CBC, complete blood count; ESR, erythrocyte sedimentation rate; CRP, C-reactive protein; IgA, immunoglobulin A; MAG, myelin-associated glycoprotein; MRI, magnetic resonance imaging.

Data from England JD, Gronseth GS, Franklin G, et al. Practice parameter: evaluation of distal symmetric polyneuropathy: role of laboratory and genetic testing (an evidence-based review). *Neurology*. 2009;72:185-192.

The *thoracodorsal nerve* that supplies the latissimus dorsi and the *subscapular nerve* that supplies the teres

major each branch medially off the posterior cord. The posterior cord persists distally, becoming the *radial nerve*, after giving off a smaller lateral branch, the *axillary nerve*, which supplies the deltoid. The lateral and medial cords then each contribute a branch to form the *median nerve*, composed of the medial branch of the lateral cord and the lateral branch of the medial cord, joined in the middle of the plexus. The lateral branch of the lateral cord persists distally, becoming the *musculocutaneous nerve*, whereas the medial branch of the medial cord becomes the *ulnar nerve* (Fig. 87.1; Tables 87.3 and 87.4).

The brachial plexus may be injured by traumatic, neoplastic, infectious, radiation, and other processes. Careful history and neurologic examination, in concert with a detailed understanding of plexus anatomy, is the first step in recognizing plexus injury and differentiating it from injury to the nerve roots or peripheral nerves.

Electrophysiologic assessment with EMG and nerve conductions is often critical in confirming the diagnosis, and imaging studies may also be indicated. Mixed syndromes of radicular plexus and peripheral nerve injury may also occur, making localization even more challenging. The roots or trunks of the brachial plexus may be damaged by lacerations, gunshot wounds, or direct trauma. They may be compressed by tumors or aneurysms or stretched and torn by violent movements of the shoulder in falls, dislocation of the shoulder, carrying heavy loads on or over the shoulder, and by traction during birth. The syndromes of the roots and trunks cause deficits principally in the distribution of the affected nerve roots. Partial paralysis and incomplete sensory loss are common because many muscles of the arm receive innervation from two or more roots. Compression at the level of the thoracic outlet (*thoracic outlet syndrome*) is addressed separately in Chapter 78.

FIGURE 87.1 The brachial plexus. (From Haymaker W, Woodhall B. *Peripheral Nerve Injuries*. Philadelphia: WB Saunders; 1945.)

TABLE 87.3 Innervation of the Muscles of the Shoulder Girdle

Muscle	Nerve	Spinal Nerve Roots
Sternocleidomastoid	Accessory	X1, C2, C3
Trapezius	Accessory	C3, C4
Serratus anterior	Long thoracic	C5, C7
Levator scapulae	Dorsal scapular	C5, C6

Rhomboideus major	Dorsal scapular	C5, C6
Rhomboideus minor	Dorsal scapular	C5, C6
Subclavius	Subclavian	C5, C6
Supraspinatus	Suprascapular	C5, C6
Infraspinatus	Suprascapular	C5, C6
Pectoralis major	Medial and lateral pectoralis	C5, C6
Pectoralis minor	Medial pectoralis	C5, C6
Teres major	Subscapular	C5, C6
Latissimus dorsi	Thoracodorsal	C6, C7
Subscapularis	Subscapular	C5, C6
Deltoid	Axillaris	C5, C6
Teres minor	Axillaris	C5, C6

Trunk and Root Injury

UPPER RADICULAR SYNDROME

Upper radicular syndrome (Erb or Erb-Duchenne palsy) results from damage to the upper roots (C4, C5, or C6) or the upper trunk. Such lesions are most commonly the result of stretch injuries during difficult deliveries, especially when forceps are used, and cause paralysis of the deltoid, biceps, brachioradialis, pectoralis major, supraspinatus, infraspinatus, subscapularis, and teres major muscles in varying combinations. If the lesion is near the roots, the serratus anterior, rhomboids, and levator scapulae are also paralyzed. Clinically, this causes weakness of flexion at the elbow and of abduction and internal and external rotation of the arm. There is also weakness or paralysis of apposition of the scapula and backward-inward movements of the arm. Sensory loss is incomplete and consists of hypesthesia on the outer surface of the arm and forearm. The biceps reflex is absent. Unless treated by passive range-of-motion exercise, these patients may develop chronic contractures with the arm extended at the side, fully adducted, and pronated, with the hand flexed and facing rearward (e.g., the waiter's tip position).

MIDDLE RADICULAR SYNDROME

Middle radicular syndrome results from damage to the seventh cervical root (C7) or the middle trunk. Such lesions cause paralysis primarily of the muscles supplied by the radial nerve except the brachioradialis, which is entirely spared. Clinical weakness parallels that of injury to the radial nerve below the level of its branch to the brachioradialis. Sensory loss is variable and when present is limited to hypesthesia over the dorsal surface of the forearm and the external part of the dorsal surface of the hand.

TABLE 87.4 Innervation of Muscles of the Arm and Forearm

Muscle	Nerve	Root
Biceps brachii Brachialis	Musculocutaneous	C5, C6
Triceps	Radialis	C7, C8
Anconeus	Radialis	C7, C8
Brachioradialis	Radialis	C5, C6
Extensor carpi radialis	Radialis	C6, C7
Pronator teres	Medianus	C6, C7
Flexor carpi radialis	Medianus	C7, C8
Palmaris longus	Medianus	C7, C8
Flexor digitorum sublimis	Medianus	C7, C8
Flexor digitorum profundus	Medianus, ulnaris	C7, C8
Flexor carpi ulnaris	Ulnaris	C7, C8
Supinator	Radialis	C7, C8
Extensor digitorum communis	Radialis	C7, C8
Extensor digiti minimi	Radialis	C7, C8
Extensor carpi ulnaris	Radialis	C7, C8
Abductor pollicis longus and brevis	Radialis	C7, C8
Extensor indicis proprius	Radialis	C7, C8

LOWER RADICULAR SYNDROME (KLUMPKE PALSY)

Lower radicular syndrome (Klumpke palsy) results from injury to the lower trunk or lower roots (C7-T1), which causes paralysis of the flexor carpi ulnaris, the flexor digitorum, the interossei, and the thenar and hypothenar muscles. This pattern mimics a combined lesion of the median and ulnar nerves. Clinically, a flattened or simian hand is seen, with loss of all intrinsic hand musculature and with loss of sensation on the inner side of the arm

and forearm and on the ulnar side of the hand. The triceps reflex is lost. If the communicating branch to the inferior cervical ganglion is injured, there is paralysis of the sympathetic nerves, causing a Horner syndrome.

Cord Injury

Lesions of the cords cause motor and sensory loss resembling that seen after injury to two or more peripheral nerves. *Lateral cord* injury causes weakness in the distribution of the musculocutaneous nerve and the lateral head of the median nerve, including weakness in the pronator teres, flexor carpi radialis, and flexor pollicis. *Posterior cord* injury causes weakness paralleling that resulting from combined damage to the radial and axillary nerves, whereas *medial cord* injury mimics combined damage to the ulnar nerve and the medial head of the median nerve (finger-flexion weakness).

Diffuse Plexus Injury

Generalized injury to the brachial plexus is usually unilateral but occasionally appears bilaterally. Such injury results from a more diffuse polyneuropathy, such as chronic inflammatory demyelinating

P.755

neuropathy, or from multifocal motor neuropathy. A variety of insults may produce injury selectively affecting the brachial plexus, but tumor infiltration, radiation plexitis, and idiopathic plexitis are among the most important. Almost any neoplasm with a propensity for the chest may affect the plexus, but those cancers originating locally, such as lung and breast cancer, are most likely to cause injury. Such tumors may cause extrinsic compression of the plexus as they grow or may directly infiltrate the nervous tissue. Other neoplasms, such as lymphoma, may infiltrate the plexus and cause progressive deficits without any apparent mass effect or enlargement of the plexus itself in the initial stages. Magnetic resonance imaging (MRI) with contrast is the best way to confirm these lesions.

Idiopathic brachial plexitis (also known as the *Parsonage-Turner syndrome* or *neuralgic amyotrophy*) usually begins with a sudden, sharp pain affecting one shoulder, often with radiation down the ipsilateral arm, later followed by arm or shoulder weakness. The pain persists for hours or a few days with gradual improvement and usually resolves completely within days to weeks, leaving some sensory and motor dysfunction. It may be bilateral or asymmetric. Localization is often difficult, because plexus involvement ranges from diffuse to multifocal, and often includes patchy injury to the nerve branches off the plexus (e.g., the axillary nerve).

Electrodiagnostic studies, if performed at least 14 to 21 days after onset, usually localize the injury to the plexus but may demonstrate multifocal involvement. Patterns of both axonal and demyelination injury have been reported. The diversity of physiologic disorders in different nerves or even within the same nerve is attributed to involvement of the terminal nerve twigs or to patchy damage of discrete bundles of fibers within the cords or trunks of the brachial plexus or its branches. The long thoracic and anterior interosseous nerves are commonly affected. Autoimmune or infectious causes have been suggested, but the etiology is obscure. Some cases have occurred in small epidemics, and the disorder may follow intravenous heroin use, HIV seroconversion, surgery, and delivery.

There is no clear evidence that immunosuppressive therapy alters the course of the disease. However, short courses of tapering oral steroids are often prescribed if the patient presents shortly after symptom onset. Variants of this syndrome have also been described, including one with isolated, pure sensory injury affecting the lateral, antebrachial, cutaneous, and the median nerves.

A hereditary form that is frequently recurrent and bilateral is rarely encountered. Lumbosacral plexitis also occurs but much less frequently. Recovery depends on the severity of the initial insult. Although most patients recover well over 6 to 12 months, some are left with permanent disability. It is considered good in about 66%, fair in 20%, and poor in 14%. Clinical recovery may take 2 months to 3 years.

Thoracic Outlet Syndrome

The term *thoracic outlet syndrome* (TOS) encompasses different syndromes that arise from compression of the nerves in the brachial plexus or blood vessels (i.e., subclavian or axillary arteries, or veins in the same area). The putative compression sources are also diverse. How often these lesions are actually responsible for symptoms and how the symptoms should be treated are matters of intense debate. Studies done mainly by orthopedists, vascular surgeons, and neurosurgeons have included reports on several hundred patients who were treated surgically for this syndrome. When neurologists write about the neurogenic form of TOS, however, the tone is always skeptical, and the syndrome is described as exceedingly rare, with an annual incidence of about 1 per 1 million persons.

PATHOLOGY

The T1 and C8 nerve roots and the lower trunk of the brachial plexus are exposed to compression and angulation by anatomic anomalies that include cervical ribs and fibrous bands—of uncertain origin. Other nearby structures, such as scalene muscles, are dubious sources of compression. Cervical ribs are commonly found in asymptomatic people, and it is therefore difficult to assume that the presence of a cervical rib necessarily explains local symptoms. In addition to the neural syndromes, the same anomalies may compress local blood vessels and cause vascular syndromes, usually separated into arterial and venous entities. These conditions are also rare and may cause neurogenic symptoms by distal nerve ischemia but not pressure on the brachial plexus. Some cases follow local trauma.

CLINICAL FEATURES

Patients have pain in the shoulders, arms, and hands, or sometimes in all three locations. Hand pain is often most severe in the fourth and fifth fingers. The pain is aggravated by use of the arm and arm “fatigue” may be prominent, meaning local discomfort after brief effort. There may or may not be hypesthesia in the affected area.

Critics have divided cases into two groups: the *true* neurogenic TOS and the *disputed* syndrome. In the *true* syndrome, there are definite clinical and electrodiagnostic abnormalities. This disorder is rare and is almost always caused by a taut fibrous band extending from a cervical rib or abnormally elongated C7 transverse process; the band stretches the distal C8 and T1 roots or lower brachial plexus trunk. There is unequivocal wasting and weakness of hand muscles innervated by these segments. Changes are almost always unilateral.

EMG and nerve conduction studies demonstrate a pattern of low-amplitude median motor, ulnar sensory, and medial antebrachial cutaneous-evoked responses. Ulnar motor responses to hypothenar muscles may be involved to a lesser degree. EMG signs of active and chronic denervation are limited to involved muscles, most severely in the abductor pollicis brevis, and are attributed to a major contribution from T1.

In the *disputed* form, there are no objective motor or sensory signs or consistent laboratory abnormalities. Attempts to reproduce the syndrome by passive abduction of the arm (i.e., the Adson test) or other maneuvers have been cited, but the same abnormalities may be found in normal people and have no specific diagnostic value. The diagnosis is usually made by the treating surgeon; symptoms are frequently bilateral and complicated by legal or other nonmedical issues.

Similarly, studies of the application of electrodiagnostic techniques have not been blinded or controlled, so less specific abnormalities have been noted; the findings include isolated abnormalities of ulnar sensory nerve amplitude, conduction velocity after stimulation of the Erb point, ulnar F waves, and ulnar somatosensory-evoked potentials. MRI may show deviation or distortion of nerves or blood vessels, bands extending from the C7 transverse process, or other local anomalies. MRI quantitative estimates of the size of the thoracic outlet may show smaller than average dimensions, as were the cases in blinded reviews of series that compared vascular and neurogenic patients together with controls but do not prove that the differences are causative. Magnetic

resonance angiography and Doppler ultrasonography may help assess possible vascular compression.

DIAGNOSIS AND TREATMENT

In cases of *true* TOS, diagnosis must exclude entrapment syndromes in the arm and compressive lesions in the cervical spine. The “upper

P.756

limb tension test” is said to be comparable to straight leg raising, is carried out by abducting the arms to 90 degrees in external rotation, bringing on symptoms within 60 seconds. EMG, MRI, and sonography after raising the arm have been used to aid in diagnosis. However, warnings continue to appear about false-positive maneuvers to evoke pain. Danielson and Odderson injected botulinum toxin into the anterior scalene muscle under ultrasound guidance. Subclavian artery flow rates were measured with Doppler ultrasound. Three weeks later, symptoms had improved and blood flow in the artery, tested with the arm extended, had improved. A placebocontrolled formal study of this “scalene muscle chemodenervation” would help resolve the uncertainty of the procedure which could be used for diagnosis, treatment, and screening for surgery. However, no consensus has been achieved for the surgical procedure of choice, which may or may not include botulinum, rib resection, brachial plexus neurolysis, scalenectomy, or release of the subclavian artery and vein. Exercise programs have also been advocated.

In the *disputed* form, when no objective findings are noted on neurologic examination, there are problems. Each case must be evaluated separately, but caution is reasonable when symptoms are not accompanied by objective changes. Conservative therapy should be given an adequate trial; postural adjustments, passive exercise to increase mobility of shoulder muscles, and an exercise program have all been advocated. The results of surgery are difficult to evaluate without objective signs or diagnostic laboratory abnormalities to track; placebo effects are rarely considered in the evaluation of surgery. Symptomatic improvement also appears to be unrelated to the surgical procedure or the particular structure that has been excised or resected. Surgery is not without hazard; complications may include causalgia, injury of the long thoracic nerve, infection, and laceration of the subclavian artery.

THE SPINAL ROOTS AND LUMBAR AND SACRAL PLEXI

The Lumbar Plexus

The spinal roots at L2, L3, and L4 join to form the *lumbar plexus* in the psoas major muscle. This plexus gives off a number of principally sensory nerves, including the iliohypogastric, the ilioinguinal, the genitofemoral, and the lateral femoral cutaneous. The *femoral nerve* is derived from the L2, L3, and L4 roots, passing to the anterior leg along the lateral aspect of the psoas muscle (which it supplies); exiting the pelvis; and passing under the inguinal ligament to supply the pectineus, sartorius, rectus femoris, vastus lateralis, vastus intermedius, and vastus medialis muscles; and terminates as the pure sensory saphenous nerve in the medial lower leg.

The *obturator nerve* arises from anterior branches of the L2, L3, and L4 roots, forming in the psoas muscle and entering the pelvis anteriorly to the sacroiliac joint. It passes through the obturator canal, branching anteriorly to supply the adductor longus and brevis, and the gracilis, as well as posteriorly to supply the obturator externus, and half of the adductor magnus. It carries sensation from a small and variable area on the inner surface of the medial thigh, knee, and occasionally just below the medial knee.

The Sacral Plexus

The sacral plexus is formed from the L5, S1, and S2 roots, with variable contributions from L4. The *superior gluteal nerve* arises from the L4, L5, and S1 roots and supplies the gluteus medius and minimus and tensor

fascia lata; the *inferior gluteal nerve* arises from the L5 and S1 roots and supplies the gluteus maximus.

The *sciatic nerve* is formed from the posterior fusion of the L4, L5, and S1 roots, exiting the pelvis via the greater sciatic foramen and passes through or under the piriformis muscle. It is functionally divided into a lateral fibular portion, which supplies the short head of the biceps femoris, and a medial tibial portion, which supplies the long head of the biceps femoris, the semitendinosus, and the semimembranosus. The nerve divides into the common fibular (formerly called the *peroneal*) and tibial nerves above the posterior knee.

The *common fibular nerve* branches laterally from the sciatic trunk in the popliteal fossa then moves superficially to wind around the head of the fibula. It then divides into the *superficial fibular nerve* to supply the peroneus longus and peroneus brevis and the *deep fibular nerve*, which supplies the tibialis anterior, extensor hallucis longus, peroneus tertius, and extensor digitorum brevis. The *tibial nerve* supplies the gastrocnemius and soleus, tibialis posterior, flexor digitorum longus, and flexor hallucis longus. It descends through the lower leg between the medial malleolus and the flexor retinaculum, dividing into the *medial plantar nerve* to supply the abductor hallucis, flexor digitorum brevis and flexor hallucis brevis, and the *lateral plantar nerve* to supply the abductor digiti minimi, flexor digiti minimi, abductor hallucis, and interosseous muscles. Both the tibial and fibular nerves supply sensory branches, which join to form the *sural nerve* below the popliteal space.

Radiation Plexopathy

Irradiation for carcinoma may damage nervous tissue, especially with high-voltage therapy. Brachial plexopathy is seen after radiotherapy for breast cancer; caudal roots and lumbosacral plexus are sometimes affected by radiation therapy for testicular cancer or Hodgkin disease. The first symptom is usually severe pain, followed by paresthesia and sensory loss. There may be a latent period of 12 to 20 months; in milder cases, several years may elapse before symptoms appear. Limb weakness peaks many months later. Latency intervals of up to 20 years have been reported. The damage may affect a single peripheral nerve initially and then progress slowly to involve others. Clinically, tendon reflexes disappear before weakness and atrophy becomes obvious; fasciculation and myokymia may be prominent. EMG and conduction studies reveal evidence of axonal damage; myokymic discharges are characteristic and can help differentiate plexopathy caused by radiation from plexopathy caused by tumor infiltration. High-resolution MRI is also potentially useful. No effective treatment is known. Radiation-induced fibrosis and microvascular injury are suspected mechanisms.

THE PROXIMAL NERVES OF THE ARM

The Axillary Nerve

The axillary nerve is the last branch of the posterior cord of the brachial plexus before forming the radial nerve. It arises from C5 and C6, supplies the deltoid and teres minor muscles, and transmits cutaneous sensation from a small patch on the lateral shoulder. Axillary neuropathy may be caused by trauma, fracture, humeral head dislocation, and brachial plexitis. Weakness of arm abduction after the first 15 to 30 degrees of movement is typical. Outward, backward, and forward movements of the arm are also weakened, although less dramatically. Sensory loss is limited to a small patch over the lateral deltoid.

The Long Thoracic Nerve

The long thoracic nerve arises from C5, C6, and C7 and supplies the serratus anterior muscle. This nerve is most commonly injured in isolation by forceful, downward pressure on the shoulder, which

P.757

stretches and compresses it. Typically, such pressure is caused by carrying excessively heavy loads on the shoulder (e.g., furniture, carpets, heavy sacks, backpacks slung over one shoulder, etc.), although it may also appear after acute impact, such as that occurring while playing football. A more archaic term, although one still in

use, is *hod-carrier's palsy*, in reference to the hod or container bricklayers formerly placed on the shoulder to carry bricks up to roof tops when constructing chimneys. Injury of this nerve destabilizes the scapula, causing winging, and prevents the rotation of the scapula needed to enable the last few degrees of abduction of the arm from 90 to 180 degrees over the head. Injury following acute or chronic trauma is characterized by weakness in elevation of the arm above the horizontal plane. Winging of the scapula is most prominent when the arm is fully abducted or elevated anteriorly (Fig. 87.2). Winging is often not readily apparent with the arm resting at the side.

FIGURE 87.2 Paralysis of the serratus anterior muscle with winging of the scapula.

The Brachial Cutaneous and Antebrachial Cutaneous Nerves

The brachial and antebrachial cutaneous nerves branch directly from the C8 to T1 plexus and provide sensation to the medial arm and upper two-thirds of the forearm. These nerves are usually injured in conjunction with the medial cord of the brachial plexus and are rarely injured in isolation.

The Suprascapular Nerve

The suprascapular nerve fibers arise from C5 and C6, ultimately branching from the upper trunk of the brachial plexus. The primarily motor nerve innervates the supraspinatus and infraspinatus muscles. Affected patients have difficulty moving the arm from the side through the first 15 to 30 degrees of abduction and with external shoulder rotation. Shoulder trauma or more diffuse brachial plexus injury is most common; isolated nerve injury is rare.

THE PERIPHERAL NERVES

The Radial Nerve

The radial nerve is a continuation of the posterior cord and contains elements of the C5, C6, C7, C8, and T1

nerve roots. It is predominantly a motor nerve and innervates the chief extensors of the forearm, wrist, and fingers. It descends through the axilla to supply the triceps, giving off three minor sensory branches to the upper arm, then winds posteriorly around the humerus in the *spiral groove*. After exiting the spiral groove, the nerve innervates the brachioradialis and extensor carpi radialis longus muscles then moves laterally to enter the forearm between the brachialis and brachioradialis muscles. There, it branches into a primary sensory component, the *superficial radial nerve*, which supplies sensation to the dorsoradial aspect of the distal forearm and the dorsal surface of the hand, and a motor component, the *posterior interosseous nerve*, which supplies all the remaining forearm extensor muscles and often the supinator as well (Table 87.5).

The clinical findings after radial nerve injury depend on the level of the lesion. Injury in the axilla, classically caused by improperly fitting crutches that are too long, causes triceps weakness as well as weakness of the remaining radial myotome and numbness in the radial dermatome. Injury in the spiral groove caused by humeral fracture or extrinsic compression (e.g., *Saturday night palsy*) causes weakness of the radial myotome below the elbow, with prominent wrist-drop, weakness of finger extension, and sensory loss in the distribution of the superficial radial nerve but preserved elbow extension. Mild elbow flexor weakness may be present as a result of involvement of the brachioradialis, which should be easy to distinguish on physical examination. The posterior interosseous branch may also be injured by entrapment as it passes through the supinator muscle in the tight space of the arcade of Frohse.

Injury of the posterior interosseous nerve spares the brachioradialis and the extensor carpi radialis longus, as well as the superficial radial nerve, causing radial deviation of the wrist with attempted wrist extension but no sensory loss (i.e., posterior interosseous neuropathy). Damage to the superficial radial branch may occur at the wrist as a result of tight-fitting jewelry or handcuffs, causing pure sensory loss over the dorsum of the hand without weakness. Evaluation of radial nerve injury often includes electrodiagnostic studies and may include imaging studies, depending on the site of the lesion. Treatment focuses on relieving the cause of compressive injury, if possible. Posterior interosseous nerve syndrome is sometimes treated with surgical release.

The Median Nerve

The median nerve derives from the C6 through T1 nerve roots, passing through the lateral and medial cords of the brachial plexus, which each contributes a segment to the nerve. The median nerve passes down the arm and through the two heads of the pronator teres at the level of the forearm, ultimately supplying the pronator teres as well as the flexor carpi radialis, palmaris longus, and flexor digitorum superficialis muscles. It then branches into the pure

P.758

motor *anterior interosseous nerve*, which supplies the flexor pollicis longus, pronator quadratus, and flexor digitorum profundus I and II, and into a main branch, which passes through the carpal tunnel, further branching into the *recurrent thenar nerve*, supplying the abductor and the lateral flexor pollicis brevis and the opponens pollicis before terminating in the palm, where it supplies lumbricals I and II. Pronation is mediated by the pronator quadratus and pronator teres, wrist flexion by the flexor carpi radialis and palmaris longus, flexion of the thumb and the index and middle fingers by the superficial and deep flexors, and opposition of the thumb by the opponens pollicis (Table 87.6).

TABLE 87.5 Muscles Innervated by the Radial Nerve

Triceps	Extensor digiti minimi
Anconeus	Extensor carpi ulnaris

Brachioradialis	Abductor pollicis longus
Extensor carpi radialis longus and brevis	Extensor pollicis longus and brevis
Supinator	Extensor indicis proprius
Extensor digitorum communis	

TABLE 87.6 Muscles Innervated by the Median Nerve

Pronator teres	Pronator quadratus
Flexor carpi radialis	Abductor pollicis brevis
Palmaris longus	Opponens pollicis
Flexor digitorum sublimis	Flexor pollicis brevis
Flexor digitorum profundus	Lumbricales (digits one and two)
Flexor pollicis longus	

The median nerve supplies sensation to the radial side of the palm, the ventral thumb, index and middle fingers, the radial half of the ring finger, as well as the dorsal surfaces of the distal phalanx of the thumb, and the middle and terminal phalanges of the index and middle fingers. Isolated lesions of the median nerve cause weakness and sensory loss in the aforementioned distributions, but only a few movements are paralyzed because of the synergistic contributions of muscles innervated by other nerves to these movements. However, there may be absence of flexion in the index finger and near-complete paralysis of the opponens pollicis. The median nerve may be injured by trauma, ischemia, and other processes but most commonly is damaged by anatomic compression. It may be entrapped between the heads of the pronator teres muscle, causing weakness and sensory loss in the above distributions, with sparing of the pronator teres itself, which is innervated more proximally (i.e., the pronator teres syndrome).

Entrapment of the anterior interosseous nerve (i.e., the anterior interosseous neuropathy) often presents with pain but produces no sensory loss. Symptoms include weakness of the flexor pollicis longus, flexor digitorum profundus I and II, and the pronator quadratus. Attempts to make the “OK” sign with the thumb and index finger produces a triangle rather than a circle (e.g., the pinch sign). The most common of all the nerve entrapment syndromes is the *carpal tunnel syndrome*. This syndrome results from entrapment of the median nerve as it passes through the tunnel defined by the carpal bones and the transverse carpal ligament, resulting in pain and sensory loss in a distal median distribution; wasting and weakness of thenar muscles and median innervated lumbricals is seen in severe cases. Although the diagnosis is primarily clinical, electrophysiologic studies may confirm the lesion and provide information on severity. Conservative treatment with application of a neutral position wrist splint is often effective. More severe or refractory cases, especially when motor deficits appear or

splinting or other conservative measures fail to provide relief, may be treated by surgical release of the carpal tunnel. Many underlying disorders may predispose to the condition including diabetes, uremia, hypothyroidism, amyloidosis, and pregnancy.

The Ulnar Nerve

The ulnar nerve arises from C8 to T1 roots and the medial cord of the brachial plexus. It passes between the biceps and triceps, moving posteriorly to pass behind the medial epicondyle in the ulnar groove. It enters the forearm through the cubital tunnel, supplying the flexor carpi ulnaris and the flexor digitorum profundus II and IV, then moves medially to enter the hand through Guyon canal, where it divides into a superficial sensory branch and a deep motor branch, which supplies the abductor, opponens, and flexor digiti minimi medially. It then moves laterally to the adductor pollicis and the medial half of the flexor pollicis brevis (Table 87.7).

The nerve supplies sensation to the palmar and dorsal surfaces of the little finger, the medial half of the ring finger, and both the palmar and dorsal sides of the ulnar portion of the hand. Complete lesions of the proximal ulnar nerve are characterized by weakness of flexion and adduction of the wrist and of flexion of the ring and the little fingers, paralysis of abduction and opposition of the little finger, paralysis of adduction of the thumb, and paralysis of adduction and abduction of the fingers, along with atrophy of the hypothenar muscles and the interossei. Atrophy of the first dorsal interosseous is especially obvious on the dorsum of the hand between the thumb and the index finger. Sensory loss is greatest in the little finger and is present to a lesser extent on the inner side of the ring finger. Chronic lesions result in clawing of ulnar innervated fingers. The ulnar nerve may also be injured by trauma, ischemia, and other causes but similar to the median nerve, it is most commonly injured by compression. Entrapment primarily occurs in three locations. The most common site is at the elbow, in or just proximal to the ulnar groove. Just distal to the elbow, the nerve may become entrapped in the cubital tunnel, the tunnel formed by the aponeurosis connecting the two heads of the flexor carpi ulnaris. Proximal nerve injury causes weakness in the ulnar myotomes of the hand and may include the flexor carpi ulnaris (FCU) and flexor digitorum profundus (FDP) III and IV, depending on the precise site of the compression. The nerve is potentially compressed at the elbow by direct pressure from arms of chairs, table edges, and excessive elbow flexion. A protective elbow pad is useful in some cases. Various forms of surgical decompression are available for the most extreme cases. Guyon canal stenosis in the wrist, most commonly associated with a ganglion cyst, causes weakness and atrophy of intrinsic hand muscles. Sensory symptoms may be minimal, although nerve conduction studies to the digits are abnormal. However, the FCU and FDP III and IV are spared, in addition to sensation on the dorsal hand surface, which is innervated by the dorsal ulnar cutaneous nerve that arises in the distal forearm. The innervation of hand muscles is summarized in Table 87.4.

TABLE 87.7 Muscles Innervated by the Ulnar Nerve

Flexor carpi ulnaris	Flexor digiti minimi
Flexor digitorum profundus (digits four and five)	All interossei
Palmaris brevis	Lumbricales (digits three and four)
Abductor digiti minimi	Flexor pollicis brevis
Opponens digiti minimi	

The Musculocutaneous Nerve

The musculocutaneous nerve originates from the C5 and C6 nerve roots and the main branch of the upper trunk of the brachial plexus. It provides innervation to the coracobrachialis, biceps brachii, and brachialis muscles and provides sensation to the ventrolateral forearm (lateral antebrachial sensory nerve), as well as to a small area on the dorsolateral outer surface of the forearm. Isolated injuries of the nerve are rare and it is not typically prone to focal compression. Lesions of the musculocutaneous nerve produce weakness of flexion and supination of the forearm, sensory loss in the musculocutaneous myotomes, and loss of the biceps reflex. Forearm flexion may still be performed by the brachioradialis muscle innervated by the radial nerve. However, because the biceps is the chief supinator of the forearm, this movement is paralyzed. Excessive windsurfing is associated with compression of the lateral antebrachial sensory branch.

THE NERVES OF THE LEG

The Obturator Nerve

Lesions of the obturator nerve are uncommon and may be caused by pelvic tumors, obturator hernias, and by passage of the head of the fetus during difficult labor. Injuries to the obturator nerve result in severe weakness of adduction and to a lesser extent, internal and external rotation of the thigh. Pain in the knee joint is sometimes caused by pelvic involvement of the geniculate branch of the obturator.

The Iliohypogastric Nerve

The iliohypogastric nerve is a predominately sensory nerve that originates from the uppermost part of the lumbar plexus. It provides sensation to the outer and upper parts of the buttocks and the lower part of the abdomen and supplies partial innervation to the internal oblique and transversalis muscles. Lesions of the iliohypogastric nerve are rare. It may be divided by incisions in kidney operations or together with the ilioinguinal nerve in operations in the inguinal region, such as hernia repair. Lesions of these nerves produce no significant motor loss and only a small area of cutaneous anesthesia.

The Ilioinguinal Nerve

The ilioinguinal nerve is also a branch of the upper lumbar plexus. It provides sensation to the upper inner portion of the thigh, the pubic region, and the external genitalia and supplies the transversalis, internal oblique, and external oblique muscles. The ilioinguinal nerve is usually injured in concert with the iliohypogastric nerve and is only rarely injured in isolation.

The Genitofemoral Nerve

This predominately sensory nerve originates from the second lumbar root and provides sensation to the scrotum and the contiguous area of the inner surface of the thigh. Lesions of the genitofemoral nerve are rare. Irritative lesions of the nerve in the abdominal wall are accompanied by painful hyperesthesia at the root of the thigh and the scrotum.

The Lateral Femoral Cutaneous Nerve of the Thigh

This nerve is formed by fibers from the second and third lumbar roots. It crosses beneath the fascia iliaca to emerge at the anterosuperior iliac spine, descends in the thigh beneath the fascia lata, and divides into two branches. The posterior branch passes obliquely backward through the fascia lata and provides sensation to the superior external buttock. The anterior branch, which is more important clinically, pierces the fascia lata through a small fibrous canal located about 10 cm below the ligament and provides sensation to the outer surface of the thigh.

Lesions to this nerve principally affect the anterior branch, causing the clinical syndrome of *meralgia paresthetica*, and includes dysesthesias and sensory loss along the lateral thigh. The use of tight, heavy, utility belts or corsets and religious talismans; obesity; weight loss; and pregnancy are implicated as possible contributors to compression. Pains in the lateral thigh may also be caused by spinal lesions or pelvic tumors, which must be excluded by appropriate diagnostic studies. The course of *meralgia paresthetica* is variable. Occasionally, symptoms disappear spontaneously. In most patients, removal of contributing factors aids in resolution of symptoms.

The Femoral Nerve

The femoral nerve may be compressed by tumors, other pelvic lesions, pubic ramus or femur fractures, as well as by ischemia in diabetic neuropathy and other conditions. Assessment of hip adduction helps to separate this condition from lumbar plexopathy or radiculopathy.

Injury to the nerve produces weakness of leg extension and thigh flexion. Walking on level ground is possible so long as the leg is extended, but if the slightest flexion occurs, the patient's knee may collapse. Climbing stairs or walking uphill is difficult or impossible. The quadriceps reflex is lost on the affected side. Saphenous sensory loss is also diagnostically useful. In severe cases, orthopedic appliances that fix the knee joint in extension or tendon transposition may be considered.

The Sciatic Nerve

The main trunk of the sciatic nerve is derived from the lower lumbosacral nerve roots and retains a strict segregation of fibular and tibial fibers. Total paralysis of muscles innervated by the sciatic nerve is rare. Even with a lesion in the thigh, the common fibular division is often more severely damaged than the tibial.

Important sources of injury include gunshot, shrapnel, or stab wounds to the leg or pelvis; fractures of the pelvis or femur; dislocations of the hip; pressure of the fetal head during delivery; or pelvic tumors. The nerve is sometimes inadvertently injured by intramuscular injection of drugs, especially in infants. Compression can occur in the posterior thigh by sharp chair edges or operating room tables. Injury by the piriformis muscle (*piriformis syndrome*) is controversial but very rare, but convincing cases are described. *Sciatica* is a term used to describe pain in the low back and in the leg along the course of the nerve, but the vast majority of these patients have nerve root injury at the L5-S1 level, often caused by intervertebral disk herniation. The clinical features of cervical and lumbar disk herniation are considered in Chapters 109 and 110.

Complete injury of the sciatic nerve causes paralysis of all the movements of the ankle and toes, as well as weakness or paralysis of knee flexion. Gait is marked by footdrop and the ankle jerk is lost, along with sensation on the outer surface of the leg, on the instep and sole of the foot, and over the toes.

The Common Fibular Nerve

The common fibular branch of the sciatic nerve is a mixed nerve innervating the extensor muscles of the ankle and toes and the foot evertors. It provides sensation from the outer side of the leg, the

P.760

front of its lower one-third, the instep, and the dorsal surface of the four inner toes over their proximal phalanges. The common fibular nerve is highly subjected to trauma. It may be damaged by wounds near the knee. The nerve is readily compressed or stretched as it curves around the fibular head by leg crossing, squatting, or resting the edge of the leg against a hard surface while sleeping, intoxicated, or anesthetized. Ganglion cysts, sometimes palpable at the fibular head, are well described. Common fibular neuropathy results in foot drop and weak foot eversion. The patient may not dorsiflex the ankle, straighten or extend the toes, or evert the foot, and there is sensory loss in the nerve distribution. Recovery is dependent on the extent of injury, which usually

correlates with the degree and duration of extrinsic compression. Ambulation in patients with footdrop may be greatly aided by ankle-foot orthoses.

The Tibial Nerve

Tibial neuropathy is uncommon. It may be injured by gunshot wounds or leg fractures. A complete lesion of the nerve produces paralysis of plantar flexion and inversion of the foot, flexion and separation of the toes, and sensory loss in the nerve distribution. The ankle jerk and plantar reflex are lost. Rarely, compression of the posterior tibial branch of the nerve at the medial malleolus produces pain and paresthesia in the soles of the feet in a manner similar to compression of the median nerve at the wrist (*tarsal tunnel syndrome*); however, this process is much less prevalent. Other conditions that produce foot pain and/or numbness, including digital neuropathy, focal disorders of the foot, plantar fasciitis, early polyneuropathy, and Morton neuroma that produce foot pain and numbness are all more frequent.

SPECIFIC ACQUIRED POLYNEUROPATHIES

GUILLAIN-BARRÉ SYNDROME

The GBS is characterized by acute onset of peripheral and cranial nerve dysfunction. Viral respiratory or gastrointestinal infection, immunization, or surgery often precedes neurologic symptoms by 5 days to 4 weeks. Symptoms and signs include rapidly progressive symmetric weakness, loss of tendon reflexes, facial diplegia, oropharyngeal and respiratory paresis, and impaired sensation in the hands and feet. The condition worsens for several days to 3 weeks, followed by a period of stability and then gradual improvement to normal or nearly normal function. Early plasmapheresis or intravenous immunoglobulin (IVIG) (2 g/kg in divided doses) accelerates recovery and diminishes the incidence of long-term neurologic disability.

In North America and Europe, acute inflammatory demyelinating polyneuropathy accounts for over 90% of GBS. GBS also includes acute motor axonal neuropathy (AMAN), acute motor and sensory axonal neuropathy (AMSAN), Miller Fisher syndrome, and acute autonomic and sensory neuropathies.

Etiology

The cause of GBS is incompletely understood. There is evidence that it is immune mediated. There is inflammatory pathology and patients improve with immunomodulatory therapy. A disease with similar clinical features (i.e., similar pathologic, electrophysiologic, and cerebrospinal fluid [CSF] alterations) can be induced in experimental animals by immunization with whole peripheral nerve, peripheral nerve myelin, or, in some species, peripheral nerve myelin P2 basic protein or galactocerebroside. An important first step in autoimmune disease is the impairment of self-tolerance, and there is evidence that this occurs by molecular mimicry in two forms of GBS, AMAN, and Miller Fisher syndrome, with cross-reactive epitopes between *Campylobacter jejuni* and peripheral nerve. When GBS is preceded by a viral infection, there is no evidence of direct viral infection of peripheral nerves or nerve roots.

FIGURE 87.3 Focal demyelination in acute GBS. (Courtesy of Dr. Arthur Asbury.)

Electrophysiology and Pathology

Nerve conduction velocities are reduced in GBS, but values may be normal early in the course. Distal motor latencies may be prolonged. Because of demyelination of nerve roots, minimal F-wave latency is often increased or responses are absent from proximal conduction block. Conduction slowing may persist for months or years after clinical recovery. In general, the severity of neurologic abnormality is not related to the degree of conduction slowing but is related to the extent of conduction block or axonal loss. Long-standing weakness is most apt to occur when compound motor action potential (CMAP) amplitudes are reduced to less than 20% of normal.

Histologically, GBS is characterized by focal segmental demyelination (Fig. 87.3) with perivascular and endoneurial infiltrates of lymphocytes and monocytes or macrophages (Fig. 87.4). These lesions are scattered throughout the nerves, nerve roots, and cranial nerves. In particularly severe lesions, there is both axonal degeneration

P.761

and segmental demyelination. During recovery, remyelination occurs, but the lymphocytic infiltrates may persist.

FIGURE 87.4 Diffuse mononuclear infiltrate in peripheral nerve in GBS. (Courtesy of Dr. Arthur Asbury.)

Incidence

GBS is the most frequently acquired demyelinating neuropathy, with an incidence of 0.6 to 1.9 cases per 100,000 population. The incidence increases gradually with age, but the disease may occur at any age. Men and women are affected equally. The incidence increases in patients with Hodgkin disease, as well as with pregnancy or general surgery.

Clinical Features

GBS often appears days to weeks after symptoms of a viral upper respiratory or gastrointestinal infection. Usually, the first neurologic symptoms are a result of symmetric limb weakness, often with paresthesia. In contrast to most other neuropathies, proximal muscles are sometimes initially affected more than distal muscles. Occasionally, facial, ocular, or oropharyngeal muscles are affected first; more than 50% of patients have facial diplegia, and dysphagia and dysarthria develop in a similar number. Some patients require mechanical ventilation. Tendon reflexes may be normal for the first few days but are then lost. The degree of sensory impairment varies. In some patients, all sensory modalities are preserved; others have marked diminution in perception of joint position, vibration, pain, and temperature in stocking-and-glove distribution. Patients occasionally exhibit papilledema, sensory ataxia, and transient extensor plantar responses. Autonomic dysfunction, including orthostatic hypotension, labile blood pressure, tachyarrhythmia, and bradyarrhythmia or resting tachycardia is frequent in more severe cases and an important cause of morbidity and mortality. Many have muscle tenderness, and the nerves may be sensitive to pressure, but there are no signs of meningeal irritation such as nuchal rigidity.

Variants

AMAN is a variant of GBS. There is motor axonal degeneration and little or no demyelination or inflammation. Despite the axonal involvement, recovery is similar to the demyelinating form. AMAN may follow infection with *C. jejuni*, *Mycoplasma pneumoniae*, or parenteral injection of gangliosides.

The *Miller Fisher syndrome* is characterized by gait ataxia, areflexia, and ophthalmoparesis; pupillary abnormalities are sometimes present. It is considered a variant of GBS because it is often preceded by respiratory infection, it progresses for weeks and then improves, and CSF protein content is increased. There is no limb weakness, however, and nerve conductions are generally normal; however, H reflexes may be affected. In some cases, MRI shows brain stem hyperintense lesions.

Other GBS variants include *AMSAN*, acute sensory neuropathy or neuronopathy, and acute autonomic neuropathy or pandysautonomia (see [Chapter 112](#)).

Laboratory Data

The CSF protein content is elevated in most patients with GBS but may be normal in the first few days after onset. The CSF cell count is usually normal, but some patients with otherwise typical GBS have 10 to 100 mononuclear cells/ μ L of CSF. Antecedent infectious mononucleosis, cytomegalovirus (CMV) infection, viral hepatitis, HIV infection, or other viral diseases may be documented by serologic studies. Increased titers of immunoglobulin G (IgG) or immunoglobulin A (IgA) antibodies to GM1 or GD1a gangliosides may be found in the axonal form of GBS; anti-GQ1b antibodies are closely associated with the Miller Fisher syndrome.

Outcome

Symptoms are usually most severe within 1 week of onset but may progress for 3 weeks or more. Death is uncommon but may follow aspiration pneumonia, pulmonary embolism, intercurrent infection, or autonomic dysfunction. The rate of recovery varies. In some, it is rapid, with restoration to normal function within a few weeks. In most, recovery is slow and not complete for many months. Recovery is accelerated by early institution of plasmapheresis or IVIG therapy. In untreated series, about 35% of patients have permanent residual hyporeflexia, atrophy, and weakness of distal muscles or facial paresis. A biphasic illness, with partial recovery followed by relapse, is present in fewer than 10% of patients. Recurrence after full recovery occurs in about 2%.

Diagnosis and Differential Diagnosis

The characteristic history of subacute development of symmetric motor or sensorimotor neuropathy after a viral illness, delivery, or surgery, together with compatible electrophysiology and an elevated CSF protein content with normal cell count, defines GBS.

In the past, the principal diseases to be differentiated from GBS were diphtheritic polyneuropathy and acute poliomyelitis. Both are now rare in the United States. Diphtheritic polyneuropathy can usually be distinguished by the long latency period between the respiratory infection and onset of neuritis, the frequency of paralysis of accommodation, and the relatively slow evolution of symptoms. Acute anterior poliomyelitis was distinguished by asymmetry of paralysis, signs of meningeal irritation, fever, and CSF pleocytosis. Acute West Nile viral infection, however, can lead to a similar picture. Acute encephalitis is the most common West Nile neurologic manifestation, but an acute paralytic syndrome is the next most frequent. Asymmetric or monomelic weakness is characteristic, but some cases develop in a GBS-like manner. Some cases have a flulike prodrome without notable encephalitis. Occasionally, patients with HIV infection have a disorder identical to GBS. Porphyric neuropathy resembles GBS clinically but is differentiated by normal CSF protein, recurrent abdominal crisis, mental symptoms, onset after exposure to barbiturates or other drugs, and high urinary levels of δ -aminolevulinic acid and porphobilinogen. Development of a GBS-like syndrome during prolonged parenteral feeding should raise the possibility of hypophosphatemia-induced neural dysfunction. Toxic neuropathies caused by *n*-hexane inhalation or

thallium or arsenic ingestion may begin acutely or subacutely. Botulism may be difficult to discriminate on clinical grounds from purely motor forms of GBS, but ocular muscles and the pupils are frequently affected. Electrophysiologic tests in botulism reveal normal nerve conduction velocities and a facilitating response to repetitive nerve stimulation. Tick paralysis, which occurs almost exclusively in children, should be excluded by careful scalp examination.

Treatment

Early plasmapheresis [Level 1]^{1,2} or IVIG [Level 1]³ therapy has proved useful in patients with GBS. Glucocorticoid administration does not shorten the course or affect the prognosis. Mechanically assisted ventilation is sometimes necessary, and precautions against aspiration of food or stomach contents must be taken if oropharyngeal muscles are affected. Exposure keratitis must be prevented in patients with facial diplegia.

P.762

CHRONIC INFLAMMATORY DEMYELINATING POLYNEUROPATHY

Chronic inflammatory demyelinating polyneuropathy (CIDP) may begin insidiously or acutely, as GBS, and then follow a chronic progressive or relapsing course. It often follows nonspecific viral infections, although less often than in GBS. Segmental demyelination and lymphocytic infiltrates are present in peripheral nerves, and a similar disease can be induced in experimental animals by immunization with peripheral nerve myelin. The CSF protein content is often increased but less consistently than in GBS. An infantile form of CIDP begins with hypotonia and delayed motor development. Optic neuritis has been noted in some patients. Nerves may become enlarged because of Schwann cell proliferation and collagen deposition after recurrent segmental demyelination and remyelination (Figs. 87.5 and 87.6).

In contrast to GBS, glucocorticoid therapy is often beneficial. CIDP is also responsive to plasmapheresis [Level 1]⁴ or IVIG [Level 1].⁵ Immunosuppressive drug therapy may be effective in resistant cases. Research criteria for the diagnosis of CIDP have been recommended, but there is no specific test, and the diagnosis is often made on clinical grounds. A predominantly sensory or distal form of CIDP and a multifocal form (the Lewis-Sumner syndrome) have been described. Tests for HIV-1, monoclonal paraproteins, antibodies to myelin-associated glycoprotein (MAG), and occasionally, CMT disease type 1 or hereditary neuropathy with liability to pressure palsy are performed in suspected patients to evaluate possible causes of demyelinating neuropathy.

MULTIFOCAL MOTOR NEUROPATHY

Multifocal motor neuropathy (MMN) is a clinical syndrome of lower motor neuron dysfunction. Typically, there is weakness, wasting, and fasciculation with preserved or absent tendon reflexes. The findings are typically asymmetric and affect the arms and hands more than the legs. Electrophysiologic evidence of denervation is accompanied by the defining abnormality, physiologic evidence of multifocal motor conduction block, at sites other than typical compression sites. Other signs of demyelination are also described; conduction block is not present in all patients, including some with positive antibody titers. MMN is associated with increased titers of immunoglobulin M (IgM) anti-GM1 in approximately 60% of patients; less frequently, anti-GD1a antibodies are found. The clinical syndrome also occurs in patients with normal anti-GM1 antibody titers. It is important to distinguish these patients from patients with typical motor neuron disease because the weakness of MMN is potentially reversible with IVIG [Level 1]⁶ or immunosuppressive drug therapy.

FIGURE 87.6 Teased fiber showing demyelination in a patient with CIDP (magnification $\times 400$).

SENSORY NEURONOPATHY AND NEUROPATHY

Sensory neuropathy may result from primary involvement of the sensory root ganglia, as in ganglioneuritis or sensory neuronitis, or the nerve may be directly affected as in distal sensory neuropathy. *Ganglioneuritis* may be acute or subacute in onset and is characterized by numbness, paresthesia, and pain that can be distal or radicular or can involve the entire body, including the face. Ataxia and autonomic dysfunction may be evident. Small- or large-fiber sensation or both may be affected to varying degrees. Tendon reflexes may be present or absent, and strength is normal. The disease may be self-limiting or chronic, with relapses or slow progression. Motor nerve conduction velocities are normal or near normal, but sensory potentials are reduced in amplitude or absent. Routine electrophysiologic studies may be normal if the disease is mild or if only small fibers are affected. CSF protein content is normal or slightly elevated. Response to glucocorticoids or immunosuppressive therapy is variable. Pathologic studies of spinal root ganglia show inflammatory infiltrates with a predominance of T cells and macrophages. Some patients have sicca or Sjögren syndrome with anti-Ro (SSA) and anti-La (SSB) antibodies.

Several autoantibodies to peripheral nerve antigens are associated with sensory neuropathy. Some patients with sensory axonal

P.763

neuropathies have monoclonal or polyclonal IgM antisulfatide antibodies, and monoclonal IgM autoantibodies with anti-GD1b and disialosyl ganglioside antibody activity have been associated with large-fiber sensory neuropathy. Other causes of sensory neuropathy include HIV-1 infection, vitamin B₆ deficiency or toxicity, celiac disease, paraneoplastic neuropathy, amyloidosis, and toxic neuropathy.

IDIOPATHIC AUTONOMIC NEUROPATHY

This condition is characterized by sympathetic, parasympathetic, or enteric nerve dysfunction. Acute, subacute, and chronic forms are known and discussed in Chapter 112.

VASCULITIC AND CRYOGLOBULINEMIC NEUROPATHIES

Vasculitic neuropathy is manifested as mononeuritis multiplex or distal symmetric polyneuropathy. Nerve conduction studies may show electrical inexcitability of nerve segments distal to an injury caused by vascular occlusion. If some nerve fascicles are spared, conduction proceeds at a normal rate, but summated response amplitude is diminished. The diagnosis of peripheral nerve involvement may be established by nerve and muscle biopsies (Fig. 87.7), which typically show inflammatory cell infiltrates and necrosis of blood vessel walls. The biopsy specimen, however, may show only axonal degeneration if vasculitis produced a nerve injury that is proximal to the biopsy site or if no affected vessels are encountered in the specimen.

Vasculitis may be confined to the peripheral nerves or may be associated with systemic disease, such as polyarteritis or cryoglobulinemia. The most common systemic cause of vasculitic neuropathy is polyarteritis nodosa, which may cause purpuric skin lesions, renal failure, Raynaud phenomenon, constitutional symptoms, and sometimes, mixed polyclonal cryoglobulinemia; hepatitis B or C virus (HBV or HCV) or HIV infection may be found. Cryoglobulins are immunoglobulins that precipitate in the cold and are classified as types I through III. Type I contains a monoclonal immunoglobulin only, type II contains both monoclonal and polyclonal immunoglobulins, and type III contains mixed polyclonal immunoglobulins. Types I and II are associated with plasma cell dyscrasia, and type III may be associated with polyarteritis nodosa and HBV or HCV infection. Cryoglobulin testing samples must be kept warm to prevent precipitation prior to laboratory analysis.

Other causes of vasculitic neuropathy include the Churg-Strauss syndrome with asthma and eosinophilia; Sjögren syndrome with xerophthalmia, xerostomia, and anti-Ro and anti-La antibodies; and Wegener granulomatosis with necrotizing granulomatous lesions in the upper or lower respiratory tract, glomerulonephritis, and antineutrophil cytoplasmic antigen antibodies. Less commonly, vasculitic neuropathy is seen in rheumatoid arthritis, systemic lupus erythematosus, and systemic sclerosis. Vasculitis may respond to therapy with prednisone (60 mg qd) and cyclophosphamide (1 g/m² every month × 6 months). Plasmapheresis is also useful in the treatment of cryoglobulinemia.

FIGURE 87.7 Necrotizing vasculitis (magnification $\times 200$).

NEUROPATHIES ASSOCIATED WITH MYELOMA AND NONMALIGNANT IMMUNOGLOBULIN G OR IMMUNOGLOBULIN A MONOCLONAL GAMMOPATHIES

Peripheral neuropathy is found in approximately 50% of patients with osteosclerotic myeloma and IgG or IgA monoclonal gammopathies. Some patients have the POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes) or Crow-Fukase syndrome with hyperpigmentation of skin, edema, excessive hair growth, hepatosplenomegaly, papilledema, elevated CSF protein content, hypogonadism, and hypothyroidism. POEMS syndrome is sometimes associated with nonosteosclerotic myeloma or with nonmalignant monoclonal gammopathy. The IgG or IgA light-chain type is almost always λ . Electrophysiologic and pathologic abnormalities are consistent with demyelination and axonal degeneration; the patterns may resemble CIDP.

Malignant or nonmalignant IgG or IgA monoclonal gammopathy may also be associated with neuropathy in primary amyloidosis, in which fragments of the monoclonal light chains are deposited as amyloid in peripheral nerve, and in types I and II cryoglobulinemia, in which the monoclonal immunoglobulins are components of the cryoprecipitates.

The significance of IgG or IgA monoclonal gammopathies is uncertain in the absence of myeloma, POEMS syndrome, amyloidosis, or cryoglobulinemia. Nonmalignant monoclonal gammopathies are found more frequently in patients with neuropathy of otherwise unknown etiology; however, they are also present in approximately 1% of normal adults, and the frequency increases with age or in chronic infections or inflammatory diseases, so the association with neuropathy in some cases could be coincidental. Other causes of neuropathy, particularly inflammatory conditions such as CIDP, should be considered. In cases of myeloma, irradiation, chemotherapy, or bone marrow transplantation may be beneficial. Some patients with neuropathy associated with IgG and IgA monoclonal proteins of undetermined significance (MGUS) improve with plasmapheresis.

NEUROPATHIES ASSOCIATED WITH IMMUNOGLOBULIN M MONOCLONAL ANTIBODIES THAT REACT WITH PERIPHERAL NERVE GLYCOCONJUGATE ANTIGENS

In several syndromes, peripheral neuropathy is associated with polyclonal or monoclonal IgM autoantibodies that react with glycoconjugates in peripheral nerve. IgM antibodies that react with MAG are associated with a chronic demyelinating sensorimotor neuropathy. Pathologic studies show deposits of the monoclonal IgM and complement on affected myelin sheaths, and passive transfer of the autoantibodies in experimental animals reproduces the neuropathy. Treatment consisting of plasmapheresis and chemotherapy

P.764

to reduce autoantibody concentrations, or IVIG, frequently results in clinical improvement.

Other syndromes associated with monoclonal or polyclonal IgM autoantibodies include the following: MMN or lower motor neuron syndrome-associated anti-GD1a ganglioside antibodies, large-fiber sensory neuropathy with anti-GD1b and disialosyl ganglioside antibodies, and axonal sensory neuropathy associated with antisulfatide antibodies. Antisulfatide antibodies typically are associated with small-fiber or small- and large-fiber neuropathy, but 25% of cases demonstrate a CIDP-like demyelinating neuropathy.

PROGRESSIVE INFLAMMATORY NEUROPATHY (AMONG SWINE SLAUGHTERHOUSE WORKERS)

Beginning in 2007, 24 patients who worked in three different porkprocessing plants developed an inflammatory neuropathy that resembled CIDP. Those affected worked at the head table, where a compressed air device was used to extract pig brains. Patients had a polyradiculoneuropathy with weakness and pain. Some patients had facial neuropathy. The symptoms progressed from 8 to 213 days. The CSF protein was elevated in the majority from 63 to 210 mg/dL, with pleocytosis in only one patient. Nerve conduction studies showed demyelinating and axonal changes. Serum from the patients demonstrated IgG staining of neural tissue.

AMYLOID NEUROPATHY

Amyloid is an insoluble extracellular aggregate of proteins that forms in nerve or other tissues when any of several proteins is produced in excess. The two principal forms of amyloid protein that cause neuropathy are immunoglobulin light chains in patients with primary amyloidosis and plasma cell dyscrasias and transthyretin in hereditary amyloidosis. The syndrome is often that of a painful, small-fiber sensory neuropathy with progressive autonomic failure, symmetric loss of pain and temperature sensations with spared position and vibratory senses, carpal tunnel syndrome, or some combination of these symptoms. The diagnosis of amyloid neuropathy can be established by histologic demonstration of amyloid in nerve ([Fig. 87.8](#)), followed by immunocytochemical characterization of the deposits with the use of antibodies to immunoglobulin light chains or transthyretin. Mutation of the transthyretin gene is detected by DNA analysis. Other hereditary amyloidosis causes, such as apolipoprotein A1 and gelsolin, lead to less severe and less frequent neuropathy. Electrophoresis of serum and urine with immunofixation can assist in the diagnosis of primary amyloid neuropathy. Prognosis is generally poor. Liver transplantation has been reported to be beneficial for hereditary amyloidosis, and high-dose chemotherapy followed by bone marrow transplantation has been reported to help some patients with primary amyloidosis. Medications that stabilize the transthyretin tetramer and decrease the formation of amyloid, including tafamidis 20 mg qd [**Level 1**][7](#) and diflunisal 250 mg qd [**Level 1**],[8](#) may improve the neuropathy. Also under development are RNA silencers, which block the production of transthyretin.

FIGURE 87.8 Amyloid neuropathy. Massive deposits of endoneurial amyloid compress nerve fiber bundles. (Courtesy of Dr. Arthur Asbury.)

NEUROPATHY ASSOCIATED WITH CARCINOMA (PARANEOPLASTIC NEUROPATHY)

Both direct and indirect effects of malignant neoplasms on the peripheral nervous system are recognized. In some patients, the nerves or nerve roots are compressed or infiltrated by neoplastic cells. In others, there is no evidence of damage to the nerves by the neoplasm, and dietary deficiency or metabolic, toxic, or immunologic factors may be responsible.

The most characteristic paraneoplastic disorder is a sensory neuropathy of subacute onset associated with small cell carcinoma of the lung. Electrodiagnostic studies reveal loss of sensory-evoked responses. Autoantibodies against the Hu antigen (antineuronal nuclear or ANNA-1) are characteristic, and postmortem studies show loss of neurons, deposition of antibodies, and inflammatory cells in dorsal root ganglia.

Less consistently associated with carcinoma is a distal sensorimotor polyneuropathy without specific features. Nerve biopsy may reveal infiltration by tumor cells, axonal degeneration, or demyelination. A primarily motor syndrome of subacute onset rarely occurs in Hodgkin disease and other lymphomas. In these patients, the predominant lesion is degeneration of anterior horn cells, but demyelination, perivascular mononuclear cell infiltrates, and alterations in Schwann cell morphology in ventral roots are also observed.

The diagnosis of malignancy should be suspected in a middleaged or elderly patient with a subacute sensory neuropathy or polyradiculopathy of obscure cause, particularly with weight loss. The course is often progressive unless the primary malignancy is successfully treated. CSF examination for malignant cells is valuable in the diagnosis of malignant meningeal infiltration. In some instances of meningeal infiltration, radiotherapy or intrathecal chemotherapy may be valuable.

HYPOTHYROID NEUROPATHY

Entrapment neuropathies are relatively common in patients with hypothyroidism, probably because acid mucopolysaccharide protein complexes (mucoid) are deposited in the nerve. Painful paresthesia in the hands and feet is the most common symptom of hypothyroidism. Weakness is not a feature. Tendon reflexes are reduced or absent and, when present, may show the characteristic delayed or “hung-up” response. Direct muscle percussion produces transient mounding of the underlying skin and muscle (myoedema). Nerve conduction studies show mild slowing of motor nerve conduction and decreased sensory response amplitude.

Morphologic

P.765

studies show evidence of demyelination, axonal loss, and excessive glycogen within Schwann cells. CSF protein content is often more than 100 mg/dL. Rarely, dysfunction of cranial nerves IX, X, and XII causes hoarseness and dysarthria, probably as a result of local myxedematous infiltration of the nerves. The peripheral neuropathy may occur before there is laboratory evidence of hypothyroidism. Once identified, thyroid replacement causes clinical, electrophysiologic, and morphologic improvement.

ACROMEGALIC NEUROPATHY

Entrapment neuropathy is also relatively common in patients with acromegaly. Rarely, acromegalic patients note distal paresthesia but in contrast to myxedematous patients, weakness may be severe and peripheral nerves may be palpable. There is a significant correlation between total exchangeable body sodium and the severity of the neuropathy. The nerves are enlarged because there is increased endoneurial and perineurial connective tissue, perhaps stimulated by increased levels of somatomedin C (IGF-1). Tendon reflexes are reduced. Nerve conduction velocities are mildly slow with low evoked response amplitudes.

HYPERTHYROID NEUROPATHY

Hyperthyroidism can produce a syndrome consisting of diffuse weakness and fasciculations with preserved or hyperactive tendon reflexes, resembling amyotrophic lateral sclerosis (ALS). However, the symptoms and signs disappear with treatment of the toxic state. No convincing pathologic studies have established the presence of chronic sensorimotor neuropathy with hyperthyroidism.

CELIAC NEUROPATHY

Celiac disease is a chronic inflammatory enteropathy with a prevalence of 1:250. Peripheral neuropathy is the most common neurologic condition associated with celiac disease. It is not thought to be a result of nutritional deficiency. In over half of patients with celiac neuropathy, gastrointestinal complaints are absent. Celiac disease is caused by exposure to ingested gluten, the storage proteins of wheat, and similar proteins found in barley and rye. Patients have specific HLA-DQ2 and HLA-DQ8 alleles.

The neuropathy is usually predominantly sensory. Multifocal involvement is frequent, with early involvement of the hands and face, although some have a length-dependent pattern. A small-fiber neuropathy is more common initially, but a sensorimotor polyneuropathy is also seen. Diagnosis is suspected with elevated gliadin or transglutaminase antibodies and confirmed by a duodenal biopsy demonstrating inflammation, crypt hyperplasia, and villous atrophy in the small intestine mucosa. Gastrointestinal symptoms improve with a gluten-free diet. The symptoms of peripheral neuropathy have improved in some, but not all, patients on a glutenfree diet. Only small amounts of gluten exposure can trigger an active immune response.

UREMIC NEUROPATHY

Peripheral neuropathy is only one of the neuromuscular syndromes associated with chronic renal failure. Restless legs, cramps, and muscle twitching may be early manifestations of peripheral nerve disease. Peripheral

neuropathy is present in 70% of patients with chronic renal failure, but most are subclinical and are identified only by nerve conduction studies. Symptoms include painful dysesthesia and glove-stocking loss of sensation, as well as weakness of distal muscles. Electrodiagnostic studies show a sensorimotor neuropathy with axonal features. Pathologic studies confirm the axonopathy. Secondary demyelination may result from axonal loss. Dialysis rarely reverses the neuropathy but may stabilize symptoms; peritoneal dialysis is more effective than hemodialysis. Serial nerve conduction studies can measure the effectiveness of hemodialysis but is no longer routinely used. Renal transplantation often resolves the neuropathy following surgery.

Mononeuropathy, particularly carpal tunnel syndrome, often appears distal to an implanted arteriovenous fistula, suggesting ischemia as a possible mechanism. Distal ischemia from implanted bovine shunts may cause a more severe ischemic neuropathy in the median, ulnar, and radial nerves, possibly from excessive arteriovenous shunting. Chronic hemodialysis (>10 years) causes excessive accumulation of β_2 -microglobulin (generalized amyloidosis), another possible cause of carpal tunnel syndrome and uremic polyneuropathy.

The cause of uremic neuropathy is uncertain. An accumulation of a toxic metabolite is most likely, but its identity is unknown. A 2- to 60-kDa molecular weight compound in the plasma of uremic patients induced an axonal neuropathy in experimental animals.

NEUROPATHY ASSOCIATED WITH HEPATIC DISEASE

Peripheral neuropathy is rarely associated with primary diseases of the liver. A painful sensory neuropathy is seen with primary biliary cirrhosis, probably caused by xanthoma formation in and around nerves.

Electrodiagnostic studies may be normal, or the amplitude of the sensory-evoked response may be low or absent. Nerve biopsy shows loss of small-diameter nerve fibers. Sudanophilic material is seen in cells of the perineurium. Treatment is directed at pain control. Tricyclic antidepressants or anticonvulsants may relieve paresthesia.

Infectious diseases of the liver may also be associated with peripheral neuropathy. Viral hepatitis (especially hepatitis C associated with cryoglobulinemia), HIV or CMV infection, and infectious mononucleosis may be associated with acute demyelinating neuropathy (GBS), chronic demyelinating neuropathy, or mononeuropathy multiplex. Immunologically mediated diseases such as polyarteritis and sarcoidosis may also cause liver abnormalities and mononeuropathy multiplex.

Peripheral neuropathy is often seen with toxic liver disease or hepatic metabolic diseases such as acute intermittent porphyria and abetalipoproteinemia.

NEUROPATHIES ASSOCIATED WITH INFECTION

Neuropathy of Leprosy

Direct infiltration of small-diameter peripheral nerve fibers by *Mycobacterium leprae* causes the neuropathy of leprosy. It was formerly the most common neuropathy in the world, although it is now overtaken by diabetic neuropathy, largely because of a recent sharp decline in incidence in many endemic areas, especially India. From 2002 to 2007, the incidence globally had dramatically decreased at an average rate of nearly 20% per year based on WHO reports. In the United States, the disease is less endemic but is seen in immigrants from India, Southeast Asia, and Central Africa.

Peripheral nerves are affected differently in tuberculoid and lepromatous forms. In tuberculoid leprosy, there are small hypopigmented areas with superficial sensory loss, and the underlying subcutaneous sensory nerves may be visibly or palpably enlarged.

Large nerve trunks, such as the ulnar, fibular, facial, and posterior auricular nerves, may be enmeshed in

granulomas and scar tissue. Endoneurial caseation necrosis may occur. The clinical picture is one of mononeuritis or mononeuritis multiplex.

FIGURE 87.9 Lepromatous leprosy. Few myelinated fibers are scattered in fibrotic endoneurium. Abundant foam cells (*arrows*) contain *M. leprae* bacilli when viewed at higher magnification. (Courtesy of Dr. Arthur Asbury.)

In lepromatous leprosy, Hansen bacilli proliferate in large numbers within Schwann cells and macrophages in the endoneurium and perineurium of subcutaneous nerve twigs (Fig. 87.9), particularly in cool areas of the body (pinnae of the ears and dorsum of the hands, forearms, and feet). Loss of cutaneous sensibility is observed in affected patches; these may later coalesce to cover large parts of the body. Position sense may be preserved in affected areas, whereas pain and temperature sensibility is lost, a dissociation similar to that in syringomyelia. Tendon reflexes are preserved.

Acute mononeuritis multiplex may appear during chemotherapy of lepromatous leprosy in conjunction with erythema nodosum. This complication is treated with thalidomide, which is also associated with neuropathy.

Treatment is designed to eradicate the bacterium and to prevent secondary immune reactions that may damage nerves. Dapsone is effective but may cause toxic motor neuropathy. Because of the dense sensory loss, painless and inadvertent traumatic injuries, such as self-inflicted burns, may occur without extreme caution to avoid trauma to the anesthetic areas.

Diphtheritic Neuropathy

Although diphtheria itself is rare, diphtheritic neuropathy occurs in approximately 20% of infected patients. *Corynebacterium diphtheriae* infects the larynx and pharynx, as well as cutaneous wounds. The organisms release an exotoxin that causes myocarditis and, later, symmetric neuropathy. The neuropathy often begins with impaired visual accommodation and paresis of ocular and oropharyngeal muscles, and quadriplegia follows. Nerve conduction velocities are slow, reflecting the underlying demyelinating neuropathy. Diphtheria may be prevented by immunization, and if infection occurs, antibiotic therapy may be used. Recovery may be slow, and physiologic measures resolve after the clinical syndrome.

HIV-Related Neuropathies

Several neuropathies afflict patients infected with HIV, depending on the stage of the illness and the immunocompetence of the patient. An acute demyelinating neuropathy indistinguishable from sporadic GBS may occur early in the course of infection, often with no signs of immunodeficiency or at the time of seroconversion, as well as once AIDS develops. Sometimes a CSF pleocytosis is present, which is not typical of GBS in non-HIV-infected patients.

Subacute demyelinating neuropathy, clinically indistinguishable from idiopathic CIDP, is usually found in HIV-positive patients before there is evidence of immunodeficiency (AIDS). The CSF protein content is increased in both idiopathic CIDP and HIV-associated demyelinating neuropathy. Steroids, plasmapheresis, and IVIG therapy have been reported to be effective treatments.

In patients who fulfill diagnostic criteria for AIDS, there is frequently a distal sensorimotor polyneuropathy with axonal features. The syndrome is dominated by severe painful paresthesia most intensely affecting the feet. This painful neuropathy can be the most functionally disabling manifestation of AIDS. Nerve conduction studies may be normal, but reduced intraepidermal nerve fiber density is seen on skin biopsy. The exact mechanism is uncertain. HIV infection of dorsal root ganglion neurons has been demonstrated. Because of the scarcity of neuronal infection, other causes such as toxicity of activated macrophages and cytokines and viral protein toxicity have been considered. No treatment reverses the symptoms, but symptomatic medications, such as lamotrigine or gabapentin, may help. One form of neuropathy in HIV-infected patients is the diffuse infiltrative lymphocytosis syndrome (DILS), a hyperimmune reaction to HIV infection.

Mononeuropathy multiplex can occur in HIV-infected patients at any stage of the disease, sometimes with hepatitis. When CD4 cells number fewer than 50/mm³, the likely cause of the mononeuropathy is CMV, and prompt treatment with ganciclovir sodium (Cytovene) may be lifesaving. CMV infection is also associated with polyradiculopathy.

The dideoxynucleotide antiretroviral medications, used to treat HIV infection, may cause painful sensory neuropathy, which is problematic to separate from primary painful HIV sensory neuropathy.

Neuropathy of Herpes Zoster

Varicella-zoster virus infection of the dorsal root ganglion produces radicular pain that may precede or follow the appearance of the characteristic skin eruption. Although primarily a sensory neuropathy, weakness from motor involvement occurs in 0.5% to 5% of infected patients. Herpes zoster (shingles) is a common phenomenon most frequent in elderly patients, cancer patients, or immunosuppressed patients. Postrash pain (postherpetic neuralgia) usually in the same distribution as the dermatomal rash occurs in a minority, but risk increases significantly with age (50% over 70 years). For diagnosis, pain should persist for 1 to 6 months after the rash disappears. Severe acute pain, more intense rash, scarring, sensory loss, and fever increase the risk of postherpetic neuralgia. Zoster infections are also associated with GBS and CSF pleocytosis. Zoster infection often occurs in patients with HIV infection; the combination of herpes infection and focal weakness in a young person should alert the clinician to the possibility of HIV infection.

Herpes zoster may affect any level of the neuraxis, but it most often involves thoracic dermatomes and cranial nerves with sensory ganglia (V and VII). Ophthalmic herpes infection characteristically involves the gasserian ganglion and the first division of the trigeminal nerve. There may be weakness of ocular muscles and ptosis. Infection of the geniculate ganglion of the facial (VII) nerve causes a vesicular herpetic eruption in the external auditory meatus, vertigo, deafness, and facial weakness (Ramsay Hunt

syndrome). Pain is constant and burning and may include paroxysms of very severe pain.

Treatment with acyclovir (Zovirax), 4 g/day in five doses for 7 to 10 days or other antiviral agents decreases the incidence of segmental motor neuritis and sensory axonopathy. They may also reduce the incidence of postherpetic neuralgia. Tricyclic antidepressants, opioids, anticonvulsants (pregabalin), and lidocaine patches may show symptomatic benefit, some verified in randomized clinical trials. An attenuated varicella-zoster virus vaccine is recommended in adults 60 years and older, without contraindications, to prevent the development of herpes zoster.

SARCOID NEUROPATHY

Neurologic symptoms appear in 4% of patients with sarcoidosis. Most commonly, there are single or multiple cranial nerve palsies that fluctuate in intensity. Of the cranial nerves, the seventh is most commonly affected, and, as in diabetes mellitus, the facial nerve syndrome in sarcoidosis is indistinguishable from idiopathic Bell palsy. Some cranial neuropathies in sarcoidosis result from basilar meningitis. One distinguishing feature of sarcoid mononeuropathy is a large area of sensory loss on the trunk.

Patients with sarcoidosis occasionally experience symmetric polyneuropathy months or years after the diagnosis is established. The neuropathy may be the first manifestation before the diagnosis of sarcoidosis is made. The clinical syndromes may include GBS, lumbosacral plexopathy, mononeuritis multiplex, pure sensory neuropathy, and small-fiber and autonomic neuropathy. Cranial nerve symptoms are seen in close to one-half of patients.

Nerve biopsy shows a mixture of wallerian degeneration and segmental demyelination with sarcoid granulomas in endoneurium and epineurium (Fig. 87.10). Sarcoid neuropathy may respond to steroid therapy.

POLYNEUROPATHY ASSOCIATED WITH DIETARY STATES

Thiamine deficiency may cause two clinical syndromes: *wet beriberi*, in which congestive heart failure is the predominant syndrome, and *dry beriberi*, in which peripheral neuropathy is the predominant symptom. Patients with thiamine deficiency have severe burning dysesthesia in the feet more than in the hands, weakness and wasting of distal muscles more than of proximal muscles, trophic changes (shiny skin, hair loss), and distal sensory loss. EMG and nerve conduction studies reveal the presence of a diffuse sensorimotor peripheral neuropathy that is axonal. Axonal degeneration is also the principal finding seen on nerve biopsy specimens. Treatment of both beriberis should include parenteral B-complex vitamins followed by oral thiamine. Recovery is slow; there may be residual muscular weakness and atrophy.

FIGURE 87.10 Nerve biopsy in patient with sarcoid neuropathy showing granuloma (magnification $\times 40$).

Niacin (nicotinic acid) deficiency causes pellagra characterized by hyperkeratotic skin lesions. Peripheral neuropathy is usually present in niacin-deficient patients, but the neuropathy does not improve solely with niacin supplementation, likely because of multivitamin deficiency. Symptoms usually improve when additional thiamine and pyridoxine are added to the diet.

Vitamin B₁₂ deficiency causes the classic clinical syndrome of subacute combined degeneration of the spinal cord. Separation of the peripheral neuropathic symptoms from spinal cord involvement is difficult. Painful paresthesias are present, but sensory ataxia with loss of vibration and joint position sense is most severe. Despite the myelopathy, tendon reflexes are often diminished or absent. B₁₂-deficiency neuropathy may be present with low normal B₁₂ levels and can be established with measurement of the elevated metabolites methylmalonic acid and homocysteine.

Nitrous oxide also irreversibly inactivates cobalamin, producing the same syndrome. A single anesthetic dose in a vulnerable individual or chronic exposure usually with abuse of dental or medical sources or commercial propellants (whipped cream) may result in B₁₂ deficiency. Hematologic abnormalities are usually absent in abuse cases.

Vitamin B₆ (pyridoxine) deficiency produces a peripheral neuropathy, and the most common cause of pyridoxine deficiency is ingestion of the antituberculous drug isoniazid. Isoniazid increases the excretion of pyridoxine. The resulting neuropathy affects sensory fibers more than motor fibers and is caused by axonal loss. Treatment consists of supplemental pyridoxine to compensate for the added excretion. The neuropathy can be prevented by prophylactic pyridoxine administration. Pyridoxine excess can lead to severe sensory neuropathy as well.

Vitamin E deficiency contributes to neuropathy in fat malabsorption syndromes—including abetalipoproteinemia,

congenital biliary atresia, pancreatic dysfunction, and surgical removal of large portions of the small intestine. The clinical syndrome of vitamin E deficiency resembles spinocerebellar degeneration with ataxia, severe sensory loss of joint position and vibration, and hyporeflexia. Motor nerve conduction studies are normal, but sensory-evoked responses are of low amplitude or absent.

Somatosensory-evoked responses show a delay in central conduction. EMG is usually normal. Serum vitamin E levels can be measured. Repletion with large oral doses is often sufficient if initiated early in the disease course.

Copper deficiency can result in a neuropathy, which is often accompanied by a myelopathy and leukopenia. Some patients develop copper deficiency from excessive use of zinc. Copper supplementation stops the progression, although recovery is often not complete.

Strachan syndrome includes visual loss, oral ulcers, skin changes, and painful neuropathy. The syndrome was originally described in Jamaican sugar workers and caused an epidemic in Cuba in 1991. A nutrient-poor diet with deficient B vitamins has been implicated.

Gastric bypass surgery is associated with subacute and sometimes severe axonal neuropathy that accompanies the rapid postoperative weight loss. Vitamin deficiency of various types is to play a crucial role.

P.768

CRITICAL ILLNESS POLYNEUROPATHY

Severe sensorimotor peripheral neuropathy is seen in many patients who are critically ill, suffering from sepsis and multiple organ failure. The diagnosis may arise when a patient experiences difficulty being weaned from a ventilator after a bout of sepsis. Electrodiagnostic studies show a severe sensorimotor axonal neuropathy, but conventional studies may be unable to distinguish this entity from the more common critical illness myopathy, discussed in detail in Chapter 91. Recovery of neuronal function may occur if the underlying cause of multiple organ failure is treated successfully.

NEUROPATHIES CAUSED BY HEAVY METALS

Arsenic

Neuropathy may follow chronic exposure to small amounts of arsenic or ingestion or parenteral administration of a large amount. Chronic exposure may occur in industries in which arsenic is released as a byproduct, such as in copper or lead smelting. Because of the prevalence of these byproducts, arsenic neuropathy is the most common of all heavy metal-induced neuropathies. Acute gastrointestinal symptoms, vomiting, and diarrhea occur when a toxic quantity of arsenic is ingested, but these symptoms may be absent if the arsenic is given parenterally or taken in small amounts over long periods. Acute exposure may lead to encephalopathy or coma. The evolution of polyneuropathy is much slower in chronic arsenic poisoning. Sensory symptoms are prominent in the early stages. Pain and paresthesia in the legs may be present for several days or weeks before onset of weakness. The weakness may progress to complete flaccid paralysis of the legs and sometimes the arms, depending on the dosage. Cutaneous sensation is impaired in a stocking-and-glove distribution, with vibration and position sensation being most affected. Tendon reflexes are lost. Pigmentation and hyperkeratosis of the skin and changes in the nails (*Mees lines*) are frequently present. Arsenic is present in the urine in the acute stages of poisoning but is quickly cleared; levels persist in the hair and nails. Nerve conduction velocities may be normal or mildly diminished; the amplitude of sensory- and motor-evoked responses may be reduced. Pathologic examination of nerves shows axonal degeneration. Arsenic polyneuropathy is generally treated with a chelating agent, but the effectiveness is uncertain, given the rapid clearance in most patients.

Lead

Most toxic neuropathies cause symmetric weakness and loss of sensation in distal regions more than proximal

regions, feet worse than legs. Lead neuropathy is atypical because of motor predominance and arm involvement. Lead neuropathy occurs almost exclusively in adults. Infants poisoned with lead usually develop encephalopathy. Lead may enter the body through the lungs, skin, or gut. Occupational lead poisoning was common in earlier eras, notably in silver miners, but rarely is encountered in battery workers, painters, and pottery glazers. Accidental lead poisoning follows ingestion of lead in food or beverages or occurs in children who ingest lead paint. Lead poisoning may cause abdominal distress (lead colic). The classic description is focal wrist-drop in a radial neuropathy pattern; however, weakness is not generally limited to one nerve and produces bilateral arm weakness and wasting and lesser or later leg involvement. Footdrop is the most common leg sign. Sensory symptoms and signs are usually absent. Rarely, upper motor neuron signs occur with the lower motor neuron disorder and mimic ALS. Laboratory findings include anemia with basophilic stippling of the red cells, increased serum uric acid, and slight elevation of CSF protein content. Urinary lead excretion is elevated, particularly after administration of a chelating agent. Urinary porphobilinogen excretion is also elevated, but δ -aminolevulinic acid is normal. Primary therapy is prevention of further exposure to lead. With termination of exposure and use of chelation therapy, recovery is gradual over several months.

Mercury

Mercury is used in the electrical and chemical industries. There are two forms of mercury: elemental and organic. The organic form of mercury (methyl and ethyl mercury) is most toxic to the CNS, although distal paresthesia and sensory ataxia are prominent (presumably secondary to dorsal root ganglion degeneration). Ventral roots and motor function are spared. Inorganic mercury may be absorbed through the gastrointestinal tract, and elemental mercury may be absorbed directly through the skin or lungs (it is volatile at room temperature). Elemental mercury exposure is a rare cause of weakness and axonal motor and sensory fiber loss.

Thallium

This element is used as a rodenticide and in other industrial processes. Children exposed to thallium, as with lead, may develop encephalopathy, whereas neuropathy occurs in adults. In contrast to lead poisoning, thallium neuropathy primarily affects sensory and autonomic fibers. Severe disturbing dysesthesia appears acutely, and diffuse alopecia is a characteristic feature. Signs of cardiovascular autonomic neuropathy are sometimes delayed and recover slowly. Electrophysiologic findings are consistent with an axonal neuropathy.

Other Chemicals

Acrylamide monomer is used to prepare polyacrylamide. It is used in chemical laboratories and for the treatment of liquid sewage. Exposure to the monomer produces a distal sensorimotor neuropathy that may be associated with trophic skin changes and a mild dementia. Polyacrylamides, however, are not neurotoxic. Carbon disulfide (CS_2) is rarely inhaled in industrial settings. Exposure may lead to sensorimotor axonal neuropathy.

Many organophosphates, used in insecticides and rodenticides, are acetylcholinesterase inhibitors and may cause delayed neuropathy. The clinical and electrophysiologic features are similar to those of neuropathies caused by chemotherapeutics. Some, however, affect the CNS, as well as peripheral nerves, and some have certain specific features. *Triorthocresyl phosphate* (Jamaica ginger or jake), an adulterant used in illegal liquor (moonshine) and as a cooking oil contaminant, was responsible for neuropathy epidemics.

Dimethylaminopropionitrile, which is used to manufacture polyurethane foam, causes urologic dysfunction and sensory loss localized to sacral dermatomes. Exposure to *methylbromide*, an insecticide, results in a mixture of pyramidal tract, cerebellar, and peripheral nerve dysfunction. Accidental ingestion of *pyriminil*, a rat poison marketed under the name Vacor, gives rise to an acute severe distal axonopathy with prominent autonomic involvement accompanied by acute diabetes mellitus secondary to necrosis of pancreatic β cells.

Drugs of abuse may lead to neuropathy, notably *n*-hexane and methyl-*N*-butyl ketone, found in widely available

household solvents, fuels, and cleaning agents. Inhalation of these materials through the nose or mouth (huffing) occurs in teens and young adults. Axonal degeneration with sensory and motor impairment

P.769

is seen, but focal conduction block associated with giant axonal swellings is also characteristic. The phenomenon is similar to the rare hereditary entity, giant axonal neuropathy, linked to a defect in the gigaxonin gene.

Ingested neurotoxins from various sea creatures harboring toxins can induce nerve dysfunction, mostly through sodium channel blockade and block in nerve conduction, mostly producing sensory neuropathy, cramps, diarrhea, and vomiting. Examples include ciguatera from reef fish exposed to a ciguatoxin-producing dinoflagellate, saxitoxin (paralytic shellfish poisoning), brevetoxin B (neurotoxic shellfish poisoning), and tetrodotoxin (puffer fish [fugu]). A number of insect venoms are also neurotoxic. Most cause neuromuscular junction blockade, but some, including tick paralysis and frog skin toxins, block sodium channels and peripheral nerve conduction.

NEUROPATHIES CAUSED BY THERAPEUTIC DRUGS

Many medications have been suspected of causing neuropathy, but relatively few have convincing clinical features, laboratory support, or reproduction in animal models. Different aspects of the problem are discussed in Chapters 105 and 128. Most of these neuropathies are dose related, presenting with predominantly sensory symptoms and signs or with a combination of sensory, motor, and autonomic involvement. Most cause toxicity by targeting the axon or dorsal root ganglion neurons directly, but toxicity to Schwann cells and myelin occurs with some agents as well. Pathogenic mechanisms are agent specific and varied. Identification of a toxic effect is most simple when symptoms occur soon after drug exposure or a change in dosage. Most patients fall into this category. In contrast, it is problematic to diagnose a slowly progressive neuropathy starting many months or years on a chronic agent. For example, statin drugs provide a case in point and are discussed later. “Coasting” is a phenomenon in which neuropathy may continue to progress, usually for 2 to 3 weeks, despite drug discontinuation. Improvement after drug cessation helps support the toxic effect, but recovery may be delayed for many months or be incomplete when significant axonal degeneration occurs. Discussion of all of the numerous substances temporally linked to neuropathy is outside the scope of this chapter, and the interested reader should consult comprehensive reviews cited in the “Suggested Readings” section. Some of the more important and best established causes are discussed.

Chemotherapy is an area in which some toxicity is tolerable assuming the agent is efficacious. The most commonly used antineoplastic agents linked with neuropathy are *vincristine*, *cisplatin* (Platinol), *carboplatin*, *oxaliplatin*, and *taxoids* (paclitaxel, docetaxel). Vincristine causes a dose-dependent, symmetric, progressive sensorimotor distal neuropathy that begins in the legs and is associated with areflexia. CMT type 1A patients are especially vulnerable, and treatment may unmask subclinical cases. In contrast, platin neuropathy is a purely sensory distal neuropathy with paresthesia, impaired vibration sense, and loss of ankle jerks, likely owing to toxicity and drug access to dorsal root ganglia but not α -motor neurons. The drug binds to and alters DNA and may trigger apoptosis if DNA repair fails. An additional acute, transient syndrome of cold-induced paresthesias, painful throat and jaw tightness, and occasionally focal weakness is associated with oxaliplatin infusion; peripheral nerve hyperexcitability has been demonstrated.

Paclitaxel (Taxol) is used to treat cancers of the breast, ovary, and lung. It causes a predominantly sensory neuropathy, but administration of a single high dose may affect motor and autonomic fibers as well. Disordered arrays of microtubules are induced. Neuropathy is also a prominent feature in chemotherapy

with suramin (axonal or demyelinating), bortezomib (Velcade), misonidazole, ixabepilone, and thalidomide (sensory). Many chemoprotectant agents to blunt the neurotoxic effects have been studied; none are routinely used in humans, but some show promise. Use of numerous other therapeutic drugs may produce neuropathy, including colchicine (myoneuropathy), gold salts, isoniazid (without B₆), metronidazole, nitrofurantoin, and podophyllotoxin resin. Amiodarone (Cordarone) may cause a severe symmetric distal sensorimotor neuropathy, an autonomic or demyelinating neuropathy resembling CIDP. Phenytoin (Dilantin) may produce minor distal sensory impairment and areflexia but mostly after long-standing high dosage and is likely overdiagnosed. The major toxicity of some nucleoside analog antiretroviral medications (didanosine [ddl], zalcitabine [ddC], and stavudine [d4T]) is peripheral neuropathy, which may be difficult to distinguish from HIV neuropathy. Others, such as azidothymidine (AZT), are not linked to neuropathy. A predominantly motor neuropathy has been related to disulfiram (Antabuse) and to dapsone. Statin use was associated with idiopathic neuropathy in a single large study, especially in those with definite neuropathy and longer term exposure. The methods of this study have been criticized, and the link remains controversial. Another large study in patients with diabetes mellitus found statin use protective against developing neuropathy.

ALCOHOLIC NEUROPATHY

Peripheral neuropathy in alcohol abusers is well known, but the cause is still debated. A widely held belief is that the neuropathy of alcoholism is owing entirely to nutritional deficiency, particularly vitamin B₁ (thiamine). Koike and colleagues, however, provide the best support for a direct toxic effect of ethanol. Alcoholics with normal thiamine levels develop predominantly small-fiber sensory neuropathy, the most frequent clinical type. More subacute onset with motor involvement is also seen in alcoholics with thiamine deficiency and nondrinkers with primary thiamine deficiency. Symptoms of small-fiber neuropathy, such as burning and pain, are common in chronic alcohol drinkers. Later, loss of vibration sense, proprioception, and tendon reflexes may occur. Sensory ataxia may be problematic to separate from alcoholic cerebellar degeneration. Abstinence can lead to meaningful recovery; vitamin supplements alone are not clearly effective but advised.

DIABETIC NEUROPATHY

Peripheral neuropathy occurs in approximately 50% of patients with diabetes mellitus, most commonly as a distal symmetric neuropathy. There are, however, several other distinct neuropathy syndromes that occur in patients with diabetes.

In one form, the symptoms and signs are transient; in the other, they progress steadily. The transient category includes acute painful neuropathies, mononeuropathies, and radiculopathies. The painful type starts abruptly with a disabling and continuous pain, often a burning sensation in a stocking distribution. Sometimes, the pain is localized to the thighs as a femoral neuropathy. The onset is often associated with weight loss. This disorder has been designated “diabetic neuropathic cachexia.” The pain may last for months. Recovery from severe pain, however, is usually complete within 1 year, and the disorder does not necessarily progress to a conventional sensory polyneuropathy.

The progressive type comprises sensorimotor polyneuropathies with or without autonomic symptoms and signs. Although the actual cause of diabetic neuropathies is unknown, focal nerve involvement is considered to be immune mediated, and progressive

symmetric polyneuropathy is probably owing to microvascular disease resulting from hyperglycemia. There may be as many causal factors as there are clinical pictures. There is evidence of oxidative damage and activation of protein kinase C β -activation in endothelial cells. However, it seems that hyperglycemic hypoxia is mainly responsible for the conduction changes seen in damaged diabetic nerves. Dysfunction of ion conductances,

especially voltage-gated ion channels, could contribute to abnormalities in the generation and conduction of action potentials.

Impaired glucose tolerance is also associated with peripheral neuropathy. A 2-hour glucose tolerance test is the preferred method to screen for diabetes or impaired glucose tolerance in patients with neuropathy, being preferable to a fasting glucose or a hemoglobin A1c.

A syndrome recognized by a triad of pain; severe asymmetric muscle weakness; and wasting of the iliopsoas, quadriceps, and adductor muscles is named *diabetic amyotrophy* or *diabetic lumbosacral radiculoplexus neuropathy*. Onset is usually acute, but it may evolve over weeks. It occurs primarily in older non-insulin-dependent diabetics and is often accompanied by severe weight loss and (diabetic neuropathic cachexia). Knee reflexes are absent, but there is little or no sensory loss. Although long described as involving the proximal leg muscles, this syndrome can also involve the arms and even respiratory system. The condition improves spontaneously but may last 1 to 3 years with incomplete recovery.

Mononeuropathies

It is generally believed but incompletely proven that focal neuropathies are more frequent in diabetic patients than in the general population. The syndromes are usually localized to common sites of nerve entrapment or external compression and may imply an increased liability to pressure palsies. This applies to the median nerve at the carpal tunnel, the ulnar at the elbow, and the fibular at the fibular head. The electrophysiologic features are similar to those seen in nondiabetic patients with pressure palsies, except that abnormalities outside the clinically affected areas sometimes indicate that the palsies are superimposed on a generalized neuropathy. Cranial nerve palsies are most often localized to the third and sixth nerves. They start abruptly and usually spontaneously resolve completely within 6 months; relapses are rare.

Generalized Polyneuropathies

The most common diabetic neuropathy is a diffuse distal symmetric and predominantly sensory neuropathy with or without autonomic manifestations. Balance may be impaired from proprioceptive loss. Distal limb weakness is usually minimal. The neuropathy develops slowly and is related to the duration of the diabetes, but not all patients are so afflicted. Once present, it does not resolve or significantly recover. Intensive glucose control limited complications, including peripheral neuropathy, in the diabetes control and complication trial (DCCT) with significant differences in nerve conduction values between intensive and standard glucose control groups [Level 1].⁹ Pain and temperature sensation transmitted through the smallest fibers may be affected before the large-fiber modalities (vibration, light touch, position sense). Small-fiber function can be evaluated by determining perception thresholds for warming and cooling or increasingly by assessment of epidermal nerve fiber density from skin biopsy samples (Fig. 87.11). Many patients with diabetic neuropathy do not have pain but do have numb or anesthetic feet. Diabetic neuropathy is the major predictor of foot ulcers and amputations.

The prevalence of diabetic autonomic neuropathy (DAN) may be underestimated because nonspecific symptoms are undiagnosed or the condition may be asymptomatic. Symptoms appear insidiously after the onset of diabetes. The process progresses slowly and is usually irreversible. DAN is an important prognostic indicator with a mortality rate in diabetics without other initial complications of 23% at 8 years compared to 3% at 8 years in diabetics without DAN and similar disease duration. Noninvasive autonomic screening batteries can be performed, and dedicated autonomic testing laboratories are becoming widely available (see Chapter 112).

FIGURE 87.11 Skin biopsy with staining for PGP 9.5, which shows a reduced number of nerve fibers crossing the epidermal-dermal border (magnification $\times 400$).

Mild slowing of motor and sensory conduction is a common finding in diabetics, even among those without overt neuropathy. It is generally attributed to axonal degeneration with secondary demyelination. Therapeutic attempts, including continuous subcutaneous insulin infusion to correct hyperglycemia to prevent the diabetic complications, have been unsuccessful in most instances. Although combined pancreas and kidney transplantation may halt the progression of diabetic polyneuropathy, the long-term effect is still doubtful. Patients with pain may benefit from duloxetine or pregabalin, but side effects may preclude treatment in some.

LYME NEUROPATHY

Lyme disease is commonly diagnosed in the United States and Europe. It is caused by a tick-borne spirochete, *Borrelia burgdorferi*. The most common clinical feature of neuroborreliosis is a painful sensory radiculitis, which may appear about 3 weeks after the erythema migrans. Pain intensity varies from day to day and is often severe, jumping from one area to another and often associated with patchy areas of unpleasant dysesthesia. Onset may be subacute potentially simulating GBS but with significant CSF pleocytosis and without clear signs of demyelination. Focal neurologic signs are common and may present as cranial neuropathy (61%), limb paresis (12%), or both (16%), but detailed electrodiagnostic signs often point to mononeuropathy multiplex. The clinical pattern may appear as a mononeuropathy, plexopathy, mononeuropathy multiplex, or distal symmetric polyneuropathy. The facial nerve is frequently affected; involvement is unilateral twice as often as bilateral. Ophthalmoparesis occasionally occurs. Myeloradiculitis and chronic progressive encephalomyelitis are rare. In some, the disorder is associated with dilated cardiomyopathy. Arthralgia is common among patients in the United States but rare among

pleocytosis in the CSF is known as *Bannwarth syndrome* in Europe. Peripheral nerve biopsy shows perineurial and epineurial vasculitis and axonal degeneration. The diagnosis of neuroborreliosis is based on the presence of inflammatory CSF changes and specific intrathecal *B. burgdorferi* antibodies. In some infected patients, however, no free antibodies are detectable. Antigen detection in CSF is sometimes helpful. Polymerase chain reaction technique for detecting spirochetes or spirochetal DNA is less specific. The prognosis is good after high-dose penicillin or ceftriaxone treatment. Disabling sequelae are rare and occur mainly in patients with previous CNS lesions.

IDIOPATHIC NEUROPATHY

Patients with a peripheral neuropathy of undiagnosed cause may be later found to have an immune-mediated or hereditary neuropathy with more intensive evaluation. Even then, however, 10% to 35% of patients remain without an identified cause. Among those with painful sensory neuropathy involving the feet, this percentage is even higher. Although no cure is available for the neuropathy, treatment may include management of pain, physical therapy, and counseling related to prognosis. When there is no identifiable cause of a symmetric predominantly sensory neuropathy, after a thorough evaluation, the neuropathy rarely progresses to loss of ambulation or disability. Persistent pain is a frequent problem. Care must be taken to conduct an adequate search for treatable underlying disorders.

Inherited Peripheral Neuropathies

Chiara Pisciotta

Michael E. Shy

INTRODUCTION

Inherited neuropathies, collectively known as *Charcot-Marie-Tooth (CMT) disease*, are a group of genetically and phenotypically heterogeneous peripheral neuropathies associated with mutations or copy number variations in over 70 distinct genes. Named after the three neurologists who first described the condition in 1886, CMT is the most common inherited neuromuscular disease. CMT is a motor and sensory neuropathy (HMSN) that is closely related to two other rarer inherited neuropathies: distal hereditary motor neuropathy (dHMN), which has predominantly motor involvement, and hereditary sensory/autonomic neuropathy (HSN or HSAN), which involves only or predominantly sensory and autonomic nerves. These three disorders represent a continuum and are often collectively termed *Charcot-Marie-Tooth and related disorders*.

CMT is divided into different forms based on the pattern of inheritance and neurophysiologic studies. Autosomal dominant forms are subdivided into demyelinating (CMT1) and axonal (CMT2) forms. CMT4 and CMTX designate the autosomal recessive and X-linked forms, respectively. The term *Dejerine-Sottas neuropathy (DSN)* is currently used primarily to denote severe early-onset clinical phenotypes regardless of the inheritance pattern. The classification of CMT has been divided further into subtypes, identified by letters, as defined by the mutated gene ([Table 88.1](#)).

EPIDEMIOLOGY

The prevalence of CMT is about 1 in 2,500 people, with a global distribution and no ethnic predisposition. CMT1A, associated with 17p11.2 duplication in the region containing the peripheral myelin protein 22 gene (*PMP22*), is the most common form of CMT and accounts for 60% to 70% of demyelinating CMT patients (around 50% of all CMT cases). Mutations in the gap junction beta 1 gene (*GJB1*) causing CMTX result in approximately 10% to 20% of CMT cases and CMT1B associated with mutations in the myelin protein zero gene (*MPZ*) accounts for less than 5%. Patients with CMT2 are about 20% of all cases. The prevalence of hereditary neuropathy with liability to pressure palsies (HNPP) is not known, but about 85% of patients with clinical evidence of this syndrome have a chromosome 17p11.2 deletion.

PATHOBIOLOGY

A common feature of most genes mutated in CMT is the role they play in maintaining the structure or function of cellular components of the peripheral nervous system, myelinating Schwann cells, and the axons they ensheath ([Fig. 88.1](#)). Schwann cells and axons interact at multiple points along the peripheral nerve, including the adaxonal (opposing the axon) membrane, paranodal myelin loops, microvilli, and juxtapanodal basal lamina. These interactions are mutually beneficial, providing trophic support to the axon and myelinating cues to the Schwann cell. An example

P.776

of this important interaction is the occurrence of secondary axonal degeneration in all forms of demyelinating CMT. Indeed, although the primary metabolic or structural defect often affects either the myelin or the axon, axonal degeneration represents the final common pathway in both forms of peripheral neuropathies. In demyelinating neuropathies, the secondary axonal degeneration presumably occurs because of inadequate Schwann cell support of the axon. In these neuropathies, secondary axonal degeneration may contribute more to

clinical impairment than the primary demyelination. Impaired interactions between axons and mutant Schwann cells seem to be the common process linking all forms of demyelinating CMT. Most cases of CMT1 are caused by mutations in myelin-specific genes including *PMP22* (CMT1A), *MPZ* (CMT1B) and *GJB1* (CMT1X), or other genes associated with Schwann cell function, including those that exert transcriptional control of myelination and intracellular trafficking. At a pathologic level, dysmyelination, demyelination, remyelination, and axonal loss are characteristic features of the various demyelinating forms of CMT1. In DSN, myelin may never have formed normally, which is referred to as *dysmyelination*. In CMT1, onion bulbs of concentric Schwann cell lamellae are usually present on nerve biopsies (Fig. 88.2), with loss of both small- and large-diameter myelinated

P.777

fibers and a decrease in the number of myelinated axons. Focal, sausage-like thickenings of the myelin sheath (tomacula) are characteristic of HNPP but may also be found in other forms of CMT1, particularly CMT1B. In CMT1, disability typically correlates better with secondary axonal degeneration than with demyelination itself, again demonstrating the importance of Schwann cell-axonal interactions in demyelinating disease.

TABLE 88.1 Classification of Charcot-Marie-Tooth: Specific Genetic Types

Type	Gene/Locus
Autosomal Dominant CMT1 (ADCMT1)	
CMT1A	Dup 17p (PMP22)
CMT1B	MPZ
CMT1C	SIMPLE
CMT1D	EGR2
CMT1E	PMP22 point mutations
CMT1F	NEFL
Hereditary Neuropathy with Liability to Pressure Palsies	
HNPP	Del 17p/PMP22 point mutations
X-linked CMT	
CMTX1	GJB1
Autosomal Dominant CMT2 (ADCMT2)	
CMT2A	MFN2

CMT2B	RAB7
CMT2C	TRPV4
CMT2D	GARS
CMT2E	NEFL
CMT2F	HSP27 (HSPB1)
CMT2L	HSP22 (HSPB8)
CMT2K	GDAP1

Autosomal Recessive Demyelinating CMT (CMT4)

CMT4A	GDAP1
CMT4B1	MTMR2
CMT4C	SH3TC2
CMT4F	PRX
CMT4J	FIG4

Autosomal Recessive Axonal CMT (AR-CMT2)

AR-CMT2A	LMNA
----------	------

AD, autosomal dominant; AR, autosomal recessive; CMT, Charcot-Marie-Tooth; Dup, duplication; MPZ, myelin protein zero; SIMPLE, small integral membrane protein of the lysosome/late endosome; EGR2, early growth response 2; PMP22, peripheral myelin protein 22; NEFL, neurofilament light chain; HNPP, hereditary neuropathy with liability to pressure palsies; Del, deletion; GJB1, gap junction protein beta1; MFN2, mitofusin 2; RAB7, RAB7, member RAS oncogene family; GARS, glycyl tRNA synthetase; HSP27, heat shock 27 kDa protein 1; HSP22, heat shock 22 kDa protein 8; GDAP1, ganglioside induced differentiation associated protein 1; MTMR2, myotubularin related protein 2; SH3TC2, SH3 domain and tetratricopeptide repeats 2; PRX, periaxin; FIG4, FIG4 homologue; LMNA, lamin A/C.

(Adapted from Saporta MA, Shy ME. Inherited peripheral neuropathies. *Neurol Clin.* 2013;31:597-619.)

FIGURE 88.2 Pathologic findings in demyelinating Charcot-Marie-Tooth disease. **A:** Cross-section of a sural nerve biopsy of a patient with demyelinating CMT showing numerous demyelinated axons (arrows) and occasional classical onion bulbs (asterisk). Thionine and acridine orange stain. Bar = 10 μm. **B:** Electron micrograph showing a demyelinated axon (asterisk) surrounded by some excess basal lamina. The Schwann cells associated with small, unmyelinated axons are abnormally long and attenuated (arrows). Bar = 1 μm. (From Saporta MA, Shy ME. Inherited peripheral neuropathies. *Neurol Clin.* 2013;31:597-619.)

Several recent studies have demonstrated a susceptibility of Schwann cells to mutations yielding misfolded proteins, as seen in certain *PMP22* and *MPZ* point mutations. Misfolded proteins may accumulate in the endoplasmic reticulum (ER) of Schwann cells inducing an unfolded protein response (UPR), a series of cellular events that help the ER to cope with the increased metabolic demand caused by retention of the misfolded protein. This, in turn, causes downregulation of the myelination program genes and dedifferentiation of Schwann cells, a toxic gain of function that worsens with the demyelination and is potentially amenable to therapeutic intervention.

Spinal motor neurons and dorsal root ganglion sensory neurons that are affected in CMT have particular challenges in maintaining homeostasis, as their axons extend up to 1 m distal from the cell body. Because the majority of neuronal proteins are synthesized in the cell body, intensive transport of proteins must occur between the soma and the axonal extremity via anterograde transport. Additionally, signals from the periphery containing toxic or prosurvival factors, as well as damaged proteins, return to the cell body via retrograde transport. Indeed, axonal trafficking is emerging as a common theme of various seemingly diverse genes that are associated with CMT type 2. Mutations in genes associated with axonal structure and function result in CMT2. Some examples include mutations in proteins of the neuronal cytoskeleton (neurofilament light chain-NEFL, CMT2E), proteins associated with axonal mitochondrial dynamics (mitofusin 2-MFN2, CMT2A and ganglioside-induced differentiation protein 1-GDAP1, CMT2K), and protein associated with regulation of membrane and intracellular trafficking (Ras-associated protein RAB7, CMT2B, for example). The pathologic hallmark of CMT2 is axonal degeneration with loss of all types of nerve fibers in the absence of onion bulb formation.

CLINICAL MANIFESTATIONS

Despite phenotypic variability, there are characteristic clinical patterns for many types of CMT (Table 88.2). The “classical” CMT phenotype consists of normal early milestones such as beginning to walk by a year of age. This is followed by gradually progressing weakness and sensory loss during the first two decades of life. The classic phenotype typically features a steppage gait, pes cavus, sensory loss in a stocking or glove distribution, inverted champagne bottle legs, and atrophy in the hands (Fig. 88.3). Although both motor and sensory nerves are usually affected, the more prominent phenotypic characteristic is related to motor difficulty in most cases. Physical examination shows decreased or absent deep tendon reflexes, often diffusely but always involving the Achilles tendon. Findings are usually symmetric. Pronounced asymmetries in symptoms suggest HNPP if they are episodic. Otherwise, they are more consistent with acquired disorders. Patients with classical CMT almost always have impaired proprioception with balance difficulty. Affected children are usually slow runners and have difficulty with activities that require balance (e.g., skating, walking along a log across a stream). Ankle-foot orthotics (AFOs) are frequently required by the third decade. Fine movements of the hands for activities such as turning a key or using buttons and zippers may be impaired, but the hands are rarely as affected as the feet. Deep and superficial muscles that are innervated by the peroneal nerve, such as the tibialis anterior and peroneus brevis and longus muscles often cause more symptoms than do the plantar flexion muscles innervated by the tibial nerve, such as the gastrocnemius. As a result, tripping and spraining one's ankle are frequent symptoms. Most patients remain ambulatory throughout life and have a normal life span.

However, CMT, as well as genetically, may be clinically heterogeneous, with variability in the age of onset, speed of progression, and electrophysiologic findings. Onset may differ depending on the genetic subtype, including early-onset, infantile forms with delayed milestones (historically designated DSN) and late-onset, adult forms. Symptoms are usually slowly progressive, especially for the classic and late-onset phenotype, but can be severe, particularly in early-onset forms.

ELECTROPHYSIOLOGY

Electrophysiologic studies allow for classification of CMT into demyelinating (CMT1) and axonal (CMT2) forms. The standard cutoff for demyelinating motor nerve conduction velocity (MNCV) is 38 m/s in the upper extremities. Axonal forms (CMT2) exhibit MNCVs greater than 45 m/s but a decrease in compound muscle action potential (CMAP) amplitudes. The dominant intermediate forms (I-CMT) show MNCVs between 25 and 45 m/s. Conduction velocities are performed in the upper limbs because CMAP amplitudes are often unobtainable in the legs, even for demyelinating forms of CMT, due to either conduction failure or secondary axonal degeneration.

The usual electrodiagnostic finding in demyelinated inherited neuropathies is widespread uniform slowing of conduction velocities, as opposed to the multifocal segmental slowing found in demyelinating acquired

neuropathies in which temporal dispersion and conduction blocks are frequently seen. Exceptions to this rule are women with CMTX, patients with HNPP, and some CMT1B cases with specific *MPZ* mutations. In these cases, focal demyelination with temporal dispersion or conduction block can be seen. In other cases of CMT1, the finding of focal slowing should raise the possibility of a superimposed inflammatory neuropathy.

DIAGNOSIS

The first step is to determine whether the patient has a genetic neuropathy. Where there is an affected parent, either an autosomal dominant (AD) or X-linked (if there is no definite male-to-male transmission) inheritance is likely. If there are multiple affected siblings, no parents affected, and/or consanguineous parents, then autosomal recessive (AR) inheritance is likely. However, recognizing CMT can be challenging particularly when there is no family history or if families are small. Factors pointing to an inherited neuropathy in such circumstances include presentations in childhood, slow progression, the presence of foot deformities, and the lack of positive sensory symptoms (dysesthesias, paresthesias) in the presence of clear sensory signs. Patients may have undergone foot surgery in childhood or reported difficulties with sports at school.

Genetic testing is the “gold standard” for the diagnosis of inherited neuropathies. However, it is a challenge to keep the costs reasonable particularly because there are so many known genetic causes.

P.778

P.779

Although there are many genes associated with CMT, in North America, mutations in only four genes (*PMP22* duplication/deletion, *GJB1*, *MPZ*, and *MFN2*) account for over 90% of CMT cases.

TABLE 88.2 Specific Phenotypes of Charcot-Marie-Tooth

Type	Specific Phenotype
CMT1	
CMT1A	Classic CMT phenotype with disease onset in the first two decades of life. Patients complain of walking difficulties, distal weakness associated with wasting, sensory loss, and foot deformities. Slow progression and AFOs often required. MNCVs are uniformly slow (mean range 17-21 m/s).
CMT1B	Associated with distinct phenotypes: late mild phenotype, adult-onset, and intermediate MNCVs; DSN with early infantile onset, severe phenotype, delayed walking, and MNCV <10 m/s; classic CMT phenotype (see CMT1A)
CMT1C	CMT1 (frequently resemble those with CMT1A)
CMT1D	Usually presents with DSN
CMT1E	Distinct phenotypes depending on the location and amino acid change: DSN with early onset, delay in walking, severe phenotype (deafness may also be present), very slow MNCVs; CMT1 with later onset and milder phenotype; HNPP

CMT1F	“Demyelinating” form of CMT2E with earlier onset (infancy or childhood), more severe phenotype (delayed motor milestones), and slower MNCVs
HNPP	Recurrent episodic painless mononeuropathies, typically at entrapment sites, in response to nerve injury from pressure or stretching. Superimposed, length-dependent, sensory-predominant neuropathy of large fibers.
X-linked CMT	
CMTX1	Males have a more severe phenotype than females. MNCVs in the intermediate range (male MNCVs < female MNCVs). Nerve conduction can be patchy with temporal dispersion and conduction blocks, especially in females.
CMT2	
CMT2A	Usually severe phenotype with onset in infancy or early childhood, progressive course, and predominant motor involvement with many patients requiring a wheelchair to ambulate by the age of 20 years. Rarely, later onset and milder phenotype. Additional clinical features may be present as optic atrophy or pyramidal signs.
CMT2B	Predominant sensory involvement with ulcerations, infections, and sometimes amputations. Patients usually have in addition the typical motor symptoms of CMT. Autonomic dysfunctions can be also observed.
CMT2C	Predominant motor involvement, vocal cord paralysis (hoarseness and stridor), and respiratory dysfunction. Other distinctive clinical features may include bone deformities such as scoliosis, short stature, and/or scapular winging. The age of onset is often in the first decade of life.
CMT2D	It usually presents in the second decade with more pronounced weakness and wasting of the distal upper extremities compared to the lower extremities. Sensory findings are usually mild and may even be absent. In this situation, the disorder has been classified as dHMN type V.
CMT2E	The age of onset ranges from infancy and childhood typically with severe impairment to adulthood with mild impairment. Weakness and wasting starts in the legs with all sensory modalities reported to be affected. MNCVs can be normal, intermediate, or slow (CMT1F).
CMT2F	Most patients have a dHMN phenotype (dHMN type IIB). Typically, this is a motor distal length-dependent neuropathy with slow progression proximally of symptoms. Sensory findings may be present, especially later in the disease course. The age of onset is typically late adolescence to early adulthood.
CMT2L	CMT2 or dHMN-IIA if sensory involvement is not present (see CMT2F)
CMT2K	Typically results in a much milder phenotype than the recessive form (CMT4A) with no

vocal cord involvement and onset ranging from adolescence to adulthood

CMT4/AR-CMT2

CMT4A Infantile-onset, severe progressive neuropathy with a variable vocal cord involvement and diaphragm paralysis

CMT4B1 Infantile onset with severe phenotype (both proximal and distal) cranial nerve involvement, especially facial weakness. Wheelchair dependent by adulthood.

CMT4C The phenotype can be severe with early and severe scoliosis. The onset is slightly later than other AR-CMT.

CMT4F Severe early-onset neuropathy with prominent sensory involvement and ataxia.

CMT4J Onset in early childhood with a severe motor phenotype, sometimes asymmetric. Rapid progression to a wheelchair has been described in adulthood.

AR-CMT2A Severe axonal neuropathy with proximal involvement and rapid progression. Cardiomyopathy can be an associated feature. Onset usually in the second decade of life.

CMT1, autosomal dominant demyelinating Charcot-Marie-Tooth; AFOs, ankle-foot orthotics; MNCV, motor nerve conduction velocity; DSN, Dejerine-Sottas neuropathy; HNPP, hereditary neuropathy with liability to pressure palsies; CMT2, autosomal dominant axonal Charcot-Marie-Tooth; dHMN, distal hereditary motor neuropathy; CMT4, autosomal recessive demyelinating Charcot-Marie-Tooth; AR, autosomal recessive.

FIGURE 88.3 **A:** Wasting of distal muscles in lower limbs leading to inverted champagne bottle legs. **B:** Example of wasting of intrinsic muscles of the hands. **C:** Pes cavus with hammer toes.

GENETIC TESTING STRATEGIES

Strategies for focusing genetic testing have been in place since at least 2011, with several groups suggesting algorithms guided by MNCV results and patterns of inheritance, as well as age of onset of symptoms. These algorithms rely on careful phenotyping and sequential Sanger sequencing of candidate genes. Although this approach is reasonably successful, with over 60% of patients with CMT achieving a genetic diagnosis, it is no longer the most efficient, rapid, or cost-effective method of achieving a molecular diagnosis, especially for CMT2, dHMN, and HSAN. In fact, diagnostic approaches are shifting to incorporate rapidly developing next-generation sequencing (NGS) techniques, as the cost of these drops below that of serial candidate gene screening.

However, the authors think it is still reasonable to provide some information about how to pursue genetic testing. Genetic testing strategies must take into account the frequency of the subtypes, the phenotype and electrophysiologic characteristics, and the inheritance pattern. This can be quite challenging, as the same

gene can be involved in demyelinating, axonal, or intermediate forms and can display autosomal dominant or recessive inheritance depending on the nature and position of the mutation. Based on these elements, the clinician can address the molecular genetic investigations.

AGE OF ONSET AND PROGRESSION

Three different categories can be identified. Patients with a classical phenotype, who begin walking on time and develop weakness or sensory loss during the first two decades of life, belong to the first group. Impairment slowly increases and patients rarely require ambulation aids beyond ankle foot orthotics. The large majority of patients with CMT1A and males with CMTX fall into this category.

The second group is the early-onset phenotypes in which patients do not begin walking until they are at least 15 months of age. These patients are often severely affected and are likely to require above the knee bracing, walkers, or wheelchairs for ambulation by 20 years of age. The genetic spectrum of early-onset CMT is very heterogeneous, including both dominant and recessive forms. The majority of these represent demyelinating phenotypes with very slow MNCVs and the most common are CMT1A, CMT1B, and CMT1E for the dominant forms and CMT4A, CMT4C, and CMT4F for the recessive ones. In addition to the demyelinating phenotypes, severe early-onset axonal neuropathies can be due to *MFN2* (CMT2A) or *GDAP1* (AR-CMT2K) mutations. Patients with CMT2A are frequently severely affected in infancy and childhood and present with a predominant motor neuropathy.

The third phenotype is defined as adult onset, in which patients do not develop symptoms of CMT until adulthood, often not until approximately 40 years of age. A large group of patients with axonal CMT and patients with a later onset CMT1B fall into this group.

ASSOCIATED SYMPTOMS AND SIGNS

The recognition of additional symptoms and signs can lead to a better definition of the type of CMT. A recurrent nerve palsy history is typical of HNPP, which presents with transient focal motor and/or sensory deficits in the distribution of individual nerves or plexuses, usually precipitated by pressure. A split hand syndrome (the abductor pollicis brevis being more wasted and weaker than the first dorsal interosseus) is a distinctive sign of CMTX, especially males. Transient CNS dysfunction and stroke-like episodes characterized by dysarthria, episodic weakness, and ataxia are also rarely reported by patients with CMTX. Optic atrophy and pyramidal signs are occasionally observed in patients with *MFN2* mutations. Vocal cord paralysis is frequent in CMT2C, caused by mutations in *TRPV4* (transient receptor potential cation channel subfamily V member 4) gene, whereas tonic pupils can be an additional clinical feature of axonal late-onset form due to *MPZ* mutations. Amputations and skin ulcers are the main feature of CMT2B and other autonomic symptoms, as light-headedness or hypo-/hyperhidrosis, can be reported. Mutations in *SH3TC2* (SH3 domain and tetratricopeptide repeat domain 2) gene, causing CMT4C, are a frequent cause of severe scoliosis.

NEUROPHYSIOLOGIC PATTERN

As previously mentioned, CMT1 are characterized by MNCVs at upper limbs below 38 m/s. CMAP can be reduced in amplitude due to secondary axonal loss. In CMT1A, MNCVs are uniformly slow in all nerves with a mean range of 17 to 21 m/s. Very slow MNCVs (< 10 m/s) are suggestive of early-onset CMT1B, *PMP22* point mutations, or demyelinating recessive phenotypes (CMT4).

P.780

Preserved or mildly slowed MNCV (mostly >45 m/s at upper limbs) and reduced CMAP are in keeping with CMT2. Especially for severe phenotypes, in which CMAP and sensory nerve action potentials (SNAP) are unobtainable distally, it is recommended to perform nerve conduction on proximal nerves for a proper diagnostic workup to fully investigate the possibility of a severe demyelinating rather than an axonal pathology. Sensory nerve conduction evaluation is required to differentiate CMT2 from dHMN, and it should

be performed especially at lower limbs because SNAP amplitude could be normal at upper limbs in mild phenotypes. Some forms of dHMN can have a minimal sensory impairment and in these cases, the discrepancy between CMAP and SNAP amplitude reduction should be taken into account for the differential diagnosis.

“Intermediate” MNCV, in the range of 25 to 45 m/s, is consistent with I-CMT. MNCVs are not uniformly slow and can differ among different nerves in the same individuals or among family members. Therefore, although a single nerve can be sufficient to make a diagnosis of CMT1, multiple nerve evaluation must be performed especially in these cases. Temporal dispersion and conduction blocks can also be present. The most common intermediate forms of CMT are due to *MPZ* and *GJB1* mutations. Focal slowing at typical sites of compression (median nerve at wrist, ulnar nerve at elbow, and peroneal nerve at fibular head) and a superimposed, diffuse, sensory neuropathy is suggestive of HNPP.

INHERITANCE PATTERN

The AD transmission is the most common pattern of inheritance in CMT with a vertical transmission from a generation to another. If there is no male-to-male transmission, X-linked inheritance should be taken into account, whereas in case of consanguinity, AR inheritance is likely. However, many patients present with no clear family history and these cases should be considered as sporadic cases due to de novo mutation, reduced penetrance/intrafamilial variability, or proband of an AR inheritance. So, the absence of a family history of neuropathy should not dissuade clinicians from considering an underlying genetic cause.

ETHNICITY

It is important to be aware of the specific mutation frequencies occurring in certain populations because some genetic mutations have been reported in specific ethnic groups. In northern Europe and the United States, AD inheritance is much more common than AR, which should be considered for those patients coming from countries where consanguinity is more frequent, such as Mediterranean and Middle Eastern populations.

Currently, genetic testing is in a transition phase with both traditional Sanger sequencing and NGS technology being used by most dedicated CMT clinics, and whole exome sequencing is not far behind. A review of these techniques is beyond the scope of this chapter but a reference is provided. Ensuring that genetic testing is focused and cost-effective is important for patients and their families.

SPECIFIC TYPES OF CHARCOT-MARIE-TOOTH

AUTOSOMAL DOMINANT DEMYELINATING CHARCOT-MARIE-TOOTH

CMT1 or AD demyelinating CMT includes types that are caused by mutations in genes involved in Schwann cell function and myelin sheath formation. This group includes the majority of patients with CMT.

CMT1A is the most common form of CMT1 and is caused by a 1.4 Mb 17p11.2 duplication including the *PMP22* gene, which should be checked first in any patient with demyelinating CMT, even if sporadic (approximately 10% of CMT1A cases). Patients affected by CMT1A usually have the “classic CMT phenotype” with disease onset in the first two decades of life. They complain of walking difficulties, distal weakness associated with wasting, sensory loss, and foot deformities. Patients progress very slowly and they often require AFOs. Inter- and intrafamilial variability is frequently observed.

HNPP is caused by the reciprocal deletion of the 1.4 Mb stretch of chromosome 17p11.2 containing the *PMP22* gene. A small percentage of people with HNPP have frameshift, splice site, or point mutation of the *PMP22* gene. The hallmark feature of HNPP is recurrent episodic focal numbness, tingling, and weakness in response to nerve injury from pressure or stretching. These individual mononeuropathies (characteristically painless) typically

occur at entrapment sites, such as the carpal tunnel, ulnar groove, and fibular head, and the palsies may last hours, days, weeks, or occasionally longer. They are often superimposed on preexisting diffuse, length-dependent, sensory-predominant neuropathy of large fibers.

CMT1X is the second most common form of CMT and in families with no definite male-to-male transmission, mutations in *GJB1*, encoding the protein Cx32, should be investigated. Males have a more severe phenotype than females and their MNCVs are in demyelinating range but usually not uniform. Females present with a milder phenotype and MNCVs are in the intermediate or axonal range. Nerve conduction study can be patchy with temporal dispersion and conduction blocks mimicking inflammatory neuropathies. It has been assumed that the cause of the difference in phenotype observed in women is due to variable X-inactivation; however, there is no evidence as yet to support this theory.

CMT1B is caused by approximately 200 different mutations in the *MPZ* gene, which encodes for the major protein component of the myelin sheath. CMT1B is associated with two distinct phenotypes: (1) an early infantile-onset severe phenotype with delayed walking and MNCV less than 10 m/s often referred to as *DSN* or (2) a much later, milder phenotype with onset at around age 40 years and MNCV around 40 m/s. CMT1B can also cause the “classical CMT phenotype” in about 15% of total CMT1B cases. The phenotypes depend on the particular mutation.

CMT1E is caused by point mutations in the *PMP22* gene. Depending on the location and amino acid change, these patients may have an earlier onset with a more severe phenotype than those with CMT1A caused by the duplication. These severe cases may also have deafness and much slower MNCVs compared to CMT1A patients who simply have a duplication in the *PMP22* gene. Onset within the first 2 years of life with a delay in walking is not uncommon; however, the clinical phenotype is variable and onset may be later. The disease severity depends on the particular *PMP22* mutation and some cases can be very mild or even resemble HNPP.

Mutations in *EGR2* (early growth response protein 2) (CMT1D) and *SIMPLE* (small integral membrane protein of the lysosome/late endosome) (CMT1C) are very rare (<1%). CMT1D patients usually present with *DSN*, whereas CMT1C patients frequently resemble those with CMT1A.

AUTOSOMAL DOMINANT AXONAL CHARCOT-MARIE-TOOTH

Phenotypic clues are helpful in guiding the diagnosis of patients with CMT2, which can be difficult to distinguish from an

P.781

idiopathic axonal neuropathy when family history is negative. CMT2 may present with a “classical CMT phenotype” with lower limb symptoms (difficulty walking/foot deformity) with onset in the first two decades of life. However, these patients are often more severely affected compared to patients with CMT1A for example. Profound sensory impairment characterizes a second phenotype, as illustrated in CMT2B, and selective initial involvement of the upper limbs is distinctive of the third phenotype, typical of CMT2D. However, among patients with axonal neuropathy, genetic testing is less likely to be positive, as there are many genes known to cause axonal CMT with each gene accountable for only a very small proportion of cases with the exception of *MFN2* in northern Europe and the United States and *GDAP1* in southern Europe and Mediterranean area. However, with the advent of NGS, it is certain that the number of genetic causes of CMT2 will significantly increase over the next few years.

Mutations in the *MFN2* gene cause CMT2A. The phenotype is often severe with onset in infancy or early childhood, progressive course, and predominant motor involvement, with many patients requiring a wheelchair to ambulate by the age of 20 years. Rarely, some patients present later in life (during childhood, adolescence, or even adulthood) with a milder phenotype. Some additional clinical features such as optic atrophy or pyramidal signs are observed. Diagnosis can be difficult because there are already a number of benign polymorphisms

reported with the gene.

CMT2B is caused by mutations in the *RAB7* gene. It is characterized by mild to moderate sensory loss that typically leads to ulcerations, infections, and sometimes amputations. Patients with CMT2B usually have in addition the typical motor symptoms of CMT. On occasion, the sensory loss can be severe and patients can be clinically indistinguishable from HSN1. Autonomic dysfunctions can be also observed.

CMT2C, caused by mutations in the *TRPV4* gene, is characterized by a predominantly motor neuropathy with vocal cord and diaphragm paralysis, often presenting with hoarseness and stridor. Other distinctive clinical features may include bone deformities such as scoliosis, short stature, and/or scapular winging. The age of onset is often in the first decade of life but adolescent- and adult-onset forms have been reported with potentially marked intrafamilial variability.

CMT2D is a predominantly motor disorder associated with mutations in the *GARS* (glycyl tRNA synthetase) gene. It usually presents in the second decade with a distinct clinical phenotype characterized by more pronounced weakness and wasting of the distal upper extremities compared to the lower extremities. Patients may have a “split hand” appearance with wasting more obvious in the first dorsal interosseus and thenar eminence muscles compared to the hypothenar eminence muscles. Sensory findings are usually mild and may even be absent. In this situation, the disorder has been classified as dHMN type V.

CMT2E is caused by mutations in the *NEFL* gene. The age of onset ranges from infancy and childhood typically with severe impairment to adulthood with mild impairment. Weakness and wasting starts in the legs with all sensory modalities reported to be affected. Confusingly for the clinician, MNCVs can be in either the axonal or demyelinating range, probably due to the loss of large diameter fibers. The “demyelinating” form is also termed *CMT1F*. Neurofilaments, however, are important cytoskeletal components of the axon and therefore, patients with *NEFL* mutations are referred as having an axonal neuropathy regardless of the MNCVs. Typically, those with slowed conductions present early either in infancy with delayed motor milestones or in late childhood/early adolescence.

CMT2F is caused by mutations in *HSPB1* gene, a member of the distal heat shock protein (HSP) superfamily and is also known as *HSP27*. Most patients with mutations in this gene have a dHMN phenotype (dHMN type IIB) with nerve conduction velocities in the axonal range. Sensory findings may be present, especially later in the disease course. Typically, this is a distal length-dependent neuropathy with slow progression proximally of symptoms. The age of onset is typically late adolescence to early adulthood. Mutations in the *HSPB8* gene (also known as *HSP22*), another member of the HSP superfamily, cause either CMT2L or dHMN type IIA. It is rarer and phenotypically indistinguishable from CMT2F/dHMN type IIB.

CMT2K is caused by mutations in the *GDAP1* gene. An autosomal recessive form also exists, CMT4A, and is more common than the autosomal dominant form, CMT2K. Although the recessive form may be quite severe with vocal cord paralysis, the dominant form typically results in a much milder phenotype with no vocal cord involvement and onset ranging from adolescence to even adulthood. A recent study found that *GDAP1* mutations accounted for 15% of CMT2 cases in southern Spain, suggesting, along with data from southern Italy, that this may be the most common form of CMT2 in the Mediterranean area. This again emphasizes the importance of considering a patient's ethnic background in guiding the diagnostic workup.

Mutations in *DNM2* (dynamitin 2), *DYNC1H1* (cytoplasmic dynein heavy chain 1), and *AARS* (alanyl-tRNA synthetase) genes are very rare cause of CMT2.

AUTOSOMAL RECESSIVE DEMYELINATING CHARCOT-MARIE-TOOTH

CMT4 includes all forms of autosomal recessive CMT and are typically associated with demyelinating conduction velocities on electrophysiologic testing. CMT4 should be considered especially if there is a history of

consanguinity. As a rule, AR-CMT present with an earlier onset and a more severe phenotype than the AD forms. Weakness often progresses to involve proximal muscles and results in early loss of ambulation. The most common forms of CMT4 are briefly mentioned.

CMT4A is caused by mutations in *GDAP1*, the same gene that cause CMT2K, both discussed previously. It is characterized by an infantile-onset and a severe progressive neuropathy with a variable vocal cord involvement.

Mutations in *MTMR2* (myotubularin-related protein 2), causing CMT4B1, are associated to infantile onset with proximal and distal weakness, cranial nerve involvement, especially facial weakness. The patients usually become wheelchair dependent by adulthood.

Mutation in *SH3TC2* is a frequent cause of CMT4 (CMT4C). The hallmark of this form is an early and severe scoliosis, and the onset is slightly later than other AR-CMT.

CMT4F is due to *PRX* (periaxin) mutations, which cause prominent sensory involvement with severe ataxia. Characteristically, patients have demyelinating conduction with a severe early-onset neuropathy. There are a particularly large number of polymorphisms in periaxin and care should be taken to ensure that mutations, either homozygous or compound heterozygous, segregate with the neuropathy in a family and that the phenotype is appropriate before concluding that mutations are disease causing.

CMT4J is caused by mutations in *FIG4* (factor-induced gene 4). Again, the onset here is early childhood with a severe motor phenotype, which is sometimes asymmetric. Rapid progression to a wheelchair in later adulthood has been described.

P.782

Nerve conduction are usually very slow and abnormalities on electromyography (EMG) may be similar to those seen in motor neuron disease (mutations in *FIG4* are also associated with amyotrophic lateral sclerosis type 11).

AR-CMT2 forms are very rare except for those associated with *LMNA* (lamin A/C) mutations, characterized by a severe axonal neuropathy with rapid progression, proximal weakness, and kyphoscoliosis. It most commonly presents in the second decade of life. Cardiomyopathy can be an associated feature.

DISTAL HEREDITARY MOTOR NEUROPATHY

The dHMNs are very similar to CMT in that they are inherited length-dependent slowly progressive neuropathies with onset usually starting in the first two decades. Clinically, however, they are defined by being exclusively motor in nature, even though many of them have minor sensory abnormalities and there is a degree of overlap between CMT2 and dHMN where the same mutation in the same gene can cause both phenotypes. Clinical examination confirms distal weakness and wasting with reduced or absent reflexes. Neurophysiology testing reveals reduced CMAP amplitudes with no or mild sensory abnormalities and EMG testing may reveal a predominantly distal pattern of denervation. For many dHMN, however, the exact genetic mutation remains to be elucidated and a report shows that 80% of tested dHMN patients with dominant inheritance has no positive genetic test. However, some dHMN disorders have signature clinical features that suggest specific genetic testing. Apart from the classic distal motor phenotype, typical of dHMN type 2A and 2B (discussed earlier), other clinical features may help in the selection of genetic testing in patients. Pyramidal tract signs of hyperreflexia and spasticity with distal motor weakness are likely associated with mutations in *SETX* (senataxin) or *BSCL2* (Berardinelli-Seip congenital lipodystrophy type 2). *SETX* mutations are also linked to the phenotypes diagnosed as juvenile amyotrophic lateral sclerosis (ALS4). Among patients with *BSCL2* mutations, the upper limbs may be the first involved with a variable degree of spastic paraplegia. The upper extremity onset without spasticity could also suggest mutations in *GARS* (previously described). Vocal cord involvement with scoliosis and skeletal dysplasias may suggest *TRPV4* mutations, which can present with phenotypes of scapuloperoneal spinal muscular atrophy, CMT2C, or dHMN.

HEREDITARY SENSORY AND AUTONOMIC NEUROPATHY

HSAN is a group of severe disorders affecting peripheral sensory and autonomic neurons with considerable clinical and genetic heterogeneity. A prominent hallmark of virtually all patients is the presence of prominent small-fiber sensory loss (A δ and/or C-fibers). As a group, these patients tend to have more devastating handicaps compared with HMSN due to the frequent occurrence of ulcers, amputations, and variably severe autonomic dysfunction. Motor involvement can be present as well and it is important to realize that extremity weakness need not be excluded in consideration of these genetic disorders, as variable expression has been described. Generally, the sensory features are prominent. This is best illustrated in some HSAN1 patients with *SPTLC1* (serine palmitoyltransferase, long-chain base subunit 1) mutations, the most common AD form. This disease is very difficult to differentiate from CMT2B secondary to *RAB7* mutations, emphasizing the overlap between HMSN and related disorders. Unlike with HMSN, there is a much smaller set of known genes for HSAN. Classification within HSAN is based on the mode of inheritance and clinical features and the genetic causes. HSAN1 varieties are dominantly inherited and have a juvenile or adult onset characterized by prominent sensory loss as well as autonomic disturbance. HSAN types 2 to 5 all have autosomal recessive inheritance and usually congenital onset. Mutations in each of these varieties are commonly seen in consanguineous families from founder mutations.

TREATMENT

Despite the great improvement in our biologic understanding of inherited neuropathies, derived mostly from developments in molecular biology and transgenic animal models in the last 25 years, there is still no treatment available for any type of CMT. Physical therapy, occupational therapy, and a few orthopedic procedures are still the cornerstone of CMT treatment (Table 88.3). A detailed family history and often examination of family members are required for prognosis and genetic counseling.

A dedicated, multidisciplinary rehabilitation team can significantly contribute to the management of patients with CMT and improve functionality and quality of life. Physical therapy strategies to maintain muscle strength and tone, prevent muscle contractures, and improve balance are a common need for most patients with CMT. Orthotics also are an important component of treating these patients, providing support and improving balance for ambulation. Occupational therapy focused on developing tools and strategies to help patients with activities of daily living will benefit patients with CMT, especially those with hand weakness. Tendon lengthening and tendon transfers can benefit a subset of CMT patients with muscle contractures and tendon shortening and patients with significant weakness in functionally relevant muscles, respectively; however, the optimal timing of such procedures is still controversial. Foot surgery is sometimes offered to correct inverted feet, pes cavus, and hammertoes. This surgical intervention may improve walking, alleviate pain over pressure points, and prevent plantar ulcers. However, foot surgery is generally unnecessary and does not improve weakness and sensory loss.

NORMALIZATION OF GENE DOSAGE

Reducing the expression of PMP22 in Schwann cells (hence treating the overexpression of PMP22) is a biologic strategy being tested

P.783

to treat CMT1A. High-dose ascorbic acid (vitamin C) was shown to decrease PMP22 levels and symptoms in mice with CMT1A, so that they were able to stay on a rotating rod longer, cross a beam more rapidly, and grip for longer than untreated mice. Several studies have been performed in humans with CMT1A, testing different doses of vitamin C (1 to 4 g/day) for up to 2 years. Unfortunately, all studies failed to meet their primary outcome measures and did not show a significant effect on phenotype.

TABLE 88.3 Treatments and Aims

Physical therapy	To maintain muscle strength and tone, prevent muscle contractures, and improve balance
Orthotics	To provide support and improve balance for ambulation
Occupational therapy	To provide tools and strategies for activities of daily living, especially for patients with hand weakness
Tendon lengthening	For patients with muscle contractures and tendon shortening
Tendon transfers	For patients with significant weakness in functionally relevant muscles
Foot surgery	To correct inverted feet, pes cavus, and hammer toes. It may improve walking and prevent plantar ulcers.

Steroid hormones are epigenetic regulators of gene expression, and progesterone can stimulate PMP22 expression in cultured Schwann cells. Progesterone antagonists have been shown to decrease PMP22 expression in a rat model of CMT1A, improving their phenotype (specifically, the axonal loss seen during disease progression). Unfortunately, onapristone, the compound shown to have therapeutic effects in this study, do not have an appropriate safety profile to be administered in humans. Efforts to develop bioequivalent compounds with a better safety profile are ongoing.

NEUROTROPHIC SUPPORT

The growth factor neurotrophin 3 promotes nerve regeneration after injury and the survival of Schwann cells. Accordingly, injection of recombinant neurotrophin 3 improved regeneration and remyelination in animal models. A pilot study in eight patients with CMT1A resulted in an increase in myelinated fiber density, a reduction in the neurologic impairment score, and improved sensory modalities as compared with placebo controls, calling for a larger randomized controlled trial. An additional study provided preclinical data demonstrating efficacy of adeno-associated virus (AAV)-mediated neurotrophin 3 gene therapy in a mouse model of CMT1A.

REDUCTION OF NEUROTOXIC AGGREGATES/MISFOLDED PROTEINS

Recent studies have demonstrated the role of ER accumulation of misfolded proteins and UPR activation in the pathogenesis of several animal models of CMT associated with point mutations in myelin-related genes, including *PMP22* and *MPZ*. Furthermore, treatment with an agent that relieves ER stress (curcumin) improved the phenotype of both models. Therefore, compounds that either relieve ER stress or reduced UPR activation are promising therapeutic strategies to treat patients with mutations that cause misfolded proteins to accumulate in the ER of Schwann cells.

TARGETING TRANSPORT DEFECTS

Treatment strategies for axonal forms of CMT have not been as easily identified as for demyelinating forms. Recently, histone deacetylase-6 inhibitors have been shown to correct axonal transport defects in a mouse model of CMT2F associated with point mutations in the *HSPB1* gene, rescuing the axonal loss and clinical

phenotype of these mice. It remains to be shown whether this same strategy could be useful in other forms of axonal CMT, but correcting axonal transport defects may be a common treatment option for most of these CMT types.

CELLULAR REPROGRAMMING AND HIGH-THROUGHPUT DRUG SCREENING

Two new technologies recently developed hold enormous potential in the search for compounds to treat CMT: cellular reprogramming and high-throughput drug screening. Cellular reprogramming is a technique that allows the generation of specific cell types (including stem cell-like cells, neurons, and glia) by genetically modifying readily available somatic cells such as fibroblasts or lymphocytes. Using this technology, researchers are able to generate unlimited supplies of patient-specific cell lines for use in mechanistic studies and drug development. These patient-specific cell lines will be particularly useful when combined with high-throughput screening of drug libraries containing thousands of compounds. In these highly automated platforms, the process of identifying compounds capable of correcting certain disease-related cell phenotypes is streamlined, allowing for a faster target selection of compounds to be tested in phase 1 animal studies. The use of patient-derived human cells offer the theoretical advantage of a more translational platform, which could facilitate the process of moving from phase 1 studies to human clinical trials. Whether this is actually true remains to be proven.

OUTCOME

Phenotypic variability occurs within given phenotypes, and natural history studies of most forms of CMT are lacking. Nevertheless, most patients remain ambulatory throughout life and life span is not typically shortened. Some patients do not develop symptoms until adult years.

Vital to clinical trials in inherited neuropathy is the establishment of solid outcome measures. With neuropathies that progress slowly over many years, this can be challenging. To this end, a validated scoring system (CMT neuropathy score) based on symptoms, signs, and neurophysiologic data has been developed for adults with excellent inter- and intraobserver correlations and which can detect changes over 1 year. A more sensitive pediatric score exists for those patients between the ages of 3 and 21 years which takes into account growth-related changes and should prove useful in future clinical trials. Sequential yearly magnetic resonance imaging (MRI) of limb muscles looking at progressive replacement of muscle with fatty tissue may also prove to be a valuable outcome measurement and is currently under investigation in a cohort of CMT1A patients.

CONCLUSIONS

Although CMT is a genetically heterogeneous condition, it is often possible to determine the type of CMT a person has by distinguishing characteristics. The prevalence of the various mutations, inheritance pattern, nerve conduction, and age of onset should be taken into account when deciding what genetic testing should be ordered. New genes causing CMT continue to be found, prevalence continues to be studied, and recommendations for testing will continue to evolve over time. Just as the past two decades have witnessed a surge in gene discovery and molecular diagnosis of CMT subtypes, this knowledge will lead to innovative therapeutic directions in the upcoming years. Beyond directing genetic counseling and prognosis in the specific patient, accurate genotyping of individuals with CMT will allow gene/pathway-specific clinical trials and, ultimately, individualization of therapy according to the underlying molecular defect.

Myasthenia Gravis and Disorders of the Neuromuscular Junction

Christina M. Ulane

Lewis P. Rowland

INTRODUCTION

Pathology at the neuromuscular junction can occur at the presynaptic or postsynaptic membrane. Autoimmune disorders, hereditary diseases, and toxins are the main types of disease which affect the neuromuscular junction.

MYASTHENIA GRAVIS

Myasthenia gravis (MG) is caused by a defect of neuromuscular transmission (NMT) owing to antibody-mediated attack on nicotinic acetylcholine receptors (AChR) or muscle-specific tyrosine kinase (MuSK) at neuromuscular junction. It is characterized by fluctuating weakness that is improved by inhibitors of cholinesterase.

EPIDEMIOLOGY

Greater awareness and improved diagnosis has led to an increased incidence of MG. A systematic review spanning 1980 to 2007 of 31 studies mostly conducted in Europe found incidence rates from 3 to 30 per million per year. The prevalence in the United States is estimated at 20 per 100,000 by Philips in 2003. MG is equally present in men and women older than the age of 40 years; however, it is three times more common in women than men under 40 years of age. MuSK myasthenia is also more common in women.

FIGURE 89.1 The neuromuscular junction. Key components of the neuromuscular junction are depicted including the motor axon and muscle endplate, the synaptic cleft, and the muscle fiber. When an action potential reaches the terminal, ACh is released into the synapse and binds to the nicotinic Ach receptors on the sarcolemma, triggering a muscle fiber action potential and contraction. The antigenic targets in myasthenia gravis and LEMS are indicated, as is the site of action of botulinum toxin. LEMS, Lambert-Eaton myasthenic

syndrome; MG, myasthenia gravis.

Systemic autoimmune disorders are found with greater incidence in patients with MG. Thyroid disorders are present in up to 15% of patients with MG. Other autoimmune disorders with increased incidence in patients with MG include rheumatoid arthritis and systemic lupus erythematosus (SLE).

Familial cases are rare; single members of pairs of fraternal twins and several sets of identical twins have been affected. Young women with MG tend to have HLA-B8, HLA-DR3, and HLA-DQB1* 0102 haplotypes; in young Japanese women, HLA-A12 is prominent. These observations imply the presence of a linked immune response gene that encodes a protein involved in the autoimmune response. First-degree relatives show an increased incidence of other autoimmune diseases (SLE, rheumatoid arthritis, thyroid disease) and HLA-B8 haplotype.

PATHOBIOLOGY

The purpose of the neuromuscular junction is to transmit the electrical impulse from the motor neuron to the muscle fiber and trigger contraction. The complex synapse is depicted in [Figure 89.1](#). An electrical signal reaching the terminal motor axon results in

P.786

the release of acetylcholine (ACh) quanta into the synaptic cleft through fusion of vesicles with the membrane. The released ACh serves as a chemical signal, which then travels across the synaptic cleft and binds to AChR on the postsynaptic muscle fiber membrane, triggering a muscle fiber action potential and subsequent contraction or twitch.

The neuromuscular junction is susceptible to autoimmune pathology because there is no blood-nerve barrier to protect the neuromuscular junction. The precise mechanisms triggering autoimmunity at the neuromuscular junction are unknown; however, there is considerable knowledge regarding the pathobiology. MG is an antibody-mediated disorder in which the autoantibodies are clearly pathogenic. This is deduced from several lines of evidence:

1. Identification of circulating serum antibodies against the AChR and other components of the neuromuscular junction
2. Immunization of experimental animal models with purified AChR induces high titers of anti-AChR antibodies, weakness, and pathologic and electrophysiologic features of MG.
3. Passive transfer of human immunoglobulin G (IgG) from persons with MG to mice reproduces electrophysiologic features of MG.
4. Plasma exchange reduces anti-AChR antibody titers and ameliorates MG signs and symptoms.

Extensive research has shown the complex autoimmune nature of MG. Antibodies against the AChR are found in 80% to 85% of patients with MG. A majority of these are AChR “binding” antibodies. AChR “modulating” antibodies are found in less than 1% of MG patients without binding antibodies, and “blocking” antibodies are found in approximately 10% of MG patients without binding antibodies. The polyclonal IgG antibodies to AChR are produced by plasma cells in peripheral lymphoid organs, bone marrow, and thymus. These cells are derived from B cells that have been activated by antigen-specific T-helper (CD41) cells. The T cells have also been activated, in this case, by binding to AChR antigenic peptide sequences (epitopes) that rest on the histocompatibility antigens on the surface of antigen-presenting cells.

Most common are anti-AChR binding antibodies, which bind to the AChR on the postsynaptic membrane and cause the complement-mediated destruction of the junctional folds and accelerate internalization and degradation of AChR. Blocking antibodies prevent ACh binding to the AChR. Modulating antibodies distort the

neuromuscular junction and folds. The end result in all cases is a loss of functional AChR. The AChR antibodies react with multiple determinants, and enough antibodies circulate to saturate up to 80% of all AChR sites on muscle. A small percentage of the anti-AChR molecules interfere directly with the binding of ACh, but the major damage to endplates seems to result from actual loss of receptors owing to complement-mediated lysis of the membrane and to acceleration of normal degradative processes (internalization, endocytosis, lysosomal hydrolysis) with inadequate replacement by new synthesis. As a consequence of the loss of AChR and the erosion and simplification of the endplates, the amplitude of miniature endplate potentials is about 20% of normal, and patients are abnormally sensitive to the competitive antagonist curare. The characteristic decremental response to repetitive stimulation of the motor nerve reflects failure of endplate potentials to reach threshold so that progressively fewer fibers respond to arrival of a nerve impulse. Most AChR antibodies are directed against antigenic determinants on the extracellular portion of the protein farthest out from the membrane rather than the ACh-binding site. The summed effects of the polyclonal anti-AChR antibodies, especially those that fix complement, result in destruction of the receptors. Physiologic studies indicate impaired postsynaptic responsiveness to ACh, which accounts for the physiologic abnormalities, clinical symptoms, and beneficial effects of drugs that inhibit acetylcholinesterase (AChE). If binding or blocking antibodies are absent, tests can be done for “modulating” antibodies that enhance degradation of the receptors in cultured cells, bringing the number of positive tests to 90%, according to Howard et al.

The MuSK protein is localized to the inner surface of the muscle membrane and is involved in AChR clustering. Approximately 10% of all patients with MG and 50% of patients without antibodies to the AChR will have antibodies against MuSK. There is prominent atrophy of muscles in anti-MuSK MG. Anti-MuSK antibodies are pathogenic by inhibiting the clustering of the AChR, demonstrated in passive transfer of human IgG from patients with anti-MuSK MG to rodents.

Beginning in 2011, multiple groups of researchers found other antigenic targets in seronegative MG patients. Lipoprotein-related protein 4 (LRP4) is essential for neuromuscular junction formation, serving as an agrin receptor and participating in agrin-activated MuSK and AChR clustering. Antibodies against LRP4 were found in MG patients seronegative for AChR antibodies and MuSK antibodies. Antibodies against agrin were identified in patients both with anti-AChR antibodies and in seronegative patients. There are likely additional autoantibodies to components of the neuromuscular junction which are yet to be discovered and account for the remainder of the “seronegative” MG patients.

How the autoimmune disorder starts is not known. In human disease, in contrast to experimental MG in animals, the thymus gland is almost always abnormal; often multiple lymphoid follicles show germinal centers (“hyperplasia of the thymus”), and in about 15% of patients, there is an encapsulated benign tumor, a thymoma. These abnormalities are impressive because the normal thymus is responsible for the maturation of T cells that mediate immune protection without promoting autoimmune responses. AChR antibodies are synthesized by B cells in cultures of hyperplastic thymus gland. The hyperplastic glands contain all the elements needed for antibody production: class II HLA-positive antigen-presenting cells, T-helper cells, B cells, and AChR antigen; that is, mRNA for subunits of AChR has been detected in thymus, and “myoid cells” are found in both normal and hyperplastic thymus. The myoid cells bear surface AChR and contain other muscle proteins. When human myasthenic thymus was transplanted into severely congenitally immunodeficient mice, the animals produced antibodies to AChR that bound to their own motor endplates, even though weakness was not evident.

T lymphocytes are responsible for initiating and maintaining the autoantibody response, and the thymus gland is the site of overt pathology. About 70% of thymus glands from adult patients with MG are not involuted, weigh more than normal, and demonstrate lymphoid hyperplasia. In contrast, germinal centers in non-myasthenics are numerous in the lymph nodes and spleen but are sparse in the thymus. Immunocytochemical methods indicate that the thymic germinal centers in myasthenics contain B cells, plasma cells, HLA class II DR-positive T cells,

and dendritic cells. Approximately 10% of patients with MG will have lymphoepithelial thymomas, and the neoplastic thymic epithelial cells express self-antigens including the AChR and other skeletal muscle proteins such as titin and the ryanodine receptor. The lymphoid cells in these tumors are T cells; the neoplastic elements are epithelial cells. Benign thymomas may nearly replace the gland with only residual glandular material at the edges, or they may rest within a large hyperplastic gland. Thymomas tend to occur in older patients, but in one series, 15% were found in patients between ages 20 and 29 years. They may invade contiguous

P.787

pleura, pericardium, or blood vessels or seed onto more distant thoracic structures, including the diaphragm; however, they almost never spread to other organs. In older patients without thymoma, the thymus gland appears involuted, often showing hyperplastic foci within fatty tissue on microscopic examination of multiple samples. Excessive and inappropriately prolonged synthesis of thymic hormones that normally promote differentiation of T-helper cells may contribute to the autoimmune response. Still another possible initiating factor is immunogenic alteration of the antigen AChR at endplates; penicillamine therapy in patients with rheumatoid arthritis may initiate a syndrome that is indistinguishable from MG except that it subsides when administration of the drug is stopped.

There are few familial cases of the acquired autoimmune disease, but disproportionate frequency of some HLA haplotypes (B8, DR3, DQB1) in MG patients suggests that genetic predisposition may be important. Other autoimmune diseases also seem to occur with increased frequency in patients with MG, especially hyperthyroidism and other thyroid disorders, SLE, rheumatoid arthritis, pernicious anemia, and pemphigus.

In about 50% of cases, muscles contain lymphorrhages, which are focal clusters of lymphocytes near small necrotic foci without perivascular predilection. In a few cases, especially in patients with thymoma, there is diffuse muscle fiber necrosis with infiltration of inflammatory cells; similar lesions are only rarely encountered in the myocardium. Lymphorrhages are not seen near damaged neuromuscular junctions (although inflammatory cells may be seen in necrotic endplates in rat experimental autoimmune MG), but morphometric studies have shown loss of synaptic folds and widened clefts. Some nerve terminals are smaller than normal, and multiple small terminals are applied to the elongated, simplified postsynaptic membrane; others are absent. Other endplates appear normal. On residual synaptic folds, immunocytochemical methods show Y-shaped antibody-like structures, IgG, complement components 2 and 9, and complement membrane attack complex.

CLINICAL FEATURES

The symptoms of MG have three general characteristics that together provide a diagnostic combination ([Table 89.1](#)). Formal diagnosis depends on clinical features, demonstration of the response to cholinergic drugs, electrophysiologic evidence of abnormal neuromuscular transmission, and demonstration of circulating antibodies to AChR or MuSK.

The fluctuating nature of myasthenic weakness is unlike any other disease. The weakness varies in the course of a single day, sometimes within minutes, and it varies from day to day or over longer periods. Major prolonged variations are termed *remissions* or *exacerbations*; when an exacerbation involves respiratory muscles to a degree that intubation and assisted mechanical ventilation, it is called a *crisis*. An “exacerbation” may be ameliorated by noninvasive ventilation or may be a transient worsening without respiratory distress. Variations sometimes seem related to exercise; this and the nature of the physiologic abnormality have long been termed *excessive fatigability*, but there are practical reasons to de-emphasize fatigability as a central characteristic of MG. Patients with the disease less often complain of fatigue or symptoms that might be construed as fatigue except when there is incipient respiratory muscle weakness. Myasthenic symptoms are always owing to weakness and not to rapid tiring. Fatigue is common in MG, and at times can be difficult (especially for patients) to differentiate from true myasthenic exacerbation.

The second characteristic of MG is the distribution of weakness. Ocular muscles are affected first in about 40% of patients and are ultimately involved in about 85%. Ptosis and diplopia are the symptoms that result. Other common symptoms affect facial or oropharyngeal muscles, resulting in dysarthria, dysphagia, and limitation of facial movements. Together, oropharyngeal and ocular weakness cause symptoms in virtually all patients with acquired MG. Limb and neck weakness is also common in conjunction with cranial weakness. Almost never are the limbs affected alone. MuSK myasthenia particularly involves ocular, facial, and bulbar muscles and has high risk of respiratory insufficiency. MuSK myasthenia can follow a rapidly progressive and more severe course.

INO, internuclear ophthalmoplegia; LMN, lower motor neuron.

Aside from the fluctuating nature of the weakness, MG is not a steadily progressive disease. The general nature of the disease, however, is usually established within weeks or months after the first symptoms. If myasthenia is restricted to ocular muscles for 2 years, certainly if it is restricted after 3 years, it is likely to remain restricted, and only in rare cases does it then become generalized. Distinguishing solely ocular myasthenia from generalized myasthenia soon after onset is challenging.

Vital signs and findings on general physical examination are usually normal, unless the patient is in crisis. Weakness of the facial and levator palpebrae muscles produces a characteristic expressionless appearance with drooping eyelids, which can be asymmetric (Fig. 89.2A). Weakness of ocular muscles (Fig. 89.2B) may cause paralysis or weakness of isolated ocular muscles, limitation of conjugate gaze, complete ophthalmoplegia in one or both eyes, or a pattern resembling internuclear ophthalmoplegia. Proximal limb weakness is manifest by difficulty in raising the arms above the head (Fig. 89.2C) and difficulty climbing stairs, whereas weakness of the neck flexor and extensor muscles may result in head drop (Fig. 89.2D). Weakness of oropharyngeal or limb muscles, when present, can be shown by appropriate tests. Respiratory muscle weakness can be detected by pulmonary function tests, which should not be limited to measurement of vital capacity but should also include inspiratory and expiratory pressures, the measurement of which may be abnormal even before overt symptoms are evident. Muscular wasting of variable degree is found in about 10% of patients but is not focal and

P.788

is usually encountered only in patients with malnutrition caused by severe dysphagia. Fasciculations do not occur, unless the patient has received excessive amounts of cholinergic drugs. Sensation is normal and the reflexes are preserved, even in muscles that are weak.

FIGURE 89.2 Clinical features of myasthenia gravis. **A:** Bifacial weakness and asymmetric ptosis. **B:** Weakness of extraocular muscles causing dysconjugate gaze. **C:** Proximal arm weakness. **D:** Neck flexor weakness causing head drop. (Courtesy of C. M. Ulane.)

Crisis is most likely to occur in patients with oropharyngeal or respiratory muscle weakness. It seems to be provoked by respiratory infection in many patients or by surgical procedures, including thymectomy, although it may occur with no apparent provocation. Both emotional stress and systemic illness may aggravate myasthenic weakness for reasons that are not clear; in patients with oropharyngeal weakness, aspiration of secretions may occlude lung passages to cause rather abrupt onset of respiratory difficulty. Major surgery may be followed by respiratory weakness without aspiration, however, so this cannot be the entire explanation.

DIAGNOSIS

Clinical

Clear clinical picture of fluctuating weakness, improved with rest, and ocular symptoms can make diagnosis of MG straightforward. However, ocular MG can at times be challenging to diagnose when clinical signs are minimal during examination, symptoms do not significantly fluctuate, and symptoms are mild. The ice test is performed at bedside on patients with ptosis: A pack of ice is placed over the ptotic eye for 1 to 2 minutes, and resolution or improvement in the ptosis is considered positive and highly specific for MG.

