain monoclonal antibodies against *Chlamydia psittaci* antigens was shown to decrease the rate of placental infection and spontaneous abortion (Buzoni-Gatel *et al.*, 1990). This study suggests that antibodies directed against the proper immunogen can be protective. Immunotype- or serovar-specific antibodies are protective in the owl monkey (Nichols *et al.*, 1973) and the guinea pig model (Murray and Charbonnet, 1971; Murray *et al.*, 1973; Murray, 1977) and in cell culture (Peeling *et al.*, 1984; Lucero and Kuo, 1985) but local secretory antibody appears to play a more important role in protection against infection than humoral antibody, as has been demonstrated by numerous investigators (Murray and Charbonnet, 1971; Murray *et al.*, 1973; Nichols *et al.*, 1973; Howard *et al.*, 1976; Alani *et al.*,

1977; Murray, 1977; McComb *et al.*, 1979; Richmond *et al.*, 1980; Brunham *et al.*, 1983; Cui *et al.*, 1989,1991). Most recently, studies in our laboratory have demonstrated that oral administration of live *Chlamydia* can decrease or eliminate cervical shedding of *Chlamydia* on subsequent challenge intravaginally with live organisms (Cui *et al.*, 1991). In addition, a marked booster effect was noted in antibody responses, both locally at the site of rechallenge and in the serum (see Figures 1 and 2). However, the local and humoral antibody responses appear to decline with time, allowing reinfection to take place as demonstrated in the guinea pig model (Rank *et al.*, 1988) and by clinical observation of human disease (Katz *et al.*, 1987). Despite this decline in immunity with time, vaccination might be used to protect a delivering infant from subsequent *C. trachomatis* infection. Theoretically, one could vaccinate the pregnant female orally with live (Cui *et al.*, 1991) or inactivated (Rank *et al.*, 1990) organism to stimulate local IgA production, which might prevent subsequent colonization of the infant by decreasing or preventing colonization of the mother's genital tract. Pregnant mice, when immunized orally with live *C. trachomatis*, were capable of producing *Chlamydia*-specific IgA in the milk (Z. Cui, personal communication), but the potential protective effect of specific IgA was not investigated by *Chla*-

*mydia* challenge in this case. Approximately 30% and 15% of infants exposed to maternal *Chlamydia* acquire conjunctivitis and pneumonia, respectively, in the United States (Frommell *et al.*, 1979; Schachter *et al.*, 1986); local *Chlamydia*-specific maternal secretory IgA (or IgG or IgM) antibody, passively acquired by the infant in passage through the birth canal or through suckling, may be one of the factors explaining why these percentages are not significantly greater.

The importance of prevention of this most common STD is clearly evident, but attempts to develop an effective vaccine against *Chlamydia* have been only partially successful to date. Further careful investigation of the host immune responses will be necessary before control of this STD through immunization can be achieved.

### C. Herpes Simplex Virus Infections

Genital herpes simplex virus (HSV) infections have significant morbidity in adults, but rarely cause death in the immunologically normal host. In sharp contrast is neonatal HSV infection, with its concomitant high mortality and frequency of subsequent neurological sequelae in survivors despite antiviral therapy (Whitley, 1990). Both type 1 (10% of total cases of neonatal HSV) and type 2 have been recovered from infected infants. Interestingly, although primary mater-

nal HSV infection at the time of delivery has nearly 50% risk of viral acquisition by vaginal delivery of the infant, recurrent maternal genital HSV carries less than 5% risk for the infant at the time of vaginal delivery. Although the reasons for these differences have been explored, the role of maternal immunity in the prevention of HSV transmission to the delivering infant is far from understood.

Herpesviruses are acquired by direct exposure of the mucous membranes to viral particles, with subsequent establishment of infection. From this local entry portal, virus can disseminate in the immunocompromised host or the neonate (who has a relative immunodeficiency compared with an adult). Thus, the local immune response should play a role in the prevention of recurrent attacks. However, members of the Herpesviridae family have the unique ability to establish latency within the host, most likely within immunoprivileged sites (such as the lumbosacral ganglia following genital HSV infection), and hence are sequestered from the host's local immune response until reactivation of the virus. When infected with HSV, the host has both nonspecific and specific immune responses similar to those activated during other STDs. Although the initial and secondary host immune responses to HSV infection are under careful investigation, mechanisms that maintain latency and control subsequent events initiated during recurrences are poorly understood and hamper attempts at effective control through vaccination.