The dramatic improvement that follows the injection of neostigmine bromide (Prostigmin) or edrophonium (Tensilon) makes the administration of these drugs pertinent. The Tensilon test administers the short-acting

AChE inhibitor edrophonium; improvement in a subsequent clinical assessment is considered similarly positive and specific for MG. A test dose of 2 mg edrophonium is given intravenously, followed by up to 8 mg intravenously. Muscles weak from MG will respond within 30 to 45 seconds, with a response lasting up to 5 minutes; an objective improvement in muscle strength is considered a positive result. Although risk of serious cardiac complications is low, life-threatening bradyarrhythmias and ventricular fibrillation can occur with the Tensilon test, and it should be carried out with close monitoring and atropine at the bedside. Patients must be monitored for acute decompensation with cholinergic crisis causing increased secretions in patients with oropharyngeal weakness, cholinergic weakness, bradycardia, and gastrointestinal intolerance.

P.789

False positives can occur in motor neuron and other diseases, and the sensitivity of the Tensilon test is 60%. Both the ice test and Tensilon test require objectively measurable outcomes and thus are most useful in cases of ptosis and oculomotor abnormalities, rather than limb weakness. The only other conditions in which clinical improvement has been documented after use of edrophonium are other disorders of neuromuscular transmission: botulinum intoxication, snake bite, organophosphate intoxication, or unusual disorders that include features of both MG and the Lambert-Eaton syndrome. Denervating disorders, such as motor neuron disease or peripheral neuropathy, do not show a reproducible or unequivocal clinical response to edrophonium or neostigmine. The response should be unequivocal and reproducible. If a structural lesion of the third cranial nerve seems to respond, the result should be photographed (and published).

Laboratory and Electrodiagnostics

Routine examinations of blood, urine, and cerebrospinal fluid (CSF) are normal. Antibodies to AChR are found in 85% to 90% of patients of all ages with generalized MG if human muscle is used as the test antigen (Table 89.2). Antibodies may not be detected in patients with strictly ocular disease, in some patients in remission (or after thymectomy), or even in some patients with severe symptoms. The titer does not match the severity of symptoms; patients in complete clinical remission may have high titers. For pure ocular MG, AChR antibodies present in serum support the diagnosis; however, the sensitivity is rather low (range 25% to 70%). Antibodies to myofibrillar proteins (titin, myosin, actin, actomyosin) are found in 85% of patients with thymoma and may be the first evidence of thymoma in some cases. In the first report of seronegative myasthenia, there were no clinical differences between patients who had or lacked AChR antibodies. Subsequently, more than half of these seronegative patients were found to have antibodies to MuSK. Patients with anti-MuSK antibodies were found to have a similar clinical picture almost always with generalized MG with predominantly bulbar signs, poor and inconsistent responses to pyridostigmine, immunosuppressants, or thymectomy but excellent response to plasmapheresis. Antibodies to rapsynclustered AChR were detected on human embryonic kidney cells by fluorescence-activated cell sorting in 66% (25/38) of sera from patients that had previously tested negative for binding to AChR in solution. Other serologic abnormalities are encountered with varying frequency, and in several studies, antinuclear factor, rheumatoid factor, and thyroid antibodies were encountered more often than in control populations.

TABLE 89.2 Diagnostic Testing for Myasthenia Gravis

Laboratory Test	Comments
Acetylcholine receptor (AChR) antibodies	

- AChR binding
- AChR blocking
- AChR modulating

- 80%-85% of all MG
- 50% of ocular MG
- Binding most common
- Blocking positive in ~10% of MG with negative binding
- Modulating positive in <1% of MG with negative binding

MusK antibodies

- 10% of all MG
- 50% of AchR-negative MG

Other antibodies

- Striational
 - (titin, RyR, myosin, actin)
- LRP4, agrin
- Present in 75%-85% of thymomatous MG
- May be associated with more severe disease (titin, RyR)
- Found in other disorders

Electrodiagnostic Test

Nerve conduction studies

- Repetitive nerve stimulation reveals decrement ($\geq 10\%$).
- Sensitivity 53%-100% in generalized MG
- Sensitivity 10%-48% in ocular MG
- Not specific

Single-fiber EMG

- Most sensitive test for MG (>95%) but not specific (~70%)

Radiology

|---|---|

MG, myasthenia gravis; EMG, electromyography.

The characteristic electrodiagnostic abnormality is progressive decrement in the amplitude of compound muscle action potentials evoked by repetitive nerve stimulation at 3 or 5 Hz (Fig. 89.3). In generalized MG, the decremental response can be demonstrated in about 90% of patients if at least three neuromuscular systems are used (median-thenar, ulnar-hypothenar, accessory-trapezius). Repetitive nerve stimulation testing is often negative in ocular MG (in both distal and proximal muscles). In single-fiber electromyography (EMG), a small electrode measures the interval between evoked potentials of the muscle fibers in the same motor unit.

This interval normally varies, a phenomenon called *jitter*, and the normal temporal limits of jitter have been defined. In MG, the jitter is increased, and an impulse may not appear at the expected time; this is called *blocking*, and the number of blockings is increased in myasthenic muscle. All these electrophysiologic abnormalities are characteristic of MG, but blocking and jitter are also seen in other disorders. Single-fiber EMG is the most sensitive test for MG but is not specific.

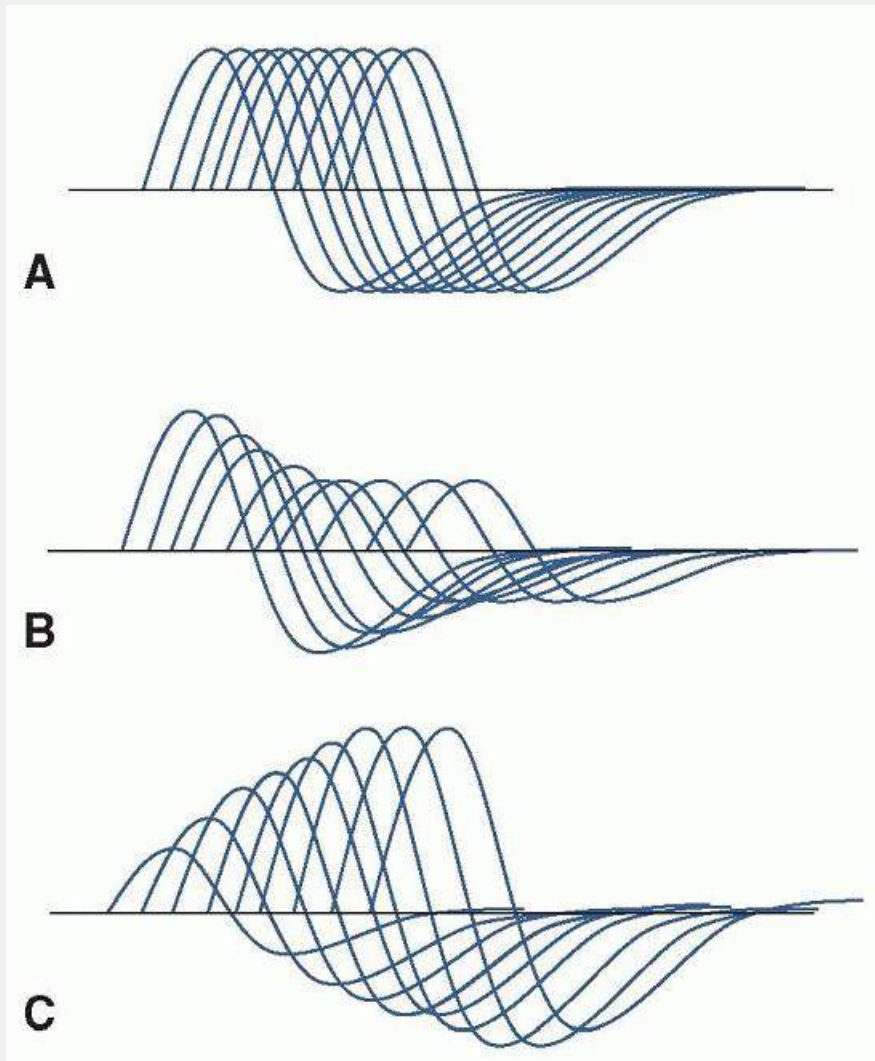

FIGURE 89.3 Repetitive nerve stimulation. Slow (3 Hz) repetitive nerve stimulation (RNS) of the median nerve-abductor pollicis brevis system reveals normal response, decrement and facilitation of the compound muscle action potential. **A:** Normal response to RNS with minimal decrement. **B:** Decremental response in MG. **C:** Facilitation in Lambert-Eaton myasthenic syndrome and botulism.

The standard-needle EMG is usually normal, occasionally shows a myopathic pattern, and almost never shows signs of denervation unless some other condition supervenes. Similarly, nerve conduction velocities are normal.

All patients diagnosed with MG should be screened for the presence of thymoma. Computed tomography (CT) of the mediastinum demonstrates all but microscopic thymomas. Magnetic resonance imaging (MRI) is not more sensitive than CT.

The differential diagnosis includes all diseases that are accompanied by weakness of oropharyngeal or limb muscles, such as the muscular dystrophies, amyotrophic lateral sclerosis (ALS), progressive bulbar palsy, ophthalmoplegia of other causes, and the asthenia of psychoneurosis or hyperthyroidism. There is usually no difficulty in differentiating these conditions from MG by the findings on examination and by the failure of symptoms in these conditions to improve after parenteral injection of neostigmine or edrophonium. Occasionally, blepharospasm is thought to mimic ocular myasthenia, but the forceful eye closure in that

condition involves both the upper and the lower lids; the narrowed palpebral fissure and signs of active muscle activity are distinctive.

TREATMENT

Treatment for MG is tailored to the individual patient. A general algorithm for treatment of MG is presented in [Figure 89.4](#). Clinicians must choose the sequence and combination of therapy: anticholinesterase drug therapy, corticosteroids, immunosuppressives, plasmapheresis, intravenous immunoglobulins (IVIg), and thymectomy ([Table 89.3](#)).

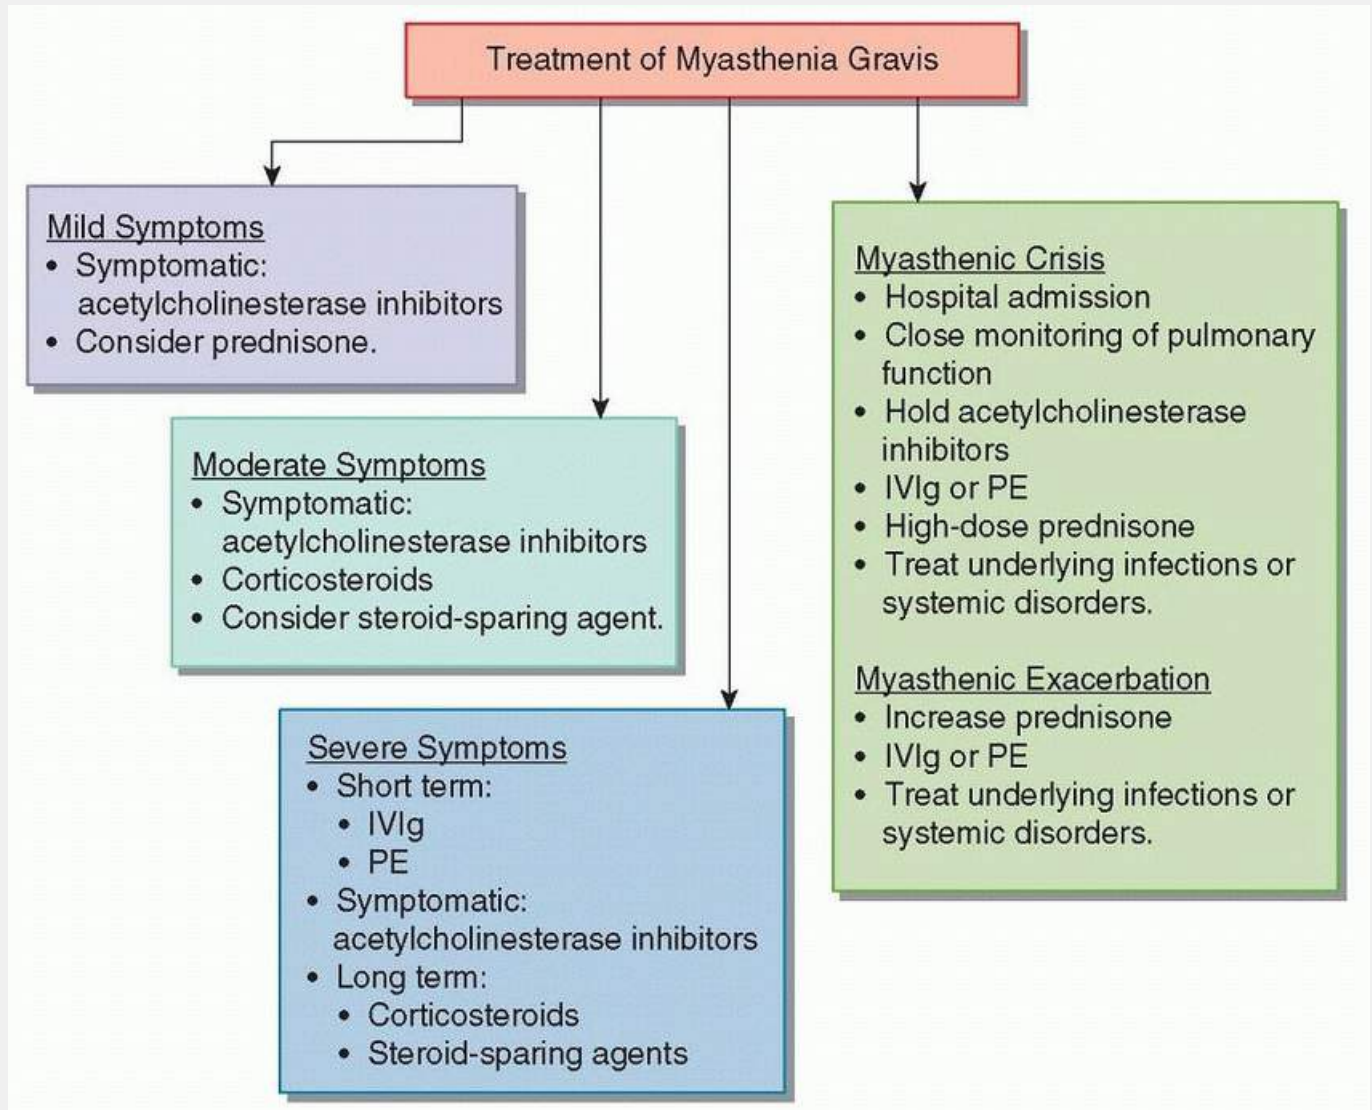

FIGURE 89.4 General treatment guidelines for MG. Treatment of MG is highly individualized and depends on many factors. Shown here are general principles to guide physicians in the treatment of MG based on severity of symptoms. IVIg, intravenous immunoglobulins; PE, plasma exchange.

Cholinesterase Inhibitors

In 1934, Dr. Mary Walker discovered the beneficial effects of AChE inhibitors in patients with MG. To this day, this remains a mainstay of treatment, yet there are no randomized trials of these agents in MG. A Cochrane review in 2011 reaffirmed the lack of controlled studies but concluded that the results from observational studies were so clear that it would be difficult to justify a trial. It is generally agreed that anticholinesterase drug therapy should be given as soon as the diagnosis is made. Of the three available drugs—neostigmine, pyridostigmine bromide, and ambenonium—pyridostigmine is the most popular but has not been formally assessed in controlled comparison with the other drugs. The muscarinic side effects of

abdominal cramps and diarrhea are the same for all three drugs but are least severe with pyridostigmine; none has more beneficial or adverse effects than another and all can be regarded as safe. The usual starting dose of pyridostigmine is 60 mg given orally every 4 hours while the patient is awake. Depending on clinical response, the dosage may be increased, but incremental benefit is not to be expected in amounts greater than 120 mg every 2 hours. If patients have difficulty eating, doses can be taken about 30 minutes before a meal. If patients have special difficulty on waking in the morning, an extended-release 180-mg tablet of pyridostigmine can be taken at bedtime. Muscarinic symptoms can be ameliorated by preparations containing atropine (0.4 mg) with each dose of pyridostigmine. Excessive doses of atropine can cause psychosis, but the amounts taken in this regimen have not had that effect. Other drugs may be taken if diarrhea is prominent. Combinations of two drugs are no better than any single drug alone.

Although cholinergic drug therapy sometimes gives impressive results, there are serious limitations. In ocular myasthenia, ptosis may be helped, but some diplopia almost always persists. In generalized MG, patients may improve remarkably, but some symptoms usually remain. Cholinergic drugs do not return function to normal, and the risk of crisis persists because the disease is not cured. Therefore, one of the other treatments is used promptly to treat

P.791

generalized MG. MuSK MG patients often do not respond as well to anticholinesterases.

TABLE 89.3 Medications Used to Treat Myasthenia Gravis

Agent	Dose	Monitoring Parameters	Side Effects
Pyridostigmine	30-90 mg q4-6h Extended release: 180 mg q.h.s	Clinical response	Common: fasciculations, diarrhea Overdose: cholinergic crisis, weakness, dysphagia, respiratory failure Rare: bromism (acute psychosis)
Prednisone	1 mg/kg/day (usually 60-80 mg/day) Alternate-day dosing Taper over months after sustained clinical response Concomitant: PPIs, H2 blockers Calcium, vitamin D	May cause initial worsening Blood pressure Serum glucose Yearly ophthalmologic exam	Hyperglycemia Hypertension Weight gain Fluid retention Cataracts/glaucoma Osteoporosis/avascular necrosis Steroid myopathy Peptic ulcer disease Depression/psychiatric effects
MG	2 g/kg over 4-5 days	Heart rate Blood pressure	Common: headache, chills, fever, nausea Rare: acute renal failure (solute-

		Clinical response (usually within 1 wk)	induced), aseptic meningitis, thrombosis (DVT/PE, stroke, MI), leukopenia
Plasma exchange	five to six exchanges	Heart rate Blood pressure Coagulation studies Fibrinogen Ionized calcium	Paresthesias Hypotension Transient arrhythmias Nausea, light-headedness, chills Complications of central lines
Azathioprine	Start at 50 mg/day Titrate up to 2-3 mg/kg/day	Complete blood count Hepatic function	Infections Gastrointestinal upset Hepatotoxicity Cytopenias Malignancy
Mycophenolate mofetil	1g b.i.d., up to 3g total daily ^a	Complete blood count Hepatic function	Infections Cytopenias Nausea Diarrhea Abdominal pain If used with other immunosuppressives: PML
Cyclosporine A	5-6 mg/kg b.i.d. Goal trough: 75-150 ng/mL	Blood pressure Renal function	Infections Renal toxicity Hypertension Many medication interactions
Tacrolimus	3-5 mg/day	Blood pressure Renal function Glucose	Infections Hyperglycemia Renal toxicity Hypertension Malignancy
Cyclophosphamide	Monthly pulsed doses 500 mg/m ^{2b}	Complete metabolic panel Urine studies Complete blood count	Myelosuppression Hemorrhagic cystitis Hyponatremia Seizures Opportunistic infection Malignancy

^aRecent randomized controlled trials (RCTs) suggest no benefit.

^bUsually reserved for severe refractory MG.

PPIs, proton pump inhibitors; IVIG, intravenous immunoglobulin; DVT, deep vein thrombosis; PE, pulmonary embolism; MI, myocardial infarction; PML, progressive multifocal leukoencephalopathy.

Glucocorticoids

Despite the widespread use and agreed upon efficacy of glucocorticoids in the treatment of MG, there are no randomized controlled studies, and at this point, it would be unethical to withhold a known beneficial treatment. Several controlled and blinded studies initially suggested the benefit of steroids for MG. Numerous retrospective studies show that steroids can induce remission in 27% to 42% and marked improvement in 29% to 52% of patients with MG. Prednisone, 60 to 100 mg daily, will achieve a response within

P.792

a few days or weeks. Within the first 2 weeks of starting prednisone, patients may experience worsening of their symptoms, and caution must be taken in those with prominent bulbar or respiratory symptoms. An equally satisfactory response can be seen with a lower dosage, but it takes longer; for instance, if the dose is 25 to 40 mg, benefit may be seen in 2 to 3 months. Once improvement is achieved, the dosage should be gradually tapered to 20 to 35 mg every other day. This has become a popular treatment for disabled patients, but there has been no controlled trial. If the patient does not improve in about 6 months or if there are unacceptable side effects from the steroids, treatment with steroid-sparing agents is pursued.

Prednisone, 15 to 35 mg on alternate days, is also recommended by some clinicians for ocular myasthenia, weighing risks against potential benefit. For some patients in sensitive occupations, the risks of prednisone therapy may be necessary (e.g., actors, police officers, roofers or others who work on heights, or those who require stereoscopic vision). Ocular myasthenia is not a threat to life, and pyridostigmine may alleviate ptosis. An eye patch can end diplopia, and prisms help some patients with stable horizontal diplopia. Currently, the Efficacy of Prednisone in the Treatment of Ocular Myasthenia (EPITOME) trial is ongoing and seeks to study the safety and efficacy of prednisone for ocular MG in a multicenter, randomized controlled trial.

Steroid-Sparing Agents

Azathioprine is one of the most studied in this category. It is a purine antimetabolite, which acts by inhibiting T- and B-cell proliferation. It is often well tolerated but it can take more than 12 months to achieve maximal benefit. Common side effects include gastrointestinal upset and an idiosyncratic flulike reaction. In addition, azathioprine may cause hepatotoxicity and transaminases need to be monitored. Rare but serious adverse effects include leukopenia and pancytopenia, which can occur at any time during treatment. In 1998, a randomized controlled trial demonstrated the benefit of azathioprine in addition to prednisolone. Patients receiving both had fewer exacerbations, longer remission, and lower total daily dose of maintenance prednisolone [**Level 1**].¹ Another study suggests that azathioprine alone may be as effective or more effective than prednisone alone in preventing clinical deterioration after 2 to 4 years of treatment [**Level 1**].²

Mycophenolate mofetil inhibits T- and B-cell proliferation by selectively blocking purine synthesis. Initial pilot and retrospective studies showed promising benefit for the treatment of MG. In one report, 73% of 85 patients improved; adverse effects led to discontinuation of treatment in 6% [**Level 1**].³ However, two randomized controlled trials in 2008 showed no benefit over placebo [**Level 1**].^{4,5} Many experts still use mycophenolate and consider it effective, and it has a favorable side effect profile. Critiques of the negative studies suggested that the patients chosen had mild disease, a better than expected response to low-dose

prednisone and the overall short duration of the trial may have obscured a positive effect.

Cyclosporine acts as a calcineurin inhibitor, thus reducing the function of effector T cells. It is used less due to renal toxicity; however, it has been shown to be effective in several randomized, controlled trials [Level 1].^{6,7}

Cyclophosphamide can also be considered in doses up to 2.5 mg/kg daily for an adult [Level 1].⁸ It is often reserved for refractory cases due to toxicity. Another agent with benefit is tacrolimus [Level 1].⁹

Methotrexate may also be considered as a second-line agent for the treatment of MG, but there is no quality data to support its efficacy. Side effects are often mild with mucositis, alopecia, and gastrointestinal intolerance, but serious adverse events such as interstitial pneumonitis, hepatotoxicity, and bone marrow suppression can occur.

The numerous side effects of prednisone must be weighed against the possibilities of marrow suppression, susceptibility to infection, or delayed malignancy in patients who are given immunosuppressive drugs.

Intravenous Immunoglobulins and Plasma Exchange

Plasma exchange (PE) is also used for exacerbations; the resulting improvement, seen in most patients, may be slight or dramatic and may last only a few days or several months. PE is safe but expensive and is not convenient for many patients. Indwelling catheters may lead to bleeding or infection. In general, 5 sessions of PE are given every other day.

IVIG therapy is usually given in five daily doses to a total of 2 g/kg body weight. There is some evidence that 1g/kg may be sufficient for treating exacerbation [Level 1].¹⁰ A randomized, double-masked, placebo-controlled trial of IVIG for the treatment of moderate to severe MG exacerbations found benefit that was both statistically significant and clinically meaningful [Level 1].¹¹ Side effects include headache, aseptic meningitis, and a flulike syndrome that can be alarming but subsides in 1 or 2 days. Thromboembolic events, including stroke, can occur. IVIG is easier to administer but is even more expensive. It is preferred over PE in those with poor venous access, including children.

Both IVIG and PE are also available for management of exacerbations. Given the differences in availability at various treatment centers and different side effect profiles, it is important to consider each carefully. A study compared IVIG to PE for moderate to severe exacerbations in a randomized, masked fashion and found both to be equally effective treatments for worsening MG with similar duration of benefits and safety profiles [Level 1].¹²

Other Immunomodulatory Agents

There is great interest in new immunosuppressive and modulatory therapies to treat MG. Recently, there is significant focus on the use of rituximab (a monoclonal antibody to CD20 B-cells which acts to deplete B-cell reserves) in MG. Many case reports and series suggest a robust response in patients in particular with MuSK antibody MG. It is also used off-label at times for refractory generalized MG. There is currently an ongoing trial to assess its efficacy in the treatment of MG.

There is interest in eculizumab for the treatment of MG; eculizumab acts to prevent terminal complement activation and therefore could function to preserve AChR and neuromuscular junction transmission in MG. Promising results from a phase II trial have instigated the initiation of a phase III trial regarding its efficacy.

Thymectomy

Thymectomy was originally reserved for patients with serious disability because the operation had a high mortality. With advances in surgery and anesthesia, however, the operative mortality is now negligible in major centers. About 80% of patients without thymoma become asymptomatic or go into complete remission after thymectomy; although there has been no controlled trial of thymectomy, these results seem to diverge from the natural history of the untreated disease. Currently, there is an ongoing randomized trial of

Decisions made for children or patients older than 65 years must be individualized. Although it is safe, thymectomy is a major operation and is not usually recommended for patients with ocular myasthenia unless there is a thymoma. The thymoma should be resected but so should the remaining thymus that may show hyperplasia. The beneficial effects of thymectomy are usually delayed for months or years. It is never an emergency measure, and other forms of therapy are used in the interim. Mantegazza et al. found a remission rate of about 50% at 6 years after surgery with either the standard transsternal operation or a minimally invasive thorascopic operation.

Patients with thymoma are likely to have more severe MG and are less likely to improve after thymectomy; nevertheless, many of these patients also improve if the surrounding thymus gland is excised in addition to the tumor.

Myasthenic Crisis

Myasthenic crisis arises in about 10% of myasthenic patients. It is more likely to occur in patients with dysarthria, dysphagia, and documented respiratory muscle weakness, presumably because they are liable to aspirate oral secretions, but crisis may also occur in other patients after respiratory infection or major surgery (including thymectomy). The principles of treatment are those of respiratory failure in general. Numerous retrospective studies have investigated what clinical and laboratory factors in MG crisis predict the need for mechanical ventilation. See [Table 89.4](#) for clinical and laboratory features of impending respiratory failure in patients with MG. Cholinergic drug therapy is usually discontinued once an endotracheal tube has been placed and positive pressure respiration started; this practice avoids questions about the proper dosage or cholinergic stimulation of pulmonary secretions. Crisis is viewed as a temporary exacerbation that subsides in a few days or weeks. The therapeutic goal is to maintain vital functions and to avoid or treat infection until the patient spontaneously recovers from the crisis. Cholinergic drug therapy need not be restarted unless fever and other signs of infection have subsided, there are no pulmonary complications, and the patient is breathing without assistance. Myasthenic crisis and exacerbations can be triggered by infections, surgery, and medications ([Table 89.5](#)).

TABLE 89.4 Signs of Impending Respiratory Failure in Myasthenia Gravis

Clinical features	Significant bulbar dysfunction <ul style="list-style-type: none"> • Dysarthria, dysphagia • Impaired gag reflex Tachypnea, dyspnea Use of accessory muscles Paradoxical breathing Count out loud in single exhale Poor cough Impaired secretion clearance

TABLE 89.5 Medications That Exacerbate Myasthenia Gravis

Contraindicated

α-Interferon
Penicillamine
Telithromycin
Botulinum toxin

Use with caution (may worsen MG)

Cardiac medications

- β-Blockers (propranolol, timolol maleate eye drops)
- Calcium channel blockers
- Quinine, quinidine, procainamide

Neuromuscular blocking agents

- Succinylcholine
- d-Tubocurarine

Antibiotics

- Aminoglycosides (gentamicin, kanamycin, streptomycin, neomycin)
- Macrolides (erythromycin, azithromycin)
- Quinolones (ciprofloxacin, levofloxacin, norfloxacin, ofloxacin)

Magnesium salts (laxatives, antacids)

MG, myasthenia gravis.

Outcome

Before the advent of intensive care units (ICUs) and the introduction of positive pressure respirators in the 1960s, crisis was a life-threatening event. In the past 60 to 70 years, advances in pulmonary critical care and in the diagnosis of MG have reduced mortality rates for myasthenic crisis from 33% to 60% to approximately 4%. With improved respiratory care, patients rarely die of MG, except when cardiac, renal, or other disease complicates the picture. Even so, pulmonary intensive care is now so effective that crisis is almost never fatal and many patients go into a remission after recovery from crisis. Because of advances in therapy, MG is still serious but not so grave.

SPECIAL FORMS OF MYASTHENIA GRAVIS

Neonatal Myasthenia

About 12% of infants born to myasthenic mothers have a syndrome characterized by impaired sucking, weak cry, limp limbs, and, exceptionally, respiratory insufficiency. Symptoms begin in the first 48 hours and may last several days or weeks, after which the children are normal. The mothers are usually symptomatic but may be in complete remission; in either case, AChR antibodies are demonstrable in both mother and child. Symptoms disappear as the antibody titer in the infant declines. Severe respiratory insufficiency may be treated by exchange transfusion, but the natural history of the disorder is progressive improvement and total disappearance of all symptoms within days or weeks. Respiratory support and nutrition are the key elements of treatment. Rare instances of arthrogryposis multiplex congenita (a syndrome of multiple joint contractures present at birth) have been attributed to transplacental transfer of antibodies that inhibit fetal AChR.

Congenital Myasthenia

Children with congenital MG, although rarely encountered, show several characteristics. The mothers are asymptomatic and do

P.794

not have circulating anti-AChR in the blood. Usually, no problem occurs in the neonatal period; instead, ophthalmoplegia is the dominant sign later in infancy. Limb weakness may be evident. The condition is often familial. Antibodies to AChR are not found, but there are decremental responses to repetitive stimulation. Ultrastructural and biochemical examination of motor endplates, microelectrode analysis, and identification of mutations have delineated a series of disorders that include both presynaptic, synaptic, and postsynaptic proteins including not only AChR but also the ColQ part of AChE, choline acetylase, rapsyn, MuSK, the Na_v1.4 sodium channel, plectin, and Dok-7. Disorders of the ion channel formed by the AChR molecule include the slow-channel syndrome, in which the response to ACh is enhanced because the opening episodes of the channel are abnormally prolonged. Forearm extensors tend to be selectively weak. More than 11 different mutations have been identified in different AChR subunits. Quinidine shortens the prolonged openings and gives therapeutic benefit. A fast-channel syndrome, with impaired response to ACh, has been reported in rare patients with mutations of the ϵ -subunit. Another mutation in the same subunit leads to abnormal kinetics of AChR activation so that the channel opens more slowly and closes more rapidly than normal. The 38 known mutations in the ϵ -subunit are inherited recessively and result in severe lack of AChR in the endplates. One syndrome results from mutations in the collagen tail subunit of AChE, creating a deficiency of the enzyme. Subsequently, clinical differences were identified between those with mutations in the AChR ϵ -subunit and those with mutations in rapsyn, the endplate AChR clustering protein. The receptor mutations caused congenital ophthalmoplegia, bulbar symptoms, and limb weakness. The rapsyn mutations caused an early-onset syndrome with arthrogryposis and life-threatening crises in childhood or a late-onset syndrome beginning in adolescence or later and resembling seronegative myasthenia. Dok-7 binding impairs MuSK signaling and this myasthenic syndrome is relatively common. It is associated with a proximal (limb-girdle) weakness. Slow-channel syndrome benefits from quinidine; fast-channel syndromes, from 3,4-diaminopyridines. Anticholinesterase drugs may help in some of these disorders, but parents should be warned that sudden apneic spells may be induced by mild infections.

Drug-Induced Myasthenia

The best example of this condition occurs in patients treated with penicillamine for rheumatoid arthritis, scleroderma, or hepatolenticular degeneration (Wilson disease). The clinical manifestations and AChR antibody titers are similar to those of typical adult MG, but both disappear when drug administration is discontinued.

Cases attributed to the anticonvulsant trimethadione have been less thoroughly studied.

LAMBERT-EATON MYASTHENIC SYNDROME

The Lambert-Eaton myasthenic syndrome (LEMS) is an autoimmune disease of peripheral cholinergic synapses. Antibodies are directed against voltage-gated calcium channels in peripheral nerve terminals (see [Fig. 89.1](#)).

EPIDEMIOLOGY

LEMS is rare and found essentially only in adults. It can be either autoimmune or paraneoplastic. About half of LEMS cases are paraneoplastic, and of these, 80% occur with small cell carcinoma of the lung. The neurologic symptoms almost always precede those of the tumor; the interval may be as long as 5 years. Other tumors have also been implicated, but about 33% of cases are not associated with a tumor. Tumor-free individuals tend to show the HLA-B8 and HLA-DR3 haplotype, which are not found in those with neoplasms.

PATHOBIOLOGY

Cell lines derived from the lung cancer bear voltage-gated calcium channels displaying the antigenic sites. If tumor cells are grown in the presence of IgG from a patient with LEMS, the number of functional channels declines. Similar antigens are found on voltage-gated calcium channels from neuroendocrine tumors. The cultured carcinoma cells also bear receptors for dihydropyridines. The abnormality of neurotransmission is attributed to inadequate release of ACh from nerve terminals at both nicotinic and muscarinic sites and is related to P/Q voltage-dependent calcium channels. When IgG from affected patients is injected into mice, the number of ACh quanta released by nerve stimulation is reduced, and there is disarray of the active zone particles that can be detected by freeze-fracture ultrastructural analysis. Purified calcium channel proteins can be directly radiolabeled. An alternative label can be generated by the use of specific ligand, omega-conotoxin, which is prepared from a marine snail (*Conus magus*) and has been used to identify P/Q-type calcium channels in extracts of small cell carcinoma, neuroblastoma, and other neuroendocrine cell lines. A diagnostic test for the autoantibodies is based on radiolabeled preparations, but it is not fully specific. In one series 92% of 72 patients had a positive reaction. A glial cell nuclear antigen identified in small cell lung carcinoma (SCLC) (a developmental transcription factor) is reactive in 22% of SCLC patients and has been identified in 64% of patients with both LEMS and SCLC but none of those with LEMS alone. This could provide a marker of concurrent SCLC in patients with LEMS. There have been a few positive tests for this antigen in paraneoplastic cerebellar disorders. Some patients have both LEMS and a cerebellar syndrome.

CLINICAL FEATURES

LEMS may be suspected in patients with symptoms of proximal limb weakness who have lost knee and ankle jerks and complain of dry mouth or myalgia. Other less common autonomic symptoms include impotence, constipation, and hypohidrosis. LEMS differs clinically from MG because diplopia, dysarthria, dysphagia, and dyspnea are lacking. Autonomic symptoms are more common in LEMS than in MG.

DIAGNOSIS

The disease is defined, and the diagnosis made, by the characteristic incremental response to repetitive nerve stimulation, a pattern that is the opposite of MG. The first evoked potential has an abnormally low amplitude, which decreases even further at low rates of stimulation. At rates greater than 10 Hz, however, there is a marked increase in the amplitude of evoked response (2 to 20 times the original value) (see [Fig. 89.3C](#)). The increment results from facilitation of release of transmitter at high rates of stimulation, which can also be achieved by exercise. At low rates, the number of quanta released per impulse (quantal content) is inadequate to produce endplate potentials that reach threshold. Similar abnormalities are found in preparations exposed to botulinum toxin or to a milieu low in calcium or high in magnesium. Appropriate

search for malignancy should be done in all patients diagnosed with LEMS, including CT chest, and possibly positron emission tomography (PET) scan. If initially negative,

P.795

screening should be repeated in the ensuing years, as the LEMS may precede the malignancy.

Some patients with LEMS have ptosis with antibodies to AChR. This combined syndrome may be an example of multiple autoimmune diseases in the same individual.

TREATMENT

Treatment is directed to the concomitant tumor. The neuromuscular disorder is treated with drugs that facilitate release of ACh, such as 3,4-diaminopyridine. Two randomized controlled trials showed both clinical and electrophysiologic improvement with 3,4-diaminopyridine in patients with LEMS [Level 1].^{13,14} A combination of pyridostigmine bromide and 3,4-diaminopyridine improves strength, but other aminopyridines may be hazardous. 4-Aminopyridine causes convulsions. 3,4-Diaminopyridine is not currently approved by the U.S. Food and Drug Administration (FDA) but is available through expanded access studies in the United States. Other drugs that facilitate release of ACh have also had adverse effects. For instance, guanidine hydrochloride (20 to 30 mg/kg/day) may depress bone marrow or cause severe tremor and cerebellar syndrome.

Other treatments that may be helpful include PE, MIG, steroids, and immunosuppressive agents. A small randomized placebocontrolled crossover trial showed short-term benefit in strength for LEMS patients treated with IVIG, presumably due to the lower levels of circulating antibodies [Level 1].¹⁵

BOTULISM

EPIDEMIOLOGY AND PATHOBIOLOGY

Botulism is a disease in which nearly total paralysis of nicotinic and muscarinic cholinergic transmission is caused by botulinum toxin, which acts on presynaptic mechanisms for release of ACh in response to nerve stimulation. The heavy chain of the toxin mediates binding of the toxin to surface receptors on motor nerve terminals. This allows the toxin molecule to be internalized via endocytosis, and the light chain is then translocated into the cytoplasm. The light chain functions as a zinc-dependent protease that cleaves different components of synaptic vesicles depending on the serotype of the toxin. Toxin types A and E cleave SNAP-25; type B, synaptotagmin, and both B, F, and G, synaptobrevin so that exocytosis of vesicles is blocked (see Fig. 89.1).

The toxins are produced by spores of clostridial agents. *Clostridium botulinum*, which may contaminate foods grown in soil, produces types A, B, F, and G or in fish, type E; *Clostridium butyricum* produces type E and *Clostridium barati* produces type F. Intoxication results if contaminated food is inadequately cooked and the spores are not destroyed or if fish are not eviscerated before drying or salt curing. Toxin can be produced in anaerobic wounds that have been contaminated by organisms and spores. Ingestion or inhalation of spores by infants may cause botulism when toxins type A or B are produced in the gastrointestinal tract during periods of constipation. An analogous syndrome occurs in adults with growth of *C. botulinum* in the intestine after surgery from gastric achlorhydria or from antibiotic therapy. The toxin does not cause cell death, although it disrupts exocytosis. The effects slowly disappear over several months.

CLINICAL FEATURES

Isolated cases in children and adolescents may be thought to be Guillain-Barré syndrome, MG, or even

diphtheria. Ptosis has responded to intravenous edrophonium chloride in a few patients, but response to anticholinesterase drugs is neither sufficiently extensive nor sufficiently prolonged to be therapeutic. Infants with botulism are usually younger than 6 months. They show generalized weakness, which is manifested by reduced spontaneous movements, lethargy, poor sucking, and drooling. Sucking and gag reflexes are decreased or absent. There is facial diplegia, ptosis, and ophthalmoparesis.

DIAGNOSIS

Diagnosis is made by the following characteristics: symmetry of signs, dry mouth or absence of saliva, pupillary paralysis, and the characteristic incremental response to repetitive nerve stimulation (see Fig. 89.3C). The Centers for Disease Control and Prevention (CDC; with a dedicated emergency 24-hour telephone number) or appropriate state laboratories should be notified so that the toxin can be identified in refrigerated samples of serum, stool, or residual food samples. In suspected infantile botulism, feces should be evaluated for the presence of *C. botulinum* as well as toxin.

Electrophysiologic evidence of severely disturbed neuromuscular transmission includes an abnormally small single-muscle action potential evoked in response to a supramaximal nerve stimulus. When the synapse is driven by repetitive stimulation at high rates (20 to 50 Hz), the evoked response is potentiated up to 400% (see Fig. 89.3C). In affected infants, muscle action potentials are unusually brief, of low amplitude, and overly abundant. This is presumably related to involvement of terminal nerve twigs in endings of many motor units. In patients treated for blepharospasm or other movement disorders by intramuscular injections of botulinum toxin, single-fiber EMG shows increased jitter in muscles remote from those injected, and the jitter is maximally increased at low firing rates. These abnormalities are not symptomatic but imply an effect of circulating toxin.

C. botulinum toxin is called the *most poisonous poison* (the lethal dose for a mouse is 10^{-12} g/kg body weight). If a patient survives and reaches a hospital, symptoms include dry, sore mouth and throat; blurred vision; diplopia; nausea; and vomiting. Signs include hypohidrosis; total external ophthalmoplegia; and symmetric descending facial, oropharyngeal, limb, and respiratory paralysis. Pupillary paralysis, however, is not invariable. Not all patients are equally affected, suggesting variable toxin intake or variable individual responses. When cases occur in clusters, the diagnosis is usually suspected immediately.

TREATMENT

Patients should be treated in intensive care facilities for respiratory care. Specific therapy includes antitoxin (a horse serum product that may cause serum sickness or anaphylaxis), available from the CDC, and guanidine hydrochloride, which promotes release of transmitter from residual spared nerve endings but may depress bone marrow. Botulinum immune globulin (BIG) is given in cases of infant botulism to reduce time on ventilator as well as time in the hospital.

ANTIBIOTIC-INDUCED DISORDERS OF THE NEUROMUSCULAR JUNCTION

Aminoglycoside antibiotics (neomycin sulfate, streptomycin sulfate, kanamycin sulfate, gentamicin, and amikacin) and polypeptide antibiotics (colistin sulfate and polymyxin B sulfate)

P.796

may cause symptomatic block in neuromuscular transmission in patients without any identified neuromuscular disease. Antibiotics occasionally aggravate MG. The problem surfaces when blood levels are excessively high, which usually occurs in patients with renal insufficiency, but levels may be within the therapeutic range. Studies

of bath-applied streptomycin in neuromuscular preparations disclosed inadequate release of ACh; the effect was antagonized by an excess of calcium ion. In addition, the sensitivity of the postjunctional membrane to ACh was reduced. Different compounds varied in relative effects on presynaptic and postsynaptic events. Neomycin and colistin produced the most severe derangements. The effects of kanamycin, gentamicin sulfate, streptomycin, tobramycin sulfate, and amikacin sulfate were moderate; tetracycline, erythromycin, vancomycin hydrochloride, penicillin G, and clindamycin had negligible effects. Patients who fail to regain normal ventilatory effort after anesthesia or who show delayed depression of respiration after extubation and are receiving one of the more potent agents should receive ventilatory support until the agent can be discontinued or another antibiotic substituted.

Inflammatory Myopathies

Rebecca Traub

Christina M. Ulane

Kurenai Tanji

INTRODUCTION

Myopathies, or disorders of skeletal muscle, are due to a variety of hereditary and acquired causes. Myopathies with genetic underpinnings are discussed in Chapters 93 and 95 and throughout Section 19. Acquired myopathies due to systemic disorders and toxins is the subject of Chapter 92. This chapter focuses on acquired myopathies due to inflammation. The focus is on prototypical, noninfectious immune-mediated inflammatory myopathies: dermatomyositis, polymyositis, inclusion body myositis, and necrotizing myopathy. Distinguishing these disorders from hereditary or toxic myopathies is essential for appropriate management of patients with muscle diseases which may have similar clinical presentations.

DERMATOMYOSITIS

EPIDEMIOLOGY

Dermatomyositis (DM) is rare and exact epidemiologic data is lacking. A recent systematic review and meta-analysis estimates an incidence of approximately 7.98 cases per million per year and a prevalence of 14 per 100,000 (range 2.4 to 33.8 per 100,000) for all inflammatory myopathies.

DM occurs in all decades of life, with peaks of incidence before puberty and at about age 40 years. In young adults, women are more likely to be affected. Familial cases are rare. Adult cases are associated with an increased risk of malignant neoplasms; most often ovarian, lung, or breast cancer, although others such as nasopharyngeal carcinoma have been reported. Most studies report 15% to 25% of adult DM is associated with malignancy.

Juvenile DM is extremely rare, with estimated incidence of 2 to 5 per 1 million children per year younger than 16 years of age. It is much more common in girls than boys (5:1) and essentially never associated with malignancy.

PATHOBIOLOGY

DM is thought to be an autoimmune disease with vasculopathy of muscle and skin. The antigenic target appears to be the endothelium of intramuscular microvessels, activating complement pathways to cause vascular injury. The loss of capillaries is thought to cause muscle ischemia resulting in myofiber injury and loss. Lymphocytic infiltrates are composed of both B and T cells, as contrasted to the T-cell-predominant inflammatory process of polymyositis and inclusion body myositis.

CLINICAL MANIFESTATIONS

The typical clinical presentation of DM is a combination of myopathy with characteristic skin findings. The rash may precede weakness by several weeks, but weakness alone is almost never the first symptom. Sometimes, the rash is so typical that the diagnosis can be made even without evidence of myopathy (amyopathic DM). In other cases, weakness may not be evident but there is electrophysiologic, pathologic, or serum creatine kinase (CK) evidence of myopathy.

Weakness in DM primarily affects the proximal muscles in the arms and legs and may be accompanied by discomfort (myalgias) and tenderness. Patients often describe difficulty going up stairs, standing from a seated

position, and lifting their arms above the head. Cranial muscles may be involved, causing facial weakness, dysphagia, and esophageal involvement. Neck weakness may occur, causing head drop. Sensation is preserved and reflexes are lost only when the myopathy is severe.

The typical rash is on the face, often on the upper eyelids as a purplish discoloration with edema (heliotrope rash). An erythematous macular rash may be found on the face, neck and chest (V-sign), and upper back (shawl sign). The initial redness may be replaced later by brownish pigmentation. Gottron sign is denoted by red-purple scaly macules on the extensor surfaces of finger joints. Dusky discoloration of the knuckles has been called *mechanic's hands* and is associated with the antisynthetase syndrome of arthritis, Raynaud phenomenon, and interstitial lung disease.

Subcutaneous calcifications can occur, more often in chronic cases and in pediatric DM. These calcifications may erode through the skin and cause ulceration and secondary infection.

Interstitial lung disease may accompany DM and is more common in the setting of anti-Jo-1 antibodies or antisynthetase syndrome, and patients should be questioned about respiratory symptoms and referred for pulmonary evaluation when appropriate. Cardiac involvement can occur, so clinical history should include questions of chest pain, palpitations, and syncope, and cardiac screening is advised.

Juvenile DM presents with a similar rash and proximal weakness.

DIAGNOSIS

DM is a clinical diagnosis (Table 90.1) aided by muscle biopsy (see the “Muscle Pathology” section later in this chapter). There should be elevations in muscle enzymes, including CK and aldolase. Other lab testing should include antinuclear antibodies (ANA), antibodies for other nuclear antigens, and myositis-specific antibodies (Table 90.2). Anti-Jo-1, which is the most common antisynthetase antibody, is associated with interstitial lung disease, arthritis, and Raynaud phenomenon. Nonsynthetase antibodies to Mi-2 are associated with a more acute onset and better response to therapy and prognosis. The presence of anti-Ro, anti-La, anti-Sm, RNP, anti-PM/Scl, and anti-Ku antibodies, among others, may suggest an overlap syndrome of a systemic rheumatologic disorder with associated myopathy.

Electrodiagnostic testing typically demonstrates normal nerve conduction studies with myopathic findings on electromyogram (EMG) with fibrillations, positive sharp waves, complex repetitive discharges, and sometimes myotonia, suggesting an inflammatory process. Magnetic resonance imaging (MRI) of the muscles can be used to look for evidence of inflammation and direct a target for muscle biopsy.

P.799

TABLE 90.1 Bohan and Peter Criteria for Myositis

Criterion	Description
Symmetric proximal weakness (over weeks to months)	Neck flexors, limb-girdle musculature
Consistent muscle biopsy findings	Necrosis, regeneration, phagocytosis, atrophy, mononuclear cell infiltrates
Elevated muscle	Creatine kinase, aldolase, transaminases, lactate dehydrogenase

enzymes

Electromyographic evidence for myopathy	Muscle fiber irritability (positive sharp waves, fibrillations), short duration, small amplitude, polyphasic motor unit potentials, with spontaneous bizarre high-frequency discharges
---	--

Characteristic skin rash	Gottron sign, Gottron papules, heliotrope
--------------------------	---

Definite PM: four criteria. Definite DM: three or four criteria plus rash. Possible PM: two criteria. Possible DM: one criterion plus rash.

PM, polymyositis; DM, dermatomyositis.

The differential diagnosis for DM includes the other inflammatory myopathies, hereditary muscular dystrophies, and toxic myopathies. Clinical features, electrodiagnostic findings, muscle pathology, and genetic testing can help distinguish these entities (Tables 90.3 and 90.4).

Once the diagnosis of DM is suspected, testing should include evaluation for underlying malignancy and associated pulmonary fibrosis. Computed tomography (CT) of the chest, abdomen, and pelvis is usually sufficient, with the addition of pelvic ultrasound in woman, although positron emission tomography (PET) may be indicated in some cases.

Cancer screening is recommended in all patients diagnosed with DM, including routine mammography and colonoscopy. CT of the chest, abdomen, and pelvis, and sometimes PET scan are indicated depending on the clinical scenario.

TREATMENT

The initial treatment for both DM and polymyositis is prednisone, typically starting with high dose (60 mg daily or higher) and then tapering slowly over months in conjunction with the addition of steroid-sparing therapies.

The usual first-line steroid-sparing agent used in DM and polymyositis is azathioprine [Level 1].^{1,2} Azathioprine is started at a low dose (50 mg daily) and slowly increased (goal of 2 to 3 mg/kg/day), with monitoring of cell counts and hepatic function. Methotrexate is another first-line alternative, given orally (start 7.5 mg/wk, titrate up by 2.5 mg weekly to goal of 10 to 20 mg weekly; given with folic acid 1 mg daily) with close monitoring of cell counts, hepatic function, and renal function. In patients with myositis refractory to these agents or with intolerable side effects, second-line options include rituximab (1,000 mg IV on days 1 and 15 may be repeated every 24 weeks) and intravenous immunoglobulin (IVIg) (doses vary, typically 1 to 2 g/kg IV every 2 to 4 weeks). Rituximab, a monoclonal anti-CD20 antibody, when studied for treatment of DM and polymyositis in a randomized controlled trial, failed to meet the primary outcome measure, but clinical improvement and a significant reduction in steroid dose was seen in all patients receiving the treatment [Level 1].³ A randomized controlled trial of IVIg in treatment-resistant cases of DM showed it to be effective in 9 of 12 cases [Level 1].⁴ The American Academy of Neurology 2012 guidelines recommend IVIg as a possibly effective therapy for refractory DM. Other medications occasionally used for refractory cases include cyclosporine (starting 2.5 mg/kg daily divided b.i.d.), tacrolimus (0.075 mg/kg/day divided b.i.d.), mycophenolate mofetil (starting 500 to 1,000 mg daily), and cyclophosphamide (doses starting at 300

mg/m² every 4 weeks). Many of these second- and third-line immunosuppressive medications have significant toxicities and side effects and should be prescribed by specialists familiar with their use.

TABLE 90.2 Myositis-Specific Antibodies

Antibody	Clinical Features
Antisynthetase Antibodies	
Anti-Jo-1 Anti-PL-7 Anti-PL-12 Anti-EJ Anti-OJ Anti-KS Anti-Zo Anti-Ha	Seen in polymyositis, dermatomyositis, and interstitial lung disease
Dermatomyositis-Specific Antibodies	
Anti-Mi-2	Treatment responsive
Anti-MDA5 (CADM-140)	Minimal myopathy; ILD
Anti-155/140	Cancer associated
Anti-140	Juvenile dermatomyositis, calcinosis
Anti-SAE	Amyopathic DM
Antibodies in Immune-mediated Necrotizing Myopathy	
Anti-SRP	Severe, acute presentation, resistant to treatment
Anti-HMGCR	Related to statin use

ILD, interstitial lung disease; DM, dermatomyositis.

Adapted from Albayda J, Mammen AL. Is statin-induced myositis part of the polymyositis disease spectrum? *Curr Rheumatol Rep.* 2014;16:433.

Treatment must include management of associated systemic manifestations, with close coordination of rheumatology, neurology, pulmonology, cardiology, and oncology when appropriate.

Physical therapy, occupational therapy, and low-intensity exercise are generally recommended for all patients with inflammatory myopathies to prevent deconditioning, help with gait training, and improve muscle

strength.

Treatment of juvenile DM is similar and high-dose daily oral prednisone or pulsed intravenous methylprednisolone is considered the gold standard and must be initiated promptly to prevent significant morbidity and mortality. Other steroid-sparing immunosuppressives in those who do not respond to or cannot tolerate steroids including methotrexate and cyclosporine may be used.

TABLE 90.3 Key Features of Inflammatory and Necrotizing Autoimmune Myopathies

	Dermatomyositis	Polymyositis	Inclusion Body Myositis	Necrotizing Autoimmune Myopathy
Autoantibodies	Antisynthetase antibodies (anti-Jo-1 and others) Dermatomyositis-specific antibodies (anti-Mi-2 and others)	Antisynthetase antibodies (anti-Jo-1 and others) Antibodies of systemic rheumatologic disease	Possibly anti-cytosolic 5'-nucleotidase 1A (cN1A)	Anti-SRP Anti-HMGCR
Muscle enzymes	Up to 50× ULN	Up to 50× ULN	Up to 15× ULN	Often >10× ULN
Associated disorders	Interstitial lung disease (antisynthetase) Malignancy (ovarian, lung, others)	Interstitial lung disease (antisynthetase) Systemic rheumatologic disorders	None	HMGCR— statin use
Treatment (see dermatomyositis treatment for typical doses)	Prednisone Azathioprine Methotrexate Rituximab IVIG Others	Prednisone Azathioprine Methotrexate Rituximab IVIG Others	None	Prednisone Rituximab

SRP, signal recognition particle; HMGCR, 3-hydroxy-3-methylglutaryl-coenzyme A reductase; ULN, upper limit of normal; IVIG, intravenous immunoglobulin.

POLYMYOSITIS

Polymyositis (PM), as a clinical syndrome of myopathic weakness, is similar in presentation and treatment to DM, absent the typical dermatologic findings of the latter. Pathologically, however, it is a distinct entity and associates

more closely with systemic autoimmune disorders. Although treated similarly with regard to immunosuppression, distinguishing PM and DM is important to establish risk of underlying malignancy or rheumatologic disease (see [Tables 90.3](#) and [90.4](#)).

EPIDEMIOLOGY

Idiopathic inflammatory myopathies as a whole are reported with a prevalence of approximately 14 in 100,000. The percentage of inflammatory myopathies identified as PM vary widely from 2% to over 50% in different series.

TABLE 90.4 Features Differentiating Dermatomyositis from Polymyositis

Dermatomyositis	Polymyositis
Typical dermatologic manifestations	No rash unless lupus associated
May be associated with malignancy	Not typically associated with malignancy
Not generally associated with systemic rheumatologic disease, except sometimes scleroderma	Often associated with a systemic rheumatologic disease, including lupus, systemic sclerosis, vasculitis
Childhood form exists	Adult disease
Muscle biopsy findings (perimysial and perivascular inflammation)	Muscle biopsy findings (endomysial inflammation)

PATHOBIOLOGY

PM is considered an autoimmune disease of disordered cellular immunity (in contrast to the presumed humoral abnormalities of DM). The antigenic target is not known, however, and the nature of the immunologic aberration is not known. The association with collagen-vascular disease increases the likelihood of autoimmune disorder. Although there is some increased risk of malignancy in association with PM, the association is not as high as that seen in DM.

CLINICAL MANIFESTATIONS

The symptoms of PM are those of a myopathy that primarily affects proximal limb muscles, similar in distribution to DM: difficulty climbing stairs or rising from low seats, lifting packages or dishes, or working with the arms overhead. Weakness of neck muscles may result in head drop. Typically, cranial muscles are spared, although dysphagia can occur when the disease is severe. Respiratory muscles are only rarely affected. Pain, or myalgias, may be present, but sensory symptoms are otherwise absent.

Symptoms of systemic disease may occur in the setting of PM related to a systemic rheumatologic disorder, including arthralgia or Raynaud symptoms. The typical rash of DM is absent, but there may be a rash of lupus in association with PM.

Interstitial lung disease can occur in PM but is more commonly associated with DM and anti-Jo-1 antibodies.

There is a mild increase in cancer risk in PM compared to the general population, but the association is not

nearly as strong as that seen in DM.

Cardiac involvement can occur with PM with myocarditis, arrhythmia, and rarely, congestive heart failure. Cardiology evaluation in all patients with inflammatory myopathy is advised.

DIAGNOSIS

The diagnosis of PM is made in the appropriate clinical setting with a combination of electrodiagnostic and muscle biopsy findings

P.801

(see “[Muscle Pathology](#)” section for the latter). The differential diagnosis includes other inflammatory myopathies, toxic myopathies, and hereditary muscle diseases ([Table 90.5](#)). Motor neuron disease (amyotrophic lateral sclerosis[ALS]) may be included in the differential diagnosis because of modestly elevated CK levels, although the clinical and electrodiagnostic findings are distinctive in ALS.

TABLE 90.5 Differential Diagnosis of Polymyositis

Mimic	Differentiating Characteristics
Dermatomyositis	Associated rash, specific pathologic findings on muscle biopsy, myositis-specific antibodies
Necrotizing myopathy	Specific pathologic findings on muscle biopsy, drug/statin exposure, more resistant to immunosuppressant therapy
Inclusion body myositis	Slower progression, older age of onset, distribution of muscle weakness, specific pathologic findings on muscle biopsy, lack of response to immunosuppressants
Overlap syndrome	Associated rheumatologic diagnosis (e.g., lupus, rheumatoid arthritis)
Muscular dystrophy	Age of onset, slower progression, family history, specific pathologic findings on muscle biopsy, genetic testing, lack of response to immunosuppressants
Metabolic myopathy	Age of onset, slower progression, family history, pathology, genetic testing, lack of response to immunosuppressants
Fibromyalgia	Prominent pain, no weakness, normal muscle biopsy
Polymyalgia rheumatica	High ESR/CRP, normal CK, normal EMG

ESR, erythrocyte sedimentation rate; CRP, C-reactive protein; CK, creatine kinase; EMG, electromyogram.

The electrodiagnostic findings of PM are indistinguishable from those in DM. Nerve conduction studies are

normal except in the case of severe myopathy, in which case motor CMAP amplitudes may be reduced. Needle EMG shows fibrillations, complex repetitive discharges, and other “inflammatory” findings in combination with myopathic motor unit potentials, which are low amplitude, short duration, polyphasic, and with early recruitment.

Lab testing will demonstrate elevations in serum CK and aldolase as markers of muscle inflammation. Antibody testing in PM may be suggestive of an underlying rheumatologic disorder, including positive ANA or scleroderma antibodies. SRP antibodies have been reported in PM but are more associated with necrotizing myopathy. Although myositis-specific antibodies (see [Table 90.2](#)) are less common in PM than DM, it is recommended that they be checked in all patients with inflammatory myopathies, as their presence may suggest association with interstitial lung disease or help guide immunotherapy.

As in DM, muscle MRI is sometimes useful in targeting muscle biopsy.

TREATMENT

Treatment of PM is similar to DM, and many clinical trials include both disorders in their recruitment. First-line and initial treatment is with high-dose steroids, typically prednisone, with the same consideration for steroid sparing and options for refractory disease as elaborated in the dermatomyositis treatment section earlier.

INCLUSION BODY MYOSITIS

Inclusion body myositis (IBM) is considered an inflammatory myopathy distinct in clinical features and treatment response to DM and PM. In addition, IBM exhibits unique pathologic features, suggesting that IBM may have dual aspects of inflammatory and degenerative muscle diseases.

EPIDEMIOLOGY

The prevalence of IBM varies from 4.9 per million in the Netherlands to 71 per million in Olmstead County, Minnesota. Both prevalence and incidence increase if restricted to age older than 50 years. There is a 2:1 to 3:1 male predominance, unlike most autoimmune disorders with female predominance. IBM is rare in African-Americans and nonwhites. Up to 15% will have an associated autoimmune disease such as lupus, Sjögren syndrome, thrombocytopenia, or sarcoidosis. There are inherited forms, the most common called *hereditary inclusion body myositis* (hIBM) or IBM2, which is found in 1 in 1,500 persons of Iranian Jewish descent.

PATHOBIOLOGY

The cause of IBM is unknown, but it is thought to be both autoimmune and neurodegenerative. The inflammatory response in the muscle and acquired nature suggest an immune etiology (see “[Muscle Pathology](#)” section). A novel autoantibody has been identified from sera of 50% of patients with IBM that recognized a 43-kDa muscle protein that was not found in other diseases or healthy controls. The protein was identified as the cytosolic 59-nucleotidase 1A (cN1A), and moderate reactivity is 70% sensitive and 92% specific.

Poor responsiveness to immunotherapy may suggest a degenerative component of the disease. Histologically, protein aggregates are found in the vacuolated muscle fibers of IBM that are not typically seen in other inflammatory myopathies. These aggregates, which are thought to be accumulation of misfolded proteins, share similar components to those found in other neurodegenerative diseases.

There are a few genetic mutations causing hIBM. hIBM/IBM2 is an autosomal recessive disorder due to specific mutation in the *GNE* gene, which encodes a dual-function enzyme (epimerase and kinase) which is important in

the synthesis of the abundant Neu5Ac sugar moiety. IBM3 is an autosomal dominant disorder related to mutations in the gene encoding myosin heavy chain IIa (MYHC2A), with the initial reports described in a Swedish family. Inclusion body myopathy with early-onset Paget disease with or without frontotemporal dementia 1 (IBMPFD1) is an autosomal dominant disease caused by mutation in the VCP gene with incomplete penetrance for the clinical phenotypes described in its name. In 30% of patients with IBMPFD, the isolated symptoms are neuromuscular.

CLINICAL MANIFESTATIONS

The clinical symptoms of IBM, in its classic form, are distinct from other inflammatory myopathies in the distribution and time course of weakness. The onset of weakness is typically slow, with worsening over the course of years, as compared to PM and DM, which typically have a more subacute presentation. Many patients will have symptoms for years before diagnosis is established. Muscles

P.802

first affected are usually proximal legs, with predilection for the quadriceps muscle group, as opposed to other myopathies affecting proximal muscles, which typically have more hip flexor involvement. In the arms, distal muscles tend to be first and more severely affected, with prominent involvement of the finger and wrist flexors in the forearm. Atrophy is often greater than is seen in other inflammatory myopathies and is usually symmetric. Pronounced atrophy, and weakness which can be asymmetric distinguishes IBM from PM and DM, and is cause for diagnostic confusion with motor neuron disease. Muscle pain (myalgia) is present in approximately 40% of patients. Neck muscles are often involved and can lead to head drop. Dysphagia occurs in half or more of patients, making it a more common symptom in IBM than in other inflammatory myopathies and may be the initial symptom. Rarely, there is involvement of respiratory muscles. Prognosis is for slow progression over years, typically leading to use of wheelchair. Death may occur as complication of respiratory infection or aspiration, but this may be 10 or more years after symptoms begin.

DIAGNOSIS

The diagnosis of IBM is often suspected based on history and physical exam findings, supported by electrodiagnostic studies, but relying on muscle pathology for confirmation (see “Muscle Pathology” section). Lab testing shows mild elevations in CK, up to 15 times the upper limit of normal but may be normal. There should be no elevation in erythrocyte sedimentation rate (ESR) or other inflammatory markers, although there are reports of an association with ANA and Sjögren antibodies. Testing should include antibodies for systemic rheumatologic disorders and myositis-specific antibodies to look for PM and DM, which are included in the differential diagnosis of IBM (Table 90.6).

Electrodiagnostic studies show primarily a myopathic pattern with inflammatory features, similar to that seen in DM and PM. There are fibrillations and abnormal spontaneous activity consistent with an inflammatory process, with short duration and low amplitude motor unit potentials and early recruitment. In some patients with IBM, however, there is a mixed electrodiagnostic picture, with both myopathic and neurogenic features. These mixed findings on EMG in combination with normal sensory responses can make the diagnosis more challenging and occasionally leads to the misdiagnosis of motor neuron disease in patients with IBM.

TABLE 90.6 Differential Diagnosis for Inclusion Body Myositis

Dermatomyositis

Associated skin findings
Muscle pathology

Polymyositis	Associated autoantibodies Muscle pathology
Hereditary distal myopathies	Family history Early age of onset Genetic testing
Drug-induced (toxic) myopathies	History of toxic or medication exposure
Motor neuron disease	Upper motor neuron findings Electrodiagnostic testing Muscle biopsy—neurogenic changes
Myasthenia gravis	Ocular and prominent bulbar symptoms Acetylcholine receptor or musclespecific kinase (MuSK) antibodies Abnormal repetitive stimulation Response to immunotherapy

Muscle MRI is increasingly being used for diagnosis in inflammatory myopathies, and in IBM, it will show atrophy and/or fatty replacement of muscle with predominant involvement of the anterior thigh muscles.

There have been a number of diagnostic criteria used to establish the definite or probable diagnosis of IBM for clinical and research use. The most recent of these is the criteria defined in the ENMC workshop in 2011 ([Table 90.7](#)).

TREATMENT

IBM is notorious for being refractory to the treatments that are effective for other inflammatory myopathies. In some patients, there is an initial response to corticosteroids; however, all will eventually become refractory. Other immunosuppressive agents have not proven to alter the natural course of IBM. A randomized controlled trial of methotrexate showed improved CK levels but no effect on strength [**Level 1**].⁵ Randomized controlled trials of IVIG with and without steroids also have not shown significant benefits for patients with IBM [**Level 1**].^{6,7} Two randomized controlled pilot studies by the Muscle Study Group did not show any benefit for IBM patients treated with interferon [**Level 1**].⁸ Despite negative trials, some neuromuscular specialists will treat patients with IBM with prednisone, steroid-sparing agents, such as methotrexate or azathioprine, or IVIG on a trial basis based on the observation that a small subset of patients appear to improve or stabilize with regard to muscle strength with treatment, but whether to offer immunotherapy is a controversial topic.

Given the limited, if any, benefit with immunomodulating therapy for IBM, treatment should focus on symptomatic and supportive therapies to improve quality of life. Low-intensity physical therapy can help with strength and mobility. Falls prevention and gait training are important for preventing complications of worsening weakness. Speech therapy can help in managing dysphagia and preventing aspiration.

NECROTIZING AUTOIMMUNE MYOPATHY

Necrotizing autoimmune myopathy (NAM) or immune-mediated necrotizing myopathy (IMNM) is a distinct type of immunemediated myopathy that show on biopsy various degree of myofiber necrosis associated with little or no inflammatory response except for myophagocytosis. NAM may occur in isolation (with or without anti-signal recognition particle [SRP] antibodies) or in association with statin use (with anti-3-hydroxy-3-methylglutaryl-coenzyme A reductase [HMGCR] antibodies) with certain connective tissue disorders and possibly with malignancies. Originally discovered as novel myositis antibodies, the target was identified as HMGCR.

EPIDEMIOLOGY

Cases of NAM in the context of statin use were reported initially in the 1980s, and subsequent case series describe myopathy that progress after statin cessation, with features on biopsy of NAM and response to immunosuppressant medication. The exact incidence of NAM is unclear. However, 21% of NAM is associated with systemic lupus erythematosus (SLE), and in patients with anti-SRP antibodies, most are female, with an average age of onset of 45 years, 65% have

P.803

comorbid hypertension, 23% have diabetes mellitus, and up to 37% will have interstitial lung disease (ILD). One-third of NAM cases do not have any myositis-specific antibodies, and these are most often associated with SLE and systemic scleroderma.

TABLE 90.7 Diagnostic Criteria for Inclusion Body Myositis from the European Neuromuscular Center Workshop, 2011

Classification	Clinical Features	Pathologic Features
Clinicopathologically defined IBM	Duration over 12 mo Age at onset older than 45 yr Quadriceps weakness greater than hip flexor weakness and/or finger flexor weakness greater than shoulder abductor weakness Serum CK not greater than 15× the upper limit of normal	Endomysial inflammation and rimmed vacuoles and protein accumulation (amyloid or other proteins) Or Filaments 15-18 nm
Clinically defined IBM		One or more of the following: Endomysial inflammation Or increased MHC-1 staining Or rimmed vacuoles Or protein accumulation (amyloid Or other proteins) Or filaments 15-18 nm
Probable IBM		One or more of the following: Endomysial exudate Or increased MHC-1 staining Or rimmed vacuoles Or protein accumulation (amyloid Or other proteins) Or filaments 15-18 nm

IBM, inclusion body myositis; CK, creatine kinase. Adapted from Barohn R, Dimachkie M. Inclusion body myositis. *Neurol Clin.* 2014;32:629-646; Machado P, Brady S, Hanna MG. Update in inclusion body myositis. *Curr Opin Rheumatol.* 2013;25(6):763-771.

PATHOBIOLOGY

NAM is characterized by muscle biopsies showing necrosis and degeneration but without the typical inflammatory cell infiltrate seen in DM and PM, despite its autoimmune physiology.

In the case of the statins, there is increased expression of HMGCR on regenerating muscle fibers, which likely triggers an immune response and the subsequent development of anti-HMGCR antibodies. This upregulation persists even after statins have been discontinued, presumably why the symptoms continue and even progress after the statin is discontinued. Whether these antibodies are pathogenic or an associated finding is unknown, especially as the target is an intracellular protein. HMGCR is the rate-limiting enzyme in cholesterol synthesis and is the target of statin medications.

Beginning in 1986, antibodies recognizing the SRP on the endoplasmic reticulum membrane were found in association with myopathy. It is also unclear if this antibody is pathogenic, as it too is intracellular. However, titers of anti-SRP antibodies and serum CK are found to correlate with one another during treatment.

CLINICAL MANIFESTATIONS

Similar to PM, patients present with symmetric proximal weakness over the course of weeks to months. However, in patients with anti-SRP antibodies, the onset may be acute and severe, and 66% to 80% of this group will have myalgias. Anti-SRP myopathy patients can have dyspnea (50%) which may be due to either neuromuscular weakness or ILD (21% to 37%). Symptoms in statin-related cases can occur at any time in treatment (2 months to 3 years) but on average, after 3 years of treatment. Symptoms continue or even worsen with cessation of statin and myalgias are a prominent feature (75%). Rarely, patients can present with HMGCR-positive myopathy in the absence of statin exposure.

DIAGNOSIS

As in other inflammatory myopathies, NAM is diagnosed with a combination of clinical, lab, and electrodiagnostic features but often relying on muscle pathology to confirm diagnosis (see [“Muscle Pathology”](#) section).

Serum CK levels are often elevated, usually more than 5,000 U/mL, as in other inflammatory myopathies. Serum can be tested for the presence of anti-SRP and anti-HMGCR antibodies which are extremely helpful in each case. Patients with anti-SRP myopathy typically do not have any other myositis-specific antibodies. Patients with non-NAM statin-induced myotoxicity do not have anti-HMGCR antibodies. Anti-SRP antibodies are found in approximately 16% of NAM.

Electrodiagnostic testing shows findings similar to that seen in PM and DM with normal nerve conduction studies, unless weakness is severe, in which case CMAP amplitudes may be reduced. There is abnormal spontaneous activity, with fibrillations and other irritable features. Motor unit potentials are myopathic, with short duration and low amplitude, and recruitment is early.

Muscle MRI shows findings similar to other inflammatory myopathies, with muscle edema, atrophy, and fatty replacement. MRI is sometimes helpful in targeting muscle biopsy.

TREATMENT

Treatment of NAM relies on both discontinuing any toxic trigger for the disease process (i.e., stopping statins) when implicated.

P.804

Although typical statin-induced myopathy will improve after discontinuation of the medication, the course of NAM is of worsening weakness despite stopping the triggering medication. Immunosuppressive treatment is necessary to address the underlying autoimmune pathophysiology in NAM. Most patients respond to steroids. Other steroid-sparing agents which have been used with success include methotrexate, azathioprine, mycophenolate mofetil, rituximab, and intravenous immunoglobulin.

MUSCLE PATHOLOGY

DERMATOMYOSITIS

Muscle pathology in DM shows perimysial, and in particular perivascular, inflammation which is often composed of a mixed population of T lymphocytes (especially helper T cells) and B lymphocytes (Fig. 90.1). Plasmacytoid dendritic cells are also present. The extent and the degree of inflammation, however, greatly vary from case to case. Except for amyopathic cases, necrotic/degenerative or regenerating fibers are present across all sections or in a perifascicular pattern (see Fig. 90.1). The endomysial capillary density may be significantly reduced. Immune complexes containing IgG, IgM, and complement, especially membrane attack complex (MAC), are found deposited in the microvessels, although it remains unclear how the complement pathway is activated. Putative antigen(s) are expressed by the endothelial cells of the microvasculature. Immunohistochemical staining of the fibers, especially in the perifascicular areas, often show the expression of MHC class I and variable expression of MHC class II. Ultrastructurally, endothelial cells of affected microvessels may show necrosis, swelling, or reactive/degenerative changes. Reactive/degenerative endothelial cells may exhibit tubuloreticular structures that appear closely related to endoplasmic reticulum and are thought to reflect type 1 interferon (INF) exposure.

POLYMYOSITIS AND INCLUSION BODY MYOSITIS

PM and IBM share certain pathologic features including muscle fiber necrosis and regeneration and lymphocyte infiltration, mainly in the endomysium (Fig. 90.2A). The infiltrating inflammatory

P.805

cells are T cells (with a large proportion of cytotoxic T cells), macrophages/histiocytes, and myeloid dendritic cells. Occasionally, cytotoxic T cells invading into non-necrotic-appearing sarcoplasm can be captured on muscle biopsy by using immunohistochemical staining for the CD8 molecule (Fig. 90.2B). Typically, untreated cases of PM and IBM show immunohistochemical expression of MHC class I expression along the surface of myofibers; there is often association with MHC class II expression. In general, muscle biopsy in IBM will display greater chronic myopathic changes than PM; other features of IBM may include rimmed vacuoles (Fig. 90.3) and mitochondrial abnormalities. Congophilic, intracytoplasmic amyloid associated with vacuoles, considered to be a hallmark of IBM, can be visualized in frozen sections stained with Congo red dye under rhodamine optics using a fluorescence microscope. The recognition of insoluble protein aggregates associated with rimmed vacuoles prompted immunohistochemical evaluation for and identified the presence of several proteins including phosphorylated tau, β -amyloid, and TAR DNA binding protein-43 (TDP43). The similarity of these protein aggregates to those found in other neurodegenerative disorders of the central nervous system and the typically poor response of IBM to immunotherapy supports a possible neurodegenerative pathobiology.

FIGURE 90.4 Muscle pathology in necrotizing autoimmune myopathy. Necrotic myofibers with minimal inflammation (*arrows*). (Hematoxylin and eosin stain, ×200 magnification.)

IMMUNE-MEDIATED (AUTOIMMUNE) NECROTIZING MYOPATHY

Muscle biopsy in NAM shows scattered necrotic myofibers associated with phagocyte (macrophage) infiltration (Fig. 90.4). There is minimal or absent T-lymphocytic infiltration and inflammation. Microvascular deposition of MAC may be present, but unlike in DM, perivascular inflammation is scant or absent and there are no tubuloreticular aggregates in the endothelial cells of the microvasculature. MHC class I and II are reported to be variably upregulated in anti-SRP-associated NAM, paraneoplastic NAM, and statin-associated NAM. MHC class I upregulation is consistently seen in the originally reported cases of statin-associated NAM.

Critical Illness Myopathy and Neuropathy

Michio Hirano

Louis H. Weimer

INTRODUCTION

Although critically ill individuals in intensive care units are typically weak due to their severe medical illnesses, a subgroup of patients develops critical illness myopathy (CIM), critical illness polyneuropathy (CIP), or both. The first case of acute quadriplegic myopathy (AQM, later renamed CIM) was reported in 1977 by MacFarlane and Rosenthal in a 24-year-old woman who received high-dose corticosteroids for status asthmaticus. In 1984, Bolton and colleagues described five critically ill patients with sepsis and multiorgan failure who developed severe sensorimotor peripheral neuropathies. Since then, hundreds of patients with CIM and CIP have been reported.

EPIDEMIOLOGY

Although incidence rates of CIM and CIP vary in reported series based on patient populations and detection methods, the disorders appear frequently common in the intensive care unit (ICU) setting. In one report, about 25% of patients in the ICU developed weakness, whereas electrophysiologic studies have detected neuromuscular abnormalities in up to 84% of patients. Among patients with sepsis or systemic inflammatory response syndrome (SIRS), the incidence has been estimated to be 70% and virtually 100% in patients with septic shock or sepsis plus coma. In most case series, the incidence of CIM has been greater than CIP; however, some patients manifest both.

PATHOBIOLOGY

For CIM, corticosteroids, nondepolarizing neuromuscular blocking agents, or both are considered the prime inciting factors, but it has appeared in some individuals who received neither agent. Patients undergoing treatment for status asthmaticus, organ transplantation, and severe trauma seem to be particularly vulnerable. In contrast, for CIP, sepsis, SIRS, and multiorgan failure are risk factors. Other factors that may contribute to CIM and CIP include severity of the illness, duration of ICU stay, duration of organ dysfunction, renal failure, neurologic failure, hyperosmolarity, hyperglycemia, and vasopressor and catecholamine supportive treatment.

Pathophysiologic mechanisms responsible for these conditions are not fully understood. In patients with CIM, direct muscle stimulation has shown a loss of muscle fiber excitability, which has been attributed to voltage-gated sodium channel fast inactivation, based on animal models of steroid-treated denervated muscle as well as biopsied muscle. Enhanced expression of ubiquitin, lysosomal enzymes, and calcium-activated proteases (calpains) has been observed in muscle and could play a pathogenic role. These catabolic pathways may be activated in muscle by induction of transforming growth factor- β /mitogen activated protein kinase pathways. Immune activation by cytokines may also contribute to the myopathy.

Although direct evidence is lacking, CIP has been attributed to microcirculation defects including increased vessel permeability and vasodilation leading to the axonal degeneration. Peripheral nerve biopsies from CIP patients have revealed expression of E-selectin in the vascular endothelium of epineural and endoneurial vessels. Because E-selectin is not normally expressed in vascular endothelium, its presence may increase nerve microvasculature permeability, which would allow circulating neurotoxins to enter the endoneurium and promote endoneurial edema.

CLINICAL MANIFESTATIONS

In CIM, severe quadriplegia and muscle atrophy commence 4 to more than 100 days after initiation of intensive care therapy. The weakness may be primarily distal or proximal but is usually diffuse; many patients lose tendon reflexes. Ophthalmoparesis and facial muscle weakness are occasionally present. Persistent respiratory muscle weakness complicates weaning patients from mechanical ventilation. Patients often manifest diffuse muscle atrophy, which can be severe. Improvement is generally evident in 1 to several months in most individuals who survive their critical illness, but protracted recovery or persistent deficits are common.

CIP presents as acute distal limb weakness and sensory loss with diminished or absent tendon reflexes. Involvement of the phrenic and intercostal nerves causes respiratory muscle weakness that often requires prolonged mechanical ventilation therapy (Table 91.1).

DIAGNOSIS

Diagnosis of CIM and CIP is typically suspected when patients have unexplained severe limb weakness, inability to wean patients off mechanical ventilation, or both. Marked muscle atrophy is common in CIM, whereas areflexia and stocking-glove sensory loss (in alert patients) are characteristic of CIP. CIM and CIP must be distinguished from the persistent weakness that may follow administration of nondepolarizing blocking agents to a person with impaired hepatic metabolism, reduced renal excretion, or both.

In patients with CIM, laboratory studies have shown normal or elevated serum creatine kinase levels. Nerve conduction studies (NCS) demonstrate absent or low-amplitude compound motor action potentials with decreased duration. Sensory nerve action potentials are normal, reduced, or absent but frequently hampered by technical constraints in the ICU environment and by limb edema. Electromyography (EMG) variably shows signs of denervation from muscle necrosis and myogenic or normal motor unit action potentials; however, motor unit and recruitment analysis are frequently suboptimal owing to severe weakness, encephalopathy, sedation, or other confounding factors. Direct muscle stimulation has shown a loss of muscle fiber excitability.

Muscle biopsies demonstrate myopathic changes. Three distinct histologic features have been described in skeletal muscle biopsies;

P.808

the abnormalities may be present in isolation or in variable combinations. Muscle fiber atrophy, often more prominent in type 2 fibers, is routinely seen. In patients with markedly elevated creatine kinase levels, necrosis of muscle fibers has been observed. The most striking feature revealed by electron microscopy is loss of thick (myosin) filaments, corroborated by antimyosin-antibody stains and reduced myosin mRNA levels but is not seen in many cases.

TABLE 91.1 Major Characteristics of Critical Illness Myopathy and Critical Illness Polyneuropathy

	Critical Illness Myopathy (CIM)	Critical Illness Polyneuropathy (CIP)
Clinical features	Weakness, typically diffuse including respiratory muscles. Muscle atrophy is common.	Distal limb weakness and sensory loss with diminished or absent tendon reflexes. Respiratory muscle weakness is common.

Risk factors	Treatment with corticosteroid, nondepolarizing neuromuscular blocking agent, or both	Sepsis, systemic inflammatory response syndrome (SIRS), multiorgan failure
Nerve conduction study and electromyography abnormalities	Myogenic abnormalities	Neurogenic abnormalities with signs of acute denervation
Muscle biopsy findings	Myofiber atrophy predominantly affecting type 2 fibers. Loss of thick (myosin) filaments is characteristic but is not always seen.	Signs of acute denervation
Treatment	Reduce exposure to corticosteroids and nondepolarizing neuromuscular blocking agents.	Intensive insulin treatment to maintain normal blood glucose levels

In CIP, NCS typically show signs of axonopathy with decreased or absent sensory and compound motor action potentials with mildly reduced conduction velocities; these changes may appear as early as 72 hours after ICU admission and can precede clinical manifestations. Electrophysiologic studies of the peroneal nerve have been proposed as a rapid and sensitive diagnostic test for CIP. EMG shows fibrillations and positive sharp waves due to acute denervation, which can be difficult to distinguish from acute muscle necrosis from CIM.

Muscle biopsies in CIP can show signs of acute denervation. Nerve biopsies are generally not useful in CIP, which typically manifests nonspecific signs of axonal neuropathy; however, if other forms of peripheral neuropathy (e.g., vasculitis or chronic inflammatory demyelinating polyneuropathy) are suspected, then nerve biopsies may be indicated.

TREATMENT

Treatment of patients with CIM and CIP is primarily directed at the underlying acute medical condition(s). Supportive care, particularly mechanical ventilation, is important. Because corticosteroids and neuromuscular blocking agents appear to trigger CIM, reducing exposure to these agents is generally recommended.

Two randomized trials of ICU patients have demonstrated that intensive insulin treatment (IIT) aimed at maintaining normal glucose levels reduces the incidence of CIP by nearly half (relative risk 0.65, 95% confidence interval 0.55-0.77) as well as duration of mechanical ventilation and 180-day mortality compared to conventional insulin treatment [**Level 1**].^{1,2} Physical therapy to passively stretch muscles may reduce muscle atrophy and may increase functional independence.

OUTCOME

Both CIM and CIP cause prolonged and often severe disability. The weakness can persist for months to

years or even indefinitely. About 28% of patients with CIP, CIM, or both may not recover ability to ambulate independently or weak completely off ventilation. CIP is more likely to cause permanent disability than CIM. The majority of patients with CIM recover in 3 to 6 months.

Endocrine and Toxic Myopathies

Christina M. Ulane

INTRODUCTION

Muscle comprises a large proportion of all tissues in the body and the energy required for its function renders it susceptible to metabolic abnormalities from endocrine dysfunction and toxic effects of medications and environmental exposures. Muscle tissue is affected by the metabolic and trophic effects of various components of the endocrine system and by direct and indirect effects of toxins. This chapter highlights features of the most common endocrinopathies and toxins affecting muscle, concisely reviews the many others, and emphasizes the fundamental principles in diagnosis and treatment of these disorders.

ENDOCRINE MYOPATHIES

EPIDEMIOLOGY

Myopathy in endocrine disorders is rather common, but the earlier diagnosis and treatment of endocrinopathies has reduced the severity of myopathic symptoms. Thyroid disorders and corticosteroid abnormalities (most often from exogenous sources) are the most common endocrinopathies encountered and thus discussed in most detail. Exogenous corticosteroid administration at doses of 30 mg or more per day of prednisone confers the highest risk.

Historical studies suggest that up to 75% of patients with hyperthyroidism will experience myopathy, but current data regarding incidence of true myopathy in endocrinopathies is not available, likely a result of earlier diagnosis and treatment. Myopathy is also found in association with acromegaly, hypopituitarism, hyperparathyroidism, and hypoparathyroidism.

PATHOBIOLOGY

The exact basis of myopathy in endocrinopathy is unknown and may be multifactorial. Often, weakness and fatigue are out of proportion to muscle wasting, suggesting energy failure as a mechanism. Thyroxine has catabolic effects on muscle, may reduce efficiency of muscle contraction, alter membrane excitability, and lead to reduced potassium in muscle and serum, leading to weakness in hyperthyroidism. Hypothyroidism reduces glycogenolysis (animal studies indicate this occurs via reduced expression of β -adrenergic receptors on muscle cells), which may be responsible for cramps and fatigue. Hypothyroidism can also reduce mitochondrial oxidation, and studies in rats demonstrate changes in myosin from fast-twitch to slow-twitch muscle types. Thyroid-associated ophthalmopathy leads to edema in the extraocular muscles from both glycoprotein accumulation and inflammation. Corticosteroids cause muscle catabolism and stimulate protein degradation.

CLINICAL FEATURES

Myopathy from endocrine disorders causes nonspecific symptoms of myopathy. Proximal limb weakness, fatigue, and cramps are common. In some cases, myalgias are present. In steroid myopathy, symptoms may occur as early as after a few weeks of treatment. See [Table 92.1](#) for clinical features of thyroid-associated myopathies and [Table 92.2](#) for other endocrine-associated myopathies, including that due to exogenous steroid administration.

DIAGNOSIS

Other features related to specific endocrine disorders are usually apparent and suggest the diagnosis. However, if corticosteroids are

P.811

P.812

being used for the treatment of a disease that also causes weakness (such as polymyositis or myasthenia gravis), it can be challenging to determine whether progression of the underlying disorder or the corticosteroid treatment is the cause of weakness. Laboratory testing for serum levels of thyroid function, adrenocorticotrophic hormone, cortisol, metabolic panel, parathormone, and growth hormone can be diagnostic. Serum creatine kinase (CK) levels are helpful in many cases.

TABLE 92.1 Myopathies Associated with Thyroid Disorders

Disorder	Clinical	Diagnostics	Treatment
Hypothyroidism	<ul style="list-style-type: none"> • Muscle stiffness, pain, and cramps, especially with cold and exercise • Delayed relaxation (pseudo-myotonia) 	<ul style="list-style-type: none"> • CK elevated, up to 10× normal • EMG: myopathic, +/- fibrillations, positive sharp waves • Biopsy: normal or nonspecific changes 	<ul style="list-style-type: none"> • Thyroxine (T4) supplementation (start 25-50 µg daily, increase to 1.6 µg/kg/day, and monitor TSH)
Hyperthyroidism	<ul style="list-style-type: none"> • Proximal weakness, wasting (shoulder girdle, scapular winging) • May involve respiratory, bulbar, or distal muscles 	<ul style="list-style-type: none"> • CK is normal (except in thyroid storm) • EMG: myopathic in proximal muscles • Biopsy: nonspecific, type 1 and 2 fiber atrophy 	<ul style="list-style-type: none"> • Correction of thyroxine levels to normal (antithyroid medications, radioactive iodine, thyroidectomy) • Weakness may take months to resolve. • Propranolol (start 10 mg t.i.d. to q.i.d., may increase to 40 mg q.i.d.) may hasten recovery.
Thyrotoxic periodic	<ul style="list-style-type: none"> • Severe weakness lasting hours to 	<ul style="list-style-type: none"> • Potassium levels low 	<ul style="list-style-type: none"> • Correction of thyroid abnormality

paralysis	<p>days, precipitated by cold, exercise, or high carbohydrate intake</p> <ul style="list-style-type: none"> • More common in men from Japan and China 	<p>during attacks</p> <ul style="list-style-type: none"> • +/- low magnesium or phosphorus • Associated HLA haplotypes 	<ul style="list-style-type: none"> • Propranolol (start 10 mg t.i.d. to q.i.d., may increase to 40 mg q.i.d.) may prevent attacks.
Thyroid ophthalmopathy	<ul style="list-style-type: none"> • Exophthalmos, pain, diplopia • May have compressive optic neuropathy • Mostly occurs with hyperthyroidism (sometimes with hypothyroidism, euthyroidism) 	<ul style="list-style-type: none"> • Edema of extraocular muscles on MRI 	<ul style="list-style-type: none"> • Correction of thyroid abnormality • Guanethidine eye drops (β-adrenergic) • Local steroid injection • Systemic steroids (prednisone 30-100 mg PO daily for at least 4 wks followed by taper or methylprednisolone 500 mg IV for one dose followed by 250 mg IV weekly) • Selenium 100 mg b.i.d. for 6 mo

CK, creatine kinase; EMG, electromyography; TSH, thyroid-stimulating hormone; HLA, human leukocyte antigen; MRI, magnetic resonance imaging; PO, by mouth; IV, intravenous.

TABLE 92.2 Myopathies Associated with Other Endocrinopathies

Disorder	Clinical	Diagnostics	Treatment
Cushing disease/exogenous corticosteroid administration	<ul style="list-style-type: none"> • Painless proximal weakness (legs affected more than arms) • +/- muscle wasting • Fluorinated corticosteroids more likely to cause myopathy (triamcinolone, betamethasone, dexamethasone) 	<ul style="list-style-type: none"> • CK is normal. • EMG: may be normal or show myopathic features • Biopsy: type 2 fiber atrophy, increased glycogen 	<ul style="list-style-type: none"> • Treat underlying Cushing etiology, but recovery may be slow or incomplete • Reduce exogenous steroid dose to minimum possible • Alternate-day steroid dosing • Use of nonfluorinated corticosteroids • Use of steroid-sparing agents
Adrenal insufficiency	<ul style="list-style-type: none"> • General weakness • Fatigue, cramps 	<ul style="list-style-type: none"> • CK is normal. • EMG: normal 	<ul style="list-style-type: none"> • Glucocorticoid replacement.

		<ul style="list-style-type: none"> • Biopsy: nonspecific 	<p>Hydrocortisone 5 mg/m² total daily, given b.i.d. with 2/3 of dose in AM and 1/3 in PM.</p>
Acromegaly	<ul style="list-style-type: none"> • Slowly progressive proximal weakness and pain • Decreased exercise tolerance • Minimal muscle wasting 	<ul style="list-style-type: none"> • CK is normal or mildly elevated • EMG: +/- myopathy • Biopsy: hypertrophy or atrophy of type 1 and 2 fibers, excess lipofuscin, glycogen 	<p>Correction of excess GH:</p> <ul style="list-style-type: none"> • Bromocriptine: start 1.25-1.5 mg daily, increase to 20-30 mg daily • Pituitary adenoma resection • Irradiation

irritative myopathy, but may be normal. Muscle biopsy may be required to distinguish other underlying causes, but findings in endocrine myopathies are usually nonspecific. Please see [Tables 92.1](#) and [92.2](#) for laboratory, EMG, and muscle biopsy findings in various endocrine myopathies.

TREATMENT

Treatment is directed at correcting the underlying endocrine abnormality, through hormone replacement therapy or by reducing circulating hormone levels. In the case of hyperthyroid myopathy, propranolol may improve time to recovery through β -adrenergic blockade. If exogenous corticosteroids are the cause for myopathy, treatment of the disease for which the steroids are indicated must be balanced with reducing the contribution of steroids to the myopathy. Several strategies can be helpful, including alternate-day dosing and the use of steroid-sparing agents when possible (see [Tables 92.1](#) and [92.2](#)).

OUTCOME

Most persons with endocrinopathy causing myopathy will recover completely with correction of the underlying abnormality. Rarely, in Cushing disease, recovery may be incomplete.

TOXIC MYOPATHIES

EPIDEMIOLOGY

Toxic myopathies arise from environmental exposures and increasingly often from medications ([Table 92.3](#)). The large number of people prescribed statin medications makes this potentially myotoxic agent a commonly encountered clinical problem. Up to 20% of people taking statins will experience myalgias or cramps. Most of statin myotoxicity is mild and self-limited; however, severe toxic necrotizing myopathy can occur in rare cases. Myotoxicity from statin use is increased in those with obesity, preexisting hepatic disease, hypothyroidism, and advanced age. There is also a dose-dependent myotoxic effect: 1.6% on 80 mg/day versus 0.1% on 20 mg/day of simvastatin. Certain statins pose greater risk (atorvastatin, simvastatin, and pravastatin), whereas others are associated with lower risk (fluvastatin, rosuvastatin). In 2001, cerivastatin was withdrawn from the market in connection with cases of fatal rhabdomyolysis. Rhabdomyolysis due to statins is rare, occurring 0.44 per 10,000 patient-years.

Genome-wide association studies identified *SLCO1B1* gene polymorphisms as a predisposition to statin-induced myopathy. This gene encodes a protein involved in the hepatic uptake of statins, and persons homozygous for the polymorphism (2% of the general population) have increased serum levels of statins and 15% develop self-limited statin myopathy (not the autoimmune necrotizing myopathy). Concomitant use of medications metabolized by the CYP3A4 (such as calcium channel blockers, antibiotics, antidepressants, and antiretrovirals) increases serum levels of statins and thus the risk of myotoxicity. Likewise, simultaneous use of fibric acid derivatives, especially gemfibrozil, increases the probability of statin myopathy.

TABLE 92.3 Toxic Myopathies

Pathophysiology	Medications/Toxins
Necrotizing	Statins (toxic necrotizing or toxic necrotizing autoimmune)

	Other cholesterol-lowering agents (fibrates, red yeast rice) Immunophilins (cyclosporine, tacrolimus) Ethanol Labetalol, propofol (rare) Snake venom
Amphiphilic (autophagic lysosomal)	Chloroquine/hydroxychloroquine (may have associated cardiomyopathy, cor-relates with duration of use and dose) Amiodarone (also causes hypothyroidism, neuropathy, tremor, ataxia)
Antimicrotubular	Colchicine Vincristine
Hypokalemic	Diuretics Laxatives Amphotericin Toluene Licorice Steroids Ethanol
Mitochondrial	Zidovudine Antiretrovirals
Inflammatory	L-tryptophan D-penicillamine Phenytoin Lamotrigine Interferon- α Hydroxyurea Imatinib (20%-50% will have myalgias) Cimetidine (rare; with interstitial nephritis)

PATHOBIOLOGY

Toxins cause myopathy either by directly affecting the muscle or indirectly through electrolyte imbalance or triggering immune reactions. Various types of pathophysiology account for toxic myopathies. Toxins may induce necrotizing myopathy, as with alcohol and statins. Autophagic lysosomal pathology is seen with amphiphilic agents such as chloroquine and amiodarone. Colchicine and vincristine induce myopathy through antimicrotubular effects. Many agents can cause an inflammatory myopathy. Antiretroviral agents lead to mitochondrial myopathy, and diuretics and laxatives among others cause hypokalemic myopathy. Self-limited

P.813

statin myotoxicity likely is due to muscle membrane destabilization secondary to reduced levels of lipid precursors, affecting mitochondrial electron transport and coenzyme Q10 production. The immune-mediated necrotizing myopathy caused by statins is discussed in detail in Chapter 90.

TABLE 92.4 Myotoxicity Associated with Statins

Syndrome	Management
Asymptomatic hyperCKemia	<ul style="list-style-type: none"> • May continue statin • Monitor CK and for clinical symptoms.

Toxic necrotizing myopathy	<ul style="list-style-type: none"> • Discontinue statin (improve within 2-3 mo). • Hospital admission • Intravenous hydration • Supportive measures • Hemodialysis if needed • Risk/benefit analysis regarding need for statin
Necrotizing autoimmune myopathy	<ul style="list-style-type: none"> • Discontinue statin (myopathy persists or progresses despite discontinuation). • Long-term immunosuppressive treatment (see Chapter 90)

CK, creatine kinase.

CLINICAL FEATURES

Symptoms of toxic myopathies are nonspecific. Proximal weakness is common, with or without associated pain. Rarely are the respiratory and bulbar muscles affected.

DIAGNOSIS

History and temporal correlation with medication use are crucial in determining whether a toxin is the cause of myopathy. Resolution of symptoms following withdrawal of the potentially offending agent is helpful in diagnosis.

Laboratory studies including CK, metabolic panel, hepatic function testing, thyroid function testing, and vitamin D can assist in diagnosis but also aid in identifying readily correctable abnormalities that may worsen myopathy. EMG may show myopathic findings. On occasion, a myotoxic medication may identify an underlying metabolic or hereditary myopathy.

TREATMENT

Most often, removal of exposure to the offending agent will reduce or resolve myopathy completely. In the case of statin-associated necrotizing autoimmune myopathy, ongoing immunosuppressive treatment is needed (see [Chapter 90](#)). Results are mixed as to whether supplementation with coenzyme Q10 is

beneficial for statin-associated myopathy. Vitamin D supplementation is recommended only for those with laboratory evidence of deficiency and it is unclear if it is helpful in the absence of deficiency. The high prevalence of dyslipidemia and ensuing statin use suggests a tiered approach to the treatment of statin-associated myopathy ([Table 92.4](#)).

OUTCOME

Prognosis for toxic myopathies depends on the etiology and specific syndrome. In general, withdrawal of the offending agent results in resolution or significant improvement of myopathy.

Periodic Paralysis and Other Channelopathies

Comana M. Cioroiu

Lewis P. Rowland

INTRODUCTION

Muscle channelopathies comprise a heterogeneous group of diseases of skeletal muscle that include both syndromes of episodic weakness (periodic paralyses) and muscle fiber hyperexcitability (nondystrophic myotonias). The clinical phenotype depends on the particular channel mutation involved, and attacks can vary in severity, duration, and constellation of symptomatic triggers (Table 93.1). Most of these disorders are inherited in an autosomal dominant fashion, although sporadic mutations do exist. Changes in neuronal membrane depolarization secondary to various ion channel mutations can either lead to sustained depolarization and resultant overt muscle weakness or to a more mild constant depolarization (or reduced repolarization) leading to myotonia and stiffness. On occasion, there is overlap between the two, and some patients may have episodes of both myotonia and paralysis. There are three main types of periodic paralysis: hypokalemic periodic paralysis, hyperkalemic periodic paralysis, and Andersen-Tawil syndrome (periodic paralysis with cardiac arrhythmia and dysmorphic features). The nondystrophic myotonic disorders are primarily composed of myotonia congenita, paramyotonia congenita, as well as a subgroup of potassium aggravated myotonic disorders. Electrodiagnostic testing is important in helping to identify particular patterns and make a correct diagnosis. Needle electromyogram (EMG) is needed to detect myotonic discharges or other abnormal spontaneous activity. In addition to routine nerve

P.815

conduction studies, short and long exercise tests are uniquely used to help characterize specific patterns. In short exercise testing, the patient is asked to exercise a muscle (typically the abductor digiti minimi), and a compound muscle action potential (CMAP) is recorded every 10 seconds thereafter and compared to a baseline. In the long exercise test, the patient is asked to exercise the muscle for an extended amount of time (usually 5 minutes), and CMAPs are recorded every 2 minutes thereafter for about 1 hour and compared to baseline. Changes in CMAP amplitude in both short and long exercise testing can be used to differentiate between the various channelopathies. For instance, CMAP amplitudes typically increase in the periodic paralyses and decrease in the myotonias. Different electrodiagnostic patterns diagnostic of each particular disease were described in 2004 by Emmanuel Fournier and are still used today and are known as *Fournier patterns*. Targeted confirmatory genetic testing is often done thereafter to confirm the diagnosis. Although patients with these diseases have a normal life expectancy, they may struggle with persistent pain or progressive weakness causing significant functional impairment.

TABLE 93.1 Clinical Features of Hereditary Periodic Paralysis and Nondystrophic Myotonias

	Hypokalemic Periodic Paralysis	Hyperkalemic Periodic Paralysis	Andersen- Tawil Syndrome	Paramyotonia Congenita	Myotonia Congenita
Gene	CACN1A5 or SCN4A	SCN4A	KCNJ2	SCN4A	CLCN-1 (AD) or SCN4A (AR)
Age of onset	Usually second or	First decade	First or second	First decade	First decade

	latter part of first decade		decade		
Sex	Male preponderance	Equal	Equal	Equal	Male preponderance
Frequency of paralytic episodes	Daily to yearly	Hourly to daily	Daily to yearly	May not be present; otherwise, weekly to monthly	Usually not present, variable frequency in AR form
Degrees of paralysis	Tends to be severe	Tends to be mild but can be severe	Variable	Tends to be mild but can be severe	Lasting seconds to minutes in AR form, usually not present in AD form
Effect of cold	May induce an attack	May induce an attack	May induce an attack	Tends to induce an attack	No effect
Oral potassium	Relieves or prevents an attack	Precipitates an attack	May relieve or prevent an attack	May precipitate an attack	No effect
Myotonia	Absent	May be present	Absent	Present	Present
Precipitants	Carbohydrate-rich food, cold	Fasting, stress, rest after exercise, K-rich foods	Carbohydrate-rich food, rest after exercise	Fasting, stress, cold, rest after exercise	Exercise
Exercise testing	Increase in CMAP with gradual decline with long exercise testing; short exercise testing normal (Fournier V)	Increase in amplitudes with gradual decrease in both short and long exercise testing (Fournier IV)	Unknown	Prominent drop in amplitudes with cooling in both long and short exercise testing; PEMPs present (Fournier I)	AD: drop in amplitude on short exercise testing, less drop with repeated testing AR: drop in amplitude with slow recovery (Fournier II)

HYPOKALEMIC PERIODIC PARALYSIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Hypokalemic periodic paralysis (hypoKPP) is the most common of the periodic paralyses, yet it is still rare, affecting only about 1.7 per 1,000,000 people in England. Clinical onset is usually within the first 2 years of life (although it may be delayed into the sixth decade) and is more prevalent in men than women in a ratio of about 2:1. Most of these patients have mutations in either the *CACNA1S* gene (CaV1.1, chromosome 1q31-32) encoding an L-type calcium channel or less commonly, the *SCN4A* sodium channel gene (NaV1.4, chromosome 17q23). In the presence of these mutations, muscle fibers become depolarized and electrically inexcitable, leading to weakness. Just how these mutations cause persistent depolarization is unknown; however, one mouse model of such a calcium channel mutation proposed a possible explanation via a “gating pore current,” described as an anomalous inward current at the resting potential triggered by low extracellular potassium content, leading to depolarization and sodium channel inactivation. At the structural level, mutations in the calcium channel lead to a vacuolar myopathy, whereas sodium channel mutations are associated with the development of transverse tubular aggregates and less vacuolization.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with hypoKPP typically note transient weakness after a period of rest after exercise. These episodes are often more prominent during sleep or on rising in the morning and are worse after a meal rich in sodium or carbohydrates. The extent of paralysis can be variable and asymmetric and can vary from slight leg weakness to complete flaccid quadriplegia. Bulbar and respiratory muscles are typically spared, but urinary or fecal retention may be seen. The duration of attacks can be variable and last anywhere from a few hours to several days. The interval between attacks may be as long as 1 year, although in some patients, attacks can occur daily. Patients have normal strength in between attacks, but some eventually develop fixed proximal weakness. Attacks may be associated with pain either preceding or following weakness. In a mild attack, tendon reflexes are diminished in proportion to the degree of weakness and are completely absent in a severe attack. Sensation remains normal. Diagnosis can be made on the basis of the presence of similar attacks of transient weakness in family members. Confirmatory tests include the finding of low potassium content (3.0 mEq/L or less) and high sodium content in the serum during an attack and the ability to induce an attack with an IV infusion of glucose and regular insulin. Serum creatine kinase (CK) levels are typically normal or mildly elevated. Short exercise electrodiagnostic testing is usually normal, but an increase in CMAP amplitude with a delayed decline can be seen with long exercise testing (Fournier pattern V). Needle EMG does not show myotonic discharges. Prior to making a diagnosis of hypoKPP, it is of crucial importance to exclude other conditions than may also lead to periodic paresis and hypokalemia including hyperaldosteronism, diuretic use, gastrointestinal loss, and thyrotoxicosis (Table 93.2). The latter in particular must be considered (particularly in those of Asian ancestry). Also, attacks of hypoKPP have been described in patients with hyperthyroidism linked to the potassium channel β subunit gene *KCNE3*, which responds completely with treatment of the thyroid disorder.

TREATMENT AND OUTCOME

Acute attacks may be treated safely with oral potassium (20 to 100 mEq), and rarely, IV potassium can be used, although it comes with the risk of subsequent hyperkalemia and cardiac arrhythmias. Prophylaxis of recurrent attacks is usually accomplished with the carbonic anhydrase inhibitor acetazolamide (Diamox) in doses of 250 to 1,000 mg daily. About 50% of patients respond to acetazolamide, and there is a greater benefit in patients with the *CACNA1S*

calcium mutation than in those with the SCN4A sodium channel mutation. In fact, on occasion, it may worsen attacks in patients with sodium channel mutations. The mechanism whereby it helps attacks of weakness is uncertain but may be related to induction of a mild metabolic acidosis, improved chloride conductance, or activation of the KCa^{2+} channel. Dichlorphenamide, another carbonic anhydrase inhibitor, has also been shown to be efficacious in reducing attacks in both hyper- and hypoKPP. Other agents that may be beneficial include triamterene or spironolactone, which promote retention of potassium. More recently, bumetanide (an Na-K-2Cl inhibitor) has been effective in preventing recurrent attacks of weakness and restoring force in a mouse model of hypoKPP with either a NaV1.4 sodium channel or CaV1.1 calcium channel mutation. Patients are also encouraged to avoid strenuous exercise and meals rich in carbohydrates. In those cases of hypoKPP secondary to a general medical condition (i.e., thyroid disease), the underlying disorder must be treated.

TABLE 93.2 Potassium and Paralysis: Noninherited Forms

Hypokalemic

- Excessive urinary loss

- Hyperaldosteronism (Conn syndrome)

- Drugs: glycyrrhizae (licorice), thiazide diuretics, furosemide, chlorthalidone, ethacrynic acid, amphotericin B, duogastrone, barium, corticosteroids

- Pyelonephritis, renal tubular acidosis

- Recovery from diabetic acidosis

- Ureterocolostomy

- Excessive gastrointestinal loss (diarrhea, vomiting, fistula)

- Malabsorption syndrome

- Laxative abuse

- Pancreatic tumor, villous adenoma

- Thyrotoxicosis

Hyperkalemic

- Uremia

- Hypoaldosteronism

- Addison disease
- Potassium-sparing diuretics (i.e., spironolactone)
- Excessive intake/supplementation of potassium
- Iatrogenic
- Geophagia

With time, patients with hypoKPP experience less attacks as they age and attacks may cease altogether after age 40 or 50 years. The disease does not shorten overall survival, and death due to respiratory involvement is rare. A progressive and persistent proximal myopathy may develop with time and cause functional impairment and disability. Finally, it should be mentioned that susceptibility to malignant hyperthermia has been linked to the CACNA1S gene (although it is usually caused by a mutation in the RYR1 gene encoding a ryanodine receptor), and cases of malignant hyperthermia have been described in patients with hypoKPP. However, to date, no conclusive evidence of a clear genetic link has been found.

HYPERKALEMIC PERIODIC PARALYSIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Hyperkalemic periodic paralysis (hyperKPP) was first described by Frank Tyler at the University of Utah in 1951, when he recognized a form of periodic paralysis not accompanied by a decrease in serum potassium. The disease is caused by an autosomal dominant genetic mutation with complete penetrance, affecting the SCN4A sodium channel gene. It is thought to cause defective inactivation of the sodium channel, thereby resulting in a complete loss of membrane excitability and weakness. Mutations involving the SCN4A gene cause three clinical variations of hyperKPP—episodic weakness without myotonia, episodic weakness with myotonia, and episodic weakness associated with paramyotonia congenita triggered by cold (to be discussed in a subsequent section of this chapter). Overall prevalence is estimated to be about 1.3 per 1,000,000 people with onset before the age of 10 years. The pathophysiology of hyperKPP was first studied by Rudel et al. in the 1980s and led to the suspicion that a defective sodium channel protein might be responsible. First, using microelectrode studies of intercostal muscle, they confirmed that muscle isolated from patients with hyperKPP was partially depolarized at rest. The abnormal depolarization was blocked by tetrodotoxin, which specifically affects the α subunit of the sodium channel. Patch clamp experiments showed faulty inactivation, leading to the conclusion that excessive sodium influx causes repetitive firing of action potentials (myotonia) and eventual inactivation of the membrane (weakness). Cloning and analysis of the gene encoding the voltage-gated sodium channel identified more than 20 missense mutations in the SCN4A gene. Some mutations exhibit both interfamilial and intrafamilial phenotypic variability. Muscle biopsy may reveal in-tracytoplasmic vacuoles.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

As opposed to hypoKPP, attacks in hyperKPP tend to occur more frequently in the daytime and are shorter (less than 2 hours on average) and less severe. Involvement of bulbar or respiratory muscles is rare. The frequency of attacks varies but they tend to occur more often than those in hypoKPP. Attacks may be precipitated by potassium-rich food, rest after exercise, fasting, and cold temperature. Strength is normal in between attacks, and during attacks, patients are areflexic. Fixed proximal weakness may develop over time. Minimal clinical

myotonia may be observed, with myotonic lid lag or lingual myotonia.

Serum potassium levels may be normal or elevated during an attack, at times in excess of 5.0 mEq/L. Serum CK can also be normal or mildly elevated. Needle EMG may show fibrillations or myotonic discharges in up to 50% to 75% of patients (indicative of hyperexcitability and muscle irritation), and later in the clinical course, motor units may become myopathic in appearance. Both short and long exercise testing reveal a rise in CMAP amplitude that decreases over time (Fournier pattern IV). Confirmatory genetic testing for the responsible mutation is often done. As with hypoKPP, noninherited causes of hyperkalemia must be excluded, such as uremia, Addison disease, and excessive potassium supplementation.

TREATMENT AND OUTCOME

Attacks may be terminated by administration of calcium gluconate, glucose, and insulin to stabilize cardiac membranes and reduce serum potassium levels. Acetazolamide in doses of 250 mg to 1 g orally may reduce the number of attacks or completely abolish them. Potassium-wasting diuretics such as thiazides can promote urinary excretion of potassium and also be effective clinically. Rarely, β -adrenergic agents can be used as well, although come with a risk of cardiac arrhythmias. In those patients with myotonia, mexiletine may give symptomatic relief but comes with a small risk of cardiovascular effects (including arrhythmias) and an electrocardiogram (ECG) is needed prior to its initiation. Patients are encouraged to avoid fasting, potassium-rich foods, and exposure to cold temperatures. As in hypoKPP, life expectancy is not affected but patients' morbidity may be related to episodic and progressive proximal weakness and myalgia with muscle stiffness may result from myotonia.

ANDERSEN-TAWIL SYNDROME

EPIDEMIOLOGY AND PATHOBIOLOGY

Also known as *Klein-Lisak-Andersen syndrome*, this rare disease is inherited in an autosomal dominant fashion (with some sporadic cases) and is most frequently due to mutations in the KCNJ2 gene encoding an inward-rectifying potassium channel, and several mutations in this gene exist. It accounts for less than 10% of all people with periodic paralysis. The syndrome is characterized by the clinical triad of periodic paralysis, ventricular arrhythmias with a prolonged QT interval, and dysmorphic features, which are usually skeletal abnormalities. Not all patients show the complete triad. The disease typically starts with episodes of periodic paralysis in the first or second decade, and serum levels of potassium vary.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Attacks are highly variable in frequency, duration, and severity. There is usually no associated myotonia or weakness in between

P.817

episodes, but some patients demonstrate mild neck flexor or facial weakness. Developmental abnormalities include hypertelorism, clinodactyly, low-set ears, scoliosis, and syndactyly, and patients are usually short statured and may have a cleft or high-arched palate. Some patients may have cognitive abnormalities. The associated cardiac manifestations of Andersen-Tawil syndrome (ATS) are inherent and unique to the diagnosis. Over 50% of patients have a prolonged QT syndrome, and an even larger proportion develops arrhythmias such as bidirectional or polymorphic ventricular tachycardia. Ventricular tachyarrhythmias are less frequent and often asymptomatic, although cardiac arrest may occur in up to 10% of patients. Patients must be questioned about any unexplained syncopal events, which may be indicative of an underlying arrhythmia. An ECG is a crucial component of the diagnostic workup because some patients may benefit from pacing or antiarrhythmic agents. Electrophysiologic testing is often useful, as long as exercise testing shows an immediate increase in CMAP

amplitude with a subsequent decline. Genetic testing for the *KCNJ2* gene mutation is confirmatory. As with hyper- and hypoKPP, secondary causes of periodic paralysis must be excluded (including thyroid disease, renal failure, and others).

TREATMENT AND OUTCOME

Management of ATS is aimed at treatment of both the episodic paralysis and the cardiac manifestations, and a multidisciplinary approach is therefore crucial. Carbonic anhydrase inhibitors may decrease the frequency of clinical attacks, as in other forms of periodic paralysis. Cardiac evaluation includes yearly ECG and Holter monitoring, as some patients benefit from a pacemaker or defibrillator. More often, however, pharmacologic agents such as β -blockers and other antiarrhythmics are used to control arrhythmias. Patients must be counseled to avoid medications that may further prolong the QT interval.

NONDYSTROPHIC MYOTONIAS

EPIDEMIOLOGY AND PATHOBIOLOGY

Paramyotonia congenita (PC; sometimes known as *Eulenburg disease*) is also caused by a mutation in the *SCN4A* sodium channel gene and, given the shared genetic locus, often overlaps with hyperKPP and different phenotypes may exist in the same family. It is typically inherited as an autosomal dominant disorder and symptoms begin early in life. Infants may have difficulty opening their eyes while crying (eyelid-opening myotonia). In PC, poor inactivation of the sodium channel prolongs the neuronal action potential and slows the rate of repolarization, thereby causing a mild state of persistent depolarization leading to clinical myotonia. This phenotype differs from hyperKPP, and there is probably a different kind of functional defect in the *SCN4A* gene in the two syndromes accounting for this variability. Genetic defects causing persistent sodium currents may lead to paralysis via stable and persistent depolarization (hyperKPP), whereas myotonic discharges result from instability of channel activation that is more variable. Histo-pathologically, muscle biopsy may show myopathic features with intracytoplasmic vacuolization and tubular aggregates.

Also known as *Thomsen disease*, myotonia congenita (MC) is also autosomal dominant and is caused by mutations in the *CLCN1* chloride channel gene. Men are affected more than women. In the autosomal dominant form, changes in chloride channel function lead to a loss of chloride conductance, thereby leading to delayed repolarization and increased neuronal excitability due to potassium accumulation in T-tubules and resultant membrane depolarization. An autosomal recessive form also exists, also known as *Becker disease*, and involves a mutation in the *SCN4A* sodium channel gene.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The first clinical signs of PC are typically seen in the first decade of life. Patients demonstrate “paradoxical” myotonia, which is defined as myotonia or stiffness that worsens with repeated exercise (as opposed to the “warm-up phenomenon” seen in other myotonic syndromes, in which myotonia decreases with exercise.) Cold ambient temperatures worsen clinical myotonia and stiffness, and short and long exercise testing in a cooled limb shows a drop in amplitude with a slow recovery (Fournier pattern I). With more trials, a further drop in amplitude can be seen, which is an electrophysiologic equivalent of the paradoxical myotonia seen clinically. Many patients demonstrate postexercise myotonic potentials (PEMPs), which are after discharges of decreasing amplitude seen after exercise. Needle EMG may show signs of muscle irritability in the form of fibrillations and myotonic discharges, which disappear completely with colder temperatures as the muscle weakens. Given the occasional overlap with periodic paralysis, in some patients, cold temperature or potassium intake can induce a paretic attack. Fixed progressive muscle weakness may develop with time.

Symptoms of Thomsen disease begin in the first decade of life with clinical signs of myotonia—for instance,

infants may have trouble opening their eyes after crying and may fall when learning to walk. In MC, myotonia demonstrates the classic warm-up phenomenon, whereby the myotonia improves with exercise and repeated muscle contraction. Both percussion and grip myotonia may be observed. Patients are described as being “herculean” with excessive muscle mass attributed to the nearly constant state of muscle contraction, although they usually do not complain of pain. Episodes of weakness are rare in the autosomal dominant form, but in Becker disease, they may occur at the onset of physical activity, lasting seconds to minutes. Moreover, in these patients, symptoms commence later in life and they may also develop proximal weakness. Serum CK is typically normal, as is serum potassium. Short exercise testing shows a transient drop in amplitude (more pronounced with cooling in autosomal dominant form) with a smaller drop with repeated trials (corresponding to the warm-up phenomenon seen clinically), consistent with a Fournier II pattern. Long exercise testing shows little if any change and PEMP may be seen. Genetic testing confirms the diagnosis.

TREATMENT AND OUTCOME

Muscle stiffness related to myotonia is often the primary complaint of patients with PC and MC, and strategies aimed at mitigating this pain vary. Mexiletine, a class IB antiarrhythmic medication, has been used for many years for symptomatic relief in both dystrophic and nondystrophic myotonic syndromes. One placebo-controlled trial done by Statland et al. in 2012 demonstrated significant improvement in stiffness after mexiletine treatment for 4 weeks in patients with nondystrophic myotonia. Mexiletine is thought to work via enhancement of fast inactivation of sodium channels, although its efficacy is not restricted to only those patients with myotonia related to SCN4A (sodium channel) mutations. The medication is generally well tolerated and is typically started at a dose of 150 mg daily, then slowly increased to a dose of 300 mg three times per day. Cardiac testing including an ECG is often done prior to initiating the drug trial, particularly in patients with cardiac symptoms or known cardiovascular disease. Some patients may find relief

P.818

from other medications with different mechanisms of action such as carbamazepine, phenytoin, or diuretics such as acetazolamide or hydrochlorothiazide.

Stiff Person Syndrome and Peripheral Nerve and Muscle Hyperexcitability

Jonathan Perk

Christina M. Ulane

Lewis P. Rowland

INTRODUCTION

The terms *muscle stiffness* and *cramps* are used for commonly experienced symptoms that are often transient and benign. Rarely, they may be harbingers of more serious pathology. Persistent limb muscle stiffness arises from involuntary continuous muscle contraction, whereas cramps and spasms are brief contractions. Lesions throughout the motor system have been implicated in generating muscle stiffness or spasm. Excessive muscular activation may result from dysfunction of inhibitory systems in central nervous system (CNS) pathology or inappropriate activation or hyperexcitability in peripheral nervous system (PNS) pathology. [Table 94.1](#) outlines features of various causes of muscle cramps and stiffness.

STIFF PERSON SYNDROME

In 1956, Moersch and Woltman, senior neurologists at the Mayo Clinic, described patients with a rare clinical syndrome of progressive fluctuating muscular rigidity and painful spasms. This condition is currently known by the gender neutral name *stiff person syndrome* (SPS). A focal variant of the disorder has been called the *stiff limb syndrome*.

TABLE 94.1 Disorders Causing Muscle Stiffness and Hyperexcitability

Localization of Abnormality	Disorder	Principal Manifestations	Treatment
Brain, brain stem, and spinal cord	Stiff person syndrome (SPS)	Rigidity and reflex spasms Anti-GAD65 antibodies	Diazepam, IMG, treatment of underlying cancer if paraneoplastic
	Progressive encephalomyelitis with rigidity and myoclonus (PERM)	Rigidity and reflex spasms, focal neurologic deficits Anti-GlyR α 1 antibodies	Similar to SPS
	Tetanus	Rigidity and reflex spasms	Diazepam, supportive care

Peripheral nerve	Acquired neuromyotonia (Isaac syndrome)	Stiffness, myokymia, delayed relaxation Anti-VGKC antibodies	Immunotherapy, phenytoin, carbamazepine, mexiletine, treatment of underlying cancer if paraneoplastic
	Schwartz-Jampel syndrome	Stiffness and myotonia	Phenytoin, carbamazepine
	Tetany	Carpopedal spasm	Correction of calcium, magnesium, or acid-base derangement
Muscle	Myotonic disorders	Delayed relaxation, percussion myotonia	Mexiletine, phenytoin, carbamazepine (see Chapter 142)
	Metabolic myopathies	Cramps during intense or ischemic exercise	See Chapter 95 and Section 19.
	Neuroleptic malignant syndrome	Rigidity during dopamine block	Supportive care, bromocriptine, dantrolene
	Malignant hyperthermia	Rigidity during anesthesia	Supportive care, dantrolene
Unknown	Ordinary muscle cramps	Cramps during sleep or ordinary activity	Stretching affected muscle to relieve cramp, medications may be used if severe (see text)

MIG, intravenous immunoglobulin; VGKC, voltage-gated potassium channel.

EPIDEMIOLOGY

SPS occurs more often in women, but both men and women can be affected (average age of symptom onset is 35 years) and develop progressive symptoms over several months or years. SPS is quite rare and exact epidemiologic data is lacking; the estimated prevalence is one in a million. It is most often an immunologically mediated disorder with the presence of anti-glutamic acid decarboxylase-65 (anti-GAD65) antibodies; it may coexist with other autoimmune disorders including type 1 diabetes mellitus (in at least 35% of patients with SPS), Hashimoto thyroiditis, Graves disease, pernicious anemia, vitiligo, and celiac disease. A paraneoplastic form of SPS accounts for about 5% of cases, most often associated with breast cancer but also reported with thyroid, renal, or colon

cancer. The disorder is extremely rare in children (eight cases identified older than 29 years at Mayo Clinic and

12 other case reports).

PATHOBIOLOGY

CNS γ -aminobutyric acid (GABA)-secreting neurons play a major role in the normal inhibition of excessive continuous motor activation. GABA synthesis from glutamic acid is catalyzed by the enzyme glutamic acid decarboxylase (GAD). The discovery of antibodies against the 65-kilodalton GAD protein in most patients suggests immunologically mediated dysfunction of inhibitory synapses. [Figure 94.1](#) illustrates the inhibitory synapse and subcellular localization of antigenic targets of antibodies found in SPS. Reported association of SPS with autoimmune diseases as pernicious anemia, thyroid disease, type 1 diabetes mellitus, and others provides further support for the role of autoimmunity. The presence of anti-GAD65 antibodies with other neurologic disorders, including cerebellar ataxia (with or without coexisting SPS), epilepsy, or progressive encephalitis with rigidity and myoclonus (PERM) suggests a spectrum of pathology associated with neuronal disinhibition in which SPS is one subtype. Although there is often an association of anti-GAD65 antibodies and SPS, the direct pathogenic role of anti-GAD65 antibodies remains uncertain. One major puzzle is that the antigenic GAD65 enzyme is intracellular and therefore supposedly hidden from the offensive antibodies. Furthermore, unlike myasthenia gravis, another antibody-mediated autoimmune disease where antibodies are directed against surface nicotinic acetylcholine receptors, passive transmission of antibodies (e.g., in maternal placental transfer) does not confer the SPS.

It may be that other associated antibodies are the pathologic culprits as, for example, the anti-GABA receptor-associated protein (GABARAP) autoantibody. Dalmau and colleagues found that antibodies directed against the glycine receptor subunit alpha 1 (GlyR α 1) IgG antibodies are present in 12% of SPS patients and are found in other hyperexcitable disorders affecting brain stem and spinal cord, most often PERM. Anti-GlyR α 1 antibodies may predict good response to immunotherapy. Mutations in the gene encoding the GlyR α 1 cause *hyperekplexia* or *startle disease*.

FIGURE 94.1 The neuronal inhibitory synapse. GABA and glycine are primary inhibitory neurotransmitters. Dysfunction of components of the synapse (presynaptic, synaptic, and postsynaptic) can lead to loss of inhibition and clinical stiffness and spasms. GAD, glutamic acid decarboxylase; GABARAP, GABA receptor-associated protein; BZD, benzodiazepine.

Over the years, a paraneoplastic subgroup form of SPS patients was identified. Many of those patients were positive for autoantibodies directed against other molecules in the inhibitory synapse such as amphiphysin (breast and small cell lung cancer) and gephyrin (mediastinal cancer).

CLINICAL MANIFESTATIONS

Progressive stiffness and intermittent spasms of the axial musculature characterize the classic form of SPS, but distal limb muscles may also be affected. Aching discomfort and stiffness tend to predominate in the axial and proximal limb muscles, causing a hyperlordotic posture, with awkward gait and slowness of movements. Unlike tetanus, trismus does not occur, but facial and oropharyngeal muscles may be affected. In some cases, respiratory muscles are involved. The stiffness diminishes during sleep and under general anesthesia, differentiating it from other motor unit hyperexcitable syndromes such as neuromyotonia. The spasms may lead to joint deformities and are powerful enough to rupture muscles, rip surgical sutures, and fracture bones. Painful reflex spasms and falls occur in response to movement, sensory stimulation, or emotional changes. Fear of attacks elicited by environmental stimulation may lead to a debilitating avoidance of public places. Anxiety and task-specific phobias can be dominant features in SPS and may contribute to the often observed delay in diagnosis or misdiagnosis.

Physical examination shows markedly increased axial and proximal muscle tone. However, strength,

coordination, and sensation are preserved. Passive muscle stretch provokes an exaggerated reflex contraction that lasts several seconds. [Table 94.2](#) highlights the dominant features of classic SPS. The startle reactions of SPS are similar to those in hyperekplexia.

DIAGNOSIS

Laboratory Data

The diagnosis of SPS is aided by the presence of serum (or cerebrospinal fluid [CSF]) antibodies against GAD65 in high titers (2,000 U/mL or more) which are found in approximately 80% of cases. Anti-GAD65 antibodies are supportive of the diagnosis of SPS but not specific; they are found in other neurologic disorders (including

P.821

cerebellar ataxia, PERM, and Batten disease), and low titers are associated with other autoimmune diseases (up to 22% of persons with type 1 diabetes mellitus). Other autoantibodies present in SPS include anti-GABARAP in 65% of SPS cases, anti-GlyR α 1 antibodies in up to 10% of cases, antiampiphysin in up to 5% of paraneoplastic cases, and antigeophyrin (found in one case of paraneoplastic SPS).

TABLE 94.2 Defining Characteristics of the Stiff Person Syndrome

- Prodromal stiffness of axial muscles

- Slow progress to proximal limbs, walking awkward

- Fixed deformity of the spine, lordosis, “permanent shrug” (neck drawn down to shoulder girdle)

- Spasms precipitated by startle, jarring, noise, emotional upset

- Otherwise normal findings on motor and sensory examination

- Anxiety and task-specific phobias

- Normal intellect and affect

- Continuous motor activity in affected muscles relieved by intravenous or oral diazepam

Modified from Lorish TR, Thorsteinsson G, Howard FM Jr. Stiff-man syndrome updated. *Mayo Clin Proc.* 1989;64(6):629-636.

Electrophysiology

Electromyography (EMG) reveals continuous firing of normal motor unit action potentials (MUAPs) even at rest. This excessive firing may be inhibited by administration of intravenous diazepam. Another hallmark of the SPS is cocontraction of agonist and antagonist muscles. Normally, contraction of an agonist muscle is associated with inhibition of the activity of the antagonist, but this is not so in SPS ([Fig. 94.2](#)).

Imaging

Magnetic resonance (MR) imaging of the brain and spinal cord is normal in SPS and are most useful in ruling out other pathologies. Brain MR spectroscopy, however, shows a marked reduction of the inhibitory GABA neurotransmitter.

TREATMENT AND OUTCOMES

Until the discovery of anti-GAD and other autoantibodies, GABA-enhancing medications were used both for diagnosis and symptomatic treatment. The realization that autoimmunity likely plays a role opened new diagnostic and treatment possibilities. Dalakas showed clear benefit for patients with SPS treated with intravenous immunoglobulin (IVIG) in a randomized, double-blind, placebo-controlled study involving 16 patients with SPS [Level 1].¹ Although most patients experience benefit after initial dose of IVIG, many require repeat treatment to sustain response. Steroids, plasmapheresis, and rituximab (antibodies directed against B cells) were all tried with varying success.

Benzodiazepines are the mainstay for rigidity and spasms, and patients often require titration up to high doses; on average 40 mg/day, but some require several hundred milligrams per day. Baclofen may be used as an adjunct and doses of 60 to 100 mg/day may be required. Other medications that may be helpful are gabapentin (300 to 1,200 mg three times daily), pregabalin (50 to 100 mg three times daily), levetiracetam (500 to 1,500 mg twice daily), and in refractory cases, dantrolene sodium (starting at 25 mg daily and titrating up to a maximum of 100 mg four times daily). Dantrolene should be used with caution and monitoring for cardiac side effects and hepatotoxicity. Some may respond to intrathecal baclofen.

FIGURE 94.2 Schematic depiction of simultaneous agonist/antagonist electromyography recordings in stiff person syndrome. The normal response tracings (*top*) show runs of agonist muscle MUAPs associated with inhibition of MUAPs in the antagonist and vice versa. In contrast, paired tracings recorded in a stiff person patient (*bottom pair*) show uninhibited simultaneous activation of both agonist and antagonist muscles. MUAP, motor unit action potential.

OTHER CENTRAL NERVOUS SYSTEM DISORDERS OF MUSCLE STIFFNESS

Common CNS disorders can show increased muscle tone. Stroke, multiple sclerosis, amyotrophic lateral

sclerosis, and primary lateral sclerosis are examples where loss of normal inhibition of the motor system occurs. These relatively more common entities are discussed elsewhere in this book.

Although tetanus and tetany share a similar name and also some clinical features, they are entirely distinct. Tetanus is discussed in Chapter 63 and is only briefly mentioned here because of the pathogenic similarities to SPS at the inhibitory synapse. Tetanus is caused by the toxin tetanospasmin released from the bacteria *Clostridium tetani* in contaminated wounds. This toxin reaches nerve terminals and travels by retrograde axonal transport to reach inhibitory interneurons in the spinal cord and brain stem. Tetanospasmin prevents the release of GABA and glycine into the synapse, effectively blocking inhibitory neurotransmission in a similar mechanism to SPS. However, unlike SPS, tetanus has a predilection for the brain stem, possibly due to the shorter length of cranial nerve axons, eliciting distinct features such as trismus and forceful satanic-like smile (“risus sardonicus”). Opisthotonic spasm of axial muscles may cause fractures and respiratory failure. Treatment includes respiratory support, antibiotics, antitoxin treatment, and muscle relaxants. Tetanus is best prevented by immunization, which is unfortunately unavailable in many developing countries. Risus sardonicus is also seen in strychnine intoxication with a similar mechanism of action; however, the clinical setting and toxin exposure set the two syndromes apart.

Tropical spastic paraparesis is caused by the human T-lymphotrophic virus (HTLV-1) retrovirus and is prevalent in the adult population of the Caribbean islands. This infectious myelopathy primarily affects the thoracic spinal cord and is manifest by progressive spasticity and weakness, bladder dysfunction, and minor sensory symptoms. There are no current effective diseasemodifying agents, which alter the long-term debilitating course. Corticosteroids, interferon- α and interferon- β , as well as other agents have been tried with limited success. Treatment is largely symptomatic and directed to relieve spasticity, painful muscle spasms, and loss of bladder control.

There are hereditary forms of spastic paraparesis, most notably the hereditary spastic paraplegias (HSPs). These are clinically and genetically heterogeneous. Clinical syndromes may be “pure” if only manifesting as spasticity and weakness in the legs with bladder dysfunction, or “complicated” if additional neurologic and systemic symptoms are present. These can be autosomal dominant, autosomal recessive, or X-linked and may be diagnosed genetically.

PERIPHERAL NERVE AND MUSCLE HYPEREXCITABILITY

ACQUIRED NEUROMYOTONIA (ISAAC SYNDROME)

Isaac first described this disorder as a state of “continuous muscle fiber activity.” The invariable clinical manifestation is myokymia, visibly

P.822

apparent constant muscle twitching likened to a bag of writhing worms. As a result of the continuous activity, patients may develop muscle cramps or abnormal postures of the limbs, which may be persistent or intermittent and are identical to carpal or pedal spasm.

Epidemiology

Neuromyotonia is a rare disorder; no specific information regarding incidence or prevalence is available. The acquired autoimmune forms can be seen in association with multiple other autoimmune diseases, either neurologic (such as myasthenia gravis) or systemic. Neuromyotonia is at times a paraneoplastic syndrome associated mainly with thymoma or small cell lung cancer but also with breast carcinoma or lymphoma.

Pathobiology

In the autoimmune form, neuromyotonia was first attributed to the presence of antibodies directed against

voltage-gated potassium channels (VGKC). Anti-VGKC complex antibodies were also found in some patients with limbic encephalitis and additionally in patients with the syndrome of benign fasciculations with cramps. This wide phenotypic spectrum associated with anti-VGKC was puzzling. However, advances in specific antibody identification have improved our understanding of the hyperexcitability syndromes and aided in clinical classification. More recent studies show that, rather than binding the potassium channel itself, the “anti-VGKC antibodies” bind antigenic neuronal targets of the macromolecular complex associated with the channel. The two main antigens are the leucine-rich glioma-inactivated protein 1 (LGI1) and contactin-associated protein-like 2 (CASPR2). Anti-LGI1 antibodies target CNS structures and are more commonly associated with limbic encephalitis. Anti-CASPR2 antibodies on the other hand, target both central and peripheral nervous tissue. They may be associated with neuromyotonia as well as the cramp-fasciculation syndrome, which may be a mild variant of Isaac syndrome. It is reasonable therefore to consider this spectrum of phenotypes under the umbrella of *autoimmune peripheral nerve hyperexcitability disorders*.

Clinical Manifestations

Isaac syndrome affects children, adolescents, or young adults and begins insidiously, progressing slowly for months or a few years. Symptoms most often begin in the distal arms and legs. Slow movement, clawing of the fingers, and toe walking are later joined by stiffness of proximal and axial muscles; occasionally, oropharyngeal or respiratory muscles are affected. The motor symptoms are often accompanied by the profuse sweating syndrome of hyperhidrosis. The stiffness and myokymia are seen at rest but, unlike SPS, continue in sleep and under general anesthesia. Voluntary contraction may induce a spasm that persists during attempted relaxation.

If patients develop higher cortical dysfunction manifest by sleep disorders, personality changes, and delirium, the condition is named the *Morvan syndrome*. The fixed postures of the limbs in Isaac syndrome can be simulated by the rare genetic Schwartz-Jampel syndrome (SJS). However, SJS is characterized by the additional features of a unique facial appearance (blepharophimosis), short stature, and bony abnormalities. In “ocular neuromyotonia,” the limbs and cranial muscles are spared and the disorder is confined to one or more extraocular muscles.

Diagnosis

Antibodies reactive against the VGKC are detected in 30% to 40% of patients with Isaac syndrome and in 80% of those with coexisting thymoma but may also be seen at very low titers in asymptomatic people (2%). They may also be found in patients with painful small-fiber neuropathy. The prevalence of distinct antibodies to CASPR2 and LGI1 in this population is unknown. It is reasonable to perform a malignancy screening, as 20% to 25% of patients with Isaac have an underlying malignancy (although the Isaac may precede malignancy by many years).

EMG shows characteristic findings. The EMG recorded from stiff muscles reveals prolonged myokymic or neuromyotonic discharges. In electrical myokymia, grouped fasciculations fire at rates up to 60 Hz and sound like marching soldiers. Myokymia may be found in the EMG of some individuals without any clinically visible twitching. Furthermore, myokymia is not restricted to Isaac syndrome; it may appear in other clinically distinct entities as postradiation neuropathy, multiple sclerosis, or after exposure to the Timber rattlesnake venom. In electrical *neuromyotonia*, on the other hand, continuous discharges occur at rates of 150 to 300 Hz, tend to start or stop abruptly, and sound like a “NAS-CAR engine” or a “dive bomber.” Voluntary effort triggers more intense discharges that persist during relaxation, accounting for the myotonia-like aftercontraction, but electrical myotonia is not found. In SJS, the more frequent EMG pattern is that of myotonic discharges, but there may be continuous motor activity with both myokymic and neuromyotonic discharges.

Treatment

The treatment of the peripheral nerve hyperexcitability disorders is multitiered. The muscle contraction symptoms are usually controlled with anticonvulsants as carbamazepine (200 to 1,200 mg daily in divided doses) or phenytoin (100 to 300 mg daily). Mexiletine may also be used at doses of 100 to 300 mg three times daily but with caution in patients at risk of cardiac arrhythmias (monitor for QTc prolongation) and can rarely cause hepatotoxicity. Plasmapheresis (three to five sessions every other day) and intravenous immunoglobulin therapy (2 g/kg over 4 to 5 days) are effective in some patients, and in the paraneoplastic group, treatment is directed primarily against the underlying cancer.

TETANY

Tetany is a clinical syndrome characterized by convulsions, paresthesias, prolonged spasms of limb muscles, or laryngospasm; it is accompanied by signs of hyperexcitability of peripheral nerves. Tetany occurs in patients with hypocalcemia, hypomagnesemia, or alkalosis. Hyperventilation may unmask latent hypocalcemic tetany, but respiratory alkalosis itself only rarely causes outright tetany.

Intense circumoral and digital paresthesias generally precede the typical carpopedal spasms, which consist of adduction and extension of the fingers, flexion of the metacarpophalangeal joints, and equinovarus postures of the feet. In severe cases, the spasms spread to the proximal and axial muscles, eventually causing opisthotonus. In all forms of tetany, the nerves are hyperexcitable, as manifested by the reactions to ischemia (Trousseau sign) or percussion (Chvostek sign). The spasms are owing to spontaneous firing of peripheral nerves, starting in the proximal portions of the longest nerves. EMG shows individual motor units discharging independently at a rate of 5 to 25 Hz (at times up to 300 Hz); each discharge consists of a group of two or more identical potentials.

The treatment of tetany consists of correcting the underlying metabolic disorder. In hypomagnesemia, tetany does not respond to correction of the accompanying hypocalcemia unless the magnesium deficit is also corrected.

P.823

NEUROLEPTIC MALIGNANT SYNDROME AND MALIGNANT HYPERTHERMIA

Acute diffuse symptoms of muscle stiffness maybe associated with exposure to neuroleptic medications that inhibit dopamine. The neuroleptic malignant syndrome (NMS) may be dramatic and lifethreatening if not aggressively treated (see also [Chapter 128](#), Neurotoxicology). The syndrome comprises acute alteration of mental status, fever, autonomic dysfunction, and muscle breakdown with high serum levels of creatine kinase (CK). Muscle necrosis may release intracellular potassium and myoglobin into the serum; the resulting hyperkalemia may lead to cardiac arrhythmias and renal failure. An often overlooked cause of sudden dopamine loss with possible similar consequences may occur with abrupt discontinuation of dopaminergic medications used by patients with Parkinson disease. The mainstay treatment of NMS is supportive with body cooling, intravenous fluids, and respiratory support. Dopamine agonists such as bromocriptine (5 to 10 mg three to four times daily) and the potentially hepatotoxic muscle relaxant dantrolene may be helpful (start 25 mg daily, titrate up to 100 mg three to four times daily).

Another syndrome similar to NMS is seen in patients exposed to anesthetic agents causing the malignant hyperthermia syndrome (MHS). The most common offensive agents are the neuromuscular blocking agent succinylcholine and the inhaled general anesthetics like halothane, sevoflurane, and desflurane. High fever is the hallmark of the syndrome, but muscle stiffness, consequences of muscle breakdown (“rhabdomyolysis” or myoglobinuria), and cardiorespiratory collapse are virtually undistinguishable from NMS. Treatment is similar to that of NMS as well. Patients with the rare inherited myopathy central core disease have mutations in the

ryanodine receptor RYR1 and are most susceptible to MHS.

MUSCLE CRAMPS

The common *muscle cramp* is a sudden, forceful, painful muscle contraction that lasts from a few seconds to several minutes. Muscle cramps are most often benign but can also accompany various neuromuscular disorders such as peripheral nerve hyperexcitability syndromes, lower motor neuron disease, medications, and myopathies (metabolic, mitochondrial, or dystrophic).

Epidemiology

Most adults have at least one episode of benign leg cramps during a lifetime, with no significant prevalence difference between men and women. In some populations, such as elderly veterans, up to 50% experience nocturnal leg cramps, as do 30% to 50% of pregnant women, worsening as pregnancy progresses. Most cramps occur only at night (73%), some have both day and nighttime cramps, and a few have daytime-only cramps. In up to 40% of those who have cramps, the attacks occur several times per week, and 6% experience daily cramps. Cramps are common (32%) in children with CMT1A. Frequent cramps tend to accompany hypothyroidism, uremia, profuse sweating or diarrhea, hemodialysis, electrolyte abnormalities, hypoglycemia, and anterior horn cell diseases. Statins and diuretics may provoke cramps as well.

Pathobiology

A cramp often starts with fasciculations, after which the muscle becomes intermittently hard and knot-like as the involuntary contraction waxes and wanes, passing from one part of the muscle to another. Normally, when an a-motor neuron fires, acetylcholine is released into the neuromuscular junction, which then binds to and elicits an action potential in the muscle fiber. This action potential is then translated into contraction by release of calcium from the sarcoplasmic reticulum and the interaction of actin and myosin to cause muscle shortening (twitch or contraction). The process ends when calcium concentration decreases; both muscle contraction and relaxation require adenosine triphosphate. If calcium levels remain elevated, relaxation cannot occur. Stretch of the muscle spindle 1a fiber excites the motor neuron and also causes muscle contraction (monosynaptic muscle stretch reflex). Inhibition occurs within the spinal cord by inhibitory interneurons.

The neuroanatomic origin and propagation of cramps is a topic of ongoing debate, and both peripheral and central mechanisms are invoked. Cramps may result from hyperexcitability of the motor neurons (induced by afferent input) resulting in an autonomous positive feedback loop, implicating a spinal contribution. Cramps can be induced distal to a peripheral nerve block with electrical stimulation, and such cramps can be terminated by stretching the muscle, favoring a nerve terminal site of origin.

Clinical Manifestations

Muscle cramps are experienced as abrupt, painful spasms lasting seconds to minutes. Cramps may be provoked by a trivial movement or by voluntary contraction of a shortened muscle. They may occur during vigorous exercise but are more likely to occur after exercise ceases. Benign fasciculations or myokymia may be associated with frequent muscle cramps in apparently healthy people. The legs and in particular the calves are most often affected by cramps. Nocturnal cramps typically cause forceful flexion of the ankle and toes. However, cramps can affect almost any voluntary muscle.

Most people have cramps at some time, but a few people have inordinately frequent cramps, often accompanied by fasciculations. This syndrome of *benign fasciculations* is disproportionately more frequent among physicians and other medical workers because they are more likely to know the ominous implications of fasciculations for the diagnosis of motor neuron disease. In fact, however, motor neuron disease almost never starts with fasciculations alone. If neither weakness nor wasting is seen, motor neuron disease is essentially excluded. The

syndrome of benign fasciculation has been reported many times with variations on the name.

True cramps must be distinguished from cramp-like muscle pain unaccompanied by spasm. The cramps of McArdle disease (myophosphorylase deficiency) occur during exercise because of the block of glycogen metabolism. Because no electrical activity is evident in the EMG during the painful shortening of muscle affected by McArdle disease, the term *contracture* is used. The origin of the contracture is not known but depletion of adenosine triphosphate in muscle has long been suspected. Muscle breakdown is associated with myoglobinuria and elevated CK values in serum.

Mild dystrophinopathies, with little or no clinical weakness, may be manifested by exertional muscle pain and myoglobinuria. These symptoms have been referred to as *muscle cramps*, but actual muscle spasm has not been described in such cases; the pain may simply be a measure of muscle injury. The dystrophic and nondystrophic myotonic disorders are discussed elsewhere in this textbook.

Myalgia and cramps are believed to be especially common in *myoadenylate deaminase deficiency*, but because this condition is common in asymptomatic people (found in 1% to 3% of all muscle biopsies), the association is difficult to confirm. Moreover, in affected families, the muscle enzyme deficiency and clinical symptoms are not well linked.

P.824

Diagnosis

The diagnosis of the common muscle cramp is essentially based on the clinical history. It is important to exclude underlying medical and neurologic causes for cramps. Routine laboratory testing for electrolytes and other underlying medical disorders can be performed as clinically indicated on a case-by-case basis. Tests may include complete blood cell count, metabolic panel, and CK.

Electrodiagnostic testing is useful in diagnosing an underlying peripheral nerve or muscle disorder, as well as characterizing any abnormal spontaneous muscle activity. EMG of a cramp shows brief, periodic bursts of motor unit potentials discharging at a frequency of 200 to 300 Hz, appearing irregularly, and intermingling with similar discharges from adjacent motor units. Several foci within the same muscle may discharge independently. This electrical activity clearly arises within the lower motor neuron.

Treatment

Passive stretching of the affected muscle usually terminates a cramp. However, a 2010 analysis by the American Academy of Neurology (AAN) found insufficient evidence for nonpharmacologic treatment (such as stretching and hydration) of muscle cramps [Level 1].²

A Cochrane Review in 2010 found that the administration of quinine derivatives at doses of 200 to 500 mg per day were effective, although modestly, with few serious adverse events [Level 1].³ Rare but serious adverse effects of quinine include thrombocytopenia, bleeding diathesis, cardiac arrhythmias, and acute hypersensitivity reactions, which may occur in 2% to 4% of persons treated. Other serious adverse effects include hypoglycemia, vision loss, psychosis, tinnitus, and esophagitis. Given the adverse effect profile, the U.S. Food and Drug Administration (FDA) has issued multiple warnings and both the FDA and AAN recommend against the use of quinine for the routine treatment of muscle cramps. Use of quinine is recommended only when cramps are disabling, not relieved by other agents, and with full patient education and monitoring for possibly serious side effects [Level 1].¹

Despite the frequency of common cramps, no other agents have been sufficiently studied, but agents that may be effective for cramps include vitamin B complex (thiamine 50 mg, cobalamin 250 µg, pyridoxine 30

mg, riboflavin 5 mg), naftidrofuryl (not available in the United States; 100 mg three times daily), and diltiazem (30 mg daily). Other agents commonly used with variable success include baclofen, benzodiazepines, carbamazepine, oxcarbazepine, verapamil, magnesium citrate, and gabapentin; however, evidence is insufficient regarding these agents. For cramps associated with hemodialysis, vitamin E and C may be effective, and zinc sulfate and branched chain amino acids may be helpful in cramps associated with cirrhosis. For cramps occurring in association with ALS, gabapentin and tetrahydrocannabinol are ineffective.

Outcome

The common muscle cramp has a good prognosis, but pain and discomfort can be troublesome. Nocturnal cramps can interrupt sleep.

Metabolic and Mitochondrial Myopathies in Adults

Michio Hirano

Salvatore DiMauro

Lewis P. Rowland

INTRODUCTION

Metabolic myopathies comprise a clinically and etiologically diverse group of disorders due to defects in cellular energy metabolism, including the breakdown of carbohydrates and fatty acids to generate adenosine triphosphate (ATP), predominantly through mitochondrial respiratory chain oxidative phosphorylation. Accordingly, metabolic myopathies can be etiologically classified into three broad categories: glycogen storage diseases (GSDs), fatty acid oxidation (FAO) disorders, and mitochondrial diseases. These metabolic myopathies present with a clinical spectrum ranging from severe infantile-onset multisystemic diseases to mild adult-onset isolated myopathies. In this chapter, we focus on metabolic myopathies that affect adults.

EPIDEMIOLOGY

Metabolic myopathies are rare diseases. The most common of these disorders is Pompe (acid maltase deficiency) disease with variable ethnic and geographic incidence from 1:14,000 births annually in African-Americans to 1:100,000 in people of European descent. Prevalence of late-onset Pompe disease has been estimated to be 1:60,000. Other frequent metabolic myopathies include McArdle disease (myophosphorylase deficiency) and carnitine palmitoyltransferase II (CPT II) deficiency. The prevalence of McArdle disease has been estimated to be 1:100,000 in the Dallas-Fort Worth, Texas region and a minimum of 1:170,000 in Spain. The prevalence of CPT II deficiency is unknown; however, over 300 patients have been reported. Although individual mitochondrial diseases are rare, collectively, the prevalence of mitochondrial disorders in adults is approximately 1:5,000.

PATHOBIOLOGY

Energy in the form of ATP is required to drive numerous cellular functions including muscle contraction. The main fuels used to generate ATP are glycogen, glucose, and free fatty acids (FFAs). Glycogen is metabolized in the cytoplasm to pyruvate, which enters mitochondria (Fig. 95.1). Short-chain and medium-chain fatty acids cross freely into the mitochondria, whereas long-chain fatty acids require binding to carnitine for transport across the mitochondrial membrane, a process mediated by acyl-carnitine translocase and CPTs I and II (Fig. 95.2). Once in the mitochondria, all these substrates are turned into acetyl-coenzyme A (CoA), which feeds into the Krebs cycle. In this critical cycle, reducing equivalents (electrons) combined with protons are bound to intermediate molecules, nicotinamide adenine dinucleotide (NADH) and flavin adenine dinucleotide, reduced (FADH₂), which deliver the electrons to the mitochondrial respiratory chain to produce ATP and water (H₂O).

Defects in any of these pathways—glycogen catabolism (glycogenolysis and glycolysis), fatty acid oxidation, Krebs cycle, and mitochondrial respiratory chain and oxidative phosphorylation—cause human disorders that often predominantly affect muscle due to its high energy requirements, particularly during exercise. Because most of the enzyme defects are partial, many of these diseases manifest in adulthood with muscle symptoms either in isolation or with other clinical features.

Abundant glucose is stored in liver and skeletal muscle in the form of a polysaccharide called *glycogen*. The glycogenoses include disorders characterized by genetic mutations in glycogen synthesis (glyconeogenesis),

degradation (glycogenolysis), or glucose degradation (glycolysis). To date, 15 glycogenoses have been identified (see [Fig. 95.1](#)); most are autosomal recessive except for phosphoglycerate kinase (PGK) and phosphorylase *b* kinase deficiency, which are X-linked.

Fatty acids are the primary energy source for muscle at rest and during periods of prolonged low-intensity exercise. Fatty acids are catabolized by the β -oxidation enzymes, which cleave two-carbon fragments with each cycle. Thus, lipidoses arise due to failure of fatty acid transport into mitochondria secondary to carnitine or CPT I or II deficiencies or to defects of intramitochondrial β -oxidation. These disorders are inherited as autosomal recessive traits. The more severe variants present in infancy or childhood with primary involvement of liver or brain, whereas the milder adult forms are predominantly myopathic and include the myopathic variant of CPT II deficiency, trifunctional protein deficiency (TFP), and very long chain acyl-CoA dehydrogenase deficiency (VLCAD).

In addition to catabolizing lipids, mitochondria perform additional essential functions including Krebs cycle and amino acid metabolism as well as energy production through the respiratory chain and oxidative phosphorylation. The respiratory chain is composed of four multisubunit enzymatic complexes (I, II, III, and IV), which generate a proton gradient across the inner mitochondrial membrane (IMM) that, in turn, drives ATP synthesis by complex V. In addition, CoQ₁₀ and cytochrome *c* are critical components of the mitochondrial respiratory chain, serving as “electron shuttles” between the complexes. Originally restricted to primary defects of the respiratory chain and oxidative phosphorylation, mitochondrial diseases have expanded to encompass defects of mitochondrial transcription, translation, protein importation, lipid membranes, and organellar dynamics (fusion, fission, and movement) (see [Chapter 139](#)).

CLINICAL FEATURES

From a clinical point of view, metabolic myopathies can be categorized into two different groups: (1) those that show symptoms and signs related to exercise (exercise intolerance, cramps, myalgias, myoglobinuria) with normal interictal examination and (2) those with fixed symptoms such as muscle weakness often associated with systemic involvement (such as encephalopathies or endocrinopathies). When evaluating a patient with

P.827

exercise-related symptoms, clinicians should ask two questions: (1) What type of exercise provokes symptoms? (2) Are there associated triggering factors? If short bursts of high-intensity exercise cause muscle cramps or myoglobinuria, the patient may have a defect of glycogen metabolism. Examples of this type of activity include weight lifting or sprinting. In young patients who play baseball or softball, the “home run” sign (Haller sign), inability to sprint around the bases due to exercise-induced muscle spasms, is a typical complaint in patients with glycogenoses, such as McArdle disease. In contrast, if the patient complains that prolonged exercise (such as hiking or playing soccer) triggers myalgias, fatigue, and myoglobinuria without acute contractures, the patient is likely to have a defect of fatty acid oxidation. The symptoms often occur when the patient is fasting or under stress. A prototypical example is a young adult with CPT II deficiency who enlists in military service and has difficulty completing long marches due to fatigue and myalgias followed by myoglobinuria.

FIGURE 95.1 Scheme of glycogen metabolism and glycolysis. *Roman numerals* denote muscle glycogenoses due to defects in the following enzymes: *0*, glycogen synthase; *II*, acid maltase; *III*, debrancher; *IV*, brancher; *V*, myophosphorylase; *VII*, phosphofructokinase; *VIII*, phosphorylase *b* kinase; *IX*, phosphoglycerate kinase; *X*, phosphoglycerate mutase; *XI*, lactate dehydrogenase; *XII*, aldolase; *XIII*, β -enolase; *XIV*, phosphoglucomutase 1; and *XV*, glycogenin-1. *Red numerals* designate glycogenoses associated with exercise intolerance, cramps, and myoglobinuria. *Blue italic numerals* correspond to glycogenoses causing weakness.

In the past, the term *myoglobinuria* was reserved for grossly pigmented urine, but modern techniques can detect amounts of this protein so minute that discoloration may not be evident. (Determination of serum myoglobin content by radioimmunoassay has similar diagnostic significance as measurement of serum creatine kinase [CK] activity.) The clinically important syndromes, however, are associated with gross pigmenturia. Numerous conditions cause myoglobinuria ([Table 95.1](#)). Sometimes, the disorder can be recognized without direct demonstration of myoglobin in the urine: For instance, acute renal failure in a patient with levels of serum CK activity over 1,000 units would suggest myoglobinuric renal failure. Inexplicably, the cumbersome neologism *rhabdomyolysis* was favored for a few years, but a 2015 Medline search found that “myoglobinuria” is holding

fast. Myoglobin is the visible pigment in the urine, and it is a toxin that injures the kidney; the syndrome originates with muscle necrosis, which does not need a new name.

Some patients with glycolytic, lipid, or mitochondrial disorders can develop isolated progressive myopathy and persistent weakness. More typically, patients with mitochondrial diseases can show a wide range of extramuscular manifestations. In this section, general clinical aspects of these metabolic myopathies with emphasis on the more common forms are described.

DISORDERS OF GLYCOGEN METABOLISM (GLYCOGENOSES)

Clinical presentations of muscle glycogenoses are protean, ranging from profound multisystem disease in infancy to exercise intolerance or isolated progressive muscle weakness in adults. Here, we focus on the adult patients. Myophosphorylase deficiency (McArdle disease, glycogenosis type V) is a prototypical

P.828

glycogenolytic disorder with episodic muscle dysfunction and myoglobinuria. It is the most common disorder of skeletal muscle carbohydrate metabolism and one of most frequent genetic myopathies. Patients with McArdle disease typically exhibit intolerance to static or isometric muscle contractions and also to dynamic exercise that can trigger episodes of reversible “muscle crises.” Acute crises manifest mainly in the form of premature fatigue and contractures, frequently accompanied by muscle breakdown (rhabdomyolysis) with elevated serum CK and sometimes by myoglobinuria. In addition to McArdle disease, five other forms of glycogenoses manifest exercise-induced myoglobinuria: type VII (phosphofructokinase [PFK] deficiency, Tarui disease), type VIII (phosphorylase *b* kinase), type IX (PGK deficiency), type X (phosphoglycerate mutase [PGAM] deficiency), type XI (lactate dehydrogenase deficiency), and type XIV (phosphoglucomutase 1 deficiency).

FIGURE 95.2 Schematic representation of mitochondrial metabolism. CPT, carnitine palmitoyltransferase; TFP,

trifunctional enzyme; VLCAD, very long chain acyl-CoA dehydrogenase; PDHC, pyruvate dehydrogenase complex; CoA, coenzyme A; ETF ox and red, electron transfer flavoprotein oxidized and reduced; NADH, nicotinamide adenine dinucleotide; FADH₂, flavin adenine dinucleotide, reduced; ETF DH, electron transfer flavoprotein dehydrogenase; CoQ, coenzyme Q; Cyt c, cytochrome c.

Another important sign considered pathognomonic is the “second wind,” which is a marked improvement in exercise tolerance about 10 minutes into aerobic exercise involving large muscle masses (jogging or cycling). The second wind, as manifested by a marked decrease in early exertional tachycardia (e.g., a decrease from ~140 to 150 beats per minute to ~120 beats per minute) starting after around 7 minutes of exercise, does not occur in patients with other disorders that are also associated with exercise intolerance, such as PFK deficiency and other glycogenoses, mitochondrial myopathies, or disorders of lipid metabolism. This phenomenon is due to increased uptake of glucose and use of fatty acid.

Hemolytic anemia (elevated indirect bilirubin and reticulocytes) is seen in glycogenosis due to defects in genes partially expressed in erythrocytes such as PFK, PGK, and aldolase A. Cognitive deficits are often associated with the adult polyglucosan body disease (APBD) form of branching enzyme deficiency (type IV) and PGK deficiency.

Acid maltase or acid α -glucosidase (GAA) is an enzyme responsible for the catabolism of glycogen within lysosomes. Infantile-onset acid maltase deficiency (type II, Pompe disease) presents as a myopathy and cardiomyopathy, which, if untreated, is typically fatal in the first year of life. In contrast, in the late-onset form of Pompe disease beginning in childhood through adulthood, patients have slowly progressive fixed proximal muscle weakness and early respiratory insufficiency. Although myopathy is the predominant manifestation, patients with Pompe disease also develop basilar

P.829

P.830

artery and aortic aneurysms, bladder or bowel incontinence, and dysphagia. An autopsy study of a late-onset Pompe patient revealed ultrastructural abnormalities in the smooth muscle of blood vessels, gastrointestinal tract, and bladder, thereby accounting for the extraskeletal muscle manifestations. Hearing loss has also been reported in this disease. It is important to diagnose Pompe disease, as enzyme replacement therapy with recombinant human GAA (rhGAA) dramatically improves the cardiomyopathy in the infantile form and less effectively improves the myopathy in both infantile and late-onset forms.

TABLE 95.1 Classification of Human Myoglobinuria

Hereditary Myoglobinuria

Disorders of Glycogen Metabolism

Alcoholic myopathy

Polymyositis or dermatomyositis

Cause unknown

CMV, cytomegalovirus.

In other cases such as debrancher deficiency (type III, Cori-Forbes disease), distal muscle weakness can be combined with cardiomyopathy and peripheral neuropathy in patients who had shown in infancy hepatomegaly, hypoglycemia, and failure to thrive, all of which usually improve around puberty. Thus, adult patients with debrancher deficiency can manifest distal muscle weakness and wasting with electromyographic myogenic and neurogenic abnormalities. Branching enzyme deficiency (type IV) presents with heterogeneous phenotypes ranging from congenital or infantile neuromuscular disorders to late-onset APBD, which manifests as progressive upper and lower motor neuron dysfunction, stocking-glove sensory loss, bladder dysfunction, and dementia. Muscle and nerve biopsies of APBD patients reveal periodic acid-Schiff (PAS)—positive but diastase-resistant polyglucosan bodies. Although reported in various ethnic groups, APBD is particularly frequent in the Ashkenazi Jewish population due to founder mutations. Polyglucosan bodies are also characteristic of a juvenile-onset myopathy often accompanied by cardiomyopathy due to mutations in *RBCK1*, which encodes a ubiquitin ligase. Striking absence of glycogen is characteristic of two disorders: glycogenosis type 0, glycogen synthase (GS1) deficiency, and glycogenosis type XV, glycogenin-1 deficiency. Both enzymes are required for the synthesis of glycogen. GS1 deficiency has presented as childhood exercise intolerance, cardiomyopathy, sudden death, or cardiomyopathy and myopathy. Glycogenin-1 deficiency has been described in one adult patient with myopathy and cardiac arrhythmias as well as in seven other adult patients with childhood or adult onset myopathy with polyglucosan bodies but without cardiopathy.

DISORDERS OF LIPID METABOLISM

Since DiMauro and DiMauro-Melis described the first patients with CPT II deficiency, this disease has been the most frequently diagnosed disorder of lipid metabolism. The first symptoms most often occur between 6 and 20 years of age, but age at onset may be older than 50 years. The symptomatology usually consists of recurrent attacks of myalgias and muscle stiffness or weakness, often associated with myoglobinuria. The duration of the attacks are usually acute and the consequences may be prolonged up to several weeks. The patients are usually asymptomatic between attacks. The frequency of these attacks is highly variable. The rhabdomyolysis may occasionally be complicated by two types of lifethreatening events: more commonly, acute renal failure secondary to myoglobinuria and, much less frequently, respiratory insufficiency secondary to respiratory muscle involvement. Symptoms are usually prompted by prolonged exercise and less commonly by prolonged fasting, high-fat intake, exposure to cold, mild infection (especially in children), fever, emotional stress, general

anesthesia, or drugs such as diazepam or ibuprofen. In all cases, the clinical symptomatology is restricted to skeletal muscle without liver or heart involvement.

Defects of most β -oxidation enzymes typically manifest in infancy with severe multisystem disease; however, the clinical presentation of VLCAD deficiency may be indistinguishable from CPT II deficiency. Trifunctional enzyme catalyzes three steps in longchain fatty acid β -oxidation: enoyl-CoA hydratase, long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD), and acylthiolase (see Fig. 95.2). Adults with trifunctional protein (TFP) deficiency present with recurrent rhabdomyolysis triggered by prolonged exercise, fasting, or infections similar to CPT II and VLCAD deficiencies; however, TFP mutations are often associated with peripheral neuropathy and pigmentary retinopathy.

Multiple acyl-CoA dehydrogenation deficiency (MADD), also known as *glutaric aciduria type II* (GA II), is an autosomal recessive disorder due to mutations in genes encoding either one of the two subunits of the electron transferring flavoprotein (*ETF A* and *ETF B*) or to mutations in the gene encoding the electron transfer flavoprotein dehydrogenase (*ETF DH*) and resulting in abnormal fatty acid, amino acid, and choline metabolism. Less severely affected patients might present with progressive muscle weakness and lipid storage myopathies with secondary muscle CoQ₁₀ deficiency, mainly in adulthood and are sometimes responsive to riboflavin treatment (riboflavin responsive MADD), CoQ₁₀ supplementation, or both.

The myopathic form of coenzyme Q₁₀ (CoQ₁₀) deficiency is characterized by proximal myopathy with premature fatigue, weakness, and increased serum levels of CK and lactate. Muscle biopsies show excessive numbers of lipid droplets, predominantly in type 1 fibers, combined deficiency of respiratory chain complexes I and III, and CoQ₁₀ levels below 50% of normal. Mutations in the *ETF DH* gene, leading to a decrement in complex electron transfer flavoprotein-ubiquinone oxidoreductase (ETF:QO) activity have been identified in adult-onset MADD and some cases of myopathy with CoQ₁₀ deficiency indicating that they can be allelic diseases.

Neutral lipid storage disease (NLS) present with mild to moderate proximal limb weakness with striking accumulation of lipid in skeletal muscle and other tissues as well as in leukocytes (Jordan anomaly). CK is persistently elevated and has preceded weakness. Mutations in *PNPLA2* encoding adipocyte triglyceride lipase (ATGL) cause neutral lipid storage myopathy, whereas mutations in *ABHD5*, which encodes CGI-58 (activator of ATGL), cause lipid storage myopathy with ichthyosis (Chanarin-Dorfman syndrome).

MITOCHONDRIAL DISEASES

Although mitochondrial diseases frequently present as infantile- or childhood-onset multisystemic diseases, many adult patients have myopathy as the predominant or only manifestation with either fixed weakness, exercise intolerance, or both. Myoglobinuria is less common in respiratory chain oxidative phosphorylation disorders relative to other metabolic myopathies.

Like most myopathies, mitochondrial myopathies cause proximal limb weakness, but extraocular muscles are also frequently affected, leading to ptosis and chronic progressive external ophthalmoplegia (CPEO). CPEO begins in childhood or adulthood and typically manifests with symmetric and slowly progressive impairment of eye movements accompanied by ptosis. Occasionally, the extraocular muscle weakness can be strikingly asymmetric. CPEO is sometimes misdiagnosed as myasthenia gravis; however, fixed weakness with minimal or no fluctuations, absence of acetylcholine receptor and muscle specific tyrosine kinase (MUSK) antibodies, as well as absence of neuromuscular junction dysfunction on electrophysiologic studies should lead clinicians to screen for myopathies such as CPEO.

CPEO often remains a pure myopathy with limb weakness and variable dysphagia and respiratory muscle involvement. In contrast, CPEO can be part of a multisystemic disease such as Kearns-Sayre syndrome (KSS) or

sensory ataxic neuropathy dysarthria ophthalmoplegia (SANDO) (see [Chapter 139](#)). Some individuals are classified as CPEO-plus because they develop additional neurologic manifestations but lack features to fulfill criteria for KSS, SANDO, or other defined clinical syndromes. CPEO can be due to maternally inherited mitochondrial DNA (mtDNA) point mutations, sporadic single large-scale deletions of mtDNA, or primary autosomal dominant or recessive mutations that cause secondary multiple deletions of mtDNA.

In patients with mitochondrial myopathies, exercise intolerance presents with premature fatigue with activities as mild as walking up a single flight of stairs. After a short rest, patients usually can resume their activity but symptoms recur. Mitochondrial disease patients often report subjective heaviness or burning of muscles with exertion but, in contrast to patients with glycogenoses, do not typically manifest stiffness, cramps, or second wind phenomenon. The exercise intolerance is often disproportionately severe relative to muscle weakness. This symptom can be isolated or associated with muscle weakness and multisystemic involvement. Exercise testing is particularly helpful as an evaluation and screening tool in mitochondrial myopathies. Elevated lactate levels at rest and exaggerated lactate responses after even trivial exercise are useful clues to the diagnosis of mitochondrial disease. One of the hallmarks of mitochondrial myopathies is a reduction in maximal whole body oxygen consumption ($\text{VO}_2 \text{ max}$) demonstrated by a characteristic deficit in peripheral oxygen extraction (A to V O_2 difference) and an enhanced oxygen delivery (hyperkinetic circulation). Alternatively, in specialized referral centers, ^{31}P nuclear magnetic resonance (NMR) spectroscopy can reveal decreased basal levels of high-energy phosphate compounds (e.g., ATP and phosphocreatine [P-Cr]) at rest or prolonged recovery of ATP and P-Cr after exercise in patients with mitochondrial myopathies.

An unusual group of mitochondrial disease patients present with sporadic isolated myopathies with exercise intolerance variably accompanied by proximal muscle weakness and myoglobinuria. It is important for clinicians to be aware of this condition, which in several cases, was misdiagnosed as chronic fatigue syndrome or fibromyalgia. Resting venous lactic acid is elevated in most patients with this condition; therefore, blood lactate is a useful noninvasive screening test for this syndrome. In most cases, muscle biopsies reveal ragged-red fibers that are cytochrome *c* oxidase (COX)-positive because the gene defect is often a mutation in the cytochrome *b* gene, which encodes a subunit of complex III, or in an ND gene, encoding a subunit of complex I. In addition, other mutations in mtDNA have been associated with exercise intolerance, including transfer RNA (tRNA) mutations as well as mutations in protein coding genes for subunits of respiratory chain complex I or IV. Because the mutations are not detectable in blood in most of these patients, muscle biopsy is generally required to make the diagnosis.

A rare clinical form of CoQ₁₀ deficiency presents as encephalomyopathy in childhood with the triad of encephalopathy (seizures, mental retardation, or ataxia), muscle weakness often with myoglobinuria, and ragged-red fibers in muscle. Patients have been diagnosed in adolescence or adulthood and have improved with CoQ₁₀ supplementation.

A rare childhood-onset mitochondrial myopathy has been identified in Northern Swedish patients who have exercise intolerance. In these patients, modest exercise triggers fatigue, tachycardia, shortness of breath, and myoglobinuria due to a founder splice site mutation in *ISCU*, which encodes the iron-sulfur (Fe-S) scaffold protein required by Fe-S subunit containing enzymes such as aconitase and complexes I, II, and III of the mitochondrial respiratory chain.

DIAGNOSIS

The diagnosis of glycogenosis should be considered in patients with recurrent myoglobinuria triggered by brief intense exercise. Presence of the “second wind” is indicative of McArdle disease (myophosphorylase

deficiency), whereas in adults, signs of hemolytic anemia with elevated uric acid (and occasionally gout) is suggestive of PFK or PGK deficiency in adults. The specific glycolytic defect can be identified by sequencing blood DNA or by measuring biochemical activity of seven glycolytic enzymes (myophosphorylase, PFK, phosphorylase *b* kinase, phosphoglycerate kinase, PGAM, lactate dehydrogenase, and phosphoglucomutase 1). In patients with limb weakness, early respiratory muscle involvement, and EMG evidence of prominent spontaneous activity of paraspinal muscles, the diagnosis of Pompe disease should be considered. A dried blood spot test can detect acid maltase deficiency. Definitive diagnosis is made by sequencing *GAA* in blood or by a muscle biopsy showing increased membrane-bound glycogen with markedly reduced acid maltase activity. Debrancher enzyme deficiency should be considered in patients with fixed distal greater than proximal limb weakness with EMG myogenic and neurogenic abnormalities and visceral organ involvement. Branching enzyme deficiency is clinically recognizable by the combination of upper and lower motor neuron dysfunction, sensorimotor neuropathy, sphincter dysfunction, and dementia. Both debrancher and branching enzyme deficiencies can be diagnosed by DNA sequencing. In many cases, muscle histology showing excessive free glycogen lead to the diagnosis of debrancher deficiency, whereas detection of polyglucosan bodies is indicative of APBD. Detecting biochemical defects of muscle debrancher or branching enzyme is diagnostic, particularly in cases when DNA sequencing reveals variants of uncertain significance.

In patients with recurrent myoglobinuria triggered by prolonged exercise, fasting, or both, defects of fatty acid oxidation should be considered. Acylcarnitine profile may reveal elevated acylcarnitines (e.g., long-chain acylcarnitines in CPT II and VLCAD deficiencies) particularly after overnight fasting; however, the profiles are often normal. The diagnosis can be made by blood DNA testing. CPT II activity can be measured in skeletal muscle or cultured fibroblasts.

In patients with suspected mitochondrial myopathy, measurement of free-flowing blood lactate and pyruvate can be useful; elevated resting lactate especially when the lactate-to-pyruvate ratio is high (i.e., >20:1) is indicative of a mitochondrial respiratory chain oxidative phosphorylation defect. In patients with evidence of maternal inheritance, whole mtDNA sequencing offers a cost-effective approach to identifying mtDNA point mutations. Individuals with sporadic CPEO, CPEO-plus, or KSS should be screened for single large-scale mtDNA deletions, which are usually undetectable in blood and occasionally identified in urine sediment but most reliably detected in muscle biopsies. In patients with autosomal CPEO, CPEO-plus, and SANDO, sequencing of nuclear genes, particularly *POLG* encoding the mtDNA polymerase catalytic subunit, can reveal the causative mutation(s). If blood and urine DNA screening

P.832

is negative or ambiguous, muscle biopsy for histology, measurement of mitochondrial respiratory chain activities, and potential molecular genetic testing (e.g., screening for mtDNA deletions or depletion) are often useful.

Although not a metabolic disorder, mutations in *RYR1* encoding the skeletal muscle ryanodine receptor are frequent causes of recurrent exercise-induced myoglobinuria. Heat, and to a lesser degree, viral infections, alcohol, and drugs can trigger episodes of myoglobinuria.

TREATMENT

Treatment of metabolic myopathies is limited. Enzyme replacement therapy for Pompe disease is the only disease-modifying therapy; however, efficacy is limited in adults. There is Level 1 evidence of mild beneficial effects of enzyme replacement therapy on respiratory function and ambulation in patients with late-onset Pompe disease [Level 1].¹ Avoidance of precipitating factors (e.g., intense exercise in patients

with myoglobinuria due to glycogenesis) is critical.

Glucose or sucrose intake before exercise exacerbates muscle's symptoms (out-of-wind phenomenon) in PFK deficiency where the metabolic block occurs below the entry of glucose into glycolysis, whereas in McArdle disease, sugar intake ameliorates symptoms because the metabolic block is upstream of glucose catabolism. In other cases, such as PGAM or PFK deficiencies, this intervention does not produce changes in the exercise performance.

In patients with FAO disorders, a carbohydrate-rich diet and avoidance of fasting is often beneficial. In patients with CPT II, VLCAD, and TP deficiencies, supplementation with medium-chain triglycerides can be beneficial.

For patients with mitochondrial myopathies, symptomatic therapy is important. Patients with severe ptosis that impairs vision, eyelid crutches, or eyelid slings can be beneficial. Screening for heart block in patients with KSS or CPEO is important, as timely placement of a pacemaker can be lifesaving. Aerobic exercise training improves oxidative capacity in patients with heteroplasmic mtDNA mutations.

OUTCOME

The long-term prognosis of patients with metabolic myopathies due to defects of glycogen or lipid metabolism is generally favorable. In patients with severe myoglobinuria, compartment syndrome and renal failure are serious complications that must be treated aggressively. In patients with recurrent myoglobinuria due to myophosphorylase or PFK deficiency, moderate fixed weakness often develops late in life. In contrast, patients with late-onset Pompe disease can develop severe restrictive lung disease that is amenable to continuous positive airway pressure (CPAP) and bilevel positive airway pressure (BiPAP) support.

The prognosis for patients with mitochondrial myopathies is variable. Patients with CPEO can have a very benign outcome with moderate to severe extraocular weakness as the main problem; however, some patients with CPEO have developed symptomatic dysphagia, restrictive lung disease, and marked limb weakness. Patients with KSS, SANDO, and other multisystemic mitochondrial diseases frequently progress and can develop severe encephalopathies and in the case of KSS, severe cardiomyopathy or visceral organ dysfunction that can be fatal in early to mid-adulthood.

Gliomas

Mikael L. Rinne

Patrick Y. Wen

INTRODUCTION

Gliomas are a group of primary central nervous system (CNS) neuroepithelial tumors that appear to arise from glial progenitor cells in the brain or spinal cord. Based on their resemblance to glial lineages, gliomas have been classified into different tumor types, including astrocytomas, oligodendrogliomas, mixed oligoastrocytomas, ependymomas, and several less common types of glioneuronal tumors. Gliomas are the most common type of tumor arising in the brain. Because they rarely metastasize outside of the CNS, gliomas are not staged like systemic malignancies. Instead, gliomas are graded based on histopathologic features that predict aggressiveness; tumors with malignant features are often referred to as *high-grade gliomas* (HGGs), in contrast to “low-grade” gliomas (LGGs), which in spite of their more benign histologic appearance, are not clinically benign. The location and invasiveness of most LGGs that occur in adults often makes them difficult to completely resect, leading to recurrent disease, as well as significant morbidity and mortality. The lowest grade gliomas (such as pilocytic astrocytomas) are an exception and are often surgically curable but they rarely occur in adults.

EPIDEMIOLOGY

Gliomas are relatively rare tumors with an estimated annual incidence of 4.67 to 6.02 per 100,000 persons. HGGs have an increasing incidence with age and are significantly more common than their low-grade counterparts, which appear more frequently in young adults. In general, the incidence of gliomas is higher in men than in women and in non-Hispanic whites than in blacks, Hispanics, Asians, or Native Americans.

There are very few known risk factors for the development of glioma, and no preventative measures or lifestyle changes are known to decrease an individual's risk. Several rare genetic tumor predisposition syndromes are associated with increased glioma incidence, including the neurofibromatoses, tuberous sclerosis, Cowden, Li-Fraumeni, and Turcot syndromes. Exposure to ionizing radiation is the only established environmental risk factor that can lead to glioma development. Frequent concerns about head injury, pesticides, occupational exposures, and foods containing N-nitroso compounds or aspartame appear to be unfounded or at least unproven. Although there has been concern about cell phones and other electromagnetic fields, existing evidence is conflicting and often limited by confounding recall bias and other shortcomings of retrospective study design. To date, there is no convincing evidence that cell phone use increases the risk of brain tumors, although studies continue.

CLINICAL FEATURES

Like patients with brain metastases, patients with gliomas present with diverse nonspecific clinical symptoms and signs that are related to tumor location, size, and growth rate rather than tumor type, except perhaps seizures which may be more common from oligodendrogliomas. Focal symptoms such as hemiparesis, aphasia, ataxia, visual field deficits, or cranial neuropathies result from localized invasion or compression of critical brain structures, whereas generalized symptoms such as headache, vomiting, lethargy, and confusion tend to be the result of increased intracranial pressure from tumor mass, edema, or hydrocephalus. Seizures resulting from an underlying glioma invariably begin focally but may rapidly generalize, making it difficult to recognize their partial onset. Although seizures or symptoms from hemorrhage appear suddenly, most other symptoms produced by gliomas present subacutely over days to weeks. HGGs tend to present with more rapidly progressive focal or generalized symptoms, whereas LGGs frequently precipitate seizures without progressive neurologic deficits. Depending on location, even large tumors can produce surprisingly few symptoms, as in the case of LGGs, to which the brain can gradually adapt. Consequently, an apparently normal neurologic exam cannot rule out an underlying glioma, and a thorough history and physical exam must be coupled with a high degree of clinical suspicion in order to know when to consider the diagnosis and obtain neuroimaging.

DIAGNOSIS

Brain or spinal cord magnetic resonance imaging (MRI) with and without gadolinium contrast is the imaging modality of choice when a CNS tumor is suspected. MRI provides superior resolution and tissue characterization compared to computed tomography (CT) scanning and has become an integral part of tumor diagnosis, treatment planning, surveillance, and therapeutic monitoring. MRI sequences required for adequate tumor characterization include T2/fluid-attenuated inversion recovery (FLAIR) and T1 pre- and post-gadolinium contrast-enhanced images. High-resolution threedimensional (3D) T1-weighted sequences allow improved visualization in multiple orientations and are often used in presurgical planning and subsequent monitoring. Additional useful imaging includes diffusion-weighted images (DWI) with apparent diffusion coefficient (ADC) maps, as well as susceptibility-weighted images (SWI).

Gliomas generally appear as infiltrating, poorly defined white matter lesions that are hyperintense on T2/FLAIR and hypointense on T1-weighted images. Gliomas predominantly arise in the cerebral hemispheres, although brain stem and cerebellar locations are

P.835

common in children. Although there are exceptions, most LGGs in adults tend to be infiltrative and nonenhancing with mild to moderate mass effect, whereas HGGs are more often heterogeneously enhancing, frequently with regions of necrosis and marked surrounding T2/FLAIR hyperintense edema contributing to more significant mass effect. Gadolinium enhancement is the result of contrast leakage from abnormal tumor vessels, and although the extent of enhancement does not always correlate with degree of malignancy, the development of new contrast enhancement can signal transformation to higher grade. It is important to remember that the area of enhancement does not define the extent of the tumor, particularly in invasive gliomas. Because of their abnormal vasculature, various tumor types, including HGGs can present with hemorrhage. For this reason, it is important to obtain delayed follow-up imaging in any patient presenting with an unexplained intracerebral hemorrhage. Similarly, although restricted diffusion on MRI is often equated with infarction or abscess, hypercellular gliomas can similarly restrict water diffusion. This finding can lead to some confusion about the diagnosis, although gliomas tend to spare cortical gray matter and do not remain confined to a single vascular territory.

In recent years, advanced imaging techniques have been developed to improve diagnostic capability and surgical planning for glioma patients. Many of these techniques aim to move beyond anatomic characterization in order to gain greater insights into tumor biology. Some of the techniques being studied for their use in glioma include magnetic resonance (MR) diffusion tensor imaging, MR perfusion, MR spectroscopy, and positron emission tomography (PET)/CT.

PATHOBIOLOGY

The diagnosis of a glioma is made based on histopathologic appearance under light microscopy, occasionally aided by immunohistochemistry and specific molecular testing. Morphologic similarity to normal glial cells is used to assign tumors to particular glioma subtypes, including astrocytoma, oligodendroglioma, mixed oligoastrocytoma, ependymoma, and glioneuronal tumors. Within each of these tumor types, the presence or absence of specific anaplastic features is used to infer tumor behavior and growth rate and to assign tumors to pathologic grades, with implications for prognosis and treatment. Some of the features that determine tumor grade include cellular atypia, anaplasia, mitotic activity, endothelial proliferation, and necrosis. Gliomas are graded using the World Health Organization (WHO) classification system that includes grades I to IV. WHO grades I and II are considered low-grade tumors, whereas WHO grades III and IV are considered high-grade, malignant tumors. Based on their pathologic appearance, LGGs have occasionally been referred to as *benign*; however, this term is a misnomer, as the clinical course of LGGs in adults almost always includes recurrence and progression to higher grade malignancy and death (except the lowest grade tumors such as pilocytic astrocytomas described further in the following text).

Glioma grade is determined by the highest grade features identified, even if those features are restricted to a small region within the tumor. Because of the location and marked heterogeneity of many gliomas, there is a risk of sampling error and undergrading, particularly when the diagnosis is made based on a stereotactic biopsy.

A rapidly increasing understanding of the molecular pathogenesis of gliomas has the potential to improve diagnosis and lead to the discovery of more effective treatments. Currently, there are a number of molecular biomarkers used to assist in establishing the diagnosis, estimating prognosis, and predicting treatment responsiveness in several glioma subtypes. Numerous additional molecular features are being studied as markers or potential targets of molecularly directed therapeutics in an attempt to improve glioma treatment.

TREATMENT

There are a number of challenges that clinicians face in the treatment of gliomas, including the location of tumors in the CNS, the tendency of gliomas to infiltrate surrounding brain or spinal cord, the potential for even low-grade tumors to transform to higher grade malignancies with aggressive behavior, the pathologic and molecular heterogeneity of many gliomas, and the ever-present blood-brain barrier that can make it difficult for systemic therapies to reach infiltrating tumor cells. Depending on the individual glioma subtype, treatment can involve any of several approaches, including surgery, radiation, and chemotherapy, in addition to medical management and close clinical and radiographic monitoring.

SURGERY

Surgical options in the management of glioma include stereotactic biopsy, subtotal resection, or more extensive surgery with attempts at gross total resection. Because of the location and invasiveness of many gliomas, complete surgical resection is often unachievable. Unfortunately, in addition, even when all visible tumors can be excised, viable microscopic glioma cells generally remain and eventually regrow. Therefore, except in cases of certain WHO grade I gliomas, where gross total resection can be curative, surgery alone is generally inadequate to serve as definitive therapy in the management of gliomas. Still, determining the extent of resection is an important consideration in the approach to glioma treatment. Because of feasibility, it has been difficult to conduct prospective randomized trials to determine whether there is a survival benefit from more extensive surgical resection. However, existing retrospective evidence and post hoc subset analyses of prospectively conducted studies support maximal safe resection and demonstrate a survival advantage with gross or near-gross total resection over biopsy. Of course, retrospective surgical data can be confounded by selection bias, as there is some evidence that tumors amenable to more extensive resection may have a more favorable prognosis independent of the extent of their resection. Still, in most cases, maximal safe resection is the goal, where the extent of resection is balanced with preservation of neurologic function. Because many gliomas can be difficult to distinguish from surrounding normal brain, intraoperative assessments of resection are often inaccurate, and the extent of resection should be measured by a postoperative MRI within 72 hours of the procedure. Functional magnetic resonance imaging (fMRI), intraoperative mapping, and the emerging use of intraoperative imaging can enable more extensive resection, particularly when tumors occupy eloquent brain regions. Even in the case of partial resection, surgery can often improve neurologic function, reduce symptoms and mass effect, and decrease corticosteroid requirements. In addition, because tissue obtained at surgery is important not only for diagnosis but also for molecular and clinical trial testing, subtotal resection can be a reasonable approach in many cases. In those cases where no significant resection can be achieved because of tumor location, a stereotactic biopsy should be performed in order to establish the diagnosis, although the limited amount of tissue obtained may preclude molecular

P.836

characterization. In the end, the major objectives of surgery for most gliomas are to obtain adequate tissue for an accurate histologic diagnosis, to reduce mass effect when necessary, and if possible, to remove as much of the tumor as can be safely resected. Following surgery for many glioma subtypes, radiation and chemotherapy can serve as important adjuncts, although the optimal timing and dose may vary.

RADIATION THERAPY

Radiation therapy (RT) induces DNA strand breaks either directly (in the case of particle therapy) or indirectly through the production of reactive oxygen free radicals (in the case of photon therapy). Cells undergoing mitosis are more sensitive to the damaging effects of RT, and cancer cells are targeted by virtue of their rapid division and impaired DNA repair mechanisms. RT is generally delivered in repeated doses known as *fractions* in order to allow normal cells to repair sublethal damage. The radiation tolerance of the CNS is primarily influenced by the dose per fraction, and

radiation side effects in the late-reacting CNS tend to appear months to years after RT is completed. Most RT for glioma involves fractionated external beam photon (x-ray) therapy generated by linear accelerators. Treatment involves delivery of radiation beams from several directions converging on the treatment area of interest. Dose varies depending on the tumor type, but fractions of 1.8 to 2 Gy are typically delivered to a total dose of 40 to 60 Gy. RT planning involves targeting the T2/FLAIR-defined glioma volume plus a 1.5- to 2-cm margin for subclinical infiltrative disease and a small volume for uncertainties in planning or treatment delivery.

A number of RT techniques improve the ability to more precisely target tumor while sparing normal surrounding brain tissue with the intent of minimizing toxicity. Intensity-modulated radiation therapy (IMRT), together with 3D conformal planning, allows for delivery of RT that better conforms to the contours of the intended treatment area. Single fraction stereotactic radiosurgery (SRS) or radiotherapy (SRT) given in a few fractions, involves the use of many focused radiation beams to target a small, well-defined area while delivering minimal dose to surrounding structures. Because of its small well-defined target volume, SRS/SRT is not ideal for most infiltrating gliomas and is not used routinely for initial radiotherapy, although it is occasionally used for focal recurrences. Proton beam RT is a particle-based therapy whose advantage is the delivery of ionizing radiation at a defined target depth while sparing tissue both superficial and deep to the target. Because of limited availability and waiting time, proton therapy is generally reserved for pediatric patients with low-grade tumors who are likely to benefit most from decreased risk of long-term side effects following RT to a developing brain. In spite of high-dose focal RT, most gliomas eventually recur at the original site of treatment, suggesting persistence of residual disease. Unfortunately, efforts to increase RT dose and to develop RT sensitizers have been unsuccessful to date. Reirradiation carries an increased risk of neurotoxicity and radiation necrosis, although it can be considered when tumor growth occurs outside of the prior radiation field or when substantial time has elapsed since the prior treatment.

CHEMOTHERAPY

Because of the infiltrative nature of glial neoplasms, microscopic cancer cells extend beyond the area of MRI abnormality. Local therapy with surgery and RT are often not enough to prevent tumor recurrence, and systemic therapy is generally required. Numerous chemotherapeutic agents have been used in the treatment of both LGGs and HGGs, including alkylating agents, antimetabolites, topoisomerase inhibitors, and taxanes, to name a few. Most traditional chemotherapeutics work by inducing DNA damage or blocking DNA replication, with the greatest effect seen in rapidly dividing cells. Unfortunately, very few drugs have been proven to be effective in the treatment of gliomas. Alkylating agents such as the nitrosoureas and temozolomide have been the most successful agents in the treatment of glioma and remain a mainstay of current therapy ([Table 96.1](#)).

More recently, molecularly targeted agents have been developed in an attempt to inhibit glioma growth. Bevacizumab is a humanized monoclonal antibody that binds vascular endothelial growth factor (VEGF) preventing activation of VEGF receptors (VEGFRs), one of the major signals used by tumors to recruit new blood vessels. In highly vascular HGGs, bevacizumab has been shown to normalize abnormal tumor vessels and improve enhancement, mass effect, and edema. Bevacizumab is used in the treatment of recurrent HGGs and occasionally newly diagnosed HGGs in select circumstances, although its ultimate benefits and role are still being defined. A large number of other molecularly targeted agents are being tested in clinical trials with gliomas. Significant preclinical research and clinical trial work aimed at identifying effective treatments for glioma are ongoing.

ASTROCYTOMAS

PILOCYTIC ASTROCYTOMA

Definition and Epidemiology

Pilocytic astrocytomas are relatively well-circumscribed World Health Organization (WHO) grade I astrocytic gliomas that primarily occur in children and young adults. Pilocytic astrocytomas make up 5% to 6% of all gliomas and are the most common glioma in children but only rarely appear in older adults. They exhibit slow indolent growth, and unlike most other LGGs, can often be cured with complete resection. Pilocytic astrocytomas are associated with neurofibromatosis type I where they are estimated to occur in 15% to 20% of patients.

Clinical and Imaging Features

Pilocytic astrocytomas can occur anywhere in the neuraxis, although they most frequently arise in the cerebellum. They also have a predilection for the anterior optic pathway, particularly in NF1, where they display an even more indolent course than sporadic tumors. In fact, optic pathway pilocytic astrocytomas are so characteristic of NF1 that any child diagnosed with this tumor should be evaluated for NF1. Pilocytic astrocytomas present insidiously with symptoms related to their location. Infratentorial tumors often present with progressive headache, nausea, and vomiting related to hydrocephalus, whereas optic pathway tumors present with progressive visual loss or proptosis. Seizures are an uncommon presentation, as these tumors rarely involve cerebral cortex. On MRI, pilocytic astrocytomas appear well-circumscribed with bright contrast enhancement and frequent cyst formation. Despite their defined border, pilocytic astrocytomas do not have a true capsule, and although they are considered noninvasive, they often microscopically infiltrate surrounding brain parenchyma.

Pilocytic astrocytomas generally maintain their WHO grade I status for years and only rarely undergo malignant transformation. Approximately 60% to 80% of sporadic non-NF1-associated pilocytic astrocytomas have been shown to contain a novel BRAF-KIAA

P.837

fusion that appears to predict improved survival following partial resection and raises the possibility that these tumors could be treated with BRAF inhibition.

TABLE 96.1 Overview of Chemotherapeutic Agents Used Most Frequently in the Treatment of Glioma

Drug	Indication	Dose Regimen	Side Effects	Monitoring
Temozolomide	GBM Anaplastic astrocytoma/oligodendroglioma Low-grade glioma	Chemoradiation: 75 mg/m ² /day PO daily for 6 wk Adjuvant: 150-200 mg/m ² /day for 5 days every 28 days	Nausea, vomiting Fatigue Myelosuppression—especially lymphopenia, thrombocytopenia	CBC with differential weekly during chemoradiation, days 21 and 28 during adjuvant dosing, or more frequently
Lomustine CCNU (PCV)	GBM (recurrent) Low-grade glioma Anaplastic Oligodendroglioma	90-110 mg/m ² PO as single dose every 6 wk	Nausea, vomiting, myelosuppression—especially lymphopenia, thrombocytopenia Pulmonary fibrosis	CBC with differential weekly × 6 wk, Hepatic and renal function Pulmonary function at baseline and periodically thereafter
Carmustine BCNU	GBM (recurrent)	150-200 mg/m ² IV as single dose every 6 wk	Nausea, vomiting, myelosuppression Pulmonary fibrosis Headache, rare infusion reaction	at baseline and periodically thereafter
Carmustine wafers	GBM	Up to eight wafers (61.6 mg) implanted in the surgical bed at time of resection	CNS edema/local inflammation, infection, CSF leak, seizures	Clinical monitoring for seizure/CNS infection/edema

Procarbazine (PCV)	Low-grade glioma Anaplastic Oligodendroglioma	60-75 mg/m ² PO days 8-21 every 6 wk	Nausea, vomiting, myelosuppression, encephalopathy	CBC with differential Hepatic and renal function tests
Vincristine (PCV)	Low-grade glioma Anaplastic Oligodendroglioma	1.4 mg/m ² IV days 8 and 29 every 6 wk	Sensorimotor peripheral neuropathy, seizures	CBC with differential, electrolytes, hepatic function, uric acid levels
Bevacizumab	Recurrent GBM	10 mg/kg IV every 2 wk	Hemorrhage, thrombosis, impaired wound healing, HTN, proteinuria	CBC with differential, blood pressure, urine protein

GBM, glioblastoma; PO, by mouth; CBC, complete blood count; PCV, procarbazine, lomustine, and vincristine; IV, intravenous; CNS, central nervous system; CSF, cerebrospinal fluid; HTN, hypertension.

Treatment and Outcome

Gross total resection of pilocytic astrocytomas can be curative and should be the primary treatment consideration whenever possible. Even partial resection can lead to long-term survival with up to 87% and 82% of patients surviving at 10 and 20 years, although significant morbidity can result from persistent unresected tumor. Regardless of the extent of resection, patients must be followed long-term to monitor for infrequent progression. Because of their indolent natural history, even partially resected pilocytic astrocytomas can be subsequently monitored without adjuvant therapy until there is evidence of further growth. Documented cases of spontaneous remission following partial resection appear to validate this wait-and-see approach. RT or chemotherapy (temozolomide, bevacizumab, and irinotecan have been used) can be considered in cases with inoperable or progressive tumors, although the long-term benefits of these modalities are uncertain. The prognosis from pilocytic astrocytoma depends on resectability, as those that cannot be completely resected tend to recur. Malignant transformation only occurs in a minority (~5%) of cases, although there is unfortunately no way to predict which tumors will transform.

DIFFUSE ASTROCYTOMA

Definition and Epidemiology

Diffuse astrocytomas are WHO grade II infiltrative astrocytic tumors that typically affect otherwise healthy young adults. They are fairly well-differentiated tumors with a slow, indolent early course, although they have the tendency to eventually undergo malignant transformation to high grade (Fig. 96.1). Diffuse astrocytomas make up 10% to 15% of all astrocytic tumors with an annual incidence of 1.4 per 1 million and a peak incidence in the fourth decade of life.

Clinical and Imaging Features

Diffuse astrocytomas can occur anywhere in the CNS, although they preferentially arise in the cerebral hemispheres in adults. In children, they often occur in the brain stem as diffuse intrinsic pontine gliomas. Diffuse astrocytomas most frequently present with seizures but depending on location can also cause focal symptoms or cognitive and behavioral change. Diffuse astrocytomas generally appear as ill-defined homogeneous regions with T1 hypointense signal and T2/FLAIR hyperintensity, although they tend to infiltrate beyond the T2/FLAIR margins visible on MRI. Diffuse astrocytomas

development of new contrast enhancement can signal progression to higher grade (see Fig. 96.1).

FIGURE 96.1 Diffuse astrocytoma, WHO II with progression to anaplastic astrocytoma WHO III. T2-weighted FLAIR (**A**) and gadolinium contrast-enhanced T1-weighted. (**B**) MRI sequences of a patient with diffuse astrocytoma that despite radiation years gradually progressed over 10 years with more extensive T2/FLAIR signal (**C**) and the development of patchy enhancement (**D**) that was proven by biopsy to represent transformation to anaplastic astrocytoma.

Pathologic and Molecular Features

Diffuse astrocytomas are made up of well-differentiated astrocytes with increased cellularity and occasionally demonstrate nuclear atypia but rare mitotic activity, with Ki-67/MIB-1 staining growth fraction typically less than 4%. By definition, diffuse astrocytomas have no necrosis or endovascular proliferation. Although they appear fairly benign histologically, diffuse astrocytomas are not clinically benign, with a high rate of transformation to malignancy over the course of years. Point mutations in the isocitrate dehydrogenase enzyme IDH1 (R132), or rarely IDH2 (R172), are present in the majority (65% to 80%) of grades II and III gliomas, including 75% of diffuse astrocytoma. The presence of an IDH mutation is a favorable prognostic factor regardless of tumor type, and IDH mutation can be detected by immunohistochemistry, polymerase chain reaction (PCR), and MR spectroscopy. Methylation of the O6-methylguanine-DNA methyltransferase (MGMT) promoter, which leads to MGMT gene silencing is also common in diffuse astrocytoma and is associated with improved prognosis and alkylating agent chemosensitivity.

Treatment and Outcome

The approach to diffuse astrocytoma is complex, and a number of questions remain regarding various aspects treatment. Management incorporating observation, surgery, RT, and chemotherapy is individualized based on tumor location, molecular profile, and patient characteristics. Because of the indolent nature of diffuse astrocytoma, the potential benefits of treatment must also be weighed against the risk of long-term side effects, and there may be a role for delayed intervention in minimally symptomatic patients with limited disease. Although diffuse astrocytoma is a low-grade tumor, current therapies do not offer a cure, and the goal of treatment is to ameliorate symptoms and delay or prevent transformation to high grade, balanced against treatment-induced toxicities. The mainstay of initial treatment involves surgery and RT, although uncertainty remains surrounding the timing of these interventions as well as the ultimate role of chemotherapy.

Available evidence increasingly supports surgical resection over observation and appears to suggest a survival benefit from more extensive resection. Immediate surgery is generally recommended for patients with large symptomatic tumors, although the management of small minimally symptomatic tumors is less clear. In this patient population, available studies also appear to show a trend toward

P.839

improved survival with immediate surgery, although monitoring for clinical or radiographic progression is also an option. Of course, the diffuse infiltrative nature of these tumors makes gross total resection difficult, and subtotal resection or a biopsy is often the only viable option. For patients with significant residual tumor remaining after surgery, adjuvant RT or chemotherapy is often considered.

Although RT is a frequent component of the treatment of diffuse astrocytoma, the optimal timing remains somewhat unclear. Clinical trial evidence has attempted to define the optimal parameters of RT as well as its benefits in diffuse astrocytoma. Two studies addressing RT dose found that lower doses of RT (either 45 or 50.4 Gy) were equivalent to higher dose RT (59.4 or 64.8 Gy) [Level 1],^{1,2} and as a result, most patients currently receive 50 to 54 Gy. Regarding the timing of RT, one seminal study showed that postoperative RT delayed the time to progression but did not prolong overall survival [Level 1].³ In light of the potential long-term neurocognitive effects of RT, these results have been used to justify delaying RT, although tumor progression may also negatively impact cognitive function. Early treatment may be most justified in patients with significant symptoms or radiographic progression or in patients at high risk for progression (those older than 40 years old, with >5-cm preoperative tumor or incomplete resection, MIB-1 >3%).

The role for chemotherapy in diffuse astrocytoma continues to be defined. Most studies addressing this question do not separate diffuse astrocytoma from other LGGs (such as oligodendrogliomas that are often more responsive to chemotherapy), making it difficult to draw specific conclusions about individual tumor types. A study examining the role of chemotherapy in “high-risk LGGs” (defined as age younger than 40 years with subtotal resection or biopsy or age older than 40 years with any extent of resection), including diffuse astrocytoma, compared RT alone to RT followed by 6 months of chemotherapy with procarbazine, lomustine, and vincristine (PCV) [Level 1].⁴ Long-term follow-up demonstrated a statistically significant improvement in overall survival (13.3 years vs. 7.8 years) from the addition of PCV chemotherapy to RT versus RT alone. Details have not yet been published, including how much of this effect is explained by the more chemosensitive oligodendrogliomas. The specific type of chemotherapy is also an area of uncertainty; PCV and temozolomide have both been studied, but there have been no trials directly comparing the two. Regardless, temozolomide is often preferred because it has fewer side effects and is easier to administer. Preliminary results of a study comparing chemotherapy to RT in high-risk LGG patients showed no difference in overall survival, although patients with retained 1p19q appeared to have improved outcomes with RT.

The prognosis for patients with diffuse astrocytoma is highly variable, driven largely by the rate of transformation to higher grade. Mean survival is in the range of 6 to 8 years, and prognostic features include age; functional status; neurologic deficits; tumor size and degree of resection; presence of enhancement; and molecular markers such as MIB-1, MGMT methylation, IDH mutation, and 1p19q codeletion. Regardless of treatment, tumors inevitably recur and often transform to anaplastic astrocytoma or glioblastoma.

Definition and Epidemiology

Anaplastic astrocytoma is a diffusely infiltrating WHO grade III glioma with significant proliferative activity and rapid growth (see Fig. 96.1C and D). Anaplastic astrocytomas have a strong tendency to progress to glioblastoma (GBM), a WHO grade IV glioma with highly infiltrative, vascular, necrotic growth (Fig. 96.2). These tumors are characterized as high-grade or malignant gliomas. GBM is the most common primary malignant brain tumor, with an annual incidence of approximately three or four cases per 100,000 persons. GBM accounts for 60% to 80% of malignant gliomas, whereas anaplastic astrocytomas make up 10% to 15%, and the remainder consists of anaplastic oligodendrogliomas, anaplastic oligoastrocytomas, and anaplastic ependymomas (see the following section). These rapidly progressive, uniformly fatal glial neoplasms can either evolve from LGGs or can arise de novo. They primarily affect adults with a mean age at diagnosis around 45 years for anaplastic astrocytoma and 64 years for GBM.

Clinical and Imaging Features

Anaplastic astrocytomas and GBMs preferentially arise in the white matter of the cerebral hemispheres. Symptoms result from tumor location and mass effect and can include headaches, focal neurologic deficits, or seizures. More than half of patients present with headache, and although classic brain tumor headaches occur in the morning and are associated with nausea and vomiting, these symptoms are only seen in a minority of patients; most headaches are indistinguishable from tension headache. Seizures are more common in anaplastic gliomas than GBM. Malignant gliomas are hypointense on T1-weighted MRI sequences and hyperintense on T2/FLAIR with poorly defined margins. They generally have marked heterogeneous enhancement, although some anaplastic astrocytomas do not enhance. Marked central necrosis and surrounding edema are frequent in GBM (see Fig. 96.2) and typically less prominent in anaplastic astrocytoma. Importantly, in up to 40% of patients receiving initial treatment with RT and chemotherapy, early imaging can demonstrate increased enhancement and edema. Although these findings appear consistent with early tumor progression, in up to half of patients, the changes are actually the result of increased vessel permeability from treatment, a phenomenon known as *pseudoprogression*. A role for MR spectroscopy, MR perfusion, and PET is being explored to better diagnose malignant glioma and to distinguish tumor progression from treatment-related pseudoprogression.

Pathologic and Molecular Features

Anaplastic astrocytomas contain diffusely infiltrating astrocytes that have increased cellularity and atypia compared with LGGs, as well as evidence of mitotic activity. GBMs additionally contain either microvascular proliferation or regions of necrosis or both.

Malignant gliomas are thought to arise as a cumulative result of a series of oncogenic alterations, and it is clear that tumors that arise de novo possess distinct molecular alterations from those that evolve from lower grade tumors. GBM was among the first human tumors to undergo comprehensive genomic characterization, and the results defined significantly amplified and deleted and mutated genes that led to an appreciation of the high incidence of p53, Rb, and receptor tyrosine kinase (RTK) pathway dysregulation in GBM. Expression profiling was subsequently used to define GBM subclasses. There are significant ongoing efforts to design and test therapeutics that will specifically target the molecular alterations found in malignant glioma. For the time being, however, and despite all that is known about the genetic alterations and subclasses within HGG, the best available treatment continues to be conventional approaches, including surgery, RT, and chemotherapy.

FIGURE 96.2 Glioblastoma. Gadolinium contrast-enhanced T1-weighted MRI images of a patient who initially presented with headaches and had unremarkable imaging (**A**). The patient developed facial weakness that led to a repeat MRI just 3 months later that revealed a centrally necrotic peripherally enhancing mass (**B**). Gross total resection led to the diagnosis of glioblastoma (**C**), but despite chemoradiation, within 6 months, the patient's tumor recurred (**D**) and infiltrated the contralateral hemisphere (**E**).

Treatment and Outcome

The overall approach to the treatment of HGGs involves maximal safe resection followed by RT and chemotherapy (Fig. 96.3). Because anaplastic astrocytoma is much less common than GBM, the approach for both tumor types is generally based on treatment established in GBM although this approach is controversial.

In spite of the fact that malignant glioma's infiltrative nature precludes a complete resection of all tumor cells, current evidence suggests that there is a survival advantage from more extensive resection. Although the data is largely retrospective, several studies have proposed thresholds for extent of resection (88% to 89% or 95% to 98%), above which there is a significant improvement in overall survival. Resection also enhances diagnostic accuracy and provides tissue for molecular testing that is important for prognostication and some treatment decisions. Still, in spite of attempts to achieve gross total resection in patients with malignant glioma, viable tumor cells inevitably remain and local recurrence is the rule (see Fig. 96.2), necessitating additional treatment with RT and systemic agents.

RT plays a central role in the treatment of patients with malignant glioma and is important for treating both gross and microscopic infiltrative disease that cannot be resected. Adjuvant RT following surgery has had the greatest impact on the survival of patients with GBM, prolonging overall survival on average from 3 to 4 months to 7 to 12 months. RT should be considered in all patients and typically consists of involved field external beam RT delivered 5 days per week in fractions of 1.8 to 2.0 Gy to a total dose of 60 Gy. Because of the infiltrative character of malignant gliomas, there is no clear role for stereotactic radiosurgery or brachytherapy in the up-front treatment of malignant glioma. In spite of prior attempts to treat microscopic disease with larger fields and higher RT doses, the majority of malignant

gliomas recur at the original site, and increasing the field size increases toxicity without improving survival. Further complicating the early picture is the fact that

P.841

P.842

early MRI changes related to RT and chemotherapy can mimic disease progression (pseudoprogression), as either can destabilize the blood-brain barrier, leading to nonspecific enhancement, edema, and mass effect. Pseudoprogression appears to be more common in patients with tumors that harbor MGMT promoter methylation, although MGMT methylation status cannot be relied on to distinguish pseudoprogression from disease progression in an individual patient.

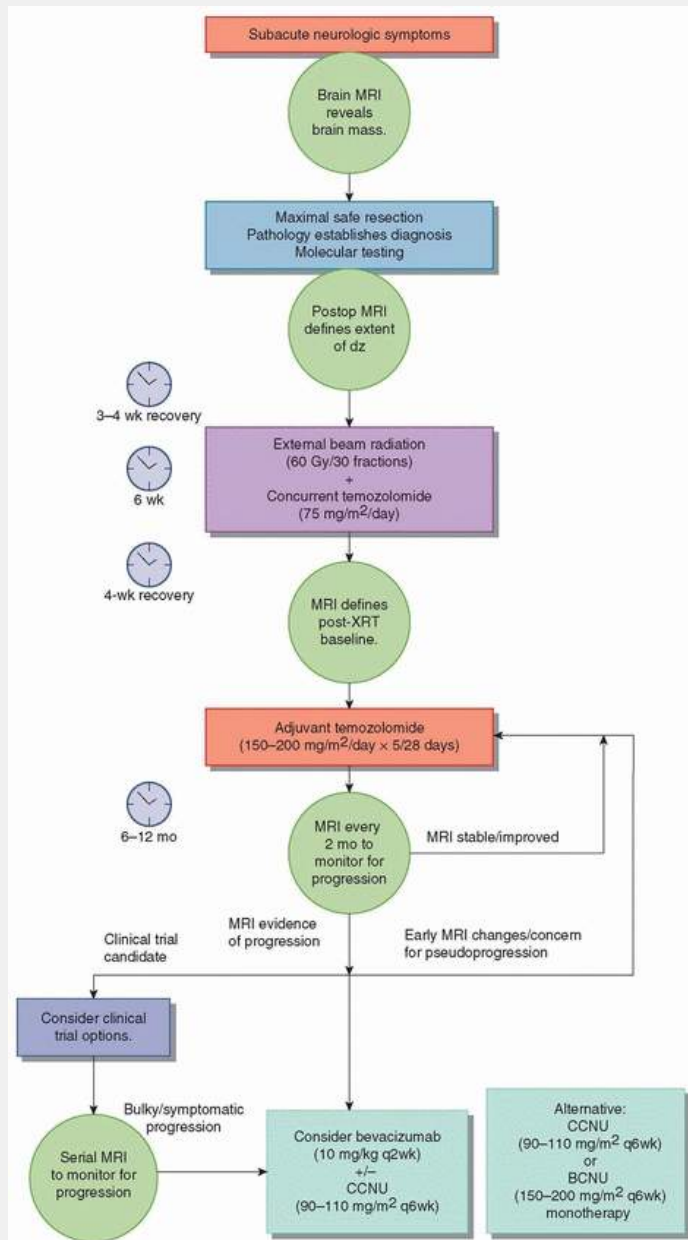

FIGURE 96.3 Overview of the treatment of glioblastoma.

Chemotherapy plays an important role in the management of patients with malignant glioma. Temozolomide is an oral DNA alkylating agent that is administered together with RT, followed by at least six monthly adjuvant cycles as a part of the current standard of care in GBM [Level 1].^{5,6} Temozolomide was shown to improve overall survival in a randomized phase III study that compared RT alone to RT plus concurrent and adjuvant temozolomide (150 to 200 mg/m²/day for 5 days every 28 days for six cycles). The addition of temozolomide prolonged median survival from 12.1 to 14.6 months and led to significantly higher rates of survival at 2 years (26.5% vs. 10.4%) and 5 years (10% vs. 2%). A companion study analyzed tumor tissue for epigenetic silencing of MGMT, the DNA repair protein that is responsible in part for reversing the effects of temozolomide. That study found that patients whose tumors had methylation of the MGMT promoter had a greater benefit from temozolomide (21.7-month median survival and 46% 2-year survival)

compared with patients without promoter methylation (12.7-month median survival, 13.8% 2-year survival) [**Level 1**].⁷ Therefore, MGMT promoter methylation has subsequently been established as a predictor of benefit from temozolomide, especially in elderly patients. However, patients with GBMs that do not harbor MGMT promoter methylation also survive longer with temozolomide than without it. Therefore, in the absence of proven effective alternatives, temozolomide continues to be used in the treatment of malignant glioma regardless of MGMT promoter methylation status. Temozolomide is easily administered and generally well tolerated, with an acceptable side effect profile that consists primarily of nausea, fatigue, and mild myelosuppression, with the greatest effects on platelet number. Perhaps more importantly, MGMT methylation is also a prognostic marker in newly diagnosed GBM, associated with longer survival regardless of treatment administered.

Another chemotherapeutic approach to the treatment of malignant glioma involves the use of biodegradable polymers containing the alkylating agent carmustine. These wafers, which can be implanted into a tumor bed immediately after resection, gradually release carmustine into the tissue surrounding the resection cavity in order to kill residual tumor cells. A phase III trial for newly diagnosed disease suggested a modest survival benefit from wafer implantation at the time of resection, with median survival increasing from 11.6 to 13.9 months, which led to U.S. Food and Drug Administration (FDA) approval for the initial treatment of malignant glioma [**Level 1**].⁸ However, the up-front use of carmustine wafers was not compared with standard temozolomide chemotherapy, so data are lacking to indicate whether there is a survival advantage over standard therapy. In addition, there are no trials assessing the safety or efficacy of adding carmustine wafers to standard chemoradiation, and there is some evidence of toxicity from carmustine wafers including increased brain edema, infection, and seizures. Wafers also confound MRI interpretability. Finally, most clinical trials for gliomas exclude patients who were treated with wafers. Accordingly, the uncertainty regarding the risks and benefits of carmustine wafers in conjunction with standard chemoradiation has limited the adoption of this approach in the initial treatment of malignant glioma, and they have fallen out of favor in recent years. Despite aggressive treatment with surgery, RT, and chemotherapy, malignant gliomas inevitably recur, on average 7 to 10 months after initial diagnosis. As mentioned earlier, progressive disease can be difficult to distinguish from the early radiographic changes caused by concurrent chemoradiation. Tissue sampling can be required to distinguish between progressive disease and pseudoprogression, although even pathology can demonstrate a mixture of both processes. Patients with early imaging changes are typically continued on adjuvant temozolomide with close radiographic follow-up, unless significant symptoms warrant treatment with corticosteroids, surgery, or bevacizumab. If resection is considered for the treatment of recurrent disease, consideration may also be given to carmustine wafers, which have been shown to prolong survival compared with placebo (31 vs. 23 weeks) in a randomized phase III trial [**Level 1**].⁹ Unfortunately, for most patients, surgery cannot be considered because of the location, extent, or multifocality of the recurrent tumor. Alternatively, reirradiation can occasionally be considered if tumor recurrence arises outside of the prior radiation field or if it has been some time since initial radiotherapy. SRS or SRT are occasionally used for focal recurrences, although the role of these treatment modalities is still being defined, as the disease is inherently diffuse.

In most cases of recurrent malignant glioma, where surgery and RT are not viable options, systemic agents are the primary therapeutic consideration. Unfortunately, none of the available salvage therapies has been definitively shown to prolong survival, and therefore, the risks of treatment need to be carefully weighed. In patients with adequate performance status, participation in clinical trials should be seriously considered. There are a large number of clinical trials testing a host of different agents in recurrent GBM, although fewer trial options exist for patients with anaplastic astrocytoma. In patients who are not clinical trial candidates, a number of salvage chemotherapy options exist, including readministration of temozolomide or other alkylating agents including nitrosoureas or carboplatin or treatment with the antiangiogenic agent bevacizumab. Another treatment that has been FDA approved for use in recurrent GBM is a portable device that applies low-intensity alternating electrical fields to the scalp. The NovoTTF-100A was approved based on a phase III trial that showed comparable efficacy but less toxicity than salvage chemotherapy. Unfortunately, the trial did not employ a noninferiority design necessary to make an adequate comparison between treatments, and the role of Novo-TTF in the treatment of recurrent GBM therefore remains unclear.

Particularly for those patients with significant symptoms or mass effect, bevacizumab is an important therapeutic option at recurrence, either alone or in combination with cytotoxic chemotherapy. Bevacizumab is a humanized monoclonal antibody directed against VEGF, a key mediator of vascular permeability and angiogenesis. In highly vascular

malignant glioma, bevacizumab often results in normalization of tumor blood vessels and a rapid decrease in enhancement, peritumoral edema, and mass effect. A phase II study of bevacizumab with or without concurrent administration of the topoisomerase inhibitor irinotecan in GBM demonstrated radiographic responses in the form of improved brain MRI scans (28% to 39%) with an increase in the percentage of patients experiencing disease control at 6 months (42% to 50%) compared with historical controls (5% to 9% radiographic response and 15% to 20% disease control at 6 months), which led to accelerated FDA approval of bevacizumab for recurrent GBM. Improvements on MRI are often accompanied by symptom

P.843

improvement and decreased corticosteroid requirements, although the effects on overall survival are less clear. Uncontrolled data suggests marginally prolonged median survival compared to historical controls, and recent evidence suggests that bevacizumab administered in combination with lomustine may lead to improved overall survival compared with either bevacizumab or lomustine alone [Level 1].¹⁰ Randomized studies of bevacizumab in the recurrent setting are ongoing.

However, two up-front phase III trials of bevacizumab in combination with temozolomide and RT confirmed an improvement in clinical and radiographic disease control but no overall survival benefit [Level 1].^{11,12} At this time, bevacizumab appears to be most beneficial for patients with significant symptoms who could benefit from tumor shrinkage or decreased peritumoral edema, either at the time of initial treatment or at recurrence. Bevacizumab is generally very well tolerated, although it does carry a low risk of thromboembolism or hemorrhage. However, even in highly vascular GBM, the risk of intracerebral hemorrhage is fairly low at approximately 2% to 3%, and the benefits of treatment generally outweigh these risks. The duration of optimal therapy is uncertain, and there is some concern that withdrawal of the antiangiogenic effects of bevacizumab, even when there is evidence of progression, may lead to a rebound in the tumor-associated edema and mass effect. In fact, there is some evidence to support a continued role of bevacizumab even after progression on that treatment. However, following progression on bevacizumab, prognosis is extremely poor (3- to 4-month median survival) and no chemotherapeutic agents have proven to prolong either disease control or survival following failure of bevacizumab. Regardless of treatment, malignant glioma carries a dismal prognosis that in spite of significant scientific and technical advances has not significantly changed in the last several decades.

Median survival for patients with anaplastic astrocytoma is approximately 3 years, whereas patients with GBM have a median survival of around 15 months. Of course, prognosis varies significantly between individuals, and a small subset of patients can live a decade or longer with anaplastic astrocytoma or rarely even GBM. Prognosis is influenced by both patient factors, such as age and functional status, as well as tumor-related factors such as grade, location, extent of resection, and molecular determinants such as deletion of chromosome 1p and 19q (most common in oligodendrogliomas), MGMT promoter methylation, and the presence of IDH1/2 mutation. The best prognosis is generally found among young, otherwise healthy patients with a gross total resection and MGMT methylation and IDH1/2 mutation, but even in these cases, treatment may control disease for a time, but tumor growth inevitably recurs. In light of the significant morbidity and mortality from malignant glioma, there is a desperate need for improved treatment in this disease.

FIGURE 96.4 Low-grade oligodendroglioma, WHO II. Gadolinium contrast-enhanced T1-weighted (A) and T2-weighted (B) MRI of a patient with a largely nonenhancing infiltrative oligodendroglioma.

OLIGODENDROGLIOMAS

DEFINITION AND EPIDEMIOLOGY

Oligodendroglial tumors are diffusely infiltrating gliomas composed of neoplastic cells that morphologically resemble oligodendrocytes. Although these tumors exist on a continuum from well-differentiated to overtly malignant, they are categorized into two distinct prognostic groups: low-grade (WHO grade II) oligodendrogliomas and anaplastic (WHO grade III) oligodendrogliomas. Together, these tumors make up approximately 5% of all glial neoplasms, but unlike astrocytic tumors, the majority of oligodendroglial tumors are low grade, with 65% to 80% being WHO grade II oligodendrogliomas. These tumors tend to occur in patients in their 30s to 50s, with grade II lesions appearing in younger patients than their grade III counterparts.

CLINICAL AND IMAGING FEATURES

Oligodendrogliomas preferentially arise in the cortex and subcortical white matter of the cerebral hemispheres, most frequently in the frontal lobe. Approximately two-thirds of patients present with seizures, although headache or focal deficits are also common. Anaplastic oligodendrogliomas can arise de novo or as a result of progression from a WHO grade II oligodendroglioma, on average 6 to 7 years after initial diagnosis. Oligodendrogliomas respond better to treatment and have a more favorable prognosis than astrocytomas. In fact, even the presence of an oligodendroglial component, seen in mixed oligoastrocytomas, may confer a better prognosis than pure astrocytic histology. Unlike most other gliomas, oligodendroglial tumors are uniquely chemosensitive, which has led to an increasing role for chemotherapy in this disease. On MRI, oligodendrogliomas are T2/FLAIR hyperintense and infiltrative with indistinct borders (Fig. 96.4). Low-grade oligodendrogliomas

P.844

are generally nonenhancing, whereas anaplastic lesions frequently have some degree of enhancement, and calcification is characteristic of oligodendrogliomas, although this finding is not specific.

PATHOLOGIC AND MOLECULAR FEATURES

Oligodendrogliomas are composed of monomorphic cells with round nuclei and characteristic perinuclear halos that are

said to look like “fried eggs” in a dense “chicken wire” network of branching capillaries. WHO grade II oligodendrogliomas may have marked cellular atypia and occasional mitoses, but the appearance of significant mitotic activity or microvascular proliferation is consistent with a diagnosis of anaplastic oligodendroglioma. The presence of necrosis warrants a diagnosis of GBM, although GBM with oligodendroglial features may have a somewhat better prognosis than a typical GBM. The majority of oligodendroglial neoplasms have evidence of codeletion of the short arm of chromosome 1 (1p) and the long arm of chromosome 19 (19q) that results from an imbalanced translocation of 1p to 19q. The frequency of 1p19q codeletion is estimated to be 80% to 90% in grade II oligodendrogliomas and 50% to 70% in anaplastic oligodendrogliomas and can be used to support the diagnosis in cases of atypical histology. This codeletion corresponds to a longer natural history and an improved response to chemotherapy and may be used to help guide therapeutic decision making. As a result of its diagnostic, prognostic, and predictive value, testing for 1p19q should be performed on all oligodendroglial tumors. Mutation in IDH1/2 is also very common, occurring in 60% to 80% of grade II and III oligodendrogliomas, where it strongly correlates with 1p19q codeletion and an improved prognosis. Recent data suggests 1p19q deleted tumors are a subset of those with IDH mutation, which also carries independent and favorable prognostic value. Together with MGMT methylation, these three correlating features are highly prognostic for longer survival of patients with oligodendroglial tumors.

TREATMENT

The approach to the management of WHO grade II oligodendrogliomas is complex, and the optimal treatment strategy for these low-grade tumors remains controversial. Because most studies have not distinguished between glioma subtypes, much of the approach to treatment is similar to that of other LGGs, although important differences are emerging. Oligodendrogliomas can be managed with a combination of observation, surgery, RT, and chemotherapy, which unfortunately, despite the indolent nature of these low-grade tumors, do not offer a cure. In light of their long natural history (average survival of approximately 10 years) and the neurotoxicity from both tumor and treatment, the central therapeutic challenge is to balance efforts to extend survival with the preservation of neurocognitive function. Although initial treatment is clearly indicated in patients older than 45 to 50 years of age, those with neurologic deficits, or with large or rapidly growing lesions, observation with close neuroradiologic follow-up can be considered in young asymptomatic patients with small or completely resected tumors.

As with other gliomas, surgery is recommended to obtain pathologic confirmation of the diagnosis, improve neurologic symptoms, and reduce tumor bulk. Gross total resection is the goal if tumor location will allow it, although tumor cells invariably remain and will eventually recur. Particularly given the highly epileptogenic nature of oligodendrogliomas, even a partial resection can improve seizure control and should be considered in cases of refractory seizure. Regardless of the extent of resection, additional therapy beyond surgery is eventually required in all patients.

Both adjuvant RT and chemotherapy are important components of treatment following resection, although optimal timing is somewhat uncertain. Early postoperative treatment is generally considered in patients who had evidence of growth, mass effect, or neurologic deficits prior to surgery but may also be considered in older patients or those with significant residual disease or large initial tumor diameter (>5 cm). Young asymptomatic patients or those with isolated preoperative seizures may be monitored closely after resection with further treatment being reserved until there is evidence of recurrent tumor growth on MRI.

In patients with oligodendroglioma that require adjuvant therapy, the roles of chemotherapy and RT continue to be defined. Early postoperative RT has been shown to improve symptoms and time to progression but not overall survival, potentially justifying delayed RT in this population with the potential for long-term survival. Some early evidence suggests that patients without 1p19q codeletion may have better outcomes with RT than chemotherapy, and adjuvant radiotherapy may be the modality of choice in this subset of patients.

In contrast, because oligodendrogliomas with 1p19q codeletion are known to be particularly chemosensitive, initial postoperative treatment with chemotherapy alone may be considered in order to delay subsequent RT and the risks of long-term neurologic side effects. Of course, the optimal chemotherapeutic regimen remains uncertain; PCV and temozolomide have both been studied, and although no trials directly compare the two, temozolomide is often preferred because of its better side effect profile and ease of administration.

With regard to survival, there is growing evidence supporting the use of both RT and chemotherapy in low-grade glioma, including oligodendroglioma, as discussed earlier with regard to low-grade astrocytoma [Level 1].⁴ The long-term results of a study examining the addition of chemotherapy to RT have recently been released, in which high-risk

low-grade glioma patients (subtotally resected or age older than 40 years) were treated with RT alone or RT followed by 6 months of PCV. Results demonstrated a statistically significant improvement in overall survival with the addition of PCV to RT (13.3 years vs. 7.8 years). Because the details have not yet been published, including whether a particular diagnostic or molecular subgroup accounts for the survival advantage, it is difficult to draw specific conclusions about oligodendrogliomas versus astrocytomas or mixed oligoastrocytomas. However, knowing that oligodendrogliomas with 1p19q codeletion are particularly sensitive to chemotherapy, it seems likely that the benefits of adjuvant chemotherapy would be greatest in this tumor type. As a result, the argument could be made that adjuvant therapy in oligodendroglioma should include both RT and chemotherapy over radiotherapy alone. Whether chemotherapy alone (with radiotherapy at recurrence rather than diagnosis to avoid late neurocognitive toxicity) shortens survival is not clear at this time.

OUTCOME

Regardless of initial treatment, oligodendrogliomas eventually recur, frequently with evidence of transformation to a higher grade. If there is radiographic evidence of new enhancement or rapid growth concerning for a malignant transformation, biopsy or resection to confirm tumor grade may be considered. At the time of recurrence, either RT or chemotherapy may be considered, particularly if one or the other was not used during initial treatment. Reirradiation after a prior complete course of RT is not usually considered out of concern for neurotoxicity, although it can occasionally be entertained if it's been several years since initial treatment.

P.845

A return to a previously effective chemotherapeutic (either PCV or temozolomide) is another option if progression has occurred off of treatment. Other agents with some reported activity include melphalan, platins, and etoposide. Even though oligodendroglioma is a low-grade tumor with marked chemosensitivity, tumor recurrence and progression to high grade significantly shorten life expectancy. There is marked variability between individuals with median survival ranging from 8 to 16 years, and some patients can survive decades without recurrence. Prognostic features include age; functional status; neurologic deficits; original tumor size and extent of resection; as well as molecular features such as 1p19q co-deletion, IDH1 mutation, and MGMT methylation. However, regardless of prognostic features, most patients with oligodendroglioma will eventually undergo malignant transformation to anaplastic oligodendroglioma or GBM.

OLIGODENDROGLIOMA SUBTYPES

Anaplastic Oligodendroglioma

Similar to low-grade oligodendrogliomas, there is no commonly accepted standard approach to the treatment of WHO grade III anaplastic oligodendroglioma. Because of the malignant growth of anaplastic oligodendrogliomas, early treatment with surgery, RT, and/or chemotherapy is necessary. Recognition of the chemosensitivity that corresponds to 1p19q codeletion in these tumors has led to the incorporation of molecular genetic analysis in treatment decision making.

In the surgical approach to these tumors, evidence suggests an association between extent of resection and survival, and although tumor location may only allow biopsy or partial resection, maximal safe resection is preferred whenever possible. Given the high likelihood of recurrence following surgery for anaplastic tumors, adjuvant treatment with RT and/or chemotherapy is recommended. Both RT and chemotherapy are active in anaplastic oligodendroglioma, although the timing and order are less clear. Codeletion of 1p19q is a strong predictive biomarker associated with improved response to chemotherapy and evidence suggests that 1p19q status can be used to guide the choice of adjuvant therapy.

Postoperative RT has been shown to improve disease control and overall survival in HGG, and although its effectiveness has not been specifically demonstrated in anaplastic oligodendroglioma, radiotherapy is considered a central component of the treatment of these tumors.

The further addition of chemotherapy to RT has recently been evaluated in randomized clinical trials of anaplastic oligodendroglioma. The long-term results of two large complementary trials demonstrated that the addition of PCV to radiotherapy was associated with dramatically improved progression-free and overall survival in tumors with 1p19q

codeletion. However, for tumors with retained 1p19q, there appeared to be limited benefit from the addition of chemotherapy. Therefore, patients with 1p19q retained anaplastic oligodendroglioma may benefit most from treatment with adjuvant radiotherapy alone, whereas patients with 1p19q codeleted anaplastic oligodendroglioma should be treated with both RT and chemotherapy [Level 1].¹³ One study suggests that IDH mutation, in the absence of 1p19q deletion, also predicts benefit from chemotherapy, but this result has not been validated to date. Open questions remain about the order of therapy (RT then chemotherapy or vice versa), although guidelines support the use of chemotherapy after RT because of better tolerability. In addition, the optimal chemotherapy is unclear whether temozolomide, which is better tolerated and easier to administer, can be substituted for PCV. Although no direct comparison has been made, current evidence suggests that both regimens are similarly active, and studies directly comparing the two are ongoing. Finally, given the chemosensitivity of anaplastic oligodendrogliomas and the concern for delayed neurotoxicity from RT, there is some interest in using adjuvant chemotherapy alone to delay radiotherapy, and this approach is currently being studied in clinical trials.

Regardless of the treatment approach taken, anaplastic oligodendrogliomas invariably recur. Reresection or reirradiation can be considered in select patients depending on the location of the recurrence and the overall clinical picture. In addition, both temozolomide and PCV have been shown to have activity at the time of recurrence, and one strategy is to treat with the regimen not used previously. Other agents with some minor evidence of activity include paclitaxel, irinotecan, carboplatin, and etoposide. Finally, although bevacizumab has beneficial effects and approval in GBM, the evidence is much less clear in anaplastic oligodendroglioma and may carry a higher risk of intratumoral hemorrhage than in GBM. In spite of attempts at salvage, the prognosis from anaplastic oligodendrogliomas is significantly worse than low-grade tumors, with median survival of 4.5 years compared with 9.8 years for oligodendroglioma. Still, some patients survive significantly longer, including younger patients with gross total resection; good functional status; and evidence of 1p19q codeletion, IDH mutation, and MGMT methylation.

Mixed Oligoastrocytomas

Mixed oligoastrocytomas are infiltrating gliomas with morphologic features of both oligodendroglioma and astrocytoma and represent an intermediate category between these two major tumor subtypes. Mixed histology can be present in WHO grade II oligoastrocytomas or in WHO grade III anaplastic oligoastrocytomas, although the proportion of oligodendroglial features required for these diagnoses is not explicitly established. Because the criteria for diagnosis are not clearly defined, the incidence of these tumors is unclear, although they may make up as much as 10% of adult gliomas depending on the pathologist. Clinically, these tumors have similar symptoms, location, and appearance to astrocytomas and oligodendrogliomas. The natural history and treatment responsiveness of mixed oligoastrocytomas likely lies somewhere between that of astrocytomas and oligodendrogliomas, and the molecular genetic alterations present in these mixed tumors reveal that some tumors are genetically similar to oligodendrogliomas and others are more like astrocytomas. Codeletion of 1p19q occurs in approximately 30% to 50% of mixed gliomas; between the frequencies observed in oligodendrogliomas and astrocytomas. Because chemoresponsiveness correlates with 1p19q codeletion, most mixed oligoastrocytomas with 1p19q loss are treated as oligodendrogliomas, whereas those with retained 1p19q are treated as astrocytomas. As with other aspects of these mixed tumors, their prognosis is likely intermediate between that of oligodendrogliomas and astrocytomas.

EPENDYMOMAS

DEFINITION AND EPIDEMIOLOGY

Ependymomas are glial neoplasms that arise from the ependymal cells lining the walls of the ventricles or spinal canal. They are uncommon tumors that primarily affect children and young adults, where the majority are infratentorial, most frequently involving

P.846

the fourth ventricle. In contrast, the majority of ependymomas in adults arise in the spinal cord, especially the cervical and thoracic spine. Ependymomas account for somewhere between 2% and 9% of all gliomas, including up to 10% of pediatric brain tumors and nearly 50% to 60% of spinal gliomas in adults. Most are well-defined slow-growing WHO grade II ependymomas, although more rapid malignant growth is seen with WHO grade III anaplastic ependymomas. In addition, rare benign WHO grade I ependymal tumors include subependymomas, which are found in the lateral or fourth ventricles and myxopapillary ependymomas, which exclusively involve the conus medullaris and filum terminale.

CLINICAL AND IMAGING FEATURES

Although ependymomas generally appear adjacent to the ventricular system, they may also arise within the parenchyma of the brain without obvious ependymal attachment. Posterior fossa ependymomas often cause cerebrospinal fluid (CSF) outflow obstruction producing headache, nausea, vomiting, and ataxia or increasing head circumference in children younger than the age of 2 years. Spinal cord ependymomas present with sensory dysesthesias or motor deficits, often with difficulty walking. Typical MRI findings in ependymoma include a well-circumscribed T1 hypointense, T2 hyperintense lesions with prominent heterogeneous enhancement. Cysts, hemorrhage, and calcification are also common. Proximity or involvement of the ventricular system, particularly the fourth ventricle, is an important clue to the diagnosis of ependymoma, although supratentorial parenchymal ependymomas can be difficult to distinguish from other types of glioma. Because of a risk of leptomeningeal dissemination, all patients should have CSF cytology and imaging of the entire neuraxis to exclude metastatic disease.

PATHOLOGIC AND MOLECULAR FEATURES

Ependymomas contain histologic features reminiscent of ependymal cells lining the ventricles. Although mitoses are rare or absent in WHO grade II ependymoma, brisk mitotic activity with microvascular proliferation and necrosis are signs of WHO grade III anaplastic ependymoma.

TREATMENT AND OUTCOME

The treatment of ependymal tumors depends on tumor histology, anatomic location, and extent of resection. The most important component of initial therapy involves maximal safe resection. Observational evidence suggests improved survival from gross total resection, which is the goal of surgery when possible. WHO grade I ependymal tumors including subependymoma and myxopapillary ependymoma can be cured with gross total resection. However, in the case of grade II ependymoma or grade III anaplastic ependymoma, tumors often recur following surgery and adjuvant RT is generally used to reduce the risk of recurrence.

In the past, prophylactic craniospinal RT was advocated for all resected ependymomas, but because most tumors recur at the original site, local radiotherapy targeting a margin around the surgical cavity has become the standard of care. More extensive radiation fields are indicated if either neuroimaging or CSF cytology reveal evidence of tumor dissemination. In the case of patients with gross total resection of supratentorial WHO grade II ependymoma, retrospective data suggests there may be a role for observation with postponement of RT until there is evidence of recurrence. This is particularly relevant for young children with ependymoma in whom RT is associated with significant long-term neurocognitive side effects.

The role of chemotherapy in the treatment of ependymoma is still being defined. Cisplatin, carboplatin, and etoposide have all been shown to have activity in ependymoma, with the best responses seen following combination therapy. Chemotherapy has been shown to be effective in patients with partially resected ependymoma, suggesting a potential role for chemotherapy in incompletely resected disease prior to either radiotherapy or a second-look surgery. Chemotherapy has also been used in an attempt to delay or avoid RT altogether, and uncontrolled results suggest that there may be some efficacy in this setting, although further study is necessary. Finally, chemotherapy is being examined as adjuvant therapy following RT, although results to date are mixed. Additional study is necessary to better define the role of chemotherapy in the treatment of ependymoma, although it may be considered in patients with incompletely resected ependymomas prior to RT.

Patients with ependymoma that develop recurrent disease after radiotherapy have a poor long-term prognosis, and most eventually die from progressive disease. Unfortunately, no treatment strategies have been proven to be effective in this setting. Treatment options include resection, reirradiation, chemotherapy, and bevacizumab. In the end, the overall prognosis from ependymoma depends on the extent of resection, tumor location, and performance status, with the best prognosis seen in patients with gross total resection. The 5-year overall survival of ependymoma ranges from 40% to 80%, with 10-year survival ranging from 47% to 68%.

GLIONEURONAL TUMORS

Glioneuronal tumors are a group of rare neoplasms that have histologic evidence of both glial and neuronal differentiation.

For the most part, they are slow-growing WHO grade I and II tumors with rare transformation to malignancy. Each of the tumors in this class has unique features that justify subclassification; however, because they are so uncommon, knowledge about natural history and optimal clinical management is limited. Much of what is known about these tumors is based on small series and case reports. There are a number of glioneuronal tumor subtypes, and although a detailed discussion of each is beyond the scope of this text, we will attempt to highlight the most important features of a couple of the most common tumors.

GANGLIOGLIOMA

Ganglioglioma is a rare WHO grade I tumor composed of neoplastic glial cells together with neoplastic mature ganglion cells. Tumors composed of neoplastic ganglion cells alone are known as *gangliocytomas*. Both are well-differentiated slow-growing tumors that can occur anywhere in the neuraxis, although the majority (>70%) are found in the temporal lobes. Most patients present with seizures, and gangliogliomas are the most frequent tumor found in patients with epilepsy, with a reported incidence of 15% to 25% of patients undergoing epilepsy surgery. They affect individuals across a wide age range and are estimated to make up approximately 1% of all primary brain tumors in adults and 4% of pediatric brain tumors. Gangliogliomas are typically well-circumscribed masses that are T1 hypointense and T2 hyperintense on MRI with frequent homogeneous enhancement, although they are occasionally nonenhancing. Many have large cystic components with an enhancing mural nodule. Gangliogliomas only rarely induce surrounding edema and they generally exhibit little

P.847

to no mass effect. Although gangliogliomas can infiltrate adjacent normal brain, they generally do not behave aggressively. Rarely, gangliogliomas may undergo anaplastic transformation involving their subpopulation of glial cells, and these anaplastic tumors are considered WHO grade III tumors with behavior similar to other high-grade gliomas. The optimal treatment for gangliogliomas has not been established, although initial treatment typically involves surgical resection. Complete resection can be achieved in most patients and may be curative. Seizures can improve even in cases where only a partial resection is possible. Radiotherapy does not seem to improve outcomes following complete resection, but it may be beneficial following partial resection or in patients with evidence of recurrence after gross total resection. Even patients with anaplastic components may be followed after resection and treated with resection and RT at recurrence. A role for chemotherapy in ganglioglioma is not well defined, although nitrosoureas, retinoic acid, and cisplatin have all been reported to be active in this disease. In general, the prognosis of ganglioglioma is very good with greater than 90% of patients achieving long-term progression-free survival (7.5-year recurrence-free survival of 94% in one report), although anaplastic features may indicate more aggressive behavior and less favorable outcomes.

DYSEMBRYOPLASTIC NEUROEPITHELIAL TUMOR

Dysembryoplastic neuroepithelial tumors (DNETs) are benign, slow-growing WHO grade I lesions that contain both glial elements and mature neurons. They are cortically based supratentorial tumors believed to have a malformative origin, and up to 80% are associated with cortical dysplasia. They have a predilection for the temporal lobes and nearly all patients develop long-standing drug-resistant epilepsy. They occur most often in children and young adults, with 90% of patients developing seizure prior to the age of 20 years. However, they may not initially be recognized as the cause of seizures, only to be discovered at the time of epilepsy surgery, where they are found in approximately 12% to 13% of surgeries. On MRI, DNETs appear as T1 hypointense, T2 hyperintense regions of cortical expansion with infrequent extension to the subcortical white matter. They may be sharply or poorly demarcated and often appear as multiple nodules or pseudocysts although they have little or no mass effect or surrounding edema. Most have little to no contrast enhancement, and in those that do, the enhancement generally represents ischemia or hemorrhage rather than transformation. As evidence of their benign slow growth, DNETs often demonstrate some deformation of the overlying calvarium. They rarely have nuclear pleomorphism, mitoses, or endothelial proliferation and essentially never undergo malignant transformation. Treatment involves surgery and is indicated in patients with refractory seizures. Gross total resection is curative, although even partial resection can improve seizure control. No additional therapy is required after surgery and even in cases of subtotal resection, patients typically do not have evidence of recurrence in long-term follow-up.

Metastatic Tumors

Enid Choi

Graeme F. Woodworth

Minesh P. Mehta

INTRODUCTION

It is estimated that 13.7 million people living in the United States today are alive with a diagnosis of cancer. The American Cancer Society projects that 1,665,540 new cancer diagnoses will be made in 2014. The American Society of Clinical Oncology predicts that cancer will overtake heart disease as the most common cause of death by 2030, and it is already the leading cause of death in England and in Americans younger than 85 years old. Metastatic disease, that is, cancer that has spread from its site of origin (from the Greek *meta*, meaning “next,” and *stasis*, meaning “placement”), is the cause of death in the vast majority of cancer patients. This chapter will focus on these tumors, first discussing them in general and then discussing more specific clinical entities, including brain metastasis, epidural spinal column metastasis, and leptomeningeal metastasis (LM).

METASTATIC TUMORS

EPIDEMIOLOGY

Although the number of new cases of metastasis to the central nervous system diagnosed yearly is estimated at over 200,000, the exact incidence remains unknown. The reason for this is that although cancer as a disease is reportable, sites of metastatic disease are not routinely reported to any registry. Autopsy studies have reported the presence of intracranial metastases in 10% to 30% of all cancer patients (15% to the brain, 5% to the leptomeninges, 5% to the dura) as well as occult LM in an average of 20% of all cancer patients. The incidence of brain metastases has risen steadily over the last few decades, a phenomenon which is likely multifactorial: High-resolution imaging allows brain metastases to be detected more readily, and increasingly effective treatments lead to prolonged survival and thus a longer period during which neural metastases may develop. One conjectured reason for the very high incidence of metastatic disease to the brain is the highly selective permeability of the blood-brain barrier, which allows tumor cells sanctuary in the central nervous system (CNS) both from immune surveillance and the cytotoxic effects of chemotherapy, as most of these agents fail to cross the barrier adequately.

Although the brain parenchyma is the location most likely to be involved (80%) with metastatic disease to the nervous system, other common sites include the epidural space and leptomeninges. Less common sites include the dura, intramedullary spinal cord, optic apparatus, and cranial and peripheral nerves. Data regarding these less common sites are generally limited to case reports and small series, and therefore, this discussion will focus on CNS metastases, primarily of the parenchymal brain.

PATHOBIOLOGY

The molecular processes within cancer cells and their microenvironment that ultimately result in the development of metastatic disease are poorly understood and are the focus of much ongoing research. It is known that the shedding of tumor cells into systemic circulation is an early phenomenon in the natural history of malignancy, but these circulating tumor cells do not always lead to metastasis. It is estimated that less than 0.01% of these cells are able to establish a metastatic lesion at a distant anatomic site. This could well be a consequence of immune surveillance mechanisms. It is also known that certain malignancies have a predilection to metastasize to

particular organs. This may be due in part to simple anatomy and physiology but may also be dependent on specific molecular characteristics, including the secretion of specific chemotactic factors by the organ or site involved; neurotropic growth factors in the CNS are thought to play such a role. Another possible factor is the expression of specific surface molecules on tumor cells that allow them to home to certain tissues. Melanoma cells are presumed to possess such molecular features, which allow them to have among the highest probabilities of metastasizing to the brain.

Possible pathways for spread of cancer include hematogenous, lymphatic, intrathecal, and perineural. (Fig. 97.1). Although not technically metastatic, tumors may directly extend into neighboring structures, including the CNS; for example, large tumors of the head and neck may invade the brain or spinal cord. The intravasation of the cancer cell requires multiple signals between that cell and its surrounding microenvironment. Some data suggest that transformation of the malignant cell into a mesenchymal, or connective tissue-like, state is crucial for this, a phenomenon referred to as *epithelial-to-mesenchymal transformation*, or EMT.

Once intravasated and in circulation, normal anatomic organs may act as a barrier. Regional lymph nodes may trap tumor cells. The hepatocytes of the liver filter the blood as the venous return from abdominal organs passes through it, and the liver is a frequent site of metastatic disease from gastrointestinal primaries. The blood-brain barrier presents another obstacle for circulating tumor cells. Logically, organs with a large volume of blood flow are more prone to metastatic disease, such as the pulmonary capillary bed with its high flow. The CNS and the bones receive approximately 20% of the cardiac output; it is therefore not surprising that the liver, lung, CNS, and bones are the most common sites of metastatic disease.

When cancer cells arrive at a distant site, they must extravasate from circulation and establish at this location, a complex process that requires multiple interactions with the new microenvironment. The nascent metastasis must also be capable of angiogenesis, the formation of new blood vessels, in order to sustain growth larger than approximately 1 mm. Despite all these required steps for the formation of distant metastases, metastatic disease from cancer is an all too real and common phenomenon, indicating that

P.850

this orchestrated process of dissociation, intravasation, circulation, avoidance of immune surveillance, extravasation, and metastatic growth is efficiently coordinated by a significant number of malignancies through sophisticated genetic interplay.

FIGURE 97.1 Routes of metastases. CSF, cerebrospinal fluid.

CLINICAL FEATURES AND WORKUP

Metastatic disease to the nervous system may present with or without symptoms, and an appropriate clinical workup is indicated to make the diagnosis. In asymptomatic patients, metastatic disease is often found incidentally during their cancer workup and staging process or while concomitant nonmalignant comorbidities are being investigated. CNS metastases are often diagnosed in the context of a known history of malignancy, but symptomatic CNS metastasis may also be the initial clinical presentation of a previously unidentified malignancy. In this situation, biopsy or resection is required in order to pathologically confirm a diagnosis of cancer and to guide treatment. The most common primary malignancy that presents with metastatic disease in the brain is lung cancer. The most common primary malignancies that presents with metastatic disease to the spine are breast and prostate cancer. In some cases, the primary malignancy responsible for the metastatic disease is never identified despite a complete and thorough evaluation.

History and Physical Exam

The clinical presentation of CNS metastasis is highly dependent on the specific neurologic structure involved and the degree to which it has been compromised. Symptoms may be of gradual or abrupt onset, which provides insight not only to the pathologic process but also prognosis and likelihood of recovery. Clinical workup of a new neurologic deficit must begin with a thorough history and physical exam, with particular focus on the elucidation of any neurologic deficits.

Laboratory Studies

Blood work has limited use in the workup of CNS metastatic disease, but one exception is tumor markers: cancer-specific or cancer-associated proteins that are measurable in the blood or cerebrospinal fluid (CSF). If markers are elevated, especially in the CSF, then systemic metastases, including neurologic, are more likely.

The converse statement, however, is not true; a tumor marker value within normal limits does not preclude malignancy or metastatic disease. Despite this limited use, any patient with general neurologic symptoms, such as altered mental status, headache, or seizures, should have basic labs drawn in order to rule out other etiologies such as infection, electrolyte imbalance, toxins, and blood gas abnormalities.

Imaging

Magnetic resonance imaging (MRI), with and without gadolinium contrast, is the gold standard imaging test for suspected CNS cancer. Computed tomography (CT) is used in patients who cannot tolerate MRI and occasionally to further evaluate hemorrhage. Magnetic resonance spectroscopy can suggest whether a lesion is neoplastic, inflammatory, or other. At present, positron emission tomography (PET) with ^{18}F -fluorodeoxyglucose (FDG) has limited use in evaluation of brain cancers due to the high background activity of the normal brain. It is important to note that none of these imaging techniques replaces histology for diagnostic accuracy.

Tissue Diagnosis

In many cases, histologic confirmation of a CNS metastasis is unnecessary, as the likelihood of metastatic disease from a known primary, especially in the setting of systemic disease, outweighs the likelihood of a new primary CNS tumor. This is particularly true if the imaging studies have characteristics consistent with metastatic disease. In other cases, however, the diagnosis of CNS metastasis is unclear from the history, physical exam, laboratory values, and radiographic studies. If the diagnosis of metastatic disease is in question, and if the lesion is surgically accessible with reasonable safety, biopsy should be performed to provide histopathologic diagnosis.

Another important possible method of identifying metastasis to the CNS is sampling of the CSF with a lumbar puncture (LP). LP may also rule in or out other etiologies and clarify the diagnosis of LM (also termed *leptomeningeal carcinomatosis*, *neoplastic meningitis*, or *carcinomatous meningitis*). It will not, however, diagnose parenchymal brain metastases in the absence of CSF involvement. LP is contraindicated due to the risk of brain herniation in cases where increased intracranial pressure (ICP) is suspected.

TREATMENT

Both symptomatic and definitive treatments are important. Symptomatic treatment includes corticosteroids, treatment of seizures, and anticonvulsant prophylaxis. Definitive treatment includes surgery, radiation therapy, and chemotherapy.

Corticosteroids and Antiepileptics

Metastatic disease may cause marked edema due to extravasation of plasma from leaky tumor vasculature. Within the narrow anatomic confines of the CNS, this edema may cause increased ICP and significant compression of the normal neural tissue (Fig. 97.2A). Symptoms of increased ICP include headache and blurred vision. Intravenous corticosteroids, most commonly dexamethasone, should be given immediately to symptomatic patients and often result in rapid improvement in symptoms. One widely used dosing of steroids begins with an intravenous bolus of 10 mg of dexamethasone (although the actual value of the intravenous route over oral as well as the larger 10-mg dose in terms of symptom resolution is unclear), followed by 4 mg given every 6 hours. The dose should be titrated upward or downward as needed. Large doses can cause acute psychiatric symptoms, and chronic administration has myriad toxicities including candidiasis, increased risk of pneumocystis pneumonia, metabolic imbalance, sleep and mood disturbance,

muscle atrophy and wasting, weight gain, osteopenia and pathologic fractures, gastrointestinal irritability, and perforation. Steroids should be tapered as rapidly as tolerated once definitive therapy has been initiated.

FIGURE 97.2 **A:** Edema from brain metastases causing significant mass effect and midline shift. **B:** Miliary brain metastases. **C:** Hemorrhagic brain metastasis. **D:** Classic appearance of brain metastases. **E:** Radiation necrosis. These are axial contrast-enhanced MR images (**B-E**) except for (**A**) which is an axial FLAIR MR sequence.

Symptomatic patients or those with radiographic evidence of significant mass effect should be stabilized with steroids as soon as possible. Steroids have been shown to improve or resolve symptoms in up to two-thirds of patients and may confer a small survival benefit compared to no treatment. Patients who present with seizures should be stabilized with antiepileptic medications, preferably selecting agents that do not induce cytochrome p450 hepatic enzymes, as such induction could interfere with some chemotherapies. Antiepileptics are generally not indicated in patients with no history of seizure, as they have no proven benefit given prophylactically and may have significant adverse effects, including fatigue and decreased cognition; however, studies suggesting

P.852

antiepileptics have risk outweighing benefit in seizure naive patients were conducted before some of the more modern drugs, such as levetiracetam, were developed, and definitive data are lacking in the modern era [Level 1].¹

Surgery

In general, surgical management is considered for patients who are medically fit, with large tumors (>2 to 3 cm), one or few tumors, and/or a tumor associated with significant brain swelling, mass effect, and

neurologic deficits. The benefits of direct tumor removal with surgery include rapid improvement in symptoms and improved local disease control. The decision for or against surgery depends on many factors, including overall clinical performance status; status of systemic disease; and location, size, and number of metastases. Surgery may be followed by radiation or, less commonly, chemotherapy. Risks of surgery include bleeding, infection, CSF leak, and transient or permanent neurologic deficit.

Radiation Therapy

Radiation therapy (RT) may be used in combination with surgery, typically as adjuvant therapy following maximal resection or as primary therapy for unresected disease. Tumor regression following radiation is a gradual process, and the therapeutic effects lack the immediacy of surgical resection, making radiation second-line therapy in situations where immediate decompression is indicated.

For patients with known brain metastases too numerous to target individually, RT is generally delivered to the entire brain (whole brain radiation therapy [WBRT]) with the rationale that the presence of brain metastases indicates that the entire organ has been compromised. The likelihood of other tumor cells with metastatic potential elsewhere within the brain is high, and WBRT not only treats the known lesions but also may prevent the development of macroscopic disease elsewhere in the brain.

WBRT alone may reduce or eliminate symptoms from brain metastases in 60% to 80% of patients and may result in a significant radiographic response in about half of all patients. WBRT is also associated with improved median survival 4 to 6 months as opposed to 1 month without treatment. Side effects include neurocognitive decline, radiation necrosis, and damage related to the specific area of the brain being irradiated.

WBRT is classically given to a total dose of 30 Gy delivered in 10 fractions, although several other fractionation schedules have been shown to have similar efficacy with no significant difference in toxicity (20 Gy in 5 fractions, 30 Gy in 15, 37.5 Gy in 15, 40 Gy in 15, and 40 Gy in 20). Doses higher than this (50 to 54.4 Gy) and hyperfractionation (more and smaller fractions) did not show a survival benefit, and larger fraction sizes were found to be detrimental, with shorter progression-free survival and higher neurologic toxicity [Level 1].^{2,3,4} Prophylactic cranial irradiation (PCI) is WBRT in the absence of known macrometastatic disease in the brain in order to decrease the likelihood of developing such brain metastasis. PCI is indicated in small cell lung cancer, which has a very high propensity for brain metastasis. Other tumors, particularly classic pediatric brain tumors such as medulloblastoma, have a high incidence of metastatic disease to not only elsewhere in the brain but also the spinal cord. Prophylactic craniospinal irradiation (CSI) is given to the entire CNS axis in these situations.

Stereotactic radiosurgery (SRS) is a more targeted radiation technique in which a much larger dose of radiation is given in a single treatment. The advantages of SRS include shorter treatment time (1 day vs. 2 to 3 weeks) and decreased radiation dose to the surrounding normal brain tissue. SRS may be used safely to treat multiple brain lesions and may also be given in combination with WBRT. In certain situations, the precision of SRS is combined with the delivery of a few large fractions of radiation, as opposed to a single fraction, an approach referred to as *stereotactic radiotherapy*.

Chemotherapy

Chemotherapy has traditionally had a limited role in the treatment of CNS metastases because the blood-brain and the blood-CSF barriers inhibit the ability of systemic agents to penetrate to the brain and spinal cord. Some agents with good CNS penetration include high-dose intravenous methotrexate and temozolomide. Chemotherapy may also be administered intrathecally, typically via a port placed into the ventricular system, which helps circumvent these natural anatomic barriers, but intrathecal chemotherapy only penetrates into brain parenchyma by a few millimeters at most and is generally ineffective against parenchymal brain metastases. Another limitation to using chemotherapy to treat neurologic metastasis is

that the primary malignancy might have previously been treated with the same agent, leading to acquired resistance.

Cancer histologies for which chemotherapy has shown efficacy, albeit modest, in CNS metastases include germ cell tumors (where the effect is dramatic), small cell lung cancer, and breast cancer. Cancers harboring specific driver mutations such as epidermal growth factor receptor (EGFR) mutations in non-small cell lung cancer (NSCLC) may respond well to appropriate targeted therapeutics (e.g., EGFR tyrosine kinase inhibitors), which do at least partially penetrate the blood-brain barrier.

BRAIN METASTASIS

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

The most common type of cancer of the brain is metastatic disease; brain metastases outnumber primary brain tumors by a ratio of approximately 9:1. Up to 20% to 40% of all cancer patients will develop lesions in the brain. The brain may be a site of relapse at any time in the clinical course. The median time interval between the development of brain metastasis and the original cancer diagnosis is approximately 1 year, but the range can exceed 10 years. NSCLC is the most common source of brain metastases, likely because it is more common than other cancers. In comparison, a larger proportion of patients with diagnoses such as melanoma, small cell lung cancer, and specific subsets of breast cancer will develop brain metastases, but due to the lower number of patients diagnosed with these diseases, the total incidence from these primary tumors is lower than that from NSCLC.

Symptoms of CNS metastases result from both focal pressure on surrounding tissue, destruction of normal neurons, and global increases in ICP from the metastases or associated peritumoral edema. Presenting symptoms most often include headache (49%), altered mental status (32%), focal weakness (30%), ataxia (21%), and seizures (18%). Diffuse, small, miliary lesions scattered throughout the brain parenchyma are particularly associated with leukemia and small cell lung cancer and may manifest as a generalized encephalopathy (Fig. 97.2B).

Untreated brain metastases generally produce worsening symptoms over days to weeks. In some cases, symptoms are more acute and may mimic ischemic or hemorrhagic stroke. The more abrupt clinical course may particularly be seen with bleeding within the metastasis; hemorrhagic brain metastases are classically associated

P.853

with certain histologies, including melanoma, renal carcinoma, choriocarcinoma, NSCLC, and thyroid (Fig. 97.2C).

IMAGING

In the setting of a known diagnosis of cancer and new neurologic symptoms, multiple, spheroidal, enhancing brain lesions, mostly at the gray-white junction, with a disproportionate degree of edema on MRI, strongly suggest a diagnosis of brain metastases. Differential diagnosis include primary brain tumor, lymphoma, abscess, other infectious processes, stroke, multifocal demyelination, radiation necrosis, etc. A seminal series of 54 patients with a single brain lesion seen on imaging who underwent resection or biopsy reported pathologic discordance in 11%; in other words, 1 of 10 patients with MRI findings consistent with a single metastatic lesion in the brain might not have a brain metastasis.

Brain metastases may be single or multiple. The classic appearance of metastatic disease in the brain is a round, irregular, ringenhancing lesion at the gray-white matter interface with associated vasogenic edema (Fig. 97.2D). In comparison, high-grade gliomas may appear more infiltrative and irregularly shaped; gliomas are most commonly single and rarely present as multiple distinct lesions. CNS lymphoma tends to appear as

periventricular, homogeneously enhancing disease. Intracranial abscesses are high on the list of differentials in the setting of immunosuppression. These appear as well-circumscribed, thick-rimmed, ring-enhancing masses with central hypodensity. Stroke, both hemorrhagic and ischemic, may produce both similar symptoms and imaging findings as brain metastases. Multifocal demyelination has been reported after treatment with certain chemotherapy agents (5-fluorouracil and levamisole) and may also mimic metastases in appearance. Radiation necrosis is a known potential complication from RT, particularly SRS, and may also appear as a contrast-enhancing mass (Fig. 97.2E).

About 80% of brain metastases involve the cerebral hemispheres, 10% the cerebellum, and 5% the brain stem, a rate of incidence that appears consistent with the relative volume and percentage of blood flow. A high proportion of brain metastases are seen in the watershed regions. This is most likely due to smaller blood vessels and slower blood flow in these areas. For reasons that are not fully understood, different histologies may preferentially metastasize to different brain locations; lung cancer tends to metastasize to the cerebrum, whereas gastrointestinal malignancies tend to metastasize to the cerebellum.

TREATMENT

Approximately 30% to 50% of patients with metastatic disease to the brain will die from progressive intracranial disease. Therefore, when considering treatment options, one must consider not only the extent of intracranial disease but also overall disease burden, clinical status, and prognosis. To predict survival in the setting of intracranial metastasis, the Radiation Therapy Oncology Group (RTOG) developed a recursive partitioning analysis (RPA) classifier that stratifies patients based on performance status, age, control of primary tumor, and presence of extracranial metastatic disease. The graded prognostic assessment (GPA) index also takes into account the number of brain metastases and is histologyspecific. Based on these categories, predictions may be made regarding overall survival, which may then be used to potentially guide therapy.

Two clinical scenarios merit additional clarification: (1) a single brain lesion, meaning known disease elsewhere with only one lesion in the brain and (2) a solitary brain lesion, meaning the one metastasis to the brain is the only known site of disease. (It should be noted the literature often uses single and solitary interchangeably.) Single or solitary brain lesions generally warrant aggressive management, as this may have a significant impact on survival. A series by Flannery et al., reported that treatment of single, synchronous brain metastases from NSCLC in addition to definitive thoracic treatment improved survival. After medical stabilization, definitive treatment with surgery, focused radiation with SRS, WBRT, chemotherapy (including targeted agents in highly selected patients), or different combinations of these modalities are considered. The only clinical trials that have ever demonstrated survival advantage from more aggressive therapy are in patients with single (inclusive of solitary) brain metastasis.

Focal Treatment

Brain metastases may be focally treated with either surgery or SRS. To date, there are no completed prospective clinical trials directly comparing surgery with radiosurgery in the treatment of brain metastases, but in retrospective comparisons, outcomes appear generally similar [Level 1].⁵

SURGERY

Resection of a limited number of brain metastases, usually one, results in improved outcomes, both for locoregional recurrence and overall survival. For patients with solitary or single brain metastases with controlled systemic disease, resection followed by WBRT prolongs survival (median 40 to 50 weeks) and functional independence and improved neurologic function versus WBRT alone. Table 97.1 summarizes the key randomized surgical trials [Level 1].^{6,7,8} Appropriate patient selection is crucial

because resection of single metastases in patients with a greater burden of systemic disease or with poorer performance status generally does not lengthen survival. This is believed to be the reason behind the lack of survival benefit seen in the trial by Mintz et al., as this study included patients with Karnofsky performance status (KPS) of 50, compared to KPS of 70 in the other two trials. The results of this trial were also potentially confounded by a high rate of surgery following disease progression among patients randomized to WBRT alone.

Surgery is preferred to radiation in the setting of extensive edema and increased ICP, as it is the most efficacious therapy for immediate reduction of mass effect. Surgery is also preferred for cases in which a pathologic sample is desired to guide treatment and for lesions larger than 4 cm. Wider application of surgery is limited by the risk of morbidity, particularly for multiple metastases for which multiple craniotomies might be necessary. Retrospective studies of resection of up to two metastases in well-selected patients suggest a possible survival advantage, but level 1 evidence to support this approach is lacking.

TABLE 97.1 Comparison of Overall Survival for Surgery plus Whole-Brain Radiation Therapy versus Whole-Brain Radiation Therapy Alone

Trial	N	Surgery + WBRT	WBRT Alone	P Value
Patchell et al.	48	40 wk	15 wk	<.01
Noordijk et al.	63	~40 wk	~24 wk	.04
Mintz et al.	84	~22.4 wk	~25.2 wk	NS

WBRT, whole-brain radiation therapy; NS, not significant.

Stereotactic Radiosurgery

SRS is used to deliver a single, high-dose treatment of radiation to a small, circumscribed target and is frequently used for metastatic disease that is not amenable to surgery due to location or to patient comorbidities. Additionally, unlike surgery, SRS may be considered in the treatment of multiple lesions. SRS results in either stability or decrease in tumor size in over 80% of patients and represents an effective means to achieve local control. With submillimetric treatment precision accomplished with increasingly sophisticated immobilization and imaging and extremely sharp dose gradients, SRS is capable of safely delivering high doses of radiation to the target with markedly reduced dose to neighboring structures. This capability for dose escalation means that metastases from radioresistant histologies, such as melanoma and renal cell carcinoma, are more likely to respond. The prescribed dose of radiation delivered by SRS is determined by the size of the lesion, with larger lesions receiving lower doses due to the increased risk of inducing unacceptable edema and necrosis. Also for this reason, the largest lesion that may be safely treated with SRS is on the order of 3 to 4 cm, although lesions up to 5 cm in size have been treated with diminishing local control.

SRS is frequently used in combination with WBRT. A randomized trial compared WBRT plus SRS to one to

three brain metastases versus WBRT alone and found an overall survival advantage with the addition of SRS in patients with a single lesion; on post hoc analysis, other subgroups with survival benefit were identified and included patients with lung cancer with up to three lesions and RTOG RPA class I patients [Level 1].⁹ A recent reanalysis of these data, using the GPA scoring system revealed that patients with high GPA scores irrespective of the number of lesions (up to three) experienced a survival advantage.

An active area of investigation is the use of SRS to prevent local recurrence post resection. Resection bed SRS is more complex than targeting an enhancing tumor due to uncertainties regarding the interpretation of a postoperative MRI. Soltys et al. reported a 1-year local control rate of 94% when a 2-mm margin was added around the defined tumor bed versus 78% when no margin was added. One concern regarding surgical bed SRS is the possibility of leptomeningeal spread secondary to the resection, especially for patients with breast cancer and those with posterior fossa disease. The North Central Cancer Treatment Group (NCCTG), in collaboration with RTOG, is conducting a randomized study comparing postoperative WBRT versus resection bed SRS. Some institutions use preoperative SRS to obviate the tumor bed definition challenges and contend that the leptomeningeal dissemination rate is lower, but no prospective evaluations of pre- versus postoperative SRS have been conducted.

Whole-Brain Radiation Therapy in Addition to Focal Treatment

Although focal therapy such as surgery or SRS can effectively control the treated lesion, the rate of relapse in the rest of the brain is still approximately 30% to 70%. WBRT following resection or radiosurgery of a single (or up to four) brain metastases yields dramatic improvement in intracranial failure and death from neurologic progression and also improves local control. The addition of WBRT to focal treatment unquestionably reduces relapse in the brain, but cognitive decline consequential to the late effects of WBRT may result in a proportion of patients. Neurocognitive effects may be seen within months, and fixed deficits become pronounced years after treatment. Half or more of all patients with brain metastases die from systemic progression rather than from their intracranial disease, but certainly, some patients have prolonged survival and clinicians must therefore consider and discuss the possible late complications of WBRT. Recent data support a protective effect for the drug memantine [Level 1].¹⁰ There are also new data suggesting that sparing critical structures within the brain, such as the perihippocampal regenerative subgranular stem cell niche, may reduce the development of neurocognitive deficits from brain radiation.

One crucial question is whether there exists a subgroup of patients with lower risk of intracranial relapse for whom WBRT can be safely withheld altogether. As an example, a retrospective analysis by Sawrie et al. demonstrated that of 100 patients treated with SRS alone, 18 could be identified as “low-risk,” with a 1-year freedom from distant brain failure rate of 83% compared to the 26% risk in all other patients. Low-risk patients included those with three or fewer brain metastases, nonmelanoma histology, and controlled extracranial disease. The median time to brain relapse was considerably longer in these “low-risk” patients, implying that brain “seeding” probably occurs at much later times in some subgroups who could therefore be treated with upfront SRS alone. Ayala-Peacock et al. recently reported a nomogram that can be used to predict an individual patient's risk of distant brain failure after SRS, and although not yet independently validated, such a tool could prove useful in selecting appropriate patients for with-holding WBRT.

SRS is increasingly used alone, particularly in elderly patients or others with fragile baseline mentation or in those whose overall prognosis is excellent. In one small randomized trial, SRS alone actually produced neurocognitive preservation superior to WBRT plus SRS; however, the small trial size unfortunately cannot exclude selection imbalance [Level 1].¹¹ In a larger Japanese trial, cognitive function, as measured using the Mini-Mental State Examination (MMSE) trended toward superiority for

the SRS + WBRT arm, with a longer period to MMSE decline favoring the WBRT arm [**Level 1**].¹² In a European Organisation for Research and Treatment of Cancer (EORTC) trial of either resection or radiosurgery, with or without WBRT, adjuvant WBRT negatively impacted some aspects of health-related quality of life (HRQOL), although these effects were transitory. However, compliance with HRQOL was only 88.3% at baseline and dropped to an abysmal low of 45% at 1 year; in trials with such large components of missing data, imputing superiority is fraught with a lot of inherent biases [**Level 1**].¹³ A larger intergroup trial in patients with up to three metastases has recently been completed and included survival as well as cognitive and quality of life end points, but results are not available to date. Another limited institution trial is testing the same concept in patients with up to 10 brain metastases. At the American Society for Therapeutic Radiology and Oncology (ASTRO) 2014 Annual Meeting, Sahgal et al. reported a meta-analysis of three trials (EORTC 22952, JRSOG99-1, NCT 00460395) with an SRS +/- WBRT design, none of which were powered to determine a survival benefit. These trials included patients with brain metastases from various histologies; included varying number of brain lesions (one to four) with significant differences in entry criteria, salvage treatment, systemic therapy, enrollment eras, SRS dose, nonspecified follow-up imaging criteria, and variable follow-up; and also included some patients having undergone resection. The overall conclusion was that overall survival was superior in the subset of approximately 70 patients (roughly 35 patients in each cohort) receiving SRS alone and aged 35 to 50 years; no biologic explanation

P.855

for this finding was offered. Crucially, none of the trials mandated pre-SRS restaging of their systemic cancer, an element that would be crucially necessary to ensure that the survival benefit was not a spurious finding because of greater systemic disease burden in one cohort. A fundamental limitation of such an analysis was articulated by Patchell et al. wherein they pointed out that to establish whether WBRT could be safely omitted in unselected groups of patients, a noninferiority design for the SRS arm would be necessary, and with an assumed median survival of 8 months, this would require in the order of 2,250 patients.

Therefore, these findings must be interpreted cautiously, especially in the context of other reports in the literature, such as the oft-forgotten study by Pirzkall et al. involving 236 patients, wherein SRS + WBRT, compared to SRS alone (not a randomized trial), yielded better tumor control and reduced intracranial relapse and a trend toward improved survival, especially in patients with no extracranial disease (15.4 vs. 8.3 months, $P = .08$), underscoring the logical expectation that WBRT added to SRS improves brain disease control, and this has the potential to translate to a survival advantage, only in patients who are less likely to succumb to extracranial progression, once again underscoring the need to perform systemic disease restaging in trials attempting to define a survival difference.

The American Society of Radiation Oncology, in 2014, recommended against routine use of WBRT in certain selected patients with limited intracranial disease treated with SRS, but if these patients have limited extracranial disease, they may well be the exact group which might actually experience a survival benefit with WBRT, analogous to the survival benefit that accrues to small cell lung cancer patients when WBRT is used to treat presumed intracranial microscopic disease in the context of well-controlled extracranial disease (the so-called prophylactic cranial irradiation, although there is nothing truly “prophylactic” about this strategy, but in reality it is therapeutic for micrometastatic intracranial disease).

It is important to understand that recurrence of cancer in any organ frequently leads to functional deterioration within that organ, and the brain should not be expected to be an exception to this; therefore, deferring WBRT or additional SRS until relapse may have potential detrimental neurocognitive and overall survival consequences, as relapse in the brain may present with potentially

devastating and irreversible symptoms. Very few studies carefully analyze the mode of death; Regine et al., in a single institution experience reported considerably increased intracranial relapses in patients treated with SRS alone but more importantly noticed that these were most often (71%) symptomatic and associated with a neurologic deficit. Patchell et al., in their seminal trial of resection, +/- WBRT tracked cause of death and identified neurologic death as occurring far more frequently in patients not receiving WBRT, a logical outcome of increased intracranial failure [Level 1].¹⁴ One option around this is frequent monitoring with screening MRI scans after initial SRS and salvage with repeat SRS at presymptomatic recurrence. However, such an option, even if it were shown to be effective in a randomized trial, would likely be associated with increased societal costs consequential to the intense MRI and salvage with repeat SRS, usually on more than one occasion. All of these factors must be weighed for each individual patient in order to optimize treatment.

Reirradiation

Despite good initial responses, most patients will eventually experience disease progression in the brain, and so the role of reirradiation must also be considered. SRS may be used to treat recurrence after WBRT and vice versa. In some cases, WBRT may be repeated and has been reported to improve symptoms in 40% to 70% of patients. To date, there is no level 1 evidence regarding the role or reirradiation for brain metastases, and clinical decisions must be made on a case-by-case basis [Level 1].¹⁵

Chemotherapy and Targeted Agents

The role of chemotherapy, targeted therapy, or immunotherapy is not well defined. There is no level 1 evidence favoring the use of systemic therapy, and therefore no standard cytotoxic chemotherapy is routinely used for the treatment of brain metastases. In patients with brain metastases that have failed local therapy, the same chemotherapeutic agents employed for the treatment of extracranial disease are often used. Alternatively, drugs with good CNS penetration, such as temozolomide, topotecan, irinotecan, and high-dose methotrexate may be employed, even in patients in whom the chemotherapy might have at most minor efficacy against the primary tumor.

Improved understanding of tumor biology has led to the identification of specific molecular drivers of cancer development and progression. Alterations involving the *EGFR* gene and *EML4-ALK* chromosomal translocation in lung cancer, HER2 protein overexpression in breast cancer, and *BRAF* mutation in melanoma are examples of distinct subsets of cancer amenable to unique treatment approaches. There have been several prospective studies in the last 3 to 5 years particularly focusing on targeted therapies or immunotherapy.

EGFR INHIBITORS IN NON-SMALL CELL LUNG CANCER

The RTOG 0320 trial did not show any additional benefit of temozolomide or erlotinib when added to WBRT and SRS in unselected patients with NSCLC with one to three brain metastases [Level 1].¹⁶ One of the limitations of this study was that patients were not stratified according to *EGFR* mutational status. In a phase II study of 40 NSCLC patients with brain metastases, WBRT and erlotinib was safe and the median survival time was 11.8 months. In the 17 patients with known *EGFR* status, the benefit of erlotinib was more pronounced in the mutant *EGFR* patients (overall survival [OS] of 19.1 months) as compared to the wild-type *EGFR* patients (OS of 9.3 months). In a large cohort of 110 patients with *EGFR* mutant lung cancer with newly diagnosed brain metastases, patients treated with WBRT (32 patients) had longer median time to intracranial progression compared to 63 patients who received erlotinib therapy upfront (24 vs. 16 months).

In a phase II study of gefitinib in 41 NSCLC patients unselected for *EGFR* mutation, an objective response rate of 10% in the brain was seen. Higher response rates were reported in studies of EGFR inhibitors in

enriched with patients with known *EGFR* mutations. Recently, Gerber et al., reported that the survival of *EGFR*-mutated NSCLC patients with brain metastases is notably long, with a median of 33 months; those receiving radiosurgery had a dramatic median survival of 64 months.

ALK INHIBITORS IN NON-SMALL CELL LUNG CANCER

Although crizotinib has limited blood-brain barrier penetrability, initial results of the novel Alk inhibitors such as alectinib, ceritinib, AP26113, etc., show better control of intracranial metastases and are in early evaluation phases regarding their activity against established brain metastases in patients with Alk-rearrangement NSCLC with brain metastases.

P.856

HER2 INHIBITORS FOR BREAST CANCER

Several prospective clinical trials have evaluated the role of lapatinib-based therapy in *HER2*-positive breast cancer patients with active brain metastases. In one phase II study of lapatinib in patients with *HER2*-positive breast cancer with progressive brain metastases after WBRT and/or SRS, a CNS response rate of only 6% was seen. In a single-arm, phase 2 study, 29 of the 45 patients with newly diagnosed, previously untreated brain metastases from *HER2*-positive breast cancer achieved an objective CNS response (66%) with the combination of lapatinib and capecitabine [Level 1].¹⁷ Newer agents such as trastuzumab emtansine are demonstrating intracranial activity in anecdotal reports.

INHIBITORS TARGETING BRAF IN MELANOMA

Activating *BRAF* mutations that result in constitutive activation of the mitogen-activated protein kinase (MAPK) pathway affect approximately half of melanoma patients and more than 95% of these are the V600E mutations (substitution of valine by glutamic acid at the 600th amino acid position). In an open-label phase II study, 172 patients with V600E or V600K mutation-positive melanoma metastatic to the brain were treated with dabrafenib. Patients in cohort A had not received any prior local therapy and cohort B had disease progression in the brain following local therapy (surgery, WBRT, SRS). Twenty-nine of 74 patients (39%) with V600E *BRAF*-mutant melanoma in cohort A and 20 of 65 patients in cohort B achieved an overall intracranial response. This study provided initial evidence that dabrafenib has activity in patients with V600E *BRAF*-mutant melanoma brain metastases irrespective of prior local therapy.

In a prospective study, 24 patients with V600E *BRAF* mutation-positive melanoma brain metastases were treated with vemurafenib. Of 19 patients with measurable intracranial disease, 7 (37%) achieved greater than 30% intracranial tumor regression, and 3 (16%) achieved a confirmed partial response (PR), whereas 13/21 patients (62%) had extracranial responses. A phase II study of vemurafenib in 146 patients with V600 *BRAF* mutation-positive melanoma brain metastases (NCT01378975) with or without prior treatment for their brain metastases has completed accrual, and results are pending.

IMMUNE-MODULATING APPROACHES

The development of immune-modulating agents, specifically immune checkpoint inhibitors, offers an exciting opportunity for treating patients with brain metastases. Recent research has demonstrated that activated T cells can be effective in brain metastases and other intracranial tumors. In a phase II study, 72 melanoma patients with brain metastases (51 asymptomatic [cohort A], 21 symptomatic and on steroids [cohort B]) were treated with ipilimumab, a monoclonal antibody against CTLA-4. Twelve of 51 patients (24%) in cohort A and 2 of 21 patients (10%) in cohort B achieved CNS disease control. Median OS was 7.0 months in cohort A and 3.7 months in cohort B. This study demonstrated that ipilimumab could have some activity in recurrent brain metastases, and further evaluation especially in a combinatorial manner is proceeding.

In the expanded access programme (EAP) in Italy, the feasibility of ipilimumab (3 mg/kg every 3 weeks for four doses) in patients with stage III (unresectable) or IV melanoma and asymptomatic brain metastases who had failed or did not tolerate previous treatments was investigated. Of 855 patients, 146 had asymptomatic

brain metastases. With a median follow-up of 4 months, the overall disease control rate was 27%, including 4 patients with a complete response and 13 with a partial response. Median progression-free survival and overall survival were 2.8 and 4.3 months, respectively, and approximately one-fifth of patients were alive 1 year after starting ipilimumab.

There is considerable interest in combining these immune checkpoint inhibitors with radiation. A retrospective analysis of 13 patients treated with WBRT within 30 days of ipilimumab showed that 4/9 patients (44 %) experienced partial response or stable disease. There was a high rate of intratumoral hemorrhage, with 10 of 10 patients with posttreatment imaging demonstrating new or increased intratumoral bleeding after WBRT. In another retrospective review, the median survival of patients with melanoma with brain metastases treated with ipilimumab and brain SRS was comparable to patients without brain metastases.

EPIDURAL SPINAL COLUMN METASTASIS

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

Metastatic disease to the spine can be leptomeningeal (discussed in the following section) or intramedullary, but by far, the most common site is epidural. Epidural spinal metastases can cause severe neurologic compromise by compressing the thecal sac and ultimately the spinal cord. The cancers that most often are responsible for epidural metastatic disease of the spine include breast, prostate, and lung cancers. This is in part due to the relatively high incidence of these malignancies but also for their predilection for metastatic spread to bones; the spinal column is the most common site of bone metastasis.

Epidural spinal cord compression can be a surgical emergency that occurs in up to 15% of patients with a history of cancer. This complication typically occurs in the setting of known bone metastases but, as with brain lesions, may be the presenting symptom for a new diagnosis of primary malignancy or for new diagnosis of metastatic disease. The most common level of cord compression is thoracic (59% to 78%), followed by lumbar (16% to 33%) and cervical (4% to 15%) (Fig. 97.3). In up to 50% of patients, disease may involve multiple levels of the vertebral column. As with bone metastases, pain is the most common presenting symptom of spinal cord compression (96%). This may be not only from the bone itself but also from spinal cord or nerve root involvement. As compression worsens, patients may also develop other signs and symptoms of spinal cord compression including gait ataxia, focal weakness (76% to 86%), sensory disturbances (51% to 80%), and autonomic dysfunction (40% to 64%). In most cases, epidural spinal cord compression occurs due to extension of disease from the bony vertebrae, but it sometimes may be due to infiltration of the neural foramina or paravertebral spaces or from pathologic vertebral fracture. Compression of the spinal cord and blood vessels causes mechanical nerve damage and ultimately ischemia and infarction. The longer the cord is compromised, the more likely that the damage is irreversible; it is well established that long-standing, gradually worsening neurologic symptoms are unlikely to be markedly improved due to the chronic nature of the damage.

The diagnostic test of choice for spine metastasis of any kind is a contrast-enhanced MRI scan, but if the patient's condition is rapidly deteriorating, or if the patient is unable to tolerate the length of this study, a noncontrast MRI may be adequate. If, however,

P.857

there is clinical suspicion for either intramedullary or leptomeningeal disease, then intravenous contrast is absolutely indicated. The entire spine should be studied in order to evaluate for multilevel involvement. Patients who are unable to undergo MRI should have a CT myelogram.

FIGURE 97.3 Spinal cord compression from metastatic disease, sagittal, T2 MRI.

TREATMENT

Initial palliation of pain from spinal metastasis is often with nonsteroidal anti-inflammatory drugs (NSAIDs), narcotics, agents to ameliorate neuropathic pain, and steroids.

For spinal cord compression, the goals of care are to preserve neurologic function and to relieve pain. The early recognition and initiation of treatment, even prior to definitive diagnosis, are critical due to the time-sensitive chance of recovery from a neurologic deficit. As soon as clinical suspicion for cord compression is raised, treatment should begin with early administration of high-dose corticosteroids to decrease swelling, as this has been shown to improve outcomes in acute spinal cord injury [Level 1].¹⁸

Surgery is the primary modality for relieving spinal cord compression, particularly in the setting of limited disease, as it can result in immediate decompression. The seminal prospective study comparing the addition of surgery to radiation in the setting of spinal cord compression showed not only improved neurologic and functional outcomes with surgery, including ambulation, continence, and decreased steroid and narcotic requirements, but also an overall survival benefit (126 vs. 100 days, $P = .033$) [Level 1].¹⁹ Even in the absence of cord compression, surgical management should be considered in the setting of an unknown primary malignancy or new metastatic disease in order to confirm the diagnoses. For patients with

vertebral fracture or spinal instability, stabilization of the spine through surgical means should be considered. Anterior epidural metastases are more challenging to access and may require thoracotomy, whereas posterior lesions are likely to be amenable to laminectomy.

Given the grave consequences of progressive disease in the spine, RT, which is a highly effective palliative treatment with up to 90% of patients experiencing a significant reduction of pain, should be considered at an early stage. This is important because pain from a compression fracture and compressive symptoms from retropulsed bony fragments are almost never adequately relieved by any modality except surgery. RT can reduce the likelihood of a pathologic fracture, as may vertebroplasty. Should a fracture occur, surgical repair is the best option when possible, and postoperative radiation is the standard of care. RT in this setting decreases the likelihood of local recurrence, which may compromise the integrity of the surgical repair. The typical timeframe is 1 to 2 weeks after surgery in order to allow adequate wound healing. In selected patients, percutaneous vertebroplasty or kyphoplasty may be effective in relieving symptoms. None of these treatments will prolong survival but may have a significant positive impact on quality of life.

RT is also a common palliative treatment for epidural spinal cord metastases, particularly for cases in which surgery is not feasible (i.e., multilevel cord involvement, multiple medical comorbidities) and in the postoperative setting. As with brain metastases, the effect from radiation is gradual and lacks the immediate decompression of surgery. RT is therefore suboptimal in the setting of spinal cord compression. The classic regimen for palliative RT is 30 Gy in 10 fractions, but other equivalent fractionation schedules exist. The target volume typically includes one whole vertebral body above and below the area involved with disease. For primary malignancies involving the bone, such as multiple myeloma or sarcoma, the prescribed dose may be lower or higher and the target volume more conservative to avoid overtreating neighboring structures, particularly the spinal cord.

RT may be contraindicated in patients who have received previous RT to the same site or for relatively radioresistant tumors such as renal cell carcinoma. Reirradiation may be considered using a highly focused, intensity-modulated technique, as this has been shown to stabilize or improve neurologic status in the majority of patients with minimal risk of radiation myelopathy. Stereotactic body radiation therapy (SBRT), highly focal fractionated radiation with sharp dose gradients similar to SRS, may also be employed in this setting in order to minimize unnecessary dose to the spinal cord. Sahgal et al. report that normalized biologically effective doses less than a point maximum of 20 to 25 Gy carry a low risk for myelopathy so long as the total effective dose does not exceed approximately 70 Gy, and the SBRT maximum dose is less than half the total normalized dose. A prospective series of 59 patients from MD Anderson who underwent reirradiation of spinal metastases demonstrated 92% freedom from neurologic deterioration from any cause at 1 year. An ongoing RTOG phase II/III trial exploring SRS in the up-front treatment of spine metastases may ultimately provide insight regarding the use of this approach [Level 1].²⁰ The phase II trial supported the feasibility of single fraction SRS for spinal metastases with no serious treatment-related toxicities. Phase III compares SRS versus classic fractionated external beam treatments with regard to pain relief and quality of life.

By far, the strongest prognostic factor for neurologic outcome is the patient's neurologic status prior to treatment. The best odds for regain of function are with surgery. With radiation, 80% of ambulatory patients remained ambulatory, but only 50% of patients with paresis and less than 10% of those with paralysis will regain the ability to walk. Pain may be relieved in over 90% of patients treated with corticosteroids and radiation. Overall survival is most strongly determined by systemic disease burden.

EPIDEMIOLOGY AND CLINICAL PRESENTATION

LM refers to metastasis to the pia and arachnoid. The disease may be focal or disseminated, but any involvement of the meninges with cancer indicates that the entire CSF compartment is compromised. This devastating complication occurs in up to 5% to 10% of cancer patients, with acute lymphocytic leukemia and other hematologic malignancies representing the most common sources. The most common solid tumors that spread to the leptomeninges are breast cancer, NSCLC, melanoma, and gastrointestinal cancers. Over half (50% to 80%) of patients with known brain metastases also have LM. Surgical resection of brain lesions, particularly of the posterior fossa, has been reported as a risk factor for the development of LM. Most cases of LM are diagnosed in the setting of known metastatic disease, but LM may be an isolated phenomenon, particularly for hematologic cancers.

The median survival without treatment is 4 to 6 weeks. Appropriate treatment may prolong survival to several months, particularly for lymphoma, leukemia, and to a lesser extent breast cancer. Treatment may also potentially reverse or prevent further neurologic symptoms. The presence of systemic disease, obstruction of the CSF, gross CNS metastases, and poor performance status are negative prognostic factors.

Headache is a common presenting symptom (30% to 50%), as are altered mental status and signs of focal neuropathy. Patients most commonly present with multifocal neurologic symptoms from spinal cord (60%), cerebral (50%), or cranial nerve involvement (40%). Increased ICP or hydrocephalus may develop due to obstruction of CSF flow or from disruption of the blood-brain barrier. Seizures occur in up to 25% of patients.

In the workup of LM, MRI of the entire CNS should be performed. Even though the sensitivity and specificity of imaging are relatively low (76% and 77%), obvious LM on imaging obviates the need for CSF sampling by lumbar or other puncture. If LM is visualized, it appears as enhancement of the leptomeninges, cranial nerves, or nerve roots or as gross tumor nodules. Visible LM is most commonly seen at the base of brain, sylvian fissures, and cauda equina, perhaps due to slower CSF flow in these regions.

LP should be performed for CSF analysis, particularly if the clinical suspicion for LM is high and MRI is negative. LP may show a combination of malignant cells, elevated opening pressure, low glucose, high protein, and leukocytosis, typically of lymphocytes. Assessing the CSF for tumor marker levels, although not standard, may aid in diagnosis. The false-negative rate for initial LP in the diagnosis of LM is relatively high at 50%, and therefore, this procedure may need to be repeated multiple times to increase diagnostic yield if clinically indicated. In as many as 20% of patients with clinical or radiographic LM, the CSF may be nondiagnostic despite multiple samples. LP is contraindicated if there is a risk for brain herniation and should therefore follow MRI to make this assessment.

TREATMENT

LM is generally an incurable condition with a poor prognosis, and a careful balance of risks and benefits must be individualized. The focus of treatment is primarily palliation of symptoms. Treatment must address the entire CSF compartment, and therefore, focal therapy with surgery and radiation has limited use.

Nevertheless, neurosurgical evaluation should be considered for CSF shunting, typically to the peritoneum, or for placement of an intrathecal reservoir. CSF shunting carries a theoretical risk of spread of tumor cells into the destination space, but this risk is generally not clinically significant in the context of such limited survival.

Symptomatic or bulky focal lesions may be treated with radiation in a similar fashion to epidural metastases. CSI is not routinely indicated, as it does not improve outcomes and can cause significant morbidity, especially in adults (nausea, dysphagia, fatigue, myelosuppression).

Intrathecal chemotherapy (ITC) is the mainstay of treatment of LM as it allows circulation to the entire CSF

volume; specific agents include methotrexate, cytarabine (in both standard and depot formulations), and thiotepa. Cytarabine, especially the depot form, should be preceded and followed by 2 to 3 days of corticosteroid prophylaxis, as a severe chemical meningitis can otherwise result. Combination chemotherapy may be considered, although data showing increased efficacy are sparse. ITC is less effective in patients with obstruction of the CSF and contraindicated in the setting of increased ICP. Occasionally, a combination ventriculoperitoneal shunt/Ommaya reservoir device is implanted to both reduce ICP and serve as a method for ITC delivery; however, this requires careful coordination of valve positioning and all too often becomes obstructed with CSF cells. ITC is typically administered intraventricularly using an implanted Ommaya reservoir. Administration via LP is also possible, but this method is more cumbersome and painful and less reliable. ITC carries a risk of meningitis, myelosuppression, and encephalopathy. Disruption in the normal flow of CSF is a common phenomenon with LM. This has important implications in the administration of ITC, as it can both decrease efficacy and increase toxicity. Assessment of the CSF flow with radionuclide cisternogram prior to ITC is beneficial but not universally available. MRI-based flow studies are emerging but the level of resolution is limited in this context. Identification of sites of obstruction may allow focal treatment with radiation prior to ITC, which may improve flow even in the absence of a discrete lesion. WBRT may be considered, as it is well tolerated and may improve CSF flow. Systemic chemotherapy has limited use in the treatment of LM due to the blood-brain barrier, but this is an area of ongoing investigation. Additional palliative care with analgesics, steroids, antiseizure medications, and CSF shunting should be initiated as indicated.

CONCLUSIONS

Metastatic disease to the neurologic system, particularly the CNS, is a widespread and clinically important scenario. The diagnosis is generally made with a combination of history, physical exam, and imaging. In some cases, blood work, biopsy, or CSF sampling may also aid in diagnosis. Management of CNS metastases is accomplished with corticosteroids, surgery, radiation, chemotherapy, or a combination of these modalities. The treatment plan and clinical outcome depend on the specific factors of that individual patient, including the location and extent of metastatic lesions, duration of symptoms, and the patient's ability to tolerate treatment.

Tumors of the Meninges

Thomas J. Kaley

INTRODUCTION

Diseases of the dura are rather uncommon, except for meningiomas. Not just the most common dural disease, meningiomas are the most common intracranial primary tumor in adults. Especially in the current environment of neuroimaging with computed tomography (CT) or magnetic resonance imaging (MRI) being performed for any and every possible neurologic symptom, both symptomatic and more frequently asymptomatic meningiomas will be found. Accordingly, meningiomas may become the most common intracranial tumor neurologists, and most physicians, will encounter. Although they are usually benign, they may enlarge and/or cause neurologic dysfunction depending on the location and because the cranium has only a limited capacity to accommodate an expanding mass. Surgery remains the treatment of choice, but not all meningiomas are amenable to complete resection, and some will recur and require further therapy. This chapter will outline the major dural diseases with the majority devoted to meningiomas.

MENINGIOMAS

EPIDEMIOLOGY

Meningiomas are the most common primary “brain” tumor in adults, although technically, they are tumors of the brain covering rather than brain parenchyma. The Central Brain Tumor Registry of the United States estimates an incidence of approximately 20,000 new meningioma cases diagnosed per year. This represents 36% of all primary brain tumors (World Health Organization [WHO]). These tumors have a clear female predominance with an almost 2:1 female-to-male ratio. These tumors are quite rare in children except within a predisposing neurogenetic syndrome. They are substantially more common in adults and tend to increase in incidence with age, particularly older than the age of 65 years. Autopsy series suggest a prevalence of 2%, typically asymptomatic and discovered incidentally during life or postmortem.

The only clear risk factors for meningiomas are prior radiotherapy involving the head and neck region as well as predisposing neurogenetic syndromes, such as neurofibromatosis type 2 (NF2). Ionizing radiation has also been demonstrated to be clear risk factor for future meningioma development. Prior radiation therapy for an extracranial malignancy such as head and neck cancer or childhood leukemia is the most common. These meningiomas that develop as a result of prior radiotherapy tend to be more aggressive in their clinical course. The latency for meningioma development is inversely proportional to the dose of radiation delivered.

Although no longer performed, scalp radiation for tinea capitis, a fungal infection, has been linked to meningioma development. Similarly, older less refined dental x-rays have been inconclusively linked to meningiomas. Currently, however, radiotherapy is no longer performed for scalp infections and newer dental x-rays probably do not have significant risk, different from the older less refined variant. Probably the most controversial potential link to meningiomas in the recent media and scientific literature has been the use of cellular phones and potential radiation exposure. To date, there has been no proven definitive link between cellular phones and the development of a meningioma.

PATHOBIOLOGY

Meningiomas are tumors that arise from the arachnoid coverings of the brain. Histologically, these tumors have various appearances depending on the subtype of meningioma, although most physicians frequently recall the

whorling pattern of tumor cells which is most common and calcium collections known as *psammoma bodies*. The WHO classifies meningiomas into three grades (in the following text).

The most common neurogenetic syndrome predisposing the patient to meningiomas is NF2, the less common form of neurofibromatosis. NF2 is an autosomal dominant disorder with full penetrance caused by alteration of the *NF2* gene (also known as *chromosome 22*, which encodes for the tumor suppressor protein merlin (moesin-ezrin-radixin-like protein), also called *neurofibromin*. Approximately 80% of sporadic meningiomas also harbor *NF2* alterations. However, there is no clear selective therapy to target merlin alterations.

Recent research efforts have focused on understanding the biology of cancer as a whole and using targeted therapies that disrupt a specific biologic pathway, typically a growth factor ligand/receptor-mediated pathway. Meningiomas are highly vascular tumors with elevated expression of the vascular endothelial growth factor (VEGF) receptor and its ligand, VEGF. Other growth factor pathways such as platelet-derived growth factor (PDGF), epidermal growth factor (EGF), insulin-like growth factor (IGF), and somatostatin are also expressed in meningiomas. Efforts at targeting these pathways are discussed in the following text.

A major thrust of cancer investigation over the last decade has been whole genome sequencing to identify drugable oncogenic driver mutations. Mutations in two pathways recently were identified in approximately 20% of meningiomas: *AKT* and *SMO*. *AKT* mutations disrupt the homeostasis that normally regulates cancer cell survival, proliferation, angiogenesis, and metabolism. *SMO* mutations alter a key pathway responsible for controlling cancer cell self-renewal.

In the Clark et al. paper, genomic analysis revealed oncogenic mutations in *AKT1* and *SMO* in 13% and 4% of specimens, respectively. These mutated tumors tend to occur more frequently in skull base locations, which also tend to be the most surgically challenging or inaccessible areas. Patients with *AKT* mutations harbored the *E17K* mutation, a well-characterized oncogenic mutation present in several other cancer types. The *E17K* mutation can be found in breast cancer, colorectal cancer, and lung cancer and results in constitutive *AKT* activation, which in turn stimulates downstream mTOR activity, resulting in overactivity of the PI3K pathway. PI3K pathway activation in turn stimulates multiple oncogenic processes including cell proliferation and angiogenesis. The *SMO* mutations included the *L412F* seen in a subset of medulloblastomas and the

P.862

W535L alteration seen in basal cell carcinoma and predictive of sensitivity to U.S. Food and Drug Administration (FDA)-approved therapy with vismodegib, a hedgehog inhibitor. When the *SMO* protein is activated, it results in ligand-independent downstream activation of the hedgehog pathway resulting in cell proliferation and cancer stem cell self-renewal.

In the Brastianos et al. paper, 65 meningioma specimens underwent analysis and revealed similar results identifying *AKT* and *SMO* mutations in a subset of patients. Five patients (8%) demonstrated *AKT* mutations, all *E17K*. Three patients (5%) demonstrated *SMO* mutations, two of which were the *W535L* mutation seen in basal cell carcinoma and one *L412F* alteration previously described in desmoplastic medulloblastoma. They then studied an additional 46 grade I tumors and 49 grade II and III tumors and found 6 *AKT1 E17K* mutated tumors (1 grade III, 5 grade I), and 2 *SMO L412F* mutated tumors (both grade I).

In summary, these two studies demonstrated that PI3K pathway activation and hedgehog pathway activation occurs in a subset of meningioma patients. The mutations seen are well characterized in other cancer types and in the case of basal cell cancer, predict therapeutic response to inhibition with an available agent. Future studies hope to define the role, if any, of these agents in the treatment of these particular molecular subtypes of meningioma.

CLINICAL MANIFESTATIONS

As with most other brain tumors, the clinical presentation of meningiomas is highly variable, depending on tumor location, size, and shape. Tumors may manifest as visual disturbances, speech dysfunction, weakness, sensory dysfunction, neurocognitive dysfunction, personality changes, or seizures. Because meningiomas are typically slow-growing neoplasms, they rarely cause acute increases in intracranial pressure, resulting in symptoms such as headache, nausea, vomiting, or alteration of consciousness. In fact, because they are such slow-growing tumors, they can often become surprisingly large without causing any clinical neurologic dysfunction. However, even a “benign” meningioma can result in disabling neurologic dysfunction if it grows beyond the capacity of the skull to accommodate the increase in volume. Rarely, these tumors may metastasize outside the central nervous system (CNS), usually to bone. This is an exceptionally rare event and typically only with malignant meningiomas.

FIGURE 98.1 MRI appearance of meningiomas. **A:** Coronal T1 postcontrast image demonstrating a recurrent grade I meningioma. **B:** Coronal T1 postcontrast image demonstrating an atypical meningioma noting significant peritumoral edema. **C:** Axial T1 postcontrast image demonstrating an anaplastic meningioma noting brain invasion. **D:** Sagittal T1 postcontrast image demonstrating extracranial growth of a recurrent surgery and radiation refractory meningioma.

DIAGNOSIS

Meningiomas are best visualized on an MRI with contrast, which demonstrates a brightly enhancing mass arising off of the dura which typically has a linear continuation with the dura known as a *dural tail* (Fig. 98.1). CT with contrast may demonstrate the same pattern of enhancement, but MRI provides a better visualization of the underlying brain. CT may be superior for demonstrating any changes in the neighboring bone, as meningiomas can trigger a reactive hyperostosis in the bone adjacent to the meningioma itself, seen in approximately 25% of patients. Without contrast, meningiomas appear on both CT and MRI as either hypodense or hypointense, or isodense or isointense.

As with most tumors, neuroimaging alone cannot definitively diagnose a meningioma, which depends on tissue analysis

P.863

acquired by biopsy or resection. The WHO classifies meningiomas in three grades (Table 98.1). WHO grade I meningiomas are classified as “benign” meningiomas and makeup approximately 80% of meningiomas. They are typically slow-growing tumors that basically fail to demonstrate any of the characteristics of higher grade meningiomas. Grade I meningiomas include most of the histologic subtypes: angiomatous, fibrous, lymphoplasmacyte-rich, meningothelial, metaplastic, microcystic, psammomatous, secretory, and transitional meningiomas. WHO grade II meningiomas include the clear cell and chordoid histologic variants, as well as atypical tumors that harbor increased mitotic activity as evidenced by four or more mitoses per 10 high-power fields or at least three of the following features: increased cellularity, small cells with a high nuclear-to-cytoplasmic ratio, prominent nucleoli, patternless or sheet-like growth, or necrosis. Importantly, brain invasion is associated with increased rates of recurrence and is sufficient to diagnose a WHO grade II tumor, regardless of the presence of other atypical features. WHO grade III meningiomas include rhabdoid, papillary, and anaplastic (malignant). The criteria for anaplastic meningiomas include increased mitotic activity as evidenced by 20 or more mitoses per 10 high-power fields and/or malignant characteristics resembling carcinoma, sarcoma, or melanoma, such as the loss of usual meningioma growth patterns, infiltration of underlying brain, abundant mitoses with atypical forms, and multifocal necrosis. Anaplasia is sufficient to diagnose a WHO grade III regardless of the presence of brain invasion.

TABLE 98.1 World Health Organization Grading Criteria for Meningiomas

WHO Grade I Meningioma

Angiomatous
Fibrous
Lymphoplasmacyte-rich
Meningothelial
Metaplastic
Microcystic
Psammomatous
Secretory
Transitional

WHO Grade II Meningioma

Clear cell

Chordoid

Atypical: greater than four mitoses per 10 high-power fields or at least three of the following features:

- Increased cellularity
- Small cells with a high nuclear-to-cytoplasmic ratio
- Prominent nucleoli
- Patternless or sheetlike growth
- Necrosis

WHO Grade III Meningioma

Rhabdoid

Papillary

Anaplastic (malignant): ≥ 20 mitoses per 10 high-power fields and/or malignant characteristics including the following:

- Loss of typical growth patterns
- Brain invasion
- Abundant mitoses with atypical forms
- Multifocal necrosis

TREATMENT

Despite advances in cancer therapy, the treatment of meningioma remains primarily surgical with the goal of maximum safe surgical resection. In patients in whom a meningioma is unresectable due to location yet needs treatment, or in patients whose tumor is only amenable to a subtotal resection with persistent neurologic symptoms or dysfunction, radiation therapy is typically offered. Oftentimes, the biggest clinical question revolves around the timing of each of these therapies, which we will discuss further within the individual grades of meningioma and is outlined in [Figure 98.2](#).

Surgery

The goal of surgical resection is always maximum resection balanced against minimal neurologic surgical morbidity. The degree of surgical resection is graded on the Simpson grading scale, ranging from grade I which includes complete removal of not only the meningioma but also any involved dura or bone through grade 5 which only includes decompression, with or without biopsy of the tumor. However, in clinical practice, the most commonly used terminology is *gross total resection* (removal of all visible tumor), *subtotal resection* (partial resection), or *biopsy* (only a small piece of tissue was removed for histologic diagnosis).

Radiotherapy

The two forms of radiotherapy used most often are external beam radiation therapy and stereotactic radiosurgery. External beam radiation therapy (EBRT) uses standard radiation techniques of delivering a lower dose of radiation per day over a longer course of treatment. Stereotactic radiosurgery (SRS) delivers a very high dose of radiation, typically within one session. SRS goes by many different names depending on the machine that is used, the energy source, and planning platform. Some centers use Gamma Knife machines, CyberKnife machines, or LINAC systems. EBRT and SRS have never been compared against one another in a randomized prospective fashion. However, both forms of radiation demonstrated efficacy in

treating meningiomas in multiple retrospective series. Similarly, the different forms of SRS have never been compared against one another in a randomized fashion, but they are likely all comparable. The decision of whether to use EBRT or SRS is typically determined by the location of the tumor, potential complications of radiation, and expertise of the physician administering the treatment.

Chemotherapy

Unlike surgery and radiation, chemotherapy has yet to demonstrate a benefit in the treatment of meningioma. However, there is a need for effective medical or chemotherapy for certain subsets of patients with meningiomas, especially those with meningiomas refractory to surgery and radiation. In this subset, no medical therapy has yet proven effective. The other subset for which a viable chemotherapy approach is needed is that subset of tumors in whom surgery and/or radiation is either technically not feasible or not advisable due to other circumstances.

Many chemotherapies have been studied in the treatment of meningioma; unfortunately, no therapy has demonstrated clear efficacy in a randomized phase III trial (Table 98.2), and no FDA-approved therapies exist. Studies investigating traditional cytotoxic chemotherapies (temozolomide, hydroxyurea, irinotecan, and triple therapy with cyclophosphamide + doxorubicin + vincristine), hormonal therapies (progesterone and estrogen modulators), interferon α -2b, somatostatin analogues, and molecularly targeted therapies including inhibitors of PDGF (imatinib) and epidermal

P.864

growth factor receptor (EGFR; gefitinib and erlotinib) have all been disappointing. The 6-month progression-free survival rates are less than 20%, similar to those for the most common and aggressive parenchymal brain tumor, glioblastomas.

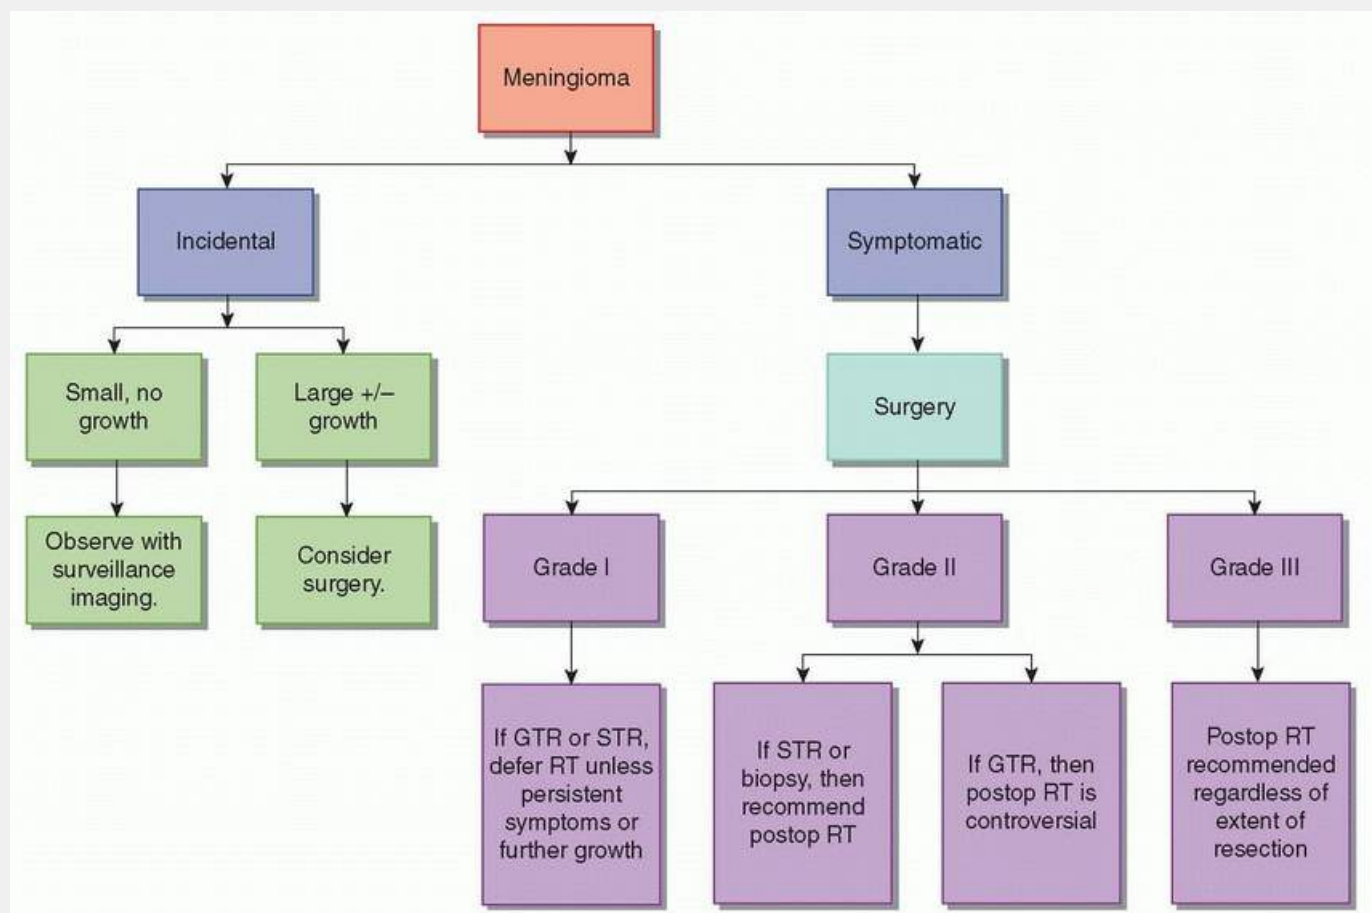

FIGURE 98.2 Algorithm for the treatment of meningiomas. GTR, gross total resection; STR, subtotal resection; RT, radiation therapy.

Meningiomas are highly vascular and targeting tumor vasculature may be a potentially effective strategy.

Targeted therapy to disrupt tumor angiogenesis (the development of new blood vessels) such as vascular endothelial growth factor receptor (VEGFR) with the tyrosine kinase inhibitor sunitinib and targeting the VEGF ligand with the monoclonal antibody bevacizumab have shown some possible benefit and may represent a viable future treatment strategy.

The recent discovery of oncogenic driver mutations in either AKT in the PI3K pathway or SMO in the hedgehog pathway may provide potential therapeutic targets in a subset of patients. Inhibitors of AKT and SMO are currently in clinical trial development. However, *AKT* and *SMO* mutant tumors are a minority, additional discoveries are desperately needed.

OUTCOMES

World Health Organization Grade I Meningioma

The preferred treatment of WHO grade I meningiomas remains surgical resection whenever feasible. With gross total resection, the 5-year recurrence rate is approximately 10% to 25% (Rogers et al.). With subtotal resection, it is approximately 25% to 50%. With either gross total resection or subtotal resection, postoperatively, these patients are managed with observation and surveillance imaging. Radiation is typically reserved for when patients have persistent neurologic dysfunction due to a tumor that cannot be completely resected or for patients who suffer a recurrence or progressive growth of their tumor.

World Health Organization Grade II Meningioma

As with grade I tumors, the initial and preferred management of WHO grade II meningiomas is also maximum safe surgical resection. If gross total resection is not achieved, postoperative radiotherapy is standard absent a contraindication. However, there is substantial controversy whether the benefits of immediate postoperative radiotherapy outweigh the risks for completely resected tumors. The 5-year recurrence rate after surgery alone is approximately 50%, and numerous retrospective series have demonstrated an increase in progression-free survival with the addition of postoperative radiotherapy. However, immediate postoperative radiotherapy (as opposed to radiotherapy at the time of recurrence) has yet to demonstrate an overall survival advantage and has risks. Fortunately, a randomized trial is ongoing.

World Health Organization Grade III Meningioma

After surgery alone, the chance of recurrence at 5 years is 70% to 80% after gross total resection and 100% after subtotal resection. Therefore, postoperative radiation is nearly always offered to these patients in an attempt to increase the time before inevitable recurrence. Regardless, however, nearly all patients recur.

Incidental Meningioma

The incidental meningioma is a common yet often puzzling clinical situation. With imaging alone, there is uncertainty as to the histology, grade, and pace of growth (if any) of the incidentally found lesion. Often, the meningioma itself is asymptomatic and unrelated to the initial complaint that led to the neuroimaging. In the case of a

P.865

small asymptomatic incidentally found meningioma, the preferred treatment is one of observation. If repeat imaging demonstrates further stability, then these tumors can be followed expectantly with periodic imaging and clinical evaluations. If there is growth, then typically, a surgical intervention is offered to these patients.

TABLE 98.2 Medical Therapies Investigated for Meningioma

Drug	Mechanism of Action
Hydroxyurea	Ribonucleotide reductase inhibitor
Temozolomide	Alkylating chemotherapy
Irinotecan	Topoisomerase 1 inhibitor
Cyclophosphamide + Adriamycin + vincristine	Combination cytotoxic chemotherapy
Interferon- α	Immunomodulation
Mifepristone (RU-486)	Antiprogestosterone
Megestrol acetate	Progesterone receptor agonist
Medroxyprogesterone acetate	Synthetic progesterone
Tamoxifen	Anti-estrogen
Octreotide	Somatostatin analogue
Sandostatin LAR	Somatostatin analogue
Pasireotide LAR (SOM230C)	Somatostatin analogue
Imatinib	PDGFR TKI
Erlotinib	EGFR TKI
Gefitinib	EGFR TKI
Vatalanib	VEGFR + PDGFR TKI
Sunitinib	VEGFR + PDGFR TKI
Bevacizumab	Anti-VEGF antibody
NovoTTF-100A (<i>external device, trial ongoing</i>)	Microtubule inhibition

PDGFR, platelet-derived growth factor receptor; TKI, tyrosine kinase inhibitor; EGFR, epidermal growth factor receptor; VEGFR, vascular endothelial growth factor receptor; VEGF, vascular endothelial growth factor.

OTHER DURAL DISEASES

HEMANGIOPERICYTOMAS

Hemangiopericytomas (HPC) are tumors that also may arise off the dura and appear radiographically similar to meningiomas. However, they usually behave more like sarcomas with a more aggressive course, multiple recurrences, and metastases to extracranial organs (particularly bone, liver, and lung). Surgery and postoperative radiation are standard, although recurrence is nearly universal.

DURAL METASTASES

The radiographic appearance of metastases to the dura from extracranial malignancies (such as breast cancer) is usually very similar to that of meningiomas. However, dural metastases are more often multiple, may appear as diffuse dural thickening (in the following text), and usually have a faster growth rate on subsequent images. These are more common in lymphoma and possibly breast cancer but should really be suspected in any patient with a systemic malignancy. The breast cancer patient is a particular challenge, as these patients also have an increased incidence of meningioma. Short-interval imaging and reassessment can usually differentiate between dural metastasis and meningioma on the basis of the growth rate (faster with metastases, slower with benign meningiomas). Occasionally, these entities are mixed ("collision" tumor). Treatment is similar to metastatic disease elsewhere in the brain, considering radiation and chemotherapy, and occasionally surgery (especially if histology is in question). Dural metastases do differ from parenchymal metastases in that dural metastases are not protected by a blood-brain barrier such as parenchymal disease.