Local and systemic immunological reactivity against HSV seems to have relevance in the moderation and eradication of infectious viral particles. Studies have demonstrated that maternal and cord blood samples possess similar levels of IgG class antibodies with antiviral activity that mediate neutralization and antibody-dependent cell-mediated cytotoxicity (ADCC) (Shore *et al.*, 1976,1977). Maternal ADCC has been shown to pass to the neonate (Shore *et al.*, 1976,1977; Kohl *et al.*, 1978). However, human cord blood monocytes have less ability to generate the ADCC response than adult leukocytes (Shore *et al.*, 1977). Kohl and colleagues found a difference between adherent (macrophages) and nonadherent (lymphocyte) populations in cord blood once these populations were separated from each other (Kohl *et al.*, 1981b). These researchers proposed that cell separation also may have removed some inhibitory factors, and altered the results of their studies (Kohl *et al.*, 1981a; Kohl, 1984). Subsequently, their group found that the route of birth, vaginal delivery compared with caesarian section, had marked effects on ADCC of cord mononuclear cells; cells from infants delivered by caesarian section had much lower ADCC activity than those from infants delivered vaginally (Frazier *et al.*, 1982). Cellular cytotoxicity and peripheral blood mononuclear leukocyte ADCC was decreased in the first months of life (Kohl, 1984), but cord blood PMNs had ADCC similar to that of adult PMNs (Kohl *et al.*, 1981b). These findings may help explain the sensitivity of the newborn to the devastating effects of HSV infection, particularly if the mother has not experienced previous HSV infection and has not generated neutralizing and ADCC antibody to provide to her infant.

Since HSV is such a devastating disease in the neonatal period despite antiviral therapy, significant impetus exists to find alternative methods of protection for the exposed infant.

Although cell-mediated immune responses to HSV are clearly important in limiting viral activity and in resolution of infection, HSV-specific antibody is an important adjunct in host immunity against this viral pathogen. Although the role of humoral antibodies is not entirely clear in humans, evidence suggests that maternal antibody against HSV is important in decreasing dissemination in neonates and in promoting recovery from HSV infections in some studies (Yeager *et al.*, 1980; Sullender *et al.*, 1987), but not in others (Whitley *et al.*, 1980). Newer tests using antibody response to gG glycoprotein are thought to be type specific for HSV-2 (Lee *et al.*, 1985,1986; Sullender *et al.*, 1988). These tests will allow clearer analysis of human HSV antibody responses without the problems of cross-reactivity with antibody against HSV-1, a problem common to many earlier assays. The data regarding the role of antibody in HSV disease are clearer in animal studies, in which passive prophylaxis of animals with hyperimmune sera against HSV can decrease the severity of induced infection, particularly lethal central nervous system infection (Evans *et al.*, 1946; Cheever and Daikos, 1950; Luyet *et al.*, 1975; Baron *et al.*, 1976; Davis *et al.*, 1979). Irradiated mice were not protected despite hyperimmune serum administration, indicating that an irradiation-sensitive arm of the host immune system is also important in the immune response to HSV (Davis *et al.*, 1979). Immunosuppressed mice also do not produce appreciable antibody, nor do they demonstrate cell-mediated activity toward HSV-1 infection (Worthington *et al.*, 1980). Whether these issues can be clarified in human studies remains to be seen.

The viral glycoproteins appear to be the most potent inducers of humoral antibody. Five surface glycoproteins (gA, gB, gC, gD, and gE) are the principal immunogens identified to date (Spear, 1976; Ruyechan *et al.*, 1979). Such antibodies are involved in ADCC and viral neutralization; antibodies against gB, gC, and gD mediate ADCC (Norriid *et al.*, 1979; Sethi, 1983) and complement-dependent cytotoxicity of HSV-infected cells (Kohl *et al.*, 1981a). High titers of neutralizing antibodies against HSV are generated by purified gD; monoclonal antibodies directed against this glycoprotein can limit infectious spread of induced HSV infection in mice (Cohen *et al.*, 1972,1984; Eisenberg *et al.*, 1982). Passive transfer of monoclonal antibodies against the principal glycoproteins inducing ADCC but not neutralization still could confer protection against HSV challenge in mice (Balachandran *et al.*, 1982). Similar studies have been conducted in the naturally HSV-exposed neonate, showing that passive transfer of HSV-specific antibody may prevent or moderate the disease in exposed infants (Yeager *et al.*, 1980; Nahmias, 1983; Prober *et al.*, 1987; Sullender *et al.*, 1987). Unfortunately, the prospect of a useful vaccine against HSV-2 to provide protection for mothers and their infants is far from realized.