HYPERTROPHIC PACHYMENINGITIS

Hypertrophic pachymeningitis refers to a thickening of the dura, either focally or diffusely, that may be caused by a variety of different etiologies. In general, this is a rather rare disorder, although the differential is broad including infections (tuberculosis, fungal, syphilis), autoimmune (rheumatoid arthritis, Sjögren disease), vasculitic (Wegener, giant cell arteritis, Behçet disease), sarcoid, histiocytosis, and metastases from systemic malignancies, as well as "idiopathic" hypertrophic pachymeningitis (IHP) where no underlying etiology is identified.

The most common symptoms are headache, followed by visual dysfunction, then other cranial nerve dysfunction, and cerebellar dysfunction. Seizures may occur due to local irritation of underlying brain. Imaging features on MRI are typically diffuse dural enhancement, which may be either nodular or smooth. Evaluation for underlying causes should be sought and lumbar puncture is typically necessary. In the idiopathic variety, there is typically a pleocytosis (usually lymphocytic) and elevated protein. Treatment is directed at the underlying cause or in the case of IHP with immunosuppressive therapy, often starting with corticosteroids.

Primary Central Nervous System Lymphoma

Tracy T. Batchelor

INTRODUCTION

Primary central nervous system lymphoma (PCNSL) is an extranodal non-Hodgkin lymphoma confined to the brain, leptomeninges, eyes, or spinal cord. The prognosis of PCNSL is inferior to that of other non-Hodgkin lymphoma subtypes. The diagnosis and management of PCNSL differs from that of other primary brain cancers and non-Hodgkin lymphoma in other parts of the body.

EPIDEMIOLOGY

PCNSL is a rare brain tumor and subtype of non-Hodgkin lymphoma. An estimated 3,855 cases of PCNSL were diagnosed in the United States from 2004 to 2006, and the number of cases is expected to increase further with the aging of the U.S. population. The median age at diagnosis is 65 years and PCNSL is slightly more common among men. PCNSL accounts for approximately 3% of all the primary central nervous system (CNS) tumors diagnosed each year in the United States. Between 1970 and 2000, the incidence of PCNSL increased, largely due to the HIV pandemic. The annual incidence rate is 0.47 cases per 100,000 person-years. Since 2000, there has been a further increase in the incidence of PCNSL, especially in the elderly. Congenital or acquired immunodeficiency is the only established risk factor for PCNSL and individuals infected with the HIV are at greater risk of developing this tumor. However, the incidence of HIV-related PCNSL has declined dramatically, and this chapter focuses on PCNSL in the immunocompetent host.

PATHOBIOLOGY

Approximately 90% of PCNSL cases are diffuse large B-cell lymphomas (DLBCL), with the remainder consisting of T-cell lymphomas, poorly characterized low-grade lymphomas, or Burkitt lymphomas. Primary CNS DLBCL is composed of centroblasts or immunoblasts clustered in the perivascular space, with reactive lymphocytes, macrophages, and activated microglial cells intermixed with the tumor cells. Most tumors express pan-B-cell markers including CD19, CD20, CD22, and CD79a. The molecular mechanisms underlying transformation and localization to the CNS are poorly understood. Limitations in molecular studies of PCNSL include the rarity of the disease and the limited availability of tissue because the diagnosis is most often made with stereotactic needle biopsy. Like systemic DLBCL, PCNSL harbors chromosomal translocations of the *BCL6* gene, deletions in 6q, and aberrant somatic hypermutation in protooncogenes including *MYC* and *PAX5*. Inactivation of *CDKN2A* is also commonly observed in both entities. Also like DLBCL, PCNSL can be classified into the three molecular subclasses by gene expression profiling: type 3 large B-cell lymphoma, germinal center B-cell (GCB) lymphoma, and activated B-cell lymphoma (ABC). In all DLBCL cases, the ABC gene expression profile is associated with an inferior prognosis versus the GCB profile. The ABC subclass accounts for a higher proportion of primary CNS DLBCL cases versus other types of DLBCL. This higher prevalence of the ABC gene expression profile subtype in PCNSL may partially account for the relatively inferior prognosis of this lymphoma versus other forms of DLBCL. Moreover, certain molecular features distinguish primary CNS DLBCL from systemic DLBCL. Gene expression profiles demonstrate that PCNSL is characterized by differential expression of genes related to adhesion and the extracellular matrix pathways, including *MUM1*, *CXCL13*, and *CHI3L1*. The ongoing somatic hypermutation with biased use of V_H gene segments that has been observed in PCNSL is suggestive of an antigen-dependent proliferation. These observations are consistent with the hypothesis that PCNSL is secondary to antigen-dependent activation of circulating B cells, which subsequently localize to the CNS by

expression of various adhesion and extracellular matrix-related genes. However, further molecular studies to investigate the transforming events and the subsequent events responsible for CNS tropism in PCNSL are needed. Insights into the molecular pathogenesis of PCNSL may allow the development of targeted therapeutic approaches for this tumor.

CLINICAL MANIFESTATIONS

The median age of immunocompetent patients diagnosed with PCNSL is 60 years. The presenting symptoms and signs are variable. In 248 immunocompetent patients, 43% had neuropsychiatric signs, 33% had symptoms of increased intracranial pressure, 14% had seizures, and 4% had ocular symptoms. Seizures are less common than with other types of brain tumors probably because PCNSL involves predominantly subcortical white matter rather than epileptogenic gray matter. Unlike patients with systemic non-Hodgkin lymphoma, PCNSL patients rarely manifest B symptoms.

DIAGNOSIS

The International PCNSL Collaborative Group (IPCG) has developed guidelines to determine extent of disease. A gadolinium-enhanced brain magnetic resonance imaging (MRI) scan is the most sensitive radiographic study for the detection of PCNSL (Fig. 99.1). Most PCNSL patients present with a single brain mass. The mass is typically isointense to hyperintense on T2-weighted MRI sequences and homogeneously enhancing on postcontrast images. The diagnosis of PCNSL is typically made by stereotactic brain biopsy, by cerebrospinal fluid (CSF) analysis, or by analysis of vitreous aspirate in patients with ocular involvement. Given the possible delay in diagnosis and treatment with the latter two methods, prompt stereotactic biopsy is advised in almost all cases that are surgically accessible. Secondary CSF and ocular involvement occurs in approximately 15% to 20% and 5% to 20% of PCNSL patients, respectively. Presenting symptoms of

P.868

ocular involvement include eye pain, blurred vision, and floaters. B symptoms such as weight loss, fevers, and night sweats are infrequent in PCNSL. A thorough diagnostic evaluation is needed to establish the extent of the lymphoma and to confirm localization to the CNS. Physical examination should consist of a lymph node examination, a testicular examination in men, and a comprehensive neurologic examination. A lumbar puncture should be performed if not contraindicated, and CSF should be assessed by flow cytometry, cytology, and immunoglobulin heavy-chain gene rearrangement. Because extraneural disease must be excluded to establish a diagnosis of PCNSL, computed tomography (CT) or CT/positron emission tomography (PET) scans of the chest, abdomen, and pelvis and a bone marrow biopsy and aspirate should be performed to exclude occult systemic disease. Involvement of the optic nerve, retina, or vitreous humor should be excluded with a comprehensive eye evaluation by an ophthalmologist that includes a slit lamp examination. Blood tests should include a complete blood count, a basic metabolic panel, serum lactate dehydrogenase, and HIV serology.

FIGURE 99.1 Magnetic resonance images from a patient with PCNSL. A T1-weighted, axial, postcontrast scan (**A**) demonstrates intense, homogenous enhancement of the tumor in the region of the left caudate nucleus. An axial T2/fluid-attenuated inversion recovery (FLAIR) scan at the same anatomic level (**B**) demonstrates hyperintense signal surrounding the tumor, reflecting vasogenic cerebral edema. (Courtesy of Priscilla K. Brastianos, MD.)

Two prognostic scoring systems have been developed specifically for PCNSL. In a retrospective review of 105 PCNSL patients, the International Extranodal Lymphoma Study Group (IELSG) identified age older than 60 years, Eastern Cooperative Oncology Group (ECOG) performance status greater than 1, elevated serum lactate dehydrogenase (LDH) level, elevated CSF protein concentration, and involvement of deep regions of the brain as independent predictors of poor prognosis. In patients with zero or one factor, two or three factors, and four or five factors, the 2-year survival proportions were 80%, 48%, and 15%, respectively. In another prognostic model, PCNSL patients were divided into three groups based on age and performance status: (1) younger than 50 years old, (2) 50 years or older with a Karnofsky performance status (KPS) greater than or equal to 70, and (3) 50 years or older with a KPS less than 70. Based on these three divisions, significant differences in overall and failure-free survival were observed. There is no staging system that correlates with prognosis or response to treatment in PCNSL. However, because PCNSL is a multicompartamental disease potentially involving the brain, spinal cord, eye, and CSF, the IPCG recommends an extent of disease evaluation, as noted earlier, that will enable clinicians to follow the response to therapy.

TREATMENT

NEWLY DIAGNOSED PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

Treatment for newly diagnosed PCNSL consists of remissioninduction (induction) and remission-

consolidation (consolidation) phases. Typically, induction consists of chemotherapy with the objective of achieving a complete response/remission. Once this response/remission is achieved, a different chemotherapy regimen or whole brain radiation therapy (WBRT) is administered to “consolidate” the response/remission. Defining response to treatment in PCNSL requires assessment of all sites (brain, CSF, eye) potentially involved by disease. The IPCG has established response criteria that have been adopted into most prospective clinical trials of PCNSL (Table 99.1).

Corticosteroids decrease tumor-associated edema and may result in partial radiographic regression of PCNSL. An initial response to corticosteroids is associated with a favorable outcome in PCNSL. However, after an initial response to corticosteroids, almost all patients quickly relapse. Corticosteroids should be avoided if possible prior to a biopsy, given the risk of disrupting cellular morphology, resulting in a nondiagnostic pathologic specimen.

Surgical resection is not part of the standard treatment approach for PCNSL given the multifocal nature of this tumor and has not been shown to prolong survival because most patients also receive additional treatment. Accordingly, the role of neurosurgery in PCNSL is to establish a diagnosis via stereotactic biopsy. However, it can be considered as a lifesaving intervention in extreme cases with large lesions and impending herniation.

Standardized induction and consolidation treatment for PCNSL has yet to be defined. Historically, PCNSL was treated only with WBRT at doses ranging from 36 to 45 Gy, which resulted in a high proportion of radiographic responses but also rapid relapse. In a multicenter phase 2 trial, 41 patients were treated with WBRT to 40 Gy plus a 20 Gy tumor boost and achieved a median overall survival (OS) of only 12 months. Given the lack of durable responses to radiation and the risk of neurotoxicity associated with this modality of therapy, WBRT alone is no longer a recommended treatment for most patients with PCNSL. Moreover, because PCNSL is an infiltrative, multifocal disease, focal radiation or

P.869

radiosurgery is not recommended. The most effective treatment for PCNSL is intravenous, high-dose methotrexate (HD-MTX) at variable doses (1 to 8 g/m²), typically used in combination with other chemotherapeutic agents and/or WBRT. However, there is no consensus on the optimal dose of HD-MTX or on the role of radiation in combination with methotrexate in the management of PCNSL. A number of randomized trials are ongoing to address these issues. Doses of methotrexate 3 g/m² or higher result in therapeutic concentrations in the brain parenchyma and CSF and when combined with WBRT lead to more durable treatment responses. In a phase 2 trial, 79 PCNSL patients were randomized to receive either (1) HD-MTX (3.5 g/m², day 1) *versus* (2) HD-MTX (3.5 g/m², day 1) + cytarabine (2 g/m² b.i.d., days 2 and 3) [**Level 1**].¹ Each chemotherapy cycle was 21 days. All patients underwent consolidative WBRT after induction chemotherapy. The HD-MTX + cytarabine arm had a higher proportion of complete radiographic responses and a superior 3-year OS. However, it is now widely recognized that there is a high incidence of neurotoxicity with combined modality treatment that includes WBRT. The latter observation prompted studies using *lower doses* of WBRT. In a multicenter phase 2 study, no significant neurocognitive decline was observed after consolidative reduced-dose WBRT (23.4 Gy) and cytarabine in patients who had achieved a complete response to induction chemotherapy including HD-MTX. However, further study and longer neuropsychological follow-up of these patients is necessary to definitively assess the safety of this regimen because numerous studies have demonstrated the delayed neurotoxic effects of WBRT in the PCNSL population and the reduced risk of neurotoxicity in regimens consisting of chemotherapy alone. Given the risk of clinical neurotoxicity, other studies have assessed whether WBRT can be *eliminated* from the initial management of PCNSL. In a multicenter phase 3 trial, patients were randomized to receive HD-MTX-based chemotherapy with or without WBRT [**Level 1**].² Five hundred fifty-one patients were enrolled, of whom 318 were treated per protocol. Intent to treat analysis revealed that patients treated in the

combined modality arm (chemotherapy + WBRT) achieved prolonged progression-free survival (PFS) but no improvement in OS, demonstrating that the elimination of WBRT from the treatment regimen did not compromise OS. This has led to deferral of WBRT and the application of chemotherapy alone approaches for newly diagnosed PCNSL patients. These approaches are based on a foundation of HD-MTX. Variable doses and schedules of HD-MTX have been used, but in general, dose 3 g/m² or higher delivered as an initial bolus followed by an infusion over 3 hours administered every 10 to 21 days is recommended for optimal outcomes and adequate CSF concentrations. Multiple phase 2 studies have demonstrated the safety, efficacy, and relatively preserved cognition of HD-MTX-based chemotherapy regimens. Moreover, longer duration of induction chemotherapy with HD-MTX (> 6 cycles) results in higher complete response proportions.

TABLE 99.1 International Primary Central Nervous System Lymphoma Collaborative Group Consensus Guidelines for the Assessment of Response in Primary Central Nervous System Lymphoma

Response	Brain Imaging	Steroid Dose	Ophthalmologic Examination	CSF Cytology
Complete response	No contrast-enhancing disease	None	Normal	Negative
Unconfirmed complete response	No contrast-enhancing disease	Any	Normal	Negative
	Minimal enhancing disease	Any	Minor RPE abnormality	Negative
Partial response	50% decrease in enhancement ^a	NA	Normal or minor RPE abnormality	Negative
	No contrast-enhancing disease	NA	Decrease in vitreous cells or retinal infiltrate	Persistent or suspicious
Progressive disease	25% increase in enhancing disease Any new site of disease ^a	NA	Recurrent or new disease	Recurrent or positive
Stable disease	All scenarios not covered by responses above	—	—	—

^aBased on longest single dimension of lesion.

CSF, cerebrospinal fluid; NA, not applicable; RPE, retinal pigment epithelium.

Several first-generation chemotherapy regimens for PCNSL included intrathecal chemotherapy. However, a number of nonrandomized studies that included intrathecal chemotherapy did not improve outcomes in PCNSL relative to regimens that did not include intrathecal injections of chemotherapy. Moreover, the ability to consistently achieve micromolar concentrations of methotrexate in the CSF at a dose of 8 g/m² has led to the elimination of intrathecal chemotherapy from most of the induction chemotherapy regimens currently in use. However, the question regarding the role of intrathecal chemotherapy in the management of PCNSL should ultimately be addressed in a randomized trial.

Rituximab, a chimeric monoclonal antibody targeting the CD20 antigen on B lymphocytes, is being incorporated in combination regimens for PCNSL. When rituximab is administered intravenously at doses of 375 to 800 mg/m², CSF levels from 0.1% to 4.4% of serum levels are achieved. Despite limited CSF penetration, radiographic responses have been observed in relapsed PCNSL patients treated with rituximab monotherapy and this antibody has been incorporated into contemporary regimens for PCNSL. Moreover, in historical comparisons, the complete radiographic response rates are higher with induction regimens that include rituximab versus those in which there is no rituximab. In a cooperative group phase 2 study, 44 PCNSL patients were treated with induction chemotherapy consisting of HD-MTX at 8 g/m² (day 1), rituximab at 375 mg/m² (day 3), and temozolomide at 150 mg/m² (days 7 to 11), all drugs with demonstrated efficacy as monotherapy in PCNSL. This induction chemotherapy was followed by consolidation chemotherapy consisting of intravenous etoposide 5 mg/kg as a continuous infusion over 96 hours and

P.870

cytarabine at 2 g/m² every 12 hours for eight doses. Sixty-six percent of these patients achieved complete response (CR); median PFS of the entire group was 2.4 years and median OS was not reached at the time of publication. These results are comparable to any regimen that *includes* WBRT. It is noteworthy that PFS was shorter in PCNSL patients in whom chemotherapy was delayed longer than 1 month after diagnosis compared to those patients who promptly initiated chemotherapy (3-year PFS of 20% vs. 59%, *P* = .05). This observation highlights the importance of early diagnosis and prompt initiation of chemotherapy in PCNSL patients.

Given the limited durability of responses observed in many studies of PCNSL, there is interest in high-dose chemotherapy (HDT) followed by autologous stem cell transplantation (ASCT) as consolidative therapy for newly diagnosed PCNSL. Conditioning regimens including thiotepa have demonstrated the most encouraging results. In a multicenter phase 2 study, 79 patients were treated with induction HD-MTX, cytarabine, rituximab, and thiotepa, followed by carmustine and thiotepa conditioning prior to ASCT. The overall radiographic response (ORR) was 91%, 2-year OS was 87%, and treatment-related deaths occurred in less than 10% of enrolled patients. The toxicities, mostly cytopenias, were manageable. There are three ongoing, multicenter, randomized trials comparing the efficacy of consolidative HDT/ASCT versus

chemotherapy or WBRT for newly diagnosed PCNSL (Table 99.2).

TREATMENT OF PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA IN ELDERLY PATIENTS

Elderly patients account for more than half of all the subjects diagnosed with PCNSL. The risk of neurotoxicity is highest in this population, and in general, chemotherapy alone is the preferred option for this subgroup. The majority of PCNSL patients older than 60 years of age develop clinical neurotoxicity after treatment

P.871

with a WBRT-containing regimen and some of these patients die of treatment-related complications, rather than recurrent disease. Several studies have indicated that HD-MTX at doses of 3.5 to 8 g/m² is well tolerated in elderly patients with manageable grade 3 or 4 renal and hematologic toxicity. In a multicenter, randomized, phase 2 trial of chemotherapy alone in elderly patients with PCNSL, 98 patients were randomized to receive three 28-day cycles of either MPV-A (methotrexate 3.5 g/m², days 1 and 15; procarbazine 100 mg/m², days 1 to 7; vincristine 1.4 mg/m², days 1 and 15) or MT (methotrexate 3.5 g/m², days 1 and 15; temozolomide 100 to 150 mg/m², days 1 to 5 and 15 to 19) with one additional cycle of cytarabine (3 g/m²/day for 2 consecutive days) in the MPV arm only [**Level 1**].³ Although trends favored the MPV-A regimen over the simpler, less toxic MT regimen with respect to complete response rate, PFS, and OS, none of these differences reached statistical difference. Subsequent studies suggest that the addition of rituximab to both MPV and MT could increase the radiographic response rate. Both of these chemotherapy regimens are options in elderly PCNSL patients.

RELAPSED AND REFRACTORY PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

Despite high initial response rates with HD-MTX-based induction therapy, most patients with PCNSL relapse. Moreover, there is a small subset of patients who have HD-MTX-refractory disease. Prognosis of relapsed or refractory PCNSL is poor with a limited number of prospective, phase 2 studies for guidance on management. Rechallenge with HD-MTX is effective in patients who had previously responded to this agent. In a multicenter, retrospective study of 22 relapsed PCNSL patients with a history of prior response to HD-MTX, 91% had a radiographic response to the first salvage treatment with HD-MTX and 100% to second salvage. The median OS from the first salvage was 61.9 months. In patients who have not previously been treated with HDT/ASCT, this is also an option at the time of relapse. In a phase 2 trial of 43 patients with relapsed or refractory PCNSL, salvage therapy with highdose cytarabine and etoposide was followed by HDT/ASCT with a conditioning regimen consisting of thiotepa, busulfan, and cyclophosphamide. Twenty-seven patients ultimately proceeded to transplantation. Twenty-six of 27 patients had a CR and the median PFS and OS in this group were 41.1 and 58.6 months, respectively. It is noteworthy that in a small series of patients with relapsed PCNSL after initial HDT/ASCT, a second autotransplantation was successful as salvage treatment. Finally, WBRT in patients who have not received it as a part of their initial treatment is an effective option in the relapsed PCNSL setting, although the risk of neurotoxicity remains high. Many clinicians reserve WBRT for those patients with chemotherapy-refractory disease or at the time of relapse. In a series of 27 relapsed or refractory PCNSL patients treated with WBRT (median dose 36 Gy), 74% achieved an overall radiographic response and the median OS was 10.6 months. Delayed neurotoxicity rates of 15% were noted at doses greater than 36 Gy even in the setting of short survival. Novel therapeutics currently under study for systemic DLBCL have entered early-phase clinical trials in primary CNS DLBCL and include bendamustine, lenalidomide, pomalidomide, everolimus, and pemetrexed.

NEUROTOXICITY

The most frequent complication in long-term PCNSL survivors is delayed neurotoxicity. Although this risk is

high, the exact incidence of delayed neurotoxicity is unclear, as most studies did not systematically assess neurocognitive function with serial neuropsychological testing. The elderly are at highest risk for this complication, with nearly all patients older than the age of 60 years developing clinical neurotoxicity following combined modality therapy. Treatment with WBRT has been identified as the major risk factor for the development of late neurotoxicity. Common symptoms and signs include deficits in attention, memory, executive function, gait ataxia, and incontinence. These deficits have a detrimental impact on quality of life. Radiographic findings include periventricular white matter changes, ventricular enlargement, and cortical atrophy. Pathologic studies reveal demyelination, hippocampal neuronal loss, and large-vessel atherosclerosis. Although the pathophysiology is unclear and likely multifactorial, damage to neural progenitor cells has been implicated to play an important role in radiation-related neurotoxicity. Currently, there are no treatments to reverse these delayed neurotoxic effects. Neuropsychological function was maintained in one long-term follow-up study of PCNSL patients treated with chemotherapy alone. It is critical that serial neuropsychological assessments are incorporated into the management of patients with PCNSL, as cognitive outcome is a critical end point. The IPCG has developed an instrument for this purpose, which is composed of quality of life questionnaires and standardized neuropsychological tests that include assessment of executive function, attention, memory, and psychomotor speed.

OUTCOME

As treatment improves for PCNSL, more patients are living longer, emphasizing the need to optimize neurocognitive function and quality of life. The IPCG recommends a schedule of follow-up neuroimaging studies and cognitive assessment in PCNSL survivors.

Tumors of the Pituitary Gland

John Ausiello

Pamela U. Freda

Jeffrey N. Bruce

INTRODUCTION

Pituitary tumors are a common medical problem often found incidentally on routine magnetic resonance imaging (MRI) scans. These tumors are overwhelmingly benign but may cause symptoms due to mass effect, compression of the optic chiasm, excess hormonal secretion, or hypopituitarism. As such, the diagnosis and management of these tumors involves the coordinated efforts of neurosurgeons, endocrinologist, and ophthalmologists.

EPIDEMIOLOGY

The true prevalence of pituitary adenomas is difficult to ascertain because most are asymptomatic; autopsy estimates of prevalence range from 1.7% to 24%. No sexual predilection exists, but the tumors are most common in adults, peaking in the third and fourth decades. Children and adolescents account for approximately 10% of cases. Pituitary tumors are not hereditary except for rare families with multiple endocrine neoplasia I (MEN-I), an autosomal dominant condition manifested by a high incidence of pituitary adenomas and tumors of other endocrine glands.

PATHOBIOLOGY

Pituitary tumors can be classified in four ways: by size, endocrine function, clinical findings, or histology. The first two remain the most common, as the majority of tumors are histologically benign and the clinical findings usually reflect the size or endocrinologic function of the tumor. With regard to size, microadenomas are less than 1 cm in diameter and macroadenomas are greater than 1 cm. Typically, when microadenomas cause symptoms, it is due to excess hormone secretion, whereas with macroadenomas, it is via compression of normal glandular or neural structures. Macroadenomas may invade the dura or bone and may infiltrate surrounding structures such as the cavernous sinus, cranial nerves, blood vessels, sphenoid bone, and sinus or brain. These locally invasive pituitary adenomas are nearly always histologically benign. In some studies, but not all, the proliferation index correlates with growth velocity and recurrence. However, their invasive character may be independent of their growth rate.

A second manner by which tumors can be classified is by the presence (or absence) of endocrine function, dividing tumors into secreting or nonsecreting tumors. Secreting tumors are less common and produce one or more anterior pituitary hormones, including prolactin (the most common secreting tumor), growth hormone (GH), adrenocorticotrophic hormone (ACTH) (causing Cushing disease), follicle-stimulating hormone (FSH), or luteinizing hormone (LH). Mixed secretory tumors account for 10% of adenomas; interestingly, these adenomas still have a monoclonal origin. Secretion of more than one hormone has implications for medical therapy, as all excess hormone secretion must be treated. *Null cells*, or nonsecreting adenomas, demonstrate no clinical or immunohistochemical evidence of hormone secretion.

In general, adenomas grow more slowly in older patients than younger patients. *Pituitary carcinomas* are rare but highly invasive, rapidly growing, and anaplastic. Unequivocal diagnosis relies on the presence of distant metastases, as certain histologic findings including pleomorphism and mitotic figures may be seen in benign

adenomas.

The posterior pituitary, which contains the terminal processes of hypothalamic neurons and supporting glial cells, is a rare site of neoplasia. *Infundibulomas* are rare tumors of the neurohypophysis; they are variants of pilocytic astrocytomas. *Granular cell tumors* (e.g., *myoblastomas* or *choristomas*), also rare tumors of the neurohypophysis, are of uncertain origin.

CLINICAL MANIFESTATIONS

Clinical manifestations arise either from endocrine dysfunction or mass effect with invasion or compression of surrounding neural and vascular structures. The manifestations and management of hormonally active tumors are discussed in Chapter 117. Here, discussion is primarily limited to nonsecretory tumors, most of which are macroadenomas by the time they come to clinical attention. Macroadenomas may present with panhypopituitarism if the normal pituitary gland is destroyed. Headaches result from stretching of the diaphragma sellae and adjacent dural structures that transmit sensation through the first branch of the trigeminal nerve. Visual field abnormalities are caused by compression of the crossing fibers in the optic chiasm, first affecting the superior temporal quadrants and then the inferior temporal quadrants, leading to a bitemporal hemianopia. Further expansion compromises the noncrossing fibers and affects the lower nasal quadrants and finally the upper nasal quadrants (Fig. 100.1).

Visual loss may be accompanied by optic disc pallor and loss of central visual acuity although papilledema is rare. Patients usually complain of blurring or dimming of vision but often are unaware of peripheral visual loss. Formal visual field testing is important because some tumors affect only the macular fibers, causing central hemianopic scotomas that may be missed on routine screening. Bitemporal hemianopia is most common, but any pattern of visual loss is possible, including unilateral or homonymous hemianopia.

Lateral extension of the tumor with compression or invasion of the cavernous sinus may compromise third, fourth, or sixth cranial nerve functions, manifesting as diplopia. The third cranial nerve is most commonly affected. Numbness may occur in the V1 or V2 distribution. Overall, however, cranial nerve dysfunction is not a common feature of adenomas and may be more suggestive of other neoplasms of the cavernous sinus.

Adenomas can become quite large before causing symptoms. Suprasellar extension may compress the foramen of Monro, causing hydrocephalus and symptoms of increased intracranial pressure (ICP). Hypothalamic dysfunction could lead to diabetes insipidus but this condition is relatively rare. If diabetes insipidus is present, it is more suggestive of inflammation or possible tumor invasion of the pituitary stalk. Extensive subfrontal extension with compression of both

P.874

frontal lobes may cause personality changes or dementia. There may be seizures or motor and sensory dysfunction. Erosion of the skull base is a risk factor for the development of cerebrospinal fluid (CSF) rhinorrhea.

FIGURE 100.1 Pituitary macroadenoma. Bitemporal hemianopia; visual acuity OD (*right eye*) 15/200, OS (*left eye*) 15/30. The blind half-fields are black. (Courtesy of Dr. Max Chamlin.)

In about 5% of pituitary tumors, the first symptoms are those of pituitary apoplexy caused by hemorrhage or infarction of the adenoma. Symptoms include sudden onset of severe headache, oculomotor palsies, nausea, vomiting, altered mental state, diplopia, and rapidly progressive visual loss. Apoplexy is diagnosed by computed tomography (CT) or MRI and occasionally is an indication for emergency surgery (Fig. 100.2). Histologically, the adenoma shows massive necrosis and hemorrhage. Apoplexy is almost always caused

P.875

by a pituitary tumor, but it has been reported in other conditions, such as lymphocytic hypophysitis. Pituitary adenomas may enlarge during pregnancy, causing acute symptoms or even apoplexy.

FIGURE 100.2 Pituitary apoplexy. **A:** T1-weighted sagittal and **(B)** coronal MRI demonstrating a pituitary mass that turned out to be partially hemorrhagic in a patient with apoplexy. Hyperintensity (*arrows*) corresponds to the hemorrhagic component. **C:** Postoperative sagittal MRI following successful tumor resection through a standard transsphenoidal approach shows CSF within the enlarged sella (*arrow*). **D:** Coronal MRI shows normal gland (*arrow*) along the floor of the sella with no residual tumor.

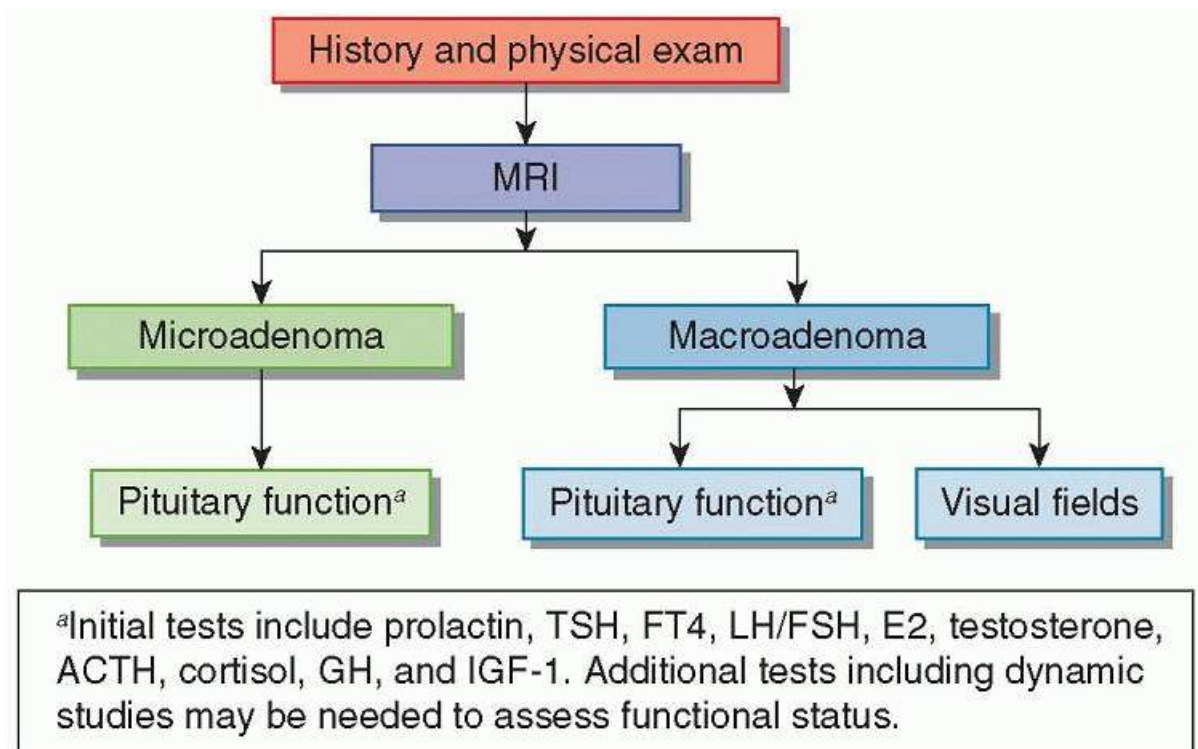

FIGURE 100.3 Initial assessment of pituitary tumors. TSH, thyroid-stimulating hormone; FT4, free thyroxine; LH, luteinizing hormone; FSH, follicle-stimulating hormone; E2, estradiol; ACTH, adrenocorticotropic hormone; GH, growth hormone; IGF-1, insulin-like growth factor 1.

DIAGNOSIS

An algorithm for the initial assessment of a pituitary mass is shown in [Figure 100.3](#).

RADIOGRAPHIC FEATURES

MRI is the best way to evaluate pituitary pathology because soft tissue is seen clearly without interference from the bony surroundings of the sella. MRI also produces images in any plane, which helps define the relationship of the tumor to the surrounding structures. Vascular structures such as the adjacent carotid artery are easily visualized by signal void. Normally, the anterior lobe of the pituitary gland has the same signal as white matter on T1-weighted imaging. With gadolinium, the normal gland enhances homogeneously. Small punctate areas of heterogeneity may be the result of local variations in vascularity, microcyst formation, or granularity within the gland. The posterior lobe shows increased signal on T1-weighted images, probably representing neurosecretory granules in the antidiuretic hormone (ADH)-containing axons.

FIGURE 100.4 Pituitary microadenoma. **A:** T1-weighted coronal MRI shows slight tilting of the pituitary stalk to the left (*arrow*), with questionable fullness of the right pituitary gland. These are secondary signs of pituitary microadenoma but are not sufficient to establish the diagnosis radiographically. **B:** T1-weighted coronal scan after gadolinium enhancement demonstrates a tiny focus of relative hypointensity within the right pituitary gland (*arrow*) consistent with a microadenoma. (Courtesy of Dr. S. Chan.)

Microadenomas are sometimes difficult to see directly on MRI but may be inferred by glandular asymmetry, focal sellar erosion, asymmetric convexity of the upper margin of the gland, or displacement of the infundibulum (Fig. 100.4).

The normal gland usually shows more enhancement than a microadenoma (Fig. 100.5). In the presence of a macroadenoma, the normal gland may not be visualized and the bright signal of the posterior lobe may be absent. Areas of increased signal on the T1-weighted image may stem from hemorrhage; areas of low signal may represent cystic degeneration. MRI alone is usually sufficient, but CT may show the bony anatomy in better detail. MRI typically excludes an aneurysm, but magnetic resonance angiography (MRA) or an angiogram is indicated if aneurysm is a serious diagnostic concern.

ACTH-secreting tumors may be too small to visualize on MRI. Diagnosis is suggested by the clinical features of Cushing disease, elevated 24-hour urinary free-cortisol levels, loss of ACTH suppression by high-dose as opposed to low-dose glucocorticoids, and elevated ACTH levels. However, the specific differentiation of an ACTH-secreting pituitary tumor from ectopic sources of ACTH may require measurement of ACTH peripherally and in each inferior petrosal sinus which drains the pituitary gland.

FIGURE 100.5 Pituitary adenoma. T1-weighted coronal MRI after gadolinium enhancement demonstrates a discrete focus of hypointensity (*arrow*) in the right pituitary gland, most consistent with pituitary adenoma. (Courtesy of Dr. S. Chan.)

ENDOCRINE EVALUATION

Complete endocrine evaluation is necessary for all patients with pituitary tumors, not only to establish the diagnosis of a secreting adenoma but also to determine the presence of hypopituitarism ([Tables 100.1](#) and [100.2](#)), which may result from compression of the normal pituitary gland.

Serum hormone levels should be obtained in all patients with adequate hormone replacement administered for any deficiencies identified. Long-term follow-up monitoring is essential because hypopituitarism may develop years after diagnosis and treatment. Nonsecreting tumors may cause slight elevations of serum prolactin levels (typically < 100 ng/mL) via compression of the pituitary stalk leading to interruption of dopaminergic fibers that inhibit prolactin release. Mild elevations are common and must be distinguished from prolactin-secreting macroadenomas that are more likely when prolactin levels are more than 200 ng/mL. This distinction is important therapeutically because nonsecreting tumors do not respond to dopamine agonists (e.g., cabergoline or bromocriptine).

TABLE 100.1 Symptoms of Pituitary Failure

4. Corticotroph failure

Fatigue

Weight loss

Decreased appetite

Hypoglycemia

DIFFERENTIAL DIAGNOSIS

Most lesions in the differential diagnosis have characteristic radiographic or clinical syndromes that

pituitary adenomas. Craniopharyngiomas have a predilection for children, are calcified, and usually include cystic areas that contain highly proteinaceous fluid with cholesterol crystals. Rathke cleft cysts are similar to craniopharyngiomas but have a cystic appearance without any solid component. Meningiomas are commonly found in the diaphragma sellae, planum sphenoidale, and tuberculum sellae and may be difficult to distinguish from a macroadenoma. Distinguishing characteristics of meningiomas include enhancement, visualization of a cleavage plane between the mass and the sellar contents, normally sized sella, and the presence of a dural tail of enhancement. Optic glioma, hypothalamic glioma, germinoma, dermoid tumor, metastasis, and nasopharyngeal carcinoma are less commonly seen entities that should be considered. Chordomas characteristically show extensive bony destruction of the clivus. Mucocoeles of the sphenoid sinus may simulate pituitary adenoma. Visual symptoms and sellar enlargement may also result from chronic, increased ICP of any origin. Characteristic signal voids on MRI usually distinguish an aneurysm. The differential diagnosis also includes sarcoidosis, lymphoma, lymphocytic hypophysitis, and other granulomatous diseases.

TABLE 100.2 Symptoms of Pituitary Hypersecretion

1. Gonadotroph excess

Typically asymptomatic

Ovarian hyperstimulation

2. Thyrotroph excess

Weight loss

Palpitations

Tremors

Loose stools

3. Somatotroph excess

Enlargement of hands, feet, jaw bone, forehead

Arthralgias, myalgias, carpal tunnel

Cardiac disease

Colonic polyps

4. Corticotroph excess

Increase appetite and weight gain

Hypertension

Hyperglycemia

Myopathy

Osteoporosis

Herniation of the subarachnoid space into the sella through an incompetent diaphragma sellae may produce the empty sella syndrome, with enlargement of the sella and flattening of the pituitary gland on its floor (Fig. 100.6). This syndrome may be associated with pseudotumor cerebri or CSF rhinorrhea. Although most are not symptomatic, an empty sella may be associated with headaches and occasionally with mild hypopituitarism, but the visual fields are usually normal. The condition is readily seen on MRI and may be a complication of previous transsphenoidal surgery.

TREATMENT

Pituitary tumors are histologically benign tumors but can be associated with a significant decrease in a patient's quality of life and functional capacity. Early intervention may minimize disability and must address both endocrinologic and neurologic function.

FIGURE 100.6 Empty sella. **A:** Sagittal T1-weighted MRI demonstrates low-intensity intrasellar signal (*long arrow*) representing CSF (compare with same signal within the fourth ventricle—*short arrow*). **B:** Coronal T2-weighted MRI increased signal within the sella (*black arrow*) representing CSF and normal optic chiasm (*white arrow*). (Courtesy of Dr. Alex Khandji.)

Treatment of pituitary adenomas begins with replacement of any deficient pituitary hormone; replacement of thyroid and adrenal hormones remains the most important. Steroid replacement must be adequate for stressful situations, including surgery on the pituitary lesion. Typically, in patients with normal adrenal function prior to surgery, dexamethasone 4 mg is administered preoperatively and tapered off by postoperative day 2 (in patients requiring a craniotomy, the starting dose may be dexamethasone 10 mg perioperatively with a more prolonged taper). A morning cortisol level can be evaluated prior to discharge. Patients with known secondary adrenal insufficiency preoperatively should be continued on replacement doses after surgery.

The goals of treatment differ according to the functional activity of the tumor. For endocrinologically active tumors, an aggressive approach toward reversing hypersecretion is essential while preserving normal pituitary function. This may often be achieved by surgical excision, although prolactinomas are generally better controlled by giving dopamine agonists, such as cabergoline, that achieve tumor shrinkage and normalization of prolactin levels in almost all microadenomas and a majority of macroadenomas (Fig. 100.7). In a subset of patients with hormonally active tumors (typically ACTH-secreting) refractory to standard therapy, chemotherapy has been used but further discussion of this treatment modality is beyond the scope of this chapter.

Candidates for surgical treatment include patients with prolactinomas who fail to respond medically or those who do not tolerate the side effects of medication. The treatment strategies for secretory adenomas are covered in detail in Chapter 117.

Nonsecreting tumors are best treated by surgical reduction of the mass while maintaining pituitary function. Resection also offers the advantage of establishing the correct diagnosis. Incidentally discovered asymptomatic adenomas require no intervention but should be followed with periodic visual field examination and

P.878

MRI. Onset of symptoms or MRI documentation of growth is an indication for treatment.

FIGURE 100.7 Prolactinoma. **A:** T2-weighted coronal MRI of a 19-year-old man with a markedly elevated serum prolactin level. The tumor is partially compressing the optic chiasm (*arrow*). **B:** Coronal MRI after treatment with a dopamine agonist shows marked decrease in the tumor size such that the infundibulum (*black arrow*) and optic chiasm (*white arrow*) are decompressed.

SURGERY

The efficacy and safety of the transsphenoidal approach make it the procedure of choice for the removal of adenomas. Endoscopic approaches have become increasingly popular and seem to produce equivalent results. Most tumors are soft and friable; transsphenoidal access, although limited, permits complete removal even if there is suprasellar extension or the sella is not enlarged. Transsphenoidal surgery was originally developed by Cushing but refinements in microsurgery and the availability of steroid replacement and antibiotics have dramatically improved the results.

A transcranial approach may be preferred for resection of exceptionally large tumors or those extending into the middle fossa or the suprasellar space through an intact diaphragma sellae with a waistband constriction of the tumor (Fig. 100.8). A transcranial approach may be necessary to decompress the optic structures before radiation when a transsphenoidal approach fails to adequately debulk the tumor or there is persistent major visual loss.

RADIATION THERAPY

Radiation therapy is complementary to surgery in preventing progression or recurrence. Standard radiation now uses conformal treatment planning to avoid unnecessary dosage to the temporal lobes. Doses of 4,500 to 5,000 cGy, delivered in 180 cGy fractions, are recommended. Radiation may be the only treatment for patients who are poor operative risks, but histologic confirmation is generally desired. Radiation therapy is usually not the initial treatment for hormonally active tumors because full normalization of hormone levels often does not occur for years afterwards.

Radiation therapy is indicated for patients with recurrent, medically refractory, hypersecreting tumors or administered postoperatively to patients with invasive or large, incompletely removed adenomas. It is not routinely administered after gross total resection; these patients are followed with serial MRI and visual field examination, and radiation is reserved for documented tumor regrowth.

Early complications of radiation therapy are transient and involve minor inconveniences such as epilation, dry mouth, and altered taste or smell. The most common and important delayed complication is hypopituitarism which may occur any time from 6 months to 10 years after treatment. Annual endocrine evaluation is necessary to treat this appropriately. Other rare complications include visual loss, radiation necrosis of the temporal lobes, and radiation-induced tumors. To minimize risk of visual loss, optic structures should be decompressed before radiation therapy.

New techniques, such as radiosurgery using proton beam, Gamma Knife, or the linear accelerator, are being investigated. In these methods, a single high-dose fraction is directed to a limited volume, giving a high biologic effect. These methods may produce more rapid clinical and hormonal responses, potentially with less toxicity. However, there is concern about damage to the optic chiasm

P.879

or cranial nerves. Radiosurgery is not used for large tumors or those less than 3 mm distance from the optic apparatus; this therapy may also be associated with a higher incidence of hypopituitarism.

FIGURE 100.8 Large pituitary adenoma. **A:** T1-weighted coronal MRI with gadolinium showing a contrast-enhancing giant pituitary adenoma reaching up to the floor of the third ventricle with extension laterally to the right (*arrow*). A large tumor such as this often requires a craniotomy to decompress the optic structures adequately. **B:** Coronal MRI after a gross total resection of the pituitary adenoma through a craniotomy. There is no residual tumor, and the optic chiasm and a portion of the infundibulum may be seen clearly (*arrow*).

RECURRENT TUMORS

Patients with recurrent tumors are difficult to manage, and treatment must be individualized. If the patient has not had prior radiation, then radiation would be the treatment of choice. Otherwise, repeat transsphenoidal surgery is usually indicated. Other treatment options include stereotactic radiosurgery, which may be effective and safe even in the patient who has had standard external beam radiotherapy.

OUTCOMES

Given the diverse clinical spectrum seen with pituitary masses, outcomes are variable and dependent on the size and characteristics of the tumor, the therapeutic modality being assessed, and the preexisting comorbidities of the patient at time of diagnosis.

SURGERY

Transsphenoidal surgery is safe with mortality rates less than 1% and major morbidity rates less than 3.5%. Morbidity includes stroke, visual loss, meningitis, CSF leak, or cranial nerve palsy; diabetes insipidus may also develop but is usually transient.

Assessing long-term clinical outcomes in patients with nonsecreting adenomas is challenging due to the scarcity of definitive data. Total resection at time of surgery is dependent on the size of tumor and the experience of the surgeon; in selected centers, it may be as high as 75%. Rates of recurrence vary from different surgical series but have been estimated to be 20%. They are dependent on a host of clinical and nonclinical factors including tumor size, presence of symptoms on presentation, nature of the tumor (solid vs. cystic), and the skill of the surgeon. The presence of a residual adenoma on postoperative MRI has been shown to correlate with increased risk of recurrence. Some improvement in visual function is estimated to occur in 80% of patients. Restoration of normal endocrine function is dependent on preoperative status in addition to the aforementioned factors. Patients with preexisting hormonal deficiencies typically will not have restoration of full pituitary function.

Regarding functional tumors, outcomes are dependent on tumor type and a full discussion is beyond the scope of this chapter. For patients with Cushing or acromegaly, cure is possible if the tumor is small and symptoms are mild on presentation but risk of recurrent or residual disease increases with larger tumors or more advanced symptoms at time of diagnosis.

RADIATION THERAPY

Radiation therapy is highly effective in controlling tumor growth (80% or higher depending on length of follow up). Gamma Knife therapy may be more effective in patients who are candidates for this modality. Some degree of hypopituitarism occurs in 30% to 50% of patients across all radiation modalities.

MEDICAL THERAPY

Dopamine agonists (cabergoline is most commonly used with starting dose of 0.25 mg once or twice a week that may be titrated based on prolactin levels and radiographic response) are highly effective in treating prolactinomas and reducing prolactin levels and tumor size in greater than 90% of cases. Tumor size does impact outcomes, as macroprolactinomas have lower response rates than

P.880

microprolactinomas but nonetheless, a majority will still respond to dopamine agonists.

Pineal Region Tumors

Jeffrey N. Bruce

INTRODUCTION

The pineal gland is composed of glandular tissue, glia, endothelial cells, and sympathetic nerve terminals. The numerous cell types that make up the normal gland and surrounding periventricular region may lead to a diverse group of tumors ranging from benign to malignant (Table 101.1), all of which may have a similar clinical presentation. Despite the common presentation, the specific histology has important implications for treatment and outcome. Optimal management of pineal region tumors therefore necessitates establishment of an accurate histologic diagnosis.

EPIDEMIOLOGY

Pineal tumors account for about 1% of all intracranial tumors in the United States. In Asia, where germ cell tumors (GCTs) are common, pineal cell tumors constitute 4% to 7% of all intracranial tumors. GCTs are found almost exclusively during the first three decades of life, whereas pineal cell tumors have a mean age of diagnosis around 30 years of age. Although intracranial germ cell tumors are overwhelmingly more common in men, there seems to be no strong gender preference among other pineal tumor types.

PATHOBIOLOGY

The pineal gland is an encapsulated structure situated between the velum interpositum of the posterior and the tectum of the midbrain. The gland produces melatonin in response to light-dark cycles and may play an ill-defined role in circadian rhythms. Pineocytomas and pineoblastomas arise from pineal glandular elements, astrocytomas and oligodendrogliomas from glial cells, hemangioblastomas from endothelial cells, and chemodectomas from sympathetic nerve cells. Arachnoid cells in the reflections of the tela choroidea, adjacent to the pineal gland, give rise to meningiomas. Ependymomas arise from ependymal cells that line the third ventricle. GCTs derive from primitive germ cell rests that are retained in the pineal and other midline structures after embryologic migration.

TABLE 101.1 Summary of Pathologically Verified Pineal Tumors at the New York Neurological Institute (1990-2013)

Type	Benign	Malignant	Male-to-Female Ratio	Average Age (yr)
Germ cell	3	29	15:1	22
Pineal cell	16	29	1:1	41
Glial cell	18	20	1:1.5	38
Meningioma	9	2	1:2.7	46

Pineal cyst	14	0	1:2.5	36
Miscellaneous (including metastases)	3	15	1:1	40
Total	63	95	1.1:1	36

GERM CELL TUMORS

GCTs account for approximately one-third of all pineal tumors and are histologically identical to gonadal GCTs. They predominate in men and usually occur in children and adolescents. Pineal GCTs occur almost exclusively in boys, but suprasellar tumors occur equally in boys and girls. GCTs fall into two major categories: germinomas and nongerminomatous (NGGCT) that include choriocarcinomas, embryonal cell carcinomas, teratocarcinomas, and endodermal sinus tumors. Benign, mature teratomas may also be seen.

Germinomas arise in the midline, usually in the pineal area and suprasellar cistern and occasionally in both areas simultaneously. Rarely do they develop in the cerebral hemispheres. Germinomas account for about half of all intracranial GCTs. They are histologically identical to the testicular seminoma and ovarian dysgerminoma. Germinomas are highly malignant; pathologically, they are frequently infiltrated by lymphocytes, which may occasionally confuse the diagnosis. Germinomas label with placental alkaline phosphatase; some contain syncytiotrophoblastic elements that produce β -human chorionic gonadotropin (β -hCG), which confers a slightly worse prognosis in some studies (Table 101.2). Germinomas may occasionally seed the cerebrospinal fluid (CSF).

NGGCTs are highly malignant and more aggressive than germinomas; they metastasize to the CSF more frequently than germinomas. Choriocarcinoma contains cyto- and syncytiotrophoblastic cells that produce β -hCG. Endodermal sinus tumors contain yolk sac elements that produce α -fetoprotein (AFP). High levels

P.882

of β -hCG or AFP in the CSF or serum indicate the presence of malignant germ cell elements. When markers are elevated, a tissue diagnosis is not necessary and patients are treated with radiation and chemotherapy.

TABLE 101.2 Biologic Markers in Germ Cell Tumors

Tumors	α-hCG	AFP
Immature teratoma	?	+
Germinoma	-	-
Germinoma with syncytiotrophoblastic cells	+	-
Embryonal cell carcinoma	+	+
Choriocarcinoma	++	+
Endodermal sinus tumor	-	++

β -hCG, β -human chorionic gonadotropin; AFP, α -fetoprotein.

All patients with histologically confirmed GCTs, regardless of subtype, should have serum and CSF tested for markers (if not done preoperatively), a complete spine magnetic resonance imaging (MRI) with gadolinium, and cytologic examination of CSF to complete staging prior to treatment.

Treatment first involves surgical resection to establish the diagnosis and debulk the tumor; if possible, gross total excision is the surgical goal. Patients with pure germinomas should be treated with radiotherapy, usually to 50.4 Gy; the port must include the whole ventricular system, and some radiotherapists treat the whole brain. If the tumor is disseminated in the CSF, craniospinal radiation is required. Chemotherapy may be useful at recurrence but is not recommended at diagnosis because most germinoma patients are cured with radiotherapy alone. NGGCTs require craniospinal radiotherapy and adjuvant chemotherapy in all cases after maximal resection. Benign GCTs such as teratomas, dermoids, and epidermoids are generally curable with surgery alone.

PINEAL CELL TUMORS

Primary pineal cell tumors are classified as low-grade pineocytomas (World Health Organization [WHO] grade I), pineal parenchymal tumors of intermediate differentiation (PPTID, WHO grade II or III), or the highly malignant pineoblastoma (WHO grade IV). Pineoblastomas are the same entity as primitive neuroectodermal tumors (PNET) of the pineal region. The higher grade tumors tend to occur in children and young adults, whereas pineocytomas usually occur in adults. Pineal tumors of all histologic grades may seed the leptomeninges, but pineocytomas do so only rarely. Complete resection of a pineocytoma does not require additional therapy, but incomplete resection should be followed by radiation. Intermediate-grade pineocytomas require radiotherapy, and pineoblastomas require neuraxis radiation and chemotherapy.

GLIOMAS

Gliomas account for one-third of pineal tumors. Most are invasive and have a prognosis comparable to astrocytomas of the upper brain stem. Some gliomas are low-grade, cystic, and may be surgically curable. Anaplastic astrocytomas and glioblastomas are less common. Oligodendrogliomas and ependymomas may also occur. Treatment of these tumors is identical to the treatment of gliomas in other areas of the central nervous system.

MENINGIOMAS

Meningiomas may arise from the velum interpositum or from the tentorial edge. They occur predominantly in middle-aged patients and in the elderly. They are amenable to surgical resection.

METASTASIS AND OTHER MISCELLANEOUS TUMORS

The pineal gland does not have a blood-brain barrier and, like the pituitary gland, may be underrecognized as a site of brain metastasis from systemic tumors. Miscellaneous tumors include sarcoma, hemangioblastoma, choroid plexus papilloma, lymphoma, and chemodectoma.

PINEAL CYSTS

Benign cysts of the pineal gland are often found incidentally on imaging studies, and it is important to distinguish them from cystic tumors. They are normal variants of the pineal gland and consist of a cystic structure surrounded by normal pineal parenchymal tissue (Fig. 101.1). Radiographically, they are up to 2 cm in diameter and often have some degree of peripheral enhancement as a result of the compressed normal pineal gland. Pineal cysts may be found in 4% of all MRI scans. These cysts are static, anatomic variants and need no

treatment unless they become symptomatic. The most common symptoms are headaches, followed by visual symptoms. The cysts may be sufficiently large to cause obstructive hydrocephalus. Decompression can occasionally be accomplished by third-ventricular endoscopic resection of the cyst.

CLINICAL FEATURES

Pineal region tumors may become symptomatic from one of three mechanisms: increased intracranial pressure (ICP) from hydrocephalus, direct compression of brain stem and cerebellum, or endocrine dysfunction. Headache, associated with hydrocephalus, is the most common symptom at onset and is caused by obstruction of third-ventricular outflow at the aqueduct of Sylvius (Table 101.3). Leptomeningeal dissemination can produce a multitude of symptoms depending on the area affected, analogous to leptomeningeal metastases from other cancers. Hydrocephalus must be surgically addressed in most patients, preferably by an endoscopic third ventriculostomy. A ventriculoperitoneal shunt is an acceptable alternative but carries greater long-term risks including peritoneal seeding of malignant tumors.

More advanced hydrocephalus may result in papilledema, gait disorder, nausea, vomiting, lethargy, and memory disturbance.

P.883

Direct midbrain compression may cause disorders of ocular movements, such as Parinaud syndrome (paralysis of upgaze, convergence or retraction nystagmus, and light-near pupillary dissociation) or the sylvian aqueduct syndrome (paralysis of downgaze or horizontal gaze superimposed upon a Parinaud syndrome). Either lid retraction (Collier sign) or ptosis may follow dorsal midbrain compression or infiltration. Fourth nerve palsy with diplopia and head tilt may be seen. Ataxia and dysmetria may result from direct cerebellar compression.

FIGURE 101.1 Sagittal T1-weighted gadolinium-enhanced MRI of a pineal cyst. These cysts may have rim enhancement (*small arrow*) and may be up to 2 cm in diameter. They rarely cause compression of the sylvian aqueduct (*larger arrow* on patent aqueduct) and are rarely symptomatic. Histologically, they are normal variants

of the pineal gland and require no treatment; they must be distinguished from cystic tumors. Growth of the cyst on serial MRIs or the development of hydrocephalus is sufficient cause to doubt the diagnosis, and surgical resection should be considered.

TABLE 101.3 Presenting Symptoms and Signs in 100 Consecutive Patients with Pineal Region Tumors at the New York Neurological Institute

Symptoms	Number	Signs	Number
Headache	87	Parinaud syndrome	75
Nausea/vomiting	32	Ataxia	39
Gait unsteadiness	32	Papilledema	36
Diplopia	31	Normal exam	12
Blurred vision	19	Fourth nerve palsy	5
Memory impairment	16	Obtundation	4
Lethargy	11	Sixth nerve palsy	3
Altered consciousness	9	Spasticity	3
Personality change	9	Visual field deficit	1
Visual obscurations	4	Psychomotor retardation	1
Syncope	3		
Polyuria/polydipsia	3		
Seizures	3		
Tremor	3		
Neck stiffness	2		
Numbness	2		
Developmental delay	2		
Incontinence	2		

Precocious puberty	1
Rigidity	1
Amenorrhea	1
Subarachnoid hemorrhage	1

Endocrine dysfunction is rare, usually arising from secondary effects of hydrocephalus or tumor spread to the hypothalamic region (Fig. 101.2). The symptoms may occur early, before any radiographic documentation of hypothalamic seeding.

Although precocious puberty has been linked with pineal masses, documented cases are rare. Precocious puberty is actually precocious pseudopuberty because the hypothalamic-gonadal axis is not mature. It occurs in boys with choriocarcinomas or germinomas with syncytiotrophoblastic cells and ectopic secretion of β -hCG. In boys, the luteinizing hormone-like effects of β -hCG may stimulate Leydig cells to produce androgens that induce development of secondary sexual characteristics and pseudopuberty. This phenomenon does not occur in girls with pineal region tumors because GCTs are rare in females, and both luteinizing hormone and folliclestimulating hormone (FSH) are necessary to trigger ovarian estrogen production.

FIGURE 101.2 Sagittal MRI with gadolinium showing multicentric germinoma involving the pineal region and infiltrating the mammillary bodies, optic chiasm, and pituitary stalk. This patient presented with diminished visual fields and diabetes insipidus.

DIAGNOSIS

MRI with gadolinium is mandatory for all pineal tumors to determine the presence of hydrocephalus and evaluate tumor size, vascularity, and homogeneity. In particular, sagittal MRI reveals the relationship of the tumor to surrounding structures and also evaluates possible ventricular seeding. Angiography is not

performed unless a vascular anomaly is suspected. Measurement of AFP and β -hCG in serum and CSF is required in the preoperative workup. If β -hCG or AFP levels are elevated, malignant germ cell elements must be present so a tissue diagnosis is not necessary and treatment with radiation and chemotherapy can commence. Despite improved imaging and CSF markers, a definite histologic diagnosis requires pathologic examination of tumor tissue, and all patients should undergo surgery.

TREATMENT

Given the rarity of pineal region tumors, studies establishing level 1 standards do not exist. Owing to the wide variety of pineal region tumor subtypes, the general approach to these tumors is to first establish a histologic diagnosis by obtaining tumor tissue through an open surgical approach or a stereotactic-guided needle biopsy (Fig. 101.3). Subsequent management is dependent on the tumor type (Fig. 101.4).

SURGERY

The pineal region may be reached surgically from one of several approaches, above or below the tentorium, depending on tumor size and coexistent hydrocephalus (Fig. 101.5). Complete excision

P.884

is the goal for any pineal tumor. Nearly one-third of pineal tumors are benign and curable with complete resection alone. With malignant tumors, aggressive tumor resection provides the best opportunity for accurate histologic diagnosis and may increase the effectiveness of adjuvant radiotherapy or chemotherapy. The overall operative mortality is about 4%, with an additional 3% permanent major morbidity. The most serious complication of surgery is hemorrhage into a partially resected malignant tumor. The most common postoperative complications are ocular palsies, altered mental status, and ataxia, which are usually transient. For patients with obviously disseminated tumor or those with medical problems that pose excessive surgical risks, biopsy via a stereotactic or endoscopic approach is a reasonable alternative for obtaining diagnostic tissue. Although gaining in popularity, stereotactic biopsy is not performed routinely because of possible sampling error through insufficient tissue analysis, increased risk of hemorrhage from the adjacent deep venous system and highly vascular pineal tumors, and a better prognosis that follows aggressive resection.

FIGURE 101.3 Axial (A) and sagittal (B) MRIs with gadolinium of a heterogeneously enhancing pineal region tumor. The tumor comprised several germ cell elements, including immature teratoma, germinoma, endodermal sinus tumor, and embryonal cell carcinoma (C). Pineal region tumors may be extremely heterogeneous, and extensive tumor sampling is necessary to avoid diagnostic errors.

POSTOPERATIVE STAGING

All patients with pineal cell tumors and GCTs are evaluated for CSF seeding (Fig. 101.6). High-resolution gadolinium-enhanced MRI of the complete spine should be performed. Even if the spine MRI is negative, CSF analysis for cytology and markers is still required in all patients.

RADIOTHERAPY

Germinomas and pineal parenchymal tumors of intermediate differentiation require radiation to a dose of 50 to 60 Gy with coverage of the ventricles. All patients with pineoblastomas, NGGCT,

and disseminated germinomas require neuraxis radiotherapy, usually to a total dose of about 36 Gy, with a boost to the primary site to achieve a dose of at least 54 Gy. Gliomas are treated according to histologic

subtype.

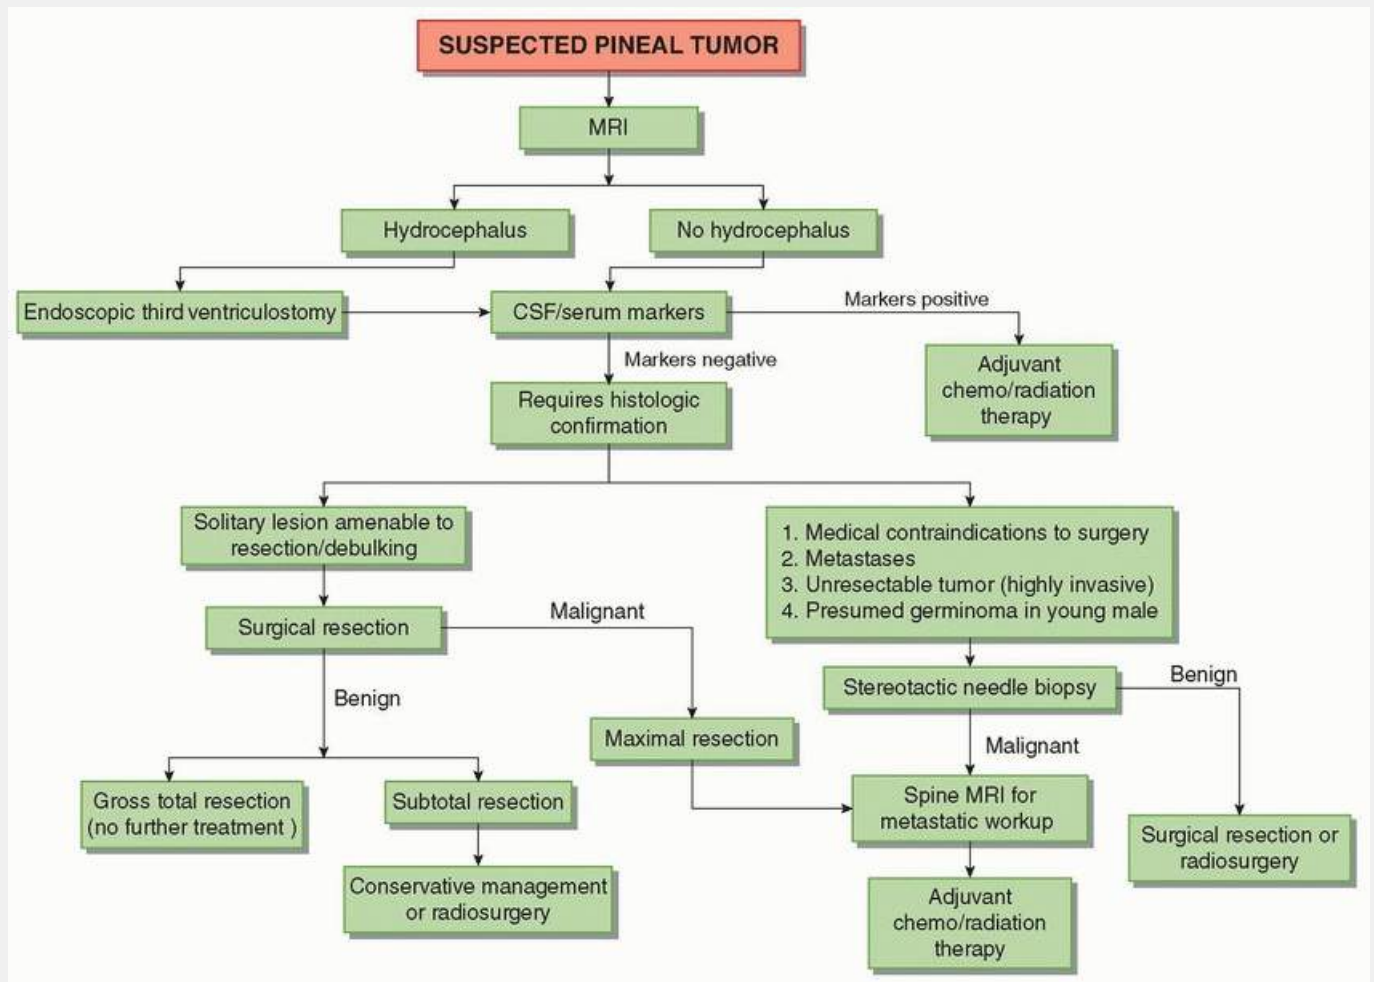

FIGURE 101.4 Algorithm for management of pineal region tumors.

Experience with stereotactic radiosurgery is limited because pineal tumors are rare. There are reports of tumor control using radiosurgery as the sole treatment for some low-grade tumors such as pineocytoma, but it rarely produces complete tumor regression and is probably not optimal initial therapy. The main problem with radiosurgery is not the response of the targeted mass but the potential for recurrence outside of the treatment volume. It has been used with some success for tumors less than 3 cm in diameter at recurrence, provided there is no evidence of CSF dissemination.

CHEMOTHERAPY

Chemotherapy has been of most benefit with NGGCTs and pineoblastomas. The most commonly used regimens are combinations of cisplatin, vinblastine, and bleomycin or cisplatin and VP-16 (e.g., etoposide). Chemotherapy is usually given after completion of neuraxis radiation, except in young children in whom radiotherapy is avoided because of the risk of severe, long-term effects on growth and cognition. Young children are treated with chemotherapy alone, and radiotherapy is deferred until they are at least 3 years or older. Initial attempts to avoid radiation in all patients by using aggressive chemotherapy resulted in an unacceptably high incidence (50%) of recurrence at 2 years, including patients with germinoma, which is curable with radiation alone. Therefore, chemotherapy is not used as part of the initial treatment of localized germinomas.

OUTCOME

Generally, benign pineal tumors and pineal cysts are curable with surgery alone. For malignant tumors,

meta-analysis of small clinical series suggests that maximal surgical resection provides survival benefits; however, class I or II evidence is lacking. Prognosis is highly dependent on tumor histology. Germinomas have a 90% 10-year survival rate following surgery and radiotherapy. Patients with NGGCT have 5-year survival rates in the range of 50%, but some may be salvaged with additional chemotherapy. Greater than 80% of patients with pineocytomas survive 5 years particularly following aggressive surgical resection. Median survival for patients with pineoblastomas is much more variable ranging from 1 to 5 years, with prognosis influenced by extent of resection, age, and disseminated disease. The outcome for patients with glial tumors is similar to gliomas found in other regions of the brain.

Acoustic Neuroma and Other Skull Base Tumors

Randy S. D'Amico

Michael B. Sisti

VESTIBULAR SCHWANNOMA (ACOUSTIC NEUROMA)

EPIDEMIOLOGY

Vestibular schwannomas (e.g., acoustic neuroma, acoustic neurofibroma) are slow-growing, benign extra-axial tumors that arise commonly from the superior vestibular portion of the eighth cranial nerve (CN VIII). Vestibular schwannomas comprise 8% to 10% of intracranial tumors. Tumors may arise either sporadically (95%) or in association with neurofibromatosis type 2 (NF2). The incidence of sporadic cases is believed to be 1 per 100,000 person-years, with a median age of 50 years. As a result of the prevalence of magnetic resonance imaging (MRI), the incidence of vestibular schwannomas has increased recently, whereas the typical size at diagnosis has decreased.

PATHOBIOLOGY

Vestibular schwannomas are histopathologically benign tumors that grow slowly from the Schwann cell sheath surrounding the vestibular branch of CN VIII. Tumors are composed of Antoni A (narrow elongated bipolar cells) and Antoni B fibers (loose reticulated pattern of cells). Verocay bodies are frequently seen and consist of acellular eosinophilic areas surrounded by parallel arrangements of spindle-shaped Schwann cells.

FIGURE 102.1 Vestibular Schwannoma. **A:** T1-weighted axial MRI before contrast shows large hypo intense mass within the CPA angle exerting mass effect on the brainstem. **B:** T1-weighted axial MRI post-contrast shows a vestibular schwannoma with expansion of the internal auditory meatus.

Vestibular schwannomas are typically unilateral lesions. Bilateral vestibular schwannomas occur in less than 5%

of patients and are a defining characteristic of NF2, an autosomal dominant disorder involving the *NF2* gene located on chromosome 22 band q11-13.1. This gene normally encodes the protein merlin (schwannomin), which is thought to play a role in membrane stability through interactions with cytoskeletal and integral membrane proteins. Loss of function of merlin in Schwann cells has been associated with both sporadic and NF2-related vestibular schwannomas, and the gene is often considered a classic tumor suppressor. Cytologically, vestibular schwannomas that arise in NF2 are identical to sporadic cases but with a greater tendency to infiltrate the nerve rather than displace it. In addition to patients with bilateral lesions, any patient younger than 40 years of age with a unilateral vestibular schwannoma should also undergo evaluation for NF2.

Tumors often originate within the internal acoustic meatus (intracanalicular; Fig. 102.1) and may extend into the cerebellopontine angle (extracanalicular). Mass effect from extracanalicular tumor may compromise function of cranial nerves, brain stem nuclei, and the cerebellum. Tumors typically follow three growth patterns: (1) no or

P.889

very slow growth; (2) slow growth (2 mm/yr linear growth on imaging studies); or (3) fast growth (> 8 mm/yr) as a result of the enlargement of cystic components or rarely, intratumoral hemorrhage.

TABLE 102.1 Symptoms in Vestibular Schwannoma (1,000 Patients)

Symptoms	%
Hearing loss	95
Tinnitus	63
Dysequilibrium/vertigo	61
Headache	12
Trigeminal nerve disturbance	9
Facial paresis	5.2
Caudal cranial nerve disturbances	2.7
Change of taste	2
Diplopia	1.8

From Matthies C, Samii M. Management of 1000 vestibular schwannomas (acoustic neuromas): clinical presentation. *Neurosurgery*. 1997;40(1):1-9; discussion 9-10.

CLINICAL FEATURES

Vestibular schwannomas most commonly present with progressive unilateral hearing loss, characterized by difficulty with speech discrimination, especially when talking on the telephone. The next most common symptoms

include tinnitus, followed by balance difficulties (Table 102.1). This triad of symptoms is related to pressure on the eighth nerve complex in the internal auditory canal. Other presenting symptoms include facial paralysis, trigeminal neuralgia, and rarely, hydrocephalus and brain stem compression in the setting of larger tumors. Although this constellation of symptoms may occur with any mass in the cerebellopontine angle, including meningioma, cholesteatoma, or trigeminal neuroma, only rarely will these other lesions cause tinnitus or hearing dysfunction.

DIAGNOSIS

Patients with hearing loss often undergo audiometric evaluation with pure tone audiogram and speech discrimination evaluation. Those with vestibular disturbances may undergo vestibular testing. Hearing loss is typically insidious and progressive, with 70% of patients demonstrating a high-frequency loss pattern and impaired word discrimination (especially noticeable in telephone conversation). Tinnitus is usually high-pitched. Weber test lateralizes to the uninvolved side, and Rinne test will be positive on both sides if there is enough preserved hearing.

FIGURE 102.2 Treatment algorithm for vestibular schwannoma management.

Asymmetric sensorineural hearing loss, or defects in other cranial nerves, indicates the need for imaging. Gadolinium-enhanced MRI is the gold standard for diagnosing vestibular schwannomas. Tumors enhance brightly, and an origin within the internal auditory canal suggests vestibular schwannoma rather than meningioma. Contrast-enhanced computed tomography (CT) can also be used to diagnose vestibular schwannomas greater than 15 mm in diameter for patients who cannot undergo MRI.

TREATMENT

The goal of treatment is to cure the tumor while preserving intact neurologic function. Following diagnosis, patients with vestibular schwannomas have several options for managing their tumor including observation with serial imaging, stereotactic radiosurgery (SRS), fractionated radiotherapy (RT), and microsurgery. Selection of treatment modality depends on tumor size, symptoms, patient age, patient health, and patient preference. Figure 102.2 represents a decision tree following initial diagnosis of vestibular schwannoma. In general, noncystic, non-NF2 intracanalicular tumors or cerebellopontine angle (CPA) tumors 20 mm or smaller may be followed with serial imaging and hearing tests. Tumors larger than 15 to 20 mm should be treated. NF2 patients present a challenge and should be evaluated on a case-by-case basis.

Observation/Expectant Management

Observation with serial clinical assessment and follow-up MRI to monitor for signs of tumor growth is an option in the management of vestibular schwannoma. Patients using this approach are monitored using MRI until progression of symptoms or tumor growth warrants more invasive treatment. Imaging is performed every 6 months for 2 years after diagnosis. If stable, imaging occurs annually until year 5 after diagnosis and then occurs at year 7, 9, and 14 after diagnosis. However, observation is not without risk, as tumor growth rates and progression of symptoms are not predictable. By 10 years, most clinical experience demonstrates that the majority of patients will have tumor growth and progression of symptoms. Therefore, the “wait and scan” approach should mainly

P.890

be used in older patients and those whose medical comorbidities preclude other treatment options.

Stereotactic Radiosurgery

Radiosurgery is a therapeutic option that improves tumor control and hearing preservation compared with observation in patients presenting with small tumors (< 30-mm diameter), serviceable hearing, or in those who wish to avoid surgery due to preference or anxiety. A dose of 12 to 13 Gy is prescribed typically and associated with improved hearing preservation. Long-term tumor control rates ranging from 91% to 98% have been reported in large series after radiosurgery, with 1.6% to 4.2% ultimately requiring resection for progressive enlargement. When applied early after diagnosis, long-term hearing preservation is achieved in greater than 60% of patients with doses of 13 Gy or lower, with higher rates achievable with intracanalicular tumors. Minimizing the radiation exposure to nearby structures (i.e., the cochlea, semicircular canals, and brain stem in larger tumors) minimizes morbidity rates associated with radiosurgery without sacrificing efficacy. Preservation of facial and trigeminal nerve function is also possible in the majority of patients.

For smaller tumors, hearing preservation and tumor control rates are equivalent following radiosurgery or surgical resection. However, radiosurgery is more effective than surgical resection in preserving postoperative facial function and is associated with lower rates of trigeminal neuropathy and other treatment-associated morbidity. In addition, hospital lengths of stay and management costs are less after radiosurgery and in general, hospital postoperative functional outcomes and patient satisfaction have been found to be greater after radiosurgery when compared with microsurgery.

Surgical Resection

Microsurgical resection remains the best cytoreductive therapy for vestibular schwannomas and is generally indicated in the setting of tumor progression after previous interventions and for those with large tumors (> 30 mm diameter). In particular, microsurgery remains the preferred treatment for large lesions causing mass effect and obstructive hydrocephalus. Additional treatment is necessary in less than 2% of cases after microsurgical treatment. Facial nerve function may be preserved in more than 95% of patients with small tumors less than 20 mm, with rates of preservation dropping in the setting of tumors larger than 30 mm. Serviceable hearing, otherwise known as *useful hearing*, is assessed using the combined results of pure tone audiogram that evaluates the functionality of hearing and speech discrimination tests. Serviceable hearing is maintained in 32% to 44% of cases, with rates closer to 50% in the setting of tumors less than 30 mm. Recent data suggest that planned neartotal or extensive subtotal resections, followed by radiosurgery for residual tumor, may be appropriate for large tumors, with excellent rates of facial nerve preservation and functional outcomes and no decrease in tumor control.

TABLE 102.2 Clinical Syndromes Associated with Metastases to the Skull Base

Syndrome	Symptoms	Cranial Nerves Affected
----------	----------	-------------------------

Orbital	Proptosis, diplopia, facial numbness, pain	II, V ₁
Parasellar	Unilateral frontal headache, diplopia, facial numbness	II, IV, VI, V ₁
Petrous apex	Facial pain, diplopia	V, VI
Middle fossa or gasserian ganglion	Facial pain, facial numbness, diplopia	V ₂ , V ₃ , VI
Jugular foramen	Hoarseness, dysphagia, pharyngeal pain	IX, X, XI
Occipital condyle or hypoglossal canal	Occipital pain, unilateral tongue weakness	XII

Chemotherapy

Patients with progressive acoustic neuromas in the setting of NF2 may derive benefit from treatment with bevacizumab, an antivascular endothelial growth factor (VEGF) monoclonal antibody with imaging response rates reported as high as 60% and minimal associated morbidity.

MALIGNANT TUMORS OF THE SKULL AND SKULL BASE

METASTASIS TO THE SKULL BASE

The skull is a common site of metastases from systemic cancers, with skull metastases occurring in 4% of cancer patients. The most common metastatic tumors to the skull base include breast, lung, and prostate cancers. Not surprisingly, prostate carcinoma is the most frequent cause of skull metastases (although it almost never metastasizes to the brain parenchyma) in men, whereas breast carcinoma is the most common in women (which also frequently metastasizes to the brain). Colon, renal, and thyroid cancers, as well as lymphoma, melanoma, and neuroblastoma may also metastasize to the skull base.

The clinical manifestation of metastases to the skull base depends on the location of the lesion ([Table 102.2](#)). Cranial nerves are vulnerable to compression by osseous metastases as they exit through the bony foramina of the skull. In addition, although metastases to the skull base are often painless, craniofacial pain in a patient with known cancer may be an initial symptom.

Contrast-enhanced MRI is the gold standard for detection of metastases to the skull base. CT scan is less effective than MRI for detecting contrast-enhancing soft-tissue masses but is the best method to demonstrate lytic bone lesions. Radionuclide bone scans have great sensitivity in detecting bone metastases. Although biopsy may be difficult and hazardous, it may be necessary to establish a diagnosis. Examination of cerebrospinal fluid (CSF) may be important to evaluate meningeal carcinomatosis in select patients.

The prognosis of skull base metastases depends on the extent of the primary disease, the location and associated extension of the tumor, and the surgical accessibility of the metastasis itself. In addition to symptomatic treatments with steroids and analgesia, specific treatments include radiotherapy, chemotherapy, and surgery. Treatment depends on the nature of the underlying tumor. Palliative radiotherapy is generally the standard treatment with a

total dose of at least 30 Gy given in 3 Gy fractions with excellent symptomatic relief. Some patients benefit from chemotherapy or hormonal therapy for appropriately sensitive tumors. Gamma Knife radiosurgery is useful for small tumors or tumors previously irradiated. Select patients may benefit from surgical resection. In general, the overall prognosis is poor with median survival less than 3 years for most tumors. Note that metastases to the skull are not synonymous with metastases to the brain and are not protected by the blood-brain barrier, an important consideration when choosing chemotherapeutics.

EXTENSION OF MALIGNANT TUMORS TO THE SKULL BASE

Several malignant tumors involve the skull base by direct extension ([Fig. 102.3](#)). These include squamous cell carcinoma (nasal sinuses and temporal bone), adenoid cystic carcinoma (salivary glands), esthesioneuroblastoma (olfactory mucosa), and nasopharyngeal carcinoma. Involvement of the skull base by these tumors may result in pain and cranial neuropathies. Erosion of the skull base and the presence of a contrast-enhancing soft-tissue mass are generally identified on CT or MRI. Biopsy of accessible lesions is diagnostic and small tumors may be cured by wide excision prior to invasion of sensitive neural structures. However, most tumors are extensive at the time of diagnosis, and prognosis is poor despite radical excision and radiation therapy.

PRIMARY MALIGNANT TUMORS OF THE SKULL AND SKULL BASE

Chondrosarcoma

Chondrosarcoma is a malignant cartilage tumor originating in the enchondral bones of the skull base that most commonly affects men in the fourth decade. Tumors arise in the paranasal sinuses, the parasellar areas, or the cerebellopontine angle, with variable symptoms depending on location. CT and MRI are the preferred imaging modalities. Maximal safe debulking followed by adjuvant radiotherapy or observation is the treatment of choice.

FIGURE 102.3 Esthesioneuroblastoma. Coronal MRI demonstrates an esthesioneuroblastoma in the ethmoid sinus with intradural extension (*arrow*). This tumor arises from olfactory mucosa.

Chordoma

Chordoma is a rare, histologically benign, locally aggressive bone tumor associated with destruction of surrounding tissues. Derived from remnants of notochord within the axial skeleton, tumors distribute equally between the skull base, mobile spine, and sacrum with predominance in men between 50 and 60 years of age. Chordomas of the skull base often arise in the clivus and cause cranial nerve palsies. Histologically, tumors are distinguished by the presence of physaliferous cells. Treatment involves maximal safe aggressive resection with an emphasis on preservation of neurologic function, followed by advanced radiotherapy such as proton beam radiation. High rates of recurrence make their prognosis similar to malignant tumors.

Osteogenic Sarcoma

Osteogenic sarcoma (osteosarcoma) is the most common primary bone malignancy. Osteosarcoma primarily affects long bones with rare involvement of the skull or skull base. Lesions are the result of osteoid or immature bone production by malignant spindle cells and are associated with destruction of normal bone ([Fig. 102.4](#)). Patients may report history of prior radiation, chemotherapy, Paget disease, fibrous dysplasia, or chronic osteomyelitis. Symptoms are variable by location. Treatment is maximal safe surgical resection with an emphasis on preserving neurologic function and avoiding cosmetic defects. Tumors are relatively radioresistant and chemotherapy with cisplatin, doxorubicin, and high-dose methotrexate may offer benefits.

Soft-Tissue Sarcoma

Soft-tissue sarcomas of the skull base are rare. Malignant fibrous histiocytoma, fibrosarcoma, angiosarcoma, and malignant peripheral nerve sheath tumors are the most frequently encountered lesions. CT and MRI are essential for assessing tumor size and location. Treatment is aggressive safe resection. However, because anatomic constraints of the skull base often limit wide excision, patients will often receive adjuvant radiotherapy and chemotherapy.

GLOMUS JUGULARE TUMORS

Jugular paragangliomas (“glomus jugulare”) are the most common tumor arising within the jugular foramen. These rare, slow-growing, locally invasive tumors arise from chromaffin cells in the region of the jugular bulb and course along the glossopharyngeal nerve, the tympanic branch of the glossopharyngeal nerve (Jacobson nerve), or the auricular branch of the vagus nerve (Arnold nerve). Tumors are highly vascularized and symptoms are the result of both compression and infiltration of adjacent temporal and occipital bone and involvement of nearby cranial nerves. In addition, tumors may extend into the middle ear and cause conductive hearing loss, pulsatile tinnitus, and audible bruits or may be discovered as a small vascular mass within the middle ear cavity. MRI with contrast best visualizes tumors, and magnetic resonance angiography (MRA) reveals their extensive vascularity. CT with contrast may also be considered in patients who cannot undergo MRI. Digital subtraction angiography (DSA) is performed for diagnosis and preoperative embolization is essential to decrease tumor vascularity and

P.892

facilitate resection. Interestingly, some paragangliomas secrete catecholamines, which may be ascertained by a 24-hour urine assay and must be blocked prior to surgery. Malignant transformation of these lesions is rare.

FIGURE 102.4 Osteogenic sarcoma (osteosarcoma). **A:** Noncontrast axial CT shows a calcified mass within the medial right parietooccipital lobes with massive extracranial soft-tissue swelling. **B:** Corresponding bone window shows thinning and eroded calvarium with several large areas of calcification and ossification noted within the extracranial soft tissues in the right parietooccipital region. These findings are classic for osteosarcoma.

Surgery offers the best chance of cure for glomus jugulare tumors and results in cessation of cardiovascular

symptoms and normalization of catecholamine levels in patients symptomatic from secreting tumors. However, total removal is difficult and accompanied by significant morbidity due to the vascularity and invasiveness of the lesions. Observation may be appropriate until patients become symptomatic or tumors demonstrate growth on imaging. Gamma Knife radiosurgery may offer improved rates of tumor control with lower risks of morbidity compared with surgery for patients with nonsecreting tumors.

BENIGN TUMORS OF THE SKULL

OSTEOMA

Osteomas are rare, benign slow-growing tumors of the skull. Histologically, tumors are composed of well-differentiated mature, compact, or cancellous bone arising from either the inner table or the outer table of the skull. Lesions frequently occur in the paranasal sinuses but may arise within the frontoethmoidal region, the petrous bone (mastoid sinuses), the cranial vault, and the mandible. Tumors are generally asymptomatic but may be associated with headache, recurrent sinusitis, and proptosis and orbital deformities secondary to orbital invasion. Rarely, tumors may present with pneumocephalus, rhinorrhea, meningitis, dural erosion, and abscess formation. Calvarial lesions are hard, painless localized masses with minimal intracranial extension. Diagnosis is based on the characteristic appearance of a circumscribed homogenous hyperdensity involving the skull that is best seen with CT scan (Fig. 102.5). Symptomatic lesions are treated surgically, and reconstruction may be necessary for extensive lesions.

CHONDROMA

Chondromas are rare, slow-growing benign tumors arising from cartilage rests at the basilar synchondroses of the skull base. Lesions have a predilection for the sphenoid, sphenopetrosal, sphenoid-occipital, or petro-occipital regions. However, rare dural, intraparenchymal, and intraventricular lesions have been described. Clinical presentation varies by anatomic location and slow-growing tumors may remain asymptomatic for prolonged periods of time. Radiographically, tumors appear as lytic lesions, with sharp margins and erosion of surrounding bone. Stippled calcification within the lesion may be apparent and helps distinguish chondroma from metastasis or chordoma. Chondromas typically display high intensity on T2-MRI and low to intermediate intensity on T1-MRI, with a heterogeneous ring-and-arc enhancement pattern after administration of gadolinium. Treatment involves radical resection for symptomatic lesions with extension to normal bone margins to prevent recurrence. Progression to malignant chondrosarcoma is rare.

HEMANGIOMA

Hemangiomas are benign, vascular bone tumors representing 0.2% of bony neoplasms of the skull. Lesions may involve the calvaria or the skull base (or vertebral bodies of the spine), with a predilection for the cavernous sinus. Commonly discovered incidentally after CT or MRI performed for other reasons, hemangiomas may present as a slowly enlarging lump associated with headaches that worsen with lesion expansion. However, neurologic findings are uncommon,

P.893

as hemangiomas rarely extend intracranially. Radiographically, tumors appear as well-circumscribed, expansive hypodense regions with a honeycomb or polka-dotted pattern on CT. MRI demonstrates heterogeneous signal on both T1- and T2-weighted sequences and may demonstrate flow voids suggestive of a vascular lesion. However, the radiographic appearance of skull base hemangiomas is variable and pathologic examination is often required for diagnosis. Resection is indicated for neurologic compromise, unremitting headache, mass effect, cosmetic deformity, or tissue diagnosis. Treatment is by safe maximal resection and the use of preoperative embolization may be beneficial. The use of radiation for incompletely resected, or multiple tumors, remains controversial.

FIGURE 102.5 Orbital osteoma. Coronal (A) and axial (B) CT with bone windows show an osteoma involving the orbit.

DERMOID AND EPIDERMOID TUMORS

Dermoid and epidermoid cysts are benign, extra-axial developmental lesions arising from trapped ectodermal tissue during closure of the neural tube. Cysts are lined with stratified squamous epithelium and contain keratin, cellular debris, cholesterol (epidermoids), and elements of the dermis, including hair and sebaceous glands (dermoids). Epidermoids most commonly arise in the cerebellopontine angle and the parasellar region but may occur in the middle cranial fossa and spinal canal. Dermoids are predominantly midline lesions, arising commonly in the diploe of the fontanel extradurally and in the parasellar region intradurally.

Cysts may remain asymptomatic for years due to slow growth, with rare acute presentations due to hemorrhage or trauma. Cyst rupture is a rare complication that can cause severe chemical or aseptic meningitis. Epidermoids and dermoids typically appear as hypodense areas on CT. On MRI, epidermoids present as polycystic irregular lesions with extensive growth in the CSF spaces. Epidermoids have slightly higher signal intensity than CSF on T1- and T2-weighted images and heterogeneous features on fluid-attenuated inversion recovery (FLAIR) sequences. Diffusion-weighted imaging (DWI) facilitates identification of epidermoids. Dermoids are usually hyperintense on both T1- and T2-weighted images. Radical surgical excision is the preferred treatment when possible and can be curative. Malignant degeneration is rare.

NEOPLASTIC-LIKE LESIONS OF THE SKULL

HYPEROSTOSIS

Hyperostosis of nonneoplastic etiology may involve either the inner or the outer table of the skull. Outer table hyperostosis is clinically insignificant aside from cosmetic concerns. Hyperostosis of the inner table may rarely become large enough to compress intracranial contents. Hyperostosis frontalis interna (HFI) is a condition occurring in postmenopausal women, characterized by increased bone deposition along the inner table of the frontal bone. HFI is usually an incidental finding on CT or MRI, although excessive growth can cause compression of brain tissue.

FIBROUS DYSPLASIA

Fibrous dysplasia is a benign condition in which normal bone is replaced by poorly organized woven bone. Progressive growth of lesions may result in swelling, cosmetic deformities, and pain. Fibrous dysplasia is most commonly monostotic with involvement of a single bone. However, 25% of cases are polyostotic involving more than 50% of the skeleton and can be associated with fractures and skeletal deformities. Fibrous dysplasia may also occur as part of McCune-Albright syndrome. Lesions mostly occur in the ribs or craniofacial bones, particularly the maxilla. Localized involvement of the skull base and sphenoid wing, particularly by the sclerotic variety, may cause symptoms secondary to cranial nerve entrapment. X-rays and CT classically demonstrate a ground-glass appearance due to thin spicules of woven bone (Fig. 102.6). Chemotherapy and radiation are not effective treatments and radiation may predispose to higher rates of malignant transformation. Neurosurgical involvement may be required for skull lesions producing refractory pain or neurologic symptoms.

PAGET DISEASE (OSTEITIS DEFORMANS)

Paget disease is a disorder of osteoclasts causing rapid remodeling of bone. Increased bone resorption is followed by reactive osteoblastic overproduction of sclerotic, brittle woven bone that

P.894

produces a characteristic mosaic pattern on x-ray. Family history is present in 15% to 30% of discovered cases and about 1% degenerate into sarcoma with the possibility of systemic metastases. Lesions commonly involve the axial skeleton, long bones, and the skull. Mostly asymptomatic or incidentally discovered, facial and skull base remodeling may result in localized pain, cranial nerve compression with deafness being the most prominent finding in most cases, or basilar invagination. Markedly elevated serum alkaline phosphatase is a constant feature. Surgical intervention should be reserved for diagnosis or relief of symptoms.

FIGURE 102.6 Fibrous dysplasia. Axial (A) and coronal (B) CT with bone windows demonstrate classic ground-glass appearance of fibrous dysplasia of the orbit and ethmoid sinus.

MUCOCELE

Occlusion of a nasal air sinus may result in an encapsulated collection of mucus or pus, known as a *mucocoele*. Progressive expansion of mucocoeles may result in erosion through the skull base with subsequent compression of intracranial contents. Lesions frequently enhance with intravenous contrast on MRI and CT (Fig. 102.7). Surgery with reconstruction is the treatment of choice.

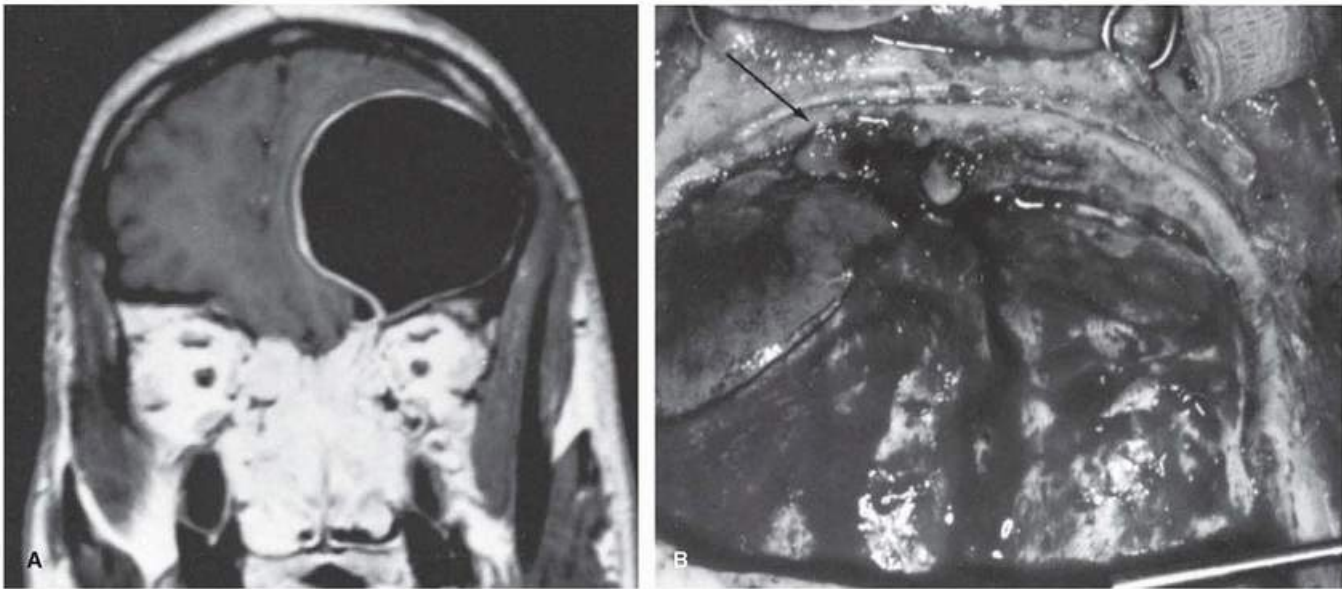

FIGURE 102.7 Mucocele. **A:** Coronal contrast-enhanced MRI shows a large mucocele compressing the frontal lobe, with chronic inflammation of the nasal mucosa obstructing the nasal sinuses. **B:** Intraoperative photograph shows the mucocele before its resection and subsequent skull base reconstruction. The frontal sinus contains inflammatory tissue (*arrow*) that had caused obstruction of the sinus.

MISCELLANEOUS

A variety of systemic disease may additionally involve the skull. These include histiocytosis X (eosinophilic granuloma is the mildest form), multiple myeloma, plasmacytoma, brown tumor of hyperparathyroidism, Wegener granulomatosis, and lethal midline granuloma. Infectious lesions such as tuberculosis, syphilis, leprosy, and fungal infections (especially aspergillosis and mucormycosis) may also occur within the skull base. In addition, lesions within the nose may communicate with the intracranial cavity such as nasopharyngeal carcinoma, esthesioneuroblastoma, encephalocele, and nasal gliomas.

Spinal Tumors

David Cachia

Claudio E. Tatsui

Mark R. Gilbert

INTRODUCTION

Tumors of the spinal cord or nerve roots are similar to intracranial tumors in cellular type. They may arise from the parenchyma of the cord, nerve roots, meninges, intraspinal blood vessels, sympathetic nerves, or vertebrae. Metastases may arise from remote tumors.

Spinal tumors are divided by location into three groups: intramedullary, extramedullary intradural, or extradural (or epidural) ([Fig. 103.1](#)). Occasionally, an extradural tumor extends through an intervertebral foramen to be partially within and partially outside the spinal canal (e.g., dumbbell or hourglass tumors; [Fig. 103.2](#)).

EPIDEMIOLOGY

Spinal cord tumors are much less prevalent than intracranial tumors, in a ratio of 1:4, but this varies by histology. The intracranial-to-spinal ratio of astrocytoma is 10:1, and the ratio for ependymomas varies from 3:1 to 20:1, although spinal tumors are the most prevalent location of ependymoma in adults. Men and women are affected equally often, except that meningiomas are more common in women and ependymomas are more common in men. Spinal tumors occur predominantly in young or middle-aged adults and are less common in childhood or after age 60 years.

FIGURE 103.1 Location of spinal tumors in relationship to spinal anatomy. (Reproduced with permission from Welch WC, Schiff D, Gerszten PC. Spinal cord tumors. UpToDate Web site. <http://www.uptodate.com/contents/spinal-cord-tumors>. Accessed April 9, 2015.)

Spinal tumors appear most often in the thoracic region, but if the relative lengths of the divisions of the spinal cord are considered, the distribution is comparatively equal.

PATHOBIOLOGY

The histologic characteristics of primary and secondary tumors are similar to those of intracranial tumors. An analyses of data from the Surveillance, Epidemiology, and End Results (SEER) and National Program of Cancer Registries that included 11,712 cases of primary spinal tumors identified over a 4-year period showed that of these, 78% were benign and 22% malignant. Histologically, the three most common tumors were meningioma, nerve sheath tumors, and ependymoma.

FIGURE 103.2 Neurofibromatosis. **A:** Gadolinium-enhanced T1-weighted axial MRI demonstrates bilateral neurofibromas seen at C1-C2, causing severe central spinal canal stenosis. **B:** Axial contrast-enhancing MRI at C2-C3 shows a large foraminal neurofibroma extending into the canal on the right and causes moderate central spinal canal stenosis.

The most recent Central Brain Tumor Registry of the United States (CBTRUS) data on primary brain and CNS tumors showed that in the age group 0 to 19 years, the most common histology were ependymal tumors followed by other neuroepithelial tumors, whereas in the 20 years and older age group, tumors of the meninges predominate (Fig. 103.3).

The most frequent extradural or epidural tumors are metastasis with the most common primary sites of metastatic tumors to the spine being, in order of frequency—lung, breast, and prostate. Other common metastatic malignancies include tumors of the gastrointestinal tract, lymphomas, melanomas, kidney, sarcomas, thyroid, multiple myeloma, and plasmocytomas.

CLINICAL MANIFESTATIONS

Extramedullary tumors cause symptoms by compressing nerve roots or spinal cord or by occluding the spinal blood vessels resulting in regional ischemia and infarct. The symptoms of intramedullary tumors result from direct interference with the intrinsic structures of the spinal cord from mass effect, edema, or development of syringomyelia. Descriptions of special syndromes follow.

EXTRAMEDULLARY TUMORS

These tumors may be either intradural or extradural (epidural). They usually involve a few spinal cord levels and cause focal signs by compressing nerve roots, particularly the dorsal roots. Extramedullary tumors may ultimately affect the spinal cord, potentially progressing to complete loss of function below the level of the lesion. The first symptoms are typically focal pain and paresthesias, arising from pressure on the dorsal nerve roots. This symptom pattern is soon followed by sensory loss, weakness, and muscular wasting in the distribution of the affected roots. Compression of the spinal cord first interrupts the functions of the pathways that lie at the periphery of the spinal cord. The early signs of cord compression usually include those referable to upper motor neurons such as spastic weakness below the lesion, overactive tendon reflexes, Babinski signs; impairment of cutaneous and proprioceptive sensation below the lesion; impaired control of the bladder and, less often, the rectum; and loss of superficial abdominal reflexes. Occasionally, symptoms may be those of lower motor neurons, such as underactive or absent reflexes with flaccid weakness, especially if the compression occurs abruptly as in spinal “shock” from trauma. If untreated, this syndrome may lead to signs and symptoms of

complete transection of spinal cord, with wasting and atrophy of muscles at the level of the root lesion and, below the lesion, paraplegia or quadriplegia. The earliest and only sign can be pain, and the absence of other signs or symptoms may give the misleading impression that the cord is not compressed.

The severity and distribution of weakness and sensory loss varies, depending in part on the location of the tumor in relation to the anterior, lateral, or posterior portion of the spinal cord. Eccentrically placed tumors may cause a typical Brown-Séquard syndrome, namely, ipsilateral signs of posterior column and pyramidal tract dysfunction, with contralateral loss of pain and temperature due to involvement of the lateral spinothalamic tract. Usually, however, because of the external compression, the Brown-Séquard features are incomplete.

Spinal vessels may be occluded by extradural tumors, particularly metastatic carcinoma, lymphoma, or abscess. When the arteries destined for the spinal cord are occluded, the resulting myelomalacia causes signs and symptoms similar to those of a severe intradural process leading to necrosis of the spinal cord. Occlusion of major components of the anterior spinal artery, however, results in segmental lower motor neuron signs at the appropriate level, bilateral loss of pain and temperature sensation, and upper motor neuron signs below the lesion with preservation of dorsal column function (proprioception, discriminative tactile function, and vibration).

Extradural (Epidural) Tumors

Extradural lesions constitute the most frequent group of spinal tumors. Metastatic spinal disease accounts for 95% of those lesions, whereas primary bone tumors account for the remaining 5% of spinal lesions. In general, benign lesions within the vertebral bones are usually asymptomatic and found incidentally, whereas malignant

P.898

vertebral tumors cause back pain, mechanical instability, pathologic fractures, and sometimes neurologic symptoms due to spinal cord compression. In addition to metastatic cancers, other malignant extradural tumors include multiple myeloma (Fig. 103.4), chordoma, Ewing sarcoma, and chondrosarcoma.

FIGURE 103.3 Distribution of spinal cord, spinal meninges, and cauda equina tumors by age group and histology. **A:** Ages 0 to 19 years ($N = 1,067$). **B:** Ages 20 years and older ($N = 14,013$). Central Brain Tumor Registry (CB-TRUS) Statistical Report: National Program of Cancer Registries (NPCR) and the National Cancer Institute, Surveillance, Epidemiology, and End Results (SEER Program, 2006-2010). (From Ostrom QT, Gittleman H, Farah P, et al. CBTRUS statistical report: primary brain and central nervous system tumors diagnosed in the United States in 2006-2010. *Neuro Oncol.* 2013;15[suppl 2]:ii1-ii56.)

The most frequent benign bone lesions are hemangioma, enostosis, osteoid osteoma-osteoblastoma, aneurismal bone cyst, eosinophilic granuloma (histiocytosis), giant cell tumor, and osteochondroma. Although considered benign, these lesions can be locally aggressive associated with pain, spinal deformity, pathologic fractures, and neural elements compression. Spinal cord metastases will be discussed in greater detail in the following section.

Epidural Spinal Cord Metastasis

Epidural spinal metastasis may be considered a disorder of the vertebral column; the neurologic consequences result from extension of tumor into the spinal canal. Although currently estimated to occur in about 5% to 10% of

all cancer patients, as the survival of patients with systemic cancers improves, the incidence of epidural spinal cord compression has increased. Most studies have demonstrated that treatment of cord compression does not prolong survival, but prompt treatment may have an important palliative role, alleviating pain and preventing neurologic disability.

Signs and symptoms of epidural spinal cord compression can be overlooked in a patient with disseminated cancer because of the presence of diffuse pain and asthenia. However, persistent neck and back pain which typically gets worse at night or at rest should prompt an investigation, not waiting for neurologic dysfunction to ensue. Limb weakness or paresthesias in the distribution of a nerve root and bowel or bladder dysfunction make this a neurooncologic emergency that commands prompt evaluation and treatment. Rarely, aside from pain, the only manifestation of cord compression may be a gait disorder, often due to sensory ataxia, without overt evidence of weakness or cutaneous sensory loss. In this situation, it may even be difficult to demonstrate impaired proprioception. The ataxia may be caused by compression of spinocerebellar pathways. The primary malignancy in more than 50% of cases of epidural cord compression is lung (Fig. 103.5) or breast cancer. Overall, more than 80% of cases arise from primary tumors in lung, breast, prostate, gastrointestinal system, melanoma, or lymphoma.

The mechanism of spread of these tumors to the epidural space includes a direct extension from a paravertebral focus through a nerve root foramen; hematogenous metastasis to the vertebrae with extension from bone into the epidural space; or retrograde spread along the venous plexus of Batson. Hematogenous spread to bone is the most common form, and computed tomography (CT) typically shows lytic

P.899

or blastic changes in the vertebral bodies in 85% of those patients. Osteoblastic changes are common with prostate carcinoma and are occasionally seen with breast cancer, whereas osteolytic changes are typically seen in multiple myeloma. CT and magnetic resonance imaging (MRI) are sensitive techniques for the detection of spinal osseous metastases. Importantly, involvement of paraspinal lymph nodes with spread to the spinal canal is common with lymphoma. In this situation, the vertebral bone may be normal on imaging studies and use of screening spinal x-rays will be misleading.

B

FIGURE 103.4 Epidural spinal metastases. **A:** T2-weighted sagittal MRI demonstrates destruction and mild collapse of the T12 vertebra (*arrow*) in a patient with multiple myeloma. Note the hyperintense marrow signal at multiple levels in the spine indicating additional metastatic deposits. **B:** Axial T1 with contrast MRI at T12 level shows moderate canal stenosis (*arrow*).

FIGURE 103.5 Epidural spinal metastases. Axial T1-weighted contrast-enhanced sequence at T5 demonstrates epidural extension of metastatic lung non-small cell carcinoma with bone destruction at this level.

Intradural, Extramedullary Tumors

Neurofibromas, schwannomas, and meningiomas are the most commonly occurring primary intradural tumors of the spinal cord. On MRI with gadolinium, the lesions enhance brightly. Meningiomas may be identified by the presence of a dural tail, where the tumor attaches to the dura (Figs. 103.6 and 103.7). Symptoms may occur slowly and some may be asymptomatic despite large size, presumably because of slow growth allowing the spinal cord an opportunity to adapt to the mass effect.

Leptomeningeal metastasis and drop metastases of intracranial tumors also involve the intradural space, but typically, they appear as small nodules attached to the surface of the cord or cauda equina nerve roots (Fig. 103.8), although many (approximately 70%) are not visible on imaging of brain or spine and are detected only by cerebrospinal fluid (CSF) analyses.

INTRAMEDULLARY TUMORS

Primary Intramedullary Tumors

The most common intramedullary tumors are ependymomas and astrocytomas. A diagnosis of von Hippel-Lindau syndrome, an autosomal dominant disorder, should be considered when a spinal hemangioblastoma is present

(most commonly involving the thoracic cord) because this association occurs in one-third of the cases. However, rarely, hemangioblastoma can also occur in the intradural extramedullary and extradural locations. Although a single lesion is the most common presentation, multiple lesions occur in one-fifth of cases.

FIGURE 103.6 Thoracic meningioma. **A:** T1-weighted contrast-enhanced sagittal MRI demonstrates a large intradural mass at T6-T7 with dural tail sign. **B:** Axial MRI demonstrates the large size of this lesion, probably a meningioma. Despite marked spinal cord compression, the patient had no abnormality on neurologic examination and only complained of left-sided thoracic pain.

Primary intramedullary tumors usually extend over many segments, causing dilatation of the spinal cord and sometimes causing syringomyelia, which can involve the whole length of the spinal cord. For this reason, the signs and symptoms of intramedullary tumors are more variable than those of extramedullary tumors (Figs. 103.9 and 103.10).

If the tumor is restricted to one or two segments, the clinical presentation can be similar to that of an extramedullary tumor. Pain may be an early manifestation if the dorsal root entry zone is affected. Compression

cord may cause loss of pain and temperature only in the affected segments. As the tumor spreads peripherally, the spinothalamic tracts may be affected; in the thoracic and cervical areas, pain and temperature fibers from the sacral area lie near the external surface of the cord and may be spared (e.g., sacral sparing). Involvement of the central gray matter destroys the anterior horn cells, with local weakness and atrophy resulting. However, pyramidal fibers may be spared. The clinical picture may be identical to that of syringomyelia with a “suspended” sensory level.

FIGURE 103.7 Meningothelial meningioma of the spinal cord. The classic variant of meningioma is composed of lobules of meningeothelial cells separated by fine collagen fibers. The intercellular borders are ill-defined characteristic of a syncytial pattern. Nuclear clearing and whorl formation are frequent. Calcifications (psammoma bodies) might be present. (Courtesy of Dr. Adriana Olar, Department of Pathology, MD Anderson Cancer Center.)

FIGURE 103.8 Leptomeningeal disease. Sagittal T1-weighted contrast-enhanced MRI shows tumor deposits along the surface of the distal thoracic cord and the nerve roots of the cauda equine in a patient with breast carcinoma.

FIGURE 103.9 Intramedullary glioblastoma. **A:** Sagittal T1-weighted contrast-enhanced MRI demonstrates T1-T4 intramedullary lesion with peripheral enhancement and hypointense center that expands the cord. **B:** T1-weighted MRI shows a contrast-enhancing intramedullary tumor at the T1-T2 level. At operation, a spinal glioblastoma with necrotic center was removed.

Intramedullary Metastases

Although rare, the most common tumors that cause intramedullary metastases are lung cancer or breast cancer. Intramedullary metastases typically occur with advanced metastatic disease, and at autopsy, 61% of patients with intramedullary metastases are found to have had multiple sites of cerebral or spinal lesions. Contrast-enhanced MRI is the preferred method for detection of intramedullary metastases. Reversal or stabilization of neurologic signs depends on early diagnosis, but survival is poor; 80% of patients in one series died within 3 months of diagnosis, likely a manifestation of the extent of systemic disease at the time of the spinal cord involvement.

FIGURE 103.10 Intramedullary ependymoma. **A:** Sagittal T1-weighted MRI shows an intramedullary enhancing mass at C5-T1. **B:** Axial T1-weighted image with contrast shows expansion and significant displacement of the cord by the tumor at C6 (*arrow*).

REGIONAL SYNDROMES

Foramen Magnum Tumors

Tumors in the region of the foramen magnum may extend up into the posterior fossa or down into the cervical region. The syndrome from tumor in the foramen magnum typically shows signs and symptoms of dysfunction of the lower cranial nerves, primarily those pertaining to the eleventh, twelfth, and rarely, the ninth and tenth. The most characteristic foramen magnum tumor, the

P.902

ventrolateral meningioma, compresses the spinal cord at the cervicomedullary junction to cause long tract signs: loss of position, vibratory, and light touch perception, with more prominent symptoms in the arms than the legs. Upper motor neuron signs are seen in all four limbs. There may be cutaneous sensory loss in distribution of C2 or the occiput, with posterior cranial headaches and high cervical pain. Progression of sensory and motor symptoms may involve the limbs asymmetrically.

Cervical Tumors

Tumors of the upper cervical segments cause pain or paresthesias in the occipital or cervical region, with stiff neck, weakness, and wasting of neck muscles. Below the lesion, there may be a spastic tetraplegia or hemiplegia. Cutaneous sensation may be affected below the lesion, and the descending trigeminal nucleus may be involved. Characteristic findings make it possible to localize the upper level of spinal tumors in the middle and lower cervical segments or T1 as shown in [Table 103.1](#).

Other signs of cervical tumors include nystagmus, which is attributed to involvement of the descending portion of the median longitudinal fasciculus. A Horner syndrome may be found with intramedullary lesions in any portion of the cervical cord if the descending sympathetic pathways are affected.

Thoracic Tumors

Clinical localization of tumors in the thoracic region of the cord is best made by the sensory level. It is not possible to determine the location of a lesion in the upper half of the thoracic cord by testing the strength of intercostal muscles. Lesions that affect the abdominal muscles below T10 but spare the upper ones may be localized by the Beevor sign (i.e., the umbilicus moves upward when the patient, lying in the supine position, attempts to flex the neck against resistance). Abdominal skin reflexes are absent below the lesion.

Lumbar Tumors

Lesions in the lumbar region may be localized by the level of the sensory loss and motor weakness typically following a dermatome or myotome distribution. Tumors that compress only the L1 and L2 nerve roots cause loss of the cremasteric reflexes and weakness in the iliopsoas muscle. The abdominal reflexes are preserved, as are the knee and ankle jerks. Lesions affecting the L3 and L4 nerve roots may present with weakness in the quadriceps muscle, loss of patellar reflex, and pain in the anteromedial portion of the lower extremity.

TABLE 103.1 Localization in the Cervical and T1 Region Based on Symptomatology

C4 Paralysis of the diaphragm

C5 Atrophy and paralysis of the deltoid, biceps, supinator longus, rhomboid, and spinati muscles. The upper arms hang limp at the side. The sensory level extends to the outer surface of the arm. The biceps and supinator reflexes are lost.

C6	Paralysis of triceps and wrist extensors. The forearm is held semiflexed and there is a partial wristdrop. The triceps reflex is lost. Sensory impairment extends to a line running down the middle of the arm slightly to the radial side.
C7	Paralysis of the flexors of the wrist and of the flexors and extensors of the fingers. Efforts to close the hands result in extension of the wrist and slight flexion of the fingers (e.g., preacher's hand). The sensory level is similar to that of the sixth cervical segment but slightly more to the ulnar side of the arm.
C8	Atrophy and paralysis of the small muscles of the hand with resulting clawhand (main-en-griffe). Horner syndrome, unilateral or bilateral, results from lesions at this level and is characterized by the triad of ptosis, small pupil (i.e., miosis), and loss of sweating on the face. Sensory loss extends to the inner aspect of the arm and involves the fourth and fifth fingers and the ulnar aspect of the middle finger.
T1	Lesions rarely cause motor symptoms because the T1 nerve root normally provides little functional innervation of the small hand muscles.

The typical involvement of the L5 nerve root causes weakness of eversion, inversion, and dorsiflexion of the foot and hallux. Decreased sensation over the anterolateral calf and dorsum of the foot, with pain radiating down the leg to the hallux which can be exacerbated by the straight leg testing (Lasègue sign) is also characteristic. The presence of weakness of foot inversion in an L5 radiculopathy is an important distinguishing factor from a peroneal palsy where foot inversion strength is typically normal.

A tumor affecting the S1 root may present with weakness of the gastrocnemius and hamstring, with absent ankle jerk and decreased sensation over the lateral calf and lateral foot including the sole.

The involvement of multiple nerve roots can occur at any lumbar level and it is usually described as cauda equina syndrome, which typically presents as flaccid paralysis of the legs with loss of knee and ankle reflexes associated with urinary retention and bowel incontinence. If both the spinal cord and cauda equina are asymmetrically affected, there may be spastic paralysis of one leg with an overactive ankle reflex on that side and flaccid paralysis with loss of reflexes on the other side.

Finally, tumors affecting the sacrum at the level of S2-S4 can cause perineal or saddle anesthesia and loss of bowel and bladder control without motor deficits observable in the lower extremities because the motor roots (L1-S1) are not affected.

Tumors of the Conus and Cauda Equina

Although a conus lesion is intramedullary involving the parenchyma of the terminal spinal cord, a cauda equina lesion is extramedullary affecting multiple exiting nerve roots. Distinguishing between the two entities is not always possible as many of the clinical features are similar. Moreover, in neoplastic processes, there is frequent involvement of both.

The first symptom of a tumor that involves the conus or cauda equina is pain in the back, rectal area, or both lower legs, often leading to the preliminary diagnosis of sciatica. Loss of bladder function and impotence are seen early especially with conus involvement. As the tumor grows, there may be flaccid paralysis of the legs, with atrophy of leg muscles, and foot drop. Fasciculation may be evident. Sensory loss may affect the perianal or saddle area and the remaining sacral and lumbar dermatomes. This loss may

be slight or so severe that a trophic ulcer develops over the lumbosacral region, buttocks, hips, or heels.

DIAGNOSIS

Tumors compressing the spinal cord or the cauda equina typically cause radicular pain. The slow evolution of signs of an incomplete transverse lesion of the cord or signs of compression of the conus medullaris or cauda equina usually bring patients to medical attention. In addition to cord compression, extradural tumors may obstruct the blood supply to the cord; if this occurs, the symptoms are often of sudden onset. In a patient with neurofibromatosis 1 (von Recklinghausen disease), the skin lesions may focus the differential diagnosis to neurofibroma, glioma, or ependymoma.

The diagnosis of an intraspinal tumor may be established before the operative procedure, with visualization by CT, MRI, or myelography. Vascular malformations or vascular tumors may be best visualized by spinal angiography. CSF examination with cytologic studies may also be helpful if positive, but negative cytology does not exclude a neoplastic process.

RADIOGRAPHY

CT and MRI have replaced standard radiographic studies (plain x-rays). However, when conventional x-ray imaging is performed, the abnormalities (listed in the following text) are seen in about 15% of spinal neoplasms:

1. Localized destruction of the vertebrae is manifest by scalloping of the posterior margin of the vertebral body or lucency of a portion of the vertebra or pedicle.
2. Changes occur in the contour or separation of the pedicles (e.g., the interpediculate distance may be measured and compared with normal values). Localized enlargement of foramina is seen with dumbbell neurofibromas. Localized enlargement of the spinal canal is usually diagnostic of an intraspinal tumor but enlargement of many segments may be a developmental anomaly.
3. Paraspinal tissues are distorted by tumors, frequently neurofibromas that extend through the intervertebral foramen or by tumors that originate in the paraspinal structures.
4. Proliferation of bone, which is rare except in osteomas and sarcomas, is also occasionally seen in hemangiomas of bone and meninges.
5. Calcium deposits are occasionally present in meningiomas or congenital tumors.

MRI has largely supplanted myelography for imaging both intramedullary and extramedullary processes. MRI is the most useful test for evaluating spinal tumors. The vertebral bodies, spinal canal, and spinal cord, itself, are clearly delineated. Most spinal neoplasms display contrast enhancement. When a metastatic tumor is suspected or demonstrated, it is advisable to image the entire cord because more than one lesion may be present.

CT is the modality of choice for imaging of the bony structures but is more limited than MRI in demonstrating the soft tissues. Injection of contrast in the lumbar cistern is used for a CT myelogram, which is an alternative in cases of contraindication for MRI (i.e., pacemakers or ferromagnetic implants). A CT myelogram may demonstrate the soft-tissue changes of intraspinal tumors and is particularly useful in the diagnosis of cystic lesions in the subarachnoid space, where the contrast material may accumulate around and create a negative contrast of the cyst. It is also useful to evaluate if there is communication between the subarachnoid space and intradural cystic lesions (i.e., arachnoid cysts, syringomyelia, or cystic tumors).

CEREBROSPINAL FLUID

When there is a complete subarachnoid block, the CSF is xanthochromic as a result of the high protein

content (Froin's syndrome). It may be only slightly yellow or even colorless if the subarachnoid block is incomplete. The cell count is usually normal, but a slight pleocytosis is found in about 30% of patients. Cell counts of between 25 and 100 per cubic millimeter are found in about 15% of patients. The protein content is increased in more than 95%. Values of over 100 mg/dL are present in 60% of the patients and values of over 1,000 mg/dL are present in 5% and may, in rare cases, lead to communicating hydrocephalus. The glucose content is normal unless there is meningeal spread. Cytologic evaluation of the CSF is useful when malignant tumors are suspected, although as mentioned previously, negative cytology does not exclude leptomeningeal cancer. More than one CSF sampling procedure may be required (some advocate up to five), although the remainder of the CSF profile (cells, protein, tumor markers) is usually abnormal in the setting of leptomeningeal metastases, notwithstanding the absence of malignant cells on cytologic analysis.

DIFFERENTIAL DIAGNOSIS

Spinal tumors must be differentiated from other disorders of the spinal cord, including transverse myelitis, multiple sclerosis (MS), syringomyelia, combined system disease, syphilis, amyotrophic lateral sclerosis, anomalies of the cervical spine and base of the skull, spondylosis, adhesive arachnoiditis, radiculitis of the cauda equina, hypertrophic arthritis, ruptured intervertebral disks, diastematomyelia, and vascular anomalies.

MS, with a complete or incomplete transverse lesion of the cord, may usually be differentiated from spinal cord tumors by the remitting course, signs and symptoms of more than one lesion, evoked potential studies, cranial MRI, and the presence of CSF oligoclonal bands. Acute transverse myelitis may occasionally enlarge the cord to simulate an intramedullary tumor.

Determining the differential diagnosis between spontaneous syringomyelia and intramedullary tumor-related syrinx is complicated because intramedullary cysts mimicking a syrinx are commonly associated with these tumors. Extradural tumors in the cervical region may give rise to localized pain and muscular atrophy in conjunction with a Brown-Séquard syndrome, producing a clinical picture similar to that of syringomyelia. The differential diagnosis may often be made by contrast-enhanced MRI that reveals a tumor nodule.

The combination of atrophy of hand muscles and spastic weakness in the legs in amyotrophic lateral sclerosis may suggest the diagnosis of a cervical cord tumor. Tumor is excluded by the lack of paresthesias, and normal sensation on examination, and by the presence of fasciculation or atrophy in leg muscles or tongue, and by imaging.

Cervical spondylosis may cause stenosis of the spinal canal and cause symptoms and signs of root irritation and/or compression of the spinal cord. Degenerative changes are extremely common and the modality of choice for diagnosis is MRI. Clinical correlation with image findings is critical for the treatment decision because most changes on imaging studies are incidental findings or do not have a clinical correlation.

Anomalies in the cervical region or at the base of the skull, such as platybasia or Klippel-Feil syndrome, are diagnosed by CT or MRI. Occasionally, arachnoiditis may interfere with the circulation

P.904

of CSF causing signs and symptoms of a transverse lesion. The CSF protein content is usually elevated. Diagnosis is made by complete or partial arrest of the contrast column on myelography or by fragmentation of the material at the site of the lesion. Slowed CSF flow will be seen using magnetic resonance flow techniques.

Epidural lipomatosis is a complication of prolonged steroid therapy but sometimes occurs without apparent cause; the fat accumulations act as an extradural mass lesion, causing low back pain and

compression of the spinal cord or cauda equina.

TREATMENT

INTRADURAL EXTRAMEDULLARY TUMORS

Once the diagnosis of an intraspinal tumor has been made, the treatment is surgical removal of the tumor whenever possible. When the neurologic disorder is severe or rapidly progressing, emergency surgery is indicated. The best results are obtained when the signs and symptoms are due solely to compression by a benign encapsulated extramedullary tumor. Some of these tumors, especially meningiomas, may lie anterior to the spinal cord and a complete resection of the involved dura is not possible or carries a significant risk of morbidity. In these cases, a gross total resection of the mass with cauterization of the dural insertion of tumor is performed. In cases of recurrence, another surgical resection may be necessary. The functional outcome of patients harboring extramedullary tumors is predicated by the severity of the preoperative neurologic disability. Overall, surgery aiming at a gross total resection is the modality of choice for the intradural extramedullary tumors (Video 103.1) and ideally should be performed before installment of neurologic dysfunction because when this occurs, it might represent evidence of irreversible damage to the spinal cord due to compression or ischemia. Radiotherapy is typically not indicated for benign intradural extramedullary tumors. In fact, most of these lesions are low-grade tumors with no tissue separation between the lesion and the spinal cord. This increases the risk of radiation-induced myelopathy, especially in cases where preexisting damage is suspected (i.e., evidence of myelomalacia or ischemia due to long-dated compression). In cases of recurrence, a second surgical procedure is usually considered a better alternative than radiation, which in general is reserved for cases where a high surgical comorbidity precludes surgery.

INTRAMEDULLARY TUMORS

In almost all World Health Organization (WHO) grade I (myxopapillary) and WHO grade II ependymomas, complete microsurgical resection of the tumor is the treatment of choice (Video 103.2). There is no consensus on the use of radiotherapy for WHO grade I and WHO grade II spinal cord tumors and overall radiation is reserved for cases with incomplete resection, with bulky residual disease or symptomatic tumor recurrence when the patient is considered not to be a good surgical candidate. Radiation treatment is indicated after initial surgery for all patients with WHO grade III ependymoma. Astrocytomas are typically infiltrating and often lack a plane of cleavage. In this case, an attempt at complete resection or extensive debulking is associated with significant risk of neurologic decline. Although radiotherapy should be given for spinal cord astrocytomas, the results particularly for WHO grade III and IV tumors are discouraging. For other less common intramedullary tumors, such as hemangioblastomas, teratomas, or dermoids, if complete removal has been achieved, typically, no further treatment is recommended aside from surveillance.

Intramedullary tumors are typically approached with multilevel laminectomies, which create disruption in the posterior tension band of the ligaments stabilizing the spine. As a result, spinal deformities that may have been present preoperatively may worsen and other deformities may develop, eventually requiring surgical correction with spinal instrumentation and fusion. If allowed to progress, these deformities may create additional functional impairment, especially in skeletally immature patients. Some surgeons have advocated replacement of the lamina after definitive surgery, rather than the standard laminectomy. However, the occurrence of postoperative kyphosis is common and the natural history of this deformity is uncertain. The additional use of radiotherapy for intraspinal tumors in younger patients may affect the growth of the spine and in adults may increase the muscle atrophy and degenerative changes leading to the development or

worsening of preexisting deformities of the spine.

EPIDURAL DISEASE FROM METASTATIC CANCER

Treatment of epidural metastasis is palliative in nearly all patients. Prognostic scoring systems based on patient age, performance status, extent of spinal and extraspinal disease, tumor histology, and availability of systemic treatments are useful to predict the expected survival of patients harboring spinal metastasis.

However, management has to be individualized in order to achieve the best balance between morbidity and palliation. A randomized trial [Level 1]¹ has demonstrated that surgery for spinal decompression and spinal stabilization followed by radiation is superior to conventional radiation alone in maintenance and recovery of ambulation, duration of ambulation, and maintenance of sphincter continence. Loss of bowel or bladder function is an ominous prognostic sign and is usually irreversible. Among patients diagnosed and treated early, 94% remain ambulatory until they die.

Conventional radiation therapy is the mainstay of treatment for most patients with spinal metastases, even those who had surgical decompression, with the typical treatment plan comprising 3,000 cGy divided in 10 fractions of 300 cGy each. More recently, high-dose hypofractionated radiotherapy using image-guided techniques (spinal stereotactic radiotherapy) has emerged as an effective modality overcoming the relative radioresistance of some tumors to conventional radiation. However, in cases of symptomatic or high-degree spinal cord compression, a judicious combination of surgery to separate the tumor from the spinal cord prior to stereotactic radiation has been shown to achieve a high degree of local control with relative low morbidity.

In general, surgery provides spinal stabilization and spinal cord and nerve roots decompression, whereas radiation therapy provides local tumor control. Usually, radiation treatment is well tolerated even by patients who are seriously ill, and in most cases, palliation is often achieved with relief of pain. In general, indications for surgery include spinal cord compression due to radioresistant tumors (renal cell carcinoma, sarcomas, melanomas, etc.), spinal instability, unknown tissue diagnosis, or rapid progression of neurologic dysfunction. Judicious use of surgery is critical to achieve a meaningful clinical improvement in patients with advanced systemic disease because the anticipated recovery time has to be weighed against the expected duration of survival.

OUTCOME

Epidural spinal cord compression is an emergency because without treatment, irreversible loss of neurologic function will lead to significant morbidity and mortality. It is estimated that patients

P.905

who were ambulatory preoperatively were 2.3 times more likely to be able to walk postoperatively.

Treatment should be initiated early, as neurologic status at presentation is predictive of functional outcome. Critical to this is the education of patients, patient families, and health care providers to recognize warning signs of cord compression early on. Recent studies do support the notion that patients with cord compression are presenting earlier. In fact, although a study published in 1998 showed that only 33% were ambulatory and 53% were catheter free at the time of initiation of therapy, in another study published in 2010, 62% of patients were ambulatory at presentation. It has also been shown that nonambulatory patients if treated surgically require more extensive surgery with consequent higher complication rates and morbidity. It is therefore of paramount importance that a careful patient selection process is pursued, always taking into consideration the patient's overall prognosis and presumed benefits balanced against the treatment-related morbidity.

For intramedullary tumors, the prognosis and outcome from surgery is strongly related to tumor histology

and the occurrence of a plane of surgical dissection between the lesion and the surrounding spinal cord and nerve roots. When a plane of cleavage exists, such as in ependymomas, a complete surgical resection is potentially curative. With more diffusely infiltrating tumors such as spinal cord astrocytic tumors, the goal of surgery in most cases is diagnostic and especially in high-grade tumors, treatment is palliative with a dismal outcome irrespective of treatment.

Overall, intradural extramedullary tumors have slow progression and usually, treatment is recommended when symptomatic or when there is a significant degree of spinal cord compression. With improved imaging, neurophysiologic monitoring, and sound microsurgical techniques, the goals of treatment for these lesions is gross total resection with curative intent. Good functional outcomes are generally observed and overall recurrence rates range between 0% and 13%.

This is in contrast to the prognosis of patients with leptomeningeal metastasis from systemic cancer where the prognosis, irrespective of the cancer of origin, is typically around 2 to 3 months, although there are exceptions, most often patients with lymphoma and occasionally breast cancer.

Paraneoplastic Syndromes

Lauren R. Schaff

Lewis P. Rowland

INTRODUCTION

Neurologic paraneoplastic disorders are caused by indirect damage to central or peripheral nervous system structures from a systemic cancer, resulting in a wide spectrum of neurologic signs and symptoms. The cause is thought to be immune-mediated as opposed to the direct effects of tumor invasion, metastases, toxicity from treatment, malnutrition, or coincidental infection.

EPIDEMIOLOGY

Paraneoplastic syndromes are quite rare, affecting less than 0.1% of all patients with malignancy. However, other studies suggest up to 7% of patients with malignancy are afflicted. They are associated with a broad range of symptoms that are typically subacute in onset, evolving over weeks to months. Most patients develop neurologic symptoms before a cancer is identified. After onset of symptoms, the cancer may still be small enough to elude detection and may not be identified for many months or years, sometimes discovered only postmortem.

Any cancer may be associated with a paraneoplastic syndrome but some syndromes are associated with a specific cancer or a particular group of neoplasms. Small cell lung cancer (SCLC) is one of the most common tumors associated with paraneoplastic syndromes. Other tumors that are associated with these syndromes are those that express neuroendocrine proteins, those that affect organs with immunoregulatory functions, or those derived from cells that produce immunoglobulins.

PATHOBIOLOGY

The pathogenesis of paraneoplastic syndromes is thought to be immune-mediated. It is generally accepted that malignancies causing these syndromes express proteins normally restricted to the nervous system. The host mounts an immune attack against those antigens in the tumor but the response is directed against central or peripheral neural antigens, resulting in neurologic deficits. In many paraneoplastic syndromes, the detection of characteristic antibodies has served as a useful diagnostic tool but the pathogenesis of these antibodies is not clearly understood.

In general, antibodies associated with paraneoplastic syndromes are classified based on location of their targeted antigen, either intracellular or on the neuronal surface. This distinction has further implications on the understanding of the pathogenic role of the antibody and the diagnostic value of its detection. Antibodies targeted against intracellular antigens, or onconeural antibodies, may predict with high frequency the presence of an underlying tumor and may be used to establish a neurologic symptom as paraneoplastic. The pathogenic role of these antibodies is not clearly understood and they may be present (often at lower levels) in a patient with an underlying cancer but without neurologic symptoms. There is evidence to suggest that the mechanism for neuronal damage is sometimes mediated by cytotoxic T cells, and these syndromes are typically poorly responsive to immunomodulatory therapy. Conversely, antibodies against surface antigens are thought to be pathogenic—interfering with neuronal cell signaling or synaptic transmission. These antibodies are often associated with well-characterized central nervous system (CNS) syndromes, although their presence does not necessarily denote a malignancy. Some syndromes are responsive to immunomodulatory therapy, often with a correlation between antibody titers and outcome. Notably, there are many cases where a neurologic syndrome

exists that is suspected to be paraneoplastic without the detection of any associated antibodies.

CLINICAL MANIFESTATIONS

Paraneoplastic syndromes encompass a broad range of clinical manifestations. Onset is typically acute (as in paraneoplastic cerebellar degeneration) or subacute. There are some symptoms that are almost always associated with a malignancy (Lambert-Eaton myasthenic syndrome, cerebellar degeneration, and opsoclonus-myoclonus as examples) and others that may occur without malignancy (encephalitides, sensory neuropathies). Discussed in the following text are some of the most well-recognized symptoms of paraneoplastic syndromes (Table 104.1).

ENCEPHALITIS/MYELITIS

Encephalitis and *myelitis* are terms used to describe inflammation of the CNS, ranging from the cerebrum to the spinal cord. When limbic structures are affected, there is a characteristic set of manifestations referred to as *limbic encephalitis*. Brain stem encephalitis may also occur resulting in bulbar symptoms. Myelitis may cause focal neurologic deficits localizable to the spinal cord. When more than one area is affected in the setting of likely malignancy, this is referred to as *paraneoplastic encephalomyelitis*.

Paraneoplastic Encephalomyelitis

Paraneoplastic encephalomyelitis (PEM) is a multifocal inflammatory disorder that can result in a variety of syndromes, which can occur in isolation or in various combinations. The cause is disseminated neuronal loss and inflammatory lesions of the nervous system. Common features are limbic encephalitis, myelitis, cerebellar ataxia, sensory neuropathies, and autonomic failure. Symptoms can be associated with almost any cancer but the majority are in patients with SCLC. The most common antibodies are anti-Hu, anti-CV2/CRMP5, and anti-amphiphysin. The syndrome is poorly responsive to treatment although can stabilize or sometimes improve with tumor therapy.

Limbic Encephalitis

Limbic encephalitis manifests as rapidly progressive personality and mood changes and within weeks is dominated by delirium and dementia with severe memory loss, often accompanied by seizures. The psychiatric symptoms may be confused with a primary

P.908

psychiatric syndrome. Symptoms may be part of PEM and can be associated with brain stem findings or sensory neuropathy. Cerebrospinal fluid (CSF) often reveals pleocytosis with elevated protein. Limbic encephalitis is one of the only paraneoplastic diseases in which imaging may be useful in establishing the diagnosis because increased T2 signal or mild enhancement of the medial temporal lobes on magnetic resonance imaging (MRI) is often seen. Tissue evaluation frequently reveals neuronal loss, perivascular infiltration by leukocytes, and microglial proliferation.

TABLE 104.1 Paraneoplastic Syndromes, Associated Cancers, and Antibodies

Syndrome	Frequent Associated Tumors	Frequent Associated Antibodies
PEM	SCLC, thymoma, breast	Anti-Hu (ANNA-1), anti-CV2/CRMP5, anti-amphiphysin

Limbic encephalitis	SCLC, testicular cancer, teratoma, thymoma, breast	Anti-Hu (ANNA-1), anti-CV2/CRMP5, anti-amphiphysin, anti-VGKC , anti-Ma2 (Ta), anti-NMDAR , anti-AMPA , anti-GABABR
Paraneoplastic cerebellar degeneration	Ovarian, breast, SCLC, Hodgkin lymphoma	Anti-Yo (PCA-1), anti-Ri (ANNA-2), anti-Hu (ANNA-1), anti-CV2/CRMP5, anti-Tr
Sensory neuronopathy	SCLC, breast	Anti-Hu (ANNA-1), anti-CV2/CRMP5
Opsoclonus-myoclonus	Neuroblastoma, SCLC, breast cancer, ovarian cancer	Anti-Ri (ANNA-2)
Retinopathies	SCLC, melanoma	Antirecoverin, antiretinal bipolar cell, anti-CV2/CRMP5
LEMS	Thymoma, SCLC	Anti-VGCC , anti-SOX-1
Stiff person syndrome	SCLC, breast cancer, thymoma, Hodgkin lymphoma, adenocarcinoma	Anti-GAD, anti-amphiphysin, anti-Ri (ANNA-2)

Bold antibodies are directed against cell surface antigens.

PEM, paraneoplastic encephalomyelitis; SCLC, small cell lung cancer; LEMS, Lambert-Eaton myasthenic syndrome.

The most common associated cancers are SCLC (associated with anti-Hu), testicular germ cell tumors (associated with anti-Ma2), and teratomas (anti-N-methyl-D-aspartate [NMDA] receptor). Antibodies in limbic encephalitis may be targeted against intracellular antigens (anti-Hu, anti-Ma2, anti-CV2/CRMP5), in which case immune response is mediated by cytotoxic T-cell mechanisms and response to treatment is often poor. If an associated malignancy is discovered, the most effective treatment tends to be cancer-directed therapy. Encephalitides associated with antibodies against cell surface antigens tend to be reversible and responsive to immunomodulatory therapy (anti-NMDA receptor, anti-voltage-gated potassium channel [VGKC]). In some cases, there is no associated malignancy and these cases are often particularly responsive to treatment.

Brain stem Encephalitis

Symptoms of brain stem encephalitis are usually part of a more widespread encephalomyelitis in the anti-Hu syndrome, but bulbar symptoms with cranial nerve dysfunction may be the first manifestation. It can also occur as an isolated syndrome in lung and other cancers associated with the anti-Ma antibody. Common findings are oculomotor disorders including nystagmus and supranuclear vertical gaze palsy, as well as hearing loss, dysarthria, dysphagia, and abnormal respiration. Movement disorders may be prominent.

Myelitis

Spinal cord symptoms evolve over days or weeks with clinical evidence of a focal lesion. Symptoms may be monophasic or relapsing and are often associated with other neurologic symptoms of encephalomyelitis. Some patients have severe isolated myelopathy with T2 changes on MRI and faint enhancement. Anti-amphiphysin and anti-CV2/CRMP5 antibodies have been described, typically in the setting of SCLC or breast cancer. CSF may show pleocytosis with high protein content and normal sugar; oligoclonal bands may be present.

PARANEOPLASTIC CEREBELLAR DEGENERATION

Paraneoplastic cerebellar degeneration (PCD) is almost always associated with malignancy. Symptoms manifest as a pancerebellar syndrome with ataxia of gait and limbs, dysarthria, nystagmus, and oscillopsia. PCD can be the presenting symptom of PEM and as such can be associated with bulbar symptoms, corticospinal tract signs, dementia, and peripheral neuropathy. Differential diagnosis may include viral encephalitis, multiple sclerosis, Creutzfeldt-Jakob disease, alcoholic cerebellar degeneration, and hereditary spinocerebellar atrophy. CSF may reveal a modest pleocytosis with high protein content with elevated immunoglobulin G (IgG) and oligoclonal bands. Computer tomography (CT) and MRI are usually normal but occasionally, diffuse hyperintensity of the cerebellum on T2-weighted images or contrast enhancement of the folia can be seen. Over time, diffuse cerebellar atrophy can occur. On autopsy, there is a loss of Purkinje cells and the dentate nucleus may also be affected. PCD is most often associated with anti-Yo antibodies in gynecologic cancers, anti-Hu antibodies with SCLC, anti-Tr with Hodgkin disease, or anti-Ri with breast cancers. Cases in which cerebellar symptoms progress to PEM are typically associated with anti-Hu or anti-CV2/CRMP5 antibodies in SCLC. Often, there may be no antibody detected. Prognosis of PCD is poor and most patients do not improve due to early and irreversible neuronal destruction. If a patient is diagnosed while symptoms are still progressing, immunosuppression may stabilize the course. Onset is typically rapid.

SENSORY NEURONOPATHY

Sensory neuronopathy is generally subacute in onset and results in the progressive loss of all sensory modalities as a result of inflammatory or autoimmune-mediated destruction of the dorsal root ganglia. The first symptom is often a painful neuropathy that

P.909

frequently progresses to result in a severe sensory ataxia. Motor function is spared or minimally affected. The pattern is often asymmetric and may affect cranial nerves, unlike more common peripheral neuropathies. Symptoms may be associated with a number of cancers but SCLC with anti-Hu antibodies in the context of PEM is the most common. Patients may experience partial improvement with steroids. Tumors responsive to treatment have been associated with improvement in symptoms.

OPSOCLONUS-MYOCLONUS

The term *opsoclonus-myoclonus* implies chaotic motion of the eyes—arrhythmic, irregular in direction, or tempo, with associated myoclonic muscle movements. The disordered physiology is not clear. In children, findings are associated with neuroblastoma and may portend a better oncologic prognosis. Symptoms respond to treatment of the tumor and directed immunotherapy although long term; these children are noted to struggle with speech and motor delays, cognitive deficits, and behavioral problems. In adults, symptoms range across a broad spectrum from opsoclonus with mild truncal ataxia to severe symptoms of opsoclonus, myoclonus, and ataxia that can progress to encephalopathy and death. Opsoclonus may be associated with tumors of the breast or gynecologic malignancies with anti-Ri antibodies although in many cases, antibodies are not well classified. In both children and adults, opsoclonus-myoclonus is due to a paraneoplastic process in only a minority of patients and other etiologies should be considered. Paraneoplastic opsoclonus-myoclonus is among the paraneoplastic syndromes that are most responsive to treatment.

VISUAL SYMPTOMS

The most common causes of visual symptoms in patients with malignancy are metastatic infiltration of the optic nerves or neurotoxicity from chemotherapy and radiation. Paraneoplastic causes include cancer-associated retinopathy (CAR) and melanoma-associated retinopathy (MAR). CAR can occur with any solid tumor but is most commonly associated with SCLC. More than 20 antibodies have been described but the most common is an antibody to recoverin (a calcium-binding photoreceptor protein). MAR is associated with antibodies that react with the bipolar cells of the retina. Onset of symptoms typically occurs months to years after diagnosis. Diagnosis is made with an electroretinogram and supported by antibody studies. CAR and MAR are difficult to treat and have poor response to immunotherapy although there are case reports of improvement with intravenous immunoglobulin (IVIG), plasmapheresis, and tumor treatment.

Paraneoplastic optic neuropathy causes subacute, painless, and bilateral visual loss. Examination may reveal papilledema or optic atrophy. Symptoms may occur in the context of PEM. Bilateral diffuse uveal melanocytic proliferation (BDUMP) is the result of diffuse proliferation of melanocytes in the uveal tract and causes bilateral vision loss. Symptoms typically precede a cancer diagnosis and have been described in carcinomas of the reproductive tract (in women) or of the lung and pancreas (in men). Corticosteroids are typically ineffective, and radiation may worsen symptoms.

MOTOR NEURON DISEASE

When cancer and motor neuron disease occur together, it is usually a coincidence of two common illnesses in the elderly. Epidemiologic studies have not definitively shown increased incidence of cancer in amyotrophic lateral sclerosis (ALS) patients. However, some patients have neurologic symptoms that disappear with treatment of the tumor. Also, there have been more than 60 reports of patients with motor neuron and lymphoproliferative disease. Lower motor neuron signs (amyotrophy) including fasciculations are also sometimes seen in combination with PEM and anti-Hu antibodies. A purely upper motor neuron syndrome (primary lateral sclerosis) has been reported in women with breast cancer, but several of those patients later developed lower motor neuron signs and the disorder became typical ALS.

SENSORIMOTOR PERIPHERAL NEUROPATHY

Sensorimotor peripheral neuropathy with or without slow conduction velocity is common after age 50 years. In cancer patients in particular, treatment with neurotoxic chemotherapies can result in distal and symmetric symptoms. Paraneoplastic syndromes rarely can result in a similar presentation. Prominent features may include stocking-glove paresthesias and sensory loss, distal limb weakness, or both. Autonomic failure may be prominent with disorders of gastrointestinal motility, especially diarrhea or pseudo-obstruction. Cranial symptoms are lacking. The syndrome is typically slow in evolution and may respond to immunotherapy. Among the diverse causes are antimyelin-associated glycoprotein (MAG) paraproteinemic peripheral neuropathy associated with Waldenström macroglobulinemia and paraneoplastic neuropathy. Vasculitis is found in some acute neuropathies and can result in proximal muscle weakness.

Sensory symptoms that are asymmetric or affect cranial nerves should raise the question of leptomeningeal spread, although sensory neuronopathy in PEM can present similarly. Mononeuropathies or plexopathies raise the possibility of metastatic infiltration of the nerves or plexuses.

NEUROMUSCULAR DISORDERS

The association of myasthenia gravis with thymoma is described in another chapter; myasthenia is not known to be associated with other malignancies. Lambert-Eaton myasthenic syndrome (LEMS) is associated with SCLC approximately two-thirds of the time, with malignancy frequently diagnosed 2 years after diagnosis of LEMS.

Voltage-gated calcium channel (VGCC) antibodies are present in nearly all cases but do not differentiate between paraneoplastic and nonparaneoplastic cases. Sox1 antibody is also a marker of paraneoplastic LEMS. Treatment often involves a combination of treatment of cancer and immunosuppression. A 3,4-diaminopyrine increases the release of acetylcholine and results in neurologic improvement in many patients. Paraneoplastic neuromyotonia is associated most often with thymoma but also with SCLC or other tumors. Stiff person syndrome is manifest by limb muscle stiffness, rigidity, and muscle aches and spasms, developing over months. Approximately 80% of cases are paraneoplastic and the most common malignancies are breast cancer, SCLC, thymoma, and Hodgkin lymphoma. Associated antibodies are anti-glutamic acid decarboxylase (GAD) and anti-amphiphysin.

MYOPATHIES

About 20% of patients with dermatomyositis starting after age 40 years have an associated tumor, which can be of almost any type. Whether there is a higher than expected association of tumor with polymyositis has not been proven.

DIAGNOSIS

Diagnosis of a paraneoplastic syndrome is not always simple and often requires a high level of suspicion based on a clinical history

P.910

of subacute neurologic dysfunction. In some cases, the diagnosis of malignancy has already been made but frequently, symptoms of paraneoplastic syndromes antedate the diagnosis of a cancer. CSF may be normal or may demonstrate elevated protein or pleocytosis. CSF sugar content is almost always normal; hypoglycorrhachia (low sugar) in a patient with malignancy suggests meningeal spread of tumor cells. MRI is usually normal and may or may not show subtle abnormalities of white or gray matter. The diagnosis of peripheral neuropathy depends in part on the demonstration of conduction abnormalities, and LEMS is virtually defined by the demonstration of an incrementing response to repetitive nerve stimulation. Ideally, the diagnosis of a paraneoplastic syndrome is established by demonstrating a specific antibody in a patient with a characteristic syndrome. Commercial tests for paraneoplastic panels are testable in serum and CSF. If the CNS is affected, tests performed on CSF may be more sensitive because high antibody titers result from intrathecal synthesis. The presence of an antibody is not always confirmed—if a paraneoplastic syndrome is suspected, the lack of a diagnostic antibody should not preclude diagnosis and malignancy workup may still need to be pursued ([Fig. 104.1](#)).

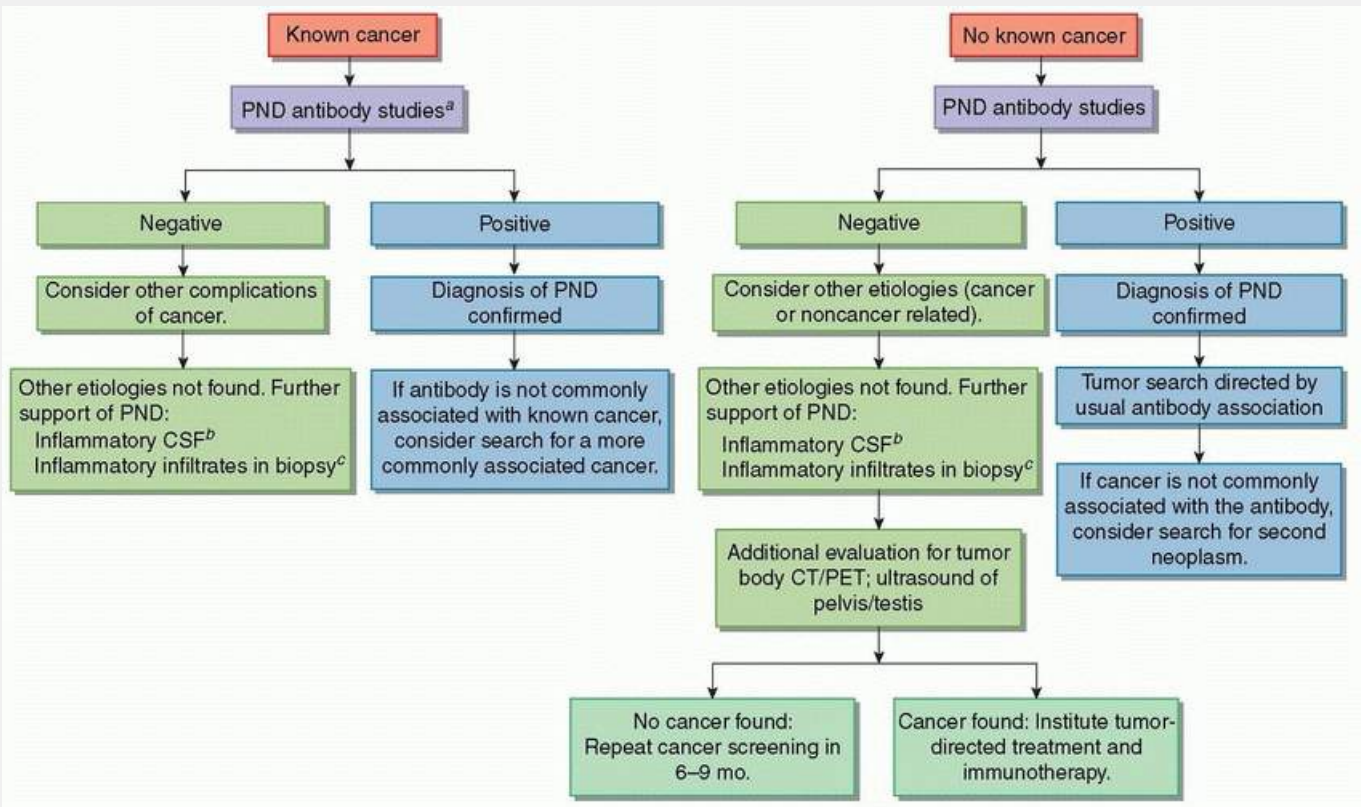

FIGURE 104.1 Diagnostic approach in a patient with a suspected paraneoplastic neurologic disorder. ^aPND antibody studies refer to well-characterized paraneoplastic antibodies. ^bCSF inflammatory changes include lymphocytic pleocytosis, elevated IgG index, and oligoclonal band with or without elevated protein concentration. ^cBiopsy should be directed to symptomatic area of the nervous system (clinical or by MRI). PND, paraneoplastic neurologic disorder; CSF, cerebrospinal fluid; CT, computed tomography; PET, positron emission tomography. (Adapted from Dalmau J. Rosenfeld MR. Paraneoplastic syndromes of the CNS. *Lancet Neurol.* 2008;7:327-340.)

DETECTION OF CANCER

If a paraneoplastic syndrome is highly suspected or confirmed with an antibody screen in the absence of a known malignancy, patients should undergo thorough cancer screening. Identification of a particular antibody may guide workup based on the associated cancer. If there is no identified antibody, a thorough cancer screen should be performed with whole body positron emission tomography (PET), mammography, pelvic ultrasound, testicular ultrasound, body CT, or MRI. If an underlying malignancy is not found, it is recommended that patients undergo regular cancer screening, as malignancy can be found months or even years later.

TREATMENT

The mainstay of treatment in paraneoplastic syndromes is cancer-targeted therapy. If no underlying malignancy is discovered but there is an identified antibody that has a strong association with a particular cancer type, surgical exploration or removal of the likely affected organ can be considered (e.g., orchiectomy in a patient with anti-Yo antibodies or oophorectomy with anti-NMDA). In cases in which an identified antibody is pathogenic, syndromes may be responsive to immunomodulatory therapies such as high-dose steroids, IVIG, and plasmapheresis. Peripheral disorders such as sensorimotor polyneuropathy, LEMS, and myasthenia gravis are particularly sensitive to this treatment. When these therapies fail,

rituximab, cyclophosphamide, azathioprine, tacrolimus, or cyclosporine may be appropriate.

P.911

Concerns that immunosuppression in malignancy could favor tumor growth have remained unfounded and immunomodulatory therapy is typically well tolerated in patients receiving chemotherapy. Paraneoplastic syndromes that are likely mediated by T-cell mechanisms or have no identified pathogenic antibody tend to be poorly responsive to therapy of any type. In general, the best chance for optimal neurologic outcome is administration of treatment while the syndrome is progressing, as this may lead to stabilization of symptoms.

OUTCOME

Outcome in paraneoplastic syndromes is variable and depends on identification and treatment of the underlying malignancy and pathogenesis of the neurologic disorder. In some cases, such as PCD, neuronal damage is permanent and irreversible. Syndromes in which the identified antibody is known to be pathogenic are frequently responsive to immunomodulatory therapies.

Complications of Cancer Therapy

Jasmin Jo

David Schiff

INTRODUCTION

Neurologic complications of cancer therapy are relatively common and may be disabling. Understanding these complications may mitigate or halt progression of injury to the nervous system through early recognition and prompt management. In this chapter, we will discuss neurotoxicities associated with the various agents used in the treatment of cancer.

NEUROLOGIC COMPLICATIONS OF RADIOTHERAPY

Cranial and spinal radiation used to treat primary or secondary central nervous system (CNS) tumors as well as for prophylaxis in certain systemic malignancies is a recognized cause of neurologic complications. The cranial and peripheral nerves are also vulnerable to adverse effects when included in the radiation field for CNS or non-CNS tumors. The risk for radiation injury increases with higher total dose and fractions, larger treatment volume, and coadministration of chemotherapy. Patients younger than 10 and older than 70 years old are more susceptible to complications of radiotherapy (RT).

PATHOBIOLOGY

Tissue injury from RT is categorized in sequential stages: acute (<1 month), early-delayed (1 to 6 months), and late-delayed reactions (>6 months). The timing is helpful in predicting reversibility of tissue damage. Capillary injury and leakiness leading to edema is the mechanism during acute injury. Late injury is generally associated with permanent tissue damage. In the brain and spinal cord, the proposed mechanism for late effects is a combination of vascular injury involving the small- and medium-sized vessels, demyelination with loss of oligodendrocytes, and immunologic response to antigens released from damaged glial cells. The pathologic end state is radiation necrosis, involving coagulation necrosis and gross demyelination. Tissue atrophy is seen upon long-term follow-up. [Table 105.1](#) summarizes RT injuries and their corresponding manifestations based on location.

TABLE 105.1 Neurologic Complications of Radiotherapy

Type	Onset	Pathology	Symptoms according to Sites			
			Brain	Spinal Cord	Cranial Nerves	Peripheral Nerves
Acute	<1 mo	BBB disruption Edema	Acute encephalopathy Pseudoprogression	—	—	Paresthesia
Earlydelayed	1-6 mo	Edema Demyelination	Somnolence Transient cognitive impairment Pseudoprogression	Lhermitte sign	Painless visual loss Tongue weakness Hearing loss Anosmia	Transient plexopathy Pain

Late/delayed	>6 mo	Vascular injury Demyelination Necrosis Cellular loss	Focal radionecrosis Leukoencephalopathy Cognitive impairment Dementia	Brown-Séquard syndrome Spastic paraplegia	Hearing loss Visual loss Lower CN palsies	Irreversible plexopathy Myokymia on EMG
---------------------	-------	---	--	--	---	--

BBB, blood-brain barrier; CN, cranial nerves; EMG, electromyography.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Brain

Acute encephalopathy, consisting of somnolence, headache, nausea, vomiting, and exacerbation of preexisting deficits, usually develops days after initiation of RT and generally responds to corticosteroids. No specific neuroimaging findings are associated with acute injury. Early-delayed complications include the somnolence syndrome, characterized by drowsiness, fatigue, anorexia, irritability, and transitory cognitive disturbances primarily affecting attention and short-term memory. Neuroimaging at this time may be unchanged or show increased edema and contrast enhancement within the tumor bed that mimics tumor progression, termed *pseudoprogression* (Fig. 105.1). The exact frequency with which this phenomenon occurs is difficult to estimate because of varying criteria defined in different reports. However, it occurs in at least 10% to 20% of patients with glioblastoma receiving concurrent RT and temozolomide; it manifests most commonly 1 to 3 months posttreatment (although may occur later) and usually improves within a few months. Late injury is associated with focal radionecrosis (causing seizures, focal neurologic symptoms, and signs of increased intracranial pressure) and leukoencephalopathy (leading to cognitive dysfunction and severe dementia). Diffuse white matter changes and atrophy are seen in the neuroimaging in nearly all cases. Magnetic resonance imaging (MRI) does not distinguish between radiation necrosis and tumor progression. Metabolic and

P.913

perfusion imaging studies may help discriminate the two entities, but surgery remains the gold standard to confirm the diagnosis.

FIGURE 105.1 Pseudoprogression in a 52-year-old man with right temporal glioblastoma, methylguanine-DNA methyltransferase (MGMT) methylated. **A:** Pretreatment MRI showed nodular enhancement along the surgical cavity (**A1**) in the right temporal lobe with minimal surrounding fluid-attenuated inversion recovery (FLAIR) signal abnormality (**A2**). No elevated cerebral blood volume noted in the perfusion study (**A3**). **B:** Repeat MRI 4 weeks after concurrent radiotherapy and temozolomide demonstrated significant increase in the size of the irregularly enhancing mass (**B1**) associated with increase in surrounding FLAIR signal abnormality with mass effect (**B2**) without evidence of elevated cerebral blood volume (**B3**). The patient underwent second resection and pathology revealed reactive changes, scattered atypical cells, and thickened vessels consistent with radiation treatment effects.

Spinal Cord

Radiation-induced damage to the spinal cord is categorized into early-delayed (6 weeks to 6 months) and late-delayed (>6 months) myelopathy. Acute worsening should prompt investigation for intratumoral hemorrhage or tumor progression. Early-delayed RT myelopathy is characterized clinically by Lhermitte sign that typically resolves spontaneously, with no distinctive imaging finding. Patients with late-delayed radiation myelopathy often presents with Brown-Séquard syndrome, spastic paraplegia with impaired sensory and autonomic functions. The condition may begin abruptly or insidiously and is most often irreversible. MRI demonstrates increase T2 hyperintensity and enhancement in the affected spinal cord levels.

Peripheral Nervous System

Any cranial nerves may be involved if included in the radiation field. The hypoglossal nerve is the most vulnerable followed by the vagus nerve and the recurrent laryngeal nerve, believed to be due to absorption of higher amount of energy from RT to the neck region. Optic neuropathy results in painless and progressive visual loss or visual field constriction. The oculomotor, trochlear, trigeminal, abducens, and facial nerves are less vulnerable and can be affected from focal RT for skull base tumors. Trigeminal neuropathy is quite rare and may result from radiosurgery for vestibular schwannoma and trigeminal neuralgia. Radiation-induced injury to vestibulocochlear nerve is rare, except in RT for acoustic neuroma. Hearing impairment, especially at high frequency, may be due to changes in the cochlea and/or retrocochlear auditory pathway. Permanent damage to cranial nerves is rare and usually occurs due to delayed effect.

RT-induced brachial and lumbosacral plexopathies may result from treatment of breast, lung, and pelvic cancers. The usual presentation includes paresthesia and hypesthesia, followed by weakness and amyotrophy. Pain is usually relatively mild and occurs late in the course, as opposed to severe pain in patients with malignant plexopathy. Myokymia seen on electromyography and hypointensity in T1- and T2-weighted sequences and absence of mass on MRI suggest RT plexopathy.

Indirect Complications to Nervous System

RT can indirectly cause endocrine dysfunction such as hypothalamic-pituitary impairment resulting in hypothyroidism, hypogonadism, hyperprolactinemia, and panhypopituitarism; vascular damage leading

P.914

to stroke, hemorrhage, vascular malformations, and rarely, SMART syndrome (stroke-like migraine attacks after radiation therapy); and secondary tumors such as meningioma, glioma, and sarcoma.

TREATMENT AND PREVENTION

Corticosteroid (dexamethasone, intravenous [IV] or oral, initially at 16 mg/day) generally reverses symptoms from acute and earlydelayed injuries but has variable benefit in radiation necrosis. Antivascular endothelial growth factor (VEGF) agents such as bevacizumab (10 mg/kg every 2 weeks or 7.5 mg/kg every 3 weeks IV) have demonstrated beneficial effects in patients with cerebral radiation necrosis. In rare occasions, surgical resection of cerebral radiation necrosis is indicated, providing both therapeutic and diagnostic benefits. The use of memantine at 20 mg/day within 3 days of initiating RT for 24 weeks results in delayed time to cognitive decline and reduced rate of decline in memory, executive function, and processing speed in patients with brain metastases receiving whole brain RT [Level 1].¹ Hippocampal sparing during brain RT may also reduce the incidence of neurocognitive injury. Pain management and physical therapy are important aspects in the management of RT-induced plexopathy. Hyperbaric oxygen and anticoagulation may ameliorate the effects of radiation necrosis, but their efficacy is limited.

OUTCOME

Recovery of symptoms is typically expected in acute and earlydelayed RT injuries. However, delayed complications of RT are progressive and irreversible, leading to poor outcome and quality of life for long-term survivors.

NEUROLOGIC COMPLICATIONS OF CHEMOTHERAPY

Cytotoxic chemotherapeutic agents may cause toxic effects to the peripheral and central nervous system, often leading to reduction or cessation of treatment. The severity depends on the treatment dose, duration, route, existing comorbidities, and coadministration of other neurotoxic agents.

PATHOBIOLOGY

The mechanism of chemotherapy-induced peripheral neuropathy (CIPN) depends on the cytotoxic agents used. Antimitotic agents, such as vinca alkaloids and taxanes, disrupt microtubule-based axonal transport leading to length-dependent axonal injury. Platinum agents such as cisplatin cause neuropathy by apoptosis of sensory neurons in dorsal root ganglion, whereas oxaliplatin additionally causes transient Na-gated channel dysfunction resulting in altered nerve excitability, particularly refractoriness. Despite the presence of the blood-brain barrier (BBB), the CNS remains susceptible to neurotoxicity effects if the protective barrier is breached by direct effects of tumor through endothelium damage or by RT, if the agent crosses the intact BBB, or if the agents are administered directly to the cerebrospinal fluid (CSF) or into the cerebral vasculature. Chemotherapy can also cause damage to neural progenitor cells responsible for neurogenesis and maintenance of white matter integrity.

CLINICAL MANIFESTATIONS

Central Nervous System

Chemotherapy agents such as ifosfamide, high-dose methotrexate, and procarbazine can cause acute toxicities occurring during or few days after treatment, characterized by confusion, hallucination, seizures, and drowsiness. A cerebellar syndrome may develop from high-dose cytarabine. Intrathecal (IT) methotrexate and cytarabine can cause aseptic meningitis and myelopathy. IT vincristine causes severe neurotoxicity that is nearly always fatal and must be avoided. Posterior reversible encephalopathy syndrome (PRES), manifesting as acute or subacute onset of headache, seizures, confusion, and visual changes, has been reported from cisplatin, cyclophosphamide, high-dose corticosteroids, and gemcitabine. Chronic leukoencephalopathy, characterized by progressive personality change, dementia, ataxia, and incontinence, may occur months to years following methotrexate, especially when given during or soon after whole brain RT. Therefore, whole brain RT should be administered after systemic or IT methotrexate.

Peripheral Nervous System

CIPN typically presents with symmetric distal paresthesia, loss of proprioception and vibratory sense, and loss of ankle reflexes. Distal motor weakness and autonomic dysfunction including atonic bladder, impotence, and orthostatic hypotension may also occur with certain agents (Table 105.2). Vestibulocochlear toxicity, with hearing loss, vertigo, and ataxia, is associated with cisplatin. Acute cold-induced dysesthesia involving the distal extremities, throat, mouth, or face occur commonly with oxaliplatin.

DIAGNOSIS

In acute CNS syndromes, the brain MRI may be unremarkable or demonstrate edema. Diffuse white matter disease, corticallsubcortical atrophy, and ventricular dilation are typical imaging findings in chronic leukoencephalopathy. Nerve conduction studies in CIPN may demonstrate decreased sensory nerve action potential, prolonged latencies, and delayed conduction velocities. For classic presentations of CIPN, diagnostic testing is not usually required. Identification and treatment of coexisting conditions that cause peripheral neuropathy, such as diabetes, alcohol abuse, and vitamin B₁₂ deficiency, is imperative in the management of CIPN. Paraneoplastic neuropathy should be distinguished from CIPN, as treatment involves further cancer-directed treatment. Patients with small cell lung cancer may develop a subacute sensory paraneoplastic neuropathy associated with anti-Hu antibodies.

TABLE 105.2 Peripheral Nervous System Toxicities from Cytotoxic and Targeted Agents

Neuropathic Syndromes	Agents
Acute sensory dysesthesia	Oxaliplatin, ifosfamide, cytarabine (rare)
Chronic pure sensory neuropathy	Cisplatin, oxaliplatin, carboplatin, docetaxel, procarbazine, etoposide, bortezomib, thalidomide
Chronic sensorimotor neuropathy	Vincristine, vinorelbine, nelarabine, paclitaxel, ixabepilone, etoposide, fludarabine, 5-fluorouracil, procarbazine, bortezomib, thalidomide (rare)
Chronic autonomic neuropathy	Vincristine, thalidomide, ixabepilone (rare)
Vestibulocochlear toxicity	Cisplatin

TREATMENT AND PREVENTION

Most patients who develop acute CNS syndromes recover within a few days with supportive treatment. Methylene blue may be effective in treatment (50 mg IV 6× per day) or prophylaxis (50 mg, IV or oral, 4× per day) of ifosfamide-induced encephalopathy. Discontinuation of the offending agent is indicated if a patient experience acute myelopathy or cerebellar syndromes. There are no effective treatments for neurocognitive toxicities. Erythropoietin (40,000 units weekly), methylphenidate (10 mg twice daily), modafinil (200 to 400 mg/day), and cholinesterase inhibitors such as donepezil (5 to 10 mg/day), nonsteroidal anti-inflammatory agents (i.e., aspirin 100 mg daily), as well as cognitive rehabilitation have been studied but no definite recommendations can be made.

Dose-reduction or discontinuation of chemotherapeutic agents causing CIPN usually improves the symptoms. Antiepileptic agents, tricyclic antidepressants, serotonin-norepinephrine reuptake inhibitors (SNRI), opioids, and topical local anesthetics may provide symptomatic relief of CIPN (Table 105.3) [**Level 1**].² Neuroprotective agents have been used to prevent or limit neurotoxicity. However, calcium and magnesium infusion (1 g of each given immediately before and after each dose of oxaliplatin) did not substantially decrease oxaliplatin-induced sensory neurotoxicity in a recent phase III randomized controlled trial [**Level 1**].³ Some nutritional supplements may worsen rather than improve CIPN [**Level 1**].⁴

OUTCOMES

Acute CNS toxicities usually resolve within few days with supportive treatments. Chronic leukoencephalopathy are often progressive and irreversible. CIPN most often resolves on appropriate dose reduction or discontinuation of the offending agents. However, worsening of peripheral neuropathy (“coasting”) may occur for a few months after cessation of treatment (e.g., cisplatin, thalidomide), preventing timely discontinuation of treatment.

NEUROLOGIC COMPLICATIONS OF BIOLOGIC AGENTS

MONOCLONAL ANTIBODIES

Bevacizumab, a humanized antibody against VEGF, increases the risk of thromboembolic stroke and intracranial hemorrhage and may cause PRES and rarely, optic neuropathy. Discontinuation of the drug, management of hypertension, and appropriate supportive care are recommended. Rituximab, a chimeric monoclonal antibody (MAb) against CD20 antigen found on the surface of normal and malignant B lymphocytes, may cause headache, myalgia, paresthesia, dizziness, and rarely, progressive multifocal leukoencephalopathy and PRES.

TABLE 105.3 Therapeutic Agents Commonly Used for Chemotherapy-Induced Peripheral Neuropathy

Agents	Dose
Carbamazepine	200 mg/day; target plasma level 4-6 mg/L
Gabapentin	100-2,700 mg/day
Pregabalin	75-150 mg/day
Lamotrigine	25-300 mg/day
Duloxetine	30-60 mg/day

Amitriptyline	50 mg/day
Morphine	10-15 mg every 4-6 h
Topical gel	Twice daily

TARGETED MOLECULAR AGENTS

Small molecule protein kinase inhibitors target both membranebound and intracellular molecules and interfere with corresponding enzymatic activities. Most agents have minimal neurotoxicity such as headache and dizziness. Mild visual disturbance is seen in 45% of patients receiving crizotinib (ALK and c-MET inhibitor). Bortezomib (proteasome inhibitor) causes a length-dependent, painful, small-fiber sensory axonal neuropathy, which occurs in about 35% of patients and can be dose limiting. Nerve conduction study is consistent with small-fiber sensory neuropathy but may also be normal. Symptoms improve with discontinuation or dose reduction of the offending agent. Lower rates of neuropathy are observed with newer proteasome inhibitor such as carfilzomib.

IMMUNOTHERAPY

Immunomodulatory agents stimulate the immune system by administration of proinflammatory cytokines such as interferon and interleukin to boost the immune system to attack cancer cells. Neurotoxicity associated with these agents tends to be dose-related. Neurologic adverse effects from ipilimumab, a human MAb that blocks cytotoxic T-lymphocytes antigen-4 used to treat melanoma, includes inflammatory myopathy, aseptic meningitis, severe meningoradiculoneuritis, temporal arteritis, and Guillain-Barré syndrome. Pituitary failure can also lead to metabolic encephalopathy associated with various endocrinopathies. Chronic inflammatory demyelinating polyneuropathy, transverse myelitis and concurrent myositis, and myasthenia gravis-type syndrome have also been reported with ipilimumab. Discontinuation of the drug and administration of high-dose IV steroids (methylprednisolone 125 mg IV for 3 days) or plasmapheresis (three to five sessions) are recommended, which generally improve neurologic symptoms within 2 weeks. Neuropsychiatric symptoms, most commonly depression, encephalopathy, hallucination, and seizures, are frequently reported with interferon- α (IFN- α). These symptoms usually improve after discontinuation of therapy, although permanent dementia and persistent vegetative state have been reported. Interleukin-2 (IL-2) crosses the BBB, causing direct toxicity to the neurons and glial cells. Transient encephalopathy and neurocognitive symptoms may develop toward the end of therapy and resolve within hours to days after discontinuation of treatment.

NEUROLOGIC COMPLICATIONS OF HEMATOPOIETIC STEM CELL TRANSPLANTATION

HSCT is commonly used for treatment of leukemias and lymphomas. The myeloablative doses of chemotherapy sometimes result in neurotoxicity not encountered with conventional doses, including seizures with busulfan; encephalopathy with ifosfamide, melphalan, etoposide, and thiotepa; and neuropathy with carboplatin, cyclophosphamide, and etoposide. Intracerebral hemorrhage due to thrombocytopenia from bone marrow suppression can also be encountered. Immunosuppressant agents such as calcineurin inhibitors cyclosporine and tacrolimus and muromonab-3 (OKT3)

P.916

are typically used to prevent graft-versus-host disease (GVHD). Major CNS complications from calcineurin inhibitors include headache, altered mental status, seizures, cortical blindness, visual and auditory hallucinations, spasticity, paresis, and ataxia. PRES is also reported, perhaps due to direct toxicity to vascular endothelium. Neurologic symptoms eventually resolve after reducing or stopping the treatment. As a result of immunosuppression, 5% to 8% of patients develop opportunistic CNS infection including toxoplasmosis; herpesvirus, cytomegalovirus, and JC virus reactivation; nocardia; and aspergillosis. Treatment is directed toward the inciting pathogen.

NEUROLOGIC COMPLICATIONS OF BRAIN TUMOR TREATMENTS

Treatment for brain tumors, including surgery, radiation therapy, and/or chemotherapy, can cause neurotoxicity.

Surgical complications are typically acute, consisting of hemorrhage, vascular damage, infarcts, coagulopathies, cerebral edema with herniation syndromes, and postoperative infections. Major neurologic morbidity from parenchymal tumor resection occurs in 8.5% of patients; usually in patients with tumor in eloquent or near-eloquent brain regions. Risk factors for chronic neurotoxicity from RT and chemotherapy include age, therapeutic modality and dosage, combination therapy, genetic background, and idiosyncratic patient predilections. Leukoencephalopathy may result from treatment with high-dose methotrexate in patients with primary central nervous system lymphoma (PCNSL), especially when given concurrently with or soon after RT. Neurocognitive dysfunction is a well-recognized long-term toxicity from RT. Several strategies have been studied to reduce or delay neurotoxicity from RT, such as use of 3D conformal RT in patients with gliomas, deferring whole brain radiotherapy (WBRT) in subsets of patients with brain metastases, reducing dose in patients with PCNSL who achieved complete remission after high-dose methotrexate therapy, modification of radiation delivery such as stereotactic radiosurgery or proton therapy, and sparing of hippocampus and neural stem cell during WBRT. Secondary tumors can develop years to decades after irradiation, including meningiomas, nerve sheath tumors, pituitary adenomas, gliomas, sarcomas, and embryonal neoplasm.

CONCLUSION

Neurologic complications of cancer treatment can result from direct toxicity to the nervous system, indirectly through toxic/metabolic effects, or from immunosuppressant effects resulting in opportunistic infection. Early recognition and differentiation from metastatic disease or paraneoplastic syndromes are imperative for proper management, as well as avoidance of inappropriate discontinuation or dose reduction of therapeutic agents.

Hydrocephalus

Michelle L. Ghobrial

Leon D. Prockop

Fred Rincon

INTRODUCTION

Hydrocephalus is characterized by an imbalance in the production, drainage, and reabsorption of cerebrospinal fluid (CSF) resulting in a dilation of the cerebral ventricles. The choroid plexus produces about 500 mL of CSF daily. The CSF circulates from the lateral ventricles to the third ventricle through the foramen of Monro. It then flows to the fourth ventricle via the cerebral aqueduct and exits into the subarachnoid space via the foramina of Magendie and Luschka. The arachnoid villi granulations reabsorb the CSF into the venous system.

CLASSIFICATION

Although various classifications of hydrocephalus have evolved historically, the several types are recognized (Table 106.1). Although all types of hydrocephalus are obstructive to some degree, the anatomic localization and severity of resistance to normal anterograde CSF flow can vary. *Obstructive hydrocephalus* is used to describe conditions that result near complete blockage of CSF flow within the ventricular system. *Communicating hydrocephalus* describes conditions in which the ventricles are enlarged despite an open flow system from within the ventricles into the basal cisterns and over the convexities. Walter Dandy first described communicating hydrocephalus in 1914. He injected a tracer dye into one of the lateral ventricles. If the dye appeared in lumbar CSF, the hydrocephalus was termed *communicating*; if the dye did not appear in lumbar CSF, the hydrocephalus was termed *noncommunicating*. Because it proved useful in surgical-shunt placement, this functional classification was widely accepted; however, by this definition, noncommunicating hydrocephalus refers only to that caused by obstruction within the ventricular system. Communicating hydrocephalus infers CSF obstruction due to damage to the absorptive system after exiting the ventricles. Normal pressure hydrocephalus (NPH) is a form of communicating hydrocephalus.

TABLE 106.1 Classification of Hydrocephalus

Obstructive hydrocephalus

- Congenital malformations (i.e., aqueductal stenosis)

- Mass lesions causing ventricular obstruction (i.e., acute intraventricular hemorrhage, third ventricular colloid cyst)

Communicating hydrocephalus (CH)

- Defective reabsorption of CSF (i.e., postinflammatory or posthemorrhagic)

- Normal pressure hydrocephalus (NPH)

-
- Venous insufficiency
-

- Overproduction of CSF (i.e., colloid plexus tumor)
-

- External hydrocephalus (i.e., preponderance of excess CSF over the convexities)
-

Hydrocephalus ex vacuo

CSF, cerebrospinal fluid.

Hydrocephalus can be *acute* or *chronic*. Acute hydrocephalus can be an immediate threat to life when it develops rapidly over several hours and leads to intracranial hypertension and downward central herniation of the brain. By contrast, even massive ventriculomegaly can be minimally symptomatic if it develops gradually over weeks, months, or years and does not represent a threat to life.

Another classification of hydrocephalus is congenital versus acquired. Congenital hydrocephalus is present at birth. Acquired hydrocephalus can develop any time after birth. These forms of hydrocephalus are distinguished from *hydrocephalus ex vacuo* in which CSF volume increases without change in CSF pressure because of cerebral atrophy.

EPIDEMIOLOGY

Population-based statistics for hydrocephalus are difficult to provide given the scope of varying ages of onset and causes. Congenital hydrocephalus occurs with an incidence of 0.5 to 1.8 per 1,000 births per year and may result from either genetic or nongenetic causes. Posthemorrhagic hydrocephalus occurs with an incidence of 25% to 70%, depending on the severity of the hemorrhage. Approximately 10% of infants with intraventricular hemorrhage (IVH) will require a shunt. The incidence of acute acquired hydrocephalus is unknown. Recent population-based studies have estimated the prevalence of NPH to be about 0.5% in those older than 65 years, with an incidence of about 5.5 patients per 100,000 per year. This is in accordance with comparable findings stating that although NPH occurs in both men and women of any age, it is found more often in the elderly population, with a peak onset generally in the sixth to seventh decades. Low-pressure hydrocephalus is reported in the literature as case series but no population statistics are known due to its uncommon occurrence.

PATHOBIOLOGY

OBSTRUCTIVE HYDROCEPHALUS

In intraventricular obstructive hydrocephalus, the obstruction causes proximal dilation of the ventricles with preservation of

P.919

normal ventricular size distally. Obstruction may occur at the foramen of Monro, the third ventricle, the aqueduct of Sylvius, the fourth ventricle, or the fourth ventricular outflow foramina of Luschka and Magendie. Obstructive hydrocephalus can be caused by congenital malformations, developmental lesions, mass lesions, or posthemorrhagic ventricular obstructions.

Congenital Malformations and Developmental Lesions

Common nongenetic causes include intracranial hemorrhage (ICH) secondary to birth trauma or prematurity and

meningitis as a cause for congenital hydrocephalus. Genetically, at least 43 mutants/loci linked to hereditary hydrocephalus have been identified in animal models and humans. In some, aqueductal stenosis has been documented by magnetic resonance imaging (MRI) or at postmortem examination. It is not clear whether aqueductal lesions (e.g., gliosis or fibrosis) occur developmentally or are the residue of prior viral inflammatory disease contracted in utero or in early life (Fig. 106.1). In some families, the occurrence of aqueductal stenosis, hydrocephalus of undetermined anatomic type, and the Dandy-Walker syndrome in siblings of both sexes suggests other modes of inheritance. In the Dandy-Walker syndrome, there is expansion of the fourth ventricle and the posterior fossa with obstruction of the foramina of Luschka and Magendie (Fig. 106.2). The Arnold-Chiari malformation may be associated with hydrocephalus at birth or it may develop later.

Mass Lesions

Intracranial neoplasms may cause obstructive hydrocephalus (Fig. 106.3). Tumors clustered about the third or fourth ventricles or the sylvian aqueduct, including pineal tumors, colloid cysts, gliomas, ependymoma, and metastases, are commonly implicated in intraventricular obstructive hydrocephalus. Prognosis, after shunting, is largely related to the type of tissue in the tumor. Other mass-like lesions, such as intraparenchymal cerebral hemorrhage, cerebellar infarction, or cerebellar hemorrhage, which assert local pressure on the ventricles may lead to acute hydrocephalus. Basilar artery ectasia and other vascular abnormalities (e.g., vein of Galen malformation) have also been associated with hydrocephalus.

FIGURE 106.1 A 76-year-old man presented with 1-month history of gait dysfunction, memory loss, and urinary incontinence. **A**, **B**, **C**, and **D** are axial FLAIR MRI images and **E** is a sagittal T1 MRI image of chronic hydrocephalus secondary to aqueductal stenosis.

FIGURE 106.2 Sagittal CT scan showing a Dandy-Walker malformation.

Posthemorrhagic Ventricular Obstruction

Intracerebral hemorrhage complicated by IVH in adults also causes hydrocephalus (Fig. 106.4). In some patients, CSF flow obstruction is transient; therefore, intracranial pressure (ICP) increases and hydrocephalus appears but then disappears spontaneously. Other patients exhibit progressive hydrocephalus.

COMMUNICATING HYDROCEPHALUS

When neither an intraventricular nor an extraventricular obstruction is documented, three other mechanisms may cause hydrocephalus: oversecretion of CSF, venous insufficiency, or impaired absorption of CSF by arachnoid villi. The absorptive capacity of the subarachnoid space is about three times the normal CSF formation rate of 0.35 mL/min (20 mL/h or 500 mL/day). Formation rates greater than 1.0 mL/min may produce hydrocephalus. Clinically, choroid plexus papilloma is the only known cause of oversecretion hydrocephalus.

Posthemorrhagic Hydrocephalus

Posthemorrhagic hydrocephalus is a major complication of cerebral IVH in low birth weight infants. Hydrocephalus results when a clot within the ventricular system obstructs CSF flow by a process of obliterative basilar arachnoiditis or by cortical arachnoiditis. Hydrocephalus also occurs in adults after subarachnoid bleeding caused by head trauma or ruptured aneurysm (see Fig. 106.4). After subarachnoid hemorrhage, distension of the arachnoid villi by packed red cells suggests an absorptive defect as a pathogenic mechanism for hydrocephalus. Consequently, fibrotic impairment of extraventricular CSF pathways after ICH may be complicated by dysfunction of arachnoid villi. In preterm infants, there is a predisposition to germinal matrix (GM)

hemorrhage leading to periventricular hemorrhagic infarction (PHI) and IVH causing hydrocephalus. GM hemorrhage is graded by severity, as I through IV, whereby grades III and IV usually develop progressive hydrocephalus that requires shunting.

FIGURE 106.3 A and B: A 61-year-old female with a history of breast cancer presented with nausea and vomiting. She was found to have hydrocephalus secondary to brain metastasis as seen here in this T1 postcontrast MRI.

Postinfectious Hydrocephalus

Among infectious diseases, bacterial, fungal, tubercular, or syphilitic meningitis may cause chronic hydrocephalus secondary to basal arachnoiditis (Fig. 106.5). Among parasitic infections, neurocysticercosis may produce both communicating and noncommunicating hydrocephalus.

FIGURE 106.4 A 54-year-old man found unresponsive. He underwent endovascular coiling of a large left middle cerebral artery (MCA) aneurysm and decompressive hemicraniectomy (A). The hydrocephalus persisted and he required a ventriculoperitoneal shunt after a restorative cranioplasty (B).

Otitic Hydrocephalus

Otitic hydrocephalus occurs in children after chronic otitis media or mastoiditis with lateral sinus thrombosis. Otherwise, impaired cerebral venous drainage, for example, thrombosis of cortical veins or intracranial venous sinuses, rarely causes hydrocephalus. Rarely, hydrocephalus due to impairment of extracranial venous

P.921

drainage follows radical neck dissection or obstruction of the superior vena cava.

FIGURE 106.5 A 47-year-old man with ventriculitis and secondary communicating hydrocephalus. **A** and **B** are postcontrast T1 MRI images. **C** and **D** are FLAIR MRI images.

Congenital Agenesis of the Arachnoid Villi

Communicating hydrocephalus has been attributed to congenital agenesis of the arachnoid villi with consequent impairment of CSF absorption. Because detailed pathologic study of the number of villi and their structural characteristics is difficult and rarely performed, this defect may be more common than statistics indicate.

Likewise, dysfunction of arachnoid villi without obstruction of basilar or transcortical CSF pathways is not easy to assess.

Hyperproteinorraquia

Hydrocephalus has also been described when lumbar CSF protein content exceeds 500 mg/dL, as in polyneuritis or spinal cord tumor. The protein may interfere with CSF absorption. Ependymoma, the most common spinal cord tumor associated with hydrocephalus, may cause tumor seeding of the arachnoid villi.

Normal Pressure Hydrocephalus

NPH is a form of chronic communicating hydrocephalus with incomplete obstruction of the normal pathway of CSF flow. NPH most likely results from a serial pattern of increased resistance to normal CSF flow at the foramen of Monro, sylvian aqueduct, fourth ventricular outflow tracts, and the arachnoid granulations. The result is a relative increase in the volume of the lateral and third ventricles, with normal ICP. Symptoms are produced by stretching and secondary dysfunction and degeneration of white matter pathways in the corona radiata, which encase the lateral ventricles, and to a lesser extent white matter tracts in the internal capsule and below.

NPH is often “idiopathic” and may relate simply to an abnormal brain aging process, whereas in some cases, it may follow subarachnoid hemorrhage from trauma or aneurysm, meningitis, tumor, or surgery. Irrespective of the underlying etiology, the ventricles expand at the expense of brain volume, causing both brain compression and periventricular white matter changes. These changes are thought to arise from brain edema caused by transependymal flow of fluid (Fig. 106.6) or to ischemic demyelination caused by compression of brain tissue. There may also be neuronal dysfunction from the compression. However, the overall effect is sufficiently chronic, or compensated, so that the CSF pressure is normal.

Low-Pressure Hydrocephalus

A clinical state has been described with low CSF pressures and acute symptomatic hydrocephalus in the setting of medium pressure

P.922

CSF diversion and ventriculomegaly. Chronic shunting, subarachnoid hemorrhage, IVH, and tumors have been associated with low-pressure hydrocephalus. It has been postulated that a decrease in cerebral elasticity coupled with the ventricular enlargement produces this syndrome. There are different viscoelastic theories that have been applied in attempts to delineate this physiologic occurrence. Ultimately, this condition improves with subzero CSF drainage.

FIGURE 106.6 A to D: An 85-year-old man presented with gait dysfunction and urinary incontinence for 3 months. His symptoms improved after a large-volume LP. Axial FLAIR MRI images of a patient with NPH. Note periventricular transependymal interstitial edema.

External Hydrocephalus

External hydrocephalus presents as collections of subarachnoid fluid over the convexities, with or without coexisting ventriculomegaly. It can occur in both children and adults. In some cases, it can be difficult to determine whether the collection of fluid is truly in the subarachnoid or subdural space, and in some cases, both may exist. The criteria for diagnosis of benign external hydrocephalus in children is a rapidly enlarging head circumference along with a computed tomography (CT) scan showing enlarged subarachnoid spaces, particularly in the frontal regions, and normal ventricular size. The etiology in most cases is idiopathic, but it has been reported in many different conditions such as prematurity with IVH, subarachnoid hemorrhage, meningitis, steroid therapy, chemotherapy, neurosurgery, and trauma. Children with external hydrocephalus also have at least one close relative with macrocephaly

in 40% of cases. An autosomal dominant mode of transmission is suspected. The most common theory of

etiology in these children is immaturity of arachnoid villi. In adults, external hydrocephalus may be seen after trauma or subarachnoid hemorrhage. Another cause is after surgical hemicraniectomy if the bone has not been replaced. It is important to differentiate adult external hydrocephalus from subdural hygromas, as the latter will worsen if ventricular shunting is attempted.

CLINICAL MANIFESTATIONS

CONGENITAL OR INFANTILE HYDROCEPHALUS

The manifestation of hydrocephalus is influenced by the patient's age. Infants will experience tension hydrocephalus if the insult occurs before the cranial sutures fuse at the end of the third year. This will cause skull enlargement and wide fontanelles. If the hydrocephalus occurs recently after suture closure, they may be separated by the pressure (suture diastasis). The face will appear relatively small and with stretching of the skin of the scalp, prominent veins appear. Upon percussion of the skull, a "cracked pot" sound is noted, known as *Macewen sign*. Scalp necrosis in these children can lead to CSF leakage and infections. If left untreated, there is failure to thrive due to poor feeding and frequent vomiting. Parinaud syndrome is caused by damage to midbrain tegmentum. The symptoms include paralysis or spasm of convergence, convergence-retraction nystagmus, visual loss and eventual optic atrophy, pseudo-Argyll Robertson pupils, eyelid retraction (Collier sign), and impaired upgaze or forced downgaze (setting-sun sign). Signs of corticospinal tract dysfunction include spasticity, increased deep tendon reflexes, positive Babinski sign, and wasting of trunk and limb muscles. The child will be developmentally delayed in motor and cognitive function.

In otitic hydrocephalus, the child may be febrile and listless. Eardrum perforation and purulent otic discharge usually occur. Often, ipsilateral sixth nerve paralysis and papilledema are noted.

ACUTE HYDROCEPHALUS

In acute hydrocephalus, there will first be headache and nausea/vomiting. This is followed by decreased mental status and may lead to coma. Corticospinal manifestations include lower extremity spasticity, increased deep tendon reflexes, and bilateral Babinski signs. It can progress to extensor posturing. The pupils are normal early in the process. Parinaud syndrome symptoms may appear as well. If untreated, pupillary mydriasis will develop. Depending on the speed of evolution, papilledema can be seen.

NORMAL PRESSURE HYDROCEPHALUS

A different symptom complex is seen with NPH, as the hydrocephalus in this disease process is slow and insidious. Patients present with a triad of gait ataxia, dementia, and urinary incontinence. Gait change is usually the first symptom, as well as the most frequent symptom, of NPH. This change may be subacute, fluctuating, or more chronic but most often worsens over weeks or months. The gait disturbance is often inconsistent and variable but has parkinsonian features, with shuffling, shortened stride length, imbalance, and often initial slowness. Frequently, the gait is wide-based (not commonly a feature of Parkinson disease), often with external rotation of the legs. The gait is classically described as "magnetic," with inability to lift the feet off the floor. It is also described as a gait "apraxia" because it appears that motor program involved in starting to move the legs is impaired, without evident impairment of strength. In addition to difficulty with the initiation of gait, there may also be difficulty maintaining gait, and there may be "freezing," with problems reinitiating movement. Tremor is uncommon, but falls are common.

Urinary symptoms are also frequent in NPH and may go unrecognized, consisting only of urinary urgency or frequency. Urinary incontinence itself is common, presumably due to loss of descending control mechanisms, with consequent unsuppressed bladder contractions, together with decreased voluntary ability to control the bladder outlet. A characteristic feature is said to be incontinence in which there is little evident concern regarding the problem.

Impaired cognition, ranging from subtle to severe, occurs in NPH, usually following after the onset of gait and urinary dysfunction. The characteristics of dementia associated with hydrocephalus include “subcortical” features. Symptoms may include not only forgetfulness but also slowness in mental processing, inertia, apathy, and impaired executive function, including decision making and task switching. Memory impairment in hydrocephalus may differ from that seen in cortical dementias such as Alzheimer disease (AD). As in AD, preservation of long-term knowledge can be seen, although the memory deficits more clearly involves poor learning. Impairment in delayed recall of learned material could relate to deficits in learning but may also involve initiation and speed of retrieval. For example, recall with simple cues may be much better than free recall, indicating a dominant deficit in retrieval rather than defective encoding of learned material. Advanced hydrocephalus results in severe slowing of mentation and possibly an akinetic mute state.

DIAGNOSIS

In infants, hydrocephalus must be distinguished from other forms of macrocephaly such as subdural hematoma. Sonography, described in Chapter 23, is useful in evaluating subependymal hemorrhage and IVH in high-risk premature infants and in following the infants for possible later development of progressive hydrocephalus (Fig. 106.7). Results correlate well with CT. As a bedside procedure, sonography requires minimal manipulation of critically ill infants. Plain-skull radiographs and skull measurements are useful to follow the course of hydrocephalus in infants and children. Skull x-ray may also demonstrate erosion of the sella turcica or thinning of the inner table, “beaten silver cranium.” Overall, CT and MRI are the best diagnostic aids for all forms of hydrocephalus. In X-linked hydrocephalus, laboratory testing for genetic analysis and counseling can be useful.

In adults, the first test to be performed in suspected hydrocephalus is CT or MRI. Although CT can essentially exclude hydrocephalus, MRI is required for accurate assessment of subtle findings such as transependymal edema. The characteristic feature of hydrocephalus is ventricular enlargement out of proportion to sulcal enlargement. In general, brain atrophy due to degenerative disease or aging involves both “central” (ventricular) and “peripheral” (sulcal) spaces. But judging whether the ventricular enlargement is disproportionate can be difficult and is often fraught with interobserver disagreement. Thus, auxiliary features can be useful in assessing the likelihood of hydrocephalus. Abnormal periventricular white matter, with low attenuation by CT or increased

P.924

T2-weighted or fluid-attenuated inversion recovery (FLAIR) signal by MRI, suggests transependymal fluid flow, consistent with hydrocephalus, but periventricular white matter signal change is nonspecific and may arise from microvascular ischemic disease. Other allied structural changes suggesting hydrocephalus may include “ballooning” of the frontal horns of the ventricles, markedly dilated temporal horns, and bowing and thinning of the corpus callosum. Rapid longitudinal change can be diagnostically useful, but multiple CT or MRI studies over several years may not be available.

FIGURE 106.7 This former 24-week premature infant suffered grade IV IVH and subsequent posthemorrhagic hydrocephalus. **A**, **B**, and **C** are axial T2-weighted MRI images and **D** is a sagittal T1 MRI image 3 months after hemorrhage. **E** and **F** are transcranial ultrasound (US) images (coronal and sagittal, respectively) 1 week after birth.

Confirmatory tests are often sought in hydrocephalus because of these uncertainties in clinical diagnosis and neuroimaging. When NPH is suspected, additional tests may be useful for diagnosis and to determine the likelihood of response to CSF shunting. Lumbar puncture (LP) is indicated to measure CSF pressure and to determine whether it contains blood or signs of chronic inflammatory or infectious disease. The opening pressure on LP in NPH may be in the upper range of normal (14 to 20 cm H₂O), and such relatively higher “normal” pressures may also be indicative of a greater likelihood of benefit from CSF shunting. Continuous monitoring of intraventricular pressure (IVP) may reveal higher pressures than lumbar CSF pressures. Either lumbar or intraventricular monitoring may reveal the presence of Lundberg B waves, mild transient ICP elevations (<10 minutes in duration and generally <20 mm Hg in amplitude).

The response of the patient with suspected NPH to CSF diversion via a ventriculoperitoneal shunt (VPS) is best evaluated with a 48-hour trial of lumbar drainage. This test, which requires hospital admission, essentially mimics the effect of a VPS, with the caveat that the CSF is drained out of the lumbar space (10 mL every 2 hours) rather than the ventricular space. The main outcome measure of the test is subjective and objective observation of gait before, during, and after the procedure. Objective measurement is best made by videotaped recording of the patient prior to and at 24-hour intervals after the tap. In responders, gait typically improves during the first few days, with gradual loss of benefit over the next week after the lumbar drain has been removed. Cognition or urination may also improve, although this is usually less evident and more difficult to assess objectively. Lack of benefit from the tap points to likely lack of likelihood of benefit from CSF shunting. Response of symptoms to a single or repeated large-volume (30 to 40 mL) LPs (the CSF “tap test”) can also be attempted, but this test is not sensitive and may not detect improvement that can result from more sustained CSF diversion.

Radionuclide cisternogram to assess CSF flow in NPH, with a positive finding being delayed appearance of radiotracer in the lateral ventricles, does not appear to be prognostically useful for assessing the likely clinical response to VPS. MRI evidence of an increased aqueductal CSF flow void, or an increased volume of CSF pulsing back and forth in the aqueduct (“aqueductal CSF stroke volume”), are similarly inconsistent and problematic as predictors of shunt-responsive NPH.

TREATMENT

The goal of treatment in hydrocephalic patients is to normalize CSF hydrodynamics. Treatment for every patient with hydrocephalus must be individualized. If the obstruction to flow is between the third and fourth ventricle, an endoscopic fenestration procedure can be attempted. In the case of a tumor obstructing CSF circulation, a surgical resection can be curative. If the cause of the alteration in CSF hydrodynamics is transient, the hydrocephalus may resolve during initial treatment, and temporary external ventricular drainage or serial LPs may be the only intervention needed. However, LP should only be employed in communicating hydrocephalus. In all forms of hydrocephalus, pharmacologic therapy is of limited value; however, there have been favorable reports of acetazolamide 500 mg orally (PO) three times a day (t.i.d.) as an adjunctive therapy to serial LP. Despite all this, most patients with symptomatic hydrocephalus will require CSF diversion through shunt insertion.

Shunt systems establish a connection between a CSF space (ventricular or lumbar) and a drainage cavity (peritoneum, pleural space, right atrium). The components of a CSF shunt include a proximal catheter, reservoir, valve, and distal catheter (Fig. 106.8). The proximal catheter is positioned intraventricularly, ideally away from choroid plexus, and exits through a burr hole to connect with a reservoir in the subcutaneous tissue. CSF may be sampled via this reservoir. A one-way valve regulates CSF flow into the distal catheter, which is subcutaneously tunneled to drain into a body cavity capable of reabsorbing fluid. All ventricular catheters are

P.925

composed of silicone rubber and may vary in terms of length, internal/external diameter, shape, tip configuration, stiffness, and radiopaque markings. The valves now used include differential pressure regulators (static and programmable), flow regulators, siphon-resistive devices, and gravity-activated valves. The valves open or close based on a differential pressure, which is the pressure at the outlet (drainage cavity) minus the pressure at the inlet (intraventricular).

FIGURE 106.8 CSF shunt system. **A:** Cranial segment with reservoir located behind the ear. **B:** Path of shunt tubing in the subcutaneous anterior which ends in the peritoneal space. **C:** Cut-away view of shunt reservoir with one-way valve. Valve pictured is a Codman valve.

There are currently three different valve designs: slit, diaphragm, and spring-loaded ball-in-cone. The slit valve is an older design with a slit in the wall of the distal catheter, which opens with sufficient fluid pressure in the lumen of the catheter. The mechanical properties of the slit (silicone stiffness, wall thickness, length of slit) determine its operating pressure. Diaphragm valves have a flexible membrane, which moves in response to pressure differentials allowing CSF to flow around it. Finally, spring-loaded ball-in-cone valves contain a metallic coiled or flat spring, which applies force to a ball located in a cone-shaped housing. When CSF pressure is high enough, the ball is pressed against the spring, which opens the valve. CSF pressures change with posture (lying, sitting, or standing) and blood flow, which can alter shunt function. There are devices, which help prevent CSF siphoning during posture changes (standing up) by reacting to hydrostatic pressure across the two ends of the catheter and closing the valve. Gravitational devices use metal balls that fall into a cone-shaped seat upon standing, adding resistance to the flow in the shunt pathway equal to the height of a hydrostatic column. When the patient returns to a horizontal position, the balls move away from the fluid pathway, creating little resistance to the flow of CSF. Overdrainage regulatory devices control CSF shunting during postural and vasogenic effects. Flow regulatory devices help maintain a continual flow through the valve at different pressures by varying the size of the valve opening and thus resistance to flow. Another treatment option for hydrocephalus is endoscopic fenestration.

Endoscopic treatment of CSF pathway obstructions can effectively treat obstructive hydrocephalus, especially with aqueductal stenosis, and be used as an adjunct in treating loculated hydrocephalus. In endoscopic third ventriculostomy (ETV), a frontal region burr hole is made after a trajectory is chosen to provide a straight line linking the foramen of Monro and the tuber cinereum, the space between the mammillary bodies posteriorly and the infundibulum of the pituitary gland anteriorly (Fig. 106.9). Stereotactic neuronavigation is commonly used for this. The endoscope is inserted and the foramen of Monro is first visualized in the lateral ventricle. The scope is advanced into the third ventricle and the tuber cinereum is identified. A probe is used to make a fenestration in the floor of the third ventricle and a balloon enlarges this hole. Endoscopic fenestration can also be performed prior to shunt insertion in cases where both foramen of Monro are obstructed. The procedure creates a connection through the septum pellucidum in these cases.

The decision which procedure is best for a patient should be individualized. In particular, treatment for NPH is neurosurgical and involves CSF diversion. ETV is less likely to be a definitive management option for these patients. Shunting is most likely to be efficacious in those patients whose symptoms initially involved only gait and in those with milder cognitive dysfunction. It may also be more effective in those with a history of meningitis, subarachnoid hemorrhage, or other identifiable “secondary” cause of hydrocephalus. More successful outcomes are obtained in patients with positive spinal tap test and if the measured ICP is higher. Patients with severe dementia, marked sulcal atrophy, or those whose first symptom is dementia, with subsequent gait and urinary involvement, are less likely to respond favorably to CSF shunting. This may relate to irreversibility of symptoms or perhaps a greater likelihood of underlying AD.

OUTCOME

Before CSF shunts were available 50 years ago, acute obstructive hydrocephalus used to be a lethal or severely disabling disease. If untreated, progressive infantile hydrocephalus carries a mortality rate as high as 50% at age 1 year and 75% at age 10 years. Treatment greatly improves these figures. For example,

with shunting, the survival rate is at least 50% after age 15 years but with a 15% incidence of mental retardation. If ICH leads to hydrocephalus in

P.926

high-risk premature infants, the outcome is usually related to factors (e.g., asphyxia) other than shunt responsiveness.

FIGURE 106.9 Endoscopic third ventriculostomy surgical approach.

Prognosis is sometimes related to an underlying disease (e.g., cerebral neoplasm). In such cases, treatment of hydrocephalus may be only palliative. However, because management of eventually terminal conditions prolongs life with quality, relief of obstructive hydrocephalus by a shunting procedure is often indicated to prevent acute brain herniation and death. Likewise, in nonneoplastic but serious conditions, such as the Dandy-Walker syndrome or postbasal arachnoiditis, shunting is indicated but eventual outcome depends on the underlying disease.

In adult-onset obstructive (noncommunicating) hydrocephalus, ETV is an established treatment, with success rates of 60% to 80%. Its role in posthemorrhagic and postinflammatory hydrocephalus is debated.

Common complications of this procedure include bleeding from injury to the basilar artery, intraventricular vessels, or brain parenchyma; infection; CSF leak; and hypothalamic injury. A large series published a mortality rate of 1% and permanent morbidity rate of 1.6% for ETV. Complications are more common with shunt procedures.

A shunt complication is any problem that requires repeat surgical intervention. This may occur due to mechanical failure causing improper device function, functional failure secondary to inadequate flow rate despite a working shunt system, or infection. The risk of shunt failure is highest in the first few months postoperatively, with a 25% to 40% failure rate at 1 year. The mean survival time for a shunt system is 5 years.

Complications can arise from any component of the shunt system. Shunt obstruction is the most frequent cause of mechanical failure in patients, with fracture of shunt tubing coming in second (Fig. 106.10).

Occlusion can occur proximally at the ventricular catheter entry point, at the level of the valve, or at the end of the distal catheter. Proximal occlusions can be caused by CSF debris, a collapsed ventricle, or choroid plexus ingrowth. Valve obstruction can be the consequence of debris accumulation, bacterial proliferation, or the development of an immune reaction. Distal occlusion is most common in distal slit catheters due to accumulation of granulomatous nodules. Disconnection or fracture can occur at any fixation point, which causes tension along the catheter course or as a host reaction to foreign material causing degradation and calcification of the catheter. The functional complication of overdrainage occurs more frequently in the older adult population. Overdrainage may cause subdural collections or slit ventricle syndrome, a state of high ICP thought to be secondary to the CSF compartment decrease removing the buffer for volume change in blood or brain tissue. Problems such as migration, misplacement, skin problems, subcutaneous CSF effusions, pediatric craniostenosis, and ventricular loculation occur less frequently. Arachnoiditis and acquired tonsillar herniation are complications unique to lumboperitoneal shunts.

Infection remains an important and potentially devastating cause of shunt failure. In large databases, the infection rate is reported as 5% to 10%. It can be divided by site of infection: meningitis, wound infection, peritonitis, or shunt equipment infection. Symptoms correlate to the site of infection. Most shunt infections occur within 2 months of surgery. In early postoperative infections, *Staphylococcus epidermidis* and *Staphylococcus aureus* are the most common organisms, but other bacteria related to skin flora such as *Propionibacterium acnes* also occur. Gram-negative bacteria are associated with late shunt infections. Treatment requires intravenous antibiotics; ceftriaxone plus vancomycin is an acceptable empiric treatment regimen. The infected hardware must be removed and external ventricular drainage performed until infection clear. Ventriculoatrial shunts may cause bacterial endocarditis as an infectious complication.

Brain Edema and Disorders of Intracranial Pressure

Stephan A. Mayer

INTRODUCTION

Brain edema accompanies a wide variety of pathologic processes. It plays a major role in head injury, stroke, brain tumor, and cerebral infections such as brain abscess, encephalitis, and meningitis. Less common but equally devastating causes of brain edema include fulminant hepatic encephalopathy, hypertensive encephalopathy and posterior reversible encephalopathy syndrome (PRES), hydrocephalus, hypoxic-ischemic injury, hyponatremia, and other disorders associated with acute hypo-osmolality (Table 107.1). Brain edema occurs in many different forms; clearly, it is not a single pathologic or clinical entity.

BRAIN EDEMA

Brain edema is defined as an increase in brain volume caused by an increase in water and sodium content. When well localized or mild in degree, brain edema is associated with little or no clinical evidence of brain dysfunction; however, when severe, it can cause massive intracranial mass effect and potentially fatal brain stem herniation. Because the brain is encased in a rigid cranial vault, focal or generalized brain edema results in intracranial hypertension when it is severe enough to exceed the compensatory mechanisms that modulate intracranial pressure (ICP).

TABLE 107.1 Conditions Characterized by Brain Edema

Intracellular Edema

Cytotoxic

- Cerebral infarction

- Encephalitis

- Meningitis

- Hepatic encephalopathy

MS, multiple sclerosis.

Brain tissue shifting or *herniation* results from the generation of compartmentalized mass effect and ICP gradients within the skull. The major forms of herniation are central, transtentorial (or uncal), subfalcine (or cingulate), and cerebellar (see Fig. 18.5). Brain edema and vascular engorgement are different processes.

Brain engorgement is an increase in the blood volume of the brain caused by obstruction of the cerebral veins and venous sinuses or by arterial vasodilatation, such as that caused by hypercapnia. Hypertension severe enough to overwhelm the brain's capacity to autoregulate and maintain a constant level of cerebral blood flow (CBF) is another common cause of brain engorgement. Brain engorgement is also known as *hyperemia* or *luxury perfusion*.

PATHOBIOLOGY

Brain edema has conventionally been classified into three major categories: *vasogenic*, *cytotoxic*, and *interstitial*. The basic features of these three forms of cerebral edema are summarized in Table 107.2 with regard to pathogenesis, location and composition of the edema

P.930

fluid, and changes in capillary permeability. A newer classification scheme focuses on the primary location of the edema fluid as *intracellular* or *extracellular*. In this scheme, the two main forms of intracellular edema are *cytotoxic* and *osmotic*, and the two main forms of extracellular edema are *vasogenic* and *interstitial* (hydrocephalic). Many causes of brain edema, including hemorrhagic stroke, venous infarction, and trauma, lead to a combination of these different forms of brain edema, and the varying contributions of each form of edema may change over time.

TABLE 107.2 Classification of Brain Edema

	Vasogenic	Cellular	Interstitial
Pathogenesis	Increased capillary permeability	Cellular swelling caused by energy failure or osmotic forces	Increased brain fluid due to block of CSF absorption

Location of edema	Primarily white matter	Gray and white matter	Periventricular white matter
Edema fluid composition	Plasma filtrate including plasma proteins	Increased intracellular water and sodium	CSF
Extracellular fluid volume	Increased	Decreased	Increased
Capillary permeability to large molecules	Increased	Normal	Normal
Clinical disorders	Brain tumor, abscess, infarction (late), trauma, intracerebral hemorrhage, hepatic encephalopathy, high-altitude cerebral edema	Hypoxia-ischemia (early), hypo-osmolality (e.g., hyponatremia), dialysis dysequilibrium syndrome	Obstructive hydrocephalus, idiopathic intracranial hypertension
Therapeutic effects			
Steroids	Beneficial in brain tumor, abscess	Not effective	Not effective
Osmotherapy	Effectiveness limited by blood-brain barrier disruption	Effective	Rarely useful

CSF, cerebrospinal fluid.

Modified from Fishman RA. Brain edema. In: Fishman RA, ed. *Cerebrospinal Fluid in Diseases of the Nervous System*. 2nd ed. Philadelphia: WB Saunders, 1992:116-137.

Vasogenic Edema

Vasogenic edema is a form of extracellular edema characterized by increased permeability of the blood-brain barrier to fluid, solutes, and macromolecules such as the plasma proteins, whose entry is normally limited by tight junctions between the capillary endothelial cells. The increase in permeability is visualized when contrast enhancement is observed with computed tomography (CT) or magnetic resonance imaging (MRI). Increased cerebrospinal fluid (CSF) protein levels are also indicative of increased endothelial permeability. MRI fluid-attenuated inversion recovery (FLAIR) sequences are more sensitive than CT for demonstrating the increases in brain tissue water content and extracellular volume that characterize vasogenic edema.

The biochemical basis of the changes in membrane integrity that underlie vasogenic edema involves the effects of free radicals (i.e., superoxide ions, hydroxyl radicals, singlet oxygen, and nitric oxide) and polyunsaturated fatty acids, most notably arachidonic acid, in the peroxidation of membrane phospholipids. The ability of glucocorticoids to inhibit the release of arachidonic acid from cell membranes may explain their beneficial effects

in vasogenic edema. By contrast, steroids such as dexamethasone have not been shown to be therapeutically useful in the treatment of cytotoxic edema or vasogenic brain edema associated with stroke or trauma.

Vasogenic edema is characteristic of clinical disorders in which a local tissue inflammatory response occurs when angiogenesis is stimulated by neoplasm or when severe hypertension overwhelms the brain's capacity to autoregulate CBF. These disorders include brain tumor, abscess, hemorrhage, infarction with reperfusion, hypertensive encephalopathy, and traumatic contusion. Vasogenic edema related to varying degrees of vasodilation and blood-brain barrier disruption is also seen with acute demyelinating lesions in multiple sclerosis, hepatic or lead encephalopathy, Reye syndrome, and meningitis or encephalitis. Functional manifestations of vasogenic edema include focal neurologic deficits, focal electroencephalogram (EEG) slowing, disturbances of consciousness, and severe intracranial hypertension. In patients with brain tumor, whether primary or metastatic, the clinical signs are often caused more by the surrounding edema than by the tumor mass itself.

Cytotoxic (Osmotic) Edema

Cytotoxic edema is characterized by swelling of all the cellular elements of the brain (neurons, glia, and endothelial cells) with a concomitant reduction in the volume of the extracellular fluid space of the brain. Capillary permeability is usually not affected by osmotic edema (i.e., hyponatremia) or in the early phase of a hypoxic-ischemic insult. The biologic basis of cytotoxic or osmotic brain edema involves astrocytic calcium signaling and activation of aquaporin-4 channels, which are the major influx route for water into the cell. Patients with pure cytotoxic edema have a normal CSF protein, and CT and MRI do not reveal contrast enhancement. MRI diffusion-weighted imaging (DWI) reflects the restricted diffusion of water within swollen cells and is by far the most sensitive method for imaging cytotoxic edema (see also [Chapter 21](#)).

There are several causes of cytotoxic or osmotic edema, the most important being hypoxia-ischemia, acute hypo-osmolality of the plasma relative to the intracellular compartment, and the

P.931

osmotic dysequilibrium syndromes. *Hypoxia* after cardiac arrest or asphyxia results in cerebral energy depletion. The cellular swelling is determined by the appearance of increased intracellular osmoles (especially sodium, lactate, and hydrogen ions) that induce the rapid entry of water into cells. Cytotoxic edema also plays a large role in the tissue swelling that occurs after cerebral infarction. *Acute hypo-osmolality of the plasma* and extracellular fluid is caused by acute dilutional hyponatremia, syndrome of inappropriate secretion of antidiuretic hormone (SIADH), or severe sodium depletion (see also [Chapter 12](#)). *Osmotic dysequilibrium syndromes* occur with hemodialysis or diabetic ketoacidosis, in which excessive brain intracellular solutes result in excessive cellular hydration when the plasma osmolality is rapidly normalized with therapy. In the case of renal failure, the intracellular solutes presumably include a number of organic acids recovered in the dialysis bath. In diabetic ketoacidosis, the intracellular solutes include glucose and ketone bodies; however, there are also unidentified, osmotically active, intracellular solutes termed *idiogenic osmoles* that favor cellular swelling.

Major changes in cerebral function can result from processes that result in cytotoxic edema, including encephalopathy, stupor or coma, ICP elevation, brain stem herniation, asterixis, myoclonus, and focal or generalized seizures. As a general rule, intracellular edema caused by osmotic derangements is much more treatable than cytotoxic edema resulting from hypoxic-ischemic injury because cellular function remains viable. The extent of cellular swelling and neurologic dysfunction resulting from acute hypo-osmolality is directly related with how quickly it develops; chronic states of extreme hypo-osmolality that are reached gradually lead to minimal symptomatology. Hypoxic-ischemic injury causes cytotoxic edema and selective cellular necrosis. If the process progresses to frank tissue infarction, vasogenic edema follows. The delay in visualizing contrast enhancement with CT following an ischemic stroke illustrates that time is needed for defects in endothelial cell permeability to develop.

Interstitial (Hydrocephalic) Edema

Interstitial edema is the third type of edema best characterized in obstructive hydrocephalus, in which the water and sodium content of the periventricular white matter is increased because of the movement of CSF across the ventricular ependymal surface. Obstruction of the CSF outflow results in the transependymal movement of CSF and thereby an absolute increase in the volume of the extracellular fluid of the brain. Interstitial edema thus is strictly periventricular on CT and MRI, with predominance at the anterior and posterior aspects of the lateral ventricles. The composition of interstitial edema is similar to CSF. The clinical manifestations of interstitial edema (dementia, psychomotor slowing, and gait disorder) are often difficult to separate from those seen with normal pressure hydrocephalus in which there is physical traction on the periventricular white matter fiber tracts.

SELECTED CAUSES OF BRAIN EDEMA

Cerebral Infarction

Most patients with arterial occlusion initially have cytotoxic edema followed by vasogenic edema, which are together termed *ischemic brain edema*. The cytotoxic phase takes place over minutes to hours and may be reversible. At this point, DWI may show dramatic changes well before evidence of completed tissue infarction can be demonstrated on MRI FLAIR sequences or by CT. Although osmotic or vasogenic edema can also be DWI positive, a phenomenon called *T2 shine through*, cytotoxic edema can be further differentiated from these causes on MRI because it is always associated with a reduction (low signal) in the apparent diffusion coefficient (ADC) of water. The vasogenic phase of infarction takes place over hours to days as the tissue swells; in many cases, spontaneous vessel recanalization may occur and accelerate this process. A patchy and heterogenous pattern of contrast enhancement on CT or MRI at this point is characteristic. Despite the theoretical concern that osmotic therapy with mannitol or hypertonic saline may aggravate tissue edema because these osmotically active substances may leak through disrupted endothelial cells into the infarcted brain tissue, clinical experience indicates that these treatments can effectively reverse the early stages of brain stem herniation.

Hemicraniectomy is the definitive treatment of choice for younger patients (younger than 60 years) who are at risk for brain stem herniation due to complete infarction of the middle cerebral artery territory (see also [Chapter 35](#)).

Intracerebral Hemorrhage

Perihematomal brain edema is a form of vasogenic edema that progressively increases over the first week after intracerebral hemorrhage (ICH, see also [Chapter 38](#)). Symptomatic mass effect related to edema formation is the major cause of delayed neurologic deterioration after ICH. Perihematomal edema is caused by the local infiltration of plasma rich in thrombin and other coagulation proteins into the surrounding brain tissue. The thrombin then triggers a unique form of *neuro-hemo-inflammation*, stimulating the surrounding tissue to produce prostaglandins, complement, leukotrienes, and other inflammatory mediators that promote apoptotic cell death and blood-brain barrier disruption. Dexamethasone is not effective for treating perihematomal edema [**Level 1**].¹ By contrast, large doses of 20% mannitol (1.4 g/kg) have been shown to effectively reduce ICP and reverse clinical brain stem herniation in uncontrolled cohort studies.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage (SAH, see also [Chapter 39](#)) can cause global cerebral edema that typically occurs at onset in poor-grade patients, as well as a variety of forms of focal edema related to focal hematoma formation, cerebral infarction, brain retraction injury, and other causes. The global brain edema is mostly vasogenic in nature ([Fig. 107.1](#)). The pathophysiology is thought to reflect

followed by reperfusion injury of the brain, with reflex hypertension in the setting of impaired autoregulation causing vascular engorgement. Global cerebral edema on CT affects 20% of patients and is associated with increased mortality and poor functional and cognitive outcome after SAH. Placement of an external ventricular drain is the first step in attaining ICP control; hypertonic saline and hypothermia are promising but untested potential interventions for mitigating further tissue damage.

FIGURE 107.1 Global cerebral edema in a patient with subarachnoid hemorrhage. Day 5: CT shows global swelling of the brain with effacement of the quadrigeminal cisterns. A focus of hemorrhage with surrounding edema is also evident in the left inferior frontal lobe. The patient was undergoing induced hypertension, which later was felt to be exacerbating brain edema. Day 14: Resolution of global cerebral edema is evident.

Venous Infarction

Venous infarction results from occlusion of the cerebral venous and dural sinuses usually in the setting of dural sinus thrombosis (Chapter 40) or as a complication of a neurosurgical procedure. The result is tissue hypoperfusion with congestion and engorgement of the microcirculation, which results in a combination of cytotoxic and prominent vasogenic edema. Imaging shows extensive mass effect, patchy enhancement, and secondary hemorrhagic transformation of the infarct in most cases. In addition to standard measures to control ICP, treatment is directed at preventing clot propagation within the venous system with heparin anticoagulation. Interventional approaches to restore venous flow with local thrombolytic therapy can also be attempted as a heroic measure.

Cardiac Arrest

After cardiac arrest (Chapter 37), massive swelling of the brain that develops over the next several days is an ominous sign. Patients are usually in deep coma, and recovery is rare. Standard measures to treat brain edema at that point are usually pointless because the extent of cellular necrosis throughout the brain is very severe.

Traumatic Brain Injury

Traumatic brain injury (TBI) can result in both focal and global brain edema (see also [Chapter 46](#)). The global

form of edema is largely vasogenic in nature and is felt to reflect neurogenic vascular engorgement and hyperemia in the setting of autoregulatory failure and dysfunction of vasomotor centers in the brain stem. In some cases, the patients present with a lucid interval after experiencing a concussion, followed an hour later by rapid progression to coma, as the brain massively swells. *Second impact syndrome* refers to rapid and catastrophic swelling of the brain that occurs when a person experiences a second concussion before symptoms of an earlier one have resolved. Standard measures to control ICP, with emphasis on hyperventilation and blood pressure (BP) control to reduce cerebral blood volume, are effective. Focal brain edema can result from contusional injury, brain compression from epidural or subdural hematoma, thrombin-mediated perihematomal edema, or cerebral infarction when brain herniation results in compression of the anterior or posterior cerebral arteries (see also [Chapter 46](#)). Steroids are not effective, and in one study, high-dose intravenous (IV) methylprednisolone (Solu-Medrol) was shown to increase mortality, which was presumably due to immunosuppression, hyperglycemia, increased muscle catabolism, and impaired wound healing [**Level 1**].²

Brain Tumors

Brain neoplasms (see also Section 13 and [Chapter 145](#)) cause a pure form of vasogenic brain edema, which is caused by the local release of cytokines, angiogenic factors, and other proinflammatory proteins that result in blood-brain barrier disruption. Malignant and highly vascular tumors as a rule cause much more local edema of the surrounding brain tissue than do benign neoplasms such as meningiomas, although exceptions can occur. The edema characteristically tracks along the white matter pathways on MRI or CT. Vasogenic edema associated with brain neoplasm is highly responsive to glucocorticoid therapy. In addition to standard measures to control ICP, *dexamethasone* is the treatment of choice; a typical starting dose is 4 to 10 mg every 6 hours.

Fulminant Hepatic Encephalopathy

Acute fulminant liver failure from any cause can result in hepatic encephalopathy producing clouding of consciousness with prominent asterixis (see also [Chapter 119](#)). As the severity of neurologic dysfunction progresses from lethargy to stupor to coma, massive swelling of the brain can occur resulting in dangerous elevations of ICP and brain stem herniation. The cause of the brain edema is poorly understood, and its onset can be unpredictable. Initially, the edema is primarily vasogenic with a large component of vascular engorgement. Ammonia (NH₃) and other substances normally metabolized by the liver cross the blood-brain barrier where they cause astrocytes to swell and disrupt endothelial tight junctions. Treatment relies on standard measures to control ICP; lactulose does not control brain edema when it is present. Optimal management requires placement of an ICP monitor after meticulous correction of the coagulopathy that usually is present. Transcranial Doppler sonography and jugular venous oxygen saturation monitoring demonstrate findings consistent with excessive hyperemia and can be used as end points to ensure that hyperventilation and BP control are not excessive. Mild to moderate hypothermia (33°C) has been shown to be effective in addition to more standard measures for controlling ICP, but liver transplantation is the only known definitive treatment. If the process is uncontrolled, herniation and brain death are a common outcome.

Reye Syndrome

Reye syndrome is a form of acute hepatitis with prominent fatty changes resulting from viral infection and exposure to aspirin that can occur in children. It is often accompanied by an encephalopathy characterized by progressive stupor and coma and a combination of cytotoxic and, to a lesser extent, vasogenic brain edema. Uncontrolled intracranial hypertension can lead to fatal brain stem herniation, and the pathogenesis is obscure. The disease is rarely seen today because of restrictions of the use of aspirin in pediatric patients.

Brain Abscess

Brain abscesses ([Chapter 62](#)) caused by localized infection with bacteria, toxoplasmosis, cysticercosis, fungal

infection, or other causes result in a pure form of vasogenic edema very similar to that produced by brain tumors. Local release of various inflammatory mediators results in increased vascular permeability. As is the case with neoplasms, the edema is highly responsive to dexamethasone 6 mg every 6 hours.

Viral Encephalitis

MRI DWI sequences in patients with viral encephalitis (Chapter 66) reveal cytotoxic edema in the limbic cortex, including the medial temporal and inferior frontal lobes, insula, and cingulate gyrus without mass effect. In milder cases, FLAIR and CT may be negative and the lesions are only apparent on DWI. In rare cases, viral encephalitis can result in a more fulminant pattern of generalized cytotoxic and vasogenic edema that requires ICP monitoring and treatment.

P.933

Meningitis

Severe generalized brain edema can occur with acute purulent bacterial or tuberculous meningitis (see also Chapter 61). Such edema is caused by the inflammatory response generated by infiltrating polymorphonuclear white blood cells (WBCs) and has been termed *granulocytic brain edema*. Vasogenic edema predominates, but interstitial edema may also occur as the result of communicating hydrocephalus. Dexamethasone 10 mg every 6 hours for 4 days diminishes the inflammatory response and has been shown to improve survival and reduce cranial nerve injury in adults and children with bacterial meningitis regardless of whether brain edema is evident on imaging [**Level 1**].³ A similar steroid regimen is also commonly used to reduce the inflammatory response in patients with tuberculous meningitis. Placement of an external ventricular drain may be required in cases with a significant component of hydrocephalus and is usually sufficient to control ICP.

Posterior Reversible Encephalopathy Syndrome

PRES is a clinical syndrome characterized by neurologic dysfunction and a characteristic pattern of brain edema that predominates in the white matter of the parietal and occipital lobes (Fig. 107.2). The edema is primarily vasogenic with cerebral perfusion pressure (CPP) breakthrough and disruption of the blood-brain barrier playing a large role in the pathogenesis of the disorder (see also Chapter 43). FLAIR imaging is highly sensitive and often reveals scattered microbleeds on gradient echo (T2*) sequences. A wide variety of very different pathologic entities can cause PRES, including hypertensive encephalopathy resulting from poorly controlled essential hypertension, eclampsia, a variety of immunosuppressive agents, and end-stage renal disease (see also Chapter 43). Clinical manifestations start with headache, confusion, visual disturbances (including cortical blindness in some cases), and seizures and can progress to stupor or coma. Massive swelling of the brain that requires ICP monitoring and therapy is unusual but can occur. Treatment is directed at removing any possible triggering agent and BP control with treatment for seizures and elevated ICP as needed. Continuous infusion antihypertensive agents that allow precise BP control, such as labetalol and nicardipine, are preferred. Magnesium sulfate 4-g bolus followed by 10 to 12 g/h has been shown to improve outcome in women with eclampsia [**Level 1**].⁴

High-Altitude Cerebral Edema

This condition is a form of global and purely vasogenic cerebral edema caused by excessive cerebral vasodilation triggered by hypoxia in high altitudes. In addition to vascular engorgement, endothelial disruption results in fluid leakage into the brain. The condition can be rapidly fatal. MRI shows posterior white matter edema with a predilection for the splenium of the corpus callosum. Immediate descent (600 to 1,200 m), acetazolamide 500 mg every 6 hours, and delivery of supplemental oxygen are the treatments of choice.

FIGURE 107.2 PRES. FLAIR images show abnormally increased signal (*arrows*) in the occipital and parietal white matter.

Postendarterectomy Hyperperfusion Syndrome

This unusual complication of carotid endarterectomy or stenting occurs in patients who have long-standing high-grade carotid stenosis. Immediately after revascularization, the cerebral circulation remains maximally dilated and is unable to recover the capacity to autoregulate. The result is a pulsatile headache; more severe cases involve focal neurologic defects related to vasogenic edema in the downstream anterior circulation. In some cases, hemorrhagic conversion occurs. Meticulous BP control can minimize the extent of injury, and the syndrome typically resolves over several days.

INTRACRANIAL PRESSURE MANAGEMENT

General Approach

As outlined earlier, the optimal therapy of brain edema depends on the cause. A patent airway, maintenance of an adequate BP, and the avoidance of hypoxia are fundamental requirements in the care of these patients. The administration of appropriate parenteral fluids to meet the needs of patients is also essential. Administration of salt-free hypotonic fluids to patients with cerebral edema should be strictly avoided because serum hypo-osmolality increases brain swelling. As a general rule, inflammatory processes that predominantly involve vasogenic edema respond to dexamethasone (with the exception of vasogenic edema in patients with stroke or trauma) and measures to minimize brain engorgement and cerebral blood volume, including tight BP control and hyperventilation. By contrast, cytotoxic or cellular edema resulting from fluid and solute overload on the intracellular compartment responds best to osmotic therapy.

Neurosurgical decompression of the cranial vault can be lifesaving and should always be the *first and last* consideration when patients are at risk for secondary deterioration due to compartmentalized intracranial mass effect. Surgical options include placement of an external ventricular or lumbar drain for drainage, craniotomy to remove an intracranial mass lesion, or as a last resort, hemicraniectomy with duraplasty to definitively decompress the cranial vault ([Fig. 107.3](#)). In all comatose patients where (1) intracranial hypertension elevation is suspected, (2) imaging shows mass effect due to brain edema, and (3) aggressive intensive care unit (ICU)

care is indicated, placement of an ICP monitor is essential. Empiric treatment of suspected ICP should be performed in the short term but only when ICP and CPP are actually being measured can the problem be optimally treated.

In a monitored patient for whom all current neurosurgical options have been exhausted, medical management of elevated ICP is best performed according to an algorithm that emphasizes the logical stepwise application of various interventions (Table 107.3). In addition to the avoidance of hypotension and hypoxia, fluid resuscitation with isotonic crystalloids, seizure prophylaxis and fever control, and head elevation to 30 degrees lowers ICP by reducing jugular venous pressure and should be performed as a general measure in all patients (Table 107.4). Subsequent first-line pharmacologic treatment of brain edema resulting in increased ICP should then progress through the steps outlined in Table 107.3. In this

P.934

algorithm, sedation is the fundamental first step to controlling ICP after rescue neurosurgical intervention has been performed. Sedation lowers thoracic and jugular venous pressure and can calm arterial hypertension and autonomic instability. CPP, calculated as mean arterial pressure minus ICP, can aggravate intracranial hypertension when it is either extremely low or extremely high (Fig. 107.4). Osmotherapy in the form of 20% mannitol or 23.4% hypertonic saline solution is the mainstay intervention for reducing ICP in critical “brain code” situations. Mannitol should be hung wide open, and 30 mL of 23.4% saline should be pushed through a central venous line over 5 minutes. Doses can be repeated as often as every 30 minutes as needed. Hyperventilation often does not have a sustained effect and should be administered in bursts, typically in tandem with bolus osmotherapy in response to ICP crisis.

FIGURE 107.3 Decompressive hemicraniectomy in a 58-year-old man with left putamen ICH. On day 3, he experienced brain stem herniation with bilateral motor posturing and a fixed and dilated left pupil despite aggressive medical intervention. He underwent urgent hemicraniectomy and duraplasty with restoration of

midline positioning of the brain evident on day 11. The day 29 image shows normalization of brain morphology after replacement of the bone flap. The patient made a near-complete recovery.

TABLE 107.3 Initial Stepwise Management Protocol for Intracranial Pressure Crisis (>20 mm Hg for >10 Minutes) in a Monitored Patient

1. **Neurosurgical intervention** including ventricular drainage or craniotomy

2. **Sedate** to attain a motionless, quiet state with fentanyl and propofol

3. **Optimize cerebral perfusion pressure** (generally 70-100 mm Hg) to minimize excessive vasodilation from low hypotension or perfusion pressure breakthrough

4. **Bolus osmotherapy** with mannitol 0.5-1.51 g/kg IV or 30 mL 23.4% hypertonic saline repeated up to every 30 min as needed

5. **Hyperventilation** to PCO₂ levels of 30-34 mm Hg

6. **Hypothermia** with external or catheter-based cooling to 35°C

See text for details.

IV, intravenous.

TABLE 107.4 Baseline Treatment Measures for Patients at Risk for Intracranial Pressure

- Avoid hypotension and hypoxia.

- Administer only isotonic fluids (avoid all sources of free water).

- Head elevation to 30 degrees

- Control fever.

- Consider seizure prophylaxis.

In patients with ICP refractory to the aforementioned measures, consideration should be given to proceeding with decompressive hemicraniectomy. If this is not feasible or desired, the final step in first-line ICP intervention is to induce mild hypothermia to a target temperature of 35°C.

As outlined in [Figure 107.5](#), escalation beyond the first line of medical intervention for refractory ICP becomes

more nuanced and should be tailored to the specific clinical situation and available resources and expertise. These second-tier interventions for super-refractory ICP crisis are extensions of each step of first-line intervention. Decompressive hemicraniectomy should be reconsidered. CPP can be further optimized with invasive brain multimodality monitoring with the intention of normalizing CBF or brain tissue oxygen tension (PbtO₂) (see [Chapter 33](#)). After a patient is sedated with conventional agents such as propofol, paralysis or barbiturate anesthesia with pentobarbital can be considered. Bolus osmotherapy can be escalated with continued good effect on ICP to serum osmolality levels far above 320 mOsm/L. When brain hyperemia is considered an important contributing factor, aggressive hyperventilation to PCO₂ levels far below 30 mm Hg can be safely attained with concurrent monitoring of PbtO₂, CBF, or jugular venous oxygen saturation (normally 70% to 90%). Finally, hypothermia can be pushed to 33°C. Temperature levels below 30°C are thought to cause an unacceptable risk of arrhythmia and other cardiac complications.

SPECIFIC TREATMENTS FOR BRAIN EDEMA

Glucocorticoids

Glucocorticoids dramatically and rapidly (in hours) begin to reduce the focal and general signs of brain edema around tumors and abscesses but are not effective for treating the edema that results from cerebral infarction, ICH, SAH, or TBI. The major mechanism explaining the usefulness in vasogenic brain edema is a direct normalizing effect on endothelial cell function and permeability when the process is triggered by local release of cytokines, angiogenic factors, vascular adhesion molecules, and other inflammatory mediators.

Long-acting, high-potency glucocorticoids are most widely used for the treatment of vasogenic edema related to tumor or infection. The usual dosage of dexamethasone is a starting dose of 10 mg followed by 4 to 6 mg administered four times a day thereafter—a dose equivalent in potency to more than 400 mg of cortisol daily. These large doses are about 20 times the normal rate of human endogenous cortisol production. There are no convincing data, clinical or experimental, that glucocorticoids have beneficial effects for the treatment of cytotoxic or osmotic cellular edema regardless of cause.

P.935

Steroids are also commonly used by neurosurgeons to enhance brain compliance and relaxation during craniotomy despite little evidence of its effectiveness. Steroids may be useful in the management of less common conditions characterized by an inflammatory CSF and brain edema, such as postinfectious acute disseminated encephalomyelitis (ADEM), CNS vasculitis, and meningeal sarcoidosis.

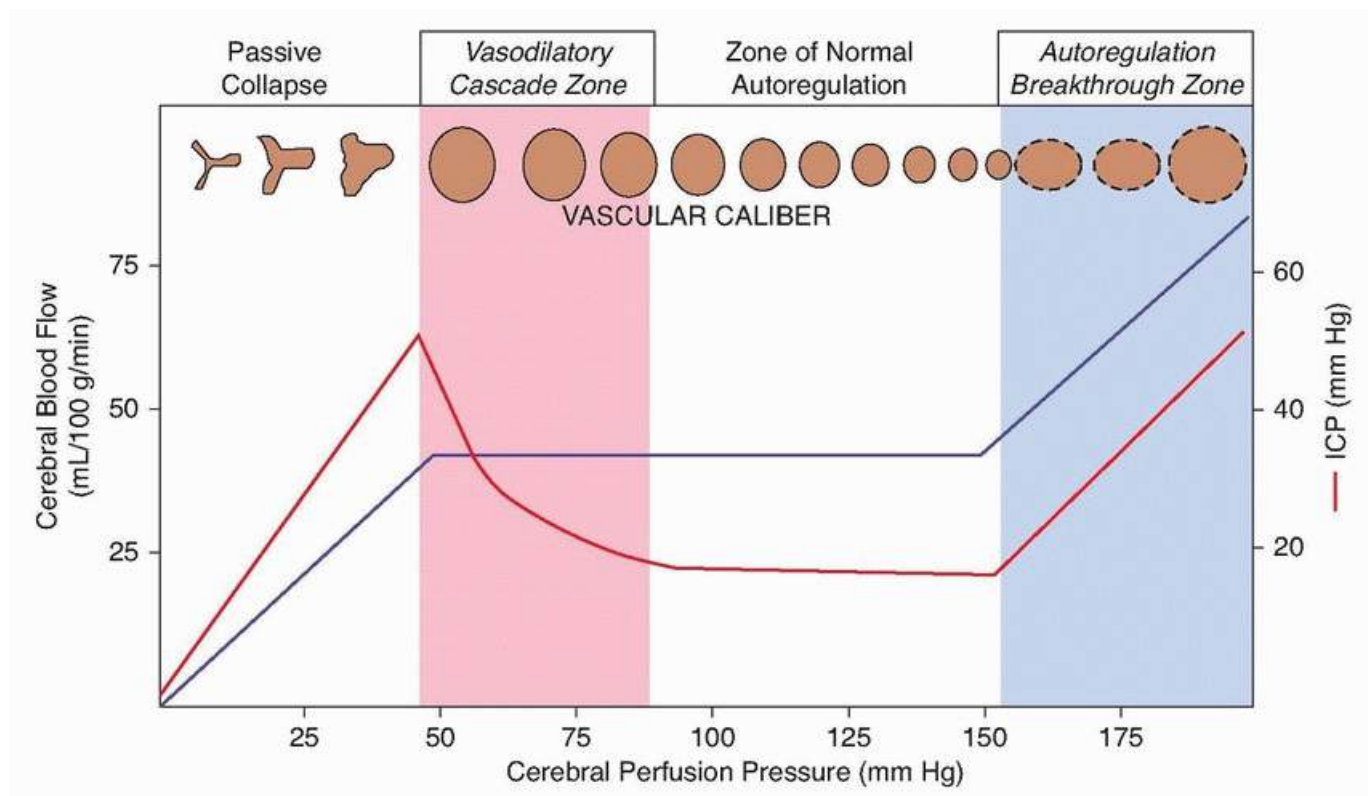

FIGURE 107.4 Cerebral autoregulation curve (*blue line*) and relationship between CPP and ICP in states of abnormal intracranial compliance (*red line*). Under normal circumstances, CBF is held constant across a wide range of CPP (50 to 150 mm Hg), and changes in vessel caliber have no effect on ICP. In disease states with reduced intracranial compliance, ICP can become elevated when CPP is low due to autoregulatory vasodilation and increased CBV (vasodilatory cascade physiology) or when CPP is too high due to passive increases in CBV due to increased hydrostatic pressure and hyperemia (autoregulation breakthrough physiology).

Mannitol

IV mannitol is the most widely used solute for the treatment of intracranial hypertension associated with brain edema. Given in a 20% solution at a dose of 0.25 to 1.5 g/kg, mannitol dehydrates brain tissue and mediates an ICP-lowering effect through several mechanisms. First, it is an osmotic diuretic that creates a concentration gradient across the blood-brain barrier and pulls free water from the brain. This decreases volume of the brain parenchyma and lowers ICP. Second, mannitol increases CPP through plasma expansion and promotes vasoconstriction and cerebral blood volume reduction by decreasing blood viscosity and improving CBF. Finally, mannitol is excreted in the urine resulting in a net clearance of free water and increased serum osmolality.

FIGURE 107.5 Stepwise ICP management protocol. Escalation of ICP therapy should advance through first-line interventions to ensure that vital steps are not skipped. The need for repeated bolus osmotherapy, burst hyperventilation, or induction of hypothermia defines ICP crisis. At the level of superrefractory ICP crisis, second-line interventions can be added based on the clinical situation and available resources and expertise. RASS, Richmond Agitation Sedation Scale; MMM, multimodality monitoring.

When given as a bolus infusion, mannitol can lower ICP within as little as 10 to 30 minutes. Dosing may be repeated as frequently

P.936

as once an hour when ICP is elevated. Complications of mannitol therapy include dehydration, electrolyte depletion, and osmotically mediated renal failure. A widened gap of more than 10 mOsm/L between the measured and calculated osmolality may indicate incomplete mannitol clearance by the kidneys and an increased risk of renal tubular necrosis. With repeated bolus, dosing a “rebound effect” with successive increases in ICP may occur. Although it is sometimes stated that mannitol loses its efficacy when serum osmolality exceeds 320 mOsm/L, there is scant evidence to support this contention.

Hypertonic Saline

Hypertonic saline has an osmotic effect on the brain because of its high tonicity and ability to effectively remain outside the blood-brain barrier. Numerous animal studies have suggested that fluid resuscitation with hypertonic saline after hemorrhagic shock prevents the ICP increase that follows resuscitation with isotonic fluids. Hypertonic saline solutions may have favorable effects on CBF by producing a boost in CPP and via local effects on the cerebral microvasculature. A clinical trial comparing hypertonic saline with isotonic crystalloid for TBI patients, however, failed to show any benefit. Infusion of a bolus dose of 3%, 7%, 10%, or 23% hypertonic saline

solution results in maximal ICP reduction between 30 and 120 minutes accompanied by a surge in CPP. In the United States, use of 30-mL “bullets” of 23.4% saline has become the most popular form of hypertonic saline bolus osmotherapy. Common complications of hypertonic saline administration include volume overload, pulmonary edema, and electrolyte depletion.

IDIOPATHIC INTRACRANIAL HYPERTENSION

Idiopathic intracranial hypertension (IIH) describes a heterogeneous group of disorders characterized by increased ICP when intracranial mass lesions, obstructive hydrocephalus, intracranial infection, and hypertensive encephalopathy have been excluded. IIH is also termed *pseudotumor cerebri*. The best documented risk factors for IIH are obesity, hypervitaminosis A, steroid withdrawal, and female gender. The term *benign* has been used because spontaneous recovery is characteristic, but the condition is far from harmless: Serious threats to vision make accurate diagnosis and therapeutic intervention a necessity.

CAUSES OF IDIOPATHIC INTRACRANIAL HYPERTENSION

Endocrine and Metabolic Disorders

IIH is most commonly seen in healthy women with a history of menstrual dysfunction. Frequently, the women are moderately or markedly overweight (without evidence of alveolar hypoventilation). Menstrual irregularity or amenorrhea is common; galactorrhea is an unusual symptom. The histories often emphasize excessive premenstrual weight gain. Endocrine studies have not revealed specific abnormalities of urinary gonadotropins or estrogens, and the pathogenesis is unknown. IIH has a complex relationship to adrenal hormones. Rarely, IIH is a complication of Addison disease or Cushing disease. Improvement occurs after restoration of a normal adrenal state; the mechanism in either circumstance is unknown.

IIH has also occurred in patients treated with corticosteroids for prolonged periods. Many of the patients had allergic skin disorders or asthma during childhood; IIH generally occurs when the steroid dosage is reduced but evidence of hyperadrenalism persisted. Hypoparathyroidism may also present with increased ICP; hypocalcemic seizures or cerebral calcifications may further complicate the clinical picture. IIH has also been reported in women taking oral progestational drugs.

Drugs and Toxins

IIH has been reported in otherwise healthy adolescents who are taking large doses of vitamin A for the treatment of acne. Oral doses as low as 25,000 IU daily may cause headache and papilledema with rapid improvement after cessation of the therapy. The syndrome is said to have occurred in Arctic explorers who consumed polar bear liver, a great source of vitamin A. Some cases of IIH that are manifested by bulging fontanel and papilledema have been reported in children given tetracycline. The mechanisms involved are obscure. Spontaneous, rapid recovery occurs when the drugs are stopped. Amiodarone and lithium carbonate, as well as the insecticide chlordecone, have also been reported to cause IIH.

Hematologic and Connective Tissue Disorders

Papilledema and increased ICP have been attributed to severe iron deficiency anemia with striking improvement after treatment of the anemia. Presumably, the mechanism partly reflects the marked increase in CBF that accompanies profound anemia. IIH has also been observed as a manifestation of systemic lupus erythematosus.

Pulmonary Encephalopathy

IIH may be a major complication of chronic, hypoxic hypercapnia caused by paralytic states such as muscular dystrophy and cervical myelopathy; it may also be a complication of obstructive pulmonary disease and obstructive sleep apnea. There is a chronic increase of CBF because of hypoxia and carbon dioxide retention.

Patients usually appear mentally dull and encephalopathic and thus differ from most patients with IIH.

Spinal Cord Diseases

IIH rarely occurs with tumors of the spinal cord or cauda equina or with polyneuritis. Papilledema and headache disappear with treatment of the spinal lesion or regression of the polyneuropathy. The mechanism may involve the effects of an elevated CSF protein on CSF absorption at the arachnoid villi in both cranial and spinal subarachnoid spaces. Occurrence of this syndrome, however, does not correlate with the degree of protein elevation.

PATHOBIOLOGY

Several mechanisms have been considered as possible explanations for the pathophysiology of IIH. These include an increased rate of CSF formation, a sustained increase in intracranial venous pressure, a decreased rate of CSF absorption by arachnoid villi apart from venous occlusive disease, and an increase in brain volume caused by an increase in blood volume or extravascular fluid volume simulating a form of brain edema.

No data are available regarding the rate of CSF formation, and the only condition in which increased CSF formation has been demonstrated is choroid plexus papilloma. Increased CSF production might explain the pathophysiology in some of the diverse conditions associated with IIH, but this mechanism remains unproven. A sustained increase in intracranial venous pressure associated with decreased CSF absorption has similarly not been documented in IIH. The currently most favored explanation for IIH is decreased CSF absorption (in the absence of venous occlusion) resulting from altered function of the arachnoid villi. For reasons

P.937

that are unclear, however, hydrocephalus does not occur in IIH. On the contrary, very often, the brain appears swollen and the ventricles are smaller than normal. It has been hypothesized that IIH might have caused by an increase in brain volume secondary to an increase in extracellular fluid volume. An increase in brain volume would be expected if the extracellular space of the brain were expanded; this might occur if there was a defect in the ability to absorb brain interstitial fluid.

Any theory of the pathogenesis of IIH must be consonant with the rapid therapeutic response of IIH to shunting of CSF by an implanted lumbar peritoneal shunt. Impaired CSF absorption or increased CSF formation would explain the occurrence of IIH in most cases; however, the limited data available, currently, do not allow any firm conclusions.

One of the more common forms of IIH appears in otherwise healthy persons in the absence of any of the aforementioned etiologic factors. Both genders are affected, women more than men, and occurrence is most often in patients between 10 and 50 years of age.

CLINICAL FEATURES

Typically, the first symptoms are headache and impaired vision. The headache may be worse on awakening and aggravated by coughing and straining. It is often mild or may be entirely absent. In some cases, pulse-synchronous tinnitus occurs. The most common ocular complaint is visual blurring, a manifestation of papilledema. Some patients complain of brief, fleeting moments of dimming or complete loss of vision occurring many times during the day, at times accentuated or precipitated by coughing and straining. This ominous symptom indicates that vision is in jeopardy. Visual loss may be minimal despite severe chronic papilledema, including retinal hemorrhages; however, blindness occasionally develops rapidly (i.e., <24 hours). Visual field testing characteristically shows enlargement of the blind spots and may show constriction of the peripheral fields and central or paracentral scotoma. Diplopia caused by unilateral or bilateral sixth nerve palsy may develop as a result of increased ICP. The neurologic examination is otherwise normal. A major clinical point is that patients with IIH usually look well; their apparent well-being belies the ominous appearance of the papilledema. Although

the disorder most often lasts for months, it may persist for years without serious sequelae. Remissions may be followed by one or more recurrences in 5% to 10% of cases. In some patients, IIH may be responsible for development of the *empty sella syndrome*, in which radiographic image showing enlargement of the sella turcica simulates the appearance of a pituitary tumor. CT reveals that the enlarged sella is filled with CSF flowing from a defect of its diaphragm.

DIAGNOSIS

The patient with headache and papilledema without other neurologic signs suggest the diagnosis of IIH. Although the diagnosis of IIH may be suspected by the appearance of well-being and a history of some of the associated etiologic features listed previously, the diagnosis is essentially one of exclusion and depends on ruling out the more common structural causes of increased ICP. Brain tumor, particularly when located in relatively “silent” areas such as the frontal lobes or right temporal lobe or when obstructing the ventricular system, may be manifested only by headache and papilledema. Patients with chronic subdural hematoma, without a history of significant trauma, may have the same symptoms. Other important conditions to exclude include viral meningitis and other CNS infections and dural sinus thrombosis.

Diagnostic evaluation depends on MRI with venography and lumbar puncture. Lumbar puncture should be deferred until imaging indicates that the perimesencephalic cisterns are open. Diagnostic lumbar puncture is mandatory to establish the diagnosis of IIH. In obesity, the normal upper limit of CSF pressure is 250 mm Hg. In IIH, the CSF pressure is elevated, usually between 250 and 600 mm Hg, but the fluid is otherwise normal. The protein content is often in the lower range of normal, and lumbar CSF protein levels of 10 to 20 mg/dL are common. CSF protein content greater than 50 mg/dL, decreased CSF glucose, or increased cell count throws doubt on the diagnosis of IIH and suggests other disease conditions.

Pseudopapilledema may be a source of diagnostic confusion. In this developmental anomaly of the fundus, the ophthalmic appearance may be indistinguishable from true papilledema; there is elevation of the optic disc, although exudates and hemorrhages are absent. Visual acuity is normal, but visual fields may show enlargement of the blind spots. The unchanging appearance of the fundus in subsequent examinations favors the diagnosis of pseudopapilledema, as does the finding of normal CSF pressure on lumbar puncture. Optic neuritis is differentiated from IIH by visual loss and normal CSF pressure.

TREATMENT

The common form of IIH in patients with menstrual disorders and obesity requires individualized management. This syndrome is self-limited in most cases, and after some weeks or months, spontaneous remissions occur, making evaluation of therapy outcomes difficult. Recurrent episodes have been noted in about 5% to 10% of patients, and the illness seldom lasts for years. In the extremely obese patient, weight reduction is recommended. Daily lumbar puncture was used in the past to lower CSF pressure to normal levels by removing sufficient fluid; 15 to 30 mL of fluid may be removed, but the value of this procedure is dubious. A CSF shunt procedure, such as a lumboperitoneal shunt, is useful in patients with intractable headache and progressive visual impairment. It may dramatically relieve symptoms. Optic nerve decompression has its advocates as the procedure of choice to preserve vision.

Acetazolamide 500 mg two to four times a day has been used because this carbonic anhydrase inhibitor reduces CSF formation. The Neuro-Ophthalmology Research Disease Investigator Consortium (NORDIC) trial has demonstrated that acetazolamide 1,000 mg titrated upward, along with a weight reduction diet, results in modest improvement in visual field function for patients with mild pseudotumor cerebri [**Level 1**].⁵ Hypertonic IV solutions (20% mannitol) to lower ICP may be used in acute situations when there is rapidly

failing vision and surgical intervention is awaited. When the pseudotumor syndrome is a manifestation of hypoadrenalism or hypoparathyroidism, replacement therapy is indicated. Vitamin A intoxication disappears when administration of the vitamin is stopped.

SPONTANEOUS INTRACRANIAL HYPOTENSION

Spontaneous intracranial hypotension (SIH) was first described in 1938. The cardinal symptom is postural headache, which is markedly exacerbated when upright and relieved by lying down. In more severe cases, downward traction on the cranial nerves can cause diplopia, visual field defects, tinnitus, and hearing loss. The symptoms are often self-limited, resolving spontaneously within several weeks to months. The peak age at onset is 40 years, and women are affected more than men.

P.938

FIGURE 107.6 Sagging brain in spontaneous intracranial hypotension. **A:** Gadolinium-enhanced T1-weighted sagittal MRI prior to lumbar epidural blood patch demonstrates enhancement of the dura, venous engorgement, displacement of the pons and cerebellum below the level of the prepontine cistern (*black solid arrows*), and inferior displacement of the optic chiasm and third ventricle (*curved white arrow*). Enhancement of the ventral cervical dura is also present (*long white arrow*). **B:** Gadolinium-enhanced T1-weighted images 5 days after large-volume (20 mL) lumbar epidural blood patch showing resolution of dural enhancement and restoration of the cisterns with elevation of the pons, tonsils, and optic chiasm. (From Fishman RA, Dillon WP. Dural enhancement and cerebral displacement secondary to intracranial hypotension. *Neurology*. 1993;43:609-610, with permission.)

SIH is most often caused by the formation of CSF leak via dural fistulas along a thoracic spinal nerve root. Such defects commonly reflect rupture of arachnoid (Tarlov) cyst that occurs without trauma. These lesions can be identified on contrast CT myelography. Cervical subarachnoid injection (C2 or C3 level) is often preferred over lumbar injection because it is usually more proximate to the CSF fistulae, which may be intracranial, cervical, or thoracic and less likely lumbosacral. Delayed CT myelography can often pinpoint the site of contrast leak and CSF leakage.

Lumbar puncture typically reveals normal CSF with a low opening pressure (<10 cm H₂O). Brain MRI in SIH commonly reveals striking, diffuse dural enhancement, which reflects meningeal venous engorgement due to a compensatory increase in cerebral venous blood volume in response to a reduction in CSF volume. MRI may also reveal subdural fluid collections, pituitary engorgement, and sagging of the brain, which manifests as

effacement of the quadrigeminal cisterns, flattening of the optic chiasm, and displacement of the pons against the clivus and cerebellar tonsils below the foramen magnum. These changes resolve rapidly after closure of the CSF fistula. [Figure 107.6](#) shows the characteristic MRI findings in the sagging brain together with their resolution 5 days after a successful, large-volume, epidural lumbar blood patch.

SIH usually resolves with bed rest and IV hydration analogous to post-lumbar puncture headache. For intractable cases, treatment with a large-volume lumbar epidural blood patch is usually preferred, with the head and spine then tilted downward (30 degrees for 10 minutes) to facilitate the movement of blood, extradurally, to the thoracic and cervical regions. In persistent cases, surgical closure of the fistula may be necessary. This requires CT myelography to identify the precise location of the fistula.

Although postural headaches in the erect position are typical of SIH, some patients are headache free despite characteristic radiologic changes. The occurrence of somnolence and stupor caused by a sagging brain has been observed. Head-down Trendelenburg positioning is the initial treatment of choice. Restoration of CSF volume and pressure to normal by the intrathecal injection of normal saline or preferably Elliotts B solution (a pH-adjusted buffered saline) dramatically and rapidly restores consciousness and a normal mental state.

Intracranial Hypotension

Emitseilu K. Iluonakhamhe

Tiffany R. Chang

Kiwon Lee

INTRODUCTION

In 1825, Magendie described a patient with symptoms of unsteadiness and vertigo resulting from hypotension of spinal fluid and ventricular collapse. A century later in 1938, Georg Schaltenbrand described a condition, which he termed *spontaneous or essential aliquorrhoea*, that was marked by postural headache and low cerebrospinal fluid (CSF) pressure. Intracranial hypotension occurs when there is loss of CSF volume. The loss of CSF can occur at different location of the neural axis depending on the underlying etiology. For example, CSF leaks can occur at a skull base fracture from trauma and post-dural puncture CSF leaks can occur at the spinal level of needle insertion. A similar syndrome of intracranial hypotension can be seen in patients with excessive CSF drainage by ventriculoperitoneal shunts and post craniotomy (i.e., brain sagging). An increasingly recognized etiology of intracranial hypotension is spontaneous intracranial hypotension (SIH).

SPONTANEOUS INTRACRANIAL HYPOTENSION

SIH is the result of an idiopathic CSF leak. Most spontaneous CSF leaks occur at the cervicothoracic junction or thoracic spine. Some of the proposed mechanisms include spontaneous rupture of an arachnoid membrane and a variety of dura abnormalities such as meningeal diverticula, perineural (Tarlov) cyst, localized absence of dura, as well as spontaneous dura tears occurring where the spinal roots leave the subarachnoid space. Some spontaneous leaks have been attributed to underlying connective tissue disorders such as Marfan syndrome and Ehlers-Danlos syndrome (type II). Other predisposing etiologies include autosomal dominant polycystic kidney disease, Lehman syndrome, and neurofibromatosis type 1.

The true incidence of SIH is unknown, but the estimated annual incidence is 5 per 100,000 and a prevalence of 1 case per 50,000. It occurs more in women than men in a 2:1 ratio. Symptoms typically begin in the fourth to fifth decade of life; however, it has been reported in all age groups.

TABLE 108.1 Diagnostic Criteria for Spontaneous Intracranial Hypotension as Defined in *International Classification of Headache Disorders, 3rd Edition*

- | | |
|----------|---|
| A | Any new-onset headache with at least two of the following: <ul style="list-style-type: none"> • Headache develops exclusively during upright posture. • Headache spontaneously improves in horizontal posture. • Headache is mostly in the back of the neck, sometimes spreading upwards to the occipital region (“coat hanger distribution”). |
| B | Low CSF opening pressure (<6 cm H ₂ O) and/or evidence of CSF leakage on imaging |
| C | Headache has developed in temporal relation to the low CSF leakage or has led to its discovery |
| D | Not better accounted for by another <i>ICHD-3</i> diagnosis |

CLINICAL FEATURES

The most common initial presentation is a new onset of headache, typically orthostatic in nature. Additional symptoms include visual changes, diplopia, hearing changes, neck pain and/or stiffness, convulsions, nausea, and vomiting. Atypical presentations include parkinsonism, dementia, hypopituitarism, seizures, and coma. Symptoms are typically reversible with normalization of CSF pressure. Spinal symptoms including radicular symptoms and quadriparesis are rare. The onset and exacerbation of symptoms can be associated with coughing, laughing, Valsalva maneuver, and post coitus.

The diagnostic criteria for SIH as defined in *International Classification of Headache Disorders*, 3rd edition (*ICHD-3*), is noted in [Table 108.1](#). A diagnosis of SIH cannot be made if patient had a dural puncture within a month of onset of headache. The headache quality resembles post-dural puncture headache, but the postural component may not be as dramatic. The onset of headache in SIH is minutes to hours compared to seconds as in postdural headaches. The location is often holocephalic but may be localized to the frontal or occipital region. It is usually described as a throbbing or pressure-like headache but can also be dull in quality. The headache is alleviated by lying flat for about 15 to 30 minutes, but resolution can be delayed or incomplete. The headache is thought to be the result of loss of CSF buoyancy resulting in downward displacement of the brain, causing traction on pain-sensitive structures such as the dura or compensatory engorgement of pain-sensitive intracranial venous structures. If unmanaged, SIH can lead to a chronic daily headache that may not be orthostatic or relieved by recumbency. It is important to elicit the orthostatic nature of the headache at the initial onset, as this feature may become less obvious to the patient as the headache becomes chronic.

Important complications of spontaneous CSF leaks include subdural hematoma, brachial amyotrophy, cerebral venous thrombosis (CVT), and, rarely, superficial siderosis.

DIAGNOSIS

In addition to history and physical examination, use of magnetic resonance imaging (MRI) of the brain, particularly T1-weighted

P.941

images post gadolinium injection, is useful in making the diagnosis ([Fig. 108.1](#)). Five characteristic features seen on post-gadolinium-enhanced MRI of the brain are subdural fluid collections, diffuse enhancement of pachymeninges, engorgement of venous structures, pituitary hyperemia, and sagging of the brain, which make up the mnemonic SEEPS ([Table 108.2](#)). Most observed MRI of the brain findings are a result of a compensatory change due to the loss of CSF volume. Based on the Monroe-Kellie principle, a decrease in CSF volume will result in brain sag and compensatory venous engorgement. There are several case reports that demonstrate improvement in MRI findings after successful treatment of CSF leak. It is important to note that in about 20% of patients diagnosed with SIH, the MRI findings will be normal; therefore, a normal MRI does not exclude the diagnosis of SIH.

Opening CSF pressure can be obtained by performing lumbar puncture (LP). It is typically employed if there is a high suspicion of SIH although MRI findings are normal. LP should be performed after MRI of the brain is obtained to avoid post-LP MRI pachymeningeal enhancement, which can confound the diagnosis. A CSF opening pressure of less than 6 cm H₂O is a diagnostic criterion for SIH but not a requirement. In approximately 25% of patients with SIH, the CSF opening pressure is normal. In addition to low CSF opening pressure, lymphocytic pleocytosis as well as elevated protein concentration and xanthochromia

have been reported.

FIGURE 108.1 Cardinal MRI findings of spontaneous intracranial hypotension (mnemonic, SEEPS). **A:** Axial postcontrast T1 (**left**) and coronal T2 (**right**) MRI of the brain showing subdural fluid collections (*arrows*), noncontrast axial CT of the head (**bottom**) showing bilateral subdural hemorrhage.

FIGURE 108.1 (continued) B: Axial (**left**) and coronal (**right**) postcontrast T1 MRI of the brain showing enhancement of pachymeninges (*arrows*). **C:** Sagittal view of postcontrast T1 MRI of the brain showing engorgement of venous structures as well as pituitary hyperemia (*arrow*). **D:** Coronal view of postcontrast T1 MRI of the brain showing pituitary hyperemia (*arrow*). **E:** Sagittal view of T1 MRI of the brain showing sagging of the brain, descent of cerebellar tonsils (*arrow*), and descent of the iter below incisural line (*dashed line*).

If the MRI and CSF findings are inconclusive despite having high suspicion of SIH, computed tomographic (CT) myelography with iodinated contrast or magnetic resonance (MR) myelography with gadolinium of the spine as well as radionuclide cisternography is advocated. Likewise, if initial treatment is ineffective and localization of the CSF leaks is desired for direct surgical intervention, these imaging modalities can accurately define the location and extent of CSF leak. CT myelography is the most accurate study for localization of CSF leak. It can also reveal the underlying

obtained at each spinal level to detect both fast and slow CSF leaks. MR myelography with intrathecal gadolinium and noninvasive MR myelography have been used increasingly as a reasonable alternative. Although historically, radionuclide cisternography has been used as an indirect indicator of CSF leak, it is seldom employed when CT or MR myelography is available, as it is less sensitive. However, simultaneous use of CT and single-photon emission computed tomography (SPECT) has improved the sensitivity of radionuclide cisternography detecting the exact location of CSF leak.

TABLE 108.2 Magnetic Resonance Imaging Features of Spontaneous Intracranial Hypotension (SEEPS)

Subdural fluid collections

Enhancement of pachymeninges

Engorgement of venous structures

Pituitary hyperemia

Sagging of the brain

Although findings from CT of the brain are not as conclusive as MRI findings, it is useful when MRI is unavailable. Nontraumatic subdural fluid collections, ventricular collapse, obliteration of subarachnoid cisterns, and displacement of pons and cerebellar tonsils below the foramen magnum all contribute to making the diagnosis (see [Fig. 108.1A](#)).

MRI of the spine may demonstrate spinal manifestations of intracranial hypotension; however, it is not always useful in localizing the site of the CSF leak. Some imaging findings on MRI of the spine include dural enhancement, meningeal diverticula, dilated epidural or intradural veins, syringomyelia, retrospinal C1-C2 fluid, and extrathecal CSF collections. Use of MRI of the spine may be indicated if patient has neuropathic or myelopathic symptoms.

TREATMENT

Many cases of SIH are self-limited, although the time course for resolution is variable. Thus, the initial treatment is usually conservative medical management with bed rest, oral hydration, oral or intravenous caffeine, and abdominal binders. Epidural and/or intrathecal infusion of saline has been used to improve symptoms by temporarily increasing CSF volume. Caffeine has been used to serve as a vasoconstrictor to mitigate symptoms that are attributable to compensatory venous engorgement.

For patients who do not benefit from conservative medical management and continue to have persistent and debilitating symptoms, the mainstay reported treatment is the use of epidural blood patch (EBP). It involves injection of about 10 to 20 mL of autologous blood into the spinal epidural space. It can be injected directly at the level of CSF leak if known or can be placed in the safer lower lumbar region ([Fig. 108.2](#)). The patient is usually placed in Trendelenburg for up to 60 minutes after injection. The proposed mechanism is twofold; first to replace the lost CSF volume with blood volume in the spinal canal and second to serve as a sealant for any dural defect. Although there are no randomized controlled trials to evaluate the effectiveness

of EBP use, it is reported to improve symptoms in 30% to 70% of patients after the first injection. Symptomatic relief is almost immediate but may not provide complete or permanent resolution of symptoms. Two or more EBP may be required to achieve sustained relief. Thirty percent to 50% of patients may benefit from multiple administrations of EBP. After the initial one, subsequent EBP may be done with much larger volume of blood (up to 100 to 150 mL). It is expected that symptomatic relief should be sustained for at least a few days. Complications from EBP are rare, but they include neck and back pain, worsening of headache due to dural puncture, meningeal irritation, and rebound intracranial hypertension.

FIGURE 108.2 EBP placement in L4/L5 level under fluoroscopy.

If the exact site of CSF leak is known from imaging studies and EBP does not provide sustained relief, use of percutaneous placement of fibrin sealant or directed EBP is advised. In refractory cases where the symptoms are debilitating and the site of leak is known, surgical repair using suture, aneurysm clip, muscle pledget with fibrin sealant, and Gelfoam may be considered.

POSTCRANIOTOMY BRAIN SAGGING

CLINICAL FEATURES

“Brain sagging” or “sinking brain syndrome” is a serious postoperative complication. It should be part of the differential diagnosis for any patient who clinically declines after craniotomy. Brain sagging may be diagnosed with three classic criteria: (1) clinical signs of transtentorial herniation, (2) excessive intracranial air with effacement of the basal cisterns (often with an oblong brain stem), and (3) improvement of symptoms when patient is placed in Trendelenburg position ([Table 108.3](#)). The syndrome typically develops as

P.944

an immediate postoperative finding, or within 48 hours of surgery, often once sedation is stopped. The hallmark presentation is anisocoria with acute mental status decline. Early recognition is paramount to avoid irreversible transtentorial herniation leading to permanent damage. Reported risk factors include presurgical presence of global cerebral edema, intraoperative lumbar drain, ventriculostomy, and prolonged surgery.

TABLE 108.3 Criteria for Postcraniotomy “Brain Sagging” Syndrome

- Clinical signs of transtentorial herniation (e.g., reduced level of consciousness, motor posturing, pupillary and oculomotor abnormalities)
- Radiographic signs of excess intracranial air and effacement of the basal cisterns
- Improvement of symptoms in Trendelenburg (head down) position

DIAGNOSIS

Neuroimaging, CT or MRI of the brain, may reveal crowding of the posterior fossa as well as flattening of the optic chiasm and anterior pons, descent of the brain stem and cerebellar tonsils, and reduction of subarachnoid cisternal spaces. On imaging, patients may have a significant amount of pneumocephalus and demonstrate Mount Fuji sign, peaking of the frontal lobes with excessive intracranial air ([Fig. 108.3](#)). Remote hemorrhage, most often cerebellar in location, may also be seen on brain imaging following cranial or spinal surgery. This is attributed to venous bleeding secondary to intraoperative CSF loss. Remote cerebellar hemorrhage may give the appearance of a “zebra sign” on neuroimaging and can be associated with local edema and mass effect ([Fig. 108.4](#)).

FIGURE 108.3 Pneumocephalus (*Mount Fuji sign*) after craniotomy for evacuation of subdural hemorrhage.

FIGURE 108.4 Gradient echo MRI of brain showing bilateral low intensity (*white arrows*) within the cerebellar sulci consistent with chronic hemosiderin staining due to remote cerebellar hemorrhage. This pattern of irregular stripes are alternating blood and cerebellum that is sometimes referred to as the *zebra sign*. (From Paul J, Jhaveri MD, Lewis SL. Teaching neuroimages: remote cerebellar hemorrhage following resection of a supratentorial tumor. *Neurology*. 2011;77[14]:e82-e83.)

TREATMENT

Most patients with brain sagging respond quickly when placed in Trendelenburg position. If after hours of Trendelenburg position does not improve neurologic condition, one should question the diagnosis and search for other causes of mental status deterioration. An injection of 10 to 15 mL of autologous blood (blood patch) into the lumbar space can resolve persistent symptoms of postural headache and neurologic symptoms (e.g., dizziness, lethargy, dysarthria) once the herniation syndrome has been reversed. In extreme cases of brain stem herniation from CSF hypovolemia, controlled infusion of isotonic crystalloid solution via a lumbar catheter has been reported to reverse the syndrome. Conservative management with bed rest, caffeine, oral hydration, and use of an abdominal binder has also been reported as effective in

less severe cases.

Intervertebral Disk Disease and Radiculopathy

Peter D. Angevine

Hani R. Malone

Paul C. McCormick

INTRODUCTION

Intervertebral disk disease is responsible for a range of pain syndromes that have been recognized since the time of Hippocrates. The first reported treatment of intervertebral disk pathology occurred in 1909, when Krause operated on a patient who had been diagnosed by Oppenheimer as suffering from a lesion localized to the L4 root. In surgery, Krause found an extradural mass that was described pathologically as a chondroma and the operation to remove it apparently affected a cure. In 1934, Mixter and Barr were the first to point out that these lesions were actually fragments of intervertebral disks and that they were responsible for radicular pain. They further proved the efficacy of surgical treatment in their series of 58 patients treated with laminectomy and discectomy for lumbar disk herniation.

EPIDEMIOLOGY

Symptoms related to intervertebral disk disease, particularly low back pain, are common. Pathologic studies have demonstrated that almost all individuals older than the age of 30 years have some evidence of disk degeneration. As individuals age, spondylosis and osteochondrosis, the long-term sequelae of degenerative disk disease, become more and more prominent. Intervertebral disk rupture is most common in the fourth to sixth decades of life. It is relatively rare before age 25 years and less common after age 60 years. Importantly, pathologic or radiographic findings consistent with disk disease are often asymptomatic and clinically insignificant. Although some maintain that degenerative disk disease is a byproduct of the modern human environment, there is no conclusive evidence that back pain has significantly increased over the past 50 years. Fortunately, the efficacy and morbidity associated with treating intervertebral disk disease has improved considerably.

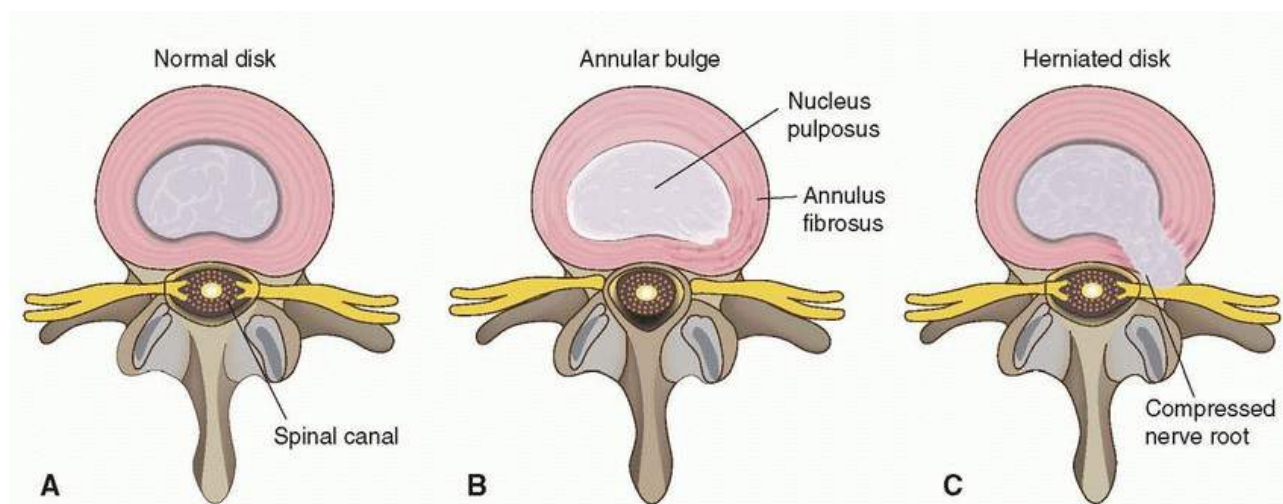

FIGURE 109.1 Anatomic illustration of the spinal canal and intervertebral disk. **A:** Demonstrating normal anatomy of the lumbar spine. **B:** An annular “disk bulge.” **C:** An annular tear with herniation of the nucleus pulposus causing nerve root impingement.

PATHOPHYSIOLOGY

INTERVERTEBRAL DISK DISEASE

Displaced disk material may cause signs and symptoms by bulging or protruding beneath an attenuated annulus

fibrosus, or the material may extrude through a tear in the annulus and project directly into the spinal canal (Fig. 109.1). In either case, the encroaching disk material may irritate or compress nerve roots as they approach their exit through the neural foramina. In cervical and thoracic regions, the problem is more neurologically complex because the spinal cord itself, as well as the adjacent nerve roots, may be involved. At cervical and thoracic levels, signs and symptoms are caused either by cord compression or a combination of cord and nerve root compression. In the lumbar region, signs and symptoms solely relate to the compression of nerve roots or to compression of the cauda equina if the disk is large enough to crowd the entire spinal canal.

P.947

There are eight spinal nerve roots in the cervical spine (C1-C8), which are numbered according to the caudal vertebra of the corresponding disk space. For example, the C4 nerve root exits through the neural foramen at the C3-C4 level and the C5 nerve root exits via the C4-C5 foramen. The C8 nerve root courses through the C7-T1 intervertebral foramen, as there is no C8 vertebra. Conversely, nerve roots in the thoracic and lumbar spine are numbered according to the vertebrae rostral to their exit through the intervertebral foramen. For example, the L5 nerve root exits the spinal canal at the level of L5-S1.

Importantly, paramedian lumbar disk herniations generally impinge on nerve roots that exit the spinal canal, a level below the site of disk herniation. For example, a paramedian herniated disk at the L4-L5 level compresses the L5 nerve root, which exits the spinal canal through the L5-S1 intervertebral foramen. This is not the case for *far lateral* disk herniations, which extend laterally to compress the rostral lumbar nerve root at the affected level. A far lateral L3-L4 lumbar disk herniation, for example, may compress the L3 nerve root either within the foramen or more distally as the root passes over the disk space (Fig. 109.2). Far lateral disk herniations account for 10% of all lumbar disk herniations, affect higher lumbar levels, and are likely to cause objective neurologic deficit. A far lateral disk herniation should be suspected with acute onset of an isolated upper lumbar radiculopathy that affects L2, L3, or L4.

In the cervical spine, degenerative disk disease most commonly affects the C5-C6 and C6-C7 levels. In the lumbar spine, most disk degeneration occurs at the L4-L5 and L5-S1 levels. This pattern suggests that the dynamics of pathologic change are partly related to wear and tear and to the trauma of motion.

Thoracic disk protrusions, except at the lower thoracic levels, differ from cervical and lumbar disorders in both genesis and histopathology. Motion does not play a significant role, as thoracic vertebrae are designed for stability rather than motion, and the heavy rib cage contributes to the rigidity of this region. Ruptured thoracic disks are markedly different on gross and microscopic examination and their consistency seldom resembles that of cervical and lumbar ruptured disks. These pathologic differences suggest a separate mechanism of injury in thoracic disk disease. Trauma has been accepted as a prime cause of thoracic disk herniation, but genetic predisposition also likely plays a role. Trauma may aggravate this susceptibility and ultimately catalyze rupture. Intervertebral disk disease is far less common in the thoracic spine compared to lumbar and cervical segments.

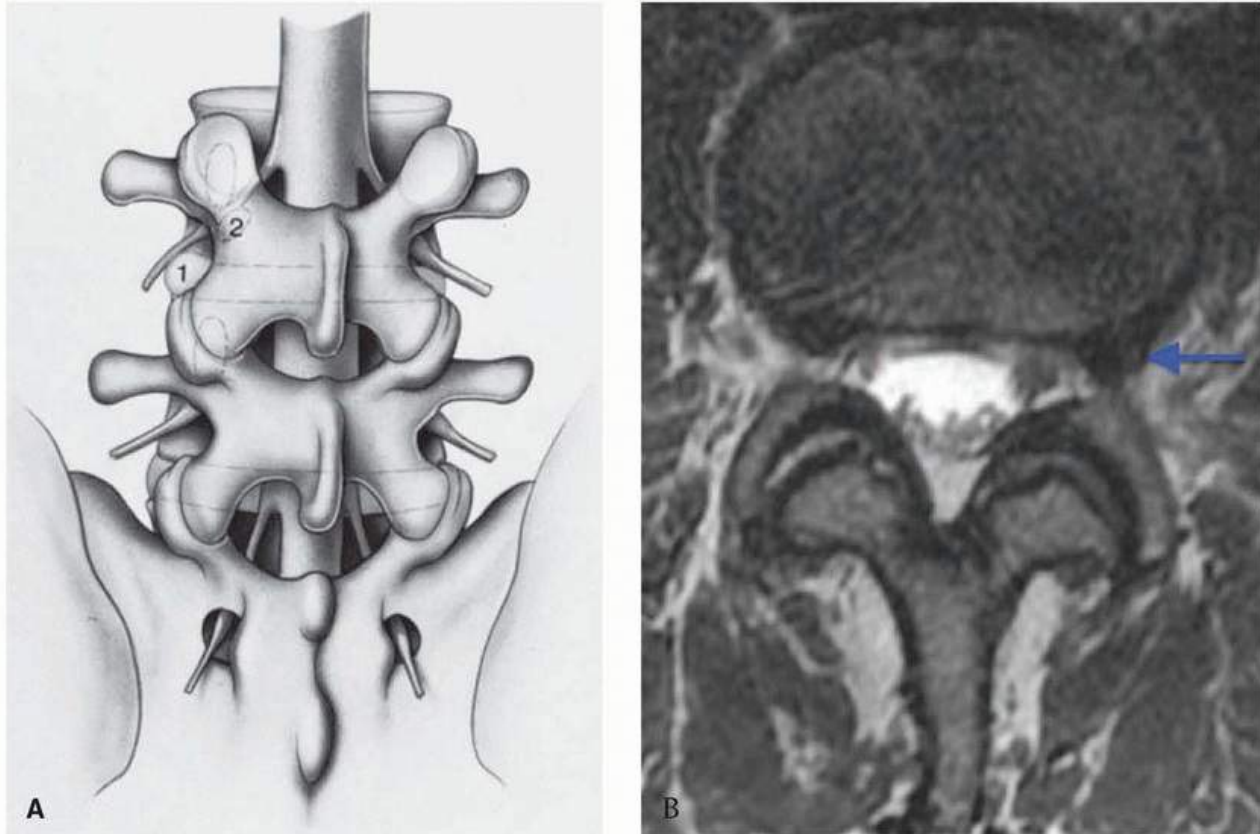

FIGURE 109.2 Far lateral disk herniation. **A:** Two sites of possible upper nerve root compression from a far lateral disk herniation. Root compression may occur at the level of the disk space (1) or from a rostrally migrated fragment into the foramen of the upper nerve root (2). **B:** MRI demonstrates a left far lateral disk herniation at the L3-L4 level (*arrow*).

The signs and symptoms of herniated disks relate not only to the size and strategic location of the disk fragments but also to the size and configuration of the spinal canal. Congenital spinal stenosis, which is an abnormally narrow spinal canal, is an example of an inherited anomaly that influences the clinical impact of disk disease. Degenerative spondylosis leads to spinal stenosis and narrowing of the neural foramina through osteophyte formation and hypertrophy of the ligamentum flavum and facet joints. Degenerative spondylosis and congenital spinal stenosis are major contributors to compression syndromes of the spinal cord and cauda equina, as even small disk protrusions in these patients can further compromise an already limited canal. In a canal of normal dimensions, the severity of neural compression and the clinical impact of a protruded disk fragment depends more on the site of rupture and the volume of the extruded material.

CLINICAL FEATURES

CHRONIC LOW BACK PAIN

In the United States, back pain is the most common reason for limiting physical activity in people younger than 45 years; it is the second most frequent cause of visits to a physician, the fifth cause of hospital admissions, and the third leading cause of surgery. In many countries, it is the most common cause of absenteeism from work, accounting for more than 12% of sick days. The aggregate economic cost in the Netherlands in 1991 was estimated to be 1.7% of gross national product. This figure likely represents the typical cost incurred by developed nations. In the United States, the aggregate cost of lower back pain is estimated to exceed \$100 billion per year.

measured in a lengthy literature and a long list of approaches to therapy. Medications and other therapies include nonsteroidal anti-inflammatory drugs, opiates, and antidepressants; extradural injection of steroids; decompressive surgery; physical therapy, including massage and exercise; chiropractic treatment; and acupuncture. In Finland, a third of the direct costs were spent on complementary therapies. Multidisciplinary spine centers and pain centers may be sources of the most effective approach to management.

RADICULAR PAIN AND LUMBAR DISK DISEASE

Root syndromes of intervertebral disk disease are often episodic, so remissions are characteristic. The pain may be restricted to the back or follow a radicular distribution in one or both legs. Lumbar pain may increase after heavy lifting or twisting of the spine. No matter how severe the pain is when the patient is erect, characteristically, it is relieved when the patient lies down. Some patients, however, are more comfortable sitting and many find no comfortable position.

Physical examination often reveals loss of lumbar lordosis or flattening of the lumbar spine with splinting and asymmetric prominence of the long erector muscles. Range of motion of the lumbar spine is reduced by the protective splinting of paraspinal muscles, and attempted movement in some planes induces severe back pain. There may be tenderness of the adjacent vertebrae. When the patient is erect, one gluteal fold may hang down and show added skin creases because the gluteus is wasted—evidence of involvement of the S1 root. Passive straight leg raise is reduced in range and increases back and leg pain. Muscle atrophy and weakness or sciatic tenderness and discomfort may occur on direct pressure at some point along the nerve from the sciatic notch to the calf. This is particularly true in older patients.

The typical syndromes of root compression at lumbar levels are described in [Table 109.1](#). Importantly, clinical signs may not be as distinct in actual practice as the table implies. More than 80% of syndromes affect the L5 or S1 nerve roots ([Table 109.2](#)). Compression of the nerve root at these levels results in “sciatica,” a sharp and burning pain that radiates down the posterior/lateral aspect of the leg to the foot or ankle ([Fig. 109.3](#)). When the lesion affects L4 or higher roots, straight leg raise does not stretch the roots above L5. The affected roots may be tensed, however, by extension of the limb with the knee flexed when the patient is prone, thus reproducing the typical radicular spread of pain. Nerve root compression is often associated with numbness and tingling. Radicular pain resulting from disk disease classically intensifies with Valsalva (coughing, defecating, sneezing).

TABLE 109.1 Common Root Syndromes of Intervertebral Disk Disease

Disk Space	L3-L4	L4-L5	L5-S1	C4-C5	C5-C6	C6-C7	C7-T1
Root affected	L4	L5	S1	C5	C6	C7	C8
Muscles affected	Quadriceps	Peroneals, anterior tibial, extensor hallucis longus	Gluteus maximus, gastrocnemius, plantar flexors of toes	Deltoid, biceps	Biceps	Triceps, wrist extensors	Intrinsic hand muscles
Area of pain and sensory loss	Anterior thigh, medial shin	Great toe, dorsum of foot	Lateral foot, small toe	Shoulder, anterior arm	Radial forearm	Thumb, middle fingers	Index, fourth, and fifth fingers

Reflex affected	Knee jerk	Posterior tibial	Ankle jerk	Biceps	Biceps	Triceps	Triceps
Straight leg raising	Many do not increase pain	Aggravates root pain	Aggravates root pain	—	—	—	—

THORACIC DISK RUPTURE

The thoracic spine is designed for rigidity rather than excursion, thus wear and tear from motion and stress may not cause thoracic disk protrusion, and clinical disorders are rare. Thoracic disk disease may result from chronic vertebral changes incident to Scheuermann disease or juvenile osteochondritis with later trauma. The radiographic changes of Scheuermann disease, when seen with thoracic cord compression, should raise the possibility of disk protrusion (Fig. 109.4). The small capacity of the thoracic spinal canal makes this region vulnerable to cord compression from disk herniation. By the same token, decompressive operations are more precarious and require meticulous care to avoid damaging the spinal cord. Calcific changes are common in pathologic thoracic intervertebral disks, which pose additional challenges when performing discectomy. The lower thoracic levels, however, are more capacious, and although the conus medullaris or cauda equina may be damaged by disk protrusions, surgical approaches are less hazardous compared to higher levels.

CERVICAL DISK DISEASE

Cervical disk herniation may involve both the nerve root and spinal cord depending on the volume of the canal and the size of the lesion. Spinal cord compression is uncommon, except with spinal stenosis or massive rupture of a disk. The sites of the most frequent disk herniations are C5-C6 and C6-C7; C4-C5 and C7-T1 are less frequently affected (Table 109.3). Movement of the cervical spine is normally incremental and any process contributing to focal stress at individual levels adds to progressive pathologic changes in the disk and to deficits in joint mechanics (Fig. 109.5). Development of a new fulcrum of motion above

P.949

a fusion or congenital block vertebrae increases susceptibility to these changes.

TABLE 109.2 Signs of Lumbar Disk Herniation in 97 Patients

Disk Space	L2-L3	L3-L4	L4-L5	L5-S1
Patients (<i>n</i>)	1	9	45	42
Weak muscles				
Anterior tibial, extensor hallucis	0	3	13	3
Gastrocnemius, plantar responses of foot	0	0	2	3
Quadriceps	0	3	0	0
Reflex affected

Ankle jerk	0	1	12	23

Data are numbers of patients. From Hardy RW Jr, Plank NM. Clinical diagnosis of herniated lumbar disc. In: Hardy RW, ed. *Lumbar Disc Disease*. New York: Raven Press; 1982:17-28.

The signs and symptoms of cervical disk disease usually begin with stiff neck, reactive splinting of the erector capital muscles, and discomfort at the medial border of the scapula. Radicular paresthesias and pain supervene when the root is more severely compromised. These symptoms are worsened by movements of the head and neck as well as by stretching of the dependent arm. For relief, the patient often adopts a position with the arm elevated and flexed behind the head, unlike the patient with shoulder disease who maintains the arm in a dependent position avoiding elevation or abduction at the shoulder joint.

FIGURE 109.3 MRI of lumbosacral disk herniation. Sagittal proton-density (A) and axial T1-weighted (B) MRI demonstrate a large L5-S1 disk herniation on the left side. Clinically, this patient had an S1 radiculopathy that did not respond to conservative therapy. Complete relief of symptoms followed lumbar discectomy.

As compression proceeds, discrete root syndromes appear (see [Table 109.1](#)). C5 lesions cause pain in the shoulder and dermatomic sensory diminution with weakness and atrophy of the deltoid. C6 lesions cause paresthesias of the thumb and depression of the biceps reflex with weakness and atrophy of that muscle. In C7 lesions, paresthesias may involve the index and middle fingers, and even the thumb with atrophy and weakness in the triceps muscles, wrist extensors, and pectoral muscles, as well as a parallel reflex depression. C8 subserves important intrinsic muscle functions in the hand and sensation in the fourth and fifth fingers. Because these are important in discriminatory and fine finger maneuvers, C8 damage may be disabling.

FIGURE 109.4 Thoracic disk herniation. Sagittal T1-weighted MRI demonstrates two large thoracic disks (*arrows*) in a patient with a subacute myelopathy.

FIGURE 109.5 Cervical disk herniation. T2-weighted MRI shows C5-C6 disk herniation (*dashed line* in **B**) in a patient with radiculopathy in **(A)** sagittal and **(B)** axial planes.

MYELOPATHY

Large disk protrusions in the thoracic and cervical spine, particularly with concurrent spinal stenosis, may compress the spinal cord resulting in myelopathic signs on clinical exam. Clinical signs of myelopathy reflect injury to upper motor neurons. Reflexes and tone are increased, whereas coordination and balance are diminished. Patients with cervical myelopathy often have difficulty using their hands for fine motor tasks and adopt a broad-based gait to improve balance while upright. Other signs of myelopathy on routine physical exam include Hoffman and Babinski signs, a positive Romberg test, and sustained clonus. Myelopathy is often combined with lower motor neuron weakness and may be subtle if compression of the cord is mild.

DIAGNOSIS

INITIAL MANAGEMENT AND EVALUATION

Radiculopathy is a clinical diagnosis based on careful history and physical examination. Immediate diagnostic testing with magnetic resonance imaging (MRI) is not necessary in patients with new-onset radicular pain that have

Patients with low back and/or radicular pain should undergo at least 6 weeks of pain control, rest, and physical therapy.

Immediate imaging should be obtained in those patients with acute and/or progressive neurologic deficits. Diagnostic imaging is particularly urgent in patients with urinary retention and or saddle anesthesia, signs of cauda equina syndrome. MRI should also not be delayed in cases with a high clinical suspicion of neoplastic or infectious systemic disease, as symptoms in these patients may be secondary to spinal metastases or epidural abscesses.

In those patients who fail conservative management, MRI should be used to confirm a diagnosis of disk disease before considering invasive treatment. When no correlation exists between radiographic and clinical findings, electromyography (EMG) and nerve conduction studies (NCS) can help elucidate the etiology of presenting symptoms.

Considerations in the Cervical Spine

Lesions such as supraspinatus tendinitis, arthritic changes in the acromioclavicular joint, and rotator cuff tears may be difficult to differentiate from cervical root compression, especially because prolonged pain and lack of range of motion lead to atrophy and frozen shoulder in these syndromes. C8 and T1 lesions commonly cause a partial Horner syndrome. A diagnostic workup for syndromes of these levels must include apical lordotic views of the chest, and special care must be taken to rule out pulmonary neoplasms and abnormal cervical ribs.

Other Diagnostic Considerations

Because many disk syndromes are genetic, abnormal skeletal features throughout the spine may be sought on radiographs. These include spinal stenosis, spondylolisthesis, widespread disk disease, or Marfan syndrome. Acquired disorders, such as osteochondritis juvenilis, and metabolic states such as osteoporosis, may contribute to pathologic changes in the disk and adjacent joints, as do several forms of arthritis. Importantly, disk syndromes may be duplicated by tumors (e.g., primary or metastatic), infections (e.g., epidural abscess), and arachnoiditis. Epidural lipomatosis, a rare cause of low back syndromes, is a complication of steroid therapy.

IMAGING AND ELECTRODIAGNOSTIC STUDIES

Magnetic Resonance Imaging

MRI is the imaging procedure of choice for disk disorders (see also [Chapter 21](#)). MRI identifies spinal cord or root compression and also shows the degree of degenerative change within the disk. It clearly delineates both intra- and extradural structures and is the ideal screening procedure for a differential diagnosis that includes structural disorders affecting the spinal cord and nerve roots.

Importantly, evidence of degenerative disk disease and even disk rupture on MRI may not correlate with clinically significant pathology that requires intervention. In studies of asymptomatic individuals, bulging and herniated disks have been identified in 50% and 27% of adults, respectively. Abnormal findings on MRI of the lumbar spine in asymptomatic adults do not appear to predict future development of low back pain. In the absence of progressive neurologic deficit or suspicion of systemic illness, such as cancer or infection, MRI should be reserved for those individuals with at least 6 weeks of persistent low back/radicular pain despite conservative therapy (see [“Initial Management and Evaluation”](#)).

Myelography and X-ray

Computed tomography (CT) myelography is more invasive than MRI, exposing patients to the intrathecal administration of contrast as well as ionizing radiation. Accordingly, CT myelography is rarely indicated. It does effectively visualize spinal nerve roots and their trajectory through the neural foramina, particularly the anatomy of the nerve root sleeve. However, myelography is unrevealing in the evaluation of far lateral disk herniations, which occur lateral to the spinal canal and root sleeve. Myelography is useful for patients with intolerance of, or contraindications to, MRI, such as cardiac pacemakers and other implanted electrical devices. In addition, CT myelography may be preferred for patients who have surgically placed spinal hardware that produces magnetic

artifacts. Plain radiographs effectively depict bony anatomy but not herniated disks. Radiographs do provide valuable information related to spinal alignment and segmental stability prior to surgical intervention.

Electromyography and Nerve Conduction Studies

The primary electrodiagnostic studies used in the evaluation of radiculopathy are EMG and NCS. These studies can be used to accurately identify radiculopathy that has been accompanied by weakness for 3 weeks or more, but they are seldom essential. Electrodiagnostic studies are most useful when radiographic findings do not correlate with clinical presentation (see also [Chapter 26](#)).

TREATMENT

Most acute attacks of back pain improve in days or weeks, and only a small minority of patients require surgery. In one meta-analysis, 82% of patients with acute low back pain returned to work within a month of onset. In the absence of neurologic deficit, conservative treatment should be pursued so long as the patient continues to improve with analgesics and bedrest for lumbar disk disorders and immobilization of the neck by a collar for cervical disk disorders. Some clinicians use epidural steroid injections, which decrease edematous swelling and thereby relieve pressure on the affected nerve root.

EXPERT REFERRAL

In the acute phase, indications for referral to a treatment specialist are similar to indications for urgent MRI. Patients who present with signs/symptoms of acute or progressive neurologic deficit, including motor weakness, myelopathy, or signs of cauda equina syndrome, should be urgently evaluated by a neurosurgeon or orthopedic surgeon with experience in spine surgery. This referral should not delay MRI, which is an essential component of any potential surgical decision making. Of note, there is no evidence that early referral to a spine surgeon, in the absence of the aforementioned criteria, improves outcome. For those patients who lack acute or progressive neurologic deficit but have persistent symptoms impairing quality of life, surgery can be scheduled on an elective basis. Importantly, no randomized trial demonstrating the benefits of surgery has enrolled patients with less than 6 weeks of conservative therapy.

LUMBAR DISKECTOMY

Lumbar diskectomy is indicated in patients with evidence of nerve root compression on neuroimaging and either corresponding radicular pain refractory to conservative therapy or corresponding acute/progressive weakness. Surgery represents an effective

P.952

treatment option in properly selected patients, as diskectomy of a herniated lumbar disk fragment almost always results in longterm satisfactory relief of symptoms. Lumbar fusion is rarely required for treatment of radiculopathy from a herniated lumbar disk. Excessively prolonged physiotherapy and bed rest may cause emotional exhaustion, muscle loss, or drug dependence.

Evidence from an early randomized controlled trial by Weber and colleagues comparing prolonged conservative management to diskectomy suggests that surgery offers greater relief from radiculopathy caused by herniated lumbar disks in the short term [**Level 1**].¹ However, patients randomized to both surgical and nonsurgical groups experienced considerable symptomatic improvement over time and the difference between groups was not statistically significant at long-term follow up. This may be partially explained by unintended crossover between groups, as approximately one-quarter of patients randomized to nonsurgical therapy elected to have a diskectomy presumably due to persistent symptoms with conservative management.

In a large multicenter, prospective, randomized, controlled trial, researchers with The Spine Patient Outcomes Research Trial (SPORT) demonstrated substantial improvement with both surgical and nonsurgical treatment of lumbar disk disease with radiculopathy. Although short-term results were consistently in favor of surgery, differences in primary outcomes were not statistically different [**Level 1**].² At long-term follow up (4 and 8 years), patients treated with surgery demonstrated greater improvement in secondary outcomes, including “sciatica

bothersomeness,” self-rated improvement, and patient satisfaction with symptoms [**Level 1**].³ Primary outcomes (bodily pain, physical function, and disability index) also favored surgery, but these differences were not significant between groups. The results of the SPORT research effort were widely touted by the lay press, and some in the medical community, as evidence for the equivalence between modern surgical and nonsurgical treatment techniques. However, as the study authors rightly conclude, “conclusions about the superiority or equivalence of the treatments under study are not warranted based on the intent-to-treat analysis.” Crossover between groups again served as a major confounder that may underestimate the relative benefit of surgery, as approximately half (49%) of patients assigned to nonoperative management ultimately elected to have surgery after a trial of conservative therapy.

Surgical techniques for lumbar diskectomy can be broadly segregated into three categories: open diskectomy, microdiskectomy, and minimally invasive diskectomy. Traditional open diskectomy involves a standard laminectomy and is performed with eyepiece magnification. Microdiskectomy is the most commonly performed procedure and typically involves a smaller incision with less bone removal in the form of a hemilaminotomy and use of the operative microscope to remove the offending disk fragment.

Minimally invasive techniques have become extremely common in modern practice. Typically, minimally invasive lumbar diskectomy includes the use of a tubular retractor system inserted through small incisions over a guidewire with fluoroscopic guidance. This technique uses muscle spitting, as opposed to the muscle cutting/detachment inherent to other methods, which its advocates purport reduces postoperative pain and recovery time. Currently, this position is not supported by data from randomized controlled trials. Arts and colleagues randomized 328 patients to minimally invasive versus conventional microdiskectomy for lumbar radiculopathy. At 2-year follow-up, similar functional and clinical outcomes were reported between groups [**Level 1**].⁴ Of note, recovery time was not shorter among patients treated with minimally invasive tubular diskectomy. A recently published meta-analysis of randomized controlled trials comparing tubular diskectomy to conventional microdiskectomy found that both methods lead to a substantial and equivalent long-term improvement in leg pain. Incidental durotomies occurred significantly more frequently during minimally invasive surgery, but total complications did not differ between study arms [**Level 1**].⁵

CERVICAL DISKECTOMY

Indications for surgery to relieve radiculopathy from disk disease in the cervical spine are similar to the indications for lumbar diskectomy. Good surgical candidates have persistent radicular pain despite at least 6 weeks of conservative treatment or acute/progressive motor weakness. Clinical evidence of myelopathy with radiographic evidence of cord compression from a herniated disk represents an additional indication for diskectomy.

Generally, spinal cord compression requires consideration of decompressive measures as soon as it is recognized. Root syndromes of the cervical spine may be separated into those that require careful supervision and early operation and those that tolerate and may respond to conservative care. The muscles served by C5 may rapidly atrophy, leaving abduction paresis, poor prognosis for restoration of function, and a painful frozen shoulder. C8 is also vulnerable, and unrelieved compression may lead to irreversible atrophy with complex shoulder-arm-hand disorders that include circulatory and sweating abnormalities. C6 and C7 innervate large muscles and tolerate pressure more benignly even for long periods and may have good functional return. Cervical root syndromes are less likely to recur than lumbar disorders, and conservative therapy is worthwhile within the outlines described.

Removal of a cervical herniated disk may be performed either through a posterior laminotomy or through an anterior approach. In most case, particularly in patients with cervical kyphosis, an anterior approach is preferred. Anterior cervical diskectomy with fusion (ACDF) is one of the most successful and widely practiced procedures in spine surgery. By combining anterior decompression with a strut graft (usually allograft) to promote fusion across the vacated intervertebral disk space, lordosis can be restored across the segment. Excellent results may be anticipated in appropriately selected patients.

Persson and colleagues conducted a randomized controlled trial comparing anterior cervical diskectomy to nonoperative therapy in 81 patients with clinical and radiologic signs of cervical nerve root compression lasting 12

weeks or more. Patients in the nonoperative arm were prescribed physical therapy and immobilization with a hard cervical collar. Individuals with clinical signs of myelopathy or radiographic evidence of cord compression were excluded. Patients treated with surgery demonstrated greater improvement in both pain and motor strength at 4 months follow up. At 1 year, no significant difference in pain remained, but patients in the surgical arm maintained a small advantage in muscle strength [Level 1].⁶

Prospective observational studies by Heckmann and Sampath provide further support for the efficacy of anterior cervical discectomy in the treatment of cervical radiculopathy without myelopathy. At 2-year follow-up, patients who underwent surgery showed greater improvements in both pain and weakness compared to conservatively treated patients. Overall, approximately 75% of patients experienced significant relief from symptoms after surgery.

SUMMARY

Radiculopathy resulting from intervertebral disk disease is self-limited in the majority of patients. Symptoms generally improve

P.953

with rest, pain control, physical therapy, and time. If symptoms persist after at least 6 weeks of conservative therapy, patients should be referred for MRI. If intervertebral disk disease identified on neuroimaging correlates with clinical presentation, patients should be referred to a spine surgeon. More urgent referral should be initiated in the presence of symptoms of cauda equina syndrome, myelopathy, or acute/progressive motor weakness. Randomized controlled trials comparing discectomy to conservative therapy in the lumbar and cervical spine demonstrate similar long-term outcomes between groups that modestly favor surgery in appropriately selected patients. The short-term benefits of surgery have been more consistently realized across studies. Crossover between randomized arms may contribute to an underestimation of the benefit of surgery, as patients frustrated by the severity of their symptoms and the slow pace of recovery with conservative therapy commonly opt to have surgery.

Cervical and Lumbar Spinal Stenosis

Lewis P. Rowland

Paul C. McCormick

INTRODUCTION

Cervical and lumbar spinal stenosis are the most common causes of neck and back pain and spinal cord and cauda equina or nerve root dysfunction and represent the most frequent indications for spinal surgery in adults older than the age of 55 years.

PATHOBIOLOGY

The term *spinal stenosis* describes an acquired condition of progressive narrowing of the spinal canal usually due to age-related progressive arthritic degeneration of the intervertebral disks and facet joints. This process results in disk bulging, facet overgrowth, synovial cyst development, and bone spur formation, as well as ligamentum flavum and facet joint capsule hypertrophy. These proliferative, so-called spondylotic, changes that occur in response to accumulated mechanical stress in the spine lead to progressive narrowing of the spinal canal and/or foramina. In some patients, these degenerative changes may compromise the mechanical integrity of the spine leading to deformity (e.g., degenerative scoliosis, kyphosis) or spondylolisthesis that may further exacerbate the clinical condition produced by spinal stenosis. In a smaller subset of patients, narrowing of the spinal canal may be due to degenerative and/or destructive changes to the articulating joints from systemic conditions such as rheumatoid arthritis, or enthesopathies such as ossification of the posterior longitudinal ligament (OPLL), ankylosing spondylitis, or diffuse idiopathic skeletal hyperostosis (DISH). OPLL may be focal or diffuse and seems to be most common in people of Asian heritage. These conditions much more commonly affect the cervical spine.

Progressive stenosis of the cervical, or rarely thoracic, spinal canal from these conditions may damage the spinal cord producing a condition known as *cervical spondylotic myelopathy* (CSM). Such myelopathy is attributed to one or more of three possible mechanisms: (1) direct compression of the spinal cord by bony or fibrous tissue overgrowth, (2) ischemia caused by compromise of the vascular supply to the cord, and (3) repeated trauma in the course of normal neck movement. Similarly, ongoing progressive or intermittent narrowing of the nerve root foramen may cause injury to the cervical nerve roots. Although the cauda equina seems less susceptible than the spinal cord to permanent injury from lumbar spinal stenosis, advanced, nontreated severe stenosis may result in irreversible injury to these nerve roots similar to cervical myelopathy.

In the cervical spine, spondylotic bars may leave deep indentations (e.g., visible at autopsy) on the ventral surface of the spinal cord. At what may be several levels of lesions, there is degeneration of the gray matter, sometimes with necrosis and cavitation. Above the compression, there is degeneration of the posterior columns; below the compression, corticospinal tracts are demyelinated. A similar process occurs in the lumbar spine where the proliferative changes due to the normal aging process produces progressive narrowing of the lumbar spinal canal and compression of the cauda equina.

CAUSES OF CERVICAL AND LUMBAR STENOSIS

Normal, albeit accentuated, wear and tear degenerative changes in the spine is the most common cause of spinal stenosis both in the cervical and lumbar spine. The water content of the intervertebral disk and annulus fibrosus declines progressively with advancing age. Concomitantly, there are degenerative changes in the disk.

The intervertebral space narrows and may be obliterated, and the annulus fibrosus protrudes into the spinal canal. Osteophytes form at the margins of the vertebral body, converge on the protruded annulus, and may convert it into a bony ridge or bar. The bar may extend laterally into the intervertebral foramen; there is also fibrosis of the dural sleeves of the nerve roots. All these changes narrow the canal, a process that may be aggravated by fibrosis and hypertrophy of the ligamenta flava. In some cases, this narrowing may be exacerbated by acute or chronic disk herniation, synovial cyst development from the facet joint, or degenerative spondylolisthesis. These last two conditions are much more common in the lumbar spine of women, especially at the L4-L5 level. The likelihood of spinal cord or cauda equina compression or vascular compromise increases in direct relation to the decrease in the original diameter of the spinal canal.

Most cases of degenerative cervical or lumbar stenosis are sporadic in occurrence, although there may be a family history in some patients. The term *congenital spinal stenosis* is a bit of a misnomer because stenosis connotes an acquired narrowing. A *developmentally small spinal canal* is a more accurate term than congenital stenosis. Patients with a developmentally small canal, a familial characteristic, may be more susceptible to develop symptomatic stenosis simply because they have less capacity to accommodate the proliferative degenerative changes associated with the progressive arthritic process of the spine. Spinal stenosis tends to develop at the most mobile and mechanically stressed spinal levels. The C5-C6 and C6-C7 levels are most commonly involved in the cervical spine, whereas L4-L5 and L3-L4 are the most commonly affected lumbar levels. Both C4-C5 and L5-S1 are slightly less commonly involved. Concomitant symptomatic cervical and lumbar stenosis can be seen in up to 15% of patients. Patients who have either congenital (i.e., Klippel-Feil syndrome) or previously performed surgical spinal fusion may be prone to develop spinal stenosis at levels adjacent to the fused level.

Systemic conditions such as rheumatoid arthritis may cause destructive changes of synovial joints, especially in the upper cervical spine leading to cervical instability and stenosis with spinal cord compression. The term *enthesitis* describes the site where ligaments or tendons attach to bone. In the spine, a number of different enthesopathies may involve the spine to produce spinal stenosis. The most common of these is OPLL, where calcification of the posterior longitudinal ligament can produce progressive spinal stenosis, particularly in the cervical spine, and myelopathy. Less commonly, diffuse idiopathic skeletal hyperostosis or ankylosing spondylitis may result in excessive ossification of either the posterior or anterior longitudinal spinal ligaments leading to spinal rigidity, fragility, and spinal stenosis.

CLINICAL MANIFESTATIONS

CERVICAL STENOSIS

Neck pain may be prominent and chronic in nature. Root pain is common in patients with predominant or concomitant foraminal stenosis, but most patients present with either myelopathy or radiculopathy. A combined “myeloradicular” presentation is unusual. The most common symptom of myelopathy is spastic gait disorder (Table 110.1). Clumsiness of the hands and loss of dexterity and fine motor control with such tasks as writing, typing, and buttoning are common early complaints in patients with CSM. Weakness and wasting of the hands may be seen but only as the condition becomes more advanced. Predominate proximal arm weakness with difficulty lifting the arm over the head is the presenting complaint in a small number of patients. Bowel bladder complaints are usually not common in the early stages of CSM. Fasciculations are rarely noted in the early stages of CSM. Overt sensory loss is uncommon, but the patient may note that the hands feel numb and clumsy.

The course of the disorder is slowly progressive, but the natural history is not well delineated. In some patients, the condition may wax and wane with periods of relative quiescence or even improvement followed by progressive worsening. Acute worsening precipitated by a fall or other traumatic event may exacerbate existing

symptoms or a central cord syndrome that is characterized by a sudden onset of predominant, often distal, upper extremity numbness/weakness with relative preservation of lower extremity function. These injuries most likely occur from sudden hyperextension of the cervical spine with infolding of the ligamentum flavum causing a pincer-type impingement of the spinal cord. Spontaneous substantial recovery from acute central cord syndromes commonly occurs.

LUMBAR STENOSIS

The classic presentation of patients with lumbar spinal stenosis is neurogenic claudication. Patients typically present with symptoms of lower extremity pain, weakness, and/or numbness with standing or walking that are reliably relieved with sitting or leaning forward. The reason for this is that upright postures and positions tend to exacerbate the degree of lumbar stenosis by infolding of the ligamentum flavum into the spinal canal. Sitting and leaning forward straightens the ligamentum flavum to increase lumbar spinal canal dimensions. Symptoms can vary from patient to patient in terms of quality (pain or numbness), distribution (bilateral or unilateral, multiroot or single root), severity, and duration. Most patients do not have a fixed neurologic deficit by the time of clinical presentation. Fixed deficits (e.g., footdrop) or cauda equina syndrome is now rare, although they can be seen in long-standing untreated patients or acute presentations from a large central disk herniation.

DIAGNOSIS

The diagnosis of cervical or lumbar stenosis is confirmed with imaging of the spinal canal. It is important to appreciate that spinal stenosis is a clinical, rather than radiologic, diagnosis because many individuals may have a narrow, or stenotic, spinal canal but no neurologic signs or symptoms. With few exceptions, these asymptomatic patients are not in need of treatment.

Formerly, the most important diagnostic tests were plain radiographs of the cervical spine and myelography. Plain radiographs show narrowing of the disk spaces and the presence of osteophytes, especially at C5-C6 and C6-C7. Posterior osteophytes tend to be smaller than anterior projections and may not be seen without computerized tomography (CT). The disk bodies may be normal or may show sclerosis. Changes in the zygapophyseal joints account for the designation of osteoarthritis and may encroach on the intervertebral foramen; the changes may cause subluxation of the articular surfaces or compression of vertebral arteries. These invasive studies have largely been supplanted by noninvasive imaging.

Magnetic resonance imaging (MRI) is the imaging procedure of choice for the evaluation of both cervical and lumbar stenosis. It is noninvasive and provides exquisite resolution of spinal cord, exiting nerve roots, and cauda equina (Figs. 110.1, 110.2, 110.3). MRI allows evaluation of spondylosis and the alternative possibilities: Chiari malformation, arteriovenous malformation, extramedullary or intramedullary tumor, syringomyelia, or demyelinating conditions such as multiple sclerosis. MRI may also identify physical changes within the spinal cord such as increase T2 signal abnormalities reflecting edema, ischemia, cyst formation, and spinal cord injury.

CT complements MRI and provides additional detail regarding bone and calcified disks. It is particularly

important in patients suspected of having calcified spurs, often in association with OPLL or DISH.

Somatosensory-evoked responses add little to aid in diagnosis of either cervical or lumbar stenosis, although they may help in

P.956

the differential diagnosis of anterior horn cell disease (amyotrophic lateral sclerosis) or peripheral neuropathy. The cerebrospinal fluid (CSF) is usually normal or the protein concentration may be 50 to 100 mg/dL. Higher protein levels or CSF pleocytosis should raise the question of multiple sclerosis or tumor, including meningeal carcinomatosis. The role of transcranial magnetic stimulation in diagnosis remains to be ascertained, but motor-evoked potentials may be more contributory than sensory potentials.

FIGURE 110.1 Sagittal proton-density MRI demonstrates extensive spinal cord compression caused by a combination of ventral bone spurs and preexisting (i.e., congenital) canal stenosis.

FIGURE 110.2 A: Sagittal T1-weighted MRI shows severe upper spinal cord compression from OPLL, which appears as dark bulges anterior to the cord along the posterior aspects of the C 3/4, C 4/5, and C 5/6 discs. This dense calcification is typical of OPLL. **B:** Axial MRI in same patient.

DIFFERENTIAL DIAGNOSIS

Two types of problems arise in the differential diagnosis. In one group, there is compression of the cervical spinal cord but not by spondylosis or not by spondylosis alone. Spinal tumors are the best example of this kind of problem. These lesions are revealed by MRI. In other compressive lesions, the primary bony changes are congenital (e.g., anomalies of the craniocervical junction) or acquired (e.g., rheumatoid arthritis or basilar impression) and may be further complicated by spondylosis. These disorders are recognized by CT or MRI. Arteriovenous malformations may also be found.

Another group of myelopathies presents more of a diagnostic problem. Cervical spondylosis is so common in the general population that it may be present by chance and may be harmless in a person with another disease of the spinal cord. The ultimate test of the pathogenic significance of spondylosis would be complete relief of symptoms after decompressive surgery, but this is rarely seen. Among the other diseases that may cause clinical syndromes similar to those attributed to spondylosis are multiple sclerosis (MS), amyotrophic lateral sclerosis (ALS), neurosyphilis, and possibly subacute combined system disease with vitamin B₁₂ deficiency (see also [Chapter 111](#)). In one series, 12% of patients diagnosed with spondylotic myelopathy proved to have some other condition.

MS is probably the most common cause of spastic paraplegia in middle life and is probably the actual cause of the disorder in some people who have had a cervical laminectomy. These conditions can generally be distinguished based on clinical presentation and imaging but for equivocal cases, it is important to test for MS by use of visual, somatosensory, and brain stem-evoked responses; examine CSF for γ -globulin content and oligoclonal bands; and carry out an MRI examination of the cerebral white matter, foramen magnum, brain stem, and cervical spinal cord. Proper use and interpretation of these test results often remove diagnostic uncertainty.

ALS must be considered whenever wasting and fasciculations are seen in arm and hand muscles and especially when there are

fasciculations in the legs. The presence of overt fasciculation makes it unlikely that spondylotic myelopathy is the cause of symptoms; when fasciculation is visible, caution is warranted when laminectomy is being considered. There is no diagnostic test for ALS, however, and the distinction may be difficult.

FIGURE 110.3 **A:** T2-weighted sagittal MRI of lumbar spine demonstrates severe lumbar spinal stenosis at the L3-L4 and L4-L5 spinal levels. **B:** T2-weighted axial MRI shows severe stenosis at the L4-L5 level in same patient.

Rare causes of spastic paraplegia in middle life are the myelopathy caused by human T-cell lymphotropic virus type I or adult-onset adrenoleukodystrophy. The diagnosis of exclusion, when no other cause is identified, is primary lateral sclerosis, which is almost as common a cause of spastic paraparesis as MS.

In northern England, a prospective survey of 585 patients with nontraumatic spastic paraparesis gave the following order of frequency of diagnosis: CSM, 24%; tumor, 16%; MS, 18%; diagnosis uncertain, 19%; and ALS, 4%. The absence of primary lateral sclerosis from this list suggests regional differences in making a diagnosis. Of course, the real problem is ascertaining the diagnosis of spondylotic myelopathy.