#### D. Cytomegaloviruses

Cytomegaloviruses (CMV) are also members of the herpesvirus family. These common viral agents infect many animal species including humans (Weller, 1971). At present,

CMV is the leading cause of congenital and perinatal viral disease in infants (Reynolds *et al.*, 1973; Stagno *et al.*, 1975; Pass *et al.*, 1981; Stagno, 1990). Although many exposed infants have mild to no obvious disease, congenitally infected infants can have severe manifestations including deafness and multiple organ system involvement (Kumar *et al.*, 1973; Reynolds *et al.*, 1974; Stagno *et al.*, 1977, 1981; Alford *et al.*, 1990; Stagno, 1990). Additionally, infants infected *in utero* can continue to shed virus from the urine for more than 5 yr and from the nasopharynx for 2–4 yr (Stagno *et al.*, 1975, 1984; Pass *et al.*, 1980). Hence, prevention of this disease in susceptible pregnant females would be beneficial to their infants. CMV, like HSV, can produce recurrences; asymptomatic shedding from the cervix, urinary tract, and pharynx is not uncommon in women. In postpartum women, the breast appears to be a common site of reactivation; more than 30% of seropositive females intermittently excrete CMV in their milk during the first year after delivery (Stagno *et al.*, 1980; Dworsky *et al.*, 1983).

Like HSV infections, primary CMV infection of the pregnant woman is much more likely to cause fetal or neonatal infection than recurrent infection. Both antibody- and specific cell-mediated immunity appear to have a role in protection against CMV. Indirect evidence for the efficacy of specific CMV antibody in disease prevention and modulation comes from studies of renal transplant patients (Syndman *et al.*, 1987). A reduction in the incidence of symptomatic CMV infection was noted in renal transplant patients given prophylaxis with high titer CMV immunoglobulin, although the overall incidence of CMV remained the same. Stern *et al.* noted that women with strong lymphocyte proliferative responses to CMV during primary infection delivered infants without infections, whereas 60% of their female patients without such responses delivered infected infants (Stern, 1984). Maternal immunity also seems to modify the severity of neonatal infection (Stagno *et al.*, 1982, 1986), a result that has led to attempts to immunize the nonimmune population to control congenital CMV infection with a live attenuated strain of CMV (Plotkin *et al.*, 1976, 1984; Stern, 1984). However, immunity appears to dissipate with time; antibody and lymphocyte transformation reactions to CMV disappeared in half the vaccinees over an 8-yr period (Stern, 1984). Additional issues regarding reactivation of viral vaccine strains, latency, and oncogenic potential of such live vaccines have not been answered adequately (Stagno, 1990). These problems, in conjunction with the issue of waning immunity, make the development and use of subunit vaccines much more attractive than live vaccines (Plotkin *et al.*, 1990). Whether or not this new vaccine, or another like it, will reduce the incidence of congenital CMV infections as effectively as vaccination of susceptible populations with rubella vaccine curbed congenital rubella syndrome in the 1960s remains to be seen.

### E. Genital Mycoplasmas

Unlike the previously discussed STDs, the roles of genital mycoplasmas and other bacterial commensals of the vagina in adverse pregnancy outcome and infant morbidity and mor-