TREATMENT

CERVICAL STENOSIS

The treatment of cervical stenosis depends on many factors. As previously noted, radiographic stenosis in the absence of signs or symptoms of neurologic symptoms rarely necessitates intervention. Occasionally, a patient with severe stenosis (<7-mm canal diameter) and an intramedullary signal abnormality within the

spinal cord may present with little or no neurologic symptoms. In these patients, preemptive surgical decompression may be offered but it is not clear if the benefit of surgery outweighs the risks in this patient population. Often, patients with minimal or no neurologic signs/symptoms are followed both clinically and with imaging over time. Surgical decompression is usually recommended if clinical progression is documented. Patients with radicular symptoms from nerve root compression from foraminal stenosis are initially managed with conservative measures such as activity modulation, physical therapy, judicious use of anti-inflammatory medications, and/or steroidal spinal injections. Surgery for decompression of the nerve root either through a posterior foraminotomy or anterior discectomy is an option for patients with persistent radiculopathy that is not responsive to conservative management.

The natural history of CSM varies greatly and is unpredictable in individual patients. The Cochrane Library listed a single, controlled trial for spondylotic myelopathy, that of Bednarik et al.; in 1999, they reported early benefit for surgery over conservative therapy but did not find differences after 1 year. However, they studied only 49 patients. Therefore, there have still been no adequately controlled trials of surgical therapy. Additionally, several different operations have been advocated (e.g., ventral vs. dorsal, with or without fusion, and with or without different kinds of stabilizing hardware). Therefore, uniform recommendations for treatment have been difficult to establish but is usually recommended for patients with progressive neurologic dysfunction. Decompressive operations include posterior laminectomy or laminoplasty, anterior discectomy, or vertebrectomy with spinal fusion.

Conservative treatment with physical therapy for gait training and with neck immobilization with a firm collar may be appropriate for some patients with mild myelopathy. Surgery should be considered if the myelopathy progresses despite conservative treatment.

LUMBAR STENOSIS

Unlike cervical stenosis, most patients with lumbar stenosis do not have neurologic deficit. Thus, treatment options are more variable. For patients with mild symptoms, conservative management with activity modification, physical therapy, and/or periodic epidural steroidal injections may provide durable stability or even improvement from the symptoms of spinal stenosis of lumbar spinal stenosis. However, if symptoms become increasingly problematic to the patient in terms of symptoms, function, or quality of life, then surgical intervention for decompression may be offered.

P.958

SURGICAL EFFICACY

The outcome following surgical treatment for cervical stenosis is variable and difficult to predict on an individual basis. Although contemporary surgical series report a 70% to 80% rate of improvement, only about 50% of patients show satisfactory functional improvement or complete reversal of symptoms that is maintained over time and up to one-third of patients show no improvement following decompressive surgery for CSM. In some patients, their condition may even become worse as a result of surgery. In these cases, irreversible injury from spinal stenosis may have already occurred or surgery did not optimally achieve the operative objective. Surgical decompression for nerve root compression in the foramina provides more reliably achieved improvement in neurologic symptoms than does surgical treatment for cord compression. At this point, it is unlikely that any randomized trial comparing surgery to nonoperative management or no treatment for CSM will be forthcoming due to the lack of clinical equipoise. Randomized controlled trials are underway, however, to evaluate both the comparative efficacy as well as the cost-effectiveness of various surgical techniques that are commonly used to treat these patients. In the absence of clear guidelines, management should be tailored to the specific circumstances of individual patients and to the experiences of the treating physicians and surgeons.

The results of surgery for lumbar spinal stenosis in patients who have failed to respond to nonoperative

treatments is much more favorable and predictable than for cervical stenosis. The Spine Patient Outcomes Research Trial (SPORT) provides level 1 evidence of both the efficacy and durability of spinal decompression through lumbar laminectomy to relieve the symptoms of spinal stenosis in appropriately selected patients who have failed to improve with standard nonoperative measures [**Level 1**].^{1,2} Additionally, level 1 evidence provided by the SPORT also demonstrated the efficacy and durability of lumbar decompression and fusion for patients with lumbar stenosis and degenerative spondylolisthesis [**Level 1**].^{3,4}

Acquired and Hereditary Myelopathies

Natalie R. Weathered

Noam Y. Harel

INTRODUCTION

Myelopathy indicates pathology of the spinal cord leading to dysfunction of central motor and sensory circuits, as opposed to radiculopathy (pathology of spinal roots), which affects solely peripheral circuits. A large number of conditions may cause myelopathy (Table 111.1). This chapter expands on key inflammatory, infectious, vascular, metabolic, genetic, and toxic insults.

SYRINGOMYELIA

A syrinx is an intramedullary fluid-filled cavity typically found within the cervical to midthoracic spinal cord (Fig. 111.1), but extension down to the conus medullaris is also possible as is upward extension to the brain stem in which case it is called *syringobulbia*. The cavity is most commonly filled with cerebrospinal fluid (CSF). However, syringomyelia should be regarded as distinct from simple cystic expansion of the central canal for which the term *hydromyelia* applies.

EPIDEMIOLOGY

The prevalence of syringomyelia in Western countries is approximately 8.4 cases per 100,000. It typically presents in the third to fourth decade of life, and men are more frequently affected than women. It is uncommon in childhood or late-adult years.

PATHOBIOLOGY

Generally speaking, primary syringomyelia arises from an impairment of normal CSF flow dynamics. Although congenital cases of primary syringomyelia do exist, syringomyelia more often arises secondary to Arnold-Chiari type 1 malformation. There has long been debate about exactly how this posterior malformation leads to syringomyelia, with no definite consensus on a single theory. Spinal cord tumors may also cause secondary syringomyelia by altering local CSF flow dynamics. Additionally, syringomyelia may be seen in the chronic phase after trauma, either as an *ex vacuo* lesion that persists after absorption of an intramedullary hematoma or due to local inflammation of the pia-arachnoid resulting in adhesions between the meninges and spinal cord. In animal models, these adhesions lead to ischemia, demyelination, and ultimately, cavitation.

CLINICAL FEATURES

The classic presentation of cervicothoracic syringomyelia is a capelike distribution of decreased pain and temperature sensation in the back, arms, and hands, which occurs due to disruption of the crossing spinothalamic tracts. There may be varying degrees of weakness in the arms (lower motor neuron type due to involvement of cervical anterior horn cells) and legs (upper motor neuron type due to involvement of lateral corticospinal fibers). A Horner syndrome may be present if a cervicothoracic syrinx affects the intermediolateral columns. Bowel and bladder function are generally preserved unless the syrinx extends toward the sacral cord segments.

DIAGNOSIS

Magnetic resonance imaging (MRI) allows visualization not only of the syrinx but also of any associated

abnormalities such as Arnold-Chiari malformation, neoplasm, or arachnoid granulations. Full cord imaging should be strongly considered. MRI CSF flow studies may also be useful in guiding treatment. There are no biomarkers associated with syringomyelia. CSF is often normal or may have a nonspecific, mild elevation in protein.

TREATMENT

Conservative observation is warranted in cases with no or only minor symptoms and in cases of Arnold-Chiari malformation with tonsillar herniation less than 5 mm below the foramen magnum in the setting of normal CSF flow studies. In more severe cases of Arnold-Chiari, however, posterior fossa decompression and cervical laminectomy with or without duraplasty is frequently pursued in hopes of restoring normal CSF flow dynamics.

In cases of syringomyelia secondary to neoplasm, if resection is not possible, then fenestration or marsupialization of the syrinx may be attempted. Lysis of adhesions and/or shunting of the syrinx to the pleural or peritoneal cavities is also performed, although the benefits have not been proven and are very difficult to predict in individual patients.

OUTCOME

A recent study by Alfieri and Pinna found that surgical decompression for Arnold-Chiari type 1 malformation associated with syringomyelia tends to be well tolerated with few complications. Additionally, 93.4% of patients experienced some degree of clinical improvement.

In contrast, a study of surgical treatment for posttraumatic syringomyelia showed much lower clinical success rates, with only 51% of patients reporting clinical improvement. Forty-one percent of patients experienced no clinical change, and 8% had further clinical deterioration. Notably, among those patients in whom surgery was not recommended based on lack of significant neurologic symptoms, 84% remained stable at 10 years. The high progression-free rate and the unsure evidence for surgical efficacy both argue for the clinician to take a conservative, watchful approach to posttraumatic syringomyelia if at all possible.

METASTATIC CORD COMPRESSION

Neoplasm should be high on the differential anytime someone presents with a previously undiagnosed myelopathy. Metastatic disease is much more common than a primary central nervous system (CNS) tumor. In fact, an estimated 12% to 20% of patients

P.960

P.961

with cancer present with spinal metastasis as the initial symptom. Primary spinal cord tumors are much rarer, with an estimated incidence of 0.74 cases per 100,000—these neoplasms are discussed elsewhere in this volume. Further information on metastatic neoplasm may also be reviewed in Chapter 97.

TABLE 111.1 Differential Diagnosis of Myelopathy

- Spinocerebellar degeneration
 - Friedreich ataxia
 - Spinocerebellar ataxia types 1-28
- Spinal muscular atrophy

FIGURE 111.1 Syringomyelia on a T2-weighted MRI. The syrinx, which appears as a high-intensity linear lesion in the central cord, extends from C4 to C7. (From Peleggi AF, Lovely TJ. Treatment of delayed Chiari malformation and syringomyelia after lumboperitoneal shunt placement: case report and treatment recommendations. *Surg Neurol Int.* 2012;3:101, with permission.)

It is important to bear in mind that not all myelopathy in the setting of neoplasm is a direct consequence of the neoplasm itself but rather may be secondary to radiation injury, chemotherapy toxicity, or a paraneoplastic disorder.

EPIDEMIOLOGY

The cancers that most frequently metastasize to the spinal column are lung, breast, renal, hematopoietic, melanoma, prostate, and gastrointestinal. At least 95% of spinal metastases are extradural, usually to the vertebrae, and may remain asymptomatic. Autopsy studies suggest that over 30% of patients with advanced systemic cancer have pathologic evidence of vertebral metastases at the time of death. In the rostrocaudal axis, the majority of spinal metastases localize to the lumbar spine. However, due to the narrower diameter of the spinal canal within the thoracic segments, most symptomatic metastases are within the thoracic spine.

PATHOBIOLOGY

Most spinal metastases travel hematologically either through the arterial system or retrogradely through Batson venous plexus. As the vertebral column comprises a large proportion of the body's bone marrow rich in growth factors, the vertebrae may provide a particularly hospitable environment for metastatic cells. Leptomeningeal metastases can also result from either extension from nearby bone or spread through the CSF.

CLINICAL FEATURES

In addition to the usual myelopathic symptoms of weakness, sensory loss, and urogenital dysfunction, spinal neoplasms are often marked by pain. The pain may be local or radicular. It may accompany myelopathic symptoms acutely, or it may precede myelopathic symptoms by weeks to months. Although nonspecific, red flags of concern for a cancerous cause of back pain include age older than 60 years, associated weight loss, worse at night, thoracic rather than lumbar pain, and tenderness to palpation. The rate of symptom progression may range from slowly progressive

P.962

(as a result of compressive tumor growth) to an acute onset (such as a pathologic vertebral fracture secondary to intravertebral tumor). In addition, metastases may alter arterial perfusion and/or venous drainage, resulting in acute ischemia, hemorrhage, or venous compression.

DIAGNOSIS

Although a computed tomography scan performs well at detecting bony metastases, MRI with contrast remains the test of choice, as it visualizes the extent of cord and soft-tissue involvement, as well as vasogenic and cytotoxic edema. If a neoplasm is identified, full neuraxis imaging should be completed to evaluate for additional lesions, as these may alter treatment and prognosis. Additionally, if the patient is not otherwise known to have cancer, then a full assessment for the primary tumor should be initiated. If the spinal lesion is intradural, a high-volume lumbar puncture should be sent for cytology and flow cytometry although the sensitivity of these studies is not high. Ultimately, biopsy of either the spinal lesion or a suspected primary tumor source if easier to access remains the diagnostic gold standard.

TREATMENT

The mainstay of treatment has traditionally been glucocorticoid and radiation therapy. Radiation tends to be well tolerated, and 65% to 80% of patients report improvement of symptoms. High-dose corticosteroids such as dexamethasone 100 mg intravenous push (IVP), followed by 10 mg every 6 hours with a rapid taper over the next few days, is often used concurrently for symptom management. A randomized trial has shown that

decompressive surgical resection plus radiation therapy for acute paraplegia results in greater ability to walk (84% vs. 57%), and a better chance of regaining the ability to walk (62% vs. 19%), compared to radiation therapy alone [**Level 1**].¹

OUTCOME

As mentioned, the prognosis after diagnosis of a spinal metastasis is poor, with an average life expectancy of 4 to 15 months. The emphasis in management, therefore, is typically in maintaining the highest quality of life possible.

INFECTIOUS MYELOPATHY

Numerous infectious causes of myelopathy may induce symptoms through direct neuroinvasion, compression, or as an inflammatory response. Symptoms may occur at the time of the acute infection, as in the case of viral myelitis, meningoencephalitis, or abscess, or they may be delayed by days to weeks as in the case of postinfectious or postvaccination myelitis or even years in the case of neurosyphilis or HIV.

This chapter expands on viral myelitis and human T-cell lymphotropic virus (HTLV)-associated myelitis. Many other infectious syndromes are detailed elsewhere in this book. Additional reference may be made to Chapters 61 to 67.

VIRAL MYELITIS

Epidemiology

The true incidence of viral myelitis is unknown. Worldwide, the viral syndrome of acute flaccid paralysis, one form of viral myelitis, occurs in approximately 40 per 1,000,000 individuals per year. Prior to widespread vaccination, polio accounted for the vast majority of cases of acute flaccid paralysis. In recent times, West Nile virus (WNV) and Japanese encephalitis are the more likely culprits. Cases of transverse myelitis number approximately 1 to 4 cases per 1,000,000 individuals per year. Viral myelitis tends to be more common in the summer and early fall with a bimodal incidence peak in adolescence and the fourth decade of life.

Pathobiology

Viral myelitis may occur through direct cellular toxicity or through parainfectious inflammation. In particular, gray matter and anterior horn cells are often targeted by enteroviruses (including poliovirus, coxsackieviruses A and B, echovirus) and flaviviruses (WNV, Japanese encephalitis, tick-borne encephalitis). In contrast, herpesviruses, including herpes simplex virus (HSV), varicella-zoster virus (VZV), cytomegalovirus (CMV), and Epstein-Barr virus, have a higher predilection for glial cells of the white matter and sensory neurons in the dorsal horn.

Clinical Features

Acute flaccid paralysis typically presents with fever and headache followed a few days later by the onset of flaccid paralysis of at least one extremity. Alterations in cognition may be seen, reflecting a common association between flaccid paralysis and meningitis and encephalitis. Sensory symptoms and alterations in bowel and bladder control are notably absent. In comparison, transverse myelitis often has prominent sensory (usually symmetric) and bowel/bladder abnormalities in addition to weakness with or without cognitive symptoms that evolves over the period of hours to days.

Diagnosis

MRI with and without contrast may show evidence of edema, demyelination, meningeal enhancement, or necrosis. In addition to cord imaging, brain MRI is warranted to evaluate for intracranial involvement—abnormalities of the deep gray matter indicate viral encephalitis, whereas white matter findings would redirect the diagnosis toward an autoimmune etiology such as postviral or parainfectious inflammation, multiple sclerosis, or neuromyelitis optica.

All patients with suspected viral myelitis should undergo lumbar puncture. Typical CSF findings include pleocytosis with a lymphocytic or mononuclear predominance, normal glucose, but elevated total protein. Additionally, most pathogenic viruses may be directly detected within CSF using either polymerase chain reaction amplification of viral nucleic acid or specific antibody titers.

Treatment

In the setting of suspected viral myelitis, supportive care is fundamental. Specific antiviral medications include intravenous (IV) acyclovir, which is typically started upon presentation and may be discontinued if testing for HSV and VZV are negative. If CMV is suspected in the setting of HIV or other type of immunosuppression, then it would be reasonable to start ganciclovir and foscarnet. If the pathogen is WNV, there is mixed data supporting the use of intravenous immunoglobulin (IVIG) and interferon- α -2b. Finally, to combat parainfectious inflammation, IV methylprednisolone is often used in parallel with these other treatments.

Outcome

Prognosis depends in no small part on whether the damage involves gray matter or white matter, with better recovery in the latter. Age, severity of abnormalities, and timing of initiation of specific treatment also affect recovery.

P.963

HUMAN T-CELL LYMPHOTROPIC VIRUS-ASSOCIATED MYELOPATHY/TROPICAL SPASTIC PARAPARESIS

Epidemiology

HTLV types 1 and 2 cause insidious, progressive myelopathy in approximately 20 million people worldwide, with the highest infection rates in Japan, South America, the Caribbean, and equatorial Africa. Similar to HIV, HTLV transmission generally occurs as a result of unprotected sex, mother-to-child via breastfeeding, sharing of needles, or blood transfusions. Roughly 3% to 5% of infected individuals develop an aggressive T-cell leukemia, whereas an additional 0.25% to 3% develops a spastic paraparesis. Women are 1.5 to 3.5 times more likely to develop human T-cell lymphotropic virus-associated myelopathy/tropical spastic paraparesis (HAM/TSP) than men and may experience a faster progression of disease.

Pathobiology

Like HIV, HTLV predominantly infects CD4+ T lymphocytes. As a retrovirus, it reverse transcribes its RNA genome into DNA that then integrates into the host genome as a provirus. How HTLV infection leads to chronic, inflammatory/demyelinating myelopathy is not well understood. Autopsy studies show perivascular infiltrates containing HTLV-infected lymphocytes as well as multiple inflammatory cytokines resulting in breakdown of the blood-brain barrier (BBB).

Clinical Features

HAM/TSP is an insidious disease that begins initially with subtle weakness or stiffness of the lower extremities, followed by progression—without remissions—toward spastic paraparesis and spastic bladder. Paresthesias in the lower extremities are also common, although sensory levels are not usually seen.

Diagnosis

In the early stages of the disease, MRI is often unremarkable. With progression, nonspecific subcortical and periventricular white matter demyelinating lesions appear in the brain followed eventually by spinal cord atrophy.

Lumbar puncture typically shows mild pleocytosis with elevated total protein and normal glucose. HTLV-1 antibodies and a proviral load can be detected in the CSF. Oligoclonal bands and evidence of intrathecal immunoglobulin G (IgG) synthesis are often present.

Treatment

Several antiretroviral drugs used against HIV have been trialed against HTLV, so far without success. In the cancer literature, there are some reports of decreased HTLV-1 expression with interferon- α treatment. Other immune-modulating medications such as corticosteroids and cyclosporine may improve HAM/TSP symptoms, but these are far from proven therapies. As such, the mainstays of treatment are symptomatic.

Outcome

HAM/TSP remains a chronic, progressive, untreatable disease. Patients almost invariably become wheelchair bound with significant bladder and bowel dysfunction.

INFLAMMATORY MYELOPATHY

The noninfectious inflammatory causes of myelopathy include transverse myelitis, multiple sclerosis (MS; see [Chapter 69](#)), systemic lupus erythematosus (SLE), antiphospholipid antibody syndrome, Sjögren syndrome, mixed connective tissue disease, sarcoidosis, Behçet disease, neuromyelitis optica (NMO), acute disseminated encephalomyelitis (ADEM), paraneoplastic syndromes (see [Chapter 104](#)), and others that remain to be identified. It is important to note that the cause remains unidentified in up to 30% of cases of spinal cord inflammation resulting in the diagnosis of idiopathic transverse myelitis.

CLINICAL FEATURES

As with any other cause of myelopathy, symptoms of inflammatory myelopathy depend on the location of the lesion. Most classically, patients present with sensory symptoms in a bandlike distribution associated with bladder dysfunction. Symptoms often progress to include motor deficits over the course of hours to days.

DIAGNOSIS

MRI with contrast usually reveals T2-hyperintense white matter lesions, often with contrast enhancement ([Fig. 111.2](#)). The pattern of cord and brain MRI involvement may help narrow the differential—for example, longitudinally extensive cord lesions suggest NMO, whereas deep brain gray matter lesions suggest ADEM. However, as many as 40% of cases may not show any MRI abnormality. CSF studies must include testing for oligoclonal bands (OCB) and IgG synthesis rate. Although not highly specific,

several of the most common inflammatory myelopathies are associated with characteristic CSF profiles. For example, MS tends to feature normal protein, lack of pleocytosis, and positive OCB/IgG synthesis; in contrast, NMO usually demonstrates increased protein and cell count and a lower rate of positive OCB/IgG synthesis. Specific serum and CSF biomarkers include aquaporin-4 antibody (NMO), angiotensin-converting enzyme (ACE) (sarcoidosis), antinuclear and anti-double-stranded DNA antibodies (SLE), anti-Ro/SSA antibodies, anti-La/SSB antibodies (Sjögren), anti-scl-70 antibodies (scleroderma), and paraneoplastic antibodies. Visual-evoked potentials and somatosensory-evoked potentials may be useful ancillary tests if MRI and CSF are unrevealing. In up to 30% of cases, none of these studies are abnormal. These cases earn the diagnostic label of idiopathic transverse myelitis, a label that has steadily become less frequent due to improved diagnostic understanding.

FIGURE 111.2 An MRI showing a transverse myelitis lesion (the lesion is the lighter, oval shape at center right). This MRI was taken 3 months after patient recovered. (From Gaillard F. Transverse myelitis. Radiopaedia.org Web site. <http://radiopaedia.org/cases/transversemyelitis>. Accessed April 25, 2015.)

TREATMENT

Once infection is ruled out, most cases of paraparesis related to acute transverse myelitis are treated with a 3- to 5-day course of IV corticosteroids, most commonly IV methylprednisolone 1,000 mg daily. More aggressive diseases such as NMO, SLE, Sjögren scleroderma, and others are treated with plasmapheresis or chronic immunosuppressive therapy.

OUTCOME

Prognosis varies widely depending on the disease, the extent of the lesion, the rate of symptom progression, and the patient's age. Disease course may be monophasic or relapsing, with complete remission or permanent disability.

VASCULAR MYELOPATHY

SPINAL CORD INFARCTION

Epidemiology

Compared to cerebrovascular ischemia, spinal cord infarction is quite rare, accounting for only 1% to 2% of vascular neurologic deficits and 5% to 8% of all acute myelopathies. In one small study by Cheshire and colleagues, men were almost twice as likely to experience an infarction of the spinal cord as women, but to our knowledge, this has not been studied in a larger context.

Pathobiology

The spinal cord is perfused mainly by direct branches of the aorta. The most common causes of spinal cord ischemia are secondary to aortic pathology and injury, such as dissection, traumatic rupture, and surgical procedures. Additionally, traditional causes of stroke in the cerebral vasculature can also cause stroke in the spinal cord vasculature—therefore, etiologies such as cardioembolism, hypercoagulable state, atherosclerosis, and vasculitis should be considered. The vast majority of spinal infarcts occur in the territory supplied by the anterior spinal artery (see [Chapter 16](#), [Fig 16.2](#)). Due to a relative paucity of collateral perfusion, the thoracic cord is especially susceptible to systemic hypotension.

Clinical Features

Symptom onset typically occurs acutely over minutes to hours, although some patients experience a slower progression of symptoms in the setting of arterial insufficiency. Back pain frequently accompanies other typical myelopathic symptoms. On acute exam, flaccid paralysis and a sensory level to pinprick and temperature below the level of the ischemic lesion will usually be present. Vibration and proprioception are typically preserved, as the dorsal columns are supplied by the posterior spinal arteries. Reflexes are initially reduced or absent but transition to hyperreflexia over subsequent days to weeks.

Diagnosis

When cord ischemia is suspected, MRI and magnetic resonance (MR) angiography should be performed, with special attention to diffusion-weighted and apparent diffusion coefficient sequences. However, due to difficulties with resolution in the spinal canal, a negative scan does not rule out the diagnosis of ischemia, especially in the first few hours after presentation. There are no specific laboratory abnormalities to confirm the diagnosis. However, as part of the diagnostic workup and to guide secondary prevention, an echocardiogram, telemetry, a lipid panel, and hemoglobin A1c are typically ordered, along with a

hypercoagulable disease workup if the patient is younger than 50 years or has a concerning family history.

Treatment

No randomized trials have looked at treatment of acute spinal cord infarction as a unique entity.

Induced hypertension with phenylephrine (20 to 100 µg/min) in association with spinal drainage to reduce CSF pressure (<5 cm H₂O) and increase spinal cord perfusion pressure has been described, in particular when spinal cord infarction occurs as a complication of aortic aneurysm surgery.

There are no reports of use of tissue plasminogen activator for the treatment of acute spinal cord infarction. This is most likely a result of the broad differential diagnosis of acute paraplegia (see [Table 111.1](#)).

Outcome

The classic teaching is that prognosis for recovery of motor or sphincter function after a spinal infarct is quite poor. However, Robertson and colleagues recently showed in a study of 115 patients that functional recovery of both ambulation and bladder control is possible in over one-third of survivors, especially if there is even a small degree of residual motor function within the first 6 months.

SPINAL ARTERIOVENOUS MALFORMATIONS

Epidemiology

Arteriovenous malformations (AVM) are inappropriate arteriovenous connections involving arteries that normally supply neural tissue. In contrast, dural arteriovenous fistulas (DAVF) are improper connections that involve the radiculomeningeal arteries. The vast majority, approximately 70%, of all spinal vascular malformations are DAVF. DAVF occur most frequently after the fourth decade of life and are more common in men than women. Intradural AVF are most common within the lower thoracic and lumbar spine. Extradural AVF are most common within the cervical cord. In comparison, spinal AVMs have no gender predominance and tend to present between the ages of 20 and 60 years old. Just over half of spinal AVMs are found within the thoracic cord, almost a third are cervical and the remaining are in the lumbar spine.

P.965

Pathobiology

Frank hemorrhage is not necessary to cause many of the symptoms of spinal vascular malformations. In both DAVF and AVM, the abnormal direct arterial flow into the venous system may result in myelopathy via cord compression as well as via the development of venous hypertension which leads to intramedullary edema. Additionally, in the setting of large arteriovenous lesions, vascular steal may occur, resulting in cord ischemia. Finally, symptoms may occur when arterial pressure overwhelms the accommodation of the venous wall, leading to hemorrhage; this is more common in AVM than DAVF.

Clinical Features

Chronically progressive motor deficits, especially paraparesis, are the most common presenting symptom. The weakness may worsen with exercise. Almost half of patients will have pain, often radicular, referable to the lesion. The diagnosis often eludes detection for years, although one clinical key may be the stepwise pattern of progression. Notably, in the case of AVMs, approximately half of patients present acutely with sudden onset of myelopathic symptoms due to hemorrhage.

Diagnosis

On standard MRI sequences, signs of AVM and DAVF include cord edema and enhancement. Gradient echo-based MRI sequences may detect characteristic abnormal flow voids. Conventional digital subtraction angiography remains the gold standard over MR angiography for diagnosis. It also has the added benefit of allowing for therapeutic intervention if the diagnosis is confirmed.

Treatment

Treatment options for AVM and DAVF include embolization of the feeding arteries, surgical clipping or resection, and gamma knife radiosurgery. Frequently, a combination of these treatment modalities is necessary. The treatment of asymptomatic and unruptured cranial lesions, especially AVM, is quite controversial. The A Randomized Multicenter Clinical Trial of Unruptured Brain AVMs (ARUBA) was stopped prematurely due to an increased rate of adverse events in the intervention arm—including all of these options—as compared to conservative medical therapy. Although this trial excluded spinal AVMs, these results should be considered.

Outcome

Prognosis can be difficult to predict; as may be expected, the patient's age, duration, and severity of myelopathic symptoms are critical variables that influence response to treatment. Overall, complete obliteration of the vascular lesion may be difficult to attain—especially with AVMs—however, in most cases, even partial treatment can result in significant clinical improvement.

TOXIC/METABOLIC CAUSES OF MYELOPATHY

Numerous causes of toxic or metabolic myelopathy may present with similar progressive myelopathic symptoms. The specific diagnosis derives from a combination of history of past exposures, systemic manifestations, and laboratory testing. Nutritional deficiencies, especially those of cyanocobalamin, thiamine, folate, vitamin E, and copper, are discussed extensively in Chapter 123.

MYELOPATHY DUE TO RADIATION OR CHEMOTHERAPY

Radiation therapy and a number of medications, especially chemotherapeutics, have been reported to cause myelopathy. The risk of myelopathy as a consequence of radiation therapy increases nonlinearly with the dose of radiation, with a reported prevalence of approximately 5% of patients who receive 60 cGy to the spinal cord as compared to only 1% of patients who were treated with 50 cGy. Radiation-induced myelopathy typically onsets months to years after treatment. Of the chemotherapeutics, methotrexate and cytarabine are the most frequent offenders and are most likely to lead to a myelopathy in those treated intrathecally or with systemic doses that are high enough to penetrate the BBB. If chemotherapy-related myelopathy occurs, it generally does so within hours to weeks after treatment and usually after the patient has received multiple doses. A number of other chemotherapeutics have been reported to cause myelopathy including fludarabine, cladribine, thiotepa, doxorubicin, and daunorubicin. In addition, amphotericin B has been reported to contribute to development of myelopathy.

NITROUS OXIDE TOXICITY

Nitrous oxide (NO) is an inhaled anesthetic that is used primarily for dental procedures. Therefore, occupational

exposure is a risk, although NO toxicity more frequently results from recreational abuse in the form of “whippets,” derived from whipped cream canisters. NO-induced myelopathy typically results relatively rapidly after abuse and is associated with functional B₁₂ deficiency due to interference with B₁₂ metabolism. Accordingly, the clinical picture is identical to subacute combined degeneration, with prominent proprioceptive loss in addition to spastic paraparesis. If a patient is expected to undergo a procedure with NO anesthesia and has moderately low B₁₂ levels, supplementation with cyanocobalamin for a few weeks prior to the procedure can prevent this complication.

HEPATIC MYELOPATHY

Hepatic myelopathy is an uncommon and overlooked consequence of advanced cirrhosis. It is characterized by a spastic paraparesis that almost always spares the arms and which progresses slowly over years. Sensory and autonomic symptoms are typically absent. The myelopathy is often preceded by hepatic encephalopathy and most frequently occurs in the setting of a portosystemic shunt. MRI is often normal, especially early in the disease; however, motor-evoked potentials may confirm an abnormality. The pathobiology is unknown. There is mixed literature on improvement after liver transplantation, with some suggesting that transplantation before symptoms become too severe may allow for some degree of recovery.

GENETIC CAUSES OF MYELOPATHY

The genetic causes of myelopathy include hereditary spastic paraplegia, motor neuron disease, disorders of metabolism, and spinocerebellar degeneration. Within this section, we focus primarily on hereditary spastic paraplegia. Additional chapters expanding on these etiologies include Chapters 79, 85, 133, 134, and 137.

HEREDITARY SPASTIC PARAPLEGIA

Epidemiology

Hereditary spastic paraplegia (HSP) is a heterogeneous group of neurodegenerative disorders associated with mutations in any of

P.966

over 50 genes that may have either autosomal dominant (AD) or autosomal recessive (AR) inheritance. HSP has a prevalence of 5.5 cases per 100,000. Among families with AD inheritance, the most frequent culprit mutations occur in SPG4 followed by SPG3A. Among families with AR inheritance, mutations within SPG11 are the most common, with SPG15 and SPG5 mutations as the second and third most common anomalies. X-linked and mitochondrial causes also exist, but the epidemiology of these is not as well studied. In addition, de novo mutations can occur in the absence of family history.

Pathobiology

HSP is classically associated with axonal degeneration at the distal ends of the lateral corticospinal tracts, often accompanied by distal degeneration within the fasciculus gracilis as well. The molecular basis for these abnormalities varies widely depending on the particular causal gene, with abnormalities involving axonal and endosomal trafficking, endoplasmic reticulum morphogenesis, lipid metabolism, and mitochondrial regulation. Further information can be found in recent reviews by Fink as well as Noreau and colleagues.

Clinical Features

HSP can present at any age. It typically begins as a gait abnormality due to impaired dorsiflexion secondary to extensor spasticity. Especially early in the disease, spasticity is a more prominent finding than actual weakness and may be mildly asymmetric. As the disease progresses, more proximal leg muscles become involved leading to a scissoring gait (adductor spasticity). Abnormalities of vibratory and position sense as well as bowel and

bladder control may also be seen. The arms are generally spared except for possible hyperreflexia. “Complicated” HSP refers to cases with additional symptoms such as cognitive impairment, epilepsy, parkinsonism, ataxia, peripheral neuropathy, amyotrophy, or vision or hearing loss.

Diagnosis

A presumptive diagnosis of HSP is usually made based on a combination of personal and family history and physical exam. Genetic testing finds the causative gene in only 33% to 55% of autosomal dominantly inherited cases and 18% to 29% of autosomal recessively inherited cases. MRI is often normal but may show distal spinal cord atrophy, especially later in disease course. Sensory-evoked potentials are often abnormal, even in patients without clinical evidence of sensory abnormalities.

Treatment

Treatment is symptomatic. Muscle relaxants such as baclofen, tizanidine, or diazepam may aid with spasticity. Botulinum toxin injection may prove helpful in more resistant cases. Physical therapy is recommended to help maintain range of motion and mobility. Symptoms of spastic bladder can be treated with anticholinergic medications such as oxybutynin.

Outcome

HSP does not typically shorten life expectancy, and many patients will experience a plateau in neurologic decline after which the degree of disability seems to stabilize. At what point this plateau will occur, however, will vary with the patient and is difficult to predict.

Neurogenic Orthostatic Hypotension, Autonomic Failure, and Acquired and Familial Autonomic Neuropathy

Louis H. Weimer

INTRODUCTION

Autonomic disorders are generally considered to be uncommon conditions, but in fact, autonomic dysfunction is ubiquitous in neurologic disease, including highly prevalent processes such as seizures, strokes, mass lesions, infections, multiple sclerosis (MS) plaques, and others, but dysautonomia is often a secondary concern. A limited number of disorders produce severe or isolated dysautonomia or autonomic failure (AF). Because autonomic systems affect virtually all organ systems, symptoms produced are multiple and varied, often affecting functions not considered by most neurologists. Problems can arise from any site of autonomic control including the central cortical and subcortical autonomic network, brain stem, spinal cord, autonomic ganglia, or peripheral autonomic nerves. The range of pathogenic mechanisms is highly varied, including degenerative, hereditary, immune-mediated, paraneoplastic, aberrant reflex, and metabolic, among others. Suspicion of autonomic dysfunction rests with the clinician and can be missed if symptoms that can appear to be nonspecific are considered in isolation ([Table 112.1](#)). Early symptoms of the most characteristic finding, orthostatic hypotension (OH), may appear as postural fatigue, cognitive change, anxiety, or vertigo. This lack of certainty in many cases makes more objective assessment desirable in these instances (see [Chapter 27](#)). Postural hypotension (OH) is a prevalent clinical sign seen in numerous and diverse neurologic and nonneurologic conditions. Shibao et al. estimated over 80,000 U.S. OH-related hospitalizations in 2004; OH was the primary diagnosis in 35%. One consensus agreement defines OH as a fall in systolic blood pressure (SBP) of 20 or 10 mm Hg diastolic within 3 minutes of standing or similar orthostatic challenge, such as upright tilt, although some require a 30 mm Hg decline. OH, however, may be asymptomatic, especially in the elderly, and varies according to underlying conditions or confounding factors ([Table 112.2](#)). The sign is one marker of advanced AF caused by either diseases of central autonomic pathways or autonomic neuropathy. Some severe and important causes are discussed; a more comprehensive list is provided in [Table 112.3](#). Acute and subacute processes are generally considered separately from more chronic conditions.

ACUTE AND SUBACUTE AUTONOMIC DISORDERS

Acute or subacute autonomic neuropathy (AAN) or acute pandysautonomia is an unusual but distinct entity, which primarily affects peripheral autonomic nerves. Roughly, half are preceded by a viral prodrome similar to Guillain-Barré syndrome (GBS). Patients typically develop generalized AF including OH, anhidrosis, parasympathetic failure, and gastrointestinal dysfunction, although predominantly adrenergic and cholinergic variants are seen. The illness is monophasic with acute or subacute onset over several weeks. Recovery generally occurs but is often slow and incomplete. Acute signs such as ileus may develop into lesser degrees of gastrointestinal dysmotility including bloating, early satiety, nausea, vomiting, and alternating diarrhea and constipation. Antecedent viruses include herpes simplex, mononucleosis, rubella, and nondescript febrile illnesses. Roughly 25% have a restricted cholinergic form (acute cholinergic neuropathy) characterized by dry eyes and mouth, gastrointestinal dysmotility, bladder dysfunction, hypohidrosis, unreactive pupils, fixed heart rate, and sexual dysfunction but without significant OH. Abnormalities on formal autonomic testing are prominent in the involved systems. Nerve conduction studies are typically normal or show minor sensory abnormalities. The lack of OH in cholinergic cases complicates the diagnosis.

Demonstration of high-titer antibodies to nicotinic ganglionic AChR α -3 subunits, which are similar but distinct

from those at the neuromuscular junction (α -1 subunits), supports an immune-mediated basis. A paraneoplastic form, which develops in a similar time course and is indistinguishable on clinical or laboratory

P.969

grounds, may appear prior to tumor discovery, most commonly thymoma. In screening patients with autonomic disorders and controls, Vernino et al. found that 41% of patients with idiopathic autonomic neuropathy had high antibody titers; paraneoplastic neuropathy patients were frequently positive as well. Rarely, patients with chronic OH and AF have high antibody titers and respond to immunotherapy, such as intravenous immunoglobulin (IVIG) or plasma exchange. Some patients with orthostatic intolerance, discussed later, and idiopathic gastrointestinal dysmotility, but none with chronic degenerative autonomic processes, also had positive assays at lower titers. Knockout mouse models of the α -3 subunit gene, rabbits immunized against the subunit, and passive antibody transfer to other animals all induce signs of AF supporting the assertion that the antibodies are causative. Antibody titers also correlate with disease severity. Of note, low-level titers may occur in patients with other disorders or nonspecific symptoms. One-third of AAN patients recover, one-third have a partial recovery with substantial deficits, and the remainder do not improve. Gastrointestinal dysfunction and OH are usually the most debilitating manifestations. Supportive care and management of the OH and system-specific problems are the mainstays of treatment. Rare cases with AAN and myasthenia gravis have both types of AChR antibodies. Autonomic involvement is common in typical GBS, discussed in Chapter 87, especially in more severe cases, and is a prominent cause of morbidity and mortality.

TABLE 112.1 Autonomic Review of Symptoms

- Secretomotor: dry eyes and mouth, often required natural tears or frequent sips of water. Excessive saliva can also occur.

- Orthostatic: dizziness, weakness, fatigue, cognitive changes, visual disturbance, vertigo, anxiety, palpitations, pallor, nausea, syncope

- Postprandial: bloating, fullness, nausea, dizziness, sweating, orthostatic hypotension

- GI: constipation, nocturnal or intermittent diarrhea

- Genitourinary (GU): urinary retention, difficulty with initiation, incomplete emptying, incontinence

- Sexual: erectile failure, ejaculatory dysfunction, retrograde ejaculation into bladder

- Visual: blurred vision, sensitivity to light/glare, reduced night vision

- Sudomotor: reduced loss of sweating ability (distally in polyneuropathies); excessive, paroxysmal, or inappropriate sweating; mixed pattern of loss and excessive areas, heat intolerance

- Vasomotor: distal color changes, change in skin appearance, persistently cold extremities, Raynaud phenomenon, loss of skin wrinkling in water, heat intolerance

- Other: unexplained syncope

GI, gastrointestinal

TABLE 112.2 Factors Affecting Orthostatic Hypotension

Aggravating Factors

- Warm environment, hot bath

- Post exercise

- Prolonged motionless standing

- Large meals (carbohydrate load)

- Early morning

- Valsalva maneuver, isometric exercise

- Volume depletion

- Rising after prolonged bed rest

- Rapid postural change

- Space flight

- Alcohol

- Medications

- Beneficial maneuvers

- Squatting, leg crossing

- Abdominal and leg compression

- Nighttime slight upright tilt

- Isotonic exercise

PARANEOPLASTIC AUTONOMIC NEUROPATHY

Subacute autonomic neuropathy or predominantly enteric neuropathy is also seen in isolation or with somatic sensory neuropathy and other underlying antibodies, especially type 1 antineuronal nuclear antibodies (ANNA-1, anti-Hu) usually in patients with small cell lung cancer. Paraneoplastic neuropathy is also associated with other paraneoplastic antibodies including Purkinje cell cytoplasmic antibody type 2 (PCA-2) and collapsing response mediator protein-5 (CRMP-5). Botulism (cholinergic), acute intermittent porphyria, and toxic neuropathy are other diagnostic considerations. A rare chronic form associated with high titers to ganglionic antibodies is known that can mimic degenerative AF. Autonomic manifestations are also common in patients with Lambert-Eaton myasthenic syndrome, especially cholinergic complaints and manifestations (see [Chapter 89](#)).

ORTHOSTATIC INTOLERANCE

Exaggerated orthostatic tachycardia may be evident in some cases without significant cardiac denervation. This led to the proposal that some patients with the common syndrome of idiopathic orthostatic intolerance without OH (postural orthostatic tachycardia syndrome), also known as orthostatic intolerance, may have an attenuated form of acute autonomic neuropathy. Orthostatic intolerance symptoms include postural lightheadedness, fatigue, cognitive changes, and presyncope despite minimal changes in blood pressure (BP). Potential mechanisms are multiple, including excessive venous pooling, idiopathic hypovolemia, adrenergic hypersensitivity, and altered cerebrovascular autoregulation. Some may have an attenuated form of AAN supported by abnormalities of sudomotor and other autonomic systems in one-third of cases and an overrepresentation of antecedent viral infection in these patients. The common physiologic thread is presumed bouts of cerebral hypoperfusion, despite a seemingly adequate systemic BP. This syndrome is the most common cause of consultation in most autonomic centers. The condition is much more common in women, roughly 5:1 and commonly initially develops between ages 15 and 25 years, often after an acute illness, such as a viral syndrome. An association with joint hypermobility and presumed or documented Ehlers-Danlos syndrome type III is increasingly recognized. Patients with grade I Chiari malformations also typically have multiple autonomic symptoms, including orthostatic intolerance. Roughly, 40% of patients have additional vasovagal syncopal episodes. The condition must be distinguished from depression, vestibular disorders, chronic fatigue, fibromyalgia, and panic disorders but many overlap cases exist; many patients have coincident chronic and not postural fatigue, insomnia, and chronic pain. Uncommon symptomatic causes must be considered, such as adrenal insufficiency, pheochromocytoma, and Sjögren syndrome. The syndrome often leads to secondary deconditioning, which complicates recovery. An indistinguishable hereditary form resulting from a mutation in a norepinephrine transporter gene is known but is exceedingly rare. Similar symptoms can be seen in patients with predominantly painful small fiber neuropathy due to additional involvement of distal autonomic nerves. Treatment must be individualized based on the most prominent symptoms but is generally based on improving standing BP, increasing blood volume, minimizing anemia, and increasing activity levels. Beta blockade is helpful in patients with bothersome palpitations and hyperadrenergic forms but is counterproductive in other subtypes.

CHRONIC NEUROGENIC ORTHOSTATIC HYPOTENSION AND AUTONOMIC NEUROPATHY

PARKINSONIAN SYNDROMES AND PURE AUTONOMIC FAILURE

Marked AF in patients with multiple system atrophy (MSA), especially the former Shy-Drager syndrome, is frequent. Other autonomic

symptoms often predate OH, including impotence, decreased sweating, and urinary incontinence. MSA is a group of disorders with overlapping neuropathology and may have autonomic, parkinsonian, or cerebellar symptoms at onset or later, as discussed in Chapter 84. Other common manifestations include sleep apnea, incontinence, impotence, dystonia, inspiratory stridor, hoarseness, lack of rest tremor, and ineffective or transient L-dopa response. Virtually all MSA patients eventually show autonomic signs or symptoms, regardless of initial manifestations. Demonstration of argyrophilic glial cytoplasmic inclusions (GCIs) in oligodendroglia is a characteristic but not a pathognomonic MSA hallmark. GCIs are prominent in sites of central autonomic control and correlate better with clinical findings than do areas of neuronal loss. Consensus diagnostic criteria first published in 1996 were simplified and refined in 2008. Increased risk of MSA has been found in families and some sporadic cases from various mutations in the gene COQ2, which is essential for the biosynthesis of coenzyme Q10. Median survival from symptom onset is approximately 10 years based on the most recent natural history studies; parkinsonism at onset and incomplete bladder emptying were the most predictive factors for faster progression.

TABLE 112.3 Selected Disorders of Autonomy Function

Isolated Degenerative Autonomic

Pure autonomic failure (PAF), “Bradbury-Eggleston syndrome”

Multisystem Degenerative Disorders

MSA

Parkinson disease with autonomic failure

Central

Brain tumors (posterior fossa, third ventricle, hypothalamus), syringobulbia, MS, tetanus, Wernicke-Korsakoff syndrome, fatal familial insomnia

Spinal Cord

MS, syringomyelia, transverse myelitis, trauma, mass lesion

Peripheral

Immune mediated

Guillain-Barré syndrome (see [Chapter 87](#)), acute and subacute autonomic neuropathy, acute cholinergic neuropathy, Sjögren disease, SLE, rheumatoid arthritis, Holmes-Adie syndrome, Ross syndrome, Harlequin syndrome, acute anhidrosis

Metabolic

Diabetes, vitamin B₁₂ and thiamine deficiency, uremia

Paraneoplastic

Paraneoplastic autonomic neuropathy and paraneoplastic syndromes with autonomic neuropathy (ANNA-1, α 3-AchR ganglionic, CRMP-5, PCA-2 antibodies), enteric neuropathy, Lambert-Eaton myasthenic syndrome (cholinergic)

Infectious

Chagas disease (cholinergic), syphilis, leprosy, HIV, Lyme disease, diphtheria

Hereditary

Familial amyloidosis, hereditary sensory and autonomic neuropathies (see [Chapter 88](#)), dopamine β -hydroxylase deficiency, porphyria, Fabry disease, norepinephrine transporter deficiency, fragile X premutation-associated tremor/ataxia syndrome, CANVAS syndrome, Hirschsprung megacolon, Ehlers-Danlos type III, myopathy, external ophthalmoplegia, neuropathy, gastrointestinal encephalopathy (MNGIE), Machado-Joseph disease, prion-induced diarrhea, and autonomic neuropathy

Toxins and Medications

Botulism, vincristine, cisplatin, taxoids, amiodarone, pyriminil (Vacor), hexacarbon, carbon disulfide, heavy metals, podophyllin, alcohol

Drug and Medication Effects

Anticholinergics: tricyclic antidepressants, atropine, oxybutynin

β -Adrenergic blockers: propranolol and others

α 2-Agonists: clonidine, prazosin, α -methyl dopa, terazosin, doxazosin

α 1-Antagonists: phentolamine, phenoxybenzamine, guanabenz

Ganglionic blockers: guanethidine, hexamethonium, mecamylamine

Others: hydralazine, nitrates, diuretics, calcium channel blockers, ACE inhibitors, antihistamines, antipsychotics, Sinemet, narcotics, sildenafil, tadalafil

Reduced orthostatic tolerance

Neurocardiogenic syncope, POTS, mitral valve prolapse syndrome, prolonged bed rest or weightlessness, Chiari malformation

Others

Acquired amyloidosis, chronic idiopathic autonomic neuropathies, small-fiber neuropathy, idiopathic hyperhidrosis, idiopathic anhidrosis, Horner syndrome

MSA, multiple system atrophy; MS, multiple sclerosis; SLE, systemic lupus erythematosus; CRMP-5, collapsing response mediator protein-5; PCA-2, Purkinje cell cytoplasmic antibody type 2; CANVAS, cerebellar ataxia, neuropathy, vestibular areflexia syndrome; MNGIE, mitochondrial neurogastrointestinal encephalomyopathy; ACE, angiotensin-converting enzyme; POTS, postural orthostatic tachycardia syndrome.

Many patients with idiopathic Parkinson disease (IPD) also have autonomically mediated complaints, most commonly constipation and urinary dysfunction, but measurable OH is often asymptomatic. However, the prevalence of autonomic symptoms in IPD patients is increasingly recognized. Exacerbation or inducement of OH from medications such as L-dopa is recognized and variably clinically significant.

Some patients with otherwise typical IPD have more severe AF including symptomatic OH and are designated Parkinson disease (PD) with AF. A separate disorder known as *pure autonomic failure* (PAF) or idiopathic OH, first described by Bradbury and Eggleston in 1925, is a profound, slowly progressive disorder with disabling OH, usually starting after age 50 years. By definition, no other neurologic impairment is seen, and the ultimate diagnosis is often

P.971

delayed 3 to 5 years to ensure that MSA or parkinsonism does not emerge. Autopsies show a similar pattern of classic Lewy bodies in peripheral autonomic and enteric ganglia in both PD with AF and PAF. Similarities between these Lewy body disorders are further supported by cardiac fluorodopamine positron emission tomography (PET) studies demonstrating loss of cardiac sympathetic innervation in both conditions but not in MSA patients. The shared neurodegenerative mechanisms between IPD, diffuse Lewy body dementia, and PAF is increasingly recognized.

Dopamine β -hydroxylase deficiency is a very rare but treatable entity with severe OH, syncope, and nearly undetectable norepinephrine and epinephrine leading to a failure of BP maintenance while standing. The norepinephrine precursor L-threodihydroxyphenylserine (L-DOPS; droxidopa), which can be beneficial for these patients and in patients with other forms of AF, was U.S. Food and Drug Administration (FDA) approved in 2014, commonly titrated to a target dose of 100 mg three times a day.

Cerebellar ataxia, neuropathy, and vestibular areflexia syndrome (CANVAS) is a recently recognized neurodegenerative ganglionopathy that commonly includes OH; in one series, 83% had evidence of autonomic dysfunction.

Numerous other common and uncommon disorders affecting the brain and spinal cord affect autonomic function but less commonly cause symptomatic OH (see [Table 112.3](#)). Additionally, some processes may be pathway or organ specific such as predominantly cholinergic, adrenergic, regional, or organ-specific disorders. Anhidrosis or hypohidrosis occurs with a variety of process, notably in length-dependent neuropathy. Regional and segmental hypohidrosis can occur; when associated with Adie pupils and hyporeflexia, the condition is known as *Ross syndrome*; some cases occur following viral infection and are presumed to be immune-mediated. Acute or subacute generalized anhidrosis also occurs. Patients, however, more commonly note increased sweating. Compensatory proximal sweating is common in patients with large areas of reduced sweating from any cause. Essential hyperhidrosis is diffuse tendency for excessive sweating and is often hereditary. Treatments directed at reducing sweating include traumatizing sweat glands with water iontophoresis, chemodenervation, or strong

antiperspirants; simple anticholinergic medications are typically ineffective at tolerable dosage. Surgical endoscopic sympathectomy is an option for severe cases.

CHRONIC AUTONOMIC NEUROPATHIES

Many of the scores of different peripheral neuropathies induce autonomic dysfunction, often limited to distal sweating and vasomotor control, especially those disproportionately affecting small-diameter fibers. The consequence is dry, cool distal extremities common in many neuropathy patients. Dysfunction is generally insufficient to impair peripheral vasoconstriction or postural reflexes enough to produce symptomatic OH. A few entities, however, lead to severe or targeted autonomic dysfunction, which can produce frank AF and symptomatic OH. Particularly noteworthy causes include diabetes, familial and acquired amyloidosis, paraneoplastic neuropathies, and selected hereditary, infectious, and toxic neuropathies. Some of the more prominent examples are listed in [Table 112.3](#).

Diabetic autonomic neuropathy (DAN) is the most common and important cause of autonomic neuropathy and the most extensively examined. Somatic peripheral neuropathy is usually concurrent. Much attention has focused on the impact of diabetic autonomic dysfunction on long-term survival. Ewing et al. found 56% of 73 patients with DAN died within 5 years, many owing to nonautonomic complications such as renal failure. Later studies showed an increased but less ominous DAN mortality rate in diabetics without other initial complications (23% at 8 years) compared with diabetics without DAN and similar disease duration (3% at 8 years). The added autonomic dysfunction risk is independent of coronary perfusion deficits. Upper gastrointestinal dysmotility, bladder complaints, impotence, sudomotor loss, constipation, episodic diarrhea, and gustatory sweating are a few common manifestations that aid in diagnosis and may require symptomatic treatment.

Amyloidosis, including both hereditary and acquired forms, is another important consideration in patients with severe AF. Certain mutations in transthyretin (TTR) are associated with more severe autonomic neuropathy than mutations in apolipoprotein A1 or gelsolin. Some forms commonly cause neuropathy, whereas others rarely do. Hepatic, bone marrow, and stem cell transplantation are evolving treatments; several other modalities of treatments such as an oligonucleotide antisense drug are in late-stage clinical trials.

Immune-mediated and paraneoplastic neuropathy are potentially treatable and often begin subacutely. A chronic form is also seen in isolation or in association with other autoimmune disorders, notably Sjögren disease. A notable report in 2005 complicated diagnosis by demonstrating a patient with presumed, very longstanding, stable AF, who demonstrated high AChR ganglionic antibodies, typically reserved for acute and subacute neuropathy, and responded markedly and repeatedly to recurrent IVIG infusions.

Idiopathic painful, small-fiber neuropathy often affects distal autonomic function but rarely causes symptomatic OH or symptomatic AF. Other forms of autonomic neuropathy are listed in [Table 112.3](#).

HEREDITARY SENSORY AND AUTONOMIC NEUROPATHY AND FAMILIAL DYSAUTONOMIA

The onset of some autonomic disorders occurs much earlier than those already discussed, including some congenital and infantile hereditary conditions. The most common and important entities are discussed.

FAMILIAL DYSAUTONOMIA (RILEY-DAY SYNDROME)

Hereditary sensory and autonomic neuropathy type III, also known as *familial dysautonomia* (FD) and was first described by Riley et al. in 1949, is a rare autosomal recessive disease with complete penetrance but variable expression. Virtually all patients are of eastern European (Ashkenazi) Jewish descent. The carrier rate may be as high as 1 in 25 and the disease prevalence was 1 in 4,100 live births. However, following the availability of genetic testing, subsequent to the gene discovery in 2001, the incidence sharply dropped. In 2009, only five new

FD cases were diagnosed worldwide. There is no sex predilection in either affected individuals or carriers. The condition affects the survival and development of sensory, sympathetic, and some parasympathetic neurons. Autonomic symptoms are prominent, and general somatic growth is affected.

The causative gene is *IKBKAP* (I kappa B kinase complex-associated protein) on chromosome 9q31-q33. Two mutations in the gene *IKBKAP* are implicated. The major FD mutation is a splice defect that displays tissue-specific expression and causes aberrant mRNA splicing. The second more infrequent mutation is a missense mutation. The end result is a nonfunctional *IKAB* protein

P.972

and a congenital sensory and autonomic neuropathy. Specific assays for mutations of *IKBKAP* have facilitated carrier screening for FD in the Ashkenazi Jewish population. Prenatal diagnosis is available, and preimplantation genetic diagnosis is also available for at-risk couples.

The condition can be identified in the neonatal period; clinical manifestations tend to increase with age. FD is currently classified as hereditary, sensory, and autonomic neuropathy type III (HSAN III).

Clinical Manifestations

Neurologic abnormalities detected in the neonatal period include decreased muscle tone, diminished or absent deep tendon reflexes, absent corneal responses, reduced Moro reflex, and weak cry and suck. The tongue tip lacks fungiform papillae and appears smooth. Uncoordinated swallowing with resultant regurgitation may cause aspiration and pneumonia. Some infants require tube feeding, gastrostomy, and fundoplication because of gastroesophageal reflux. Absence of overflow tears, which can be normal for the first 3 months, persists and becomes a consistent feature. Corneal ulceration can occur.

During the first 3 years of life, affected children show delayed physical and developmental milestones, episodic vomiting, excessive sweating, excessive drooling, blotchy erythema, and breathholding spells. Up to one-third of patients have seizures during early life, usually associated with fever or hypoxia. Less than 10% of patients have subsequent epilepsy. Dysautonomic crises occur usually after age 3 years characterized by irritability, self-mutilation, negativistic behavior, diaphoresis, tachycardia, hypertension, and thermal instability; however, episodes share many characteristics of autonomic seizures and typically respond to anticonvulsants. Episodic vomiting is frequent and can be cyclic, requiring hospitalization for stabilization with parenteral hydration and sedation.

School-aged patients tend to have short stature, awkward gait, and nasal speech. School performance may be poor, frequently 20 or more intelligence points below unaffected siblings. Scoliosis is frequent and can begin in childhood and progress during preadolescence. The prevalence of spinal deformity is high in FD patients older than 20 years. Vomiting and dysautonomic crises tend to decrease during adolescence when more frequent symptoms center on decreased exercise tolerance, poor general coordination, emotional difficulties, and postural hypotension. Vasovagal syncope may occur randomly, after micturition, or during laryngeal intubation for anesthesia.

There is a high incidence of sudden death in FD. There is also an incidence of syncope, electrocardiographic abnormalities including asystole, bradycardia, atrioventricular (AV) block, and prolonged QT interval. Pacemaker placement to protect FD patients has not been found to be protective against fatal bradyarrhythmias but may decrease the incidence of syncope.

Diagnosis

The diagnosis should be suspected because of the specific clinical symptoms and findings and the familial Ashkenazi Jewish background. The FD gene test provides definitive confirmation. DNA diagnoses and genetic screening of the Ashkenazi Jewish population is available. If both parents are carriers, prenatal

diagnosis can be done by chorionic villus sampling (10th to 11th gestational week) or by amniocentesis (14th to 17th gestational week). Preimplantation diagnosis is available for at risk couples who would not consider pregnancy termination.

The intradermal histamine phosphate test can provide additional diagnostic confirmation. An intradermal injection of 1:1,000 histamine phosphate (0.03 to 0.05 mL) normally produces pain and erythema. A central wheel forms within minutes and is surrounded by an axon flare that is a zone of erythema measuring 2 to 6 cm in diameter. The flare lasts for several minutes. In dysautonomic patients, the pain is greatly reduced and there is no axon flare. In infants, a saline solution of 1:10,000 histamine should be substituted.

Biochemical and Pathologic Data

The protein product is part of a six-protein elongator complex that plays a key role in transcription of products that affect the cytoskeleton and cell motility. How this disruption of function leads to FD is not currently understood. Plasma levels of both norepinephrine and dopamine are markedly elevated during dysautonomic crises.

Pathologic data reveal hypoplastic cervical sympathetic ganglia with diminished volume and neuronal counts. Sympathetic preganglionic spinal cord neurons seem reduced in number and size. Patients are deficient in nonmyelinated and small-fiber neurons. Lingual submucosal neurons and sensory axons are reduced. Taste buds are scant; circumvallate papillae are hypoplastic.

Treatment

Preventative treatment and supportive therapies include maintaining eye moisture to control absence of tearing, fundoplication with gastrostomy to control vomiting and reflux, and the use of benzodiazepine and clonidine for dysautonomic crises.

The use of epidural or deep conscious sedation forms of anesthesia have been advocated for surgical procedures to avoid intubation and the sometimes fatal complications of general anesthesia.

OH is treated similarly to adult forms. Symptomatic treatment is indicated for dysautonomic crises with parenteral fluids, diazepam, sedation, and antiemetic therapy. GH treatment in selected patients with FD may have the potential to increase growth.

Tocotrienols may elevate IKBKAP gene expression and cause increased functional cellular levels of IKAP protein and increased levels of monoamine oxidase A in cells and tissues. Other agents such as kinetin are under investigation for their possible therapeutic potential to improve gene splicing and increase functional protein levels.

Outcome

Long-term survival is documented; more than 40% of surviving patients are older than 20 years. Some women with FD have had pregnancies and delivered normal infants. Infant and childhood fatalities may be a result of aspiration pneumonia, gastric hemorrhage, or dehydration. A second cluster of fatalities between the ages of 14 and 24 years has been secondary to pulmonary complications, sleep deaths, and cardiopulmonary arrests. The few oldest patients are now in their fifth and sixth decades.

OTHER HEREDITARY AUTONOMIC DISORDERS

A novel prion disease associated with diarrhea and hereditary sensory and autonomic neuropathy associated

with a defect in the PRNP gene was described late in 2013. Other types of hereditary sensory and autonomic neuropathy (HSAN) typically cause more severe sensory ganglionopathy or sensory neuropathy and are often considered as a separate congenital category.

DIAGNOSIS AND TREATMENT OF AUTONOMIC DISORDERS

Nonautonomic conditions can cause OH and mimic AF; most important are adrenal failure and pheochromocytoma. Asymptomatic OH is a prevalent sign in the elderly, and causes are often multifactorial. Formal laboratory evaluation of autonomic disorders is discussed in Chapter 27. Treatment of AF is directed at symptomatic relief and improved quality of life, especially for generally the most disabling symptom—OH. Numerous pharmacologic and nonpharmacologic interventions are available to lessen OH and improve orthostatic tolerance. Asymptomatic hypotension on standing usually requires no treatment; reasonable precautions and avoidance of precipitating factors may be adequate. An exercise reflex, which immediately but transiently lowers BP on standing may become symptomatic requiring standing slowly and in stages. However, lesser indicators of hypoperfusion such as postural “coat hanger” pattern shoulder fatigue and headache (local muscle ischemia), pure postural vertigo, postprandial fatigue, and cognitive slowing are possible indicators of OH. Supplemental water and salt intake (0.5 to 2 g/day) have been independently shown to be beneficial and lessen the need for medications. Raising the head of the bed 4 inches stimulates baroreceptors and decreases nocturnal diuresis. Useful postural and physical measures to attempt and others to avoid are listed in [Table 112.2](#). Cumbersome compressive garments with abdominal compression are mildly effective in reducing venous pooling but are problematic for many with neurologic disorders; abdominal binders alone may help to a lesser degree. Small, frequent meals low in carbohydrates lessen postprandial hypotension. Reevaluation of the need for prescribed BP lowering and autonomically active agents should be considered.

If these measures are insufficient, first-line medications include fludrocortisone (starting at 0.1 mg/day) or the α -adrenergic agonist midodrine or both. Midodrine is shorter acting, and the dosage must cover vulnerable periods, especially early morning, and is not given after 6 PM; generally 2.5 to 10 mg doses three times a day. Droxidopa was FDA approved in 2014 and may become an additional treatment option commonly titrated to a target dose of 100 mg three times a day. Excessive fluid retention and heart failure are concerns, especially in the elderly. Relative anemia exacerbates OH. Pyridostigmine, which enhances autonomic ganglionic neural transmission, increases standing greater than supine BP and is a common off-label option, especially in patients with supine hypertension, which is a perennial and unresolved controversial concern with fludrocortisone, midodrine, and droxidopa. Typically, 30 or 60 mg doses are given every 6 to 8 hours. Clinical judgment is required to balance the need for adequate standing and reasonable supine pressures; this balance is challenging in severe cases. Second-line agents are numerous and are sometimes effective if earlier agents have failed. Concomitant treatment of urinary dysfunction, gastric and intestinal dysmotility, impotence, and secretomotor dysfunction is often necessary. In MSA, inspiratory stridor may lead to tracheostomy, and nocturnal positive pressure ventilation may be needed for sleep apnea.

Exacerbating factors are important considerations for both patient and physician to take appropriate precautions or avoid certain situations (see [Table 112.2](#)). Patients with delayed OH (3 to 15 minutes after standing) or situational triggers must anticipate potential problems. Patients with chronic, symptomatic OH may learn to recognize these conditions but often need physician instruction. Chronic OH also results in optimized cerebral autoregulation and relative tolerance of low BP but provides a narrow window between an asymptomatic state and syncope.

ACKNOWLEDGMENT

The author acknowledges Dr. Alan M. Aron for contributions to an earlier version of the hereditary autonomic

disorder section of this chapter.

Paroxysmal Sympathetic Hyperactivity after Acute Brain Injury

Huimahn Alex Choi

Sophie Samuel

Teresa A. Allison

INTRODUCTION

After surviving acute brain injury, patients can develop paroxysmal sympathetic hyperactivity (PSH), a syndrome of episodic physiologic hyperactivation manifesting in fevers, diaphoresis, tachycardia, tachypnea, hypertension, and dystonic posturing. Since the first description in 1929 by Wilder Penfield, numerous terms have been used to describe this syndrome: episodic autonomic instability, dysautonomia, autonomic dysregulation, central autonomic dysfunction, paroxysmal autonomic instability with dystonia (PAID), sympathetic storming, autonomic storming, dysautonomic crises, and diencephalic fits. First believed to be epileptic in nature and now believed to be a syndrome caused by a disconnection of inhibitory pathways, the etiology of PSH is still not well understood. The unifying principle describing this syndrome is the episodic nature of the dysregulation of the autonomic nervous system, manifesting as episodic sympathetic hyperactivity.

PSH can develop abruptly and last a short time period but can also be prolonged and a main driver of complications after acute brain injury. Delayed recognition leading to unnecessary workup and medications can further prolong hospitalization with potentially harmful results to patients. Additionally, uncontrolled symptoms can lead to secondary brain injury from hypertension, hyperthermia, cardiac damage, and even death.

EPIDEMIOLOGY

The absence of a unified diagnostic criterion, the unclear etiology, and the multiple different causes of PSH has hindered the study of the syndrome. There are widely differing estimates of prevalence of PSH from 8% to 33% of patients admitted to the intensive care unit (ICU), reflecting the differences in population of patients.

The cause of brain injury is an important risk factor for the development of PSH. Most reported cases of PSH result from traumatic brain injury (TBI) (80%), followed by hypoxic brain injury (10%) and stroke (5.4%). The main risk factor for developing PSH after acute brain injury is the severity of the initial brain injury, younger age, and male gender. Although TBI may be the etiology for most cases of PSH, patients with other diseases may actually be at a higher risk for PSH. For instance, *N*-methyl-D-aspartate (NMDA) receptor-associated encephalitis is characterized by an aggressive and difficult to treat PSH-like syndrome.

PATHOBIOLOGY

Most believe PSH is caused by a functional disconnection leading to unbalanced activation of brain stem systems controlling the autonomic nervous system. Brain regions implicated range from the cerebral cortex to the anterior hypothalamus to the medulla and the connections in between. Regardless of the lesion location, the final common pathway is an imbalance of adrenergic outflow.

The Excitatory-to-Inhibitory Ratio (EIR) Model has been used to explain the pathophysiology of PSH and it takes into account the hypersensitive, overreactive nature of the responses to normal stimuli. Autonomic efferents at the level of the spinal cord are modulated centrally by a balance of sympathetic and parasympathetic inputs from higher brain stem nuclei. Afferents from the spinal cord can modulate this balance in response to stimuli from the environment. The EIR model proposes that the afferent stimuli from the spine have an allodynic tendency, which is normally controlled by tonic inhibitory drive from diencephalic centers. Damage to these inhibitory centers or

their inhibitory processes down to the mesencephalon releases the inhibition of the allodynic tendency. Once the tonically inhibitory cycle is broken, there is a positive feedback loop that produces sympathetic overactivity to any afferent stimuli. This model explains how a normally nonnoxious stimulus can become a very noxious stimulus associated with an uncontrolled sympathetic response.

Imaging studies have shown that injury to the deep brain structures, periventricular white matter, corpus callosum, diencephalon, or brain stem may be associated with the development of PSH. PSH is associated with an increased number of lesions in the midbrain and upper pons compared with number of lesions in cerebral cortex, subcortex, corpus callosum, and diencephalon. Bilateral diencephalic lesions have also been attributed to PSH in hypoxic-ischemic encephalopathy. The evidence from imaging studies showing damage to brain stem structures emphasizes the importance of the diencephalic and mesencephalic regions to the pathophysiology of PSH.

CLINICAL MANIFESTATIONS

PSH usually occurs, or at least is noticed, once patients are being weaned off of continuous intravenous sedation and they begin to awaken. Usually, it occurs in patients with a depressed mental status and episodes are associated with worsening mental status. The clinical manifestation of PSH define the syndrome: Episodic increases in heart rate, blood pressure, respiratory rate, temperature, diaphoresis, at times with pupillary dilatation, and motor hyperactivity manifested in abnormal posturing and dystonic movements. Episodes of exacerbation may last from minutes to hours and can occur several times a day or in refractory cases nearly continuously. PSH can be difficult to differentiate from opiate withdrawal or agitation from mechanical ventilation. It may persist into the rehabilitation phase and last weeks to months after the injury. In severe cases, it may persist for a year.

P.976

DIAGNOSIS

The overlapping symptoms of PSH with other neurologic sequelae of acute brain injury make the diagnosis difficult and only made after excluding other causes for symptoms. Clinical suspicion and careful examination are of paramount importance in the detection of PSH. Infections, sepsis, pain, opiate withdrawal, and seizures are all diagnoses that have overlapping clinical presentations that need to be excluded in order to diagnose PSH.

There are at least nine unique diagnostic criteria describing this syndrome. Most include increased heart rate, diaphoresis, motor hyperactivity, tachypnea, hyperthermia, and hypertension. Some diagnostic criteria have included pupillary dilatation and decreased level of consciousness. Although multiple proposed diagnostic criteria overlap significantly in descriptive ways, consensus regarding specifics of timing, severity, and number of episodes does not exist. Characteristically, PSH tends to be triggered by minimal external stimuli, such as touching, passive movement (turning, moving limbs, and bathing), or endotracheal tube suctioning. This feature of overreactivity, allodynic response, may be a helpful characteristic for diagnostic purposes.

TREATMENT

Effective clinical management of PSH requires a combination of pharmacologic as well as nonpharmacologic treatment modalities. There are few large-scale prospective studies and no level 1 evidence is available. Management is guided predominantly by case reports, case series, and personal

experience using different medications and treatment strategies. Therapy is focused on control of symptoms. Medical treatments for PSH include opioids, β -blockers, dopamine agonists, α_2 -agonists, GABAergic agents, benzodiazepines, gabapentin, and muscle relaxants (Table 113.1). The mechanisms by which these agents improve symptoms of PSH remain speculative; however, a combination of medications from different classes should be used.

TABLE 113.1 Medications Used for Treatment of Paroxysmal Sympathetic Hyperactivity

Medication	Location of Action	Proposed Mechanism	Symptoms Treated
Baclofen	Centrally	GABA _B agonist	Pain, clonus, rigidity
Benzodiazepines	Centrally	GABA _A agonist	Agitation, hypertension, tachycardia, posturing
Bromocriptine	Centrally; at hypothalamus	Dopamine agonist	Dystonia, fever, posturing
Clonidine	Centrally; decreased sympathetic outflow	α_2 -Receptor agonist	Agitation, hypertension, tachycardia
Dantrolene	Peripherally	Direct-acting skeletal muscle relaxant	Muscle rigidity, posturing
Dexmedetomidine	Centrally; decreased sympathetic outflow	α_2 -Receptor agonist	Agitation, hypertension, tachycardia
Gabapentin	Centrally	GABA agonist	Spasticity, allodynic response
Opioids	Centrally; medullary vagal nuclei and peripherally	μ -Opioid receptor agonist	Hypertension, tachycardia, allodynic response
Propofol	Centrally	GABA _A agonist	Agitation, hypertension, tachycardia
Propranolol	Peripherally; decreasing effect of catecholamines	Nonselective β -blocker	Hypertension, tachycardia, fever

GABA, α -aminobutyric acid.

The goal of treatment is to optimize symptom control while minimizing side effects, mainly sedation and

hypotension. Treatment should focus on nonpharmacologic management first. Potential stimuli which can trigger acute episodes of exacerbation should be identified and minimized. Because patients usually are unable to communicate, this process can be difficult but an important first step. Pharmacologic management of PSH focuses on three treatment approaches: maintenance, symptom abortion, and refractory treatment. A suggested treatment algorithm is presented on [Figure 113.1](#).

When a paroxysm of hyperactivity occurs, abortive medications are indicated to control discrete breakthrough episodes. These medications have a rapid onset of action with a short half-life. The targets of the abortive medications usually depend on the predominant symptoms: treating hyperthermia with antipyretics, agitation with sedation, and hypertension with antihypertensive agents. Morphine, other opiates, and short-acting benzodiazepines are first-line treatment options for this indication. Dose of medication should be titrated to symptom relief and is limited by the potential side effects, mainly sedation, respiratory depression, and hypotension. Medications with a short half-life should be used for abortive treatment to minimize undesired effects. If frequency bouts of hyperactivity occur, maintenance medication should be adjusted accordingly. Importantly, once the frequency of episodes of exacerbation is controlled, maintenance medications should be aggressively tapered to maximize the alertness of patients.

First-line maintenance pharmacologic agents include medications which are less sedating and reduce the frequency and intensity of exacerbations. These medications include nonselective β -blockers, α_2 -agonists, bromocriptine, baclofen, gabapentin, opiates, and long-acting benzodiazepines such as clonazepam.

P.977

Propranolol, a competitive nonselective α -blocker, is an ideal drug for controlling symptoms of PSH due to its mechanism of action and broad control of symptoms with minimum sedation. In addition to its cardiovascular effects, propranolol decreases the hyperthermic response to brain injury. Clonidine, a presynaptic α_2 -receptor agonist, is a useful agent to manage hypertension and tachycardia. Because increased blood pressure due to excitation of the sympathetic nervous system is one of the major features of PSH, clonidine is often an effective medication. Its use as monotherapy usually does not work in resolution of other symptoms. Morphine is a potent μ -opioid receptor agonist. In addition to morphine's analgesic properties, its cholinergic effects and histamine-releasing actions make it a good agent for the management of tachycardia and hypertension. Morphine is the most commonly used medication and can be used as maintenance as well as abortive treatment for breakthrough episodes. Bromocriptine is a synthetic dopamine agonist, the mechanism by which resolution of symptoms including hyperpyrexia and dysautonomia are achieved is unclear. Baclofen, a γ -aminobutyric acid (GABA)_B receptor agonist, is indicated for treatment of spasticity associated with PSH and to improve mobility. The benefit is to decrease the number and severity of spasms, thus relieving associated pain, clonus, and muscle rigidity. Benzodiazepines, GABA_A receptor agonists, are useful for symptoms of motor activity, tachycardia, and hypertension. The concern with benzodiazepines is the possibility of worsening neurologic functioning in newly injured brain. A long-acting benzodiazepine, clonazepam, is helpful as a maintenance medication to reduce episodes. Gabapentin, an analog of GABA, was originally developed as an anticonvulsant. However, it may be more useful in the management of painful neuropathies, spasticity, and tremor. It is most useful as an adjunct medication, which is less sedating than benzodiazepines. Dantrolene acts directly on skeletal muscle, decreasing the force of contraction by interfering with release of calcium ion from sarcoplasmic reticulum and can be used in cases when severe dystonia or posturing continues to persist. Dantrolene can possibly be effective for the amelioration of dystonic posturing, but the risk of causing hepatotoxicity can limit its use.

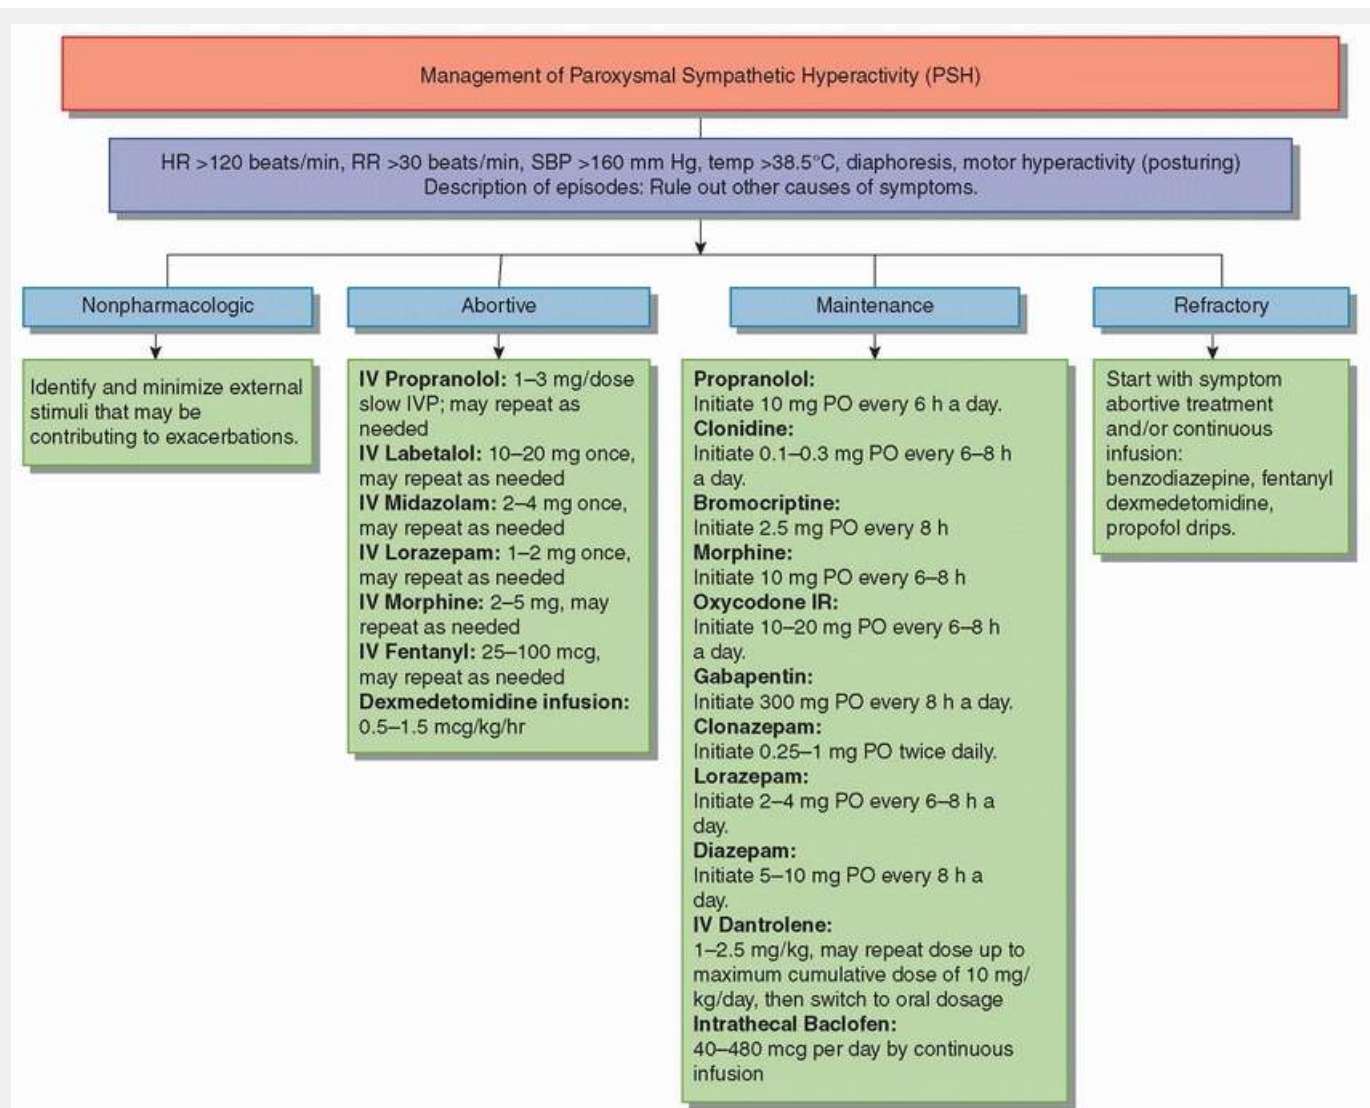

FIGURE 113.1 Management of paroxysmal sympathetic hyperactivity (PSH). Combination of medications from different doses likely results in the most effective approach in managing PSH.

Finally, in some cases, patients develop refractory PSH when symptoms do not respond to isolated intermittent treatment modalities and symptoms become life threatening. In these cases,

P.978

continuous intravenous medications with benzodiazepines, opioids, dexmedetomidine, or propofol drips are required. At times, antipyretics with or without temperature control devices is necessitated for aggressive temperature modulation. In addition to continuous infusions of opiates (morphine, fentanyl) and benzodiazepines, dexmedetomidine, an α_2 -receptor agonist, can be administered as a continuous intravenous infusion predominantly for sedation. Given its favorable effects on heart rate, blood pressure, and agitation, dexmedetomidine is a useful intravenous treatment choice. If symptoms are not controlled with other medications, propofol, a general anesthetic, can be used. However, the side effects from the medication limit its use to only severe cases, and it can only be administered with close intensive care monitoring. Unlike dexmedetomidine, patients on propofol require mechanical ventilation support. If posturing persists, the use of intrathecal infusion of baclofen may be helpful. Concerns with using intrathecal infusions include an increased risk in cerebrospinal fluid (CSF) leak and infection as well as mechanical problems with the catheter or pump. Dopamine antagonists such as chlorpromazine and haloperidol should be avoided, as reports of exacerbation of cognitive deficits, psychosis, and neuroleptic malignant syndrome have been reported.

OUTCOME

Although the risk factors and pathobiology remain controversial, the impacts on clinical outcomes are clear. Patients who experience PSH have worse Glasgow outcome scores (GOS) and worse functional independent measures compared to their counterparts. Additionally, patients with PSH have longer ICU stays, longer hospital stay, longer mechanical ventilation days, higher infectious episodes, more tracheostomy, and higher health care costs. The mechanisms as to how PSH causes worse outcomes are multifactorial. The symptoms and treatments for the symptoms cause longer period of days on the ventilator, leading to more tracheostomy and longer length of stay. PSH has a direct impact on fever burden after brain injury, which has been associated worse outcome after brain injury. In addition, the influence of the autonomic nervous system and its effects on inflammation has been studied in other disease states and may be very active in the acutely brain-injured population. The dysregulated autonomic nervous system may have an influence in causing unopposed inflammation and leading to secondary brain injury.

Sleep Disorders

Carl W. Bazil

Andrew J. Westwood

INTRODUCTION

Sleep and sleep disorders are frequently overlooked as a cause or exacerbating factor in neurologic dysfunction. Neuronal activity and the networks involved are different in each state of sleep (nonrapid eye movement [NREM] and rapid eye movement [REM] sleep) compared with the normal waking brain. Sleep and sleep disorders therefore offer unique opportunities to understand the physiology of the brain and its impact on daily functioning. Sleep is involved in the regulation of endocrine and autonomic output and is integral to learning and memory, areas whose complexity and relationship to sleep are only beginning to be understood.

This chapter begins with a brief description of normal sleep and its impact on functioning. Diagnostic testing in sleep is discussed in Chapter 29. An overview of sleep disorders follows with particular relation to their impact on neurologic diseases.

PHYSIOLOGY OF NORMAL SLEEP

Sleep is an active process that involves numerous distinct neuronal networks, which are ultimately expressed as altered physiologic functions. Heart rate, blood pressure, gas exchange, gastrointestinal function, hormonal secretion, and even kidney function are altered during sleep. The exact purpose of sleep remains unclear, but there is considerable evidence of essential associations with immune function, memory, learning, energy conservation, and toxin clearance.

Sleep is classified into stages based on three parameters: electroencephalography (EEG), eye movement or electro-oculography (EOG), and muscle tone as assessed by electromyography (EMG) of the mentalis muscle. Arbitrary classification of 30 second recordings, or epochs, divide the process into wakefulness, three stages of NREM sleep (stages N1, N2, and N3), and one stage of REM sleep (stage R).

Wakefulness (stage W) is identified by a low-voltage fast-frequency EEG, high muscle tone, and REMs. *Stage N1* sleep is characterized by a low-voltage, mixed-frequency EEG and slow, rolling eye movements. Reactivity to outside stimuli is decreased, and mentation may proceed but is slowed. *Stage N2* consists of a moderate low-voltage background EEG with sleep spindles (bursts of 12- to 16-Hz activity lasting 0.5 to 2 seconds) and K complexes (brief high-voltage discharges with an initial negative deflection followed by a positive component). *Slow-wave sleep (stage N3)* consists of high-amplitude delta (0 to 2 Hz) frequencies occupying 20% or more of the epoch. During this deeper sleep, heart and respiratory rates are slowed and regular. In NREM sleep, the tonic chin EMG is of moderately high amplitude but less than that of quiet wakefulness (Fig. 114.1).

The EEG pattern during REM sleep (stage R) consists of low-voltage, mixed-frequency activity and is similar to that of stage N1 sleep. Moderately high-amplitude, 3- to 6-Hz triangular waveforms referred to as *sawtooth waves* are intermittently present and are unique to REM sleep. Intermittent bursts of rapid conjugate eye movements occur. Tonic chin EMG activity is absent or markedly reduced, and phasic muscle discharges occur in irregular bursts. The decreased EMG activity is a reflection of muscle paralysis resulting from active inhibition of muscle activity. During REM sleep, surges of parasympathetic and sympathetic activity are denoted by greater variability in heart and respiratory rates. This stage is also associated with complex vivid imagery, but visual imagery can occur in all sleep stages. When occurring in deep NREM sleep, dream images are typically fragmented and may be associated with actions such as the sensation of falling.

During a normal night, sleep comprises recurring cycles. Within each cycle of 90 to 120 minutes, NREM sleep alternates with REM sleep. The normal healthy adult typically falls asleep within 10 minutes and goes through the sequence of stages N1 through N3, followed by reversion to stage N2 sleep. Afterward, the first REM sleep period occurs 70 to 100 minutes into sleep. The first REM period is usually the shortest, about 10 minutes. This pattern of NREM and REM sleep is repeated three to five times during a normal night's sleep. Typically, most stage N3 sleep is seen in the first two sleep cycles, and REM sleep periods increase in duration and intensity of REM activity as the night progresses. Stage N2 sleep, however, is the most common sleep stage, typically making up half of a normal adult's night. In the normal adult, wakefulness accounts for approximately 5% of the night. N3 and REM sleep typically account for 25% each of total sleep and N1 approximately 5% (Fig. 114.2).

NEUROANATOMY AND NEUROCHEMISTRY OF SLEEP

Anatomically, NREM sleep is expressed when a network of neurons in the anterior hypothalamus suppresses the reticular activating system and monoaminergic neuronal activity. This network causes a functional disconnection of sensory input to the cortex and decreases the metabolic rate of most of the cortex. During stage N3, cortical neuronal synchrony is promoted, and this may be related to synaptic pruning. REM sleep, however, is an activation of cholinergic neurons in the pontine dorsal tegmentum that subsequently excite neurons responsible for REM-associated atonia, REMs, increase in cortical metabolic rate, loss of thermoregulation, and other features. REM sleep is inhibited by activation of the dorsal raphe and locus ceruleus. A network of neurons in the hypothalamus midbrain and thalamus seems to regulate REM sleep cycling.

Hypocretin—named so because it structurally resembles secretin in the gut—appears to stabilize the ability to remain awake. It is also referred to as *orexin* codiscovered by another group—named so because of its ability to stimulate food intake (from the Greek *orexis* meaning appetite).

Throughout the 24-hour day, the human body has a symphony of endocrinologic and metabolic variations that are timed to maximize performance during wakefulness and promote quality rejuvenation during sleep. Because we evolved on a planet that

P.980

rotates every 24 hours, we developed a delicate neurochemistry anticipatory cycle that prepares the body for the upcoming sleep/wake state. This circadian cycle is approximately 1 day as captured in the Greek meaning of *circadian*. Many body functions, including body temperature, plasma and urine hormones, renal functions, psychological performance measures, and internal sleep-stage organization, participate in this circadian rhythm. Humans have a circadian rhythm that is approximately 24.3 hours and is driven by the suprachiasmatic nucleus. This nucleus is influenced by external time clues to synchronize the body clock with the outside world, including bright light, activity, meals, and social interactions. Evidence for the importance of circadian rhythms comes from studies of acute phase shifts, such as those that occur after jet lag or shift work. Because our internal clock is longer than 24 hours, adaptation is slower after an eastward flight (phase advance) than after a westward flight (phase delay).

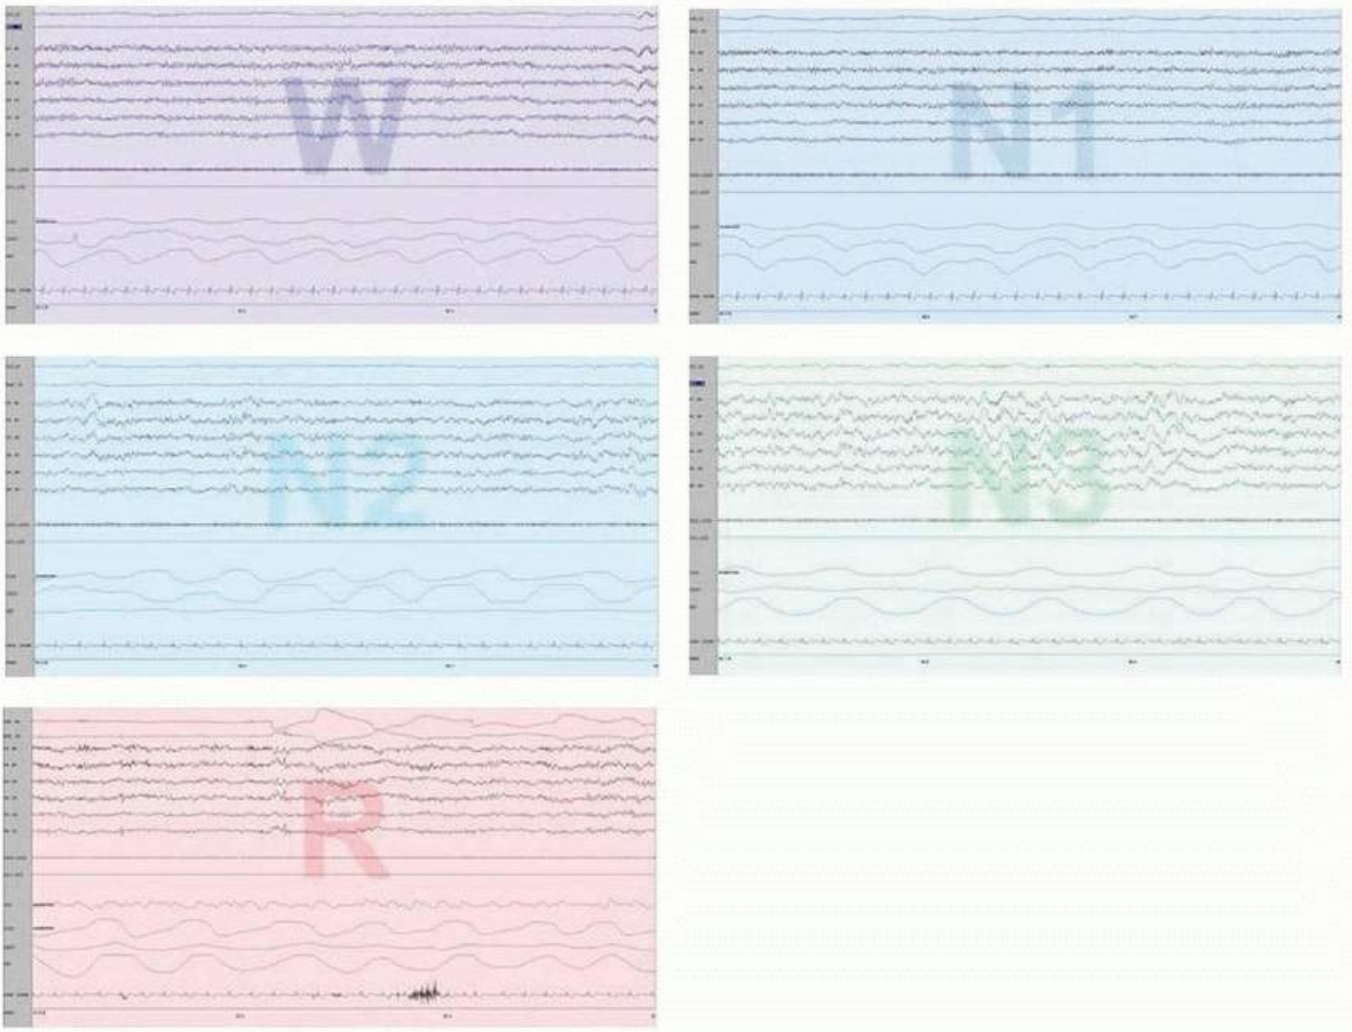

FIGURE 114.1 Stages of sleep. Each 30-second recording represents a different stage of sleep. Wake (*W*), NREM is divided into three stages (*N1*, *N2*, *N3*) and REM (*R*). For each recording, the top two channels are electro-oculogram (LOCA2 and ROC-A1); the following six are EEG, followed by chin EMG and leg EMG (LAT1-LAT2), airflow, chest and abdominal movements, ECG, and oxygen saturation.

FIGURE 114.2 Hypnogram. Graphical representation of sleep stages as a function of time. This hypnogram shows normal sleep architecture with the majority of slow-wave sleep in the first third of the night, REM sleep

majority in the last third of the night, and progressive longer durations of REM.

SPECIFIC DISORDERS OF SLEEP

Diagnostic procedures are discussed in Chapter 29.

Nearly all patients with disorders of the central nervous system (CNS) are at high risk for sleep dysfunction, which may be a direct result or a secondary effect of the neurologic condition. Sleep disorders may exacerbate the symptoms of the underlying neurologic disorder and impair quality of life. In this chapter, we describe selected disorders. *Fatal familial insomnia*, a prion disease, is discussed in Chapter 68. Sleep-associated headache disorders and epilepsy syndromes are also discussed in their respective chapters.

P.981

INSOMNIA

Insomnia can consist of difficulty falling asleep (sleep-onset insomnia), difficulty staying asleep (sleep maintenance insomnia), both, or sleep that is nonrefreshing or nonrestorative. The daytime symptoms include excessive fatigue, impaired performance, or emotional change. Most people have an occasional night fraught with difficulty falling asleep or trouble maintaining sleep, usually caused by an alerting response to short-term stress; this is a normal property of the brain and is not considered insomnia if it resolves quickly. In the past, insomnia has been categorized into primary or secondary types but these were difficult to reliably ascertain. Insomnia is now considered as *short-term*, *chronic*, or *other* [Level 1].¹

Short-term insomnia lasting less than 3 months duration might be closely linked to the surrounding events, psychological disturbances, or sudden changes in a medical condition. Typically, there is an identifiable precipitant that an individual is able to recall. Individuals may complain of disturbances fewer than three times per week but this results in a general dissatisfaction in their quality of sleep. It may also result in the individual catastrophizing that they may never sleep again. The 1-year prevalence of short-term insomnia is around 20% in the general adult population. Circadian rhythm disorders should be considered as mimickers of insomnia. In delayed sleep phase syndrome, individuals typically complain that they cannot fall asleep until later in the night and due to morning commitments have to curtail their sleep, and this results in sleep deprivation. Early morning arousal raises the possibility of advanced sleep phase if the patient falls asleep early in the evening.

Chronic insomnia, lasting greater than 3 months on 3 or more days per week, is usually attributed to multiple factors. The factors may be divided into predisposing, precipitating, and perpetuating, which outline the formation of insomnia as an ongoing process. Characteristics that predispose an individual for insomnia are female gender, older age, psychiatric or chronic medical illness, lower socioeconomic status, poor education, obsessive-compulsive nature, poor coping strategies, and hyperalertness (Table 114.1).

Insomnia may be precipitated by sudden changes in environment or challenges to the body or mind. These challenges may come in the form of acute medical illness, psychological or psychiatric events, shift in schedule, or changes in medications or supplements. After the start of the insomnia, patients adopt behaviors or rituals that perpetuate the insomnia. Patients may use maladaptive habits that occur during the day or night and include heavy caffeine or alcohol use; watching television, working, or playing video games while in bed; or even eating or exercising during the usual sleep period. They may become dependent on certain somnogenic substances. Some patients develop associations of not sleeping with the bedroom and may fear going to bed. These poor associations and expectations of poor sleep promote the apprehension toward sleep. The insomnia symptom complex may indicate an underlying disorder related to primary failure of the sleep mechanism or one in which sleep disruption is a result of another disorder. Patients with obstructive sleep apnea, restless legs syndrome, and even narcolepsy may complain of insomnia. Sleep diaries, accounting bedtime and wake time, can be useful in determining potential links to schedule or circadian rhythm issues. Perception of good sleep is an important

factor in evaluating the complaint of insomnia.

TABLE 114.1 Principles of Good Sleep Hygiene Are the Basis for a Sound Night of Sleep

Principles of Sleep Hygiene

- Establish regular bedtimes.

- Wake regularly at a fixed time.

- Regulate the amount of sleep obtained each night.

- Exercise daily and regularly (particularly aerobic) but not in the late evening.

- Sleep in a quiet, cool, comfortable environment.

- Avoid caffeinated beverages and other stimulants (including tobacco) especially close to bedtime.

- Avoid alcohol within 3 h of bedtime.

- Avoid hypnotic drugs.

- Do something relaxing before bedtime.

Some patients exaggerate their symptoms, whereas other patients may not perceive they are asleep. These individuals display the normal physiologic parameters of sleep but do not recognize that they have slept. This is referred to as *sleep-state misperception* or *paradoxical insomnia*.

Insomnia may also be produced by medical or neurologic disorders. Derangement of almost any system in the body can disrupt sleep. Patients with diseases affecting the nervous system, heart, liver, kidneys, gastrointestinal tract, or lungs commonly complain of insomnia. Musculoskeletal discomfort such as in arthritis or other rheumatologic disorders may become worse with periods of rest. Pain from entrapment neuropathies such as carpal tunnel are typically worse at night, and headaches such as cluster headache or pain related to increased intracranial pressure or brain mass lesions can become more intense during sleep. Nearly all of the psychiatric illnesses have some link to poor sleep. Patients with depression or anxiety disorders may have insomnia years prior to the presentation of the affective component. Although a causal relationship is still in debate, the association is clear. Insomnia may also herald the onset of psychosis or mania.

Treatment of insomnia should be directed toward symptom improvement and avoidance of maladaptive behaviors. Therapy for neurologic and psychiatric disorders should be optimized, and a multipronged approach addressing the patient's behaviors, psychological attitudes, and the potential underlying neurochemistry should be constructed. Cognitive behavioral therapy for insomnia (CBT-i) consisting of sleep restriction therapy, relaxation therapy, stimulus control, and sleep hygiene (see [Table 114.1](#)) provides a solid therapeutic

foundation. CBT-i is the most effective longterm therapy for insomnia. The use of acupuncture for insomnia remains equivocal due to the lack of methodologic consistency in the trials [**Level 1**].²

There are also a number of safe, effective hypnotic substances that may be used particularly in short-term insomnia to help restore normal sleep patterns and reverse negative associations with sleep time and the bedroom environment. These differ mainly in half-life, with zaleplon (5 to 20 mg) very short acting, zolpidem (5 to 10 mg) short, and eszopiclone (1 to 3 mg) the longest (therefore most useful in sleep maintenance insomnias). Ramelteon (8 mg) is a melatonin agonist that is also a mild hypnotic. Suvorexant (5 to 20 mg), a nonselective orexin antagonist was approved in 2014 for insomnia. When these agents fail, benzodiazepines and sedating antidepressant drugs are alternatives. Short-acting benzodiazepines are usually preferable to avoid daytime sedation, although if anxiety is also present, longer acting compounds can be useful. Many medications are used offlabel for insomnia particularly if there are concomitant symptoms

P.982

that could be effectively treated at the same time, such as headaches or depression. Many medications typically used for insomnia have not received formal approval by the U.S. Food and Drug Administration (FDA) because they have not applied for insomnia as a specific indication. Substances that promote alertness should be minimized when possible, and additional medicinal therapy should be directed toward a specific disease process. The goal of treatment with any hypnotic should be to help restore normal sleeping patterns, followed by slow elimination of the drug (Table 114.2).

TABLE 114.2 A List of Current Medications Approved by the U.S. Food and Drug Administration for Insomnia

Class	FDA-Approved Pharmaceutical Treatment of Insomnia			
	Agent	Dosage (mg)	Half-life (h)	Comments
Nonbenzodiazepine-benzodiazepine receptor agonists (NBZRAs)	Zaleplon	5-20	1	—
	Zolpidem	5 (women) 5-10 (men)	1.4- 3.6	Available as oral, oral spray, and sublingual forms
	Zolpidem ER	6.25- 12.5	1.4- 3.6	Women metabolize zolpidem at a lower rate than men.
	Eszopiclone	1-3	5-7	—
Orexin antagonist	Suvorexant	5-20	8-14	—
Benzodiazepines	Estazolam	0.5-2	10- 24	—

	Flurazepam	15-30	47-100	—
	Quazepam	7.5-15	47-100	—
	Temazepam	7.5-30	8-20	—
	Triazolam	0.0625-0.125	1.5-5.5	—
Tricyclic antidepressants	Doxepin	3-6	8-24	Approved in low-dose 3- and 6-mg formulations only
Selective melatonin receptor agonist	Ramelteon	8	8	—

Many others are used off-label.
FDA, U.S. Food and Drug Administration.

When an individual has less sleep than what is generally considered normal, concern may arise from those around them. Some individuals are *short sleepers* requiring less than 6 hours of sleep but do not complain of sleep/wake disturbances and therefore are not insomniacs per se. Others may spend excessive amounts of time in bed. This pattern may occur, for example, from parents allocating too much time for their children to sleep, but the child functions normally. Some adult individuals are *long sleepers*, requiring 10 or more hours of sleep to function without signs of sleep deprivation. Although frustrating to patients, this condition is best treated with longer sleep times so long as no other source of ineffective sleep is found.

THE HYPERSOMNIAS

Sleepiness is defined as the propensity to enter sleep. This is a normal feeling as one approaches a typical sleep period, but excessive sleepiness occurs when one enters sleep at an inappropriate time or setting. Excessive sleepiness can occur in degrees. In mild sleepiness, one might have only limited impairment, such as falling asleep while reading a book. Greater degrees of sleepiness, however, may be associated with bouts of irresistible sleep or sleep attacks that intrude on such activities as driving, having a conversation, or eating meals. This degree of sleepiness places the patient at significant risk for accidents and has a major impact on the person's well-being. It must occur for at least 3 months prior to diagnosis.

Clinicians should always question their hypersomnic patients for clues of potential sleep debt, sleep disorders, or other medical or psychiatric causes. Sleep deprivation is the most common cause of sleepiness. Information regarding sleep habits, schedule during the week and weekends, and environment often discloses other important contributing factors. Excessive sleepiness may result from a wide range of medical disorders and medications. Patients with heart, kidney, or liver failure or rheumatologic or endocrinologic disorders such as hypothyroidism and diabetes may note sleepiness and fatigue. Neurologic disorders such as strokes, tumors, demyelinating diseases, epilepsy, and head trauma can evoke excessive sleepiness. Sleepiness is frequently the cardinal symptom of many sleep disorders ([Table 114.3](#)). Patients with sleep apnea, narcolepsy, restless

legs syndrome-periodic limb movements, or even parasomnias may note excessive daytime sleepiness as their main complaint. Thus, the clinician should question the patient further to elucidate potential etiologies.

About 2% of men and 1.5% of women report sleeping at least 10 hours per night and are regarded as *long sleepers* (in children, it is 2 hours more than the age-specific normative data). The additional sleep time is spent in REM and N2 compared to other individuals. Providing that these individuals obtain sufficient sleep prior to testing, the multiple sleep latency test (MSLT) is normal.

Narcolepsy

Narcolepsy is an incurable lifelong neurologic disorder characterized by the tetrad of (1) excessive daytime sleepiness, (2) cataplexy, (3) sleep paralysis, and (4) hypnagogic hallucinations. Patients with narcolepsy also typically have fragmentation of nocturnal sleep. Estimates of prevalence range between 2 and 10

P.983

per 10,000 individuals in North America and Europe. It is about five times more prevalent in Japan, and the incidence is only 1 per 500,000 in Israel. The symptoms of narcolepsy typically present between ages 10 and 30 years, although cases have been reported with onset as early as age 2 years and as late as 76 years. Men and women are equally affected. There appears to be a bimodal distribution occurring in teenage years and later around age 35 years. Symptoms gradually develop over several years but once it has fully developed, there is usually only a minor fluctuation in the severity. Sleepiness is often minimized or thought to be related to other causes, and diagnosis can be delayed for years or even decades. As weight gain and depression are common other causes for excessive daytime sleepiness in a previously well-rested individual should be considered.

TABLE 114.3 Differential Diagnosis of Excessive Daytime Sleepiness

- Insufficient sleep syndrome

-
- Sleep apnea syndromes

-
- Narcolepsy

-
- Idiopathic hypersomnia

-
- Demyelinating disease

-
- Infections

-
- Sarcoidosis

-
- Neurodegenerative diseases

-
- Tumors of the hypothalamus or rostral midbrain

-
- Metabolic disorders, e.g., hypothyroidism, pancreatic insufficiency, renal insufficiency, hepatic

encephalopathy

- Drugs, e.g., antidepressants, hypnotics, and antihistamines
-

- Withdrawal of stimulants
-

- Periodic limb movement disorder
-

- Circadian rhythm disorders
-

- Depression

Narcolepsy is a prototype disorder of loss of control of sleepwake determination. Patients have bouts of irresistible sleep and frequent arousals during nocturnal sleep, with episodes of partial intrusion of REM sleep into wakefulness. Intrusion of fragments of REM sleep into wakefulness is most evident in the presence of the symptoms of cataplexy, sleep paralysis, and hypnagogic hallucinations.

Daytime sleepiness is usually the first and most prominent symptom to appear, but hyperactivity may be seen in children as they attempt to fight off sleep. Patients often complain of attacks of irresistible sleep that occur at inappropriate times, such as during conversation, driving, and eating. Brief naps for some are refreshing. The symptom of excessive daytime sleepiness is disabling and often leads to personal, social, and economic problems.

Cataplexy is the abrupt onset of paralysis or weakness of voluntary muscles without change in consciousness; it is typically precipitated by strong emotions. Events can be triggered by a joke, surprise, anger, fear, or athletic endeavors. These events last seconds to minutes, and patients have clear memory for the complete event with no postictal confusion or deficits. Longer events may proceed to the patient entering sleep. The severity of cataplexy is variable. Some patients may have as few as two or three episodes in a lifetime, whereas others may have several episodes every day. A full range of severity exists between these extremes. Cataplexy may be partial and affect only certain muscles; common examples include dysarthria; drooping of the head, face, and eyelids; and slight buckling of the knees. Severe global attacks affect all skeletal muscles except muscles of respiration and cause collapse. Onset of the attack usually takes seconds with brief moments of partial regaining of muscle tone at the beginning. Examination of the patient during the cataplectic attack will demonstrate paralysis with diffuse hypotonia, absence of deep tendon reflexes, diminished corneal reflexes, preserved pupillary responses, and phasic muscle twitching with preserved consciousness. Phasic muscle twitching can occur as single jerks or repetitive muscle twitching and is most frequently seen in the face. Most episodes last only seconds to 1 minute, but severe attacks can last minutes. Sudden withdrawal of antidepressants can result in status cataplecticus. Cataplexy typically follows onset of excessive daytime somnolence, usually beginning within 5 years if present.

The combination of excessive daytime sleepiness and cataplexy is nearly always related to narcolepsy. Cataplexy can rarely be seen as an isolated symptom, suggesting an underlying neurologic disorder. Cataplexy has been reported in cases of demyelinating disease, stroke, and Niemann-Pick type C. The historical feature of clear emotional triggers differentiates cataplexy from hypotension, vertebral basilar insufficiency, and the group of neuromuscular disorders known to produce periodic paralysis. Autoimmune or paraneoplastic disorders associated with the aquaporin-4 or anti-Ma2 as well as myotonic dystrophy, parkinsonism, and severe head

trauma can also present with narcolepsy.

The presence of cataplexy was previously diagnostic of narcolepsy; however, narcolepsy type 1 now requires an abnormal MSLT (as described in Chapter 29) and/or cerebrospinal fluid (CSF) hypocretin-1 concentration, measured by immunoreactivity to be less than 110 pg/mL. Cataplexy does not need to be present if hypocretin-1 levels are below 110 pg/mL. Ten percent of individuals with cataplexy will not have hypocretin-1 levels below this cutoff and are now considered to be narcolepsy type 2. Narcolepsy type 2 is diagnosed if the patient has an abnormal MSLT but cataplexy is absent or CSF measurements are greater than 110 pm/mL (or not measured). In the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*), narcolepsy with the absence of cataplexy is considered *primary hypersomnia*.

Sleep paralysis is a global paralysis of voluntary muscles that occurs at the entry into or emergence from sleep. These events may include the feeling of being chased or impending danger. The terror associated with the events can be recounted by the patient years later. The events are aborted with a tactile stimulation. The paralysis associated with the event is thought to result from the same motor inhibition that occurs in REM sleep. Sleep paralysis without narcolepsy can occur in an isolated form in sleep-deprived healthy individuals but is also frequently seen in patients with depression. Prevalence of a single episode of sleep paralysis is estimated to be between 15% and 40% of the general population. Differential diagnoses for sleep paralysis should include cataplexy, atonic seizures, and familial periodic paralysis syndromes.

Hypnic hallucinations are vivid dreamlike images that occur during sleep onset (hypnagogic) or at sleep offset (hypnopompic). They may include simple to complex visual, auditory, or somatosensory hallucinations. Patients are usually aware of their surroundings and may have difficulty in discerning the hallucinations from reality. The hallucinations can be relatively pleasant or terrifying. Patients may note a feeling of weightlessness, falling, or flying or have out

P.984

of body-like experiences that may sometimes terminate with a sudden jerk (hypnic jerk). Hypnic hallucinations are most likely the result of dissociated CNS processes involved in dreaming during REM sleep. They can be precipitated by sleep deprivation, medications, and alcohol in normal individuals. Hallucinations typically accompany sleep paralysis in 25% to 75% of cases.

Narcolepsy has been associated with several of the human leukocyte antigen (HLA) subtypes. *DQB1*0602* is found in isolation in blacks and together with *DR2/DRB1*1501* in Caucasians and Asians. Most with narcolepsy type 1 will have the *DQB1*0602* but it is also found in 12% to 38% of the general population. The risk of narcolepsy type 1 in first-degree relatives is approximately 1% to 2%.

Identification of the hypocretin-orexin gene and receptors in mouse models and humans revealed that narcolepsy type 1 is associated with loss of hypocretin-orexin-producing neurons in the lateral hypothalamus. Hypocretin-orexin in the CSF is found low in patients with cataplexy. Brains from narcolepsy patients show a loss of hypocretin-orexin-producing neurons. This loss of hypocretin-orexin-producing neurons is thought to permit the rapid switching between sleep and wake states.

Narcolepsy symptoms produce major social, familial, educational, and economic consequences for both the patient and the family. Patients often do not achieve their intellectual potential and suffer frequent failures of occupation, education, and marriage. Family members, friends, and even patients often interpret the symptoms as indicating laziness, lack of ambition, delayed maturation, or psychological defects. Because these symptoms begin during the crucial period of maturation from puberty to adulthood, misinterpretation and lack of diagnosis can greatly affect a patient's personality and feelings of self-esteem ([Table 114.4](#)).

The current treatment for the sleepiness of narcolepsy is the use of stimulant drugs, behavioral modifications, and/or γ -hydroxybutyrate (6 to 9 g). The stimulants can be categorized into the amphetamine and

nonamphetamines types. Modafinil (100 to 200 mg) and armodafinil (the R-enantiomer of modafinil, [150 to 250 mg]) are wake-promoting agents chemically and pharmacologically distinct from the amphetamine stimulants [Level 1].³ Use of stimulant drugs should be carefully monitored; patients and physicians should cooperate in adjusting the amount and timing of doses to meet functional daytime needs and scheduling of patients' activities. Cataplexy, when present to a significant degree, is usually well controlled with the selective serotonin reuptake inhibitors (paroxetine hydrochloride [20 to 60 mg] or fluoxetine hydrochloride [20 to 60 mg]) and tricyclic compounds (imipramine hydrochloride [10 to 100 mg], protriptyline hydrochloride [5 to 60 mg], or clomipramine [10 to 150 mg]); however, impotence may be an undesirable side effect in men. These medications are thought to treat cataplexy effectively because they suppress REM sleep. γ -Hydroxybutyrate (6 to 9 g) is given at bedtime and again during the night to improve sleep and reduce the frequency and severity of both sleepiness and cataplexy. Due to its potential for abuse, it is highly regulated and only available from a single central pharmacy.

TABLE 114.4 Comparison between the *International Classification of Sleep Disorders-3* and the *Diagnostic and Statistical Manual of Mental Disorders-5* for the Criteria of Narcolepsy Variants

DSM-5 Criteria	Narcolepsy-Hypocretin Deficiency		Primary Hypersomnia
ICSD-3 Criteria	Narcolepsy Type 1	Narcolepsy Type 2	Idiopathic Hypersomnia
Findings on MSLT	<8 min with two or more SOREMPs	<8 min with two or more SOREMPs	<8 min and fewer than two SOREMPs ^a
Cataplexy	Present	Rarely present	Absent
CSF hypocretin	<110 pg/mL	>110 pg/mL	>110 pg/mL
Description of naps	Short and refreshing	Short and refreshing	Long and unrefreshing
Sleep efficiency	Low	Low	High (>90%)

^aIf longer than 8 minutes, the individual must have 11 hours of sleep in a 24-hour polysomnogram or averaged from 7-day wrist actigraphy. *DSM*, *Diagnostic and Statistical Manual of Mental Disorders*; *ICSD*, *International Classification of Sleep Disorders*; MSLT, multiple sleep latency test; SOREMPs, sleep onset rapid eye movement periods; CSF, cerebrospinal fluid.

An important adjunctive treatment for narcolepsy is the rational scheduling of daytime naps, two 20-minute naps for example, and the maintenance of proper sleep hygiene. The physician's role in providing the patient with a clear understanding of the nature of the symptoms and with emotional support in coping with the many adaptive difficulties cannot be overemphasized.

Kleine-Levin Syndrome

Kleine-Levin syndrome (recurrent hypersomnia) consists of recurrent episodes of hypersomnia and binge eating lasting from 2 days to 5 weeks (rarely to 80 days), with intervals less than 18 months between episodes. Neurobehavioral and psychological changes, such as disorientation, automatic behavior, forgetfulness, depression, depersonalization, hallucinations, irritability, aggression, and sexual hyperactivity, often accompany the episodes of hypersomnia. During the episodes, the EEG shows general slowing with 0.5- to 2-second bursts of bisynchronous generalized moderate- to high-voltage 5- to 7-Hz waves. This resolves in between episodes. Onset is typically in early adolescent boys and is less common in girls. Prevalence is estimated to be around one or two cases per million. Episodes decrease in frequency and severity with age and are rarely present after the fourth decade. Differential diagnosis for this condition includes encephalitis, hyperammonemic encephalopathy, demyelinating disease, head trauma, porphyria, basilar migraine, and complex partial status epilepticus as well as psychiatric conditions such as

P.985

depression, seasonal affective disorder, or somatoform disorder. A menstrual variant of this condition has been reported in 18 women worldwide.

A definitive treatment for *Kleine-Levin syndrome* is not known, but there are reports of limited success with stimulants (especially amantadine [100 to 200 mg]), sodium valproate [250 to 60 mg/kg], and antidepressant therapy (including lithium [300 to 1,800 mg]).

SLEEP-RELATED BREATHING DISORDERS

Control of respiration during sleep is an excellent model of state-dependent neuronal regulation. Respiratory patterns vary with sleep stage. Near sleep onset, occasionally, individuals will have normal pauses in breathing. Mild periodicity to breathing can be noted in light sleep, but on entrance into slow-wave sleep, breathing is very regular and response to high CO₂ and low oxygen levels is blunted. During REM sleep, chest musculature is paralyzed and ventilation occurs only via diaphragmatic movement. REM sleep is also characterized by significant variation in respiratory pattern and the least response to high CO₂ levels and low oxygen. Each of these stages allows for the expression of dysfunction in the regulation of breathing during sleep. Some individuals with brain or cardiac pathology may express dramatic periodic breathing or Cheyne-Stokes respiration in NREM sleep, whereas others who have impairment of ventilation owing to diaphragmatic impairment or impediment will demonstrate hypoventilation during REM sleep. More commonly, individuals may have obstruction of the upper airway during sleep.

Snoring

Snoring is created by turbulent airflow vibrating upper airway soft tissue and is more prominent during inspiration and loudest during N3 and REM sleep (the periods of greatest muscle relaxation). Snoring occurs in approximately two-thirds of adults, more commonly in men and over 10% of children. Persistent loud snoring is a classic symptom of obstructive sleep apnea syndrome (OSAS), but the absence of snoring does not exclude the diagnosis. Some patients' airways do not resonate to produce snoring. This is especially true in patients who have had upper airway surgical procedures that tightened tissue. Other individuals may not generate enough inspiratory force, such as those with neuromuscular disorders.

Catathrenia

Catathrenia is the term associated with sleep-related groaning typically associated with a prolonged expiration that disturbs the bed partner or family members. It is more common in men although remains rare. There are no known long-term consequences of it and it can be treated effectively with positive airway pressure.

Sleep Apnea

Apnea refers to a pause in breathing, and on overnight sleep studies, the pause must persist for at least 10 seconds to be considered apnea. *Hypopneas* are defined as the partial reduction in airflow for a similar time. These respiratory events are accompanied by oxygen desaturation and/or arousals. Apneas and hypopneas are typically more prevalent during light NREM sleep and REM sleep.

Historically, bed partners may describe these events as though the breathing has stopped or the patient is holding his or her breath during sleep. These events may be aborted with a loud gasp, snort, body jerks, or the quiet resumption of breathing. Some patients have hundreds of events per night and are unable to obtain quality sleep. These individuals are typically unaware of any sleep disruption but feel unrefreshed in the morning. Patients with neurologic disorders are also at higher risk for sleep apnea. Sleep apnea is more commonly seen in individuals with CNS disease such as epilepsy, strokes, and head trauma and “classical” peripheral disease such as muscular dystrophy and myotonic dystrophy. Sleep apnea is classified into two major forms: obstructive and central.

Obstructive apnea is the most common form of sleep apnea. These apneas occur due to obstruction or collapse of the upper airway. The OSAS is the cluster of features including snoring, witnessed apneas, excessive daytime sleepiness, insomnia, morning headache, and impairment of daytime performance caused by the repetitive apneas. However, up to half of patients with documented obstructive sleep apnea on overnight polysomnography have no complaints of daytime symptoms. OSAS is frequently seen in individuals with hypertension, diabetes mellitus, and vascular disease. In adults, OSAS occurs predominantly between the fourth and sixth decades and is more common in men. The prevalence of OSAS increases with age and is higher in individuals with habitual snoring and obesity. Many patients are obese, yet some have normal body habitus. Common structural abnormalities such as narrow nasal passage, long soft palate, large tonsils, or retroflexed mandible leading to a small airway contribute to airway obstruction. Individuals with CNS disease are found to have a higher prevalence of sleep apnea than the general population.

OSAS is an independent risk for hypertension and the development of vascular disease. Recognized systemic complications of OSAS are systemic hypertension, pulmonary hypertension, diabetes mellitus, cardiac enlargement, myocardial infarction, stroke, elevated hematocrit, and an increased risk of sudden death during sleep.

Sleep apnea also occurs in infants and children. In infants, sleep apnea is associated with familial, congenital, and acquired dysautonomia syndromes and craniofacial disorders. Distinguishing apnea from normal periodic breathing is critical in infants, as some of these disorders are associated with either central or obstructive apneas. In children, obstructive sleep apnea is often associated with adenotonsillar hypertrophy, and daytime sequelae of hyperactivity, poor school performance, behavior problems, and limited growth have been associated.

Central apnea is the absence of ventilation owing to an absence of generation of respiratory effort. Central apneas can cause complaints of frequent awakenings and restless unrefreshing sleep. These respiratory events can be caused by neurologic abnormalities involving respiratory regulatory neuronal networks. Apneas may also follow neurologic events such as nocturnal seizures or acute strokes. One form of periodic breathing, Cheyne-Stokes breathing, can be seen in individuals with heart/renal failure, neurologic lesions, and metabolic or toxic encephalopathies. Patients with central apnea need a complete cardiac and neurologic examination. Certain medications such as opiates may also result in central sleep apnea.

When a single event is a combination of the two, the term *mixed apnea* is used. The term *complex sleep apnea* has no standard definition and should be avoided. Some may use it to describe an individual who has both central and obstructive events on diagnostic testing; others use it to describe the emergence of central events

when obstructive events are treated.

Treatment for sleep apnea consists primarily of methods of promoting airway patency for obstructive apnea and stimulation of breathing in central apnea. Continuous positive airway pressure

P.986

(CPAP) is the most common and effective treatment. Constant air pressure is generated by a small pump and delivered via tubing to a mask covering the nose and/or mouth. Patients may be given this treatment during polysomnography to determine the pressure required to alleviate airway obstruction during sleep. Autotitrating devices alter the pressure required depending on the level of resistance; these can be prescribed for most individuals without in-laboratory titrations. In some circumstances, the positive airway pressure may need to be altered in both inspiration and expiration to maximize each breath. A bilevel-CPAP device is then used. In some cases of central sleep apnea, adaptive servoventilation may be required. These devices provide variable support to overcome the oscillations between hyperpneas and hypoventilation seen in this condition and may reduce mortality in certain individuals. It is unclear whether treatment is needed for individuals where central sleep apnea is related to opioid use. This breathing pattern resolves with cessation of the offending medications [Level 1].4

In those with neuromuscular disorders, volume-assured pressure support (VAPS) may be indicated although there is no clear benefit compared to bilevel CPAP. It can, however, adapt as the disease progresses. Typically, those with progressive neuromuscular disorders are monitored with nocturnal oximetry for evidence of sleep-related hypoventilation.

In individuals unable to tolerate any devices but have desaturations during sleep, oxygen may be prescribed. However, there is limited evidence whether sleep-related desaturations (with the absence of wake-related desaturations) are deleterious to health.

Key elements for compliance with positive airway pressure therapy include patient education of the importance of therapy, close follow-up, and addressing patient problems with the therapy. Oral appliances advancing the mandible are reasonable alternative therapies for patient with mild sleep apnea particularly if unable to tolerate positive airway pressure.

The level of obstruction in obstructive sleep apnea may be found at various levels of the airway. In some patients, especially children and young adults, the removal of enlarged tonsils and adenoids relieves the obstruction. Stimulation devices of the airway have recently been developed to reduce the risk of airway collapse during sleep. The surgical procedure, uvulopalatopharyngoplasty, has been an inconsistently beneficial treatment, and selection criteria are not well established. Genioglossal and maxillary-mandibular advancements have successfully treated patients with structural abnormalities causing hypopharyngeal obstruction. Other treatments for less severe cases have been sustained weight loss and (for those with significant sleep apnea only when supine) sleeping in the lateral position.

Hypoventilatory and Hypoxemic Disorders

Several causes of hypoventilation during sleep are known and require detection of hypercarbia (sleep-related hypoxemia requires a diagnosis of hypoxia). *Obesity hypoventilation syndrome* result in sleep as well as daytime hypercarbia and requires a body mass index (BMI) of 30 or to be greater than the 95th percentile for age and sex in children. *Congenital central alveolar hypoventilation syndrome*, previously Ondine's curse, is a syndrome of the automatic central control of breathing due to the PHOX2B gene. It must be distinguished from mimickers such as Chiari malformation, obesity hypoventilation syndrome, Leigh disease, or congenital heart disease when cor pulmonale coexists. *Late-onset central hypoventilation with hypothalamic dysfunction* presents after the first few years of life with hyperphagia and respiratory failure from minor provocation. Temperature dysregulation, precocious puberty, thyroid disease, and other endocrinologic disorders may occur from inappropriately elevated

or reduced levels of hypothalamic hormones.

SLEEP-RELATED MOVEMENT DISORDERS

RESTLESS LEGS SYNDROME AND PERIODIC LIMB MOVEMENT DISORDER

Periodic limb movements in sleep (PLMS) are found in most patients with restless legs syndrome who are studied with polysomnography but are more commonly associated without symptoms of restless legs syndrome. Although most patients do not complain of symptoms related to the PLMS, patients or their bed partner may notice leg or arm movements during sleep. These movements may occur as periodic events or appear random. PLMS are repetitive stereotyped movements of any of the extremities. These most commonly occur in NREM sleep and activate the lower extremities as extension of the great toe with dorsiflexion of the ankle and flexion of the knee and hip. Movements can also occur in the arms and axial muscles. The individual movements are relatively brief, lasting 0.5 to 5.0 seconds, occur at 20- to 90-second intervals, and may continue for minutes to hours. Limb movements may be accompanied by an arousal or awakening. In contrast to most movement disorders, which are diminished by sleep (e.g., cerebellar and extrapyramidal tremors, chorea, dystonia, hemiballism), PLMS are initiated by sleep or drowsiness. They are also different from *hypnic jerks* (sleep starts), which are normal, nonperiodic, isolated myoclonic movements. Similar to restless legs syndrome, periodic limb movements are provoked by uremia, anemia, peripheral neuropathy, antiemetics, antidepressants, and caffeine use.

In individuals with restless legs syndrome, limb movements can be seen on the polysomnography. Periodic limb movements of sleep, however, are not necessary and are not correlative with restless legs syndrome. Eighty percent of sufferers have periodic limb movements of sleep. Periodic limb movements during wakefulness have also been noted and have been proposed as a better marker.

Restless legs syndrome is discussed in detail in Chapter 75. It is important to note that restless legs syndrome is a clinical diagnosis based on questioning the individual. It does not require a sleep study to diagnose.

In a case of hypersomnia where all medical causes, psychiatric diseases, and other sleep disorders have been excluded and the only abnormality is periodic limb movements, then *periodic limb movement disorder* is diagnosed. Periodic limb movement disorder is mutually exclusive of restless legs syndrome and the two disorders cannot be codiagnosed. There is limited literature on the treatment but is empirically treated with similar therapeutic approaches as restless legs syndrome.

Sleep-Onset Movements

Some movements occur at the transition between wake and sleep. *Sleep-related rhythmic movement disorder* involves large muscle groups moving in a stereotyped repetitive fashion that is not a tremor. It may involve the head, torso, or limbs in isolation. Sleep-related movement disorder is common in children and typically does not require treatment except protection from injury if movements are violent. It rarely persists into adulthood, in which case it can be disruptive to bed partners and treated with low-dose clonazepam (0.25 to 1 mg). When smaller muscle groups

P.987

are involved, other diagnoses such as bruxism, thumb sucking, or hypnagogic foot tremor, excessive fragmentary myoclonus should be considered. *Propriospinal myoclonus* results in difficulty initiating sleep and affects mainly the abdomen, trunk, and neck. When it is persistent into the daytime, a structural cause is found in 15% to 20% of cases. It typically spreads slow to rostral and caudal muscles from the axial muscles. *Sleep starts* or *hypnic jerks* involve one or more body segments in a single contraction and often asymmetrically. These may occur in association with a sensory component such as loud noise or a sensation of falling. Sleep deprivation, excessive stimulants, prior intense exercise, and emotional stress can increase frequency and severity of sleep starts. They

are also prominent in heredity hyperekplexia [Level 1].5

Sleep-Related Movements

Body movements may occur during sleep such as the presentation of parasomnias or sleep-related leg cramps. *Benign sleep myoclonus of infancy* occurs only in sleep, whereas myoclonic seizures and myoclonic encephalopathy will also occur in wakefulness.

CIRCADIAN RHYTHM DISORDERS

Disorders of the circadian sleep-wake cycle are divided into two major categories, transient and persistent. The *transient disorders* include the temporary sleep disturbance following an acute work shift change and a rapid time zone change (jet lag). Both sleep deprivation and the circadian phase shift produce symptoms including insomnia, disrupted sleep, and excessive sleepiness. These disorders usually resolve as external and internal cycles become aligned. The *DSM-5* removed jet lag disorder from its list of conditions; however, the *International Classification of Sleep Disorders* still recognizes its existence.

Other disorders are more persistent. Sleep-wake cycle disorders that persist are divided into several major clinical categories. Persons who voluntarily and frequently change their sleep-wake schedule (e.g., shift workers) have a mixed pattern of excessive sleepiness alternating with arousal at inappropriate times of the day or have minimal circadian pattern. Sleep is typically short and disrupted. Waking is associated with a decrease in performance and vigilance. This syndrome often disrupts social and family life.

The *delayed sleep phase type* is a specific chronobiologic sleep disorder characterized by going to bed late and waking up late in the morning. Patients are typically unable to fall asleep earlier and go to sleep between 1 and 6 AM. On weekends and vacation days, they sleep until late morning or early afternoon and feel refreshed but have great difficulty awakening at the required 7 or 8 AM for work or school. These patients have a normal sleep length and internal organization of sleep when clock time of sleep onset and sleep offset coincides with the circadian timing that controls daily sleep.

Successful treatment has been a phase shift of the time of the daily sleep episode by progressive phase delay of the sleep time. By delaying the time of going to sleep and awakening by 2 or 3 hours each day (i.e., a 26- or 27-hour sleep-wake cycle), the patient's sleep timing can be successfully reset to the preferred clock time. Additionally, treatment with bright light in the morning and melatonin (0.2 to 0.5 mg) or a melatonin agonist in the evening may help shift and lock the circadian rhythm to a desired schedule [Level 1].6

The *advanced sleep phase type* is a condition in which individuals go to bed early in the evening and wake early in the morning. Typical sleep onset is between 6 and 8 PM, with wake times between 1 and 3 AM despite efforts to delay sleep time. This pattern is more likely to occur in elderly persons. Treatment of bright light in the evening and extended-release melatonin may help the sleep-wake schedule.

The rare individual with the free running type or *nonentrained type* maintains a 25- to 27-hour biologic day that does not entrain to the world's 24-hour cycle. This is more common in individuals who have prechiasmatic blindness, as light stimulus (a primary zeitgeber) does not reach the suprachiasmatic nucleus. This is in contrast to a person with an *irregular sleep-wake type* consisting of considerable irregularity without an identifiable persistent sleep-wake rhythm. There are frequent daytime naps at irregular times and a disturbed nocturnal sleep pattern. This disorder indicates dysfunction of the pacemaker, and most patients with this syndrome have congenital, developmental, or degenerative brain dysfunction, although it does occur rarely in cognitively intact patients. Treatment is difficult but should include regularly scheduled activities and time in bed based on sleep hygiene principles.

NOCTURNAL BEHAVIORS

Parasomnias

Parasomnias are undesirable physical or behavioral phenomena that occur predominantly during sleep. They include disorders of arousals, such as sleepwalking or night terrors; sleep-wake transition disorders, such as sleep talking; and REM parasomnias, such as REM sleep behavior disorder (RBD). These behavioral events may mimic epileptic seizures or other psychiatric events. Key features of age of onset, time of night of the events, stereotypic behavior, memory for the events, and family history are important in historically distinguishing the etiologies. Although RBD is the only disorder requiring polysomnography for diagnosis, most patients require polysomnographic recording (with complete EEG if epilepsy is in the differential) to delineate the cause or other potential sleep disorders provoking the parasomnia.

Non-Rapid Eye Movement Parasomnias

The classic disorders of arousal occur out of slow-wave sleep and include *sleepwalking*, *sleep terrors*, and *confusional arousals*. These behaviors are more common in children and adolescents and are characterized as events occurring as partial arousals from the deeper stages of NREM sleep. These patients are caught in a transition of part of the brain in NREM sleep and another portion in wake. These nonstereotypic events are more common in the first half of the night (when N3 is more prevalent), and typically, patients have little to no memory for the events; recall may increase with age. Sleepwalking usually involves a series of simple motor behaviors, such as sitting up in bed, walking, opening and closing doors, or climbing stairs, however, can rarely result in jumping out of bed as well as violent behaviors. Higher cognitive functions are significantly impaired, and there is reduced vigilance although motor behavior is intact. Self-injury and injury to those around them can occur.

Sleep terrors, however, start with a piercing scream or fright with significant sympathetic nervous system output. Patients have tachycardia, pupillary dilation, and sweating and appear wide eyed and inconsolable. A subgroup of patients may be harmful to themselves or others, such as fighting, throwing objects, and climbing out or walking through a window.

P.988

Confusional arousals occur following sudden awakening and may be accompanied with disorientation and the patient striking out. Other variations include sleep-related eating disorder, which is hallmarked by patients eating in a messy, haphazard manner with little or no recall. Sleep-related abnormal sexual behaviors can involve masturbatory behavior and sexual vocalizations and may have criminal consequences due to the initiation of sexual intercourse, molestation, or assault.

A small nightly dose of a benzodiazepine, such as clonazepam (0.25 to 4 mg) or temazepam (7.5 to 30 mg), is useful, especially when potential exists for the patient or bed partner to be injured. Medication such as zolpidem, phenothiazines, anticholinergics, and lithium may provoke these episodes. Hypnosis has also been used. Generally, treatment is not required but safety is a priority especially when the individual has a tendency to leave the bed.

Rapid Eye Movement Parasomnias

RBD, a REM sleep-related parasomnia, is characterized by intermittent loss of REM sleep atonia with dream enactment. Patients usually have clear recall of the dream, and witnesses can relate the activity to the dream mentation. Events are more likely to occur in the latter half of the night (when REM is more prevalent) and do not have stereotypic behavior. Injury to self or bed partner is common. It appears that as many as 80% of those with idiopathic RBD progress to a synucleinopathic neurodegenerative condition within a decade; this association is less clear when idiopathic RBD begins at a younger age. The prevalence of RBD is unknown but appears to be more common in older men. Some patients may develop RBD due to structural lesions interrupting the REM atonia pathway. Medications such as serotonin reuptake blockers and norepinephrine reuptake blockers have

been cited to result in RBD-like behavior, although there is no evidence currently that these predispose to the condition.

The diagnosis is usually suggested by history and is required to be confirmed by polysomnography. Recordings show persistent muscle tone and complex behaviors during REM sleep. Most patients respond to clonazepam (0.25 to 4 mg) at bedtime, but success has been reported with melatonin (2 to 12 mg) and donepezil (10 to 15 mg) [Level 1]. 7 Restraints to the individual during the night are sometimes required to avoid self-injury and to those around them, such as bedrails or placing the individual in a sleeping bag (Table 114.5).

Other REM parasomnias include painful erections, nightmares, and REM sleep-related sinus arrest, which are beyond the scope of this chapter.

CONCLUSION

Nearly every CNS process has been associated with disruption of sleep. The ubiquity of sleep and the brain makes this dynamic relationship even more important. Sleep may be abnormal because of involvement of brain structures that control and regulate sleep and wakefulness or because of abnormal movements or behaviors that occur during sleep. Additionally, the loss of sleep provokes further dysfunction of the brain. For example, patients with epilepsy have fewer seizures once treated for their previously unrecognized obstructive sleep apnea. Other small studies have shown patients with neuromuscular disorders improve their daytime function when their sleep-related respiratory disturbances are treated. As

neurologists, we must be keenly aware that sleep provides another dimension of diagnostic and therapeutic avenues for diseases of the nervous system. More importantly perhaps, we need to be vigilant for sleep disorders contributing to morbidity in our patients, particularly as nearly all are treatable, potentially resulting in increased quality of life.

Stephan A. Mayer

INTRODUCTION

The heart-brain interaction is a vital physiologic circuit often implicated in neurologic and cardiovascular injury. Cerebral complications of cardiac procedures and stroke due to atrial arrhythmias represent important causes of neurologic disability. Recent advances and complications of cardiopulmonary support with left ventricular assist device and extracorporeal membrane oxygenation have opened the door to new neurologic diagnostic and therapeutic challenges. Conversely, severe acute brain injury is being increasingly recognized as a cause of catecholamine-mediated myocardial dysfunction, an entity that is known by many names ([Table 115.1](#)) but is most accurately described as *neurogenic stunned myocardium*.

Autonomic storming is similarly caused by exaggerated sympathetic effect after brain injury and is characterized by cardiovascular abnormalities including coexistent hypertension and tachycardia. Neurogenic hypotension in the absence of cardiac dysfunction usually results from abnormal vasomotor tone and is discussed in Chapter 112.

CEREBRAL COMPLICATIONS OF CARDIAC PROCEDURES

EPIDEMIOLOGY

Cerebrovascular injury is one of the most feared complications of cardiac surgery. Ischemic strokes occur in 0.8% to 5.2% of coronary artery bypass graft (CABG) surgeries, although the incidence may be decreasing with more recent publications from 2011 reporting incidence closer to 1.6%. One single-center study of more than 45,000 patients found that 40% of the strokes occurred intraoperatively with the postoperative risk for stroke peaking at 40 hours following surgery. The risk for stroke is greater for patients undergoing CABG with aortic atherosclerosis and concomitant carotid artery disease and the risk is directly proportional to the degree of stenosis. Other risk factors for perioperative stroke with CABG include atrial fibrillation, prior stroke or transient ischemic attack (TIA), and female gender. Cognitive disability in the absence of acute infarct occurs in up to 70% of patients following CABG. The reported incidences of postoperative cognitive decline are widely variable and likely reflect variability of the cardiac procedure itself to differing neuropsychiatric testing methods and control groups.

TABLE 115.1 Synonyms for Neurogenic Stunned Myocardium

Takotsubo cardiomyopathy

Apical ballooning syndrome

Broken heart syndrome

Stress-induced cardiomyopathy

Atrial fibrillation occurs in up to 40% of patients within a few days following CABG. It occurs in up to 50% of patients after valve surgery and up to 60% of patients following valve replacement plus CABG. Eleven percent of patients develop atrial fibrillation as a late complication of CABG. In the general population, the most common causes of atrial fibrillation are hypertension, coronary heart disease, and rheumatic heart disease, with the latter being uncommon in developed countries. The risk of ischemic stroke due to atrial fibrillation may be stratified using scoring systems such as CHADS₂, which incorporate additional risk factors for stroke including heart failure, advanced age, diabetes, prior stroke, female gender, etc. Refer to Chapter 44 for detailed discussion of stroke risk due to atrial fibrillation.

Left ventricular assist device (LVAD) and extracorporeal membrane oxygenation (ECMO) have dramatically changed the therapeutic landscape of severe, medically refractory cardiopulmonary failure. Neurologic complications are, however, common and occur in 8% to 25% of patients with LVADs. In a series from the University of Pittsburgh Medical Center, 61% of LVAD-related neurologic complications were due to embolic strokes and 25% were intracerebral hemorrhages. In another single center study from Columbia University, 14% of patients with LVADs developed neurologic complications of which 81% were either due to ischemic or hemorrhagic stroke. A recent review on LVAD-related bleeding and thrombosis from 2012 found that the incidence of ischemic strokes was 0.04 to 0.13 per patient-year and 0.05 to 0.8 per patient-year and for hemorrhagic strokes. Relatively, little has been reported on the neurologic complications of adult patients on ECMO. In one series, 50% of patients receiving ECMO suffered neurologic injury of which 17% were strokes defined as either ischemic stroke, hemorrhagic stroke, or subarachnoid hemorrhage. The frequency of neurologic events was likely underestimated in this study, as less than one-third of the patients underwent cerebral imaging.

PATHOBIOLOGY

The majority of strokes after cardiac surgery are ischemic, although hemorrhagic conversion of ischemic infarcts is possible. Intraoperative strokes occur due to arterial emboli arising from atherosclerosis of major vessels such as the aorta or carotid arteries or due to cerebral hypoperfusion resulting from intraoperative hypotension or diminished cardiac output. Fat and air emboli may also occur. Transcranial Doppler (TCD) ultrasonography monitoring of the middle cerebral artery has been used to quantify microemboli

P.991

during coronary bypass surgery, which in some cases exceed 60 per operation. High-risk periods for embolization include manipulation of the heart and aorta, particularly during aortic clamping and cannulation. No causal relationship has been confirmed between number of microemboli and cognitive decline, although increased burden of new ischemic lesions has been associated with postoperative cognitive decline.

Postoperative strokes are generally cardioembolic and related to postoperative arrhythmias such as atrial or ventricular fibrillation. Cerebral complications of atrial fibrillation occur due to embolization of thrombus from the left atrium or atrial appendage. Strokes due to atrial fibrillation are more likely to cause large-vessel occlusion and hemispheric injury than embolic sources arising from the carotid arteries. This was demonstrated in a study that showed that cardioembolic etiologies of stroke were 25 times likely to cause hemispheric events than retinal events. The presumed mechanism for this difference is the larger size of cardioembolic particles compared to emboli arising from the carotid arteries.

LVADs pose extraordinary challenges related to coagulopathy. Although anticoagulation is required to decrease risk of device thrombosis and thromboembolism, this comes at the cost of increased hemorrhagic complications. Furthermore, high-shear stress conditions related to LVADs are thought to induce an

acquired von Willebrand syndrome by mechanical destruction of von Willebrand multimers. As a result, LVAD patients are at higher risk for both hemorrhagic and ischemic strokes. Hemorrhagic strokes in patients with mechanical circulatory devices should raise suspicion for endocarditis. The role of infections and inflammatory milieu on neurologic complications is an ongoing debate in patients both with and without mechanical circulatory devices. In one study of LVAD patients, 42% of cerebrovascular accidents occurred in patients with infections. An elevated white blood cell count was noted in patients with neurologic complications regardless of the presence or absence of infection, although it is unclear whether this represented a stress reaction from acute brain injury. The same study found thromboelastogram abnormalities in periods with infection than without infection suggesting that infection may activate platelet function and contribute to the risk of neurologic injury.

Similar to the LVAD, anticoagulation is required to decrease the risk of ECMO-related thrombosis and thromboembolism. Also analogous to the LVAD, increased platelet activation and consumption due to exposure to foreign surface area is common, further contributing to a bleeding diathesis. The net result is a significantly increased risk of bleeding in up to 40% of patients receiving ECMO. Thromboembolic complications are more common in venoarterial compared to venovenous ECMO, as blood is infused directly to the systemic circulation with the former. Greater risk of retrograde aortic blood flow and stasis of the blood due to worsening left ventricular output also increase the risk of thrombus formation.

CLINICAL FEATURES

The clinical manifestations of post-CABG strokes (or strokes due to atrial fibrillation) reflect the dysfunction of the affected neuroanatomic structures. Approximately 20% of strokes involve the posterior circulation. Symptoms attributable to the posterior circulation such as eye movement abnormalities, behavioral abnormalities, and cortical blindness should raise suspicion for a “top of the basilar” syndrome. Hemiparesis is not an invariable finding of post-CABG strokes, as isolated aphasia syndromes or cortical blindness is also encountered. When hemiparesis is present, it may be limited to hand or fine finger movements and mistaken for a compression neuropathy.

The clinical manifestations of LVAD- or ECMO-related stroke are similar to post-CABG stroke patients. Intracranial hemorrhagic complications related to these devices are more likely to have a more fulminant presentation with impairment in consciousness and rapid progression of symptoms.

DIAGNOSIS

Initial diagnosis of stroke is suggested by history and physical examination and then corroborated by cerebral imaging. The National Institute of Health Stroke Scale is a reliable 15-item scale that is validated as a measure of stroke impairment (see [Chapter 15](#)). Computed tomography (CT) of the brain is often used as an initial diagnostic test for intracranial hemorrhage because hyperacute ischemic changes may not be evident. Magnetic resonance imaging of the brain with diffusion-weighted imaging may detect ischemic abnormalities as early as within 3 minutes of symptom onset, however, may be contraindicated in patients with metallic devices such as LVADs and certain pacemakers. Blood cultures, fungal cultures, and transesophageal echocardiograms should be obtained when there is a suspicion for endocarditis and septic emboli and particularly in patients with mechanical circulatory devices. Cerebral angiography may be indicated to diagnose mycotic aneurysms.

TREATMENT

Prevention

It is critical to employ measures to prevent neurologic complications during cardiac surgery. Preoperative evaluation involves assessment of risk factors including carotid stenosis. The risk of stroke during cardiac surgery may be lowered by performing simultaneous carotid endarterectomy. Avoiding relative hypotension during cardiac surgery may improve outcomes. This was shown in a randomized trial of 248 patients where maintaining higher pressures (mean artery pressures 80 to 100 mm Hg vs. 50 to 60 mm Hg) during cardiopulmonary bypass was significantly associated with lower rates of neurologic and cardiac complications or death at 6 months [**Level 1**].¹ Systemic hypothermia at 32°C for closed chamber and 28°C for open chamber procedures during cardiopulmonary bypass may reduce cerebral metabolic rate and prevent ischemia. Transesophageal echocardiogram reduces the risk of intraoperative strokes by enhanced detection of aortic atheroma enabling the surgeon to alter technique to reduce risk of embolization. Electroencephalography can also be used to detect cerebral ischemia during cardiac surgery, although the use of this is debated.

Acute Ischemic Stroke

Thrombolytic therapy is often contraindicated for acute ischemic stroke during the postoperative period and in patients being treated with therapeutic levels of anticoagulation. Strokes occurring due to septic emboli from infected hardware also increase the risk of hemorrhage due to thrombolysis. Alternative reperfusion techniques including endovascular therapies may be considered in the appropriate circumstances. In patients with LVADs or patients receiving ECMO, the benefits of anticoagulation for thromboembolism need to be balanced with the risks of hemorrhagic conversion of ischemic infarct for a given patient based on stroke severity and size. There are currently limited data on the optimal time frame for restarting antithrombotics; however, significant delays in restarting these medications further increase the considerable risk of thromboembolism. Other management strategies of acute ischemic stroke are discussed in Chapter 15.

P.992

Intracranial Hemorrhage

Intracranial hemorrhage is primarily a risk of LVAD and ECMO support due to the need for anticoagulation and concurrent risk of brain embolism. Initial management should involve discontinuation of all antiplatelet medications and anticoagulation. Anticoagulation reversal should be strongly considered for life-threatening hemorrhages with the understanding that these interventions may increase the risk of device thrombosis in patients with cardiopulmonary devices. Hemostatic therapy should be tailored to the specific anticoagulant exposure (see [Table 38.2](#)). For example, protamine sulfate may be used for heparin-related intracerebral hemorrhage and vitamin K with prothrombin complex concentrate/fresh frozen plasma may be used for warfarin-related intracerebral hemorrhage. Antifibrinolytics and recombinant factor VIIa may also be considered in the appropriate clinical setting. Patients undergoing treatment with LVAD or ECMO should receive platelet transfusions and DDAVP. Blood pressure should be managed as per current guidelines (see [Table 38.2](#)). Endocarditis should be treated with antibiotics and surgical evaluation (see also [Chapter 63](#)). There is currently limited data on when to restart antithrombotics after intracerebral hemorrhage. A rational approach that balances the risk of hemorrhage expansion with the considerable benefits of thromboembolic prophylaxis based on the individual clinical circumstance is appropriate until further research is available.

OUTCOME

Perioperative stroke increases hospital mortality by up to 10-fold and long-term survival is worse among stroke survivors. A study by Tarakji et al. found that perioperative stroke decreased the likelihood of survival at 1, 10, and 20 years by 25%, 41%, and 23%, respectively.

In The Randomized Evaluation of Mechanical Assistance in Treatment of Chronic Heart Failure trial, cerebrovascular complications were the third leading cause of death (9.8%). This finding was supported by two other publications; 1 of over 1,000 LVADs where a central nervous system event was the third leading cause of mortality accounting for 14% of deaths. Little has been reported on neurologic complications of adult ECMO patients. This may be in part due to the difficulty in knowing whether the neurologic consequences are the result of the pathology prompting ECMO or related to the ECMO process itself. In one series, 63% of subjects who underwent cerebral imaging had pathologically abnormal findings, and 90% of patients who underwent brain autopsy had evidence of intracranial pathology ranging from ischemic/hemorrhagic lesions to diffuse cerebral edema. In one study of infants receiving ECMO, major intracranial hemorrhage accounted for 55% of deaths.

CARDIOVASCULAR COMPLICATIONS OF NEUROLOGIC INJURY

NEUROGENIC STUNNED MYOCARDIUM

Epidemiology

Neurogenic stunned myocardium may be defined as an acute, reversible cardiac injury commonly associated with various forms of acute brain injury including subarachnoid hemorrhage, intracerebral hemorrhage, ischemic stroke, and seizures. Electrocardiographic abnormalities are seen in up to 70% of patients with subarachnoid hemorrhage and in up to 40% of patients with intracerebral hemorrhage and ischemic stroke. Left ventricular systolic dysfunction has been found in 10% to 28% of patients with subarachnoid hemorrhage, and diastolic dysfunction is seen in up to 71% of patients.

Pathobiology

Neurogenic stunned myocardium (NSM) is presumed to occur due to dysregulation of autonomic control, primarily of the sympathetic system. A proposed instigating mechanism is injury to the insular cortex or hypothalamus, which are important areas for autonomic control. Right cerebral hemispheric injury is more likely to be associated with sympathetic dysautonomia, whereas the left cerebral hemisphere predominantly causes parasympathetic responses. Similar neuroanatomic specialization was demonstrated in cats where lateral hypothalamic stimulation caused sympathetic responses such as tachycardia and ST-segment depressions, whereas anterior hypothalamic stimulation caused parasympathetic responses such as bradycardia. There is evidence that primary brain stem injury in the setting of transtentorial herniation can also produce a massive sympathetic discharge. All of these states are characterized by abnormal hyperactivity of the locus coeruleus, a nucleus in the pons that mediates sympathetic tone.

Catecholamine release and overload, primarily released by the cardiac sympathetic nerves, produces a state of overstimulation of myocardial cells with a characteristic histopathology termed *contraction band necrosis*. Affected myocardial cells are overloaded with calcium, remain hypercontracted, and no longer respond to β_1 -receptor agonists due to uncoupling of the adenylyl cyclase secondary messenger system. For this reason, attempts to improve left ventricular contractility with exogenous catecholamines such as norepinephrine in

patients with cardiogenic shock tend to be ineffective.

Clinical Features

NSM tends to occur in the setting of acute severe brain injury. Subarachnoid hemorrhage is the best known and most common cause of NSM, but the condition can develop in response to any cause of massive sympathetic outflow, including intracerebral hemorrhage, cerebral infarction with herniation; Guillain-Barré syndrome; acute hydrocephalus; traumatic brain injury; or status epilepticus, acute emotional stress, and pheochromocytoma. Mild to moderate elevations in cardiac enzymes may accompany characteristic electrocardiographic features, which include long QT intervals, widespread symmetric inverted T waves, and U waves. Left ventricular dysfunction manifests as diastolic dysfunction in mild cases. More severely affected patients develop regional left ventricular wall motion abnormalities that do not respect typical vascular territories in association with mild to moderate reduction of the left ventricular (LV) ejection fraction (20% to 40%). In fulminant cases, patient can develop acute cardiogenic shock with ejection fractions of 20% or less. The level of cardiac enzyme elevation is typically low in relation to the extent of LV dysfunction. A retrospective study to differentiate between acute coronary syndrome and NSM found troponin levels were 10-fold higher with infarcted heart (based on historic controls) compared to stunned myocardium (2.8 ng/mL vs. 0.22 ng/mL). A troponin level of less than 2.8 ng/mL and ejection fraction less than 40% in the setting of acute aneurysmal were consistent with stunned myocardium rather than acute coronary syndrome.

Acute neurogenic pulmonary edema (NPE) can occur in isolation, or in addition to, NSM. In its purest sense, NPE is thought to represent a neurally mediated noncardiogenic form of pulmonary

P.993

edema characterized by disruption of the integrity of the pulmonary microvasculature (i.e., “leaky lung” pulmonary edema). Acute peripheral vasoconstriction has been shown to cause a massive increase in intrathoracic blood volume, which causes a “blast effect” which then leads to increased pulmonary vascular permeability (Fig. 115.1).

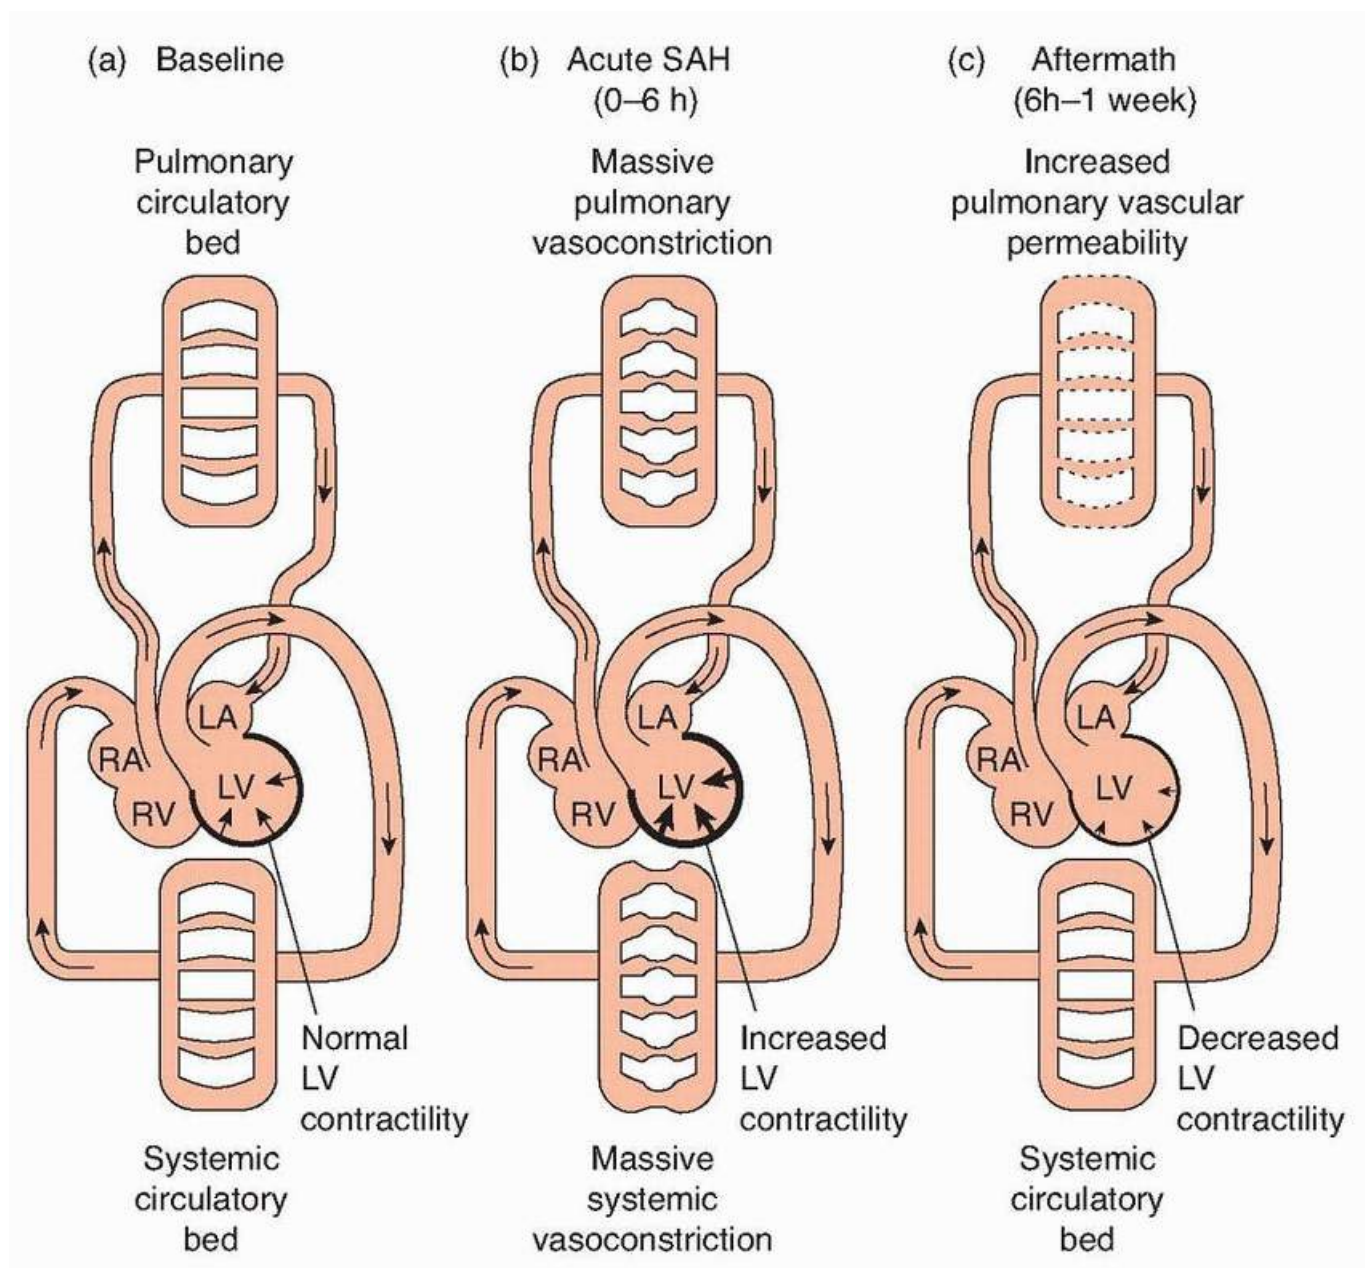

FIGURE 115.1 Diagram explaining how neurogenic stunned myocardium and pulmonary edema characterized by increased pulmonary vascular permeability can coexist after subarachnoid hemorrhage and other forms of catastrophic brain injury. The unifying inciting event is a massive catecholamine discharge (b), which leads to concomitant decreased left ventricular contractility and leaky lung pulmonary edema after the initial phase of injury (c). RA, right atrium; RV, right ventricle; LA, left atrium; LV, left ventricle. (Adapted from Mayer SA, Swarup R. Neurogenic cardiac injury after subarachnoid hemorrhage. *Current Opinion Anaesth.* 1996;9:356-361.)

Diagnosis

The takotsubo variant of NSM features characteristic echocardiographic findings of apical akinesis and ballooning with left ventricular diastolic and systolic dysfunction (Video 115.1). It is important to appreciate that NSM occurs on a spectrum of variants that includes a “reverse takotsubo” pattern where the apex of the heart is normal and the base is hypokinetic (Video 115.2). If clinical suspicion is high for acute coronary syndrome, coronary angiography may be required to definitively exclude underlying coronary artery disease. Serial echocardiography by definition shows progressive improvement and eventual normalization of LV function over days to weeks.

Treatment and Outcome

Patients with severe acute intracranial pathology should have continuous electrocardiographic monitoring for at least 72 hours and cardiac enzymes should be obtained. Management should be focused on treating the underlying cause of the neurogenic stunning such as securing the ruptured aneurysm. Euvolemia should be maintained using isotonic intravenous fluids as needed. There is evidence from cohort studies that NSM is less common among subarachnoid hemorrhage patients previously on β -blockers; for this reason, there may be some rationale for use of the β 1-blocker esmolol (starting at 50 $\mu\text{g}/\text{kg}/\text{min}$, titrated to attain heart rate below 100 beats per minute). When cardiac function is significantly diminished, inotropic vasopressors or inotropes such as norepinephrine, dobutamine, and milrinone may be required to augment cardiac output. There is evidence that milrinone, a phosphodiesterase inhibitor, is a more effective inotrope than norepinephrine because it bypasses α 1 receptors, which are prone to receptor desensitization. NPE tends to be fragile and often responds to gentle diuresis with furosemide. Reversibility is a hallmark feature of NSM and echocardiographic abnormalities usually improve within days.

PAROXYSMAL SYMPATHETIC STORMING

Synonyms for paroxysmal sympathetic storming include autonomic storming, paroxysmal dysautonomia (PDA), autonomic dysfunction syndrome, hypothalamic-midbrain dysregulation syndrome, paroxysmal autonomic instability with dystonia (PAID), and neurostorming. The condition is characterized by irregular, recurrent violent sympathetic discharges in the acute or subacute phase of severe brain injury in the intensive care unit.

Epidemiology

Paroxysmal sympathetic storming occurs in up to 33% of patients with severe traumatic brain injury and severe diffuse axonal shearing injury and is also relatively common in patients with anoxic brain injury. It is less frequently seen in poor-grade subarachnoid hemorrhage, coma resulting from intracerebral hemorrhage, malignant middle cerebral artery infarction syndrome, and in patients with brain stem pathology. It seems to be more common in younger patients.

Clinical Features

Autonomic storming presents with paroxysmal episodes of hypertension and tachycardia, fever, hyperventilation, diaphoresis, extensor posturing, and severe dystonia. The onset typically occurs days to weeks after the original brain injury event. The posturing and dystonia may at times resemble generalized seizures consistent with prior descriptions of autonomic storming as “diencephalic seizures.”

TABLE 115.2 Diagnostic Criteria for Paroxysmal Sympathetic Storming

Four of the following, occurring in episodic surges at intervals of 30 min to 4 h:

- Fever ($>38.3^{\circ}\text{C}$)
- Tachycardia (120 beats/min or 100 beats/min if on β -blockers)
- Tachypnea (respiratory rate >30 breaths/min)^a

- Hypertension (systolic blood pressure >160 mm Hg or pulse pressure >80 mm Hg)

- Diaphoresis

- Extensor posturing or motor dystonia

- Severe dystonia

^aIn the absence of sepsis or airway obstruction.

Diagnosis

Autonomic storming is a clinical diagnosis. A diagnostic algorithm is summarized in [Table 115.2](#). One of the easiest ways to make the diagnosis is to establish the presence of episodic parallel surges in blood pressure and heart rate when reviewing vital signs over 24 hours on a bedside monitor. Seizures may need to be excluded using continuous video electroencephalography because the episodes are often paroxysmal. Autonomic storming may need to be differentiated from the typical pressor response to elevated intracranial pressure or cerebral ischemia, which is a common compensatory sequel of acute brain injury and likely reflects efforts to maintain adequate cerebral perfusion pressure in the face of elevated intracranial pressure.

FIGURE 115.2 Suppression and stabilization of sympathetic storming with propofol infusion in a patient with paroxysmal sympathetic storming. Note the immediate stabilizing effect on intracranial pressure, which fell from levels as high as 70 mm Hg to normal at the start of the infusion. HR, heart rate; MAP, mean arterial pressure; ICP, intracranial pressure.

Management

Management of sympathetic storming is focused on brain sedation, analgesics that blunt nociceptive inputs that trigger storms, agents that specifically suppress the locus coeruleus, and blunting of the peripheral manifestations of hypertension and tachycardia with β -blockers. Acute control of severe symptoms can be quickly attained with infusion of propofol (50 to 200 $\mu\text{g}/\text{kg}/\text{min}$), fentanyl (50 to 100 mg/h), or dexmedetomidine (0.7 to 1.4 $\mu\text{g}/\text{kg}/\text{h}$) alone or in combination (Fig. 115.2).

Pharmacotherapeutic options to control symptoms and allow weaning of analgosedative infusions in the intensive care unit (ICU) are summarized in Table 115.3. These agents should be started sequentially and evaluated during daily interruptions of continuous intravenous (IV) analgosedation. Concurrent use of IV antihypertensive agents such as nicardipine or labetalol is rarely needed after IV sedative agents have been administered. It is important to realize that neurogenic autohypertension is fragile and can be easily overtreated and result in impaired cerebral perfusion pressure. As such, antihypertensive medications may need to be started at lower doses and titrated up while monitoring response.

Outcome

Paroxysmal sympathetic storming typically persists for weeks to months before it resolves. Storming treated with prolonged IV infusions of analgosedatives such as propofol and fentanyl leads to increased ICU length of stay and a concomitant increase in the risk of hospital-acquired infections and complications. Outcome can be improved by aggressively advancing the agents used for subacute to chronic control of symptoms in Table 115.3, which allows discontinuation of IV sedation, liberation from the ventilator, and advancement to rehabilitation.

P.995

TABLE 115.3 Pharmacotherapy for Paroxysmal Sympathetic Storming during the Subacute to Chronic Phase

Analgosedatives	<ul style="list-style-type: none">• Fentanyl patch 25-300 $\mu\text{g}/\text{h}$• Morphine (Roxanol, MS Contin) 5-20 mg q4h• Lorazepam 2-24 mg/day• Klonopin 1-8 mg/day
α -Blockers	<ul style="list-style-type: none">• Propranolol 160-640 mg/day• Labetalol 400-3,600 mg/day
Central antiadrenergic agonists	<ul style="list-style-type: none">• Clonidine PATCH 0.1-0.9 mg/day• Bromocriptine 10-40 mg/day

Respiratory Support for Neurologic Diseases

David B. Seder

Stephan A. Mayer

INTRODUCTION

Much of the high morbidity and mortality from acute neurologic disorders results from abnormalities of breathing. Respiratory abnormalities can themselves worsen neurologic injury, whereas neurologic abnormalities conversely predispose to aspiration, impaired airway clearance, atelectasis, and pneumonia. In stroke, traumatic brain injury, status epilepticus, Guillain-Barré syndrome, myasthenia gravis, and many other neurologic disorders, oropharyngeal and respiratory muscle weakness predispose to aspiration of secretions into the airways, mucus plugging, hypoventilation, atelectasis, and pneumonia. Accordingly, respiratory monitoring and support are among the most common indications for the admission of neurologic patients to an intensive care unit (ICU).

RESPIRATORY PHYSIOLOGY AND PATHOPHYSIOLOGY

PULMONARY GAS EXCHANGE

Hypoxemia is characterized by reduced oxygen content of the bloodstream. Hypoxemia is caused by five conditions: (1) a low inspired oxygen concentration, (2) alveolar hypoventilation, or impaired gas exchange within the lungs due to (3) ventilation-perfusion (V/Q) mismatching, (4) transpulmonary or intracardiac right-to-left shunting, or (5) impaired diffusion of gases between the alveoli and the capillaries. It can also be caused by low mixed venous oxygen saturation.

Impaired gas exchange can be quantified by measuring the gradient between the partial pressure of oxygen in the alveoli and the arterial blood (the A/a gradient, which is normally <20 mm Hg) or the P/F ratio, which is the partial pressure of oxygen in the arterial blood (PaO_2 , normally 90 to 100 mm Hg) divided by the fraction of inspired oxygen (FiO_2 , normally 21% in room air). Alveolar oxygen tension (PA_{O_2}) can be calculated from the equation $PA_{O_2} = (FiO_2 \times 713) - (PaCO_2/0.8)$, where $PaCO_2$ is the arterial carbon dioxide tension.

The cause of impaired gas exchange leading to hypoxemia can be differentiated according to the response to supplemental oxygen. *Shunting*, defined as hypoxia unresponsive to oxygen supplementation, results from the direct transfer of deoxygenated venous blood into the arterial circulation through an intracardiac atrial septal defect, pulmonary arteriovenous malformation, or perfused but nonventilated lung parenchyma (i.e., dense airspace consolidation due to pneumonia). With V/Q mismatching, ventilation and perfusion relationships are heterogeneously deranged, but systemic oxygenation improves in response to a higher FiO_2 . Diffusion abnormalities are characterized by abnormalities of the intra-alveolar septae, which may be fibrotic (i.e., interstitial lung disease), reduced in number and surface area (i.e., emphysema), and inflamed or edematous (i.e., acute respiratory distress syndrome, congestive heart failure). Low inhaled FiO_2 is typical of extreme altitude but can also result from equipment malfunction such as rebreathing of exhaled gases.

Hypercarbia results from impaired alveolar ventilation and is caused by some combination of inadequate "bellows function" of the lung (characterized by reduced minute ventilation, the product of the respiratory rate and tidal volume), increased carbon dioxide production, and impaired gas exchange. Hypoventilation

can only be mechanism of hypoxia when concomitant hypercarbia is present.

RESPIRATORY FAILURE

The diagnosis of *respiratory failure* depends on arterial blood gas analysis and on the chronicity of the event. Three separate processes can contribute to the development of respiratory failure: (1) hypoxia, which results from impaired gas exchange in the lung; (2) ventilatory failure, which results from inadequate ability to move air into and out of the lungs; and (3) failure to protect the upper airway, which can result in airflow obstruction or aspiration of secretions, food, or gastric contents.

Chronic respiratory failure is said to be present when a patient cannot maintain adequate oxygenation ($\text{PaO}_2 > 59$ mm Hg) or ventilation ($\text{PCO}_2 < 50$ mm Hg) without supplemental oxygen or ventilatory assistance.

In contrast, *acute hypoxemic respiratory failure* describes a state in which adequate oxygenation cannot be maintained despite supplemental oxygen delivery. In these patients, positive pressure ventilation and supplemental oxygen administered through an endotracheal tube or by noninvasive positive pressure ventilation are required to maintain normal oxygenation of arterial blood. In the hospital, hypoxemia can be easily and noninvasively diagnosed and monitored by measuring the percent oxygen saturation of hemoglobin in the blood (SpO_2). The clinical hallmark of hypoxemic respiratory failure is cyanosis.

Hypercarbic respiratory failure may be clinically obvious, as seen when the accessory muscles of respiration are activated and the patient appears “working hard to breathe” or can be subtle, manifest only by decreased mental acuity, myoclonus, confusion, agitation, or lethargy. Acute hypercapnia leads to acidosis and cerebral vasodilatation, which in turn can cause depressed level of consciousness (“ CO_2 narcosis”), aggravation of elevated intracranial pressure (ICP), and blunted respiratory drive, leading to further hypoventilation. Arterial blood gas analysis is the most reliable method for diagnosing hypercarbic respiratory failure, but end-tidal carbon dioxide monitoring has gained popularity as a noninvasive method to monitor changes in alveolar carbon dioxide tension.

Failure of airway protection is diagnosed clinically when patients appear to be aspirating oral secretions, cannot maintain the upper airway open for gas exchange, have a rapid neurologic decline with a diminished gag and cough reflexes, or are experiencing repeated oxyhemoglobin desaturation due to intermittent plugging of the airways by secretions. Under unstable conditions, such as during a period of acute neurologic instability or during patient transport between hospitals or departments, it is advisable to intubate these patients and start mechanical ventilation to prevent sudden respiratory decompensation. Conversely, it may be safe to extubate

P.997

such patients later in their hospital course under controlled circumstances, despite significantly decreased mental status. There is no absolute measure of adequate upper airway protection, and unfortunately, such determinations remain for most part subjective.

TABLE 116.1 Pulmonary Function Tests in Neuromuscular Respiratory Failure

	Normal	Criteria for Intubation and Weaning	Criteria for Extubation
Vital capacity (mL/kg)	40-70	15	25
Maximal inspiratory pressure (cm H_2O)	>80	20	40

Maximal expiratory pressure (cm H ₂ O)	>140	40	50
---	------	----	----

Adapted from Mayer SA. Intensive care of the myasthenic patient. *Neurology*. 1997;48(suppl 5):S70-S75.

The pathophysiology of neuromuscular respiratory failure resembles a vicious cycle. Increased mucus production and/or weak cough leads to mucus plugging and atelectasis, which in turn cause decreased efficiency of ventilation. Hypoxemia usually precedes hypercapnia because atelectasis and V/Q mismatching are an early development. As fever and infection develop, carbon dioxide production increases, and ventilatory needs rise. The downward spiral of increasing carbon dioxide production, decreasing efficiency of ventilation, and progressive mucus plugging and atelectasis ultimately results in hypercarbia and respiratory failure. As ventilation fails, rapid shallow breathing and hypercapnia develop. At this stage, ventilatory reserves are exhausted, and there is the danger of sudden life-threatening hypoxemia, respiratory acidosis, or respiratory arrest.

EFFECTS OF RESPIRATORY COMPROMISE ON NEUROLOGIC INJURY

Many types of neurologic injury are exacerbated by respiratory compromise. Carbon dioxide and pH are powerful determinants of cerebral vascular tone, and the intended or unintended effects of hyperventilation (decreased cerebral blood flow, decreased intracranial blood volume, and decreased ICP) should be anticipated and monitored by clinicians. Conversely, hypoventilation and hypercapnia cause cerebral vasodilation and increased ICP. Hyperoxia is a potent exacerbant of reperfusion injury, whereas hypoxia is strongly associated with worse outcome in stroke, hypoxic-ischemic encephalopathy, and traumatic brain injury. Finally, when work of breathing is markedly increased, up to 50% of the cardiac output may be diverted to the respiratory muscles, driving metabolic stress, and potentially “stealing” blood flow from the ischemic brain or spinal cord. This metabolic stressor can be effectively managed by sedation, intubation, and initiation of full mechanical ventilatory support.

PULMONARY FUNCTION TESTING

Pulmonary function testing should be routinely used to monitor respiratory function in patients with neuromuscular respiratory compromise ([Table 116.1](#)). Arterial blood gases and end-tidal carbon dioxide monitoring are helpful, but abnormalities of gas exchange usually develop later in the cycle of respiratory decompensation and are therefore insensitive for early detection of ventilatory decline. Forced vital capacity (FVC), the volume of air exhaled after maximal inspiration and exhalation, normally ranges from 40 to 70 mL/kg. Reduction in vital capacity to 30 mL/kg is associated with a weak cough, accumulation of oropharyngeal secretions, atelectasis, and nocturnal hypoxemia. FVC below 15 mL/kg (1 L in a 70-kg person) is the level at which invasive or noninvasive ventilatory support should be considered ([Table 116.2](#)). Maximal inspiratory pressure (MIP), normally more than 80 cm H₂O, measures the strength of the diaphragm and other muscles of inspiration and generally reflects the ability to maintain normal lung expansion and avoid atelectasis, whereas maximal expiratory pressure (MEP), normally more than 140 cm H₂O, measures the strength of the muscles of expiration and correlates with cough and the ability to clear secretions from the airway.

MANAGEMENT OF RESPIRATORY FAILURE

EXAMINATION

The initial management of the patient with impending respiratory failure is directed toward assessing the adequacy of oxygenation and ventilation, workload and stability of breathing, and assessment of the airway. In patients with fulminant respiratory failure, intubation can be lifesaving and is preferentially performed under safe, controlled circumstances well before the threat of impending cardiopulmonary arrest.

The patient's overall comfort and anxiety levels and the rate of progression of respiratory compromise should be assessed. Hypoxia is usually easy to diagnose with pulse oximetry and arterial blood gas analysis. Hypoventilation and hypercarbia may be present without distress or increased work of breathing if central respiratory drive is compromised, whereas increased respiratory

P.998

effort with intact respiratory drive manifests as respiratory alkalosis. Sidestream end-tidal carbon dioxide monitoring, less well established than oximetry but effective, is increasingly used to provide early warning of hypoventilation in patients at risk. Rapid, shallow breathing, the use of accessory muscles of the neck and the shoulder, and visible gulping or gasping with inability to generate adequate tidal volumes are signs of respiratory muscle fatigue and impending collapse, although such signs may be absent when central respiratory drive is impaired. Diaphragmatic strength can be estimated by palpating for normal outward movement of the abdomen with inspiration; with severe diaphragmatic paralysis, inspiration is associated with spontaneous inward movement of the diaphragm (abdominal paradox). Activation of respiratory muscles during the expiratory phase often indicates airflow obstruction.

TABLE 116.2 Criteria for Intubation and Mechanical Ventilation

- PaO₂ <70 mm Hg with maximal oxygen delivery by face mask

- PaCO₂ >50 mm Hg associated with acidosis (pH <7.35), which cannot be rapidly and durably reversed

- Severe oropharyngeal paresis or decreased level of arousal with inability to protect or maintain the airway

- Need for deep sedation or general anesthesia to control seizures or elevated ICP

- Maximal inspiratory pressure <25 cm H₂O or FVC <15 mL/kg

- Respiratory rate >35 breaths/min or visibly excessive work of breathing

These physiologic criteria are intended to serve only as guidelines; treatment decisions must be individualized. As a general rule, intubation in neurologic patients with impending respiratory failure should be performed *before* significant blood gas abnormalities develop.

PaO₂, partial pressure of oxygen; PaCO₂, partial pressure of carbon dioxide; pH, potential of hydrogen; ICP, intracranial pressure; FVC, forced vital capacity.

When neuromuscular weakness is present, ventilatory reserves can be assessed by checking the patient's ability to count from 1 to 20 in a single breath. The strength of the patient's cough should be noted. A wet gurgled voice and pooled oropharyngeal secretions are clinical signs of dysphagia and ongoing aspiration. When severe, weakness of the glottic and oropharyngeal muscles can lead to stridor, which indicates possibly life-threatening obstruction of the upper airway.

Dysphagia is assessed by asking the patient to sip 3 ounces of water; coughing is diagnostic of aspiration, and if present, oral feeding should be avoided until swallowing can be formally assessed. Patients with decreased cough and gag reflexes, however, may have aspiration without obvious clinical signs. Clinicians should have a low threshold to arrange for formal swallowing evaluation in patients with bulbar dysfunction.

NONINVASIVE POSITIVE PRESSURE VENTILATION

Mechanical ventilatory support is the primary treatment of respiratory failure. If airway protection is adequate and the patient is relatively cooperative, noninvasive positive pressure ventilation (NPPV) administered via a snug-fitting face mask should be considered. In medical patients with an acute exacerbation or chronic obstructive pulmonary disease or congestive heart failure, NPPV has fewer complications than invasive mechanical ventilation. In neurologic patients, the use of NPPV is becoming increasingly common as an initial intervention for early neuromuscular respiratory failure from myasthenic exacerbation and in others with chronic neuromuscular weakness and acute respiratory disease. Its use in Guillain-Barré syndrome is suspected, however, with mixed results and some concerns about safety due to the potential for respiratory arrest.

TABLE 116.3 Intubation and Respiratory Concerns Specific to Patients with Neurologic Disease

Problem	Assessment	Management
Elevated ICP	Mass lesion, cerebral edema, hydrocephalus	Preadministration of mannitol or hypertonic saline solution, minimize head-flat positioning, adequate analgesia and sedation, avoidance of hypoventilation
Brain ischemia	Acute stroke with penumbra	Administration of fluids and/or vasopressors, avoidance of vasodilators, end-tidal CO ₂ monitoring, avoidance of hyperventilation
Cervical spine injury or instability	Mechanism of injury suggesting cervical spine injury or radiographic injury	In-line spinal stabilization Intubation techniques to minimize anteroposterior cord displacement
Ischemia-reperfusion injury	Minimize biochemical harm	Normalize oxygenation (keep PaO ₂ 60-300 mm Hg) and ventilation (keep PaCO ₂ 30-50 mm Hg or ETCO ₂ 30-45 mm Hg)

ICP, intracranial pressure; CO₂, carbon dioxide; PaO₂, partial pressure of oxygen; PaCO₂, partial pressure of carbon dioxide; ETCO₂, end-tidal carbon dioxide.

Among patients with neuromuscular weakness, early use of NPPV maintains lung expansion, reduces the work of breathing, and minimizes the risk of severe respiratory failure requiring intubation. Only patients with adequate airway protective reflexes should be treated, and NPPV should *not* be used as a substitute for endotracheal intubation when acute respiratory failure is severe or complete elimination of the work of breathing is desirable. NPPV requires close observation in a monitored setting and the availability of rapid intubation in the event of respiratory decompensation. Many clinicians prefer the security of invasive mechanical ventilation with an endotracheal tube (ETT) or tracheostomy, but neurologists should be aware that in ICUs where high-quality, safe NPPV can be provided; it is often strongly preferred by patients and reduces the incidence of hospital-acquired infections, the need for sedation and analgesia, and the length of ICU stay. NPPV should be used in conjunction with mechanical cough assist devices to aid in airway clearance—a combination that effectively treats mucus plugging and atelectasis and keeps many patients off the ventilator.

ENDOTRACHEAL INTUBATION AND MECHANICAL VENTILATION

Indications for endotracheal intubation due to respiratory failure may include compromised ventilation or oxygenation, the need for airway protection, or both. For patients needing endotracheal intubation, clinicians should consider the patient's comfort level, as well as intracranial and arterial pressures. IV access should be obtained prior to intubation and infusion because sedation and positive pressure ventilation may cause a precipitous drop in BP. All patients should be preoxygenated with an FiO₂ of 100% prior to intubation, and in patients with elevated ICP, mild hyperventilation should be considered before lowering the head of the bed, and extra efforts made to avoid hypoventilation.

Special concerns related to the intubation of neurologic patients are described in [Table 116.3](#).

The administration of 50 to 100 mg of IV lidocaine immediately before intubation blunts the anticipated rise in ICP. *Rapid sequence intubation* involves administration of a combination of IV sedatives (i.e., etomidate or fentanyl), amnestics (i.e., midazolam), and muscle relaxants (i.e., vecuronium); depolarizing muscle relaxants

P.999

such as succinylcholine should be avoided in patients suffering from immobility or paresis because of a possibly abrupt rise in serum potassium level after drug-induced muscle depolarization. The trachea may be intubated orally or nasally; a high-volume, low-pressure cuff is then inflated in the trachea to prevent leakage of air and secretions around the tube.

TABLE 116.4 Ventilator Modes and Functions

Abbreviation	Stands for Description
SIMV	Synchronized intermittent mandatory ventilation
CMV	Continuous mandatory ventilation
PS	Pressure support
CPAP	Continuous positive airway pressure
PEEP	Positive end-expiratory pressure

Modes of mechanical ventilatory support include volume- and pressure-cycled ventilation, pressure support with continuous positive airway pressure (CPAP), and many others (Table 116.4). Although no ventilatory mode is intrinsically superior to the others, in general, patients should be ventilated according to the basic principles of lung-protective ventilation to avoid ventilator-induced lung injury (VILI). Lung-protective ventilation endeavors to minimize barotrauma and volutrauma due to overdistention of aerated lung segments, trauma from atelectasis due to repetitive opening and closing of collapsed alveoli, and biotrauma due to inflammation. This is accomplished by minimizing peak and plateau airway pressures (goal <30 cm H₂O), providing positive end-expiratory pressure (PEEP) to prevent alveolar collapse at end-expiration and to recruit collapsed lung units, limiting exposure to toxic levels of oxygen and using small tidal volumes (4 to 6 mL/kg of *ideal* body weight) to prevent overdistention of vulnerable alveolar units. In general, “permissive” hypercapnia and hypoxia—part of most “lung protective ventilation” protocols—should be employed cautiously and after consideration of the effects of dysventilation on neurophysiology. Unless required for control of elevated intracranial pressure, prolonged uninterrupted “deep” sedation and paralysis are discouraged because spontaneous respiratory efforts by the patient prevent dependent atelectasis and respiratory muscle atrophy.

MANIPULATION OF VENTILATION: EFFECTS ON INTRACRANIAL PRESSURE AND CEREBRAL BLOOD FLOW

Hyperventilation results in acute hypocarbia and respiratory alkalosis. This causes arteriolar constriction in the brain, leading immediately to decreased cerebral blood flow and lower intracranial pressure (ICP). Conversely, hypoventilation results in hypercarbia and cerebral arteriolar dilation, causing increased cerebral blood flow and intracranial pressure. These physiologic responses are frequently manipulated to treat elevations of intracranial pressure and because of the potential for harm should be carefully monitored in patients with impaired cerebral perfusion or elevated ICP.

Hyperventilation is a powerful tool to reverse critical increases in ICP and is a standard measure to reverse uncal or transtentorial herniation syndromes. The negative effects of hyperventilation on cerebral blood flow prohibit prolonged and excessive usage unless brain oxygenation is concurrently monitored (see Chapter 33).

Hyperventilation should not be used at all when active brain ischemia is present, such as in acute large vessel stroke or cerebral vasospasm. In addition to the danger of precipitating brain ischemia, prolonged hyperventilation is rarely effective as a treatment for elevated ICP, as compensatory mechanisms in the central nervous system rapidly buffer the pH changes in peripheral pH, and CBF is restored. Hyperventilation below a PCO₂ of 20 mm Hg causes progressive hemodynamic deterioration but does not result in additional arterial constriction or reduction in ICP. It is not known whether spontaneous hyperventilation puts the brain at risk of ischemia or whether it simply reflects a physiologic compensatory mechanism at work.

End-tidal carbon dioxide (ETCO₂) tension correlates modestly well with the partial pressure of alveolar carbon dioxide, and inline ETCO₂ can be monitored as a continuous vital sign in mechanically ventilated patients, whereas sidestream ETCO₂ is used to monitor alveolar carbon dioxide tension in nonintubated patients. ETCO₂ tends to run slightly lower than arterial PCO₂; differences between the two measurements reflect not only dead space ventilation but also increasing age, chronic obstructive pulmonary disease (COPD), and circumstances in which alveolar dead space increases such as hypovolemia, pulmonary embolism, and a low cardiac output state.

PREVENTION OF VENTILATOR-ASSOCIATED PNEUMONIA

Ventilator-associated pneumonia (VAP) is the most common and serious complication of endotracheal intubation. The endotracheal tube serves as a conduit for bacterial invasion of the airway and deep lung segments and compromises natural defenses against infection. About 20% of patients who are intubated for more than 1 week

develop VAP, which adds an average of 1 week to the ICU length of stay, \$40,000 to the cost of care, and carries an attributable mortality exceeding 30%. The clinical diagnosis is established by the appearance of a new pulmonary infiltrate on chest radiography more than 48 hours after intubation and the new onset of fever, leukocytosis, or purulent secretions. Neurologic patients are at particularly high risk for VAP because they are immobile and tend to aspirate.

A standardized protocol of measures that minimize bacterial colonization of the upper airway and digestive tract and the risk of aspiration can reduce the risk of VAP. These measures include 30-degree head elevation to minimize gastric regurgitation, mouth care with chlorhexidine-based solutions, avoidance of unnecessary antibiotics, and removal of the ETT as soon as possible by combining daily interruption of sedation with spontaneous breathing trials (SBTs). Some ICUs employ selective gut decontamination or prophylactic antibiotics in patients with neurologic disease to decrease the incidence of respiratory infections, but these measures are not widely recommended and require further study.

WEANING FROM MECHANICAL VENTILATION

Weaning from mechanical ventilation is a continuous process that should begin as soon as a moderate level of medical and respiratory stability is achieved. Although excessive work of breathing should be avoided as a stressor in patients with neurologic or cardiac ischemia, respiratory work is necessary to prevent muscle atrophy, and the duration of mechanical ventilation is strongly correlated with the development of VAP and other medical complications.

P.1000

Ventilator weaning should be delayed in only dire circumstances ([Table 116.5](#)).

TABLE 116.5 Contraindications to a Daily Spontaneous Breathing Trial

- $FiO_2 > 80\%$, PEEP > 10 cm H_2O , or high risk of lung derecruitment in severe ARDS

- Deep sedation or paralysis for control of seizures, ICP, or shivering

- Active and clinically important brain or myocardial ischemia

- Severe and unstable cerebral vasospasm

FiO_2 , fraction of inspired oxygen; PEEP, positive end-expiratory pressure; ARDS, acute respiratory distress syndrome; ICP, intracranial pressure.

Weaning of mechanical ventilation begins with the downward titration of FiO_2 and mean airway pressure to levels consistent with spontaneous ventilation and face mask oxygen delivery. This is typically consistent with an FiO_2 of 40% and PEEP of 5 cm H_2O . Compared to gradually reducing the respiratory rate using synchronized mandatory ventilation or the level of pressure support triggered by each breath, the best results are obtained through the use of daily SBTs. SBTs vary widely in design but reflect a measured period of breathing in which most or all of the work of breathing is performed by the patient and after which a protocolized assessment is performed to determine suitability for the discontinuation of mechanical ventilation. The most common types of SBTs involve placing the patient on CPAP with a low-level pressure support (usually 5 cm H_2O) sufficient to

overcome ETT resistance and T-piece trials, in which the patient breathes spontaneously for a predetermined duration through an open tubing system with oxygen flow-by.

The ability of the patient to tolerate a T-piece or CPAP trial for 2 hours, while maintaining a ratio of respiratory rate (breaths/minute) to tidal volume (liters) less than 100, is a useful predictor of successful extubation. In patients with depressed level of consciousness or neuromuscular respiratory weakness, the ability to tolerate a T-piece or CPAP ventilation overnight offers additional reassurance that the patient has adequate stamina to tolerate breathing off the ventilator indefinitely. Indications of tiring during an SBT include an increasing respiratory rate with decreasing tidal volumes, a drop in arterial oxygen saturation, diaphoresis, the progressive use of accessory muscles of respiration, or hemodynamic instability. Failure of a weaning trial is a physiologic stressor, and patients with these signs should be returned to mechanical ventilation.

In patients with tracheostomy or receiving NPPV, detachment from and reconnection to the ventilator is uneventful and easy to perform. Extubation and reintubation, however, always entail risk. Before a planned extubation, the patient's volume status, airway reactivity, secretions, and cardiac function should be optimized (Table 116.6). Despite the best predictors of successful extubation, it is not possible to evaluate the airway itself prior to extubation. Even with careful patient selection and medical optimization, as many as 20% of extubated patients are reintubated within 48 hours, and patients with neurologic diseases are among the most difficult to predict.

TRACHEOSTOMY

Clinicians have traditionally performed tracheostomy when mechanical ventilation has been used for more than 14 days. Tracheostomy has several advantages over prolonged endotracheal intubation, including increased comfort, reduced risk of permanent tracheolaryngeal injury, increased ease of weaning from the ventilator (reduced dead space and less resistance to flow from the ETT), and improved ability to manage and suction secretions. In comatose patients or in those with profound neuromuscular weakness for whom a prolonged period of ventilator dependence is anticipated, early tracheostomy within 3 to 5 days of intubation extends these benefits and has been associated with reduced ICU length of stay and mortality. Most patients with significant bulbar dysfunction following an acute brain injury will require tracheostomy for secretions management, although they can often be weaned rapidly from mechanical ventilation, and many will ultimately be decannulated when cough strength and airway protective reflexes have partially recovered.

TABLE 116.6 General Criteria for Extubation

- Successful completion of a spontaneous breathing trial

- Neurologic and medical condition is stable or improving

- Cough and gag reflexes present, minimal pooling of secretions

- PaO₂ >70 mm Hg with 40% oxygen and PEEP ≤8 cm H₂O

- Minute ventilation <12 L/min at rest

- Vital capacity >15 mL/kg and maximal inspiratory pressure >25 mm Hg

-
- No pending procedures, operations, or radiographic studies requiring airway protection
-
- Minimal secretions or moderate secretions with strong cough
-
- Volume status optimized, airway reactivity assessed and treated, feeds held
-
- Equipment, medications, and personnel necessary for reintubation readily available

PaO₂, partial pressure of oxygen; PEEP, positive end-expiratory pressure.

Percutaneous tracheostomy creates a temporary stoma that is easily and rapidly reversible upon decannulation, whereas surgical tracheostomy creates a more durable and permanent stoma that typically requires surgical closure. In some patients with severe persistent oropharyngeal muscle weakness, a tracheostomy is necessary to manage secretions and prevent aspiration, even though respiratory muscle function is adequate.

LONG-TERM VENTILATION

In chronic respiratory failure (CRF), patients and clinicians should work together to determine the best interface for mechanical ventilatory support. Patients with good bulbar function and normal level of consciousness can often tolerate intermittent daytime and continuous nocturnal NPPV by nasal or face mask, whereas those at high risk of aspiration, or with a low or waxing and waning level of arousal, are more safely ventilated by tracheostomy. Patients with CRF often describe improved quality of life with NPPV and may be at lower risk of developing respiratory infections than patients with permanent tracheostomy—this has been dramatically demonstrated in patients with respiratory failure due to progressive Duchenne muscular dystrophy. Yet patients with a tracheostomy can sometimes speak and eat; an experienced speech therapist can determine the safety of and capacity for these activities. Adjustments in tidal volume and tracheostomy size may be important in facilitating speech, and cuff deflation dramatically improves the ability to speak and swallow but leaves the airway open to aspiration.

P.1001

Some patients need ventilatory support for months or years. Small suitcase- or laptop-sized ventilators are available for use at home, and battery-powered portable ventilators can allow wheelchair-bound patients to travel out of the home. For patients with respiratory failure after brain stem or high cervical cord lesions, an implantable phrenic nerve pacemaker can be used to stimulate diaphragmatic contraction, liberating the patient from connection to a machine.

Endocrine Diseases and the Brain

Gary M. Abrams

Hyman M. Schipper

INTRODUCTION

Endocrine secretions and disorders of metabolism have a profound influence on the nervous system. Disturbances of consciousness and cognition along with a variety of other neurologic symptoms may accompany primary endocrine diseases. In addition, endocrine secretions may influence the expression of neurologic disorders such as migraine, epilepsy, or movement disorders. This chapter considers common endocrine conditions that may cause important neurologic symptoms.

PARATHYROID DISEASE

HYPERPARATHYROIDISM

Epidemiology

Primary hyperparathyroidism is the most common cause of hypercalcemia. The most recent estimated incidence was approximately 22 cases per 100,000 per year. The incidence peaks in the seventh decade and there is a fivefold excess of women in those older than 75 years. The incidence is similar in men and women before 45 years of age. A single-gland adenoma secreting excess parathyroid hormone (PTH) is the most common cause (75% to 85%).

Pathobiology

PTH regulates calcium by direct effects on kidney and bone and indirect effects on the gastrointestinal tract. PTH secretion, in turn, is regulated by ionized calcium concentration in extracellular fluid. Thyrocalcitonin and vitamin D also play important roles in calcium metabolism. The principle effects of PTH on the nervous system are via calcium regulation. However, PTH receptors occur in the brain and an endogenous neuropeptide is the natural ligand. Their exact function is uncertain.

Clinical Features

The classic syndrome of hyperparathyroidism is hypercalcemia with a combination of renal lithiasis, osteitis, and peptic ulcer disease ("stones, bones, and abdominal groans"). However, with the ease of determining serum calcium concentration by routine automated blood chemistry tests, the diagnosis is frequently made with minimal clinical symptoms and the classic triad is rarely seen today. Currently, it is estimated that 70% to 80% of individuals have no symptoms or signs of disease at the time of diagnosis.

Common symptoms include fatigue and subjective weakness. Mental status changes include impaired memory, personality changes, affective disorders, delirium, and psychosis. Elderly patients may be particularly susceptible to the effects of hypercalcemia. Parkinsonism and a syndrome resembling motor neuron disease reversing with parathyroid surgery have been described. "Brown tumors" seen in osteitis fibrosa cystica may cause myelopathy. Neuromuscular symptoms include proximal weakness, muscle pain and stiffness, and paresthesias. Tendon reflexes may be normal or hyperactive.

Diagnosis

The initial diagnosis typically occurs by finding hypercalcemia with hypophosphatemia on routine laboratory

screening. This will be followed by an elevated PTH level. Differential diagnosis includes other causes of hypercalcemia, including drugs or conditions causing secondary hyperparathyroidism (e.g., renal failure) or familial hypocalciuric hypercalcemia. Hypercalcemia with low or undetectable PTH levels may suggest cancer-associated hypercalcemia mediated by PTH-related protein, or alternatively, ectopic production of PTH. Electromyography (EMG) and muscle biopsy can show evidence of myopathic or neuropathic disease. Brown tumors show variable intensities on T2-weighted images with intense enhancement on T1-weighted contrast studies. Fluid-filled cysts may be detected.

Treatment

Parathyroidectomy normalizes serum calcium and is the treatment of choice for patients with symptomatic primary hyperparathyroidism. Localization of a parathyroid adenoma with a variety of imaging techniques or by an experienced surgeon occurs in 95% of cases. In patients with mild disease or who are not surgical candidates, bisphosphonates are an option. The calcimimetic drug cinacalcet often normalizes serum calcium concentration and modestly decreases PTH levels.

Outcome

Although the degree of hypercalcemia does not always correlate with clinical severity, most neurologic and neuromuscular manifestations typically improve with treatment. It remains controversial as to whether symptoms such as fatigue, subjective weakness, or neuropsychiatric symptoms remit with parathyroidectomy.

HYPOPARATHYROIDISM

Epidemiology

Hypoparathyroidism occurs most commonly after thyroidectomy (~1% to 2% with experienced endocrine surgeons) or other neck surgery. Autoimmune hypoparathyroidism is the next most common cause. Hypoparathyroidism may also be a feature of inherited disorders (e.g., Kearns-Sayre syndrome or DiGeorge syndrome) or glandular destruction from infiltrative processes or radiation. An estimated 60,000 individuals may have chronic hypoparathyroidism in the United States.

Pathobiology

Hypoparathyroidism is due to deficiency of PTH or lack of peripheral response to PTH (pseudohypoparathyroidism). The latter results from abnormal PTH receptors, defects in receptor-linked enzyme activity, or circulating antagonists. Chronic PTH

P.1003

deficiency has profound effects on the skeleton, and hypoparathyroidism disrupts normal calcium and phosphorus metabolism. Intracranial calcifications occur in vascular and perivascular locations. The action of PTH in brain is unknown but is hypothesized to be a cause of behavioral deficits seen in some forms of hypoparathyroidism.

Clinical Features

Tetany is the most distinctive sign that may be manifested by carpopedal spasm. Latent tetany can be demonstrated by contracture of the facial muscles on tapping the facial nerve in front of the ear (Chvostek sign)

or by evoking carpal spasm by inducing ischemia in the arm with an inflated blood pressure cuff (Trousseau sign). Patients may also present with paresthesias and cramps, and if hypocalcemia is acute, may manifest with seizures, bronchospasm, laryngospasm, or cardiac arrhythmias. Seizures are usually generalized, tend to be frequent, and respond poorly to anticonvulsant drugs.

Intracranial calcifications are common in hypoparathyroidism. The basal ganglia are the predominant site for calcium deposition, but other regions such as the cerebellum may be affected. The calcifications are usually not associated with symptoms, but cognitive impairment and a variety of hypokinetic (parkinsonism) and hyperkinetic (choreoathetosis, hemiballismus, torticollis) movement disorders have been reported. Increased intracranial pressure may complicate hypoparathyroidism. The mechanism is unexplained. Sensorineural hearing loss and myopathy occur rarely.

Diagnosis

Hypocalcemia with an inappropriate low intact PTH level should lead to the suspicion of hypoparathyroidism. Hypomagnesemia can lower calcium and PTH. Hypocalcemia with low PTH essentially rules out other causes of hypocalcemia, such as vitamin D deficiency, malabsorption syndrome, or renal disease. In pseudohypoparathyroidism, PTH levels will be elevated and there are a variety of associated physical abnormalities. In most cases, there may be a relevant prior surgery or history of some destructive process (e.g., radiotherapy) involving the parathyroid. Autoimmune hypoparathyroidism may present with vitiligo or hypoadrenalism. Other forms of hypoparathyroidism may be associated with developmental anomalies (e.g., DiGeorge syndrome or Kearns-Sayre syndrome).

Treatment

There are no formal guidelines for management of chronic hypoparathyroidism. Treatment options include the use of calcium, vitamin D metabolites and analogues, and thiazide diuretics to enhance renal calcium reabsorption. Various forms of PTH are also being explored for treatment. Antiepileptic drugs that increase metabolism of vitamin D (e.g., phenytoin) should be avoided so as not to potentially interfere with calcium absorption from the gut or calcium mobilization from bone.

Outcome

Neuromuscular symptoms and seizures resolve with restoration of calcium to normal levels. Movement disorders may also be reversible with appropriate treatment. However, the response of cognitive-behavioral symptoms is variable. A study of women with postsurgical hypoparathyroidism treated to maintain calcium in a therapeutic range did not improve elevated levels of anxiety and sense of well-being.

ADRENAL DISEASE

HYPERADRENALISM

Epidemiology

Excessive secretion of glucocorticoids from the adrenal glands produces *Cushing syndrome*. However, the most common cause of Cushing syndrome is exposure to exogenous, often supraphysiologic doses of glucocorticoids. The incidence of endogenous Cushing syndrome is 0.7 to 2.4 per million population per year. There are two main forms, corticotropin (adrenocorticotrophic hormone [ACTH])-dependent (80%) and ACTH-independent

(20%). ACTH-dependent Cushing syndrome (Cushing disease) is primarily due to pituitary tumors hypersecreting ACTH and is addressed in Chapter 115. Approximately 20% of ACTH-dependent Cushing syndrome is due to ectopic production of ACTH, usually from carcinoid tumors or small cell carcinoma of the lung. ACTH-independent Cushing syndrome is usually due to an adrenal tumor.

Pathobiology

Hippocampus, amygdala, and cerebral cortex are rich in glucocorticoid receptors. Global cerebral atrophy occurs with Cushing syndrome. Hippocampal atrophy occurs and hippocampal formation volume is positively associated with performance on cognitive testing. Glucocorticoids decrease protein synthesis and increase protein degradation in muscles.

Clinical Features

The physical examination in Cushing syndrome may demonstrate hypertension, plethoric facies, hirsutism, centripetal obesity, a posterior neck fat pad (buffalo hump), purple abdominal striae, and bruising. Diabetes mellitus (DM), gonadal dysfunction, and osteoporosis are prominent features. Cognitive changes (impaired memory, visual-spatial processing, verbal learning, and language performance) with mood disorders (particularly major depression), myopathic weakness, and headache are the most common neurologic features. Myelopathy or radiculopathy may result from epidural lipomatosis.

Diagnosis

The diagnosis of Cushing syndrome is very challenging and despite the classical clinical manifestations, the presentation can be quite nonspecific. The initial step is distinguishing Cushing syndrome from individuals with Cushing-like states where hypercortisolism is a common feature. These include obesity, depression, or alcoholism. There is no test that has absolute diagnostic accuracy, with first-line screening being a 24-hour urinary free cortisol and overnight dexamethasone suppression test or late night salivary cortisol. After Cushing syndrome has been established, plasma ACTH is measured. If ACTH is elevated, then ACTH-dependent causes should be investigated. If ACTH is suppressed, then adrenal-dependent Cushing is suspected. There are many potential pitfalls, thus consultation with an experienced endocrinologist is essential. Adrenal tumors or tumors as a source of ectopic ACTH will require imaging for localization.

Treatment

Treatment depends on the etiology. In cases where there is an adrenal tumor secreting cortisol or an ACTH-secreting tumor, surgical

P.1004

removal of the tumor is the first-line treatment. Medical therapy includes various drugs that interfere with synthesis and secretion of cortisol. Ketoconazole (200 to 400 mg twice a day to three times a day), an antifungal compound that inhibits steroidogenesis, is the most widely used medication in the United States for this purpose.

Outcome

Evidence suggests that resolution of hypercortisolism does not completely resolve symptoms. After successful surgery, hippocampal volume increased and correlated with the magnitude of decrease in cortisol levels. Caudate volume increase has also been described with improvements in depression, anxiety, and obsessive-compulsive behavior. However, reduced brain volume and cognitive behavioral

symptoms may only be partially reversible. Cognitive problems and psychopathology may persist even after long-term serum cortisol normalization.

HYPERALDOSTERONISM

Epidemiology

Hyperaldosteronism is the most common disorder of the adrenal zona glomerulosa with a prevalence of 5% to 20% of patients with resistant hypertension. It is the most common form of secondary hypertension.

Pathobiology

Aldosterone, typically produced by an adrenal adenoma or bilateral adrenal hyperplasia, is inappropriately elevated. The resulting volume expansion causes hypokalemic alkalosis and hypertension, although hypokalemia and hypertension are not generally correlated with aldosterone levels. Activity-dependent conduction block responsive to potassium replacement has been reported with neurophysiologic studies obtained in a patient with primary aldosteronism, weakness, and severe hypokalemia.

Clinical Features

The principle clinical feature is hypertension. There appears to be an excess incidence of stroke in patients with hypertension from primary aldosteronism versus essential hypertension. Hypokalemic alkalosis can lead to muscle weakness, paresthesias, tetany, or paralysis. Recurrent attacks of muscle weakness may simulate periodic paralysis. Paresthesias may occur as a result of the alkalosis. Vertigo may be caused by abrupt fluid and electrolyte shifts. Idiopathic intracranial hypertension has been reported. Many patients may suffer from an anxiety disorder and diminished sense of well-being.

Diagnosis

Endocrine Society clinical practice guidelines recommend case detection for a variety of types of individuals with hypertension including individuals with a family history of early-onset hypertension or stroke at a young age (younger than 40 years). The aldosterone-to-renin ratio is a widely used screening test, but many antihypertensive medications, oral contraceptives, or selective serotonin reuptake inhibitors can compromise sensitivity or specificity.

Treatment

Normalization of blood pressure should be a goal, but some adverse effects of primary aldosteronism seem to be partially independent of the hypertension. Surgical removal of adrenal tissue/tumor is recommended where appropriate. Medical therapy with spironolactone can be effective, with several other agents now available.

Outcome

Surgery is essentially curative and corrects the hypokalemia. Antihypertensives may need to be withdrawn gradually.

HYPOADRENALISM

Epidemiology

Primary adrenal insufficiency, also known as *Addison disease*, has a prevalence of approximately 100 per million and an incidence of 5 per million in white populations. Age of diagnosis peaks in the fourth decade with women more frequently affected than men. In developed countries, 80% to 90% is due to autoimmune adrenalitis, occasionally in association with other autoimmune disorders, such as thyroid disease, hypoparathyroidism, or DM. Secondary adrenal insufficiency due to reduced pituitary ACTH has an estimated prevalence of 150 to 280 per million and is also more frequent in women. The peak age is in the sixth decade and is related to therapeutic administration of glucocorticoids.

Pathobiology

Destruction of the adrenal gland results in both corticosteroid and mineralocorticoid deficiency. It also results in dehydroepiandrosterone deficiency, which leads to androgen deficiency in women. In secondary adrenal insufficiency, mineralocorticoid production is preserved. These hormones are critical for sustaining the function of multiple physiologic systems. Glucocorticoids have pleiotropic effects on the nervous system, working at both the genomic level to alter gene expression and protein synthesis and at cell membranes to affect cell permeability and neurotransmitter release. They have effects on brain microstructure and influence production of nerve growth factors. The absence of adrenal hormones has widespread cognitive and behavioral consequences.

Adrenocortical insufficiency due to mutations in the ABCD1 gene results in abnormal metabolism of long-chain fatty acids that characterizes X-linked adrenoleukodystrophy. It may be the only clinical expression in about 10% of cases. In one study, one-third of young boys or men diagnosed with primary adrenal failure (Addison disease) were found to have adrenoleukodystrophy after measurement of long-chain fatty acids (see also [Chapter 134](#)).

Clinical Features

In primary adrenal insufficiency, typical systemic features are fatigue, anorexia, weight loss, hypotension, changes in skin, and hair loss. Headache is a common complaint. Mineralocorticoid deficiency produces hyponatremia with salt craving. Cortisol deficiency leads to increased production of melanocyte-stimulating hormone derived from pituitary proopiomelanocortin, which stimulates melanocytes to produce hyperpigmentation. These characteristics distinguish primary from secondary adrenal insufficiency. Cerebral symptoms include apathy, depression, confusion, and rarely, psychosis. Muscle pain and cramping may occur and hyperkalemic periodic paralysis has been observed.

In adrenoleukodystrophy, there is progressive central demyelination with impairment of cognition, vision, hearing, and motor function in children. In a second phenotype with onset in the late 20s, adrenomyeloneuropathy, there is spastic paraparesis and sphincter disturbances.

P.1005

Diagnosis

Measurement of early morning serum cortisol and plasma ACTH generally separates patients with primary adrenal insufficiency from healthy individuals and those with secondary adrenal insufficiency. The standard short corticotropin test, in which serum cortisol is measured after intravenous ACTH, demonstrates the impairment of the adrenal cortex response to ACTH. In secondary adrenal insufficiency, there may be little difference in baseline hormone measurements from healthy individuals. The insulin tolerance test, which is a powerful activator of the hypothalamic-pituitary axis, remains the gold standard for assessment of secondary pituitary insufficiency. However, this test poses a significant burden on both the patient and the physician and tests such as the short corticotropin test, which capitalizes on the relative adrenal

unresponsiveness to ACTH in secondary disease, are used. Because hypoadrenalism may antedate neurologic symptoms in adrenoleukodystrophy or adrenomyeloneuropathy, this diagnosis should be considered in young men with adrenal insufficiency.

Treatment

Hydrocortisone 15 to 25 mg/day is given in two or three divided doses daily, with a larger dose administered in the morning to mimic the pattern of physiologic cortisol secretion. Mineralocorticoid replacement (fludrocortisone (50 to 200 µg/day) is required only for primary adrenal insufficiency. Dehydroepiandrosterone (50 mg daily) can be replaced in a single morning dose.

Outcome

Glucocorticoids are lifesaving in acute adrenal insufficiency. However, despite adequate adrenal hormone replacement to meet basic physiologic requirements, health-related quality of life is reduced in adrenal insufficiency. Chronic complaints include fatigue, lack of energy, depression, and anxiety. Dehydroepiandrosterone replacement may improve well-being and libido in women.

PHEOCHROMOCYTOMA

Epidemiology

Pheochromocytomas are rare neuroendocrine tumors with approximately 80% arising from the chromaffin cells of the adrenal medulla. They secrete catecholamines and cause an estimated 0.1% to 0.6% of cases of secondary hypertension.

Pathobiology

Pheochromocytomas may occur sporadically or as part of a hereditary syndrome. Pheochromocytoma may be seen with neurofibromatosis, von Hippel-Lindau disease, ataxia-telangiectasia, Sturge-Weber syndrome, or multiple endocrine neoplasia type 2 consistent with the neuroectodermal origin of the adrenal medulla. It is estimated that 25% are associated with known genetic mutations.

Clinical Features

Hypertension of a moderate or severe degree is characteristic. The hypertension may be paroxysmal or sustained and is associated with palpitations, episodic hyperhidrosis, headaches, and other nonspecific systemic symptoms, such as nausea, emesis, or diarrhea. Anxiety attacks are common. Death may result from cerebral hemorrhage, pulmonary edema, or cardiac failure complicating an acute attack or as a result of sustained hypertension.

Diagnosis

Diagnosis is made by demonstrating increased excretion of catecholamine metabolites in urine and localization of the tumor. Measurement of fractionated plasma or urine metanephrines (or both) is recommended. Food, caffeinated beverages, strenuous physical activity, or smoking are not permitted for at least 8 to 12 hours prior to testing. A greater than fourfold elevation of plasma metanephrines is highly suggestive of the presence of the tumor. Tumors may occur in sites other than the adrenal (e.g., organs of Zuckerkandl). Computed tomography (CT), magnetic resonance imaging (MRI), or functional imaging

techniques are helpful in localization.

Treatment

Surgical removal of the pheochromocytoma is the treatment of choice. Preoperative blockade of catecholamines, most commonly with phenoxybenzamine (10 mg once or twice a day), for 2 weeks prior to surgery is required. Volume contraction is associated with chronic vasoconstriction; thus, volume expansion is recommended to reduce postoperative hypotension.

Outcome

Surgery is curative for local disease and surgical debulking for more advanced disease will facilitate radiotherapy or chemotherapy. Essential hypertension may persist in up to 20% of cases. Long-term follow-up with yearly measurement of catecholamines is recommended and is especially important for patients identified with mutations associated with pheochromocytoma.

THYROID DISEASE

HYPOTHYROIDISM

Epidemiology

Hypothyroidism is a common disorder with an estimated prevalence of 0.4% to 1.2% in the United States. Approximately 40% of cases are overt, with 60% being subclinical. Congenital hypothyroidism due to maternal iodine deficiency or dysgenesis of the thyroid occurs in 1:3,000 to 1:4,000 births.

Pathobiology

The most common causes of hypothyroidism are autoimmune destruction and thyroidectomy or radioablation of the gland. Thyroid hormone is important in early growth and development, and the neurologic consequences of hypothyroidism depend on the age when the deficiency begins. Severe thyroid deficiency *in utero* or early life results in delayed physical and mental development (cretinism) or myxedema in adults. Thyroid hormone affects neurofilament gene expression, mitochondrial protein synthesis, and the appearance and distribution of laminin, which provides guidance to migrating neurons. Hypothyroidism is associated with pathologic changes in muscle, including accumulation of glycogen and lipids, abnormal and increased mitochondria, dilated sarcoplasmic reticulum, and focal myofibrillar degeneration. The biochemical changes produced in the brain or muscle induced by hypothyroidism are still not well correlated with clinical symptomatology.

Clinical Features

CONGENITAL HYPOTHYROIDISM

In congenital hypothyroidism, subcutaneous tissue thickens; the cry becomes hoarse; the tongue enlarges; and the infant has widely

P.1006

spaced eyes, a potbelly, and an umbilical hernia. Neurologically, there is mental retardation with pyramidal and extrapyramidal signs in a proximal and truncal distribution. Strabismus, deafness, and primitive reflexes are common. The severity of physical and mental retardation in juvenile hypothyroidism is usually less than in infantile myxedema. Precocious puberty may occur. Idiopathic intracranial hypertension has been reported in

hypothyroid children receiving thyroid replacement therapy.

NEUROLOGIC MANIFESTATIONS

The neurologic complications of hypothyroidism include headache, disorders of the cranial and peripheral nerves, sensorimotor abnormalities, and changes in cognition and level of consciousness. Mental status changes may be prominent, with decreased attentiveness, poor concentration, lethargy, and dementia. Psychiatric symptoms—delirium, depression, or frank psychosis (myxedema madness)—may appear, depending on the severity and duration of thyroid deficiency. Cranial nerve abnormalities, other than visual and acoustic nerve problems, are unusual. Decreased vision from chiasmal compression may occur secondary to pituitary hypertrophy. Hearing loss, vertigo, and tinnitus may be present.

MYXEDEMA

Adult myxedema is primarily associated with primary thyroid failure as opposed to secondary hypothyroidism due to hypothalamic-pituitary disease. It is characterized by lethargy, somnolence, or impairment of attention and concentration; weakness; slowness of speech; nonpitting edema of the subcutaneous tissues; coarse, pale skin; dry, brittle hair; thick lips; macroglossia; and increased sensitivity to cold. In severe cases, myxedema coma may occur, accompanied by hypothermia, hypotension, and respiratory and metabolic disturbances. If untreated, myxedema coma has a high mortality rate.

NEUROMUSCULAR MANIFESTATIONS

Neuromuscular findings include slowing of voluntary movements and slow relaxation of tendon reflexes, particularly the ankle jerks. Electrically silent mounding of muscles on direct percussion is called *myoedema*. There may be exercise intolerance or myopathic weakness. In hypothyroid infants, a remarkable generalized enlargement or hypertrophy of muscles (“infant Hercules”; [Fig. 117.1](#)) constitutes the Kocher-Debré-Sémélaigne syndrome. Enlargement of muscles with pain and stiffness in adults produces the Hoffmann syndrome.

FIGURE 117.1 Enlargement of muscles in the Kocher-Debré-Sémélaigne syndrome. (Courtesy of Dr. Arnold Gold.)

A mild, primarily sensory neuropathy is characterized mainly by paresthesias in the hands and feet. Entrapment neuropathy of the median nerve (carpal tunnel syndrome) is attributed to the accumulation of acid mucopolysaccharides in the nerve and surrounding tissues. Cerebellar ataxia (myxedema staggers) may occur in adults, manifesting as incoordination with a slow or stiff, unstable gait. Sleep apnea may result from myxedematous changes in the upper airway and hypertrophy of the tongue.

Diagnosis

The characteristic findings are low circulating thyroxine (T₄) and triiodothyronine (T₃), elevated thyrotropin (thyroid-stimulating hormone [TSH]), and low radioiodine uptake by the thyroid. Hypothyroidism due to hypothalamic-pituitary disease will have reduced circulating thyroid hormones with low TSH. Cerebrospinal fluid (CSF) protein content is increased; values greater than 100 mg/mL are not exceptional.

Electroencephalogram (EEG) abnormalities include slowing and generalized decrease in amplitude. Serum creatine kinase levels are elevated with myopathy.

Treatment

The treatment of hypothyroidism depends on the severity of the deficiency. Myxedema coma should be treated rapidly with intravenous administration of T₄ (200 to 400 µg), although the optimal approach to rapid thyroid hormone replacement is still uncertain. In other patients, gradually increasing doses of oral levothyroxine (to 1.6 µg/kg/day) are recommended. Older patient should be started on lower doses (25 to 50 µg daily). Angina pectoris or heart failure can be precipitated by too rapid replacement in adults. In

secondary hypothyroidism, thyroid replacement should not be started without concomitant corticosteroid replacement, so as not to precipitate cortisol insufficiency. Prophylactic treatment of cretinism is important in goiter districts, where iodine should be given to all pregnant women.

Treatment of subclinical thyroid disease (i.e., normal thyroid hormone levels with elevated or depressed TSH levels) is controversial. Subclinical hypothyroidism has been reported to be associated with deficits in working memory that were reversible with T4 replacement.

P.1007

Outcome

In many patients, thyroid hormone therapy administered within the first 2 months of life results in nearly complete restoration of normal physical and mental function. Treatment should begin during the first 2 weeks of life for optimal intellectual development. Despite early treatment, mild hearing and vestibular dysfunction may persist. Mortality for myxedema coma may be as high as 20%. In general, neuromuscular signs and symptoms resolve with treatment.

HYPERTHYROIDISM

Epidemiology

Hyperthyroidism or thyrotoxicosis has several causes, the most common being Graves disease. It affects an estimated 1% of the U.S. population, with 40% of cases being overt and 60% being subclinical. It affects women more commonly than men.

Pathobiology

In Graves disease, which is characterized by diffuse goiter, ophthalmopathy, and dermopathy, immunologic mechanisms play an important role in the thyroid, eye, and skin manifestations. In Graves ophthalmopathy, there is an increase in the orbital contents with edema, hypertrophy, infiltration, and fibrosis of the extraocular muscles (Fig. 117.2). Other common causes of hyperthyroidism are thyroid nodules, thyroiditis, or ingestion of thyroid hormone.

Clinical Features

Hyperthyroidism typically presents with an increased metabolic rate, abnormal cardiovascular and autonomic functions, tremor, and nervousness. Hyperthyroidism may be subtle in older patients, with apathy, myopathy, and cardiovascular disease as the most prominent symptoms. It is associated with atrial fibrillation and cardioembolic stroke. Mental disturbances range from mild irritability to psychosis.

FIGURE 117.2 Magnetic resonance imaging of the orbits, showing congestion of the retroorbital space and enlargement of the extraocular muscles (*arrows*) consistent with the diagnosis of Graves ophthalmopathy.

THYROID STORM

Thyroid “storm” or “crisis” is usually precipitated by infection, surgery, or trauma in individuals with unrecognized hyperthyroidism. The cardinal symptom is fever greater than 102°F accompanied by cardiac symptoms and central nervous system (CNS) dysfunction. Nausea, vomiting, and abdominal discomfort are common. Affected individuals are confused or agitated and may present with psychosis. If untreated, level of consciousness may deteriorate to coma with seizures. Neurologic signs such as bulbar weakness and corticospinal tract dysfunction have been observed.

OCULAR SYMPTOMS

Ocular symptoms are common. These may be seen as infrequent blinking, lid lag, or weakness of convergence and are distinct from the infiltrative ophthalmopathy known as *Graves ophthalmopathy*. The relationship of the eye disorder to thyroid status is not entirely clear. Onset of symptoms is gradual; exophthalmos is often accompanied by diplopia secondary to paresis of one or more ocular muscles.

Clinically, eyelid retraction (Dalrymple sign) is the first evidence in 75% of cases, and pain is the most common symptom. Both eyes may be involved simultaneously, or exophthalmos in one eye may precede the other by several months. Papilledema sometimes occurs, and ulcerations of the cornea may develop secondary to failure of the lid to protect the eye. The symptoms progress rapidly for a few months and may lead to complete ophthalmoplegia.

NEUROMUSCULAR MANIFESTATIONS

Thyrotoxic myopathy is characterized by painless weakness and wasting of proximal muscles of the arms and legs. Tendon reflexes are normal or hyperactive, and sensation is normal. The occurrence of hyperthyroidism and periodic paralysis (see [Chapter 93](#)) is more common in people of Asian ancestry and is similar to hypokalemic periodic paralysis in terms of precipitants and treatment. There is an association between hyperthyroidism and myasthenia gravis (see [Chapter 89](#)). About 5% of patients with myasthenia gravis have hyperthyroidism.

Diagnosis

A low TSH is the best test for diagnosis. This should be followed by obtaining a free T4. If the free T4 is not elevated, a free T3 measurement may be elevated, indicative of T3 toxicosis. The radioiodine uptake by the thyroid is the next test, which will be most helpful in distinguishing the different causes of hyperthyroidism. Other tests are available if the use of radioisotope studies is contraindicated. Orbital imaging will be abnormal in thyroid ophthalmopathy.

Treatment

β -Adrenergic blockade (e.g., propranolol 10 to 40 mg four times a day [q.i.d.]) is appropriate for symptomatic treatment of tremor or myopathy. Methimazole (5 to 120 mg daily, depending on severity) and propylthiouracil (50 to 300 mg t.i.d. to q.i.d.) are antithyroid medications that inhibit thyroid hormone synthesis. Ablation with radioactive iodine (^{131}I) or thyroidectomy is useful in treating

P.1008

various etiologies of hyperthyroidism that cannot be managed with medical therapies. Thyroid storm is a medical emergency with a mortality of around 20%. Immediate goals of treatment are to inhibit thyroid hormone synthesis and release, control cardiac symptoms, and support systemic circulation. Treatment of thyroid ophthalmopathy is controversial and may include immune suppression with corticosteroids, radiotherapy, or surgical decompression of the orbit.

Outcome

Successful treatment of hyperthyroidism results in improvement of most symptoms. Patients will need to be followed at varying intervals depending on the type of treatment that is selected.

PANCREATIC DISEASE HYPOGLYCEMIA

Epidemiology

Hypoglycemia is uncommon in the general population but accounts for approximately 3% of deaths in patients with type 1 DM. The average patient with type 1 DM experiences two episodes of symptomatic hypoglycemia per

week with one episode of temporarily disabling hypoglycemia each year.

Pathobiology

Hypoglycemia is most commonly associated with an overdose of insulin in the treatment of DM. Spontaneous hypoglycemia is usually the result of pancreatic hyperinsulinism. Hypersecretion of insulin by the pancreas may be due to a tumor of the islet cells or functional overactivity of these cells. Hypoglycemia may also occur when liver function is impaired or when there is severe damage to the pituitary or adrenal glands. The CNS depends almost entirely on glucose for its metabolism; dysfunction develops rapidly when the amount of glucose in the blood falls below critical levels. Hypoglycemia may cause cerebral ischemic damage, possibly by inducing endothelial dysfunction.

Clinical Features

The symptoms of hypoglycemia and hyperinsulinism are paroxysmal, tending to occur when the blood glucose could be expected to be low (in the morning before breakfast, after a fast, or after heavy exercise). Occasionally, symptoms follow a meal. The duration of symptoms varies from minutes to hours. The severity also varies. There may be only nervousness, anxiety, or tremulousness, which is relieved by the ingestion of food. Severe attacks last for hours, during which the patient may perform automatic activity with complete amnesia for the entire period or seizures followed by coma. The frequency of attacks varies from several per day to infrequent episodes.

Spontaneous hypoglycemia is occasionally seen in infants. Risk factors include immaturity, low birth weight, or severe illness. Infants of diabetic mothers may exhibit hyperinsulinism. A host of genetic or metabolic defects may cause hypoglycemia, including galactosemia, fructose intolerance, or leucine sensitivity. The symptoms of infantile hypoglycemia are muscular twitching, myoclonic jerks, and seizures. Mental retardation results if the condition is not recognized and adequately treated. Hypoglycemic symptoms can be divided into two groups: autonomic and cerebral. Sympathetic symptoms are present in most patients at the onset of hypoglycemia, usually preceding the more serious cerebral manifestations. Autonomic symptoms include light-headedness, sweating, nausea, vomiting, pallor, palpitations, precordial pressure, headache, abdominal pain, and hunger. In DM, hypoglycemia-associated autonomic failure may occur due to repeated episodes of hypoglycemia with attenuation of the physiologic and, subsequently, symptomatic responses to hypoglycemia.

Cerebral symptoms usually occur with the sympathetic phenomena but may be the only manifestations. The most common manifestations are paresthesias, diplopia, and blurred vision, which may be followed by tremor, focal neurologic abnormalities, abnormal behavior, or convulsions. After prolonged severe hypoglycemia, coma may ensue. Confusion and abnormal behavior from episodic hypoglycemia may simulate complex partial seizures, although hyperinsulinism only rarely causes epilepsy. Chronic or repeated hypoglycemia may produce dementia or other behavioral abnormalities. Distal axonal neuropathy has also been observed.

Diagnosis

Findings on neurologic examination are usually normal, except during attacks of hypoglycemia. The diagnosis is established by documentation of hypoglycemia during a symptomatic episode, but the timing of the specimen is important because homeostatic mechanisms may return the blood glucose level to normal. The level of blood glucose at which symptoms appear varies from person to person but is generally less than 30 to 40 mg/dL. The EEG shows focal or widespread dysrhythmia during an attack of hypoglycemia and, in some patients, even in the interval between attacks.

The diagnosis of hyperinsulinism is made by the paroxysmal appearance of signs of autonomic and cerebral dysfunction in association with a low blood glucose level and an inappropriately high circulating insulin level. Factitious hypoglycemia may be caused by self-administration of insulin or inappropriate use of oral

hypoglycemic agents. If it is not possible to obtain a blood specimen during an attack, a diagnostic fast should be considered. After 12 to 14 hours, 80% of patients with islet cell tumors have low glucose and high insulin levels. Longer fasts may be needed. The diagnosis of islet cell adenoma can be difficult; additional endocrine tests and imaging studies may be required. Hypoglycemia associated with diseases of the liver, adrenal, or pituitary can usually be distinguished by other signs and symptoms of disease in these organs.

Treatment

Ingestion of glucose or carbohydrate-containing foods can correct insulin-induced hypoglycemia. Administration of 10 g of oral glucose can raise blood glucose levels by approximately 40 mg/dL over 30 minutes and 20 g of oral glucose can raise blood glucose levels by 60 mg/dL over 45 minutes. Administration of glucagon is the treatment of choice for severe hypoglycemia. Comatose patients should be given glucose intravenously. Long-term management of hyperinsulinism is directed at optimizing diabetic control and/or identification and correction of the underlying cause.

Outcome

Early intensive treatment of acute hypoglycemia is important to prevent CNS damage. Long-term effects include adverse cardiovascular events and cognitive impairment.

P.1009

DIABETES MELLITUS

Epidemiology

DM is a systemic metabolic disorder characterized by hypoinsulinism or peripheral resistance to the action of insulin that affects an estimated 250 million people worldwide. The primary neurologic complication of DM is peripheral neuropathy, which is the most frequent type of neuropathy in Western countries. DM neuropathy affects up to 60% of individuals with diabetes. It increases with duration of DM and with poor glycemic control.

Pathobiology

Abnormalities reported in diabetic neuropathy include axonal degeneration in nerve fibers, primary demyelination resulting from Schwann cell dysfunction, secondary segmental demyelination related to impairment of the axonal control of myelination, onion bulb formations, and hypertrophy of the basal lamina. Endoneurial capillaries often show signs of diabetic microangiopathy with marked thickening of the basal lamina. Metabolic and ischemic mechanisms have a role in diabetic neuropathies. Mononeuropathies are attributed to inflammatory and/or vascular lesions of peripheral nerves, whereas metabolic abnormalities are likely to predominate in length-dependent diabetic polyneuropathy. Genetic factors might explain why some individuals develop a more severe polyneuropathy than others with similar diabetic status.

Clinical Features

The neuropathies include mononeuropathies (peripheral and cranial nerves), polyneuropathy, autonomic neuropathy, radiculopathies, and entrapment neuropathy (median, ulnar, and peroneal; see [Chapter 87](#)). Common cranial neuropathies involve the oculomotor and abducens nerves. Pupillary sparing is common but not invariable and is related to the pattern of presumed vascular damage within the oculomotor nerve. The prognosis for recovery from mononeuropathy or radiculopathy is good.

Diagnosis

Onset of symptoms is rapid, and pain is common in both mononeuropathies and radiculopathies caused by DM. In the more common distal symmetric polyneuropathies, there is typically a gradual onset of symptoms, the character of which depending on the type(s) of peripheral nerve fiber affected. Numbness and burning are common complaints. In symptomatic diabetic neuropathy, there is slowing of nerve conduction velocity owing to demyelination and loss of large myelinated fibers and a decrease in nerve action potentials owing to loss of axons. However, if the neuropathy primarily affects small myelinated or unmyelinated fibers, nerve conduction studies may be normal.

Treatment

Optimal glycemic control diminishes the risk of developing a disabling peripheral neuropathy. Attention should be paid to protection of hyposensitive areas, notably the foot. Treatment of neuropathic pain is addressed in Chapter 57. Treatment of autonomic dysfunction is addressed in Chapter 130. Painful diabetic polyradiculopathies often respond to antineuralgia medications, such as carbamazepine, gabapentin, and pregabalin.

Outcome

Spontaneous improvement in focal diabetic neuropathies typically occurs. Good glycemic control is the only way to minimize occurrence and/or progression of neuropathy.

PITUITARY DISEASE HYPOPITUITARISM

Epidemiology

In one population-based study, the prevalence of hypopituitarism was 45.5 cases per 100,000 with an incidence of 4.2 cases per 100,000 per year. Tumors were the most common cause. In recent years, there has been increased recognition that hypopituitarism is frequently associated with traumatic brain injury, subarachnoid hemorrhage, and cranial irradiation.

Pathobiology

Pituitary dysfunction can be caused by mechanical vascular or neural disconnection from the hypothalamus as is seen with various mass lesions of the sellar region, such as pituitary adenomas or craniopharyngiomas. Direct damage to the hypothalamus or altered neurotransmitter input is the likely cause of neuroendocrine dysfunction leading to hypopituitarism associated with cranial irradiation, traumatic brain injury, or subarachnoid hemorrhage. Hypotension or shock from obstetric hemorrhage or infection causes occlusive spasm of pituitary arteries with anoxic-ischemic necrosis (apoplexy) of a pituitary gland that has hypertrophied under estrogen stimulation from pregnancy (Sheehan syndrome).

Clinical Features

The skin is often thin, smooth, and dry; the peculiar pallor (alabaster skin) and inability to tan have been related to loss of melanocytostimulating hormone or ACTH. Axillary and pubic hair may be sparse, with relatively infrequent facial shaving. Depending on the severity of the decrease in ACTH and TSH, patients may note lethargy, weakness, fatigability, cold intolerance, and constipation. There may be an acute adrenal crisis with nausea, vomiting, hypoglycemia, hypotension, and circulatory collapse, particularly in response to stress. Loss of

vasopressin will lead to diabetes insipidus with polyuria and polydipsia, which is potentially life threatening in patients with obtundation or coma. In children, loss of growth hormone (GH) will result in reduced growth velocity. In adults, the clinical manifestation of GH deficiency is less clear, but emerging data suggest that GH therapy may improve cognitive function. Loss of prolactin inhibitory factor (dopamine) from the hypothalamus can lead to raised prolactin concentrations which may cause galactorrhea and breast tenderness. Both hyperprolactinemia and loss of gonadotropins may manifest with symptoms of hypogonadism. The presentation of hypopituitarism may often be accompanied by signs and symptoms of the underlying disease responsible for pituitary dysfunction.

Diagnosis

Evaluation of patients with pituitary insufficiency depends on measurement of pituitary hormone levels in the peripheral blood, coupled with functional assessment of the target organs. The basic endocrine evaluation includes thyroid function tests (T4, T3, and TSH), prolactin determination, and assessment of adrenal reserve, such as ACTH stimulation for cortisol responsiveness. Pituitary hormone levels must be interpreted in the context of clinical findings. For example, normal gonadotropin levels (follicle-stimulating hormone, luteinizing hormone) may indicate pituitary insufficiency after menopause when elevated levels would be expected. Elevated levels of gonadotropins or TSH suggest primary gonadal

P.1010

or thyroid failure but, rarely, may be secreted by pituitary tumors. Dynamic tests of pituitary reserve or stimulation tests with synthetic hypothalamic releasing factors are sometimes needed to detect mild hypopituitarism or to distinguish between pituitary and hypothalamic causes of hypopituitarism.

Treatment

Treatment is initially determined by cause. Medical or surgical treatment of a pituitary tumor or other mass lesion may restore pituitary function (see [Chapter 100](#)). Hormone replacement is essential to restore normal adrenal and thyroid status, with replacement therapy of corticosteroids preceding thyroid replacement. Treatment of hypogonadism in both women and men can restore libido and sense of well-being and protect bone mass and in men, restore sexual function and increase muscle mass. There are oral, intranasal, and intravenous options for vasopressin replacement to treat diabetes insipidus.

Outcome

Replacement of pituitary hormones can greatly reduce morbidity and mortality and enhance quality of life. Hormonal needs may change with time and patients should be monitored regularly, especially during the first year after diagnosis. In many situations, such as traumatic brain injury, the issue of optimal hormone replacement remains uncertain and will depend on clinical judgment.

SEX HORMONE DYSFUNCTION

The brain-pituitary-ovarian axis provides an excellent example of the rich interplay between the brain and endocrine organs ([Fig. 117.3](#)). Hormonal changes linked to specific phases of the menstrual cycle, pregnancy, and menopause may impact the release and metabolism of neurotransmitters and neuromodulators and give rise to or modify a host of neurologic and neuropsychiatric conditions. Migraine is about three times as common in adult women as in men. Meningeal tumors are more prevalent in women than men. Early menopause has been touted as a risk factor for the development of Parkinson disease.

Pathobiology

MIGRAINE

The decline in plasma estradiol in the late luteal phase plays an important role in the expression of catamenial migraine. Estrogens may influence migraine by acting directly on vascular smooth muscle or by modulating the activity of vasoactive substances at the neurovascular junction. Perimenstrual fluctuations in circulating estrogens may also stimulate vasoregulatory elements in the hypothalamus or brain stem resulting in symptomatic alterations in cerebrovascular tone.

CEREBROVASCULAR DISEASE

Estrogen induces hypercoagulability by increasing plasma levels of fibrinogen and clotting factors VII, VIII, IX, X, and XII; enhancement of platelet aggregation; and suppression of antithrombin III activity and fibrinolysis. Fluctuating sex hormone levels may compromise the integrity of cerebral arterial walls akin to their effects on endometrial spiral arteries. Sex hormones may also exert direct trophic influences on arteriovenous malformations analogous to their effects on other highly vascularized lesions such as gingival epulis, spider angiomas, and meningiomas.

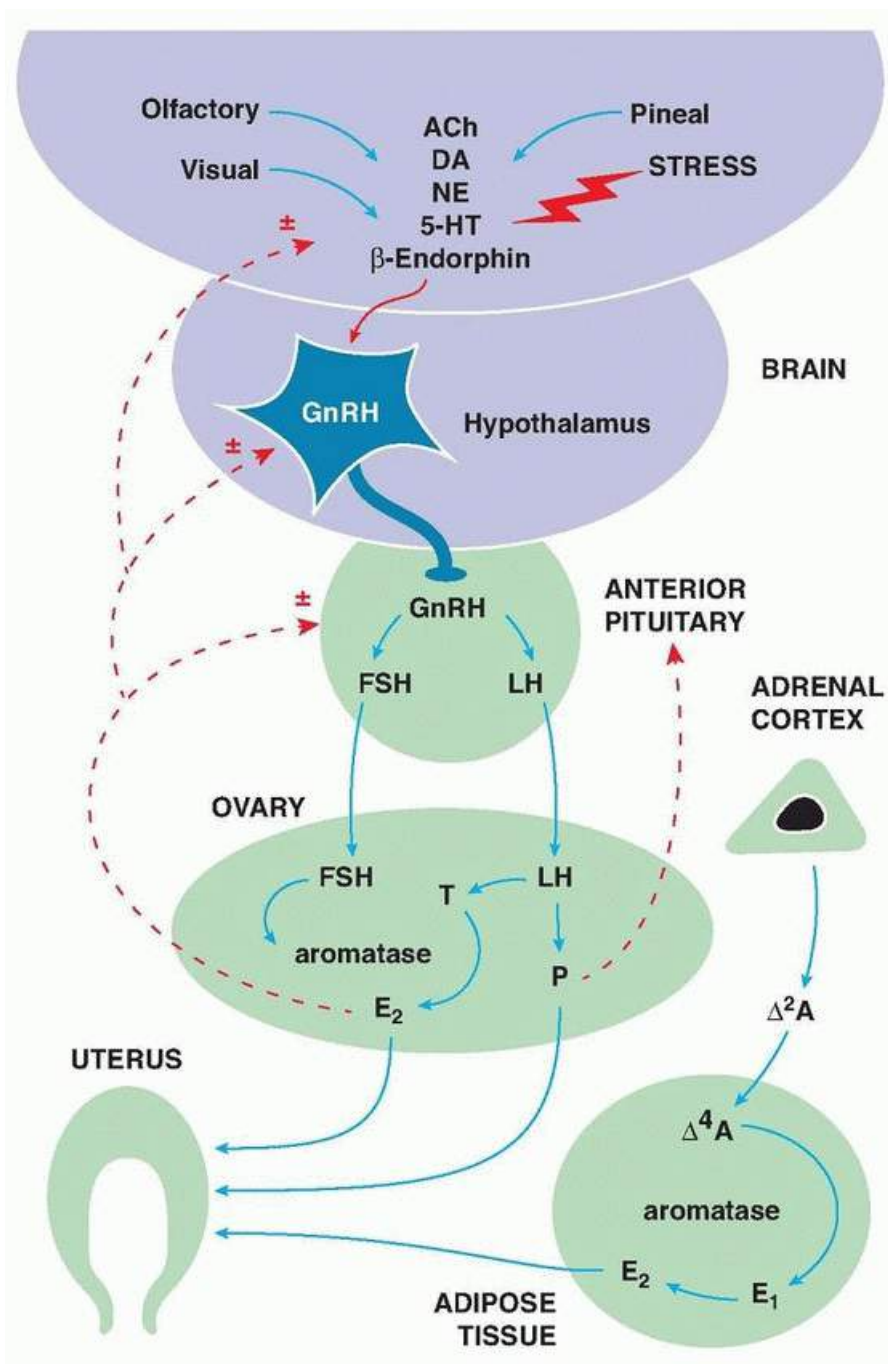

FIGURE 117.3 The brain-pituitary-ovarian axis. δ^4A , delta-4-androstenedione; ACh, acetylcholine; DA, dopamine; NE, norepinephrine; 5-HT, 5-hydroxytryptamine (serotonin); GnRH, gonadotropin-releasing hormone; FSH, folliclestimulating hormone; LH, luteinizing hormone; T, testosterone; E₂, estradiol; P, progesterone. (Modified from Schipper HM, Jay CA, Abrams GM. Sex hormone, pituitary, parathyroid, and adrenal disorders and the nervous system. In: Aminoff MJ, Josephson SA, eds. *Aminoff's Neurology and General Medicine*. 5th ed. San Diego, CA: Academic Press; 2014:369-397.)

MOVEMENT DISORDERS

Pregnancy may unmask latent chorea by facilitating dopaminergic neurotransmission in basal ganglia previously injured by hypoxic or rheumatic encephalopathy. Estrogens may influence motor manifestations of parkinsonism by modulating dopaminergic tone within the nigrostriatum.

BRAIN TUMORS

Perimenstrual and gestational changes in tumor size may be due to direct trophic effects of gonadal hormones on meningioma cells, steroid-induced fluid retention by the tumor, or increased vascular engorgement of the

pituitary adenomas, acoustic neuromas, ependymomas, and other neuraxial tumors. Astrocytomas may selectively bind estrogens, progestins, or androgens. In astroglial neoplasms, expression levels of estrogen receptor-beta may vary inversely with the degree of histopathologic dedifferentiation.

PORPHYRIA

Estradiol and other steroid hormones may trigger porphyric crises by inducing the heme biosynthetic enzyme, δ -aminolevulinic acid synthase. In women with acute intermittent porphyria, cyclical attacks may occur during the late luteal phase or at ovulation.

EPILEPSY

Estrogens and progestins have epileptogenic and anticonvulsant properties, respectively. Perimenstrual seizure activity may be precipitated by rising estrogen-to-progesterone ratios during the late luteal phase.

Clinical Features

Perimenstrual worsening of headaches (catamenial migraine) occurs in approximately 60% of female migraineurs (see also [Chapter 54](#)). The severity or frequency of migraine attacks often diminishes with pregnancy, particularly in individuals whose headaches are associated with the menstrual cycle. Menstruation, pregnancy, and menopause may also influence cluster headache, other autonomic cephalalgias, and hemicrania continua.

Pregnancy may be complicated by the appearance of choreiform movements, which are more prevalent in individuals with prior rheumatic fever and Sydenham chorea. Women with gestational chorea may additionally exhibit fever, neuropsychiatric symptoms, dysarthria, pendular reflexes, or limb hypotonia. Fluctuating sex hormone levels have also been reported to influence symptoms in other movement disorders including Parkinson disease, Tourette syndrome, tardive dyskinesia, and posthypoxic myoclonus.

Various seizure disorders may worsen premenstrually (catamenial epilepsy), at ovulation, or during pregnancy. Women may experience exacerbations of symptoms related to meningiomas in the luteal phase of the menstrual cycle. There is clinical and radiologic evidence for the rapid growth of meningiomas during pregnancy, followed by their spontaneous regression postpartum. Astrocytomas have been reported to expand during pregnancy and regress in the puerperium.

Endometriosis may cause back or pelvic pain by invading lumbar vertebrae, the lumbosacral plexus, or the sciatic nerve sheath (catamenial sciatica). Pain usually begins several days before the onset of menses and may continue until cessation of flow. Leg weakness, numbness, and loss of ankle reflexes may accompany the pain. Rarely, subarachnoid hemorrhage may be cyclic in women with hormone-sensitive ectopic endometriomas of the spinal canal.

Diagnosis

In patients with suspected chorea gravidarum, appropriate clinical and laboratory investigations may be indicated to exclude other etiologies, such as hyperthyroidism, rheumatic fever, Wilson disease, or systemic lupus erythematosus. Neuroimaging in endometriotic sciatica is generally unremarkable. Surgical exploration of the sciatic nerve may be required for diagnosis. Characteristic glandular elements are observed at histopathology.

Treatment

Perimenstrual migraine can usually be managed with standard dietary, psychological, and pharmacologic modalities employed in the general migraine population. Treatment with estrogen implants and the antiestrogen tamoxifen have yielded contradictory results. There are reports of significant symptom alleviation in women with menstrual migraine following treatment with the testosterone derivative danazol or the dopamine agonist bromocriptine. Late luteal phase therapy with prostaglandin inhibitors and mild diuretics may be helpful in refractory cases of severe catamenial migraine.

Approaches to the management of catamenial epilepsy include (1) premenstrual or periovulatory supplementation of anticonvulsant doses or addition of an adjunctive antiepileptic drug, (2) cyclic administration of a mild diuretic such as acetazolamide (which has weak anticonvulsant activity), and (3) progesterone supplementation by mouth or suppository.

Chorea gravidarum and oral contraceptive-related dyskinesias usually resolve by parturition or after discontinuation of the medication, respectively. In severe cases, neuroleptics may afford symptomatic relief. Individuals with a history of chorea gravidarum or contraceptive-induced dyskinesias should probably avoid further exposure to estrogen-containing medications.

In porphyria, chronic administration of GnRH agonists, such as leuprolide or D-His, downregulates gonadotrope GnRH receptors, resulting in long-term suppression of the pituitary-ovarian axis. In one report, complete remission of catamenial acute intermittent porphyria was observed during 6 months of D-His treatment. Subsequent cases of perimenstrual acute intermittent porphyria and hereditary coproporphyrinemia also exhibited beneficial responses to GnRH agonist therapy.

Symptoms of endometriotic sciatica and periodic subarachnoid hemorrhage due to spinal canal endometriosis may improve dramatically with standard therapy for endometriosis, including progestins, danazol, GnRH agonist, or (in refractory cases) oophorectomy.

RED BLOOD CELL DISORDERS

Anemia is a common complication of acute, severe neurologic illnesses such as stroke and traumatic brain injury. Maturation of hematopoietic stem cells into red blood cells (RBCs) in bone marrow is regulated by the glycoprotein hormone erythropoietin (EPO), which is released by peritubular cells in the kidneys in response to reductions in oxygen (O_2) delivery. Production of RBCs is also dependent on sufficient quantities of bone marrow substrate, including iron, folate, and vitamin B_{12} . RBCs normally have a life span of 100 to 120 days before being removed by the spleen.

ANEMIA

Anemia is defined as a hemoglobin (HB) concentration of less than 12 g/dL in women and 13 g/dL in men. There are numerous possible etiologies for anemia, which are presented in [Figure 118.1](#). Measurement of the reticulocyte count helps determine whether the bone marrow is responding “appropriately” to anemia—if so, it implies that the cause is hemorrhage or hemolysis; if not, there is a problem with RBC production. RBC indices, especially the mean cell volume (MCV), provide further information concerning the differential diagnosis. Microcytosis (MCV <80) implies that there is a cytoplasmic problem with the production of HB and the maturation of RBCs. Specific causes of microcytic anemia include iron deficiency and various hemoglobinopathies. Macrocytosis (MCV > 100) implies that there is a nuclear defect in developing RBCs, which may be due to vitamin B_{12} and folate deficiency or drug toxicity. Normocytic anemia suggests that there is a pathologic bone marrow process or that there is reduced stimulation for RBC production. This section will focus on the neurologic implications of anemia and on sickle cell disease, which is a major cause of stroke in children and young adults.

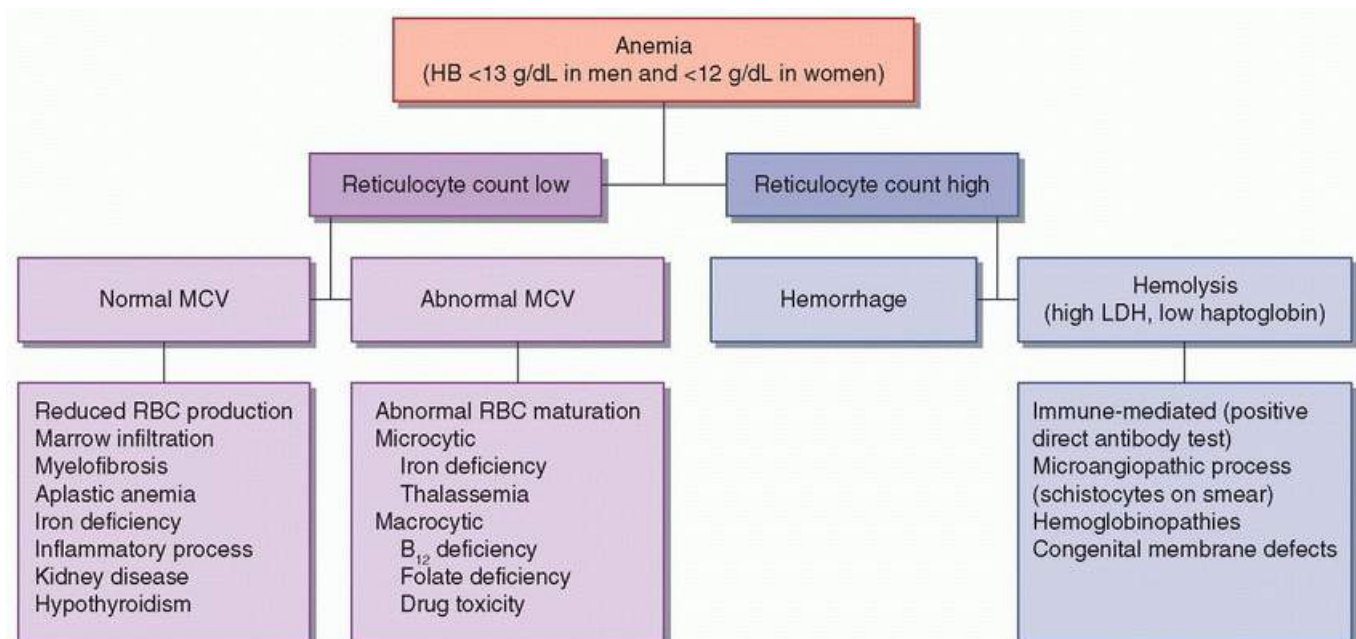

FIGURE 118.1 Approach to determining the etiology of anemia. MVC, mean cell volume; LDH, lactate dehydrogenase; RBC, red blood cell.

Anemia and Transfusion in Hospitalized and Critically Ill Neurologic Patients

Anemia is one of the most common medical complications to be encountered among hospitalized patients, especially in the intensive care unit. The development of an HB concentration less than 10 g/dL has been reported in about 40% to 50% of neurocritical care patients with traumatic brain injury (TBI) or subarachnoid hemorrhage (SAH). The etiology of anemia in hospitalized patients is multifactorial. RBC production is impaired during systemic inflammation, as cytokines blunt the production of EPO and prevent progenitor cells from incorporating iron. RBC loss is accelerated by the need for frequent phlebotomy, reduced RBC survival, and (in some cases) hemorrhage. Hemodilution produced by administration of large volumes of intravenous fluids or phlebotomy may also contribute.

Optimal care of patients with acute brain injury and various forms of stroke involves the protection of salvageable brain tissue and the prevention of secondary injury. Reduced O₂ delivery to ischemic penumbra may produce increasing neurologic damage. The amount of O₂ reaching tissues is the product of local blood flow and arterial O₂ content, which in turn is dependent on the HB concentration and the degree to which it is saturated with O₂.

Anemia is initially well tolerated by most patients for several reasons: systemic O₂ delivery exceeds O₂ consumption by a large amount, tissues have the capacity to increase O₂ extraction in the

P.1014

setting of reduced delivery, and sympathetic stimulation results in increased cardiac output. In the brain, the normal response to anemia is cerebral vasodilation, with a resulting increment in cerebral blood flow (CBF). Experiments in healthy volunteers demonstrate that neurocognitive impairment begins at an HB concentration below approximately 7 g/dL. It is likely that the HB threshold for neurologic deterioration is higher in brain-injured patients, in whom autoregulatory mechanisms may be impaired.

The development of anemia is associated with worsened outcomes in patients with TBI, SAH, and intracerebral hemorrhage (ICH). Studies using invasive multimodal neurologic monitoring have found that anemia is associated with lower brain tissue O₂ tension and high cerebral lactate concentrations. Patients with SAH, in particular, are vulnerable to delayed cerebral ischemia. Administration of RBC transfusions improves O₂ delivery to the brain and increases physiologic “reserve” in regions of the brain with a high O₂ extraction fraction.

Historically, clinicians would give RBC transfusions to maintain HB concentrations greater than 9 to 10 g/dL in brain-injured patients. However, allogeneic RBC transfusions have potential adverse effects, including transfusion-related acute lung injury (TRALI) and immunosuppression with an increased risk of nosocomial infections. Randomized trials in general critical care patients have found no advantage, and possible harm, when RBC transfusions are used to maintain HB concentrations above 10 g/dL compared with a transfusion threshold of 7 g/dL [Level 1].^{1,2} However, there were few brain-injured patients in these studies and HB concentrations of 7 to 9 g/dL may be too low in some brain-injured patients. There is substantial variability of practice, which will continue until clinical trials are performed specifically in brain-injured patients. Consensus guidelines in the setting of SAH recommend maintaining HB levels greater than 8 to 10 g/dL.

Sickle Cell Disease

Sickle cell disease (SCD) is a group of genetic disorders characterized by the presence of “sickle hemoglobin” (HBS) caused by a mutation in the β -globin gene, whereby the sixth amino acid changes from glutamic acid to valine. The most common and severe form is sickle cell anemia, which occurs in patients homozygous for the HBS allele. There are other SCD variants where HBS is inherited from one parent and another abnormal HB from the other. Stroke is the most common neurologic complication of SCD.

EPIDEMIOLOGY

The global burden of SCD is increasing, especially in Africa and India. About 8% of African-Americans are

heterozygous for HBS and 1 in 600 are homozygous. Another 2% to 3% carry the HBC allele, which is attributable to a glutamic acid to lysine substitution. The incidence of stroke in children with SCD is about 300 to 400 times higher than the rate of stroke in other children, such that the chance of having a stroke by 20, 30, and 45 years of age is estimated to be about 11%, 15%, and 24%, respectively. The highest incidence occurs between the ages of 2 and 9 years. Intracranial hemorrhage is less common but increases in incidence between 20 and 30 years of age. Stroke is a major cause of premature death and disability in patients with SCD. Untreated, stroke may recur in as many as two-thirds of patients within 2 years. By far the strongest risk factor for stroke is a previous stroke or transient ischemic attack (TIA). Other risk factors include the degree to which HB is reduced, hypertension, frequent episodes of acute chest pain syndrome, leukocytosis, and lower pulse oximetry values.

Even in patients who have not developed overt stroke, magnetic resonance imaging (MRI) studies demonstrate that silent cerebral infarcts are common, occurring in more than a third of patients. Previous infarcts are seen especially in watershed regions and are associated with cognitive impairment and a higher subsequent risk of overt stroke. Areas of restricted diffusion, suggestive of recent cerebral ischemia, can be detected even when patients are asymptomatic, suggesting that patients are at constant risk. Identified risk factors for silent cerebral infarcts include lower baseline HB concentration, higher systolic blood pressure, and male gender.

PATHOBIOLOGY

O₂ is normally transported by adult hemoglobin (HBA) consisting of two α and β polypeptide chains that encircle a heme moiety. Unlike HBA, HBS has a tendency to polymerize when it is deoxygenated, which in turn disrupts the normal architecture and flexibility of RBCs, causing them to take on sickle-shaped morphology. Sickling of RBCs interferes with their transit through capillaries and venules, causes them to adhere to endothelium, and increases blood viscosity, all of which may produce microvascular occlusion and tissue ischemia. Increased hemolysis occurs in the spleen. Most of the clinical manifestations of sickle cell anemia are attributable either to vaso-occlusion or hemolysis.

Multiple factors other than just stasis and sluggish microvascular flow are implicated in causing cerebral ischemia. Adherence of sickled RBCs to vascular endothelium induces a cascade of events that produce leukocyte recruitment, inflammation, intimal hyperplasia, fibrosis, and thrombosis. Intravascular hemolysis and release of free HB scavenges nitric oxide, the production of which may also be impaired by endothelial damage, thereby interfering with maintenance of normal vascular tone. These factors contribute to impaired CBF autoregulation, making the brain vulnerable both to hyperemia and ischemia.

Imaging studies with digital subtraction or magnetic resonance (MR) angiography demonstrate that many patients have various forms of vasculopathy. By far the most common cerebrovascular abnormality is stenosis of proximal intracranial vessels, especially in the anterior circulation, which may be accompanied by relative hypoperfusion if perfusion imaging is performed. Involvement of extracranial vessels is less common but does occur and may lead to cervical artery dissection and/or embolic strokes. Over time, with persistent severe intracranial stenosis, there may be development of collateral vessels resembling those of Moyamoya disease. The presence of such collaterals is a marker of a greater degree of vasculopathy and has been identified as a major risk factor for future stroke. These friable vessels are also vulnerable to bleeding. Intracranial aneurysms may develop in unusual locations with a possible predilection for the posterior circulation.

CLINICAL MANIFESTATIONS

SCD patients with cerebrovascular disease present most often with TIA or ischemic stroke. Among those with hemorrhage, SAH is more common than ICH or intraventricular hemorrhage. Repeated silent infarcts cause progressive neurologic deterioration. Children in whom previous infarcts are detected on a MRI scan have, on

average, lower performance on neurocognitive testing and worse school performance. They are also more likely to have psychological concerns, such as anxiety and depression. Similar observations have been made in adults with sickle cell anemia, in whom the degree of anemia is associated with more severely impaired cognitive function. Neuroimaging reveals that patients with SCD have

P.1015

a greater degree of thinning of the frontal lobe cortex, as well as reduced basal ganglia and thalamus volumes.

SCD may rarely cause complications in the spinal cord and peripheral nervous system. There have been numerous case reports of spinal cord infarction, most often involving the cervical cord and causing quadriparesis. Ischemic injury of peripheral nerves presents as mononeuritis multiplex. Functional asplenia is a well-recognized complication of SCD. The resulting immunosuppression predisposes to bacterial infections, including meningitis, with the risk being high enough to justify prophylactic penicillin usage until at least the age of 5 years. Fever should therefore be considered a medical emergency.

DIAGNOSIS

The diagnosis of SCD is confirmed by HB electrophoresis. Quantification of the percentage of HBS, determined by high-performance light chromatography, is important for therapeutic decision making. Ischemic strokes are rare in the absence of detectable abnormalities in the cerebral vasculature. When vasculopathy is present, the risk of stroke can be significantly ameliorated with appropriate therapy. Thus, screening of patients for cerebrovascular disease is important. Cerebral vasculature is best imaged with digital subtraction angiography (DSA), but noninvasive imaging is preferred. Both computed tomography (CT) and MR angiography can be used, although published experience is larger with the latter. Previous concerns that intravenous contrast could precipitate sickling crisis have likely been exaggerated.

In experienced hands, transcranial Doppler (TCD) ultrasonography correlates well with angiography. Increased TCD velocities in the anterior circulation are highly predictive of the risk of subsequent stroke [Level 1].³ In one prospective single-center study, the sensitivity and specificity for subsequent overt stroke exceeded 85% when TCD velocity exceeded 170 cm/s. In children, when TCD velocities in either middle cerebral or intracranial internal carotid artery consistently exceed 200 cm/s, a randomized controlled trial demonstrated that a stroke prevention strategy using RBC transfusions decreased the risk of stroke over the ensuing 2 years from 16% to 2% [Level 1].⁴ The risk of stroke is even higher if there are elevated velocities in more than one vessel. Annual screening with TCD is recommended for children with SCD beginning at 2 years of age. Implementation of screening has been temporally associated with a reduction in the incidence of stroke in some jurisdictions. Most studies assessing the use of TCD in SCD have been in children. TCD velocities that are associated with vascular stenosis seem to be somewhat lower in adults, and it is unclear whether TCD is as predictive of subsequent stroke risk.

Apart from imaging of the intra- and extracranial cerebral vasculature, patients with SCD who develop ischemic strokes should undergo a similar diagnostic evaluation to that of other patients, including an echocardiogram, lipid panel, and assessment for diabetes mellitus. In patients with SAH or ICH, if CT or MR angiography does not demonstrate a cause, a DSA should be considered to ensure that a small aneurysm or vascular abnormality is not being missed.

TREATMENT

SCD is a multisystem condition, and the management of neurologic complications occurs in the context of other concomitant treatment considerations. In the management of cerebrovascular complications, therapeutic goals are the primary and secondary prevention of strokes, including those that are silent and

may contribute to cognitive decline as well as minimization of brain injury when strokes do occur.

Transfusion Strategies and Stroke Prevention

The Stroke Prevention Trial in Sickle Cell Anemia (STOP) demonstrated that using RBC transfusions to keep the fraction of HBS less than 30% (Table 118.1) significantly reduces the risk of stroke [Level 1].⁴ Apart from diluting HBS with the addition of HBA, transfusions also temporarily reduce EPO production, thereby reducing the production of new HBS. O₂ binds more efficiently to HBA than HBS, such that the O₂ saturation is temporarily increased. Although the STOP trial was a primary prevention study, chronic transfusion therapy has also been widely adopted as a secondary prevention strategy. The target HB concentration is generally greater than 9 g/dL. Simple transfusions can be performed when patients are very anemic. Exchange transfusions refer to the transfusion of RBCs together with the removal of the patient's blood, which is more effective at reducing the concentration of HBS and at lowering stroke incidence.

The need for regular transfusions also has risks, most notably the development of iron overload. Over time, excess iron overwhelms the capacity of reticuloendothelial system to sequester it, and iron begins to accumulate in organs, especially the liver. The consequence of unchecked iron accumulation is hepatic fibrosis and eventually cirrhosis. Rather than performing repeated biopsies, liver iron burden can be accurately monitored noninvasively with annual quantitative MRI scans. Increasing liver iron concentration or serum ferritin (>1,500 µg/L) is an indication to initiate treatment with an iron chelator, most often deferasirox, which has similar efficacy to deferoxamine but is orally available. In an attempt to avoid long-term dependence on blood transfusions, the STOP 2 trial assessed the safety of discontinuing prophylactic transfusions in children whose TCD results had normalized over time. Unfortunately, cessation of transfusions was associated with a clear increment in TCD velocities over time as well as an increased risk of recurrent stroke [Level 1].⁵

Post hoc analyses of the STOP trials indicated that new silent infarcts were reduced by the use of transfusions and that discontinuation of transfusions led to an increment in the occurrence of new infarcts. However, patients treated with chronic transfusion still commonly develop progressive cerebral vasculopathy. Increased TCD velocities are not necessarily predictive of the development of

P.1016

silent infarcts. MR angiography may be more predictive, but the relationship between burden of vasculopathy and risk of infarction is imperfect. Until recently, it was unclear whether performing serial MRI scans to document silent infarcts is helpful and should modify the therapeutic approach. However, the Silent Cerebral Infarct trial has demonstrated that regular transfusions to maintain HBS less than 30% and HB greater than 9 g/dL reduces the incidence of subsequent overt or silent infarcts [Level 1].⁶ Patients should be periodically screened for silent infarcts (the optimal interval has not been defined) and enrolled in a transfusion program if they are present.

TABLE 118.1 Indications for Chronic Transfusion Program for the Prevention of Stroke in Patients with Sickle Cell Disease

Primary prevention (screen annually with TCDs of MCA and distal ICA between 2 and 16 yr)

-
- If >220 cm/s, initiate transfusion program
-
- If 200-220 cm/s, repeat TCDs in 1-2 wk and initiate transfusion program if confirmed >200

cm/s

-
- If 170-200 cm/s, repeat TCDs in 3-6 mo; consider MRI scan to assess for SCI.
-

- If <170 cm/s, repeat TCDs annually; consider MRI scan to assess for SCI.
-

Secondary prevention (if patient has had symptomatic stroke)

MRI evidence of silent cerebral infarction (Note: Optimal frequency of MRI screening has not yet been defined.)

TCD, transcranial Doppler; MCA, middle cerebral artery; ICA, internal carotid artery; MRI, magnetic resonance imaging; SCI, silent cerebral infarction.

Management of Acute Stroke

There have been no randomized trials of thrombolysis in the treatment of pediatric stroke. The pathophysiology of acute stroke in the setting of SCD may not be the same as in other settings. Nevertheless, although the risk of iatrogenic hemorrhage may be higher, the presence of SCD is not necessarily a contraindication for the use of thrombolytics, especially if the stroke mechanism involves acute thrombotic or embolic vascular occlusion. CT angiography, performed immediately after an initial noncontrast CT scan, can help clarify the mechanism while concomitantly identifying vascular abnormalities that may constitute a relative contraindication. Urgent transfusion to lower the HBS concentration and raise the total HB concentration to about 10 g/dL is appropriate to maximize O₂ delivery to the affected penumbra. Adequate hydration and avoidance of hypotension, hyperglycemia, and fever are other standard measures. Antiplatelet therapy is indicated in adults sustaining acute strokes in other settings but there is no data specifically in patients with SCD. The very high risk of recurrent stroke with SCD justifies the use of chronic transfusion for secondary prevention.

Hydroxyurea as an Alternative to Chronic Transfusion

Fetal hemoglobin (HBF) consists of two gamma, rather than beta, globulins. For this reason, an increased concentration of HBF in the circulation prevents the sickling of RBCs. Hydroxyurea is thought to exert its beneficial effects in SCD by increasing the formation of HBF. A large randomized trial found hydroxyurea to reduce painful vaso-occlusive crises. Long-term follow-up demonstrated a possible mortality benefit [**Level 1**].⁷ Hydroxyurea is currently recommended in patients older than 24 months with frequent pain crises, acute chest syndrome, or severe symptomatic anemia. There has been interest in using hydroxyurea as an alternative to chronic transfusion in the prevention of cerebrovascular disease. Early data suggested that hydroxyurea might be efficacious. However, the recent Stroke with Transfusions Changing to Hydroxyurea (SWITCH) trial demonstrated that discontinuing regular transfusions and instead treating patients with hydroxyurea resulted in an increased stroke risk [**Level 1**].⁸

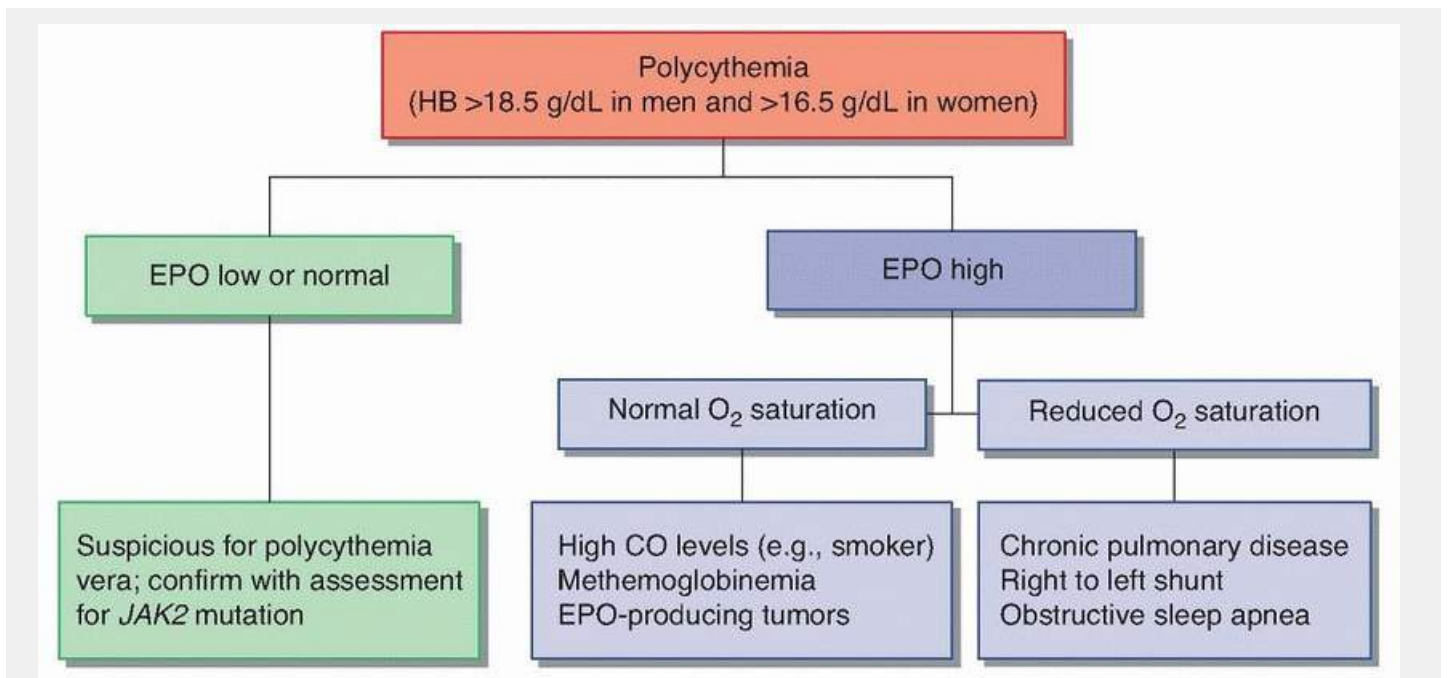

FIGURE 118.2 Approach to determining the etiology of polycythemia. EPO, erythropoietin; O₂, oxygen; CO, carbon monoxide.

Intracranial Hemorrhage and Moyamoya Syndrome

Supportive care of SAH and ICH is not different compared with patients who do not have SCD. Immediate priorities with SAH are cardiopulmonary stabilization and treatment of hydrocephalus. Cerebral angiography (invasive or noninvasive) is required to identify the source of bleeding. Most aneurysms with SCD appear to be saccular and are amenable to clip ligation or coil embolization. Some aneurysms are fusiform and can be treated with endovascular stenting. Nimodipine should be used for prevention of delayed cerebral ischemia. Moyamoya syndrome, a syndrome of progressive intracranial large-vessel occlusion, is a recognized and relatively common complication of sickle cell vasculopathy that is associated with an increased risk of stroke and cognitive decline (see also [Chapter 43](#)). There are no controlled studies assessing the optimal management of moyamoya syndrome in the context of SCD. In the setting of an acute ischemic stroke, physiologic targets (blood pressure, partial pressure of carbon dioxide and O₂, core body temperature) should be directed at optimizing cerebral perfusion and protecting vulnerable ischemic penumbra. Surgical revascularization is generally preferred for secondary prevention. Small case series have suggested a reduced risk of ischemic stroke with surgery. In adults, direct revascularization with a superficial temporal artery to middle cerebral artery bypass procedure may be possible. In children or in adults without a suitable target vessel, indirect revascularization procedures (e.g., pial synangiosis) are more often performed.

POLYCYTHEMIA

Polycythemia is present when the HB concentration is greater than 16.5 g/dL in women and 18.5 g/dL in men (or the hematocrit is >48% and 52%, respectively). True polycythemia should not be attributable solely to a reduction in plasma volume (hemoconcentration). “Primary” polycythemia refers to increased production of RBCs without increased release of EPO and occurs as a result of congenital or acquired mutations in RBC progenitors. “Secondary” polycythemia is an appropriate response to increased EPO production ([Fig. 118.2](#)). Management of secondary polycythemia should be directed at the underlying cause.

Polycythemia vera (PV) is of interest to neurologists primarily as a cause of stroke. The median age of diagnosis is about 60 years, but PV can occur across all age categories. In almost all cases, PV is associated with a mutation involving JAK2, a gene located on chromosome 9 that codes for the production of tyrosine kinase, a family of proteins that participate in the regulation of hematopoietic cell proliferation. The same mutation is present in about 50% of patients with essential thrombocythemia (ET) and primary myelofibrosis.

PATHOBIOLOGY

PV is a myeloproliferative neoplasm characterized by the clonal proliferation of RBC progenitors resulting in an elevated RBC mass. A small proportion of patients with PV will develop leukemic transformation usually after many years. A major concern with PV and other myeloproliferative disorders is a predisposition to thrombosis. It is thought that persistently elevated viscosity produces high shear stress in blood vessels, which in turn is complicated by endothelial dysfunction, as well as platelet and leukocyte activation. Increased levels of thromboxane and other markers of platelet activation can be detected in the blood of patients with PV. High viscosity may reduce CBF to a degree that overall O₂ delivery is impaired despite the higher O₂-carrying capacity produced by a higher HB concentration. However, other factors must be at play because there is no clear evidence that secondary polycythemia increases the risk of thrombosis.

CLINICAL MANIFESTATIONS

PV is sometimes detected incidentally on routine blood work. However, a sizable proportion of patients have already had thrombotic events by the time they come to medical attention. Arterial thrombosis is more common than venous thrombosis. Patients may also present with transient visual disturbances, headaches, and dizziness attributable to hyperviscosity and sluggish blood flow. Other common complaints include pruritus that is exacerbated by contact with water and erythromelalgia (burning sensation in extremities with erythema or pallor). Physical examination commonly demonstrates hepato- and splenomegaly as well as facial plethora. Apart from an elevated HB concentration, other laboratory findings include thrombocytosis, leukocytosis, high lactate dehydrogenase (LDH), and low EPO levels. Major diagnostic criteria for PV include an elevated HB concentration and the presence of the JAK2 mutation. Minor criteria include characteristic findings on a bone marrow aspirate or biopsy and reduced serum EPO.

TREATMENT

The goal of treatment is to reduce symptoms and the risk of thrombosis while also minimizing long-term complications, especially leukemia. In a multicenter randomized trial involving patients with JAK2-positive PV, treatment with phlebotomy or hydroxyurea to achieve a hematocrit of less than 45% was associated with a significant reduction in thrombotic events. This target hematocrit should therefore be maintained with phlebotomy in essentially all patients [Level 1].⁹ For patients at especially high risk of thrombosis (those older than the age of 60 years or having had previous thrombotic events), treatment with hydroxyurea is recommended, as it appears to further reduce the risk of thrombosis with a smaller increase in the risk of leukemia over time compared with other myelosuppressive drugs. The addition of low-dose aspirin (80 mg/day) can further reduce thrombotic risk [Level 1].¹⁰

WHITE BLOOD CELL DISORDERS

MALIGNANCIES OF LYMPHOID CELLS

Lymphoma and Lymphoblastic Leukemia

Lymphoid malignancies present primarily as mass lesions, which are referred to as *lymphoma*, or with cancer

cells in the blood, referred to as *leukemia*. They are most often categorized using the World Health Organization classification system. Lymphoma is divided broadly as Hodgkin (HL) and non-Hodgkin (NHL). NHL encompasses a heterogeneous group of malignancies, arising from B lymphocytes in about 85% to 90% of cases, and T lymphocytes in about 10% to 15% of cases. B- and T-cell lymphomas are further subdivided based on whether the malignancy involves proliferation of immature precursor cells or mature cells. Neurologic involvement is rare with HL. However, with NHL and acute lymphoblastic leukemia (ALL), neurologic complications may occur because of direct infiltration of cancer cells into the central nervous system (CNS) (Table 118.2).

EPIDEMIOLOGY

The distribution of NHL subtypes varies by region. In western countries, diffuse large B-cell lymphoma and follicular lymphoma account for more than 50% of cases. CNS involvement is most common with very high-grade lymphomas, especially Burkitt lymphoma and acute lymphoblastic lymphoma, where it may be present at the time of diagnosis in as many as a third. However, CNS involvement also occurs with intermediate- and high-grade

P.1018

lymphoma subtypes (e.g., diffuse B-cell lymphoma, the most common subtype in North America), especially when there is lymphoma spread to testes, orbits, or the nasopharynx and when there is a high serum LDH concentration. Most cases with neurologic involvement manifest as disease relapses during or after initial treatment, even when there has been a favorable systemic response to treatment, suggesting that subclinical disease was present at the time of diagnosis. The proportion of patients developing CNS relapses may have decreased over time with the addition of rituximab to standard CHOP therapy.

TABLE 118.2 Classification of Most Common Subtypes of Non-Hodgkin Lymphoma and Approximate Prevalence of Central Nervous System Involvement

Type of Lymphoma	Prevalence of CNS Involvement
Indolent lymphomas <ul style="list-style-type: none"> • Follicular lymphoma (grades I and II) • Marginal zone B-cell lymphoma • Small lymphocytic lymphoma/B-cell CLL 	1%-3%
Aggressive lymphomas <ul style="list-style-type: none"> • Diffuse large B-cell lymphoma • Follicular lymphoma (grade III) • Mantle cell lymphoma • Peripheral T-cell 	3%-5% Note: prevalence higher with certain risk factors (e.g., involvement of testes, orbits, nasopharynx, breasts, multiple extranodal sites, high serum LDH)

lymphoma

- Anaplastic large cell lymphoma

Highly aggressive lymphomas **25%-50%**

- Burkitt lymphoma
- Precursor T and B lymphoblastic lymphoma
- Adult T-cell lymphoma

CNS, central nervous system; CLL, chronic lymphocytic leukemia; LDH, lactate dehydrogenase.

More than half of cases of ALL occur in children, with a peak incidence between the ages of 2 and 5 years. CNS infiltration is detected at diagnosis in about 5% to 10% of patients. This is likely to be an underestimate, given that identification of CNS involvement may be challenging and is not routinely pursued. Before routine use of prophylactic therapy, CNS relapses occurred in as many as 80% of cases. CNS involvement was sometimes identified at autopsy in patients previously thought to have had more limited disease. Risk factors for CNS leukemia include younger age, high white blood cell (WBC) count, positive Philadelphia chromosome, and T-cell ALL.

CLINICAL MANIFESTATIONS

The usual location of CNS involvement is the leptomeninges and subarachnoid space. Brain parenchyma involvement is less common. The predilection of certain tumor subtypes for CNS penetration may relate to expression of various surface adhesion molecules. The most frequent manifestations of leptomeningeal involvement include headache, neck pain, and various cranial neuropathies. If there is spread to the lumbar cistern, patients may develop low back pain and radiculopathies. The degree of subarachnoid involvement may occasionally be severe enough to interfere with CSF flow and cause hydrocephalus. With brain parenchymal involvement, there is a risk of developing seizures and focal deficits. Intramedullary spinal cord involvement is rare. In contrast, NHL and multiple myeloma are among the most common malignancies to cause epidural spinal cord compression (see [Chapter 16](#)).

DIAGNOSIS

Gadolinium-enhanced MRI can identify leptomeningeal or brain parenchymal spread. There may be enhancement and thickening of the meninges or individual cranial nerves or nerve roots. There are no characteristic MRI features that definitively identify cerebral mass lesions as lymphoma rather than other tumors; surgical biopsy may be required. CSF findings include lymphocytic pleocytosis, elevated protein, reduced glucose, and high opening pressure, although most patients do not have all of these findings. CSF cytology and flow cytometry should both be performed, as they provide complementary information. Sampling CSF more than once may reduce false-negative rate. CNS leukemia is defined by the presence of leukemic blasts in CSF. Blasts may occur regardless of whether or not the CSF WBC count is increased. The presence of CSF blasts predicts a worse prognosis.

TREATMENT

Lymphoma

When NHL is complicated by secondary CNS involvement, the usual treatment approach must be modified. Options include intensification of the chemotherapeutic regimen, with inclusion of higher doses of drugs that cross the blood-brain barrier or delivering chemotherapy directly into the CNS using either an Ommaya reservoir or repeated lumbar puncture. It is unclear which of these approaches is preferred, as they have not been compared in large clinical trials.

When systemic chemotherapy is used, the regimen usually includes high-dose methotrexate. Combining high-dose chemotherapy with autologous stem cell transplantation appears to be a particularly promising approach. Intrathecal therapy consists of methotrexate in combination with cytarabine. Preliminary data suggest that cytarabine is more efficacious when administered as a slow-release liposomal formulation, which has the additional advantage of requiring less frequent administration. Systemic corticosteroids are effective in some patients at temporarily ameliorating neurologic symptoms and providing analgesia. Radiation therapy may be helpful in selected cases where there are radiographically visible lesions that are causing symptoms.

Because the prognosis of NHL is much worse with relapses that involve the CNS, some experts favor administration of prophylactic CNS therapy as a component of the initial chemotherapeutic regimen in patients deemed to be at high risk. The risk of CNS involvement, even if not documented at diagnosis, is sufficiently high with Burkitt lymphoma and lymphoblastic lymphoma to justify CNS prophylaxis. This may also be appropriate for other forms of NHL if risk factors for CNS involvement are present.

Acute Lymphoblastic Leukemia

Phases of treatment for ALL include induction, consolidation, and maintenance. Induction therapy includes glucocorticoids, vincristine, asparaginase, and possibly an anthracycline. Philadelphia chromosome-positive patients have a worse prognosis and are also treated with tyrosine kinase inhibitors. Essentially all treatment protocols include CNS prophylaxis, which is administered during the induction phase. Consolidation and maintenance therapy involves the administration of further chemotherapy or, in some high-risk cases, hematopoietic cell transplantation.

Cranial radiotherapy used to be a standard component of CNS prophylaxis but induces CNS toxicity in a substantial proportion of patients. Radiation has been largely replaced by use of intrathecal chemotherapy [**Level 1**]. A variety of regimens have been used but most often include intrathecal methotrexate, cytarabine, and hydrocortisone. Neurotoxicity, with MRI evidence of leukoencephalopathy, has been described with high doses of intrathecal methotrexate.

Established CNS leukemia at the time of diagnosis is still commonly treated with the combination of whole-brain irradiation and intrathecal methotrexate. Given that the prognosis of adults with CNS leukemia is guarded, there may be a role for allogeneic hematopoietic cell transplantation, but further research is required.

Plasma Cell Malignancies

MULTIPLE MYELOMA

Multiple myeloma (MM) is a malignancy of marrow plasma cells characterized by the production of monoclonal immunoglobulins. It is the most prevalent hematologic malignancy after NHL and is particularly common in the elderly with a median onset age in the early 60s. MM has a higher incidence in African-Americans and in men.

Plasma cell proliferation in the marrow interferes with the production of other hematopoietic cells, resulting in anemia and thrombocytopenia. Lytic bone lesions cause pain and make

P.1019

patients vulnerable to pathologic fractures. Increased bone metabolism precipitates hypercalcemia. Production of immunoglobulins by other plasma cells is impaired, resulting in hypogammaglobulinemia and impaired humeral immunity with increased vulnerability to bacterial infections. Renal failure may occur for a variety of reasons, including acute tubular necrosis from lightchain casts, glomerulonephropathy from amyloidosis, and the effects of hypercalcemia.

The various complications of MM (e.g., hypercalcemia, infections, or uremia) may produce neurologic symptoms (e.g., altered level of consciousness). Vertebral body fractures or plasmacytomas can cause spinal cord compression. Brain involvement is less common and may be due to plasmacytoma extension from the skull or the development of leptomeningeal myelomatosis with resultant cranial nerve palsies or spinal radiculopathies. CNS involvement can generally be diagnosed with MRI scans and assessment of CSF. There have been no prospective studies assessing optimal therapy of CNS involvement, but preliminary experience with adjunctive intrathecal chemotherapy and selective use of cranial irradiation has been favorable.

MM is the second most common cause of hyperviscosity syndrome (discussed in the following text). There have been an increasing number of case reports of hyperammonemic encephalopathy complicating MM. Although myeloma cells appear to produce significant quantities of ammonia, the pathogenesis remains unclear. As with other causes of hyperammonemia, patients develop lethargy, confusion, and seizures. In severe cases, there may be diffuse cerebral edema and coma. The relationship between serum ammonia concentration and clinical manifestations is imperfect, although most reported cases had markedly elevated levels. Clinical improvement has been reported with the initiation of chemotherapy. In several reports, hemodialysis was used successfully to lower ammonia levels more rapidly.

WALDENSTRÖM MACROGLOBULINEMIA

Waldenström macroglobulinemia (WM) is a form of lymphoplasmacytic lymphoma associated with production of circulating immunoglobulin (Ig) M monoclonal antibodies. Other lymphoid malignancies (e.g., chronic lymphocytic leukemia), as well as monoclonal gammopathy of undetermined significance and primary amyloidosis, may also result in increased production of IgM antibodies. WM is a rare condition with an incidence of only 3 per million population per year.

As with MM, patients may develop clinical manifestations related to tumor infiltration in hematopoietic tissues. However, most neurologic complications are related to the effects of circulating IgM. WM is the most common cause of the hyperviscosity syndrome, which is present in as many as one-third of patients at the time of diagnosis. Serum viscosity is generally expressed in centipoises (cP), where 1 cP is the viscosity of water. Serum usually has a viscosity of 1.4 to 1.8 cP. Clinical manifestations typically occur when viscosity exceeds 4 cP and are almost always present above 6 cP. High viscosity results in sluggish blood flow and relative hypoperfusion. Consequently, patients develop blurry vision, altered mental status, and focal neurologic deficits. In severe cases, cerebral venous thrombosis or ischemic strokes may occur. Circulating proteins also interfere with platelet aggregation, leading to prolonged bleeding time and a tendency toward mucosal hemorrhage. Funduscopy classically demonstrates segmental dilatation of retinal veins, as well as retinal hemorrhages or exudates. A significant proportion of patients with WM also develop a progressive sensorimotor peripheral neuropathy. The neuropathy is usually demyelinating, affects sensation to a greater degree than motor function, and targets primarily the lower extremities. Monoclonal IgM antibodies are detected by serum protein electrophoresis and direct measurement of IgM levels. Bone marrow biopsy reveals infiltration of lymphocytes with plasma cell differentiation (> 10% of cells).

Hyperviscosity syndrome is a medical emergency. The need for treatment is based primarily on the presence of clinical manifestations rather than the specific serum viscosity. Apart from fluid resuscitation, patients should undergo urgent plasmapheresis using albumin rather than plasma for fluid replacement. Each treatment reduces serum viscosity by about 20% to 30% and repeated plasmapheresis is performed until symptoms have resolved. Further therapy consists of appropriate chemotherapy administered together with rituximab [Level 1].¹¹

ACUTE MYELOID LEUKEMIA

Acute myeloid leukemia (AML) is a group of hematologic malignancies involving clonal proliferation of myeloid precursor cells (destined to become granulocytes, monocytes, RBCs, or platelets). AML may occur because of defined genetic abnormalities as part of the natural history of myelodysplastic syndrome or as a complication of exposure to cytotoxic drugs. AML “not otherwise specified” is most often categorized according to the French, American, and British classification system based on the specific cell type that is implicated.

Patients with AML usually come to medical attention with manifestations attributable to pancytopenia, such as fatigue, weakness, infections, or bleeding. Leukemic infiltration of various tissues can produce additional symptoms. If the WBC is high enough, manifestations of hyperviscosity (“leukostasis”) may develop, which may be severe enough to cause stupor and coma. There appears to be an increased risk of ICH for several days after the high WBC has been corrected, possibly because of reperfusion injury.

CNS leukemic involvement is uncommon at presentation and is less of a concern for AML than with ALL. It is more common with acute monocytic and myelomonocytic leukemia, as well as with relapses of acute promyelocytic leukemia. In studies where lumbar puncture is routinely performed, the incidence of CNS disease approaches 20%. Additional risk factors include African-American ethnicity, younger age, and a high serum LDH. Cytarabine is commonly used as part of combination chemotherapy in AML and is thought to be relatively effective at treating CNS leukemia even when clinicians are unaware that it is present. CNS disease with AML may manifest especially with meningeal involvement and cranial neuropathies. Although the pathogenesis is not always clear, some patients have evidence of raised intracranial pressure with headaches, visual impairment, and papilledema. Patients may present with extramedullary granulocytic sarcomas, which sometimes develop in the brain. Other manifestations may include intracranial hemorrhage and spinal cord compression.

CNS leukemia is most often detected by lumbar puncture. There is, however, a concern that traumatic lumbar puncture could introduce leukemic cells into CSF. Traumatic lumbar puncture is more common in the presence of thrombocytopenia, such that some experts recommend only performing the procedure once the platelet count has been corrected to more than 40,000 to 50,000. Apart from the presence of blast cells, CSF protein counts are usually moderately elevated and glucose levels may be low. MRI scans may be helpful in occasional patients who have intracranial mass lesions.

P.1020

There have been no clinical trials to specifically direct therapy of AML involving the CNS, such that treatment strategies are largely extrapolated from experience with other malignancies. Initial intrathecal treatment usually consists of either intrathecal methotrexate or cytarabine. As with lymphoid malignancies, intrathecal therapy can be administered either by repeated lumbar puncture or an Ommaya reservoir. The dosage is reduced by about 20% when drug is delivered directly into cerebral ventricles. Treatment is usually given two or three times per week until leukemic cells have cleared and then approximately every week for 1 year. Liposomal cytarabine has the advantage that it only needs to be administered every 2 weeks initially and then monthly. Radiation therapy is reserved for refractory cases or when patients have intracranial mass lesions or cranial neuropathies.

HEMATOPOIETIC CELL TRANSPLANTATION

Hematopoietic cell transplantation (HCT) refers to the use of high-dose preparative chemotherapy followed by the

intravenous infusion of autologous or allogeneic progenitor cells. The source of transplanted cells can be bone marrow, peripheral blood, or umbilical cord blood. HCT is used primarily to treat hematologic and lymphoid cancers but occasionally also nonmalignant marrow disorders. Pretransplant preparative regimens may be myeloablative or nonmyeloablative with the goal of eradicating malignant cells. In the case of allogeneic transplantation, conditioning regimens also provide immunosuppression to prevent graft rejection. Nonmyeloablative “reduced-intensity conditioning” (RIC) regimens are used in patients who may not tolerate more intensive induction therapy. The efficacy of RIC depends in part on a graft-versus-tumor effect. Frequently used myeloablative drugs include busulfan, cyclophosphamide, and melphalan. In the treatment of lymphoma, the most common myeloablative regimen consists of combination chemotherapy with carmustine, etoposide, cytosine arabinoside, and melphalan (“BEAM”). Fludarabine is used in RIC regimens and may also be combined with lower doses of the same drugs used for myeloablation. Coadministration of total body irradiation targets sites that may not otherwise be affected by chemotherapy. Monoclonal antibodies directed at specific antigens on bone marrow cells can be radiolabeled and used to provide directed radiation therapy, which helps avoid the adverse systemic effects of total body irradiation. Conditioning regimens are invariably complicated by the development of pancytopenia within a few days.

One of the major complications of allogeneic HCT is *graft-versus-host disease* (GVHD), which becomes more common with a greater degree of disparity in HLA matching. Calcineurin inhibitors (cyclosporine and tacrolimus), in combination with either mycophenolate or methotrexate, are used in the prevention of GVHD. T-lymphocyte depletion with antithymocyte globulin is performed in high-risk cases.

In the setting of autologous HCT, peripheral blood progenitor cells are preferred over bone marrow because this approach leads to more rapid engraftment and fewer complications. With allogeneic HCT, there seems to be little difference in survival between use of peripheral progenitor cells and bone marrow. Peripheral cells are associated with more rapid engraftment but a somewhat higher rate of GVHD. Umbilical cord blood is another widely available source of progenitor cells that is increasingly used, but it is associated with a higher rate of graft failure and delayed immune reconstitution. Engraftment typically requires between 10 days and 4 weeks, during which patients are at especially high risk of bacterial infections and require repeated RBC and platelet transfusions.

Epidemiology

Neurologic complications occur in about 15% to 20% of patients within the first 3 to 4 months after HCT. If carefully sought, delirium may develop at some point in as many half of patients. The risk of CNS complications is higher with allogeneic compared with autologous HCT, especially when donors are unrelated and there is a greater degree of HLA mismatch. The most common causes of CNS complications are drug toxicity and infections. Ischemic stroke and intracranial hemorrhage are relatively unusual. Some late CNS complications may be due to disease relapse.

Pathobiology

During the initial 2 to 4 weeks after HCT, before engraftment, patients are neutropenic, resulting in a relative loss of phagocytic defenses. Chemotherapy-induced mucositis enables pathogens to translocate from the gut. Patients are therefore especially vulnerable to bacterial and fungal infections and sepsis is a common cause of nonfocal encephalopathy. Common respiratory virus (e.g., influenza) and herpes simplex virus (HSV) infections may occur throughout the post-HCT course but do not usually involve the CNS. Opportunistic viruses that reactivate in the setting of impaired cell-mediated immunity, including cytomegalovirus (CMV) and varicella-zoster virus (VZV), become a concern in the postengraftment period. Patients remain vulnerable to such infections for months. Toxoplasmosis and mycobacteria are nonviral pathogens that may reactivate. During the late postengraftment period, months to years after HCT, reactivation of Epstein-Barr virus (EBV) may induce

polyclonal B-cell proliferation, which causes posttransplant lymphoproliferative disorder, a syndrome that resembles lymphoma and may involve the CNS. Because of the concerns about infection, many HCT protocols use prophylactic antimicrobials. Fluoroquinolones (e.g., levofloxacin) are typically used as prophylaxis against bacteria. Acyclovir and fluconazole are the most common regimens used for prophylaxis and against HSV and fungal infections. Surveillance for CMV and *Aspergillus* sp. enables preemptive therapy if infection is considered to be imminent.

Clinical Manifestations, Diagnosis, and Treatment

COMPLICATIONS OF CONDITIONING DRUGS

Potential neurologic complications of drugs used in HCT conditioning are summarized in [Table 118.3](#). Several drugs, especially busulfan, have been associated with development of seizures. Some centers give prophylaxis to patients who receive busulfan. Although data to support this practice is limited, the incidence of seizures appears to be very low with prophylaxis. Because of concerns about drug interactions, clonazepam or levetiracetam are preferred over phenytoin by some clinicians. Although less common, there have also been case reports of neurotoxicity with cyclophosphamide, melphalan, fludarabine, and cytarabine, all of which may present with encephalopathy.

COMPLICATIONS OF CALCINEURIN INHIBITORS

Cyclosporine and tacrolimus are widely used in the prevention of GVHD (see [Table 118.3](#)). Posterior reversible leukoencephalopathy syndrome (PRES) is the most common serious neurologic complication of calcineurin inhibitors (see also [Chapter 43](#)). This condition is characterized by vasogenic edema that preferentially (but not exclusively) involves the posterior regions of the brain. Typical manifestations of PRES include seizures, an altered or depressed level of consciousness, and visual disturbances. The diagnosis is

P.1021

established with MRI. Substitution with another immunosuppressive drug is generally required. Other complications that have been reported include tremors and other movement disorders, optic neuropathy, pseudotumor cerebri, akinetic mutism, plexopathy, and demyelinating lesions.

TABLE 118.3 Neurologic Complications of Chemotherapeutic Drugs Used in Hematopoietic Cell Transplantation

Drug	Indication	Associated Complications
Busulfan	Conditioning	Seizures
Carboplatin	Conditioning	PRES, peripheral neuropathy, ototoxicity
Carmustine	Conditioning	Delayed encephalopathy
Cyclophosphamide	Conditioning	Transient encephalopathy
Cyclosporine	GVHD prophylaxis	PRES, seizures, movement disorders, optic neuropathy, mutism, pseudotumor cerebri,

polyneuropathy

Cytarabine	Systemic: conditioning Intrathecal: CNS prophylaxis	Seizures, cerebellar dysfunction, lymphocytic meningitis, cauda equine syndrome
Etoposide	Conditioning	PRES, peripheral neuropathy, acute dystonia
Fludarabine	Reduced intensity conditioning	Toxic leukoencephalopathy, PRES, retinal toxicity
Ifosfamide	Refractory lymphoma	Encephalopathy, seizures, movement disorders
Melphalan	Conditioning	Encephalopathy
Methotrexate	Systemic: conditioning Intrathecal: CNS prophylaxis, GVHD prophylaxis	PRES, necrotizing leukoencephalopathy, transient stroke-like syndrome (may have restricted diffusion), seizures, movement disorders, optic neuropathy
Sirolimus	GVHD prophylaxis	PRES, polyneuropathy
Tacrolimus	GVHD prophylaxis	PRES, seizures, movement disorders, optic neuropathy, mutism, polyneuropathy, hearing loss, demyelinating lesions

PRES, posterior reversible leukoencephalopathy syndrome; GVHD, graft-versus-host disease; CNS, central nervous system.

BACTERIAL INFECTIONS

Encephalopathy attributable to sepsis is a common neurologic complication in the early post-HCT period. However, bacterial infections specifically involving the CNS are unusual. Initial antibiotic coverage with sufficient dosing to reach the CNS needs to be broadly directed at both gram-positive and gram-negative organisms. *Listeria monocytogenes* is a pathogen that occurs particularly in immunosuppressed patients and requires additional coverage with high-dose ampicillin or, in penicillin-allergic patients, trimethoprim-sulfamethoxazole.

FUNGAL INFECTIONS

Candida does not have a particular predilection for the CNS, but involvement may occur in the context of disseminated disease. *Candida tropicalis* is the most likely species to be implicated. It most often causes meningitis but may also produce microabscesses. The CSF WBC count is usually elevated with either a predominance of neutrophils or leukocytes. Liposomal amphotericin B is the preferred drug because it achieves relatively high CNS concentrations and has a higher rate of success compared with other agents. It can be transitioned to fluconazole after the initial 2 weeks of therapy, but a total duration of several weeks is required, depending on the clinical and radiographic course.

Severe and prolonged neutropenia, as well as GVHD, predisposes patients to invasive *Aspergillus* infections, which most often appear early in the postengraftment period. CNS involvement may occur in the context of disseminated disease or because of local spread from sinuses and has a particular predilection for the corpus callosum. Patients usually present with seizures or focal neurologic deficits. Imaging may demonstrate multiple ring-enhancing mass lesions, sometimes with concomitant infarction. The diagnosis of invasive *Aspergillus* infections can be challenging because cultures of sputum and CSF are not always positive. A positive serum galactomannan assay has a sensitivity of about 60% to 70% and specificity for invasive disease of about 90%. The sensitivity is further increased if galactomannan can be detected in a bronchoscopy sample. When feasible, histologic assessment of biopsy material can be diagnostic. The mortality associated with CNS *Aspergillus* infections is high. Voriconazole in combination with an echinocandin, as well as surgical abscess drainage when feasible, is the preferred treatment [Level 1].¹²

VIRAL INFECTIONS

Although rare, several viruses have been reported to cause encephalitis after HCT. Human herpesvirus 6 (HHV-6) infections have been reported to occur in as many as 3% to 4% of patients undergoing allogeneic HCT, with a median posttransplant time interval of about 3 weeks. A major risk factor is the use of umbilical cord hematopoietic cells. MRI findings, if present, are most likely to involve the temporal lobes. Other viruses tend to occur later in the course. VZV reactivation is common after HCT but usually does not involve the CNS. Cases used to occur in the immediate postengraftment period. However, with use of antiviral prophylaxis, infections more often develop weeks to months later. Cases of encephalitis due to CMV, EBV, HSV, and West Nile virus have also been primarily described well after engraftment. Diagnosis of viral infections is supported by MRI findings and relevant cerebrospinal fluid polymerase chain reaction (PCR) analysis.

P.1022

Progressive multifocal leukoencephalopathy (PML) is a demyelinating condition attributable to John Cunningham (JC) virus. PML may complicate various conditions characterized by significant immune suppression. PML has been described after both allogeneic and autologous HCT with a median lag of about 11 months. Clinical manifestations include seizures and subacute onset of focal neurologic deficits, ataxia, and visual disturbances. MRI shows white matter lesions, which may show contrast enhancement. The diagnosis can be made in most cases with PCR of CSF for JC virus, which has a sensitivity of about 75% to 85% and a specificity of more than 90%. Falsely negative cases can only be diagnosed definitively with brain biopsy. There is no specific therapy for JC virus. Apart from cessation of immunosuppressive agents, drugs with theoretical action against JC virus include cidofovir and mefloquine. Mirtazapine has also been administered based on the observation that JC virus uses serotonin receptors to infect cells.

PROTOZOAL INFECTIONS

The protozoan *Toxoplasma gondii* exists in a quiescent form in some recipients of HCT and may reactivate in the postengraftment period because of impaired cell-mediated immunity. Most patients who develop invasive disease are seropositive before undergoing transplantation. The presence of moderate to severe GVHD is a risk factor. Onset of symptoms typically occurs after about 2 to 3 months. Toxoplasmosis may present with isolated CNS involvement or as part of a disseminated infection. Clinical manifestations include fever, seizures, and a depressed level of consciousness. Extracerebral manifestations may include pneumonitis or chorioretinitis. Neuroimaging usually reveals ring-enhancing lesions. A presumptive diagnosis can be based on characteristic clinical findings in patients who have positive *Toxoplasma* serology and did not receive prophylaxis. The diagnosis can be made with CSF PCR with a high specificity but variable sensitivity. Biopsy of affected brain is usually diagnostic in patients that can safely undergo the procedure. Initial therapy consists of pyrimethamine, sulfadiazine, and leucovorin for about 6 weeks.

Corticosteroids should be considered for patients with evidence of significant vasogenic edema and mass effect.

GRAFT-VERSUS-HOST DISEASE

Acute GVHD affects primarily the gastrointestinal tract, skin, liver, eyes, and lungs; neurologic involvement is uncommon. Chronic GVHD (occurring after > 100 days) involves the peripheral nervous system more often than the CNS. Conditions that have been associated with GVHD include polymyositis, immune-mediated polyneuropathy comparable to Guillain-Barré syndrome and myasthenia gravis. CNS conditions that have been associated with GVHD include vasculitis, acute demyelinating encephalomyelitis, and aseptic meningitis. In most cases, it is unclear to what degree the GVHD is causative, and treatment does not differ from idiopathic cases.

PLATELET DISORDERS

THROMBOCYTOPENIA

After formation in the bone marrow from megakaryocytes, platelets circulate for 7 to 10 days. Thrombocytopenia is defined as a platelet count less than 150,000/ μ L. The risk of spontaneous hemorrhage, including intracranial hemorrhage, increases especially below 10,000 to 20,000/ μ L. A review of reported cases of ICH among children in the United States with immune thrombocytopenic purpura (ITP) found that 90% had counts less than 20,000/ μ L and 75% had counts less than 10,000/ μ L. Excessive bleeding during surgery may be encountered below 50,000/ μ L. Thrombocytopenia may occur because of reduced production, increased destruction or consumption, and splenic sequestration ([Figs. 118.3 and 118.4](#)).

FIGURE 118.3 CT scan of a 19-year-old man who presented with acute promyelocytic leukemia, complicated by disseminated intravascular coagulation and severe thrombocytopenia, demonstrating multiple areas of hyperdensity consistent with intracerebral hemorrhage.

Prophylactic platelet transfusions are generally not recommended unless the platelet count reaches 10,000/ μL . Transfusion strategies that are even more restrictive than this have been associated with a higher risk of spontaneous bleeding [Level 1].^{13,14} The minimum platelet count required before performing lumbar puncture is not well defined but is recommended to be greater than 40,000 to 50,000/ μL , particularly because the consequences of iatrogenic hemorrhage could be catastrophic. For neurosurgical procedures, counts greater than 80,000 to 100,000/ μL have been suggested. A similar target seems reasonable when spontaneous ICH occurs in thrombocytopenic patients, especially in the first few hours. The expected increment in the platelet concentration per unit transfused is about 10,000/ μL . More frequent administration of lower doses may be a more efficient approach, with less overall need for allogeneic platelets than less frequent higher doses [Level 1].¹⁵ Certain causes of thrombocytopenia have other important neurologic effects and merit further discussion.

Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

Thrombotic thrombocytopenic purpura (TTP) is a clinical syndrome characterized by the presence of microangiopathic hemolytic anemia, thrombocytopenia, and various degrees of organ failure in the absence of another recognized cause (e.g., malignant hypertension or scleroderma). TTP and hemolytic uremic syndrome (HUS) are likely to represent different spectrums of the same disease, with the former classically having neurologic manifestations and the latter presenting with renal involvement. The comprehensive term *thrombotic thrombocytopenic purpura-hemolytic uremic syndrome* (TTP-HUS) is increasingly used. The classic “pentad” consisting of hemolysis, thrombocytopenia, fever, neurologic manifestations, and kidney failure is not required for a diagnosis of TTP-HUS and is actually not present in the majority of cases. It is possible that, over time, TTP-HUS has been recognized and treated earlier, such that

P.1023

progression to fulminant disease has become less common. Some patients with TTP-HUS have reduced activity of ADAMTS13, a metalloprotease responsible for cleaving von Willebrand factor (vWF). About half of patients with TTP-HUS have neurologic involvement.

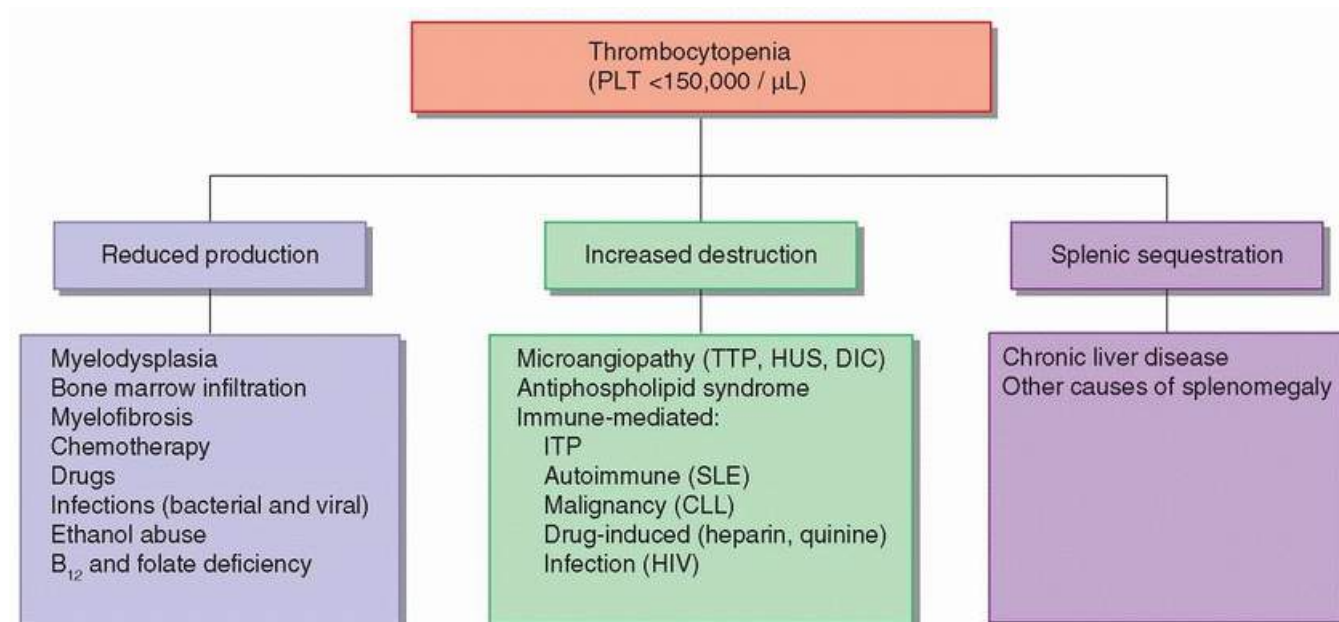

FIGURE 118.4 Causes of thrombocytopenia. PLT, platelet; TTP, thrombotic thrombocytopenic purpura; HUS, hemolytic uremic syndrome; DIC, disseminated intravascular coagulation; ITP, immune thrombocytopenic purpura; SLE, systemic lupus erythematosus; CLL, chronic lymphocytic leukemia.

EPIDEMIOLOGY

The incidence of TTP-HUS is about 4 to 11 cases per million population per year. About 40% of cases are

idiopathic; about a third occur in the setting of various autoimmune, infectious, or malignant disorders; and the remainder is associated with various drugs, HCT, or pregnancy. A form of TTP-HUS that is particularly common in children follows diarrheal illness caused by toxin-producing enterohemorrhagic *Escherichia coli* (EHEC).

PATHOBIOLOGY

TTP is characterized pathologically by the formation of platelet-rich thrombi in arterioles and capillaries. There is also thickening of the intima, hypertrophy of underlying smooth muscle, and deposition of fibrin. Many idiopathic cases of TTP-HUS are associated with severe deficiency of ADAMTS13 activity (< 10% of normal). Reduced activity is commonly related to an inhibitory antibody. The consequent accumulation vWF multimer promotes platelet activation and aggregation. Other mechanisms that have been implicated include relative deficiency of vascular endothelial growth factor, increased amounts of plasminogen activator inhibitor type 1, and dysregulation of complement. In patients with TTP-HUS complicating EHEC diarrheal illness, toxins penetrate into the circulation bound to neutrophils and then target endothelial cells. Although kidney involvement is common with this disorder, it is not universal and some patients present with neurologic manifestations.

Some chemotherapeutic agents (e.g., cisplatin) and immunosuppressive drugs (e.g., cyclosporine) produce direct endothelial toxicity that resembles TTP-HUS. The most common drug to be implicated in causing TTP-HUS is quinine; in this case, the pathogenesis appears to be antibody-mediated. The mechanism of TTP-HUS that is occasionally associated with use of the antiplatelet agent clopidogrel is not well understood. Although the pathogenesis of TTP-HUS occurring in pregnancy is not clear, it has been noted that ADAMTS13 levels decline progressively beginning in the second trimester, which may increase vulnerability.

Autopsy specimens show similar changes in cerebral microvasculature as in other organs. Some patients develop acute ischemic strokes but these do not usually involve large vascular territories. In a series of patients with TTP who had neurologic manifestations and underwent brain MRI scans, about a third had small ischemic strokes. When angiography is performed, large-vessel occlusion is rarely observed. By far the most common radiographic findings are those of PRES, which was present in almost half of cases. As with other causes of PRES, the mechanism likely involves vasogenic edema induced by endothelial damage and disruption of the blood-brain barrier. When clinicians observe hypodensities on CT scans, they should not necessarily conclude that they are infarcts or that they are irreversible.

CLINICAL MANIFESTATIONS

TTP-HUS is invariably characterized by the presence hemolysis and thrombocytopenia. Hemolysis results in increased concentrations of serum indirect bilirubin and LDH and reductions in serum haptoglobin. Levels of LDH are often very high and can be used as a surrogate for response to therapy. RBCs become fragmented by fibrin in the microcirculation, resulting in the formation of schistocytes, which can be visualized on peripheral blood smears. Thrombocytopenia ranges from profound to relatively mild. In patients with renal involvement, there may be some hematuria and proteinuria, although it is usually not as severe as in patients with glomerulonephritis. A minority of patients requires renal replacement therapy. The most common neurologic manifestation is altered mental status occurring in about one-third of all patients. Seizures occur in about 15% to 20%, whereas coma and strokes occur in about 10%. When PRES occurs in its most characteristic location, cortical blindness may ensue.

DIAGNOSIS

In patients who are anemic and thrombocytopenic, crucial diagnostic tests to assess for TTP-HUS are a peripheral blood smear, serum LDH, and bilirubin. Sepsis with disseminated intravascular coagulation (DIC) produces some of the same findings as TTP-HUS but

usually also causes prolongation of the prothrombin time (PT) and partial thromboplastin time (PTT) and a reduction in serum fibrinogen levels. Measurement of ADAMTS13 is recommended. A low level of ADAMTS13 activity (< 10%) is a specific finding that essentially confirms the diagnosis of TTP-HUS. On the other hand, patients with TTP-HUS may not have low ADAMTS13 activity, and intermediate (10% to 50%) or normal (> 50%) values should not be used as criteria to stop therapy. Patients who present with higher ADAMTS13 activity do, however, appear less likely to relapse after initial therapy.

If patients have acute kidney injury that does not respond readily to fluid resuscitation, a kidney biopsy can be considered and may be diagnostic. Potential causes of TTP-HUS should be sought. If there is a history of diarrhea, stool should be assessed for the presence of toxin-producing bacteria, especially *E. coli* O157:H7. In women of appropriate age, pregnancy should be ruled out. Clinicians should determine whether patients have been taking various drugs that have been associated with TTP-HUS.

TREATMENT

In original descriptions of TTP-HUS, mortality was very high. Outcomes have improved markedly with use of plasma exchange (PLEX), which has been demonstrated to be efficacious in randomized controlled trials [Level 1].¹⁶ It is thought that one of the main mechanisms of PLEX is the removal of inhibitory antibodies targeting ADAMTS13 and concomitant replacement with plasma. However, the efficacy of PLEX is not necessarily limited to patients who are shown to be ADAMTS13 deficient. It is therefore reasonable to initiate PLEX even before the diagnosis is entirely certain. The benefit of PLEX is less clear in TTP-HUS associated with other conditions compared with idiopathic cases. PLEX is usually performed daily until platelet counts have normalized and evidence of hemolysis (high LDH and presence of schistocytes) is abating. Because of the presumed autoimmune etiology of idiopathic TTP-HUS, some experts recommend treatment with corticosteroids. Preliminary data suggest rituximab may be beneficial in refractory cases. When TTP-HUS occurs in pregnancy, it may be difficult to distinguish from other obstetrical syndromes, including preeclampsia and HELLP syndrome, such that early delivery should be considered. PLEX is safe during pregnancy and should not be withheld.

Treatment of neurologic complications is largely supportive. Usual measures aimed at preventing and treating cerebral edema should be implemented. Neurologic involvement in TTP-HUS is a clear risk factor for failure to respond to therapy and worse outcomes. Longer term follow-up of patients who survived TTP-HUS reveals that many have persistent neurocognitive deficits. Future research should investigate whether modifications in the care of patients with TTP-HUS might prevent such deficits.

TABLE 118.4 The 4T Score in the Diagnosis of Heparin-Induced Thrombocytopenia

Variable	2 Points	1 Point	0 Point
Thrombocytopenia severity	Platelet fall >50% and platelet nadir ≥ 20	Platelet fall 30%-50% or platelet nadir 10-19	Platelet fall <30% or platelet nadir <10
Timing of platelet count reduction	Clear onset day 5-10 or ≤ 1 day with prior heparin exposure	Consistent with day 5-10 fall but not clear; onset after day 10; or fall ≤ 1 day with prior heparin 30-	Platelet fall <4 days without

	past 30 days	100 days ago	recent exposure
Thrombosis	New thrombosis, skin necrosis	Progressive or recurrent thrombosis	None
Thrombocytopenia alternative causes	None apparent	Possible	Definite

Score of 0 to 3: <1% chance of HIT; score of 4 to 5: 10% to 15% chance of HIT; score of 6 to 8: >50% chance of HIT.

Data from Cuker A, Gimotty PA, Crowther MA, et al. Predictive value of the 4Ts scoring system for heparin-induced thrombocytopenia: a systematic review and meta-analysis. *Blood*. 2012;120:4160-4167.