tality are less clearly established. Genital mycoplasmas have been implicated in the development of chorioamnionitis, preterm labor, and low birth weight infants (Cassell *et al.*, 1986; Driscoll, 1986; Gravett and Eschenbach, 1986; Kass *et al.*, 1986; Hillier *et al.*, 1988; Liepmann *et al.*, 1988; Watts *et al.*, 1989). *Ureaplasma urealyticum* has been implicated in the development of neonatal pneumonia and chronic lung disease of the premature infant (Quinn *et al.*, 1985; Cassell *et al.*, 1988; Wang *et al.*, 1988; Waites *et al.*, 1989), although the pathogenesis has not been clarified entirely. Depending on the study population, as many as 80% of pregnant women have been noted to be colonized with *U. urealyticum* in their genital tracts at some point during pregnancy (Harrison, 1986). However, only a small subset of exposed premature infants develops chronic lung disease (bronchopulmonary dysplasia, BPD) and the multiple factors involved in the generation of BPD will be difficult to evaluate. Clearly *Ureaplasma* and *Mycoplasma* species produce phospholipases, particularly A<sub>2</sub>, which may contribute to relative surfactant deficiency in the sick premature infant, despite surfactant replacement therapy. Clearly this avenue of research must be pursued to assess the maternal response to these organisms and to clarify their role in neonatal pneumonia.

*Mycoplasma hominis*, a less common isolate in pregnant women than *U. urealyticum*, has been recovered occasionally from multiple sites in infants and children (McDonald and Moore, 1988). Meningitis (Wealthall, 1975; Mardh, 1983; McDonald and Moore, 1988; Waites *et al.*, 1988), pericardial effusion (Miller *et al.*, 1982), and sepsis (Unsworth *et al.*, 1985) all have been documented with *M. hominis* as the only organism recovered from these sites. However, a prevalence study of *M. hominis* and other genital mycoplasmas as agents in sepsis and meningitis in young infants failed to recover these agents from the blood or cerebral spinal fluid in nearly 200 cases, whereas 6 *M. hominis* and 9 *U. urealyticum* isolates were recovered from the urinary tract, indicating colonization of the infants with these organisms (Likitnukul *et al.*, 1986).

Despite evidence to suggest the role of genital mycoplasmas in maternal and neonatal disease, very little is known about the local host response to these organisms. Humoral antibody responses have been documented for most *Mycoplasma* species in human and animal hosts, but a direct relationship between the level of circulating antibody and resistance to mycoplasma infection is not always obvious. Although little or no data are available on the local antibody responses to genital mycoplasmas in humans, some data from a mouse model of genital tract infection suggest that specific IgG and IgM are produced in the genital tract (Taylor-Robinson, 1988). However, although IgA would be speculated to be present, it could not be confirmed (Taylor-Robinson, 1988). Additionally, resistance to reinfection appeared to correlate with the presence or absence of local IgG (P. Furr and D. Taylor-Robinson, unpublished data). As the role of mycoplasmas is better defined in the neonate, a clearer cause and effect relationship may be established between carriage of genital mycoplasmas by the mother and her ability to transmit the organisms to her offspring.

## V. SUMMARY

The evidence presented thus far indicates that the mucosal surfaces of the female genital tract are able to mount a locally induced specific antibody and specific cell-mediated immune response. The local antibody response appears to be independent of the serum antibody response and is associated mostly (but not exclusively) with secretory IgA immunoglobulin and locally reactive lymphocyte populations. The precise origin of cells responsible for cell-mediated immunity is unknown. Data suggest that the sparse amount of IgA immunocompetent tissue observed in the female genital tract may be derived largely from immunoreactive cells from the gastrointestinal tract, particularly Peyer's patches. Additional data regarding the immune response of the breast suggest that a similar population of antigen-primed IgA-producing cells from the gastrointestinal tract migrates to the female breast and secretes specific IgA into the milk. Thus, antigen exposure in the gut-associated lymphoid tissue produces a sharing of immune experience at all mucosal surfaces, with particular enhancement at the surface of secondary exposure which, in this case, is the genital tract. Reduction of female genital tract colonization by pathogens through immunization programs may be able to reduce the incidence of transmission of the offending organisms to the neonate's mucosal surfaces. The neonate's own immune system, although not as active against certain organisms that require cytotoxic responses, also is capable of a broad range of immunological responses. Hence, the exploitation of antigen-sensitized precursor cells in the gastrointestinal tract of the mother by oral priming with genital pathogens (or antigenically reactive components of the pathogens, such as OMPs) may provide protection against genital pathogens in the near future. This benefit would be dual: not only could the infection rate and subsequent morbidity and mortality in newborns be decreased, but it may be possible to reduce the rampant spread of STDs through such immunization programs in the ensuing decade.