Heparin-Induced Thrombocytopenia

Heparin is one of the most common medications known to induce thrombocytopenia. Immune-mediated heparin-induced thrombocytopenia (HIT) occurs after at least 5 days of heparin exposure and is associated with a high risk of thrombotic (rather than hemorrhagic) complications, including stroke. The incidence is approximately 2% to 3% with more than 5 days of heparin exposure. The risk is higher with unfractionated rather than low molecular weight heparin in surgical patients and in women. Onset beyond 2 weeks of heparin exposure is relatively uncommon.

PATHOBIOLOGY AND CLINICAL FEATURES

HIT is due to the formation of antibodies targeting the heparinplatelet factor 4 (PF4) complex. When antibodies bind to this complex on platelet surfaces, they induce platelet activation and aggregation, which in turn promotes thrombin generation. Consumption and clearance of activated platelets causes the platelet concentration to fall. The risk of thrombosis over the 4 weeks following the diagnosis of HIT is greater than 50%. Most patients with HIT have relatively mild thrombocytopenia (rarely <20,000/ μ L). The development of lower extremity deep venous thrombosis (DVT) is the most common complication of HIT, but arterial thrombosis can occur. Neurologic complications, primarily arterial ischemic strokes and to a lesser degree cerebral venous thrombosis, have been reported to occur in 3% to 9% of patients with established HIT.

DIAGNOSIS

A clinical scoring system, the 4T score, can be used to assess the pretest probability that a patient could have HIT (Table 118.4). Patients are assigned 0 to 2 points for each of four variables: the degree of thrombocytopenia, the timing of the drop in platelets, the development of thrombosis, and the presence of alternative causes of thrombocytopenia. A score of 0 to 3 indicates a low risk of HIT and is justification to not pursue additional testing. A score of 4 to 5 suggests an intermediate risk and 6 to 8 indicates a

P.1025

high risk. Heparin-PF4 complexes can be detected with enzymelinked immunosorbent assay (ELISA) with a high sensitivity but somewhat lower specificity. The gold standard test, with sensitivity and specificity greater than 95%, is the C14-serotonin release assay, which is only performed at specialized centers.

TREATMENT

When HIT is suspected, all heparin must be discontinued, including that used for DVT prophylaxis or to flush venous or arterial catheters. If the suspicion for HIT is at least moderate, the risk of thrombosis is sufficiently high to justify therapeutic anticoagulation with an alternative drug that does not cross-react with heparin. Appropriate alternatives include the direct thrombin inhibitors argatroban, bivalirudin, or danaparoid. Successful use of the pentasaccharide fondaparinux has been described in a few patients, but this drug has also been reported to induce HIT and is therefore currently not preferred. Treatment with warfarin is recommended after the platelet count has risen to more than 150,000/ μL . Warfarin should overlap with the thrombin-specific inhibitor for at least 5 days and should then be continued with a target international normalized ratio (INR) of 2 to 3 for 3 months in the setting of thrombosis and 4 to 6 weeks for HIT without thrombosis.

IMPAIRED PLATELET FUNCTION

Platelet function may be impaired by numerous genetic disorders and acquired medical conditions, including uremia, plasma cell dyscrasias, advanced liver disease, and myeloproliferative disorders. More often, platelet dysfunction is iatrogenic from antiplatelet drugs used in the prevention and treatment of cardiovascular disease.

Many patients that develop spontaneous ICH or subdural hematomas are receiving antiplatelet drugs. The degree of hematoma expansion over the initial few hours after intracranial hemorrhage is a crucial predictor of outcome. Although literature is conflicting, numerous studies have suggested that the degree of hematoma expansion and the chance of poor outcomes are greater among patients receiving antiplatelet drugs. Aspirin (ASA) is the most common agent and works by inhibiting the effects of cyclooxygenase-1 (COX-1) in converting arachidonic acid to prostaglandin H_2 , thereby reducing levels of thromboxane A_2 , an inducer of platelet aggregation. The antiplatelet effects of ASA are irreversible and last for the life span of the platelet. Clopidogrel is a thienopyridine drug, which works by permanently modifying platelet ADP receptors, thereby inhibiting platelet aggregation. The addition of clopidogrel to ASA is particularly important for patients who have undergone percutaneous coronary interventions (PCI). Prasugrel and ticagrelor are newer antiplatelet drugs that work on the same receptor as clopidogrel and may have a greater degree of antiplatelet effect and in turn a slightly higher risk of bleeding.

Newer assays enable point-of-care assessment of platelet function, thereby allowing the effects of antiplatelet drugs to be rapidly measured. This information could potentially be used in therapeutic decision making. Platelet transfusions can improve platelet activity and may reduce hematoma expansion. Similarly, desmopressin improves platelet activity by promoting the release of vWF from endothelium. However, whether platelet transfusions or desmopressin improve outcomes in acute ICH requires further study.

THROMBOCYTOSIS

Thrombocytosis refers to an elevation in the concentration of platelets and is usually defined using a threshold of 450,000/ μL . Thrombocytosis may be “reactive” in response to a systemic condition or may be a manifestation of ET or another myeloproliferative disorder (“autonomous thrombocytosis”). A reactive etiology (e.g., inflammation, tissue damage, anemia) is much more common, even when thrombocytosis is extreme ($>1,000,000/\mu\text{L}$). Clinical manifestations, including vasomotor symptoms (e.g., headache and visual disturbances) as well as thrombotic or hemorrhagic complications, occur with autonomous thrombocytosis and are uncommon with reactive thrombocytosis.

Essential Thrombocythemia

ET is a clonal myeloproliferative disorder characterized by an elevated platelet count. There is no specific diagnostic test for ET and excluding reactive thrombocytosis and other myeloproliferative disorders makes the diagnosis. ET is associated with an increased risk of thrombosis, including stroke. The median age of patients diagnosed with ET is about 60 years and it is more common in women.

PATHOBIOLOGY

Numerous factors contribute an increased risk of thrombosis, including activation of platelets, resistance to the effects of endogenous coagulation inhibitors (protein C and S), increased levels of thrombomodulin, and activation of leukocytes. Risk factors for thrombosis include a previous history of thrombotic events, the presence of the JAK2 mutation, leukocytosis, and other cardiovascular risk factors.

CLINICAL MANIFESTATIONS

Many patients are asymptomatic at the time of diagnosis. The most common complaints are vasomotor symptoms and erythromelalgia. The risk of thrombosis is not directly related to the degree of platelet elevation. The risk of thrombotic events over 15 years is about 20% and stroke develops in about 10% to 15% of patients. A small proportion of patients eventually develop AML or myelofibrosis.

DIAGNOSIS

Bone marrow aspirates and biopsies demonstrate hyperplasia of megakaryocytes. Cytogenetic studies reveal absence of the Philadelphia chromosome (characteristic of chronic myelogenous leukemia). About half of patients with ET will have the JAK2 mutation. To be diagnosed with ET, there should be no evidence of myelofibrosis and a normal RBC mass.

TREATMENT

Patients at low risk of thrombosis include those younger than 60 years, with no previous events and a platelet count less than 1,000,000/ μ L. These patients do not necessarily require treatment. Vasomotor symptoms and erythromelalgia often respond to treatment with low-dose ASA. Patients with previous thrombosis and those who are older than 60 years are generally treated with a combination of ASA and hydroxyurea, with an initial dose of 15 mg/kg/day, adjusted to achieve a target platelet count less than 600,000/ μ L [Level 1].¹⁷ Achieving counts less than 400,000/ μ L may further reduce the risk of subsequent thrombosis.

COAGULATION DISTURBANCES

Coagulation disturbances develop when there is insufficient production, increased consumption, or inhibition of clotting factors. Apart from rare congenital deficiencies of specific clotting factors

P.1026

(e.g., factor VIII with hemophilia A), reduced production of clotting factors occurs because of liver disease, vitamin K deficiency, or the use of the vitamin K antagonist warfarin. Other anticoagulants work primarily by inhibiting thrombin. Consumption of clotting factors occurs with DIC and massive hemorrhage. Coagulation disturbances are of interest to neurologists and neurosurgeons because of their association with intracranial hemorrhage.

NORMAL COAGULATION

When endothelium is damaged, there is immediate activation and aggregation of platelets. Apart from forming an initial barrier to bleeding, the platelet plug also provides the phospholipid template upon which coagulation can

proceed. Tissue factor is a membrane protein that is expressed by subendothelial cells and interacts with circulating factor VII, which in turn activates factor X. This process is further amplified by factors VIII and IX. Activated factor X, together with factor V, converts prothrombin to thrombin, which in turn promotes conversion of fibrinogen to fibrin. Thrombin also has a positive feedback effect, whereby it further activates platelets, factor VIII, and factor XI (Fig. 118.5).

To avoid unregulated clotting, there exist a number of natural anticoagulant mechanisms. Antithrombin is a protease inhibitor that blocks the activity of factor X. Thrombomodulin is protein on the surface of endothelial cells that inhibits thrombin and activates protein C, which together with protein S inactivates factors V and VIII. The endothelial enzyme tissue plasminogen activator (tPA) stimulates the conversion of plasminogen to plasmin, which is responsible for cleaving cross-lined fibrin.

IMPAIRED COAGULATION

Warfarin-Induced Intracranial Hemorrhage

Warfarin is widely used to reduce the risk of thromboembolic complications in patients with atrial fibrillation, to prevent valve thrombosis in patients with mechanical heart valves, and as treatment of venous thromboembolism. Warfarin antagonizes the formation of vitamin K-dependent clotting factors (II, VII, IX, and X) in the liver. Its effect on clotting is measured by the PT and the measurement is standardized using the INR. For most conditions, the target INR is 2 to 3. The risk of intracranial hemorrhage with warfarin has been in the range of 1% in clinical trials, but it is somewhat higher in usual practice, where patients may not be as carefully selected and the INR not as carefully monitored. Warfarin use has traditionally accounted for as many as a quarter of spontaneous ICH cases at some centers, although this proportion will decrease with increasing use of new oral anticoagulants.

FIGURE 118.5 Traditional model of the coagulation cascade with extrinsic (*left*) and intrinsic (*right*) pathways. Although this laboratory model is useful to understand the factors which may influence coagulation times (PT, *left*; PTT, *right*), it is not a physiologic model that describes exactly how coagulation functions *in vivo*. HMWK, high molecular weight kininogen; PK, prekallikrein; PL, phospholipid.

Hematoma expansion is more pronounced and outcomes worse among patients with warfarin-induced ICH. Although fresh frozen plasma (FFP) reverses the effects of warfarin, the time required for cross-matching, thawing, and administering 20 to 40 mL/kg of fluid results in major delays. The INR can be corrected more rapidly with the use of four-factor prothrombin complex concentrate (PCC), which contains vitamin K-dependent clotting factors in a relatively small volume of fluid that can be administered over a few minutes [Level 1].¹⁸ Several commercially available three-factor PCC products lack factor VII and do not appear to be as effective in normalizing the INR. The 2010 iteration of American Heart Association guidelines recommends the use of either FFP or PCC, whereas the 2012 American College of Chest Physicians guidelines recommend the use of four-factor PCC. The optimal dose of PCC remains unclear but is generally recommended to include 25 to 50 IU/kg of factor IX_a activity. Vitamin K should also be administered either enterally or intravenously.

Reversal of Novel Oral Anticoagulants

Several novel oral anticoagulants (NOACs) have been demonstrated to be equally or more efficacious than warfarin in the prevention of stroke among patients with atrial fibrillation, with a comparable or lower risk of intracranial hemorrhage. Dabigatran is a direct thrombin inhibitor, whereas rivaroxaban, apixaban, and edoxaban are all factor X_a inhibitors. The PTT and INR do not measure the effects of these agents. Measurement of the thrombin time (TT) or ecarin clotting time (ECT), if available, provides a better reflection of the anticoagulant effect of dabigatran. Anti-factor X_a activity can be measured to assess the effects of X_a inhibitors.

There are currently no specific reversing agents available when use of newer oral anticoagulants is complicated by intracranial hemorrhage. Because these drugs do not reduce levels of clotting

P.1027

factors, FFP is ineffective at reversing the coagulopathy. In contrast, standard PCC, activated PCC (factor VIII inhibitor bypassing activity), and recombinant factor VIIa may all have some limited efficacy. Despite the inability to reverse newer oral anticoagulants, outcomes do not appear to be worse than with warfarin-induced ICH. Hemodialysis can be used to rapidly reduce levels of dabigatran, but it is unlikely that this can be accomplished in a time frame that would have a major impact in preventing hematoma expansion in ICH.

Bleeding Associated with Thrombolytic Therapy

When tPA is administered to treat acute ischemic stroke, the risk of intracranial hemorrhage is in the range of 3% to 7%. This rate is 1% to 2% when tPA is used for other conditions, such as myocardial infarction or pulmonary embolism. Apart from discontinuation of the infusion, patients should receive 10 units of cryoprecipitate to increase fibrinogen levels because there is some evidence that hemorrhagic infarction after tPA is associated with a systemic consumption coagulopathy and fibrinogen depletion.

HYPERCOAGULABLE STATES

Familial Thrombophilia

The possibility of thrombophilia should be considered, especially when stroke occurs in children and young adults. It should also be pursued when there are recurrent thromboembolic events or when there is a strong family history. Several familial conditions cause deficiencies or dysfunction of naturally occurring anticoagulants, including protein S, protein C, antithrombin III, and factor V. A mutation of prothrombin (factor II) has been identified as a risk factor for both ischemic strokes and cerebral venous thrombosis, especially with concomitant use of oral contraceptives.

Antiphospholipid Antibody Syndrome

The antiphospholipid syndrome (APLS) is a condition characterized by arterial or venous thrombosis and/or

pregnancy morbidity, occurring in combination with persistently detectable antiphospholipid (APL) antibodies. It is of interest to neurologists primarily because it predisposes patients to ischemic stroke and cerebral venous thrombosis and is also associated with neuropsychiatric manifestations and cognitive decline.

EPIDEMIOLOGY

Approximately half of patients have “primary” APLS, whereas the remainder has either systemic lupus erythematosus (SLE) or another connective tissue disorder. APLS is more common in women and has a mean age at diagnosis of 40 to 45 years. Ischemic strokes occur in 10% to 20% and TIAs in about 5% to 15% of patients meeting established criteria for APLS.

PATHOBIOLOGY

There are several mechanisms whereby APL antibodies may contribute to an increased risk of thrombosis, including interference with natural anticoagulant mechanisms (e.g., inhibition of protein C and antithrombin III activity), activation of platelets and endothelial cells, and triggering of the complement cascade. Some cases of ischemic stroke in APLS develop because of in situ thrombosis, whereas others are cardioembolic. Valvular cardiac abnormalities that can be detected by transesophageal echocardiography range from thickening of valve leaflets to the development of frank vegetations (nonbacterial endocarditis). The mitral valve is affected more often than the aortic valve. Spontaneous echo contrast is also sometimes found in the left atrium, but a definitive association with stroke risk has not been established.

CLINICAL MANIFESTATIONS

Prospective studies have shown that APL antibodies can be detected in a sizable proportion of patients diagnosed with ischemic strokes. However, in some cases, the antibodies are only transiently and slightly elevated and therefore not consistent with true APLS. Studies are somewhat conflicting regarding the question of whether the presence of detectable APL antibodies purports an increased risk of subsequent stroke. The association with stroke appears to be strongest and most definitive in young women and when more than one type of APL antibody is elevated.

Venous thrombosis is more common than arterial thrombosis with APLS. The possibility of APLS should always be considered in patients presenting with idiopathic cerebral venous thrombosis. A significant proportion of patients with APLS develop cognitive deficits even without previously diagnosed strokes. The specific mechanism is not well understood, although MRI scans commonly reveal white matter disease. Apart from pregnancy loss and thrombosis, APLS can also present in some cases with microangiopathy, similar to TTP-HUS. Catastrophic APLS refers to a small subset of patients who develop multiorgan failure as a result of widespread thrombosis; this occurs in less than 1% of patients.

DIAGNOSIS

APLS should be considered in the setting of idiopathic episodes of thrombosis, recurrent pregnancy loss, unexplained thrombocytopenia or abnormal PTT, and thrombotic microangiopathy. APL antibody titers should not be routinely assessed in all patients with ischemic strokes. Diagnostic workup for APLS consists of ELISA testing for IgG and IgM anticardiolipin and anti- α 2-glycoprotein antibodies, as well as testing for a lupus anticoagulant. If positive, these assays should be repeated after at least 12 weeks for confirmation. Criteria for catastrophic APS have been proposed and include a history of APLS, thrombosis in three or more organ systems within a week, biopsy confirmation of microthrombosis, and exclusion of other causes of thrombosis. Patients are considered to have definite catastrophic APLS if all four criteria are met. Patients have probable APLS if there are only two organs involved, if the only missing criterion is histopathology, or if the time frame of recurrent thrombosis exceeds 1 week but is less than 1 month.

TREATMENT

Optimal treatment of stroke in the context of APLS is somewhat controversial. American Stroke Association guidelines state that antiplatelet drugs remain appropriate treatment for patients with cryptogenic ischemic stroke or TIA in whom APL antibodies are detected (class 2b, level of evidence B). The rationale for this recommendation is that the largest prospective series have not demonstrated a difference in the rate of subsequent thrombotic events based on whether or not APL antibodies are present. On the other hand, the guidelines also state that oral anticoagulation is appropriate therapy for patients in whom a diagnosis of APLS is confirmed, which would be the case for any patient with stroke in whom repeat antibody testing after 12 weeks is confirmatory. In several retrospective series of confirmed APLS, treatment with aspirin had limited efficacy.

Despite availability of newer oral anticoagulants, most experience treating APLS has been with warfarin. The goal INR

P.1028

is 2 to 3. Although some older literature advocated for more intensive anticoagulation (INR 3 to 4), subsequent clinical trials did not demonstrate any advantage to justify the higher risk of hemorrhage [Level 1].^{19,20} For patients with thrombosis in the setting of APS, indefinite anticoagulation is recommended. For patients with other reasons for a thrombotic event, in whom the elevation in APL antibody titers is mild or transient, cessation of therapy after a few months can be considered.

For patients with APL antibodies and risk factors for stroke, it is reasonable to administer antiplatelet drugs as primary prophylaxis. Antiplatelet therapy is also recommended for patients with APL antibodies and neuropsychiatric manifestations but no clear evidence of a stroke. There are no randomized trials specifically in patients meeting criteria for catastrophic APLS. Retrospective series suggest that mortality may be lower when patients are treated not only with anticoagulation but also with corticosteroids and PLEX.

Hepatic Disease and the Brain

Charles L. Francoeur

Stephan A. Mayer

INTRODUCTION

Neurologic manifestations of liver disease have been recognized for centuries. The liver is indispensable in its functions of synthesis, metabolism, and detoxification, and its dysfunction can cause symptoms ranging from subtle neuropsychiatric finding to rapid death. Tremendous advances in our understanding of the pathophysiology and in available treatments now allow for better outcomes. In this chapter, we will focus on two distinct clinical presentations of hepatic disease: hepatic encephalopathy (HE) associated with chronic cirrhotic liver disease (CLD) and the syndrome of encephalopathy and brain edema caused by fulminant acute liver failure (ALF).

HE associated with cirrhosis is a neuropsychiatric syndrome ranging from barely detectable changes to profound coma. It often presents in an episodic and recurrent fashion, can be precipitated by extrinsic factors, and is graded according to the West Haven Scale (Table 119.1). As a general rule, the severity of the encephalopathy is proportional to the underlying severity of liver disease. ALF, on the other hand, is a less common but highly lethal entity. Core components include the acute onset of hepatocellular dysfunction, which triggers a different set of complications dominated by cerebral edema with intracranial hypertension, unregulated systemic inflammation, and multisystem organ failure.

TABLE 119.1 West Haven Hepatic Encephalopathy Grading Scale

Grade	Description
Minimal	<ul style="list-style-type: none"> • Psychometric or neuropsychological alterations of tests exploring psychomotor speed/executive functions or neurophysiologic alterations without clinical evidence of mental change
1	<ul style="list-style-type: none"> • Trivial lack of awareness • Shortened attention span • Impaired performance of addition • Euphoria or anxiety
2	<ul style="list-style-type: none"> • Lethargy or apathy • Minimal disorientation for time or place • Subtle personality change • Inappropriate behavior • Impaired performance of subtraction
3	<ul style="list-style-type: none"> • Somnolence to semistupor, responsive to verbal stimuli • Confusion

4

- Coma (unresponsive to verbal or noxious stimuli)

CIRRHOSIS AND HEPATIC ENCEPHALOPATHY

EPIDEMIOLOGY

In 2013, chronic liver disease was the 12th leading cause of death in the United States accounting for more than 36,000 deaths and over 100,000 hospitalizations. Those figures are probably an underestimate and the prevalence is steadily increasing. Hepatitis C patients, typically born between 1945 and 1965, are contributing to a large number of new cases and the obesity epidemic accounts for an increase in nonalcoholic fatty liver disease.

The less severe form of neurologic impairment, minimal hepatic encephalopathy (MHE), afflicts between 60% and 80% of cirrhotic patients. Often qualified of “subclinical,” MHE is nonetheless a tremendous social burden with the majority of patients being unfit to drive and half of them unable to keep a permanent job.

Overt hepatic encephalopathy occurs in 30% to 45% of cirrhotic patients. It is responsible for the bulk of hospitalization days attributed to cirrhosis and its complications. Depending on the time course, it is subdivided into episodic, recurrent (6 months or less between episodes), or persistent (behavioral alterations that are always present).

PATHOBIOLOGY

Causes of chronic liver damage are numerous ([Table 119.2](#)), and the final common pathway is cirrhosis defined by parenchymal fibrosis with hepatic architecture distortion and the formation of regenerative nodules. The numerous associated complications are related to a loss of synthetic and metabolic functions, relative immunosuppression, and portal hypertension often associated to portosystemic shunting.

TABLE 119.2 Causes off Cirrhosis

- | | |
|---|---|
| • Alcoholic Liver Disease | • Wilson Disease |
| • Chronic viral hepatitis (hepatitis B and C) | • α 1-Antitrypsin deficiency |
| • Hemochromatosis | • Polycystic liver disease |
| • Nonalcoholic fatty liver disease | • Veno-occlusive disease (including Budd-Chiari syndrome) |
| • Autoimmune hepatitis | • Infections (e.g., brucellosis, syphilis, echinococcosis, schistosomiasis) |
| • Primary and secondary biliary cirrhosis | • Medication (e.g., isoniazid, methotrexate) |

- Primary sclerosing cholangitis
- Celiac disease

Most of the existing evidence points to ammonia (NH_3) as the main culprit behind HE. It is generated from glutamine by the enterocytes and from catabolism of nitrogenous products (proteins and urea) by colonic bacteria. Detoxification normally takes place in the liver through the conversion of NH_3 to urea and glutamine basically reversing what took place in the digestive tract. Cirrhosis and portosystemic shunting bypasses this process, allowing systemic levels of NH_3 to rise, which easily crosses the blood-brain barrier by diffusion and ion channels. Once in the brain, NH_3 is taken up by astrocytes, where it triggers oxidative stress, increases intracellular calcium, induces mitochondrial dysfunction, and activates NF- κ B and an inflammatory response. Some data suggest that severity of HE correlates more with inflammatory indices than with NH_3 levels. Many other molecules have been implicated in the pathobiology of HE, such as neurosteroids. Synthesized by astrocytes and microglia, they appear to upmodulate the α -aminobutyric acid (GABA)-A receptors leading to the clinically obvious increased GABA-ergic tone (depression of central nervous system [CNS] function) seen in HE.

CLINICAL FEATURES

Cirrhosis

Compensated cirrhotic patients may be asymptomatic, but eventually, most will develop one of the myriad of possible clinical manifestations as the disease progresses (Fig. 119.1). They may report nonspecific symptoms like anorexia, weight loss, fatigue, and weakness. They often have a low blood pressure, and they may present jaundice, pruritus, severe muscle cramps, or abdominal distention from ascites.

Classically, cirrhotic patients are classified according to the Child-Turcotte-Pugh score. Designed 30 years ago to predict outcome after surgery for portal hypertension (Table 119.3) (<http://www.mdcalc.com/child-pugh-score-for-cirrhosis-mortality>), it is now used to grade clinical severity and follow the evolution of most patients. Alternatively, the Model for End-Stage Liver Disease (MELD) score evaluates serum creatinine, bilirubin, and international normalized ratio (INR) to predict 3-month mortality following transjugular intrahepatic portosystemic shunt (TIPS) procedures (<http://www.mdcalc.com/meld-score-model-for-endstage-liver-disease-12-and-older/>). The MELD score is currently used to prioritize candidates for liver transplantation scaled from 6 (less ill) to 40 (gravely ill).

FIGURE 119.1 Common complications of cirrhosis. GI, gastrointestinal.

Minimal Hepatic Encephalopathy

Patients with MHE, by definition, have no clinically detectable abnormalities at the bedside but manifest clear deficits on psychometric testing. They usually reveal impairment of vigilance, alertness and orientation, executive functions, working memory, learning processes, visuospatial coordination, and reaction time. When looked at closely, daily functioning is usually impaired in all spheres. They have a higher risk of car accidents with less than 20% of them fit to drive. Verbal ability is characteristically unimpaired.

Overt Hepatic Encephalopathy

Overt hepatic encephalopathy (OHE) can manifest itself from subtle clinical signs to profound coma. As it sets in, one of the earliest manifestations is usually a change in the sleep pattern (usually hypersomnia). Once it progresses, behavioral changes such as apathy, anxiety, and irritability appear. Attention span diminishes and short-term memory becomes impaired. Patients sometimes suffer from visual perception disturbances, both as a result of cortical and retinal dysfunction, with visual agnosia, macropsia, spatial disorientation, and problems with visuospatial construction. Visual hallucinations can occur. Neuromuscular impairments include ataxia, dysarthria, hyperreflexia, and extensor plantar responses. Asterixis, although not pathognomonic, was first described in HE patients. This “flapping tremor” is a negative myoclonus characterized by brief interruptions of sustained voluntary muscle contractions causing loss of postural tone. It is usually bilateral, nonrhythmic, and with a frequency of 3 to 5 Hz. It can be elicited by hyperextension of the wrists but is also seen in the feet, tongue, or eyelids. Parkinsonian features are at times prominent with tremor, rigidity, bradykinesia, hypomimia, slowness of speech, and monotony. Focal deficits have been described but are rare. As patients deteriorate, the most striking feature is the mental status change from lethargy to stupor and coma. At the point of coma, most patients are hyperventilating and have loss of deep tendon reflexes. Seizures are unusual. Mental status and motor changes

do not always progress in a synchronized fashion.

Hepatic Myelopathy

Another well-described long-term neurologic complication of cirrhosis is hepatic myelopathy (HM). It is characterized by severe spastic paraparesis with minimal sensory involvement. Spasticity

P.1032

and weakness usually affect the lower limbs more severely and are progressive. It is caused by symmetric demyelination of the lateral pyramidal tracts. It does not respond to NH₃-lowering therapy, although some improvement might follow liver transplantation.

TABLE 119.3 Child-Turcotte-Pugh Score

	1	2	3
Bilirubin	<2 mg/L	2-3 mg/L	>3 mg/L
Albumin	>3.5 g/L	2.8-3.5 g/L	<2.8 g/L
INR	<1.7	1.7-2.2	>2.2
Ascites	No ascites	Ascites, medically controlled	Ascites, poorly controlled
Encephalopathy	No encephalopathy	Encephalopathy, medically controlled	Encephalopathy, poorly controlled

Persistent Hepatic Encephalopathy

Often preceded by multiple episodes of OHE, a chronic and largely irreversible syndrome characterized by dementia, dysarthria, gait ataxia, intention tremor, and choreoathetosis might appear. This persistent form of HE, previously referred to as *acquired hepatolenticular degeneration*, afflicts 4% of cirrhotic patients. The associated neuropathologic findings are neuronal necrosis in basal ganglia, cerebellum, and cerebral cortex in addition to Alzheimer type II astrocytosis. It does not respond to standard therapies.

DIAGNOSIS

Minimal Hepatic Encephalopathy

MHE diagnosis cannot be made at the bedside with usual examination techniques and requires neuropsychometric or neurophysiologic testing. Numerous tests have been designed and, although sensitive enough, they are usually not very specific. Most importantly, many are time-consuming or require specialized personnel, and the lack of standardized testing is a hindrance to routine testing implementation. The reader is referred to the suggested readings for a comprehensive description and critical analysis of available tests.

Overt Hepatic Encephalopathy

The diagnosis of OHE is made with the compatible clinical picture in the context of cirrhosis after exclusion of plausible alternative explanations. It is graded according to the West Haven criteria (see [Table 119.1](#)).

The majority of OHE episodes are not spontaneous and precipitated by an event, and the absence of such cause in the setting of altered mental status should alert the clinician for other organ failures. Although blood NH_3 level per se does not allow staging or prognostication in chronic liver disease, a normal level puts the diagnosis of OHE in question. Brain imaging does not help in diagnosis but is used to rule out other pathologies, such as intracerebral hemorrhage, which is five times more prevalent in this population.

TREATMENT

Minimal Hepatic Encephalopathy

MHE rarely presents in clinical practice as a medical complaint and has not been widely evaluated in clinical trials. Several lines of evidence suggest a benefit on cognitive function and quality of life when patients are treated with lactulose, rifaximin, or probiotics, as discussed in the following text. Whether the benefits outweigh the costs is unknown at present.

Overt Hepatic Encephalopathy

OHE management focuses on identification and correction of the precipitating factor, exclusion of alternative causes for mental status changes, and measures to lower blood levels of NH_3 (Table 119.4), all the while supporting the patient appropriately.

Identification of the precipitating factor is paramount because its specific treatment is central to recovery. Precipitants are not always obvious and a careful history, physical examination, and appropriate laboratory tests are required. The most common causes are infection (especially spontaneous bacterial peritonitis and urinary tract infection), alcohol abuse, gastrointestinal (GI) bleeding, and iatrogenic insults such as dehydration from diuretics or lactulose or oversedation from benzodiazepines or opiates.

The mainstay of NH_3 -lowering therapy is the use of nonabsorbable disaccharides such as lactulose, although efficacy in clinical trials has been variable. The putative mechanisms of action are multiple. The cathartic effect due to the osmolar load is thought to reduce time allowed for NH_3 absorption, as well as to increase fecal nitrogen excretion. Lactulose catabolism generates lactic acid, thereby acidifying colonic contents, which causes protonation of NH_3 into ammonium (NH_4^+), which is poorly absorbed, remains trapped in the lumen, and is excreted. Lactulose is titrated to achieve two to three bowel movements per day.

Sodium benzoate also lowers NH_3 levels by combining with glycine to form hippurate, which is water-soluble and allows greater elimination of NH_3 through renal excretion. It has been shown to improve symptoms of HE improvement just as well as lactulose.

A concomitant approach is through modulation of fecal flora with antibiotics. The most promising treatment by far is rifaximin, a minimally absorbed antibiotic with broad-spectrum activity against gram-positive, gram-negative, and anaerobic bacteria. Its preferential site of action is the small bowel, where it lowers the bacterial load up to 1,000-fold. Recent data demonstrated that it is more effective for improvement of OHE as an add-on therapy than lactulose alone and, most importantly, showed a significant reduction in mortality [Level 1].¹

General care measures include appropriate hydration and nutritional support with protein intake of 1.2 to 1.5 g/kg/day and correction of electrolyte abnormalities. Treatment of chronic hyponatremia must be done carefully, as cirrhotic patients are at higher risk

mmol/L per 24 hours. Correction of hypokalemia is also an essential component of therapy because it increases renal NH_3 production. After a first episode of OHE, secondary prophylaxis is recommended with lactulose and rifaximin to prevent recurrence. This therapy should be continued indefinitely.

TABLE 119.4 Ammonia-Reducing Pharmacologic Therapies

Agent	Dose
Lactulose	15-45 mL PO b.i.d. to q.i.d.
Sodium benzoate	5 mg PO b.i.d.
Rifaximin	400 mg PO t.i.d.

PO, by mouth.

OUTCOME

Even without obvious clinical manifestations, MHE patients do not fare well. After diagnosis, 50% of patients will be hospitalized within a year and 75% will die within the next 4 years. The future is even grimmer after a first episode of OHE: 40% will have a recurrent episode by the end of the year. The cumulative survival at 1 year is 42% and at 3 years, it is a mere 23%.

ACUTE LIVER FAILURE AND CEREBRAL EDEMA

EPIDEMIOLOGY

ALF is rare in developed countries, with an incidence ranging from 1 to 8 cases per million per year representing approximately 2,000 cases annually in the United States. It is seen most commonly in previously healthy adults in their 30s, and the most prominent cause is drug-induced liver injury dominated by acetaminophen-induced hepatotoxicity (Fig. 119.2). It is of interest to the neurologist to know that causes of ALF include carbamazepine, phenytoin, and valproic acid.

PATHOBIOLOGY

Multiple Organ Failure

Acute liver dysfunction results in a shutdown of its synthetic, metabolic, detoxification, and immunologic functions. Loss of coagulation factor synthesis leads to coagulopathy, and necrotic hepatocytes trigger an intense systemic inflammatory syndrome. This inflammatory state produces vasoparesis and is often complicated by acute renal failure and acute lung injury. Loss of neoglucogenesis may lead to hypoglycemia and reduced lactate clearance. Immunoparesis puts patients at high risk of sepsis, and bone marrow suppression manifests as cytopenia.

Encephalopathy and Cerebral Edema

Acute NH_3 accumulation produces different consequences than the chronic hyperammonemia seen in cirrhotic

patients. The rapid transformation of NH_3 to glutamine inside the astrocytes does not allow for compensatory mechanisms such as the release of taurine or myoinositol. The osmotic effect causes astrocytes to take in water and swell, creating cytotoxic brain edema. This is why arterial NH_3 levels in ALF are highly correlated with prognosis and the extent of cerebral edema. Patients with NH_3 levels less than $75 \mu\text{mol/L}$ usually do not develop encephalopathy at all, and those with NH_3 greater than $200 \mu\text{mol/L}$ have a 55% risk of developing cerebral edema with concomitant intracranial hypertension. The rapid buildup of glutamine is partially transformed to glutamate, which may explain the aggressive and agitated delirium seen in some patients and their propensity for seizures. Numerous other causal pathways explaining cerebral dysfunction are being studied, including loss of autoregulation, elevated cerebral lactate concentrations, and inflammatory cytokines.

FIGURE 119.2 Common causes of acute liver failure in the United States. HAV, hepatitis A virus; HBV, hepatitis B virus.

CLINICAL FEATURES

The clinical picture of ALF is dominated by acute hepatic dysfunction, unregulated systemic inflammation with multiorgan dysfunction, and cerebral edema with intracranial hypertension, which is the most feared complication (Fig. 119.3).

The characteristic sleepiness and asterixis of cirrhotic patients are not reliable indicators of early encephalopathy in ALF. Instead, forewarning signs of impending cerebral edema are usually onset of aggressive behavior and agitated delirium associated with hyperreflexia and ankle clonus. Mental status changes can quickly follow with the patient lapsing into coma in just a few hours. Multifocal myoclonus and excessive startle response are well described and later stages may reveal spasticity and extensor posturing, as well extensor plantar responses. Pupillary responses are impaired only when intracranial pressure (ICP) is frankly elevated and brain herniation has occurred. Oculomotor dysfunction is uncommon but dysconjugate gaze and periodic alternating gaze deviation are reported. Cushing response is a late and unreliable finding. Seizures, albeit generally nonconvulsive, are also a frequent occurrence in ALF. Up to 30% of patients monitored with continuous electroencephalogram (cEEG) have evidence of electrographic seizures.

DIAGNOSIS

ALF is defined as the onset of coagulopathy (INR > 1.5) and encephalopathy (any degree of altered mentation) secondary to liver injury in a patient without preexisting liver disease. The time from the start of illness to encephalopathy is variable from hyperacute (less than a week) to subacute (up to 26 weeks). Patients with Wilson disease, vertically transmitted hepatitis B virus, or autoimmune hepatitis may be included if the disease has only been recognized for less than 6 months.

When ALF is suspected, the history must be very thorough, with a focus on drug and medication ingestion, including over-the-counter medications or supplements, as well as a possible viral exposure, including travel history. Although the cause of ALF remains unknown in close to 20% of cases, it is the single most important prognostic factor and might call for specific treatment, so it must be sought aggressively. In addition to laboratory testing and imaging, serial biochemical testing should be done, including NH₃, glucose, and lactate levels; liver and renal function; electrolytes; and coagulation panels.

TREATMENT

General Management

Patients with a diagnosis of ALF must be hospitalized, and those developing encephalopathy should be transferred to a critical care unit, as they can deteriorate in a matter of hours. Frequent neurologic assessments are mandatory in ALF patients. Special attention should

P.1034

be dedicated to development of delirium, mental status changes, abnormal motor tone and deep tendon reflexes, and myoclonus. Those progressing to West Haven stage III or IV (see [Table 119.1](#)), which usually corresponds to a Glasgow Coma Scale score of 8 and less (see [Table 18.1](#)), should be intubated and strong consideration should be given to invasive ICP monitoring. Communication with a transplant center is essential and transfer criteria have to be determined very early in the evaluation process. Depending on the etiology of ALF, specific treatment should be instituted promptly, especially in the case of acetaminophen poisoning ([Table 119.5](#)). Hypoglycemia and hyponatremia are common, can exacerbate the severity of neurologic insult, and must be carefully prevented.

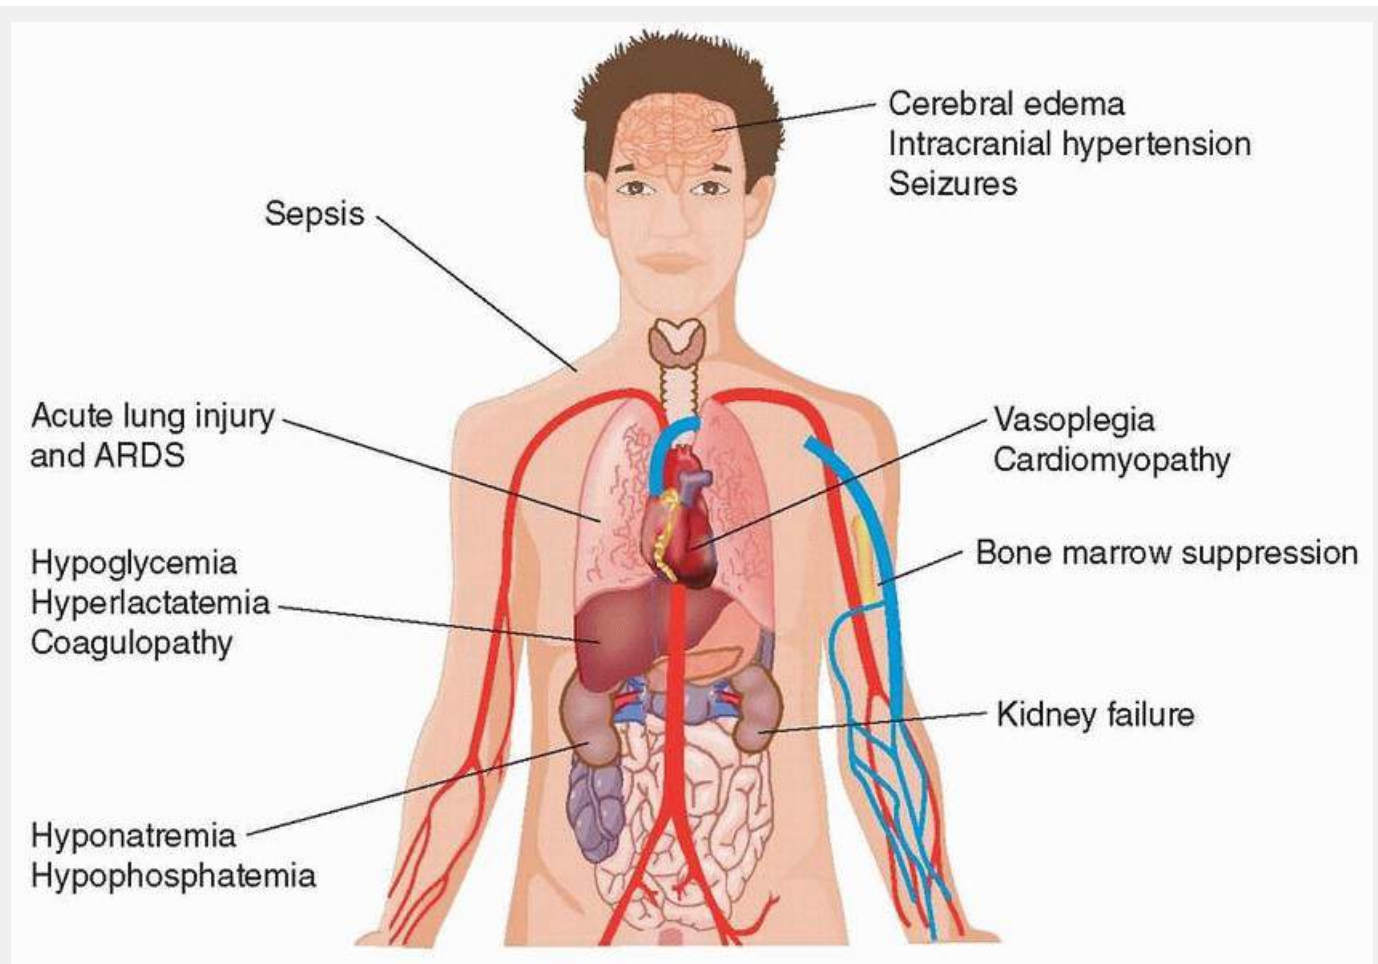

FIGURE 119.3 Multiorgan dysfunctions associated with acute liver failure. ARDS, acute respiratory distress syndrome.

Intracranial Pressure and Transcranial Doppler Monitoring

Patients with grade III encephalopathy (see [Table 119.1](#)) have a risk of experiencing elevated ICP of 30%, whereas in grade IV patients, it climbs to 70%. Noncontrast head computed tomography (CT) is often done to rule out other concomitant pathologies, such as bleeding, but the usual finding that implies a high risk of intracranial hypertension is global cerebral edema with convexity sulcal effacement, effacement of the basal cisterns and small ventricles, and loss of gray-white matter differentiation.

TABLE 119.5 Acute Liver Failure Etiologies and Specific Treatments

Etiology	Specific Treatment
Acetaminophen poisoning	IV NAC ^a
Nonacetaminophen ALF	IV NAC ^a
Drug-induced liver injury	IV NAC ^a
Mushroom poisoning (<i>Amanita phalloides</i>)	Penicillin G (1 million U/kg/day) and IV NAC ^a

HBV	Lamivudine
Herpesvirus or varicella-zoster virus	Acyclovir (10 mg/kg IV every 8 h)
Autoimmune	Prednisone (40-60 mg/day)
ALF of pregnancy or HELLP	Delivery

^aLoading dose is 150 mg/kg in 5% dextrose over 15 minutes; maintenance dose is 50 mg/kg given over 4 hours followed by 100 mg/kg administered over 16 hours (or 6 mg/kg/h).

IV, intravenous; NAC, *N*-acetylcysteine; ALF, acute liver failure; HBV, hepatitis B virus; HELLP, hemolysis, elevated liver enzymes, low platelets.

Transcranial Doppler (TCD) is a noninvasive technique allowing indirect evaluation of both cerebral blood flow (CBF) and ICP (see [Chapter 23](#)). In ALF, because the global cerebral edema is primarily vasogenic and caused by hyperemia and vasodilation, the rise in ICP is usually preceded by an increase in CBF and hence in TCD flow velocities. Early on, TCD flow velocities are elevated above normal values (60 cm/s in a healthy young person), and the pulsatility index (peak systolic minus diastolic flow velocity divided by mean flow velocity) is reduced below the normal value of 1.0 due to downstream vasodilation. Brain injury is highly reversible at this stage, and for this reason, the triad of coma, global cerebral edema on CT, and elevated flow velocities on TCD is the ideal time for an ICP monitor to be inserted.

After ICP has been massively elevated for a sustained period of time, the brain remains engorged but hypoperfused, CBF falls, metabolic changes in the brain cause cellular swelling, and cytotoxic brain edema ensues. At this late stage, TCD evolves toward a picture consistent with brain death: Mean flow velocities drop, the pulsatility index increases, and eventually, readings evolve to isolated systolic flow velocity spikes with diastolic flow arrest diagnostic of brain death (see [Chapter 19](#)).

As for other neurocritical care patients, invasive ICP monitoring (see [Chapter 33](#)) is the gold standard for monitoring when intracranial hypertension is the main threat to life. Although its use in ALF is still contentious, it is now recommended in patients with high-grade encephalopathy awaiting transplantation in centers with appropriate expertise. Associated with encephalopathy, the following factors are considered indications for placement of an ICP monitor.

- Global cerebral edema on CT
- Arterial NH₃ greater than 150 mmol/L
- Age younger than 40 years
- TCD indices of high CBF
- Concurrent renal or cardiovascular organ failure

The main concern of placing an invasive ICP monitor is bleeding because most patients with ALF are coagulopathic. Recent series report clinically significant bleeding in ALF patients after standard reversal procedures at the same order of magnitude as for other intracranial pathologies. Reversal of coagulopathy when placing an intracranial monitoring device should be taken seriously. Off-label

usage of recombinant factor VIIa (40 µg/kg given 30 minutes before the procedure) is used at many liver transplant centers throughout the world to correct the coagulopathy prior to ICP monitor placement. Recombinant factor VIIa has been associated with a 5% risk of thrombotic complications, including brain and myocardial infarction.

We also recommend keeping platelets over 50,000 and to correct hypofibrinogenemia (fibrinogen <100 mg/dL) with cryoprecipitate prior to insertion. Elevated prothrombin time (PT)/INR can also be corrected with fresh frozen plasma (15 mL/kg).

Intracranial Pressure Management

Usual ICP management principles (see [Chapter 107](#)) apply to ALF patients but with some particularities. Hypertonic saline (30%) given prophylactically (at a rate of 5 to 20 mL/h) with a sodium target of 145 to 155 mEq/L has been shown to reduce the incidence and severity of ICP crisis. Prophylactic induction of hypernatremia is thus recommended [**Level 1**]² in high-risk patients (encephalopathy grade III or IV, $NH_3 >150$ µmol/L, acute renal failure or requiring vasopressors). In the event of a herniation event, mannitol boluses (20% solution at a dose of 0.5 to 1 g/kg) are successful in resolving ICP crisis in ALF patients and it improves survival compared to placebo. Corticosteroids are useless in cerebral edema caused by ALF and are probably harmful and should not be used [**Level 1**].²

The role of therapeutic hypothermia is debated. Case series show great improvement in ICP control and impressive survival rates, but a randomized controlled trial (RCT) and retrospective cohort studies have failed to show better outcomes with cooling, albeit showing no higher rates of bleeding or infection. Induction of hypothermia to 33°C may be considered as a rescue intervention in patients with refractory ICP crisis, refractory to sedation and paralysis, bolus osmotherapy, and hyperventilation as a bridge to liver transplantation. Indomethacin (25 mg intravenously [IV]) has been shown in a few ALF patients with ICP refractory to mannitol to dramatically reduce ICP without documented adverse effects.

Seizures

With a reported frequency of nonconvulsive seizures in up to 30% of patients, grade III or IV encephalopathy should be monitored with cEEG. Prophylactic phenytoin failed to improve outcomes in one RCT and is thus not recommended.

Ammonia Clearance

Therapies used for HE, such as lactulose, have not been proven useful in acutely reducing blood level of NH_3 in ALF patients. Recent clinical data shows that hemofiltration with continuous renal replacement therapy (CRRT) might be the best way to control arterial NH_3 levels. Clearance is closely correlated with ultrafiltration rate up to 90 mL/kg/h, and glutamine is also likely to be cleared in the process. CRRT also allows for tighter control of serum sodium levels, intravascular volume, pH, and temperature.

Artificial Liver Support Systems

Numerous extracorporeal liver support systems have been developed; currently, the only U.S. Food and Drug Administration (FDA)-approved device is the Molecular Adsorbent Recirculating System (MARS). This nonbiologic artificial liver support system is based on a dialysis technique using an albumin-coated membrane. It allows detoxification by removal of water-soluble toxins but also, in contrast to CRRT, albumin-bound substances. Among proven benefits in ALF patients, there is improvement in hemodynamic stability, reduction in ICP, and improvement of HE. The only large RCT did not show a survival benefit, although it was highly underpowered. At present, MARS should only be considered as a “bridge to transplant.”

Transplantation

Orthotopic liver transplantation is the only definitive therapy for those whose liver function does not recover. Given the usually rapid evolution toward cerebral edema, candidacy must be assessed promptly. Numerous prognostic scores have been developed trying to predict who has a poor prognosis with medical management alone and hence who will benefit most from emergent liver transplantation. None of them is universally accepted, but the most widely used are the King's College criteria (Table 119.6). Adult patients with sudden acute- and severe-onset ALF according to the King's College criteria have a life expectancy less than 7 days without transplant and are granted 1A status, making them the highest priority, but up to 25% will die while on the waiting list. As of 2012, more than 12,000 patients were on the liver transplant waiting list in the United States with about 10% of livers usually allocated to ALF patients.

TABLE 119.6 King's College Criteria for Acute Liver Failure

Acetaminophen-Induced ALF	
Strongly consider OLT listing	<ul style="list-style-type: none"> • Arterial lactate >3.5 mmol/L after early fluid resuscitation
List for OLT	<ul style="list-style-type: none"> • pH <7.3 <i>or</i> • Arterial lactate >3.0 mmol/L after adequate fluid resuscitation
List for OLT if all three occur within a 24-h period	<ul style="list-style-type: none"> • Presence of grade 3 or 4 hepatic encephalopathy • INR >6.5 • Creatinine >3.4 mg/dL
Non-Acetaminophen-Induced ALF	
List for OLT	<ul style="list-style-type: none"> • INR >6.5 <i>and</i> • Encephalopathy present (irrespective of grade)
List for OLT if any three of the following (and any grade of encephalopathy present)	<ul style="list-style-type: none"> • Age younger than 10 yr or older than 40 yr • Jaundice for >7 days before development of encephalopathy • INR ≥3.5 • Serum bilirubin ≥17 mg/dL • Unfavorable etiology, such as Wilson disease, idiosyncratic drug reaction, seronegative hepatitis

ALF, acute liver failure; OLT, orthotopic liver transplantation; INR, international normalized ratio.

OUTCOME

With optimization of medical management and improved organ allocation system, the overall mortality of ALF is now between 30% and 40%. The etiology of ALF is one of the most important predictors of outcome. For example, transplant-free survival is largely over 50% for acetaminophen poisoning, hepatitis A, or pregnancy-related disease. On the contrary, survival without transplantation is less than 25% in Wilson disease, Budd-Chiari syndrome, or autoimmune hepatitis. With emergent transplantation, although the survival at 1 year is less than for elective transplantation (mainly due to infection in the first 3 months), ALF patients have a better long-term survival.

Renal Disease and the Brain

J. Kirk Roberts

Stephan A. Mayer

INTRODUCTION

Renal disease is most commonly associated with neurologic disease when both are related to an underlying condition (e.g., diabetes mellitus, hypertension) that damages both systems. However, renal disease and resultant azotemia (blood urea nitrogen elevation or uremia) can injure both the central nervous system (CNS) and the peripheral nervous system. With the increase in aggressive kidney dialysis and transplantation, the incidence of many neurologic conditions associated with chronic renal failure has declined, but a new constellation of neurologic complications associated with dialysis and transplantation has become more important.

UREMIC ENCEPHALOPATHY

The differential diagnosis of encephalopathy in a patient with renal failure is wide and includes metabolic, infectious, structural, and other causes. Fluid and electrolyte disturbances are common. Drugs that are excreted in the urine may accumulate and dosing must be adjusted.

PATHOBIOLOGY

Uremia itself can cause encephalopathy. The symptoms of *uremic encephalopathy* are usually more severe in patients with more severe azotemia; they are often evident earlier and more severely in patients with acute as opposed to chronic renal failure. The specific factors that cause encephalopathy are still not identified. The earliest indicator is sensorial clouding, which progresses to delirium, obtundation, and even coma. In addition to cognitive changes, patients are usually weak, uncoordinated, and unsteady. Focal symptoms or signs may wrongly suggest a focal process. Asterixis is a dramatic problem, with jerking movements arising from lapses of posture holding, as of the outstretched hands. Multifocal myoclonus, involuntary twitches occurring randomly throughout the body, may become apparent, usually after stupor or coma has supervened. Tetany may be overt, with spontaneous carpopedal spasm, or latent as manifest by a Trousseau sign (sustained muscle contraction and cupping of the hand, induced by arterial occlusion). Seizures are a late manifestation of uremic encephalopathy. Fluctuation of clinical symptoms and signs from day to day is characteristic.

DIAGNOSIS

No laboratory value, including specific evaluations of renal function, correlates well with clinical symptoms and signs of uremia. Lumbar puncture may reveal elevated cerebrospinal fluid (CSF) protein, sometimes exceeding 100 mg/dL, and occasionally a mild pleocytosis but is primarily performed to exclude an infectious cause of encephalopathy. Computed tomography (CT) or magnetic resonance imaging (MRI) findings are usually nonspecific but may help to exclude ischemic stroke, intracerebral hemorrhage, subdural hematoma, or hydrocephalus. Electroencephalogram (EEG) like the clinical state, is usually more strikingly abnormal in acute renal failure than in chronic renal failure. The background activity is slow with theta and delta waves more prominent in the frontal regions. Triphasic waves may appear. Nonconvulsive status epilepticus is an important treatable cause of encephalopathy that can be identified only by EEG with dramatic improvement when appropriately managed.

TREATMENT

Uremic encephalopathy usually responds dramatically to dialysis, suggesting that one or more dialyzable substances are responsible. Sometimes, response is delayed for 1 to 2 days. A variety of metabolites acting toxically when accumulating have been postulated as the etiology of uremic encephalopathy, but no single substance has been identified as the sole or major cause. Hormonal changes, electrolyte abnormalities, altered calcium homeostasis, and imbalance of excitatory and inhibitory neurotransmission are all thought to play a role.

DIALYSIS DISEQUILIBRIUM SYNDROME

Dialysis disequilibrium syndrome is usually seen with rapid correction of uremia at the start of a dialysis program. It is more common in those with more severe azotemia. Symptoms vary from mild headache, nausea, and muscle cramps to, rarely, delirium, obtundation, and convulsions. The syndrome is usually self-limited, subsiding in hours, but delirium may persist for several days. Although the pathogenesis is controversial, shift of water into brain is probably the cause of syndrome. The rapid reduction in blood osmoles cannot be paralleled as rapidly by a reduction in brain osmoles, resulting in an osmotic gradient between blood and brain, causing movement of water into brain and cerebral edema and encephalopathy. With improvements in dialysis, this syndrome is much less frequent now. Gradual initiation of dialysis may help prevent. Before diagnosing dialysis disequilibrium, other causes of cerebral symptoms should be excluded. If it seems likely, dialysis should be stopped and supportive care provided. Some have suggested hypertonic saline or mannitol for severe cases but this is not routine.

DIALYSIS DEMENTIA

A subacute, progressive, usually fatal encephalopathy rarely occurs in patients who are chronically dialyzed. The first symptom is usually a stammering, hesitancy of speech and at times, speech arrest. The speech disorder is intensified during and immediately after dialysis and at first may be seen only during these periods. As the disorder progresses, speech becomes more dysarthric and aphasic along with personality change, psychosis, myoclonus, seizures, and occasionally focal neurologic abnormalities. Brain imaging and CSF findings are usually unremarkable and, again, are most helpful in excluding other causes of encephalopathy. Increased dialysis

P.1038

time and renal transplantation do not seem to alter the course of the disease. Aluminum content is consistently elevated in the cerebral gray matter of patients who die from this condition. Municipal water supplies heavily contaminated with aluminum have been linked to the syndrome in epidemiologic studies. The frequency of the disease markedly diminished when aluminum was removed from the water used during dialysis but did not disappear completely. Another possible source is absorption of aluminum from orally administered phosphate-binding agents that are given to uremic patients.

CEREBROVASCULAR DISEASE

Stroke is prevalent in patients with renal failure, mostly because of shared risk factors. However, renal failure may additionally promote atherogenesis through several mechanisms. Hypotension during dialysis may result in watershed infarction. Renal failure is associated with platelet dysfunction, and anticoagulants used during hemodialysis may contribute to intracerebral hemorrhage or subdural hematoma. Chronic subdural hematoma may present with an encephalopathic picture without focal motor or sensory symptoms and signs. Autosomal dominant polycystic kidney disease is associated with an increased risk of saccular aneurysm and subarachnoid hemorrhage (SAH).

RESTLESS LEGS SYNDROME

At least 20% of patients with chronic renal failure suffer from creeping, crawling, prickling, and pruritic sensations deep within the legs particularly when at rest and improving with movement (see [Chapter 75](#)). Periodic limb movements of sleep may coexist. Dialysis often does not lead to significant improvement, and treatment is similar to that in patients without renal failure.

BENIGN INTRACRANIAL HYPERTENSION

Benign intracranial hypertension or pseudotumor cerebri is thought to occur more frequently in patients with chronic renal failure (see also [Chapter 107](#)). Symptoms typically include headache, visual obscurations, and possibly sixth nerve palsies. Focal mass lesions and CSF infections must be excluded. Treatment consists of managing renal failure, weight loss, low-salt diet, and often diuretics, in particular, acetazolamide 500 mg orally (PO) three times a day (t.i.d.).

PERIPHERAL NEUROPATHY

The most common neurologic consequence of chronic renal failure is a distal, symmetric, predominantly axonal, mixed sensorimotor neuropathy affecting the legs more than the arms. Cranial nerves, particularly vision and hearing, and the autonomic nervous system may be affected. The rate of progression, severity, prominence of motor or sensory symptoms and signs, and degree of pain varies. Decreased vibratory and temperature sense in the feet are the earliest signs and sensory symptoms and signs usually predate motor. In general, the neuropathy evolves over several months but may be fulminant.

PATHOBIOLOGY

Pathologically, uremic neuropathy is usually a primary axonal degeneration with secondary segmental demyelination; there is also a predominantly demyelinating type. Because uremic neuropathy improves with hemodialysis, it seems likely that the neuropathy results from the accumulation of dialyzable metabolites. The control of neuropathy in some patients depends on increased hours of dialysis each week. The use of erythropoietin has also been reported to improve uremic neuropathy.

DIAGNOSIS

Other causes must always be considered given the coexistence of renal diseases and conditions that predispose to peripheral neuropathy (e.g., diabetes mellitus, amyloidosis). Mononeuropathies, such as carpal tunnel syndrome caused by damage to the median nerve at the wrist or ulnar neuropathy, may occur, perhaps owing to an increased susceptibility of at-risk nerves to injury or as a vascular steal phenomenon after arteriovenous fistula. Electrophysiologic studies are often abnormal, even in those with no symptoms, with both decreased amplitudes and slowing. Among most patients who enter chronic dialysis programs, the neuropathy stabilizes or improves slowly. Patients with mild neuropathy often recover completely, but those who begin dialysis with severe neuropathy rarely recover even after several years, and some may continue to progress. However, lack of improvement or progression of symptoms while on dialysis should suggest an evaluation for an alternative diagnosis.

TREATMENT

Successful renal transplantation often leads to a significant beneficial effect on uremic neuropathy. Motor nerve conduction velocities can increase within days of transplantation along with continued improvement for several months, sometimes with complete recovery, unless there was severe axonal degeneration before transplantation.

The symptomatic treatment of painful uremic neuropathy is similar to the treatment of any painful peripheral neuropathy (see [Chapter 87](#)) but with careful attention to medication dosing, given the presence of renal failure.

MYOPATHY

In patients with renal failure, myopathy with proximal limb weakness, fatigability, and atrophy is a poorly understood condition. Muscle enzymes and electromyogram (EMG) are usually normal. Muscle biopsy may reveal nonspecific alterations and sometimes type II fiber atrophy. Electrolyte abnormalities, in particular potassium, calcium, and magnesium, must be considered. If the patient has been treated with a kidney transplant and is taking steroids, a steroid myopathy may be considered.

NEUROLOGIC COMPLICATIONS OF RENAL TRANSPLANTATION

Renal transplantation is the preferred treatment of end-stage renal disease, and with advances in transplantation medicine, these patients live longer and are more at risk for the adverse consequences of long-term immunosuppression.

A femoral neuropathy may complicate renal transplant surgery caused by perioperative compression or traction. It can usually be managed expectantly.

Transplant patients suffering systemic features of rejection may also present with encephalopathic symptoms including confusion and even seizures. Symptoms usually begin within a few months of transplant, but some occur later. Treatment of rejection usually leads to improvement.

P.1039

POSTERIOR REVERSIBLE ENCEPHALOPATHY SYNDROME

Several drugs are used to prevent transplant rejection, and each has adverse effects. Of particular interest to the neurologist is the *posterior reversible encephalopathy syndrome* (PRES) usually seen in those patients treated with cyclosporine or tacrolimus (see also [Chapter 43](#)). PRES may also be seen in nontransplanted patients with renal disease and hypertension. Symptoms include headache, visual disturbance, encephalopathy, and seizures. Blood pressure is usually elevated. MRI reveals changes in the white matter, most extensive in the occipital and parietal regions, that suggest vasogenic edema. Treatment involves lowering blood pressure and, whenever possible, discontinuing immunosuppressive agents. Obviously, patients with transplanted organs require immunosuppression; if medications are substituted, the patient will need continued monitoring for PRES. Patients with seizures should be treated with anticonvulsants. Late recurrence of seizures after successful treatment is low and the anticonvulsant can usually be discontinued in the uncomplicated patient once symptoms and imaging have resolved, although some advocate continuing for 1 to 3 months.

PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

The risk that a lymphoma will develop after a transplant is about 35 times more than in normal people; the increased risk depends almost entirely on the increased incidence of primary CNS lymphoma. These are almost always B-cell lymphomas developing from immunosuppression-related Epstein-Barr virus (EBV) infection causing lymphocyte proliferation. The tumor typically appears between 5 and 45 months after transplantation. The resulting clinical syndromes include increased ICP, rapidly evolving focal neurologic signs, or combinations of these. Convulsions are rare. The lymphoma may be multicentric and may involve the meninges. Treatment may include immunosuppression withdrawal, chemotherapy, and radiation.

OPPORTUNISTIC INFECTIONS

Infections occur often in transplant patients, and a high index of suspicion must be maintained because the usual inflammatory response may be impaired diminishing the severity of symptoms. New headache or mental changes should lead the clinician to consider brain imaging and lumbar puncture. Viral infections with cytomegalovirus (CMV), herpes zoster virus (HZV), varicella-zoster virus (VZV), human herpes virus (HHV)-6, EBV, and John Cunningham (JC) virus can often be diagnosed on CSF with culture or polymerase chain reaction (PCR). Bacterial and tuberculous meningitis are also considerations. Systemic fungal infections are common and secondary brain abscess formation may occur. In almost all cases, the primary source of infection is in the lung. Chest radiographs and the presence of fever aid in differentiating fungal brain abscess from brain tumor in recipients of transplants. *Aspergillus* has a unique predilection for dissemination to brain and accounts for most fungal brain abscesses; *Candida*, *Nocardia*, and *Histoplasma* are found in the others. The clinical syndrome resulting from these infections is usually delirium accompanied by seizures. Headache, stiff neck, and focal signs also occur but not commonly. The CSF is often remarkably bland, and brain biopsy may be the only reliable way to establish a diagnosis. The distinction of fungal brain abscess from possibly radiosensitive brain tumor makes it important to consider this procedure.

HYPONATREMIA

Sodium and fluid homeostasis is under the control of the brain and kidneys. The neurologist, particularly in the neurologic intensive care unit (ICU), is frequently confronted by hyponatremia (serum sodium <135 mEq/L). In this setting, the most common causes of hyponatremia are volume depletion, the syndrome of inappropriate antidiuretic hormone secretion (SIADH), and cerebral salt wasting (CSW).

CLINICAL FEATURES

Hyponatremia can not only be caused by brain injury but can also further impair neurologic function and cause a vast array of clinical manifestations, ranging from mild confusion to death. The severity of symptomatology is primarily related to the speed of sodium reduction, rather than the absolute sodium level itself. Sodium is the principle osmotically active solute in the extracellular fluid compartment. If the sodium concentration falls quickly (>1 mEq/h), free water moves into the intracellular compartment, leading to cellular swelling and edema. Unlike other organs, the CNS tolerates this process extremely poorly. Acute hyponatremia can lead to global cerebral edema and dramatic clinical manifestations, including seizures, coma, or death from brain stem herniation.

When sodium levels drop gradually, cells compensate by reducing the intrinsic osmolality of the intracellular compartment. This process, which involves release of intracellular electrolytes such as potassium and elimination of organic osmolytes, takes hours to days. As a result, normal cellular volume is maintained in chronic hyponatremia, but subtle neurologic dysfunction in the form of neurocognitive dysfunction, impaired reaction times, and gait instability results from these intrinsic changes in neuronal intracellular composition. Hospitalized patients with chronic hyponatremia have an increased risk of mortality and a two- to fourfold increased fall risk compared to normonatremic patients.

DIAGNOSIS

The medical history is an important first step in the evaluation of hyponatremia and in particular includes information about fluid loss (or excess intake), low protein intake, medications, history of heart failure, cirrhosis, kidney failure, hypothyroidism, adrenal insufficiency, lung cancer, and, of course, CNS disease.

In addition to the history, physical examination should start with an assessment of *volume status* by evaluating blood pressure and heart rate, skin turgor, the mucous membranes, and jugular venous pressure. Measurement of fluid inputs and outputs (Is and Os) typically demonstrate positive net fluid balance in patients who are hypovolemic, as the kidneys appropriately retain fluid to correct the problem. A spot urine sodium concentration is typically low in hypovolemic states (<25 mEq/L), representing avid renal

sodium retention. A low central venous pressure (CVP) is fairly specific for hypovolemia; otherwise, CVP is a poor indicator of volume status. Advanced diagnostic methods in the ICU for evaluating volume status include use of bedside ultrasound to diagnose collapsibility of the inferior vena cava (IVC) with spontaneous respirations and cardiac output monitors that can measure the global end-diastolic volume index (GEDV) of the heart.

Essential laboratory testing in hyponatremia includes serum osmolality, urine osmolality, and urine electrolytes, in addition to standard serum chemistries. If serum osmolality is low, then

P.1040

true hypotonic hyponatremia is confirmed (Fig. 120.1). If serum sodium is low but serum osmolality is normal, elevated lipids or proteins may account for a measured pseudohyponatremia. If sodium is low and osmolality is elevated, then another substance is contributing to osmoles such as glucose, urea, alcohol, or mannitol.

FIGURE 120.1 Diagnostic algorithm for identifying the cause of hyponatremia. Step 1 is to confirm the presence of hypotonic hyponatremia by checking serum osmolality. Step 2 is to evaluate volume status. Euvolemic hyponatremia is usually due to SIADH. Hypovolemia hyponatremia may be due to extrarenal

sodium losses such as vomiting or diarrhea, or inappropriate renal losses, as occurs with cerebral salt wasting.

When hypotonic hyponatremia is confirmed, classification of volume status as hypovolemic, euvolemic, or hypervolemic is key for identifying the cause (see Fig. 120.1). Analysis of urine sodium is a key ancillary test. Calculation of the fractional excretion of sodium (FENa; Table 120.1) is less than 1% in patients who are hypovolemic or have reduced effective circulating blood volume and normal renal function, reflecting a corrective pattern of avid sodium retention. An important exception is when fluid losses and hypovolemia are caused by excessive and inappropriate sodium excretion, as occurs with untreated CSW (Table 120.2).

In this setting of SIADH, patients are euvolemic, spot urine sodium is greater than 40 mEq/L, and the FENa is greater than 1%. Because antidiuretic hormone (ADH) is inappropriately elevated, urine osmolality is more than a maximally dilute urine of 100 mOsm/kg and usually more than 300 mOsm/kg.

SIADH from enhanced ADH release may occur in the setting of almost any CNS disease, including stroke, trauma, brain tumor, or encephalitis, and with acute peripheral neuropathies such as Guillain-Barré syndrome.

CSW is typically encountered in patients with SAH but can occur with other forms of acute CNS injury as well. In this condition, sympathetic nervous system activation release of circulating factors such as brain natriuretic factor drive excessive sodium excretion while suppressing the normal renin-angiotensin system response to hypovolemia. CSW as a cause of hyponatremia is about one-tenth as common as SIADH. In some cases, most often SAH, hyponatremia can be the result of dual physiologic processes that favor the combination of excessive sodium losses and inappropriate ADH elevation.

TREATMENT

Acute Symptomatic Hyponatremia

Treatment of hyponatremia in neurologic patients, whether acute or chronic, is important. Symptomatic acute hyponatremia leading to brain edema is a medical emergency and should be treated

P.1041

with hypertonic saline. The mainstay of therapy is a 3% sodium chloride-acetate solution, infused at a rate of 0.25 to 1.0 mL/kg/h, depending on the severity of symptoms and sodium level. Serum sodium level should be monitored every 4 hours, with the rate of the infusion adjusted to attain a rate of correction of no more than 12 mEq/L over 24 hours (0.5 mEq/L/h). More rapid aggressive correction of hyponatremia must be avoided because of the possibility of osmotic demyelination or central pontine myelinolysis (CPM; see Chapter 70).

TABLE 120.1 Syndrome of Inappropriate Antidiuretic Secretion versus Cerebral Salt Wasting

	SIADH	CSW
Serum sodium (mEq/L)	<135	<135
Serum osmolality (mOsm/kg)	<275	<275
Urine osmolality (mOsm/kg)	>100 (usually >300)	>100 (usually >300)

Urine sodium (mEq/L)	>40	>40
Volume status	Euvolemic to hypervolemic	Hypovolemic
Response to isotonic saline	No effect	Improved hyponatremia

SIADH, syndrome of inappropriate antidiuretic secretion; CSW, cerebral salt wasting.

Chronic Hyponatremia

The mainstay of treating *hypovolemic hyponatremia*, whatever the cause, is isotonic fluid resuscitation in the form of normal (0.9%) saline. In most cases, correction of the volume deficit results in normalization of the sodium concentration.

The conventional first-line treatment for SIADH commonly involves fluid restriction, but this should more correctly be termed *free water restriction*. All sources of free water, whether oral or in the form of hypotonic intravenous (IV) fluids or enteral feeds, should be restricted in SIADH, but isotonic crystalloids can still be given to maintain intravascular volume, particularly in SAH patients who require volume expansion.

In most cases of SIADH, the usual treatment of oral free water restriction is slow; this treatment prevents more free water from being retained but does not eliminate the free water excess that currently exists. Addition of sodium tablets also does little to correct the problem because 2 g of sodium chloride is the equivalent of only 34 mEq of NaCl, an amount not nearly sufficient to correct the problem.

TABLE 120.2 Interpretation of Fractional Excretion of Sodium (FENa) and Urinary Sodium Concentration

	Prerenal	Intrinsic Renal Disease	Postrenal Obstruction
FENa	<1%	>1%	>4%
U _{Na} (mmol/L)	<20	>40	>40
Examples	Hypovolemia	Acute tubular necrosis	Bladder obstruction
	Heart failure	Glomerulonephritis	Ureteral obstruction
	Renal artery stenosis	Acute nephritis	

U_{Na}, urine sodium.

FENa is calculated as $[(P_{Cr} \times U_{Na}) / (P_{Na} \times U_{Cr})] \times 100$

Recently, a novel therapy of vasopressin receptor blockade has been introduced, which targets the V2 receptor in the distal collecting tubule. By causing a conformational change, aquaporin-2 allows more free water to exit (“aquaresis”) leading to a significant free water clearance. *Tolvaptan* 15 mg PO daily leads to an average increase in serum sodium of 3 mEq/L over 24 hours, whereas *conivaptan* 20 mg IV over 1 hour,

followed by a 20 mg infusion over 24 hours, results in an mean increase in sodium 6 mEq/L over 24 hours. By blocking the ADH receptor, so-called vaptan therapy targets the underlying pathophysiologic abnormality that underlies SIADH. Both agents have a U.S. Food and Drug Administration (FDA) indication for patients with euvolemic or hypervolemic hyponatremia due to SIADH.

Gastric and Genitourinary Function and the Brain

Alden Doerner Rinaldi

Charles C. Esenwa

INTRODUCTION

The brain shares intricate connections with the gastrointestinal (GI) and genitourinary (GU) organ systems. Injury to the nervous system at any anatomic level and by a number of mechanisms—ischemia, trauma, inflammation, infection, toxic-metabolic insult, developmental anomaly, or degeneration—can provoke GI or GU symptoms. Inversely, primary GI disorders may have deleterious effects on neurologic function. In both cases, the human consequences, in terms of quality of life, morbidity, and mortality can be enormous. Here we describe (1) the general neurologic mechanisms that lead to disruption of the healthy physiologic function of the GI and GU systems, (2) specific neurologic disorders that have comorbid GI or GU manifestations, and (3) GI disorders that are associated with neurologic complications.

NEUROANATOMY

The autonomic nervous system is central in the regulation of the GI and GU systems. Autonomic impulses are mediated by the cortex and hypothalamus and affect nuclei in the brain stem, thoracolumbar, and sacral spinal cord. Parasympathetic cholinergic outflow from the dorsal nucleus of the vagus nerve in the medulla promotes the vegetative functions of secretion, digestion, absorption, and gut motility, whereas sacral parasympathetics stimulate voiding, defecation, and tumescence.

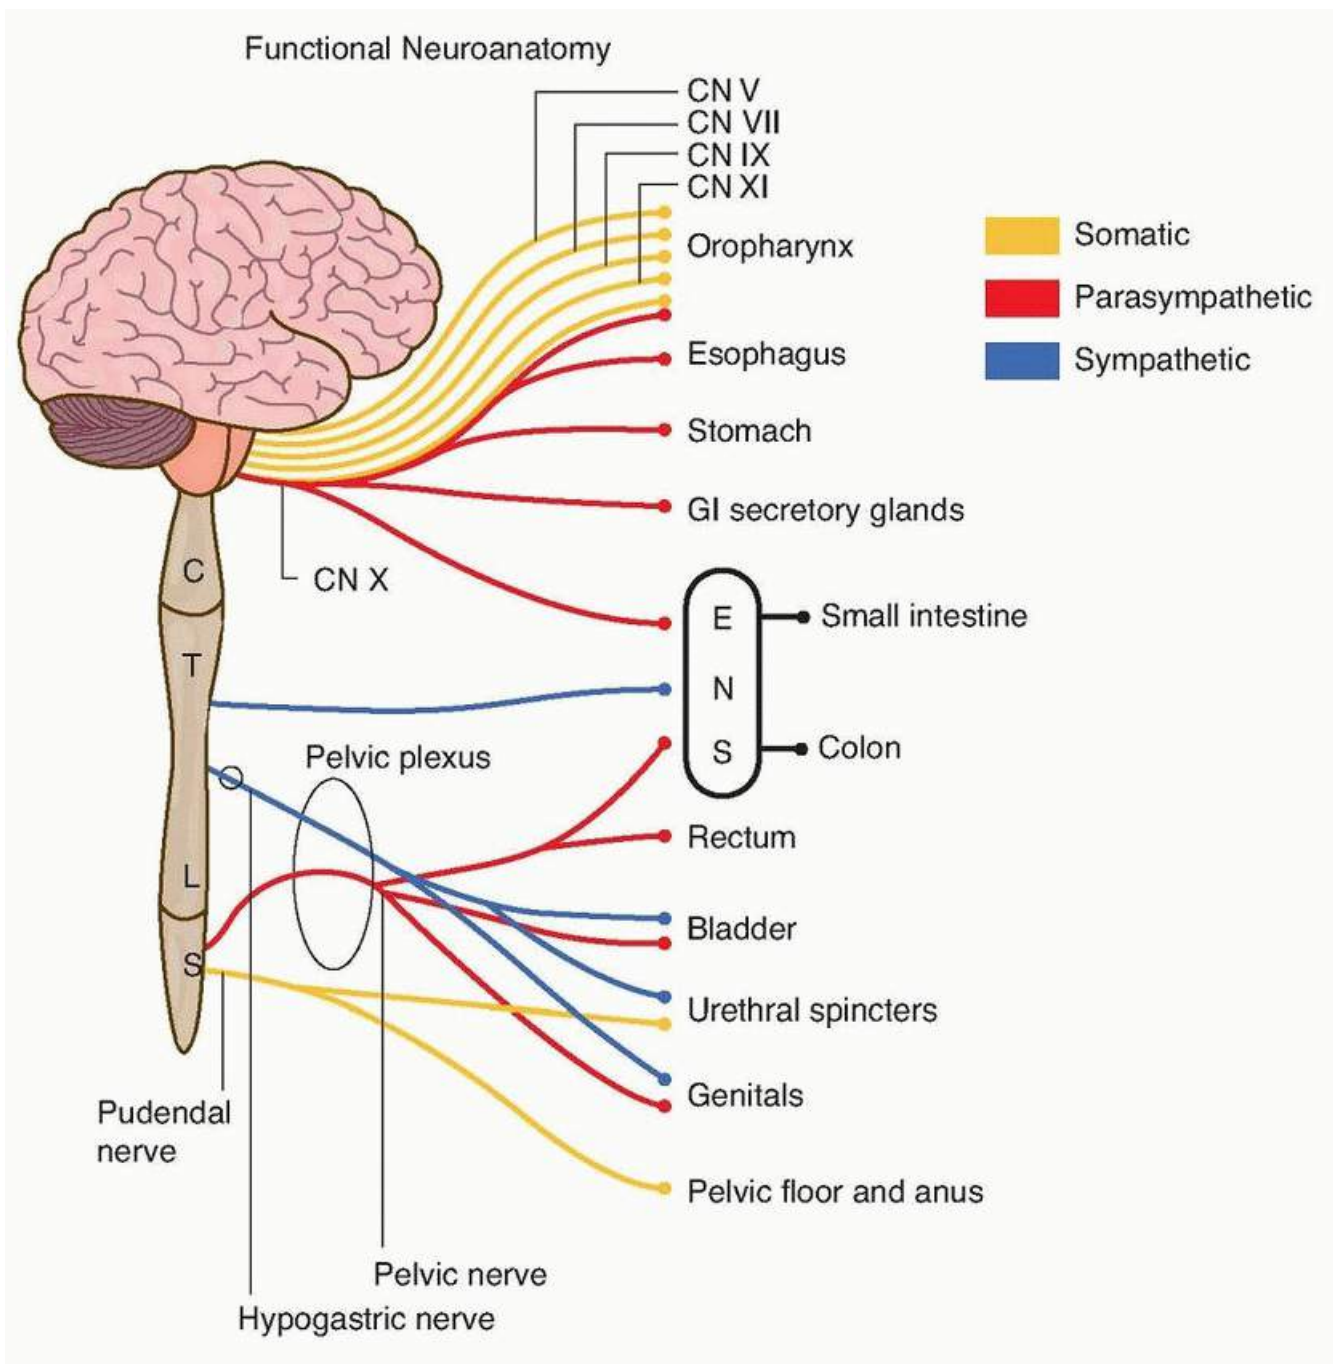

FIGURE 121.1 Peripheral neuroanatomy of the GI and GU systems. Somatic innervation predominantly by cranial nerves V, VII, IX, and XI as well as the pudendal nerves appear in *yellow*. Parasympathetic innervation, depicted in *red*, is carried rostrally from the brain stem to the oropharynx and proximal enteric nervous system by the vagus nerve (cranial nerve X). Caudal parasympathetic innervation arising from the sacral cord, instead, travels by way of the pelvic nerves. Sympathetic output, on the other hand, reaches the enteric nervous system by way of three principle ganglia—the celiac, superior, and inferior mesenteric. The pelvic organs receive their sympathetic innervation via the hypogastric nerve, which complexes with sacral parasympathetic outputs at the pelvic to richly innervate the distal colon, rectum, and GU organs.

Sympathetic adrenergic outflow from the thoracolumbar cord directly opposes parasympathetic function by decreasing secretions, gut motility, and splanchnic blood flow while also increasing sphincter tone to promote urinary and fecal continence. Somatic motor neurons arising from Onuf's nucleus at the S2-S4 segments of the sacral cord pass via the pudendal nerve to innervate muscles of the pelvic floor and sphincters at the anus and urethra maintaining volitional control over continence (Fig. 121.1).

GASTROINTESTINAL MANIFESTATIONS OF NEUROLOGIC DISEASE

The enteric nervous system (ENS) is a quasi-independent branch of the autonomic nervous system with an estimated 400,000 to 600,000 neurons, nearly equal to that of the entire spinal cord.

P.1044

Its function is to (1) orchestrate gut motility, (2) control secretomotor function, (3) regulate local blood flow, (4) control fluid and nutrient absorption, and finally, (5) interact with and modulate the enteric immune system. It has two anatomically distinct subdivisions. The submucosal plexus, which includes Meissner plexus, is located in the gut wall and monitors the local epithelial environment exerting secretomotor control in response to parasympathetic stimuli, whereas the myenteric, or Auerbach, plexus located superficially in the muscular layer of the gut, mediates motility through both sympathetic and parasympathetic inputs. The most proximal and distal parts of the GI tract are somatically innervated, making these areas particularly susceptible to neurologic injury.

DYSPHAGIA

The process of deglutition is initiated in the cerebral cortex and overseen by the nucleus ambiguus in the medulla. Chewing, bolusing, and initiation of the swallow reflex occur in the oropharynx through a coordinated effort involving multiple cranial nerves. The swallow reflex and esophageal peristalsis are the involuntary phases and are overseen by glossopharyngeal and vagal inputs. Difficulty with swallowing, or dysphagia, can manifest as drooling, inability to effectively maneuver the food bolus, a sensation of esophageal fullness, and choking or coughing when attempting to ingest food.

A disease process affecting the primary motor cortex or supplementary motor areas, such as stroke or neurodegenerative dementia, can disrupt the preparatory and oral phases of swallowing. Direct injury to the brain stem or corticobulbar tracts by ischemia, the Parkinson-plus syndromes, or multiple sclerosis (MS) can disrupt inputs to the nucleus ambiguus, affecting the involuntary phase of swallowing. Motor neuron disorders such as amyotrophic lateral sclerosis (Lou Gehrig disease) or spinal and bulbar muscular atrophy (Kennedy disease) cause prominent dysphagia by affecting the motor neurons that supply the muscles of mastication, the oropharynx, and upper esophagus. Peripherally, disorders of the neuromuscular junction, such as myasthenia gravis and botulism, and disorders of muscle, including the muscular dystrophies and inflammatory myopathies, can also have significant effects on all phases of deglutition.

Videofluoroscopy has been the gold standard in the evaluation of dysphagia and direct visualization using videoendoscopy is now being used more commonly. In stroke, where deglutition is expected to recover, percutaneous endoscopic gastrostomy (PEG) is sometimes used as a bridge to independent swallowing. Dysphagia due to a degenerative disorder, although mitigated by swallow therapy, will naturally progress to malnutrition, dehydration, and ultimately carries a high risk of aspiration pneumonia.

ESOPHAGEAL DYSMOTILITY

The lower esophageal sphincter (LES) is controlled by the dorsal motor nucleus of the vagus nerve and is meant to serve as a oneway valve for food contents passing from the esophagus to the stomach. Achalasia is characterized by loss of esophageal peristalsis with sustained contraction of LES leading to megaesophagus and a classic “bird's beak” appearance on videofluoroscopy. Although typically a primary idiopathic disorder, there is evidence implicating an underlying inflammatory or autoimmune process affecting the ganglion cells of the myenteric plexus. Similarly, in the chronic stages of Chagas disease, achalasia can occur by infectious destruction of the myenteric plexus by the protozoa *Trypanosoma cruzi*

GASTROPARESIS

Peristalsis in the stomach is controlled by independent rhythmic contractile waves paced by the interstitial cells

of Cajal and overseen by vagal inputs. Gastroparesis is delayed gastric emptying from impaired antral motility and usually presents as postprandial bloating, pain, nausea, and vomiting. Diabetic vagal neuropathy and diabetic autonomic neuropathy are common causes that can similarly affect bowel motility, causing alternating diarrhea and constipation. Prokinetic agents such as metoclopramide, cisapride, and erythromycin are used to treat acute exacerbations, whereas severe cases may require venting gastrostomy with feeding enterostomy.

STRESS GASTRIC ULCER

Neurologic dysfunction from traumatic brain injury, spinal cord injury, or neurologic surgery predisposes to stress-related mucosal injury and hemorrhage. Stress ulcers are particularly exacerbated by injury involving brain stem and diencephalon. Dysregulation of hypothalamic function with simultaneous overactivation of parasympathetic and sympathetic efferents both increase gastric acid production and compromise mucosal protection. Stress ulcer prophylaxis is recommended in patients with coagulopathy or those requiring mechanical ventilation but should also be considered in patients with traumatic brain or spinal cord injury. Proton pump inhibitors serve as first-line therapy.

BOWEL DYSMOTILITY

Motility of the small and large intestines is coordinated exclusively by reflex loops made up of motor neurons, interneurons, and intrinsic sensory neurons. Primary Hirschsprung disease is a condition in which this neuronal network fails to form. Failure of neural crest cells to migrate during development leaves a section of colon or rectum without functional enteric plexus. Newborns can have delay in passage of meconium and in severe instances will have massive secondary dilation of the bowel termed *megacolon*. In less severe cases, diagnosis can be delayed to late childhood and even adulthood. Patients in this subgroup come to medical attention because of chronic symptoms of constipation. Diagnosis is suggested by videofluoroscopy and is made by rectal biopsy. Surgical resection of the affected bowel is the mainstay in treatment. Destruction of the enteric plexus by *T. cruzi* infection in Chagas disease is a secondary form of megacolon that has a similar diagnostic and therapeutic approach.

INCONTINENCE

Much like the esophagus, autonomic and somatic nerves innervate the anorectum. Reflex muscle contractions and paired inhibitions drive fecal movements through the rectum and into the anal vault. Motor neurons arising from Onuf's nucleus at the sacral level traverse the lower sacral plexus and pudendal nerves, ultimately exerting their effect on the external anal sphincter and muscles of the pelvic floor. Lower motor neuron injuries at this level cause sphincter dysfunction with loss of formed stool and fecal incontinence. Anorectal manometry and anal sphincter electromyography can help in such cases.

URINARY MANIFESTATIONS OF NEUROLOGIC DISEASE

The lower urinary tract (LUT) serves as both reservoir and outlet by the reciprocal action of detrusor and urethral sphincter muscles.

P.1045

Anatomically, the periaqueductal gray (PAG), located in the pons, integrates rostral input from the midbrain, limbic system, and cortex to promote bladder compliance and storage through a direct tonic inhibition of the pontine micturition center (PMC). This inhibition results in a *storage reflex* by which suppression of parasympathetic and activation of sympathetic pathways causes synergistic detrusor relaxation and urethral smooth muscle contraction to close the urethral outlet. A *voiding reflex* is similarly directed by the PAG, whereby release of the PMC activates parasympathetically driven circuits throughout the thoracosacral spinal cord. Cholinergic stimulation contracts the bladder, whereas nitric oxide (NO) released from nonadrenergic noncholinergic parasympathetic (NANC) fibers relaxes the internal urethral sphincter. This action is facilitated by

volitional control of somatically innervated striated muscle of the external urethral sphincter to open the urethral outlet and permit micturition. These distinct reflexes may be disrupted by neurologic injury leading to symptoms that are broadly classifiable as (1) *voiding dysfunction* with hesitancy, intermittency, slow stream, straining, terminal dribble, and retention or (2) *storage dysfunction* with urgency, frequency, nocturia, incontinence, and altered bladder sensation (Fig. 121.2).

VOIDING DYSFUNCTION

Lower motor neuron lesions of the sacral roots, plexus, or peripheral nerves cause parasympathetic denervation of the detrusor muscle resulting in a large, areflexic, and underactive bladder. When occurring alone, functional voiding symptoms may be difficult to differentiate from urinary outlet obstruction, but decreased rectal tone and impaired defecation often accompany. In the extreme form, the patient will have acute urinary retention, which is a urologic emergency. Causes include spinal cord shock from traumatic injury, Guillain-Barré syndrome, conus medullaris syndrome, and cauda equina syndrome; however, additional neurologic symptoms such as sensory loss, weakness, and areflexia will typically predominate in all of these. Less commonly, acute infection of the sacral roots by varicella or herpesviruses can also cause urinary retention accompanied by unilateral sacral pain, sensory loss, and classic zoster or herpetic rash. Opiates, anticholinergic medications, α -adrenoreceptor agonists, benzodiazepines, nonsteroidal anti-inflammatory agents, and calcium channel blockers can all cause reversible voiding dysfunction.

FIGURE 121.2 Symptoms of neurogenic bladder dysfunction. Particular bladder symptoms may be classified as relating to voiding dysfunction, storage dysfunction, or a mixed picture in which both occur simultaneously. Pure voiding (*purple area*) and storage (*coral area*) dysfunction are synonymous with detrusor areflexia and detrusor overactivity, respectively, whereas a combination of voiding and storage dysfunction (*area of overlap*) will lead to detrusor-sphincter dyssynergia. Each condition leads to its own unique pattern of symptomology as listed. OAB,

overactive bladder.

Upper motor neuron lesions of the spinal cord can functionally uncouple the reciprocal action of the pathways responsible for bladder control. Although typically associated with storage dysfunction, it can cause detrusor-sphincter dyssynergia (DSD) with intermittent and simultaneous contraction of the detrusor and urethral sphincter muscles and resultant urinary retention accompanied by hesitancy and interrupted stream.

Bladder scan, postvoid residuals (PVR), urinalysis, and voiding diary will help assess degree of dysfunction, whereas spinal magnetic resonance imaging (MRI), clinical neurophysiology, and lumbar puncture can help to determine the underlying etiology. Patients with either acute or chronic voiding dysfunction are at high risk of developing urinary tract infections and bladder stones and may require intermittent urethral catheterization or a continuous suprapubic catheter. Less definitive symptomatic management may include reflex voiding by suprapubic pressure (Credé maneuver), vibratory stimulation, or cold water applied to the genitals. Detrusor areflexia has a variable response to muscarinic receptor agonists or a parasympathomimetic agent such as bethanechol. Relaxation of the urethral sphincter by α -adrenergic blockade or botulinum toxin injection can provide additional benefit.

STORAGE DYSFUNCTION

Upper motor neuron injury, either above or below the level of the pons, can result in detrusor overactivity (DO). Typically, the bladder is small and hyperreflexic. The patient will suffer from increased urinary frequency, urgency, and incontinence, a symptomatic triad commonly referred to as *overactive bladder (OAB) syndrome*. A chronic elevation of intravesicular pressures results and over time can lead to detrusor hypertrophy, vesicoureteric reflux, hydronephrosis, renal impairment, and even end-stage renal disease.

P.1046

Here too, urodynamic testing should be pursued to better assess the pathology and help plan more invasive management of refractory symptoms.

Therapeutic approaches to storage dysfunction address OAB symptoms while mitigating the long-term consequences of persistently elevated bladder pressure. Nonpharmacologic interventions such as avoiding caffeine, pelvic floor exercises, and bladder training may be efficacious for mild symptoms. Antimuscarinic agents improve bladder compliance and are considered the mainstay of pharmacotherapy. Their use is sometimes limited by adverse central nervous system (CNS) effects, constipation, and urinary retention, in which case muscarinic acetylcholine receptor M_3 specific or blood-brain barrier impermeable agents, such as darifenacin and trospium, can be employed. Desmopressin can also reduce symptoms of urinary frequency but does so by decreasing urine production. When OAB symptoms persist despite optimal pharmacotherapy, therapeutic options include detrusor botulinum toxin injection, sacral neuromodulation, and posterior tibial nerve stimulation. As an option of last resort, surgical augmentation by cystoplasty, urinary diversion, or sphincterotomy can be done to definitively reduce bladder pressures.

SEXUAL MANIFESTATIONS OF NEUROLOGIC DISEASE

The medial preoptic area (MPOA) of the hypothalamus mediates sexual stimuli and initiates the sexual response. Caudal projections to midbrain and brain stem nuclei—including the paraventricular nucleus of the hypothalamus, the ventral tegmental area, the raphe, and gigantocellular nuclei—drive spinal reflexes that initiate tumescence, emission, and ejaculation. Tumescence may occur by both psychogenic and reflexogenic mechanisms driven by cerebrum and spinal cord, respectively. A preponderance of parasympathetic tone transmitted via the pelvic plexus and cavernous nerves to the genital soft tissue relaxes the smooth muscle of the corpora cavernosa and helicine penile arteries. NO released from NANC fibers further increases blood flow and intracavernosal pressure. Subsequent venous compression against the tunic albuginea restricts the outflow of

blood to enhance and maintain erection. In women, tumescence occurs with increased vaginal blood flow and lubrication. Afferent signals carried by the pudendal and hypogastric nerves are distributed rostrally throughout the CNS. As sexual stimulation increases, sympathetic tone builds with glandular emission of the various components of sperm and the formation of semen. At sexual climax, sympathetic surge through the hypogastric nerves results in a coordinated autonomic and somatic reflex. In the male, this results in simultaneous closure of the bladder neck and expulsion of semen by rhythmic contractions of striated muscle.

MALE SEXUAL DYSFUNCTION

Injury rostral to the thoracolumbar cord preserves reflexogenic erection and ejaculation but blocks the psychogenic facilitation of the human sexual response resulting in difficulty maintaining erection. Disconnecting sympathetic pathways by injury to either the thoracolumbar cord or hypogastric nerves, often by lymph node dissection or sigmoidectomy, similarly spares reflexogenic erection but frequently inhibits ejaculation. Sacral spinal cord and root injury, on the other hand, interrupts parasympathetic outflow and reflexogenic sexual response. Plasticity of thoracolumbar outputs to the pelvic plexus provides an alternative pathway by which psychogenic erection and ejaculation may reemerge.

Phosphodiesterase-5 inhibitors improve erectile function, but their use must be weighed against the cardiovascular side effects, to which neurologic patients with autonomic dysfunction are particularly prone. Apomorphine, a dopamine agonist, acts centrally to initiate erection but requires intact efferent spinal pathways to be of benefit. Intracavernous injections of prostaglandin E1, papaverine, and phentolamine, as well as intraurethral alprostadil are effective second-line therapies. Ejaculatory dysfunction and sexual function in general may be treated with yohimbine, a mild monoamine oxidase (MAO) inhibitor, whereas midodrine, an α 1 agonist, has been shown effective in facilitating ejaculation in men with spinal cord injury. In addition, an array of mechanical and electrostimulatory techniques for men may enable sexual function, reproduction, and improve quality of life.

FEMALE SEXUAL DYSFUNCTION

Female sexual dysfunction (FSD) is a frequent, although poorly explored, comorbidity of neurologic disease, which may be categorized as disorder of sexual desire, arousal, orgasm, or sexual pain. FSD negatively impacts quality of life, both directly and by compromising sexual relationships and, thereby, psychosocial health. The prevalence of FSD in MS is double that of the general population with more than 80% of female MS patients reporting symptoms of low desire, decreased arousal, and difficulty achieving orgasm. In MS, these symptoms of sexual dysfunction typically correlate with impaired cognitive function, depressive symptoms, bladder and bowel incontinence, Expanded Disability Status scores, and MS subtype but not time since diagnosis. Similarly, FSD is overrepresented among women with epilepsy, most commonly as a lack of sexual desire and orgasmic dysfunction. Both dysregulated hypothalamic function due to ictal and interictal discharges and effects of enzyme-inducing drugs on circulating testosterone levels may contribute. Given the clear importance of sexual health on overall quality of life, a detailed sexual history should be included in any comprehensive neurologic assessment exploring any impediment to healthy sexual function, satisfaction, and relationship.

NEUROLOGIC DISORDERS AND THE GASTROINTESTINAL AND GENITOURINARY SYSTEMS

PERIPHERAL NEUROPATHY

Peripheral autonomic fibers are particularly susceptible to neuropathy with resultant and often concurrent cardiovascular, GI, and GU dysfunction. Acute cholinergic neuropathies are the exception, causing isolated GI and GU manifestations. GI symptomatology includes postprandial fullness, nausea, paralytic ileus, constipation, intermittent diarrhea, and bowel incontinence. GU symptoms are also varied, but urinary retention and erectile

dysfunction, a sensitive indicator of early autonomic dysfunction, predominate. Diabetes mellitus is the most common cause of autonomic neuropathy. LUT symptoms, gastroparesis, and constipation are present in over half of diabetic patients. Pudendal compressive injury, known as *Alcock syndrome*, is classically associated with bicycle riding or labor and results in genital sensory loss, erectile dysfunction, and fecal and urinary incontinence.

SPINAL CORD INJURY

Spina bifida is one of the most common birth defects worldwide with an incidence of 1 or 2 per 1,000 births. In addition to lower

P.1047

extremity weakness and orthopedic problems, decreased bladder sensation and storage dysfunction commonly occur. This developmental anomaly or its surgical correction is also associated with tethered cord syndrome with traction of the filum terminale and displacement of the conus medullaris below the L1-L2 disk space. As a consequence, flexion or extension of the spine may provoke pain, sphincter dysfunction, and incontinence.

In the acute phase of traumatic spinal cord injury, autonomic and reflex activities may be lost below the level of injury with paralytic ileus and voiding dysfunction. In the chronic phase, these disabled reflexes reemerge with exaggerated function. Hyperreflexia and loss of voluntary control increases bladder and colon wall tone and tightens the external anal sphincter leading to OAB with simultaneous constipation and mild incontinence. Chronic constipation requires attentive bowel care to help prevent stercoral rectal ulcers. With spinal cord transection at or above the level of T6, potentially fatal autonomic dysreflexia can occur after an uninhibited sympathetic surge is triggered by a noxious stimulus, such as bladder or bowel distention.

MULTIPLE SCLEROSIS

Bladder dysfunction is common in MS, affecting 80% to 100% of patients over the course of their disease. Given that there are often incomplete and multilevel spinal cord lesions, patients usually give a mixed picture of urinary tract dysfunction, although storage dysfunction with OAB is most frequently encountered. In addition to conventional approaches, cannabis and the cannabinoid-derived nabiximol have shown modest results in increasing bladder control and improving quality of life. Sexual dysfunction affects more than half of men and women with MS. Decreased libido and arousal; dyspareunia; and inability to achieve erection, orgasm, and ejaculation may be further compounded by associated fatigue, immobility, and allodynia.

PARKINSONISM

Patients with Parkinson disease (PD) have been shown to develop Lewy body pathology in the ENS early in the course of the disease. Moreover, involvement of the dorsal motor nucleus of the vagus nerve causes parasympathetic dysfunction and prominent gastric symptoms. Dysphagia with pooling of saliva and drooling, postprandial fullness from delayed gastric emptying, bowel dysmotility, and constipation frequently occur. Loss of libido and erectile and ejaculatory dysfunction are also common. Pathologic hypersexuality, however, may be seen in the setting of dopamine dysregulation syndrome. Late in the disease course, there can be loss in dopamine-mediated inhibition of the PMC leading to urinary storage dysfunction and OAB.

Multiple system atrophy (MSA) is characterized by ubiquitin and α -synuclein inclusion bodies and cell loss in the brain stem, basal ganglia, cerebellum, motor cortex, and central autonomic system with subsequent autonomic failure, parkinsonism, cerebellar ataxia, and pyramidal signs. Compared to PD, urogenital dysfunction is a relatively early feature. Erectile dysfunction is the initial symptom in an estimated 41% of male patients and eventually affects almost all men with MSA. Symptoms of voiding dysfunction and urinary retention develop early in the course of the disease. As a consequence, more than half of patients with MSA suffer from recurrent urinary tract infections.

CORTICAL AND SUBCORTICAL WHITE MATTER DISEASE

Urodynamic testing in patients with cortical neurodegenerative disorders such as Lewy body dementia and Alzheimer disease frequently demonstrates subclinical storage dysfunction. In normal pressure hydrocephalus (NPH), incontinence is usually the presenting symptom in the triad of gait disturbance and cognitive impairment. DO is the most common form of incontinence after stroke and has a significant impact on poststroke quality of life. Even subclinical leukoaraiosis is thought to contribute to storage dysfunction. The shared mechanism across these disparate conditions is thought to be disruption of frontal white matter tracts.

NEUROLOGIC CONSEQUENCES OF PRIMARY GASTROINTESTINAL DISEASE

Irritable bowel syndrome (IBS) is a common GI syndrome that affects up to 20% of adults. It is defined by cramping abdominal pain, altered bowel habits, and changes in stool form and frequency. The underlying cause, although largely unknown, has been related to abnormally low threshold for neurogenic gut stimulation by inflammatory mediators such as serotonin, histamine, and corticotropin-releasing factor resulting in dysregulated postprandial gut motility and visceral hyperalgesia.

Gluten sensitivity and celiac disease cause small bowel inflammation with dietary exposure to gluten. Diverse neurologic manifestations can occur, often before the GI symptoms are apparent. Gluten ataxia typically presents insidiously in the fifth decade of life as pure cerebellar ataxia. It can be accompanied by myoclonus, opsoclonus, palatal tremor, or chorea. A majority will have cerebellar atrophy on imaging. Nearly a quarter of patients with established celiac disease on a gluten-free diet will have electrophysiologic evidence of peripheral nerve damage. Although most commonly a sensorimotor axonal neuropathy, sensory ganglionopathy, small-fiber neuropathy, and pure motor neuropathy have been reported. Rarely, encephalopathy with headaches, diffuse or focal CNS white matter abnormalities, and cognitive deficits can be seen in association. Gradually progressive white matter disease can also occur and may be difficult to distinguish from MS. Other neurologic disorders reported in association with gluten sensitivity include stiff person syndrome, myopathy, and myelopathy. The common mechanism for these varied clinical manifestations is thought to involve perivascular inflammation, breakdown of the blood-brain barrier, and loss of the CNS immunoprivilege.

Inflammatory bowel disease (IBD) is made up of two entities: ulcerative colitis (UC) and Crohn disease (CD). Similar to gluten sensitivity, neurologic presentations of IBD occasionally precede GI symptoms and involve both the central and peripheral nervous systems. Peripheral neuropathies, including chronic demyelinating or large- and small-fiber axonal types, are the most common neurologic complications affecting approximately one-third of patients and are typically unresponsive to the treatment of underlying IBD.

IBD is a hypercoagulable state with increased levels of factors V and VII, fibrinogen, and von Willebrand factor; decreased levels of protein S and antithrombin; and thrombocytosis and platelet dysfunction. Cerebral venous thrombosis is a common neurologic manifestation of UC. IBD-related arterial ischemic stroke can also occur and can have multiple underlying etiologies including small-vessel disease, artery-to-artery embolism, cardioembolism with or without endocarditis, paradoxical embolism, or vasculitis. Melkersson-Rosenthal syndrome has been described in patients with IBD and is characterized by a triad of recurrent orofacial swelling, relapsing facial paralysis, and fissured tongue.

Bone Diseases and the Central Nervous System

Roger N. Rosenberg

Alison M. Pack

PAGET DISEASE

This chronic disease of the adult skeleton, formerly known as *osteitis deformans*, is characterized by bowing and irregular flattening of the bones. Any or all skeletal bones may be affected, but the tibia, skull, and pelvis are the most frequent sites. Usually, multiple bones are affected, but in 15%, only one is involved. The disease is symptomatic in 15% to 20% of affected individuals. Pain is the most common symptom. Except for the skeletal deformities and pain, the disease causes disability only when the skull or spine is involved.

EPIDEMIOLOGY

There is a postmortem incidence of 3% in patients older than 40 years of age. Men and women are equally affected. The most common age at onset is in the fourth to sixth decades; it is rare before age 30 years. Genetic and environmental factors such as paramyxovirus infection and dietary deficiency of calcium may influence the presentation.

PATHOBIOLOGY

In affected bones, there is an imbalance between the formation and the resorption of bone. In most cases, there is a mixture of excessive bone formation and bone destruction. The areas of bone destruction are filled with hyperplastic vascular connective tissue. New bone formation may occur in the destroyed areas in an irregular disorganized manner. The metabolic disturbance is unknown.

CLINICAL FEATURES

Two types of neurologic symptoms appear: those owing to the abnormalities in bone and those owing to arteriosclerosis, a common accompaniment. The cerebral manifestations that occur with arteriosclerosis are identical to those seen in patients with arteriosclerosis in the absence of Paget disease.

The neurologic defects of osteitis deformans are usually related to pressure on the central nervous system (CNS) or nerve roots by the overgrowth of bone. Convulsive seizures, generalized or neuralgic head pain, cranial nerve palsies, and paraplegia occur in a few cases. Deafness caused by pressure on the auditory nerves is the most common symptom; unilateral facial palsy is the next most common. Loss of vision in one eye, visual field defects, or exophthalmos may occur when the sphenoid bone is affected. Compression of the spinal cord is more common than compression of the brain, which is extremely rare except when there is sarcomatous degeneration of the lesions. Platybasia may occur in advanced cases. Paget disease has also been described in a patient with basilar impression and Arnold-Chiari type I malformation.

DIAGNOSIS

The diagnosis of Paget disease is made from the patient's appearance and the characteristic radiographic changes. Involvement of the skull in advanced cases is manifested by a generalized enlargement of the calvarium, anteroflexion of the head, and depression of the chin on the chest. When the spine is involved, the patient's stature is shortened, the spine is flexed forward, and spinal mobility is greatly reduced.

Radiographically, the skull shows areas of increased bone density with loss of normal architecture, mingled with areas in which the density of the bone is decreased (Fig. 122.1). The margins of the bones are fuzzy

and indistinct. The general appearance is that of an enormous skull with the bones of the vault covered with cotton wool. In advanced cases, there may be a flattening of the base of the skull on the cervical vertebrae (*platybasia*) with signs of damage to the lower cranial nerves, medulla, or cerebellum. Both computed tomography (CT) and magnetic resonance imaging (MRI) aid diagnosis.

The serum calcium content is normal, and the serum phosphorus is normal or only slightly increased. Serum alkaline phosphatase activity is increased; the level varies with the extent and activity of the process. It may be only slightly elevated when the disease is localized to one or two bones.

Diagnosis may be difficult if the clinical symptoms are mainly neurologic. In these instances, radiographs of the pelvis and legs or a general survey of the entire skeleton may establish the diagnosis. Rarely, it may be impossible to distinguish monophasic Paget disease of the skull from osteoblastic metastases. Search for a primary neoplasm, particularly in the prostate, or biopsy of one of the lesions in the skull may be necessary in those cases.

TREATMENT

Bisphosphonates such as pamidronate, alendronate, risedronate, and zoledronic acid are considered the treatment of choice. These agents inhibit osteoblastic bone resorption. They have been shown to heal radiologic lesions and restore normal histology. The longterm effects of these drugs on disease progression have not been adequately studied. The most common indication is for pain. Less potent second-line choices include etidronate and tiludronate. Calcium and vitamin D repletion is necessary to avoid hypocalcemia secondary to bisphosphonates. The value of these medical therapies can be evaluated by reduction of serum levels of alkaline phosphatase measured at 4-month intervals and annual radiographs of specific lesions. Decompression of the spinal cord may be indicated for myelopathy secondary to stenosis created by the enlarged vertebrae. Similarly, platybasia may require to decompression of the posterior fossa to relieve cranial nerve dysfunction.

Calcitonin may also be given to inhibit the osteolytic process. Salmon calcitonin is given in subcutaneous injections of 50 to 100 units daily. Improvement of osteolytic lesions and reversal of neurologic manifestations have been noted with long-term therapy. About 25% of the patients develop serum antibodies to salmon calcitonin, sometimes in titers high enough to make the person resistant to the hormonal action of calcitonin; under these circumstances, human calcitonin may be effective.

OUTCOME

The course is variable but usually extends for decades. The neurologic lesions seldom lead to serious disability other than deafness, convulsive seizures, or compression of the spinal cord.

FIBROUS DYSPLASIA

The skull and the bones in other parts of the body are occasionally involved by a process characterized by small areas of bone destruction or massive sclerotic overgrowth. The clinical picture of fibrous dysplasia is related to the site and extent of the bone overgrowth. Fibrous dysplasia can involve one (monostotic form) or multiple (polyostotic form) bones. Both types may be associated with hyperfunctional endocrinopathies and café au lait lesions referred to as the *McCune-Albright syndrome*. Fibrous dysplasia and McCune-Albright syndrome are caused by a sporadic postzygotic missense mutation in the somatic cells of the *GNAS* complex locus located on

chromosome 20q13. Overall, this leads to defects in osteoblast differentiation and proliferation of osteoblast progenitors leading to abnormal bone. The bones of the skull most often affected are the frontal (56%) and sphenoid (48%) bones. A recent Danish case series of 26 subjects revealed that 80% had involvement of craniofacial bones. Diffuse involvement of the entire skull produces leontiasis ossea, with exophthalmos, optic atrophy, and cranial nerve palsies (Fig. 122.2).

In addition to the disfiguration of the skull in the polyostotic form, symptoms of the monostotic form of the disease include headache, convulsions, exophthalmos, optic atrophy, and deafness. Most patients are, however, asymptomatic. Symptoms may begin at any age, but onset usually occurs in early adult life. The family history is negative, and there is no racial or sexual predominance.

Treatment is limited. Surgical intervention can be used to treat fracture and bony deformities. Although not well studied, bisphosphonates have been used to treat bone pain. Results are mixed and no randomized clinical trial has been done.

ACHONDROPLASIA

Achondroplasia (*chondrodystrophy*) is the most frequent form of skeletal dysplasia causing dwarfism. It is characterized by short arms and legs, lumbar lordosis, and enlargement of the head caused by mutations in the fibroblast growth factor receptor 3 gene (FGFR3). The gene product is expressed in cartilage. A frequent FGFR3 mutation is a Gl 138A codon mutation with GGG to AGG or CGG substitutions, resulting in an exchange of glycine at position 380 in the FGFR3 protein to arginine. This mutation results in a gain of negative function, producing an inactive FGFR and resultant dwarfism. The disease is rare and is estimated to occur in 15 of 1 million births in the United States. It is inherited as an autosomal dominant trait, although 80% of cases are sporadic.

Symptoms of involvement of the nervous system sometimes develop as a result of hydrocephalus, compression of the medulla and cervical cord at the level of the foramen magnum, compression of the spinal cord by ruptured intervertebral disk, and bone

P.1051

compression of the lower thoracic or lumbar cord. Seizures, ataxia, and paraplegia are the most common symptoms. Mental development is usually normal. Mortality rates are significantly elevated secondary to accidental, neurologic, and heart diseaserelated causes.

The diagnosis is made from the characteristic body configuration of short arms and legs, normal-sized trunk, enlargement of the head, and changes in the radiographs of the skeleton. Previously, CT was used to evaluate neurologic complications of achondroplasia. Currently, MRI of the brain and spine best define the presence of hydrocephalus and degree of ventricular compensation as well as whether cord compression is present. Somatosensoryevoked potential may be useful for detecting cervical myelopathy. Many affected infants die in the perinatal period, although a normal life span is possible for patients with less severe involvement of the bones.

Shunting procedures may be needed for hydrocephalus caused by involvement of the bones at the base of the skull. Laminectomy is indicated for signs of cord compression. The mutations in the FGFR3 gene at 4p are usually new mutations and result in autosomal dominant inheritance.

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis is considered the prototype of the spondyloarthropathies. It typically occurs in younger persons and men are affected two to three times more commonly than women. Its etiology is likely secondary to multiple genetic and environmental factors including a strong association with the gene for human leukocyte antigen (HLA)-B27. The condition is common, affecting an estimated 1.4% of the general population. Neurologic symptoms have been considered to be uncommon but have only received limited study. A recent study

investigated this question further among 24 patients recruited from an Egyptian outpatient rheumatologic clinic compared to age and sex matched controls. Neurologic manifestations occurred in 25% of the patients; 8.3% had myelopathy and 16.7% had radiculopathy. Subclinical neurologic complications as evident by neurophysiologic test abnormalities were common, as over 70% had at least one abnormal finding.

FIGURE 122.2 Fibrous dysplasia. CT. **A:** Axial contrast-enhanced scan shows proptosis on *right* with abnormal soft-tissue enhancement within orbit and middle cranial fossa. **B:** Bone window depicts pronounced thickening of sphenoid bone. (Courtesy of Dr. T. L. Chi.)

This inflammatory disorder affects ligamentous insertions into bones; at first, it usually affects the sacroiliac joints and lumbar spine. In some patients, the entire spine is involved, with ossification of the ligaments and fusion of the vertebra. The spine becomes rigid and susceptible to a variety of disorders that may affect the spinal cord, including fractures and dislocations, atlanto-occipital dislocation, and spinal stenosis.

A cauda equina syndrome may appear in patients with longstanding spondylitis. Signs and symptoms are symmetric, with weakness, wasting, and sensory loss in lumbosacral myotomes. Autonomic dysfunction and more specifically parasympathetic dysfunction may occur. Bladder and bowel are commonly affected, and pain may be severe. The mechanism is not clear. Although concomitant arachnoiditis has been suspected as the cause, the syndrome appears late, when there is little evidence that the underlying spondylitis is active. Moreover, there is little inflammation at postmortem examination, which is likely to show chronic fibrosis. There is erosion of posterior bone elements, and, in earlier days, myelography showed enlargement of the caudal sac and prominent diverticulae of the arachnoid. CT shows similar pathology, but MRI is more illuminating, showing nerve root thickening and sometimes enhancement of dura and nerve roots; that pattern suggests inflammation of the arachnoid structures, supporting the earlier theory. Surgery is generally ineffective and has sometimes been deleterious, although there have been rare reports of some relief. Steroid therapy has been similarly without benefit. Physical therapy may be useful. Studies suggest the use of nonsteroidal anti-inflammatory drugs (NSAIDs) or selective cyclo-oxygenase-2 inhibitors for symptomatic patients. Tumor necrosis factor (TNF) inhibitors are useful for patients whose symptoms persist despite treatment with NSAIDs.

ATLANTOAXIAL DISLOCATION

Subluxation of C1 on C2 occurs in many conditions that render the odontoid process of C2 ineffective as a stabilizing post. This occurs most often as a complication of cervical trauma but also as a congenital malformation (alone or in combination with other anomalies of the cervical spine or cranium) and is seen with disproportionate frequency with Down syndrome, ankylosing spondylitis, and rheumatoid arthritis. It can be demonstrated with plain spine films, CT, or MRI. There is risk of cervical myelopathy or medullary compression and sudden death has been reported. For symptomatic cases, surgical stabilization is indicated. For asymptomatic cases, there has to be consideration of the risks of surgery against uncertain risks of no surgery. A general recommendation is to consider stabilization or decompression if imaging shows deformation of the neuraxis, symptomatic or not. A closed reduction and brace immobilization was successfully applied to a patient with traumatic bilateral rotatory dislocation of the atlantoaxial joints.

FRACTURES AND SECONDARY OSTEOPOROSIS: NEUROLOGIC CAUSES

Epilepsy, stroke, multiple sclerosis (MS), and Parkinson disease are all neurologic diseases associated with secondary osteoporosis resulting in increased risk of fracture. In addition, certain treatments of neurologic diseases including glucocorticosteroids, antiepileptic drugs (AEDs), and unfractionated heparin have an independent negative effect on bone. Steroid-induced osteoporosis is the most common cause of secondary osteoporosis. Enzyme-inducing AEDs such as phenytoin, phenobarbital, and carbamazepine are independently associated with lower bone mineral density (BMD). Vitamin D insufficiency is reported in all of these neurologic conditions contributing to reduced BMD and increased fracture risk.

Fracture rates are increased approximately twofold in persons with epilepsy. Falls secondary to seizure activity, gait imbalance because of AED treatment, and potential direct effects of AED therapy on bone including secondary osteoporosis all contribute. Similarly, fractures occur two to seven times more commonly in patients with stroke than in patients without stroke. The fractures usually occur relatively late after stroke onset and more commonly affect the paretic side of the body. The tendency to fall as a result of poststroke hemiplegia and disuse osteoporosis increase the fracture risk. Fracture rates are also higher in patients with MS because of reduced BMD secondary to immobility, prolonged corticosteroid use, and vitamin D insufficiency. Finally, fracture risk is increased in persons with Parkinson disease. In Parkinson disease, the femur is the most commonly fractured bone, whereas in the community, it is the radius. Higher percentages of osteoporosis are found in persons with Parkinson disease.

Clinically, it is important to recognize that persons with neurologic diseases are at increased risk for secondary osteoporosis and fracture. Screening of patients at risk includes serologic 25-hydroxyvitamin D testing and BMD assessment using dual-energy x-ray absorptiometry. When necessary, vitamin D supplementation should be encouraged. For those taking enzyme-inducing AEDs, higher doses of vitamin D supplementation will be needed. Bisphosphonates are commonly used to slow progression of osteoporosis and reduce fracture risk. Randomized controlled trials have found an increase in BMD, a reduction in fracture when bisphosphonates were given to patients with epilepsy [Level 1]¹ or Parkinson disease [Level 1],² and an open-label study found similar benefits amongst stroke survivors [Level 1].³ No study has assessed their impact among MS patients.

Some reports suggest that bisphosphonates are associated with an increased risk of atrial fibrillation and may increase the risk of ischemic stroke. A Danish case-control population-based study did not find an association between oral bisphosphonates and risk of ischemic stroke. A nonsignificant increased risk was found in association with an intravenous formulation (zoledronic acid) in an international multicenter randomized study. Interestingly, animal models suggest that bisphosphonates have an antiatherosclerotic effect, and in one population study, persons who received bisphosphonates had a lower risk of stroke when followed for a 2-year period. These results need to be followed up with a randomized clinical trial.

Malnutrition, Malabsorption, and B₁₂ and Other Vitamin Deficiencies

Rebecca Traub

Laura Lennihan

INTRODUCTION

Malnutrition and malabsorption lead to isolated and multiple nutritional deficiencies with neurologic manifestations that are ascribed to lack of vitamins or other essential nutrients. An excess of certain vitamins or minerals may also cause neurologic syndromes. Obesity and caloric excess also contribute directly and indirectly to neurologic health status. The wide range of neurologic complications of obesity and dietary excess including ischemic stroke, diabetic neuropathy, and degenerative disease of the spine are covered elsewhere in this text. Treatments for the epidemic of obesity have also led to nutritional disorders and neurologic disease.

Although this chapter describes typical syndromes associated with specific vitamin deficiencies, it should be noted that in clinical practice, vitamin deficiency and malnutrition are often multifactorial with multiple deficiencies occurring together to lead to clinical symptoms and signs.

CAUSES OF NUTRITIONAL DEFICIENCIES

Nutritional deficiency may occur due to inadequate dietary intake or impaired absorption related to intrinsic or iatrogenic gastrointestinal disorders. In developing countries, inadequate nutritional intake is often due to inadequate access to food and natural sources of vitamin and minerals. In developed or industrialized countries, causes of impaired intake may include alcoholism, eating disorders, or other causes of severely restricted dietary intake. Alcohol abuse is a major cause of malnutrition and is associated with numerous neurologic syndromes, the pathophysiology of which may be direct toxicity of ethanol, single or multiple vitamin deficiencies, or a combination. Another common cause of malnutrition is *anorexia nervosa*. Severely reduced caloric intake related to eating disorders often causes neuropathy, myopathy, and other syndromes related to multiple vitamin deficiencies.

Malabsorption may arise for any of several reasons, both intrinsic and iatrogenic. Bowel diseases causing malabsorption include inflammatory bowel disease, celiac disease, and disorders of pancreatic enzyme function. In patients with these disorders, neurologic abnormalities seem to be disproportionately frequent. Alone or in combination, there may be evidence of myopathy, sensorimotor peripheral neuropathy, and degeneration of corticospinal tracts and posterior columns and cerebellum. Optic neuritis, atypical pigmentary degeneration of the retina, and dementia are less common signs of malabsorption. Bariatric surgery to treat obesity and its associated complications typically involves restricting gastric volume. Neurologic complications are uncommon but typically are attributed to a combination of malabsorption and hyperemesis resulting in multivitamin deficiency state. Vitamin and mineral supplementation is routinely instituted after bariatric surgery to prevent such complications.

VITAMIN DEFICIENCY AND EXCESS SYNDROMES

Although many presentations of neurologic disorders related to malnutrition are attributed to deficiencies of multiple vitamins and minerals occurring together, there are particular syndromes and neurologic disorders that are typically described with specific deficiencies ([Tables 123.1](#) and [123.2](#)). Oversupplementation of some vitamins or minerals may also lead to neurologic disorders. In the following sections are descriptions of some of

these more commonly seen syndromes.

VITAMIN B₁₂ (COBALAMIN) DEFICIENCY

Pernicious anemia, caused by vitamin B₁₂ deficiency, includes the triad of anemia, neurologic symptoms, and atrophy of the epithelial surface of the tongue. The term *combined degeneration of the spinal cord* to describe the nervous system consequences of B₁₂ deficiency was introduced around 1900. Replacement therapy began in the 1920s with dietary liver and parenteral liver extract in 1948, the year that vitamin B₁₂ was identified. B₁₂ deficiency continues to be common, with increased risk with older age related to atrophic gastritis, decreased dietary intake, and use of medications that interfere with acid secretion.

Physiology of B₁₂ Metabolism

Cobalamin is synthesized only in specific microorganisms, and animal products are the sole dietary source. Gastric acid is needed for peptic digestion to release the vitamin from proteins. The freed B₁₂ is bound by R proteins and then by gastric intrinsic factor, a glycoprotein produced by gastric parietal cells, which is needed for transport of B₁₂ and which is absent in people with pernicious anemia. The combined intrinsic factor-cobalamin complex is transported across the terminal ileum and binds to transcobalamin, which then enters cells for use in metabolic processes.

TABLE 123.1 Neurologic Syndromes Attributed to Vitamin or Mineral Deficiency

Vitamin or Mineral	Neurologic Symptoms or Signs in Deficiency
B ₁ (thiamine)	Seizures (infants), Wernicke encephalopathy, Korsakoff dementia, subacute peripheral neuropathy
B ₆ (pyridoxine)	Peripheral neuropathy, ataxia, altered mental status, seizures
B ₉ (folate)	Neural tube defects (prenatal deficiency)
B ₁₂ (cobalamin)	Myeloneuropathy
A	Xerophthalmia
D	Myopathy
E	Neuropathy, myopathy, ataxia
Copper	Myeloneuropathy
Iron	Restless legs syndrome

TABLE 123.2 Neurologic Syndromes Attributed to Vitamin or Mineral Excess

Vitamin or Mineral	Neurologic Symptoms and Signs in Excess States
B ₆ (pyridoxine)	Neuropathy/ganglionopathy
A	Intracranial hypertension
Manganese	Parkinsonism
Selenium	Neuropathy
Zinc	Myeloneuropathy (through copper deficiency)

Pathobiology of B₁₂ Deficiency

About 80% of adult-onset pernicious anemia is caused by lack of gastric intrinsic factor secondary to atrophic gastritis. The disorder is thought to be autoimmune in origin because antibodies to gastric parietal cells are found in 90% and antibodies to intrinsic factor occur in up to 76% of people with pernicious anemia. Pernicious anemia also coexists with other autoimmune diseases. In those with normal intrinsic factor, the vitamin is not absorbed because of jejunal diverticulosis, tropical or celiac sprue, or loss of the stomach or ileum by surgical resection. Proton pump inhibitors and H₂-blocker medications to treat gastroesophageal reflux or peptic ulcer disease also can cause B₁₂ deficiency. Chronic recreational or occupational exposure to nitrous oxide can interfere with cobalamin metabolism and cause neuropathy or combined system disease. Long-term metformin therapy for diabetes mellitus can also lead to B₁₂ deficiency through interference with calcium-dependent ileal membrane function.

Pathology of B₁₂ Deficiency

In the spinal cord, white matter is affected more than gray. Symmetric loss of myelin sheaths occurs more often than axonal loss; changes are most prominent in the posterior and lateral columns (*combined system disease*; [Figs. 123.1](#) and [123.2](#)). The thoracic cord is affected first and then the process extends into the cervical or lumbar spinal cord. Patchy demyelination may be seen in the frontal white matter, correlating with cognitive clinical symptoms.

FIGURE 123.1 Subacute combined degeneration. Sections of spinal cord at various levels showing segmental loss of myelin, which is most intense in the dorsal and lateral columns.

FIGURE 123.2 Subacute combined degeneration. Destruction of myelin predominating in the posterior and lateral columns. Swelling of affected myelin sheaths causes spongy appearance.

Clinical Features

Today, most people with B₁₂ deficiency are probably asymptomatic.

If the deficiency persists, symptoms may be those of anemia, neurologic disorder, or other problems such as vitiligo, sore tongue, or prematurely gray hair. About 40% of all patients with B₁₂ deficiency have some neurologic symptoms or signs, and these are often the first or most prominent manifestations of the disease. Usually, there are features of both myelopathy and peripheral neuropathy. The most common symptom is acroparesthesia—burning and painful sensations that affect the hands and feet. There may be sensory ataxia due to loss of proprioception. Memory loss, visual loss (owing to optic neuropathy), orthostatic hypotension, anosmia, impaired taste (dysgeusia), sphincter symptoms, and impotence are other symptoms and signs that have been described. B₁₂ levels should be checked in all people undergoing evaluation of cognitive impairment, as it is a treatable cause of memory loss.

Diagnosis

The diagnosis rests on demonstration of serum levels of vitamin B₁₂ under 200 pg/mL, but low-normal values (200 to 350 pg/mL) may be found in people who respond to therapy. Some people with low values are not deficient, and additional tests may be useful. Both methylmalonic acid and homocysteine accumulate when there is impairment of cobalamin-dependent reactions; both metabolites are abnormally increased in serum in more than 99% of patients with true cobalamin deficiency. There are limitations to these tests in certain populations, with elevated homocysteine in hereditary homocystinemia and elevated methylmalonic acid in patients with renal failure. Pernicious anemia, which often underlies B₁₂ deficiency, is best assessed with intrinsic factor antibodies. Sensitivity of these antibodies is only 50% to 70% but specificity is nearly 100%. Antiparietal cell antibodies are more sensitive but less specific.

In patients with neurologic signs, only about 20% have severe anemia. Both the hematocrit and mean corpuscular volume may be normal, although anemia and macrocytosis are the classic abnormalities. Bone marrow biopsy reliably shows megaloblastic abnormalities.

Other testing in B₁₂ deficiency may include magnetic resonance imaging (MRI) or electrodiagnostic testing. MRI may show increased T2-weighted signal and contrast enhancement of the posterior and lateral columns of the spinal cord (Fig. 123.3), with return to normal on treatment. Nerve conduction tests show an axonal sensorimotor neuropathy, although may be normal. B₁₂ deficiency must be considered in any sensorimotor neuropathy, myelopathy, autonomic neuropathy, dementia, or optic neuropathy.

Treatment

B₁₂ replacement is given intramuscularly in a dosage of 1,000 µg daily for the first week, followed by weekly injections for the first month, and then monthly injections for at least a number of months. Although some patients require lifelong B₁₂ injections, particularly those with pernicious anemia or surgical procedures affecting the terminal ileum, others may be transitioned to oral or sublingual formulations for maintenance therapy. There are some studies suggesting that high-dose oral vitamin B₁₂ (1,000 to 2,000 µg daily) may even be a sufficient treatment in place of intramuscular therapy as initial treatment of deficiency.

FIGURE 123.3 Increased T2 signal in the posterior columns on spine MRI in vitamin B₁₂ deficiency. (Courtesy of Dr. Gul Moonis, Associate Professor of Radiology, Columbia University.)

After injection of B₁₂, hematologic improvement may be evident within 48 hours, as well as a subjective sense of general improvement. Paresthesias are often the first neurologic symptoms to improve and do so within 2 weeks; corticospinal and cognitive abnormalities are slower to respond, typically within 3 months but sometimes with continued improvement up to a year. If there is no response in 3 months, the condition is probably not from B₁₂ deficiency. About half of the patients are left with some neurologic abnormality on examination; the residual disability, both related to the myelopathy or cognitive injury, depends on the duration and severity of symptoms at the time that treatment is started.

VITAMIN B₁ (THIAMINE) DEFICIENCY

Thiamine is an important cofactor in the metabolism of amino acids and carbohydrates. Thiamine also plays a role in the neuromuscular junction and neurotransmission. Thiamine deficiency most often occurs as a complication of severe caloric restriction, as in alcoholism, eating disorders, or after gastric surgery. The elderly may be at particular risk of thiamine deficiency due to poor absorption of the vitamin.

Clinical Features

The typical manifestations of thiamine deficiency include beriberi, both infantile and adult, and Wernicke-Korsakoff syndrome. Infantile beriberi typically occurs in the first few months of life, with primarily a cardiopulmonary picture, although a neurologic syndrome of vomiting, nystagmus, and seizures may occur. Infants fed with formula deficient in thiamine have developed beriberi, with a cluster of cases seen in Israel in 2003. Adult beriberi has traditionally been divided into two subtypes. Dry beriberi refers to a sensorimotor neuropathy, which usually occurs with a subacute presentation. The neuropathy can be severe, causing near quadriplegia. Wet beriberi refers to the high-output heart failure sometimes accompanying the neuropathy of adult thiamine deficiency.

Wernicke-Korsakoff syndrome is a central nervous system (CNS) manifestation of thiamine deficiency. Wernicke encephalopathy refers to the acute presentation of altered mental status, ataxia, and ophthalmoplegia. This syndrome has traditionally been described in alcoholics although can be seen in anyone with malnutrition or malabsorption. Many do not have the full clinical triad and rather have isolated ataxia or ophthalmoplegia. *Korsakoff syndrome* refers to the more chronic manifestations of CNS injury due to thiamine deficiency: dementia with prominent or isolated memory deficits and confabulation.

Diagnosis

Thiamine can be measured in a number of ways, most often as a blood level. Supplementation, often given intravenously in the emergency department or ambulance, will usually invalidate tests for B 1 deficiency. The diagnosis is usually made based on historical and clinical grounds, unless a B 1 level is measured before supplementation. In Wernicke-Korsakoff syndrome, MRI of the brain may demonstrate typical abnormalities, including T2-hyperintense signal and restricted diffusion in the mamillary bodies and thalami (Fig. 123.4). These MRI findings are often reversible with treatment.

FIGURE 123.4 Increased T2 signal in the mammillary bodies and midbrain tectum in Wernicke encephalopathy due to thiamine deficiency.

Treatment

Thiamine can be given intravenously or intramuscularly for deficiency conditions, typically 100 mg daily for 7 to 14 days, followed by oral supplementation. Acute Wernicke encephalopathy is treated with even higher doses, 500 mg intravenously three times daily for 3 days, then once daily for an additional 5 days. In any patient at risk for thiamine deficiency (e.g., history of alcoholism or other risk factors for malnutrition), thiamine should be given in the emergency setting prior to glucose administration to avoid precipitation of acute Wernicke encephalopathy, as glucose metabolism increases demand for thiamine. Some advise prophylactic oral thiamine supplementation in alcoholics, elderly, or others at risk for deficiency.

VITAMIN B₆ (PYRIDOXINE) DEFICIENCY OR EXCESS

Vitamin B₆ has a number of critical cofactor roles, including metabolism of amino acids, lipids, and carbohydrates. It also serves in neurotransmitter formation, plays a role in endocrine function through effects on

steroid hormones, and plays a role in both the humoral and cell-mediated immune system. B₆ deficiency occurs typically in combination with other vitamin deficiencies and is seen in any medical condition that causes malnutrition or malabsorption. Uremia and dialysis are specific risk factors for B₆ deficiency.

Clinical Features of B₆ Deficiency

Low B₆ levels have been associated with peripheral neuropathy, although isolated B₆ deficiency causing neuropathy is probably rare. Ataxia and altered mental status have also been reported with low levels of this vitamin. Severe B₆ deficiency leads to seizures, rarely seen from dietary deficiency. The genetic condition of pyridoxindependent seizures is a treatable cause of refractory epilepsy in neonates.

Clinical Features of B₆ Toxicity

Excessive supplementation with B₆ can cause sensory neuropathy and in severe cases, sensory ganglionopathy. Most cases are at doses of B₆ over 250 mg daily, although some have occurred at doses as low as 100 mg daily.

Diagnosis of B₆ Deficiency or Excess

Pyridoxine levels can be measured in plasma. A fasting specimen is the most accurate measure of B₆ tissue stores. In an individual person with neuropathy, it may be difficult to interpret a modestly elevated or reduced B₆ level and know whether it is responsible for clinical symptoms. The lab testing must be combined with clinical history and symptomatology to interpret values.

Treatment

Vitamin B₆ is orally supplemented in cases of deficiency at a dose of 50 to 100 mg daily.

VITAMIN B₉ (FOLIC ACID) DEFICIENCY

Folate is found in many vegetables, legumes, and animal products and in many fortified grains and foods. The primary neurologic role of folate supplementation is in women during pregnancy (or chance of pregnancy), where it plays a critical role in neural tube formation. Prenatal folic acid supplementation reduces the risk of neural tube defects by 50% to 70%. Supplements are recommended at least a month before conception, given the development of the neural tube occurs during the first weeks of embryonic development. In women at low risk for neural tube defects, 0.4 to 0.8 mg daily is recommended. In those on antiepileptics that interfere with folate absorption or use or with a prior history of pregnancy with neural tube defect, 4 mg daily is recommended.

In adults, folate deficiency has primarily hematologic manifestations, with rare, if any, neurologic symptoms. There is limited benefit to checking folate levels in patients presenting with dementia, neuropathy, or other neurologic syndromes. It should be noted that folic acid supplementation may mask vitamin B₁₂ deficiency by correcting some of the associated anemia and allowing the associated neurologic syndrome to go undiagnosed. Therefore, B₁₂ levels should be assessed before initiating folate replacement.

VITAMIN A DEFICIENCY OR TOXICITY

Vitamin A is a fat-soluble vitamin found in plants (beta-carotene or provitamin A) and animal sources, particularly fish, dairy, and meat, especially liver (retinol, preformed vitamin A). Retinoids are compounds related to retinol, many with actions similar to vitamin A. Physiologically, vitamin A has critical roles in fetal eye development and

maintenance of retinal photoreceptor cells. Vitamin A deficiency is uncommon in developed countries but remains one of the most common nutritional deficiencies worldwide. In developed countries, vitamin A deficiency may occur in disorders of fat absorption, as in cystic fibrosis, pancreatic disorders, and celiac disease.

Vitamin A deficiency causes *xerophthalmia*, a term used to describe the spectrum of eye diseases related to deficiency, from night blindness to complete blindness and dryness or ulceration of the conjunctiva and cornea. Diagnosis of vitamin A deficiency is typically made on clinical grounds, although serum retinol levels may be measured.

Vitamin A toxicity (hypervitaminosis A) may also cause neurologic disease, with a clinical presentation of increased cerebrospinal fluid pressure (pseudotumor cerebri). Most cases occur with ingestion of excessive amounts of supplements, although it has

P.1059

also been described in people consuming large amounts of dietary liver. Isotretinoin, a retinoic acid derivative used for the treatment of acne, can similarly cause pseudotumor cerebri, presumably through similar mechanism of action.

VITAMIN D DEFICIENCY

Vitamin D is a fat-soluble vitamin obtained through diet or skin exposure to ultraviolet rays in sunlight. Deficiency may occur due to inadequate dietary intake, disorders of fat absorption, and inadequate exposure to sunlight. The primary manifestations of vitamin D deficiency are related to bone development and maintenance, with rickets in children and osteomalacia in adults. However, vitamin D is implicated in a number of neurologic conditions. Severe vitamin D deficiency has been described causing myopathy but only at very low serum levels, typically in cases of malabsorption. Patients with epilepsy are at increased risk for low bone density and fracture. This increased risk is multifactorial and complex, partially related to cytochrome P450 enzyme inducing antiepileptics, which increase vitamin D metabolism. Because of this risk of bone loss in many epilepsy patients, vitamin D and calcium supplementation is generally advised. Vitamin D has effects on multiple cellular functions of the immune system, and studies have demonstrated an association between vitamin D deficiency and a number of autoimmune disorders, including multiple sclerosis (MS). Whether supplementing vitamin D in patients already diagnosed with MS is beneficial from a clinical standpoint has yet to be established.

Diagnosis of vitamin D deficiency is made by measuring 25-hydroxyvitamin D (25[OH]D) levels to assess vitamin D status. There is some variation in goal levels, with most recommending 30 to 40 ng/mL.

VITAMIN E

Vitamin E is a fat-soluble vitamin found in many foods, including meat, oil, eggs, and vegetables. It is an antioxidant and a component of cell membranes. Risk factors for vitamin E deficiency are disorders that impair fat absorption, including cholestasis and pancreatic deficiencies. There are genetic diseases causing deficient vitamin E absorption and frequent neurologic impairments. The typical neurologic manifestations of vitamin E deficiency include neuropathy, myopathy, and ataxia.

MINERAL DEFICIENCY AND EXCESS SYNDROMES

COPPER DEFICIENCY AND TOXICITY

Copper, a trace mineral present in many foods, is absorbed in the stomach and proximal small intestine. In the liver, it becomes part of ceruloplasmin, which is transported through the body. Deficiency has multisystemic effects on skin and hair, liver, bone, and the nervous system. Risk factors for copper deficiency are malabsorption, including gastric surgery and celiac disease, and excessive zinc ingestion through supplements or zinc-containing denture creams.

Symptoms of Copper Deficiency

The neurologic syndrome of copper deficiency is typically myelopathy or myeloneuropathy, often mimicking vitamin B₁₂ deficiency. There is gait ataxia, sensory loss, and spasticity, with physical exam demonstrating prominent loss of vibration and joint position sense, hyperreflexia, and extensor plantar responses.

Diagnosis of Copper Deficiency

Lab testing in copper deficiency will show a low serum copper and/or ceruloplasmin level. When excessive zinc ingestion is suspected as a cause of copper deficiency, serum zinc and 24-hour urinary zinc can be measured. Given the similar clinical features, vitamin B₁₂ levels should always be checked in patients with suspected copper deficiency myeloneuropathy, and imaging of the spinal cord is often indicated, showing abnormal signal in the posterior columns.

Treatment of Copper Deficiency

Copper is supplemented at a dose of 2 mg daily. Some recommend higher doses for initial treatment in the symptomatic patient. Usually, oral supplementation suffices; however, intravenous and intramuscular forms can be used if there is concern for severe impaired absorption.

Wilson Disease

Wilson disease, which is described in more detail in Chapter 134, is a hereditary, autosomal recessive disorder of excessive copper accumulation, which leads to liver disease and a characteristic neurologic syndrome of ataxia, dysarthria, dystonia, tremor, and parkinsonism.

OTHER MINERAL DEFICIENCIES AND TOXICITIES

- ***Iron***: Iron deficiency in childhood is associated with developmental delays. In adults, iron deficiency is a treatable cause of restless legs syndrome.
- ***Manganese***: Manganese toxicity, primarily occurring through occupational exposure, although also reported in patients receiving parenteral nutrition, can cause symptoms similar to those seen in Parkinson disease.
- ***Selenium***: Selenium toxicity, typically occurring in excessive supplementation, causes neuropathy in association with dermatologic symptoms.
- ***Zinc***: Excessive zinc ingestion, as described earlier, causes a secondary copper deficiency and associated myeloneuropathy.

Neurologic Disease during Pregnancy

Alison M. Pack

INTRODUCTION

Pregnancy and the postpartum period are times of major biologic and social changes. Pregnancy may be associated with alterations in preexisting neurologic conditions, such as epilepsy or migraine, or herald the emergence of neurologic disorders such as peripheral nerve entrapment or a movement disorder. This chapter addresses the diagnosis, management, and treatment of neurologic disorders arising in or altered by pregnancy.

BIOLOGY OF PREGNANCY

Physiologic changes during pregnancy may influence the expression of neurologic disease and complicate management. Alterations in neuroactive steroid hormones may influence the phenotypic appearance of the disease. Changes in pharmacokinetics, medication compliance, and sleep patterns may make disease management more challenging.

The concentration and type of circulating steroid hormones change during pregnancy. Estrogen production increases. In the nonpregnant state, the main circulating estrogens are estradiol, which is synthesized by ovarian thecal cells, and estrone, which is produced by the extraglandular conversion of androstenedione. Estriol is a peripheral metabolite of estrone and estradiol. In pregnancy, the concentrations of all these estrogens, particularly estriol, increase. As pregnancy progresses, maternal steroids and dihydroisoandrosterone from developing fetal adrenal glands are converted principally to estriol. Progesterone production also increases dramatically. These hormonal changes may affect neurologic conditions that are hormone responsive, including migraine, epilepsy, and multiple sclerosis (MS).

Drug pharmacokinetics is affected by the physiologic changes of pregnancy ([Table 124.1](#)). Renal blood flow and glomerular filtration increase as a function of increased cardiac output. Plasma volume, extravascular fluid, and adipose tissue increase to create a larger volume of distribution. Serum albumin decreases, which reduces drug binding, increases the free fraction, and increases drug clearance. These pharmacokinetic alterations may affect drug concentrations and are most important for drugs that are highly protein bound, hepatically metabolized, or renally cleared.

TABLE 124.1 Physiologic Changes during Pregnancy

Variable	Change
Extracellular volume	Increases 4-6 L
Plasma volume	Increases 40%
Renal blood flow	Increases 30%-50%

Glomerular filtration rate	Increases 30%-50%
Cardiac output	Increases 30%-50%
Serum albumin	Decreases 20%-30%

Data from Silberstein SD. Drug treatment and trials in women. In: Kaplan PW, ed. *Neurologic Disease in Women*. New York: Demos Medical Publishing; 1998:25-44.

Other events of pregnancy that may compromise management are hyperemesis gravidarum, sleep deprivation, and poor compliance. Hyperemesis gravidarum can make it difficult to maintain adequate concentrations of oral medications. Sleep deprivation aggravates many neurologic conditions and can be a particular problem in the third trimester. Compliance may deteriorate because of a woman's concern that taking medication might harm her baby. Women are often advised by friends, relatives, and even medical personnel to minimize fetal drug exposure. This may lead to skipped doses, reduced doses, or even self-discontinuation of an indicated medication.

EPILEPSY

Each year, 20,000 women with epilepsy become pregnant. This number has grown as marriage rates have increased for women with epilepsy, as parenting has become more socially supported, and as the medical management of pregnancy in women with epilepsy has improved.

Although most women do maintain good seizure control throughout pregnancy, particularly if they have been seizure free for the 9 months preceding conception, seizure frequency may change. Changes responsible for this include changes in sex hormones, antiepileptic drug (AED) metabolism, sleep schedules, and medication compliance. AED concentrations may change. The total AED concentration falls because of an increase in volume of distribution, decreased drug absorption, and increased drug clearance. Lamotrigine (Lamictal) concentrations decrease throughout pregnancy because of markedly increased clearance. Monitoring of this medication should be performed at least monthly and appropriate adjustments made. Concentrations of levetiracetam (Keppra), oxcarbazepine (Trileptal), and topiramate (Topamax) also decrease in pregnancy and doses need to be adjusted. For some AEDs that are highly protein bound, although the total concentration decreases, the proportion of unbound or free drug increases because albumin levels and protein binding decline. Therefore, it is necessary to follow the non-protein-bound drug concentrations for AEDs that are highly protein bound, including carbamazepine (Tegretol), phenytoin sodium (Dilantin), and sodium valproate (Depakene). Dose adjustments should maintain a stable non-protein-bound fraction.

TERATOGENICITY

The incidence of major congenital malformations (MCMs) in association with in utero AED exposure is increased at least two or threefold when compared to the general population. Current published risks are derived from data gathered from international prospective registries. A prospective U.S.-based North American

registry continues to gather information about pregnancy and fetal outcome in women using AEDs. This registry should be contacted regarding any woman who becomes pregnant while taking AEDs (1-888-233-2334). A European registry includes countries throughout Europe, Asia, and the continent of Australia and prospectively

records information about the effects of AEDs as monotherapy on the developing fetus. The Australian group has independently published their findings. A U.K. register is also actively following pregnant women with epilepsy. MCMs related to AED exposure include cleft lip and palate, cardiac defects (atrial septal defect, tetralogy of Fallot, ventricular septal defect, coarctation of the aorta, patent ductus arteriosus, and pulmonary stenosis), and urogenital defects.

Data is available for many of the commonly used AEDs. Among the currently available AEDs, valproate is consistently associated with the highest rate of MCMs including a higher risk of neural tube defects. When compared to other AEDs, the relative risk is threefold and the absolute risk is 6% to 9% of exposed pregnancies. Results from the European Surveillance of Congenital Anomalies (EUROCAT) found that in utero valproate exposure resulted in a 12.7-fold increase (odds ratio [OR] 12.7, 95% confidence interval [CI] 7.7 to 20.7) of spina bifida when compared to those with no exposure. Findings suggest the risk of valproate-associated MCMs increases at doses above 700 mg/day. Phenobarbital, which is used throughout the world, particularly in developing countries, results in a significantly increased risk of MCMs, notably cardiac malformations. First-trimester topiramate exposure is associated with an increased risk of oral clefts. The rate of oral clefts in the North American Registry was 1.4% (approximately 10-fold higher than control prevalence of 0.11%) and the U.K. Register was 2.2% (U.K. population prevalence is 0.2%). Although carbamazepine has a lower total risk of MCMs (2.6% to 3.8%) than valproate, results from EUROCAT found a 2.6-fold increased risk of spina bifida (OR 2.6, 95% CI 1.2 to 5.3) when compared to those with no exposure. The range of MCMs for lamotrigine in different studies is between 2.0% and 4.6%. Emerging data are encouraging for levetiracetam (Keppra) with published rates of MCMs between 0.7% and 2.4%. Data is limited for other commonly used AEDs including gabapentin, lacosamide, oxcarbazepine, pregabalin, and zonisamide.

Polytherapy is an independent risk factor for teratogenicity. Rates of major malformations are elevated in children exposed to multiple AEDs. Studies find that the children of pregnant women who took multiple AEDs have a higher rate of teratogenicity.

Several mechanisms have been postulated to explain the teratogenicity of AEDs. Some AEDs may be teratogenic because of free radical intermediates that bind with RNA and disrupt DNA synthesis and organogenesis. Higher concentrations of oxide metabolites increase the risk of fetal malformations. Some AEDs cause folic acid deficiency, which is associated with higher occurrence and recurrence rates of neural tube defects. The American Academy of Neurology (AAN) and American Epilepsy Society (AES) recommend that all women with epilepsy of childbearing age receive at least 0.4 mg of folic acid per day. There is currently insufficient evidence to know if higher doses of folic acid offer greater benefit.

EFFECTS OF ANTIEPILEPTIC DRUGS ON COGNITION

In addition to the teratogenicity of AEDs, AEDs may also affect cognitive outcomes of exposed infants. Retrospective and prospective studies suggest a negative effect of valproate; children whose mothers took valproate have lower scores on neuropsychological tests and have more special needs. Early studies were limited by retrospective design, size, and inability to control for confounding variables such as maternal IQ. Data from the prospective well-controlled Neurodevelopmental Effects of Antiepileptic Drugs (NEAD) study finds that in utero valproate exposure was associated with impaired cognitive development. Children exposed to valproate had significantly lower IQ scores at age 6 years (analyses controlled for maternal IQ, AED dose, gestational age, and folic acid use) when compared to children whose mothers took carbamazepine, lamotrigine, or phenytoin. In addition, findings from NEAD suggest that verbal abilities may specifically be at risk from valproate as well as the other studied AEDs (carbamazepine, lamotrigine, and phenytoin). Periconceptional folic acid use resulted in improved cognitive outcomes. The mean IQs were higher in children exposed to periconceptional folic acid (mean 108, 95% CI 106 to 111) when compared to unexposed children for all AEDs (mean 101, 95% CI 98 to

104; $P = .0009$). Valproate exposure has also been reported to increase the risk of autism and autism disorders among in utero exposed children. Cognitive outcome data is limited for other commonly used AEDs.

MANAGEMENT OF EPILEPSY DURING PREGNANCY

Management of epilepsy in women of reproductive age should focus on maintaining effective control of seizures while minimizing fetal exposure to AEDs. This applies to dosage and number of AEDs. Medication reduction or substitution should be considered prior to conception. Altering medication during pregnancy increases the risk of breakthrough seizures and exposes the fetus to an additional AED. The recommended AED management in pregnancy is monotherapy at the lowest effective dose. Higher AED doses are associated with higher risks of MCMs as well as poorer cognitive outcomes. If there is a family history of neural tube defects, an agent other than valproate and carbamazepine should be considered.

Seizures in pregnancy may result in miscarriage, preterm labor, fetal bradycardia, and injury to the mother and child. Seizures do not appear to increase the risk of MCMs. Frequent generalized tonic-clonic seizures increase risk of impaired cognitive development.

Once a woman is pregnant, prenatal diagnostic testing includes a maternal serum α -fetoprotein (AFP) and an anatomic ultrasound at 14 to 18 weeks. This combination will identify more than 95% of infants with neural tube defects. In some instances, amniocentesis may be indicated.

Enzyme-inducing AEDs may result in AED-related vitamin K deficiency, which increase the risk of early fetal hemorrhage. Although earlier AAN guidelines recommended that women taking enzyme-inducing AEDs be given supplemental vitamin K (vitamin K₁, 10 mg/day) for the last month of gestation, a recent review concluded that there was insufficient evidence to determine if prenatal vitamin K supplementation reduces neonatal hemorrhagic complications. Importantly, all neonates receive vitamin K at delivery.

For pregnant women with new-onset seizures, the diagnostic strategy is similar to that for any patient with a first-time seizure. The neurologic history and examination can be directed to signs of a specific cause, such as acute intracranial hemorrhage or central nervous system (CNS) infection. Evaluation should include screening for hypertension, proteinuria, and edema to exclude eclampsia. Follow-up studies include serologic tests for syphilis and HIV, electroencephalogram (EEG), and magnetic resonance imaging (MRI), which is the preferred imaging technique for pregnant women. As in nonpregnant women with a first-time seizure, treatment depends on seizure type and cause.

P.1063

PREECLAMPSIA AND ECLAMPSIA

Preeclampsia and eclampsia are most often seen in young primigravida women and in multiparous women with a change in partner. Preeclampsia is a multisystem disorder that is diagnosed clinically by hypertension, proteinuria, and edema. Modern consensus definitions define preeclampsia as pregnancy-induced hypertension beginning after 20th week with proteinuria. Women are also defined as having *preeclampsia* if they have pregnancy-induced hypertension without proteinuria if they have other common symptoms including cerebral symptoms, epigastric or right upper quadrant pain with nausea or vomiting, or thrombocytopenia and abnormal liver enzymes. Preeclampsia is associated with hepatic and coagulation abnormalities, hypoalbuminemia, increased urate levels, and hemoconcentration. Studies suggest that secreted antiangiogenic factors such as fms-like tyrosine kinase 1 contribute to the acute symptomatology and potential long-term effects. Women who develop preeclampsia/eclampsia should be screened for glomerular and cardiovascular disease throughout life.

EPIDEMIOLOGY

Preeclampsia can progress to eclampsia, a syndrome of diffuse multifocal brain edema that can result in

posterior reversible encephalopathy syndrome (PRES; see also [Chapter 43](#)). Fewer than 5% of women with preeclampsia progress to eclampsia. The incidence in Europe and other developed countries is 1 per 2,000. In developing countries, the incidence varies from 1 in 100 to 1 in 1,700. Worldwide, eclampsia probably accounts for 50,000 deaths annually. The main cause of death is pulmonary edema.

CLINICAL FEATURES

Neurologic abnormalities associated with *eclampsia* may include headaches, confusion or lethargy, seizures, cortical blindness or visual field defects, coma, brain hemorrhage, or death due to herniation from massive global cerebral edema. Seizures are most often generalized but may be partial. Common neurologic findings on exam include memory deficits, increased deep tendon reflexes, visual perception deficits, visual information-processing deficits, altered mental status, and cranial nerve deficits. Cortical blindness and visual field defects may occur because occipital lobes are preferentially involved.

DIAGNOSIS

The differential diagnosis of eclampsia includes subarachnoid hemorrhage and cerebral venous thrombosis. The diagnosis is established by appropriate clinical features in the presence of increased blood pressure plus proteinuria, edema, or both. A significant increase in blood pressure is defined as an increase of more than 15 mm Hg diastolic or 30 mm Hg systolic above baseline measurements obtained before or early in pregnancy. If no early reading is available, a blood pressure of 140/90 mm Hg or higher in late pregnancy is significant.

Neuroimaging, EEG, cerebrospinal fluid (CSF) analysis, and angiography may help in diagnosis. Computed tomography (CT) is usually normal in eclampsia but may show hypodense regions in areas of cerebral edema. MRI provides better detection of edema in the cortical mantle and is the mainstay for confirming the diagnosis. MRI characteristically shows sulcal hyperintensity and small multifocal microinfarcts and hemorrhages, with a predilection for the occipital lobes ([Fig. 124.1](#)). EEG may show spike-and-wave discharges. The CSF is usually normal in preeclampsia but the protein content may be moderately elevated, and the pressure may be increased. In some patients, angiography shows arterial spasm. A subset of patients with severe eclampsia also develop HELLP syndrome.

FIGURE 124.1 Symmetric posterior edema on MRI T2 fluidattenuated inversion recovery (FLAIR) images characteristic of PRES in a hypertensive pregnant woman who presented with visual changes (patches in her vision). (From Hosley CM, McCullough LD. Acute neurologic issues in pregnancy and the peripartum. *Neurohospitalist*. 2011;1:104-116.)

Pathologic examination of eclamptic brains reveals petechial hemorrhages in cortical and subcortical patches. Microscopically, these petechial hemorrhages are ring hemorrhages about capillaries and precapillaries occluded by fibrinoid material. Areas that are predisposed include the parietooccipital and occipital regions.

TREATMENT

The most accepted treatment of eclampsia is delivery of the fetus, if possible. Hypertension should be treated with continuous infusion antihypertensive agents, initially directed toward attaining the patient's baseline premonitory blood pressure levels or a 20% reduction in systolic blood pressure, whichever is higher. Presently, magnesium sulfate (a 4- to 6-g loading dose, followed by an infusion of 1 to 2 g an hour, with a target serum magnesium level of 2.0 to 3.5 mmol/L) is the first-line treatment for the prevention and treatment of eclamptic seizures and other symptoms of eclampsia. Randomized trials have compared magnesium sulfate and other agents including phenytoin and diazepam, and the results suggest that magnesium sulfate is the agent of choice. An international randomized placebo-controlled trial (MAGPIE trial) compared the use of magnesium sulfate and placebo for preeclampsia; magnesium sulfate halved the risk of eclampsia and reduced the risk of maternal death from 1.9% to 0.8% [**Level 1**].¹ Hypertension refractory to magnesium alone can be treated with intravenous nicardipine, clevidipine, or labetalol. There were no substantive harmful effects to mother or baby in the short term. For women at high risk for

STROKE

EPIDEMIOLOGY

Pregnancy is a risk factor for stroke, and the postpartum period is the most vulnerable time. The reported incidence of stroke secondary to pregnancy varies between 4 and 34 deliveries per 100,000. Data from the National Inpatient Sample of the Healthcare Cost and Utilization Project suggest that the incidence of pregnancy-associated stroke has risen since the 1990s. The analysis, which included all types of pregnancy-associated strokes found a 47% increase when comparing the time periods 1994-1995 to 2006-2007. Concurrent hypertensive disorders and heart disease explain most of the increase. Mortality is approximately 10% to 13% and is higher in black women, older women, and those with no prenatal care. Factors that increase the risk for stroke include pregnancy-related hypertension and cesarean delivery. Certain medical conditions may also increase the risk (Table 124.2). Presumptive mechanisms include changes in the coagulation and fibrinolytic systems leading to a hypercoagulable state and an increase in viscosity and stasis, which can promote thrombosis. In the postpartum period, the large decrease in blood volume at childbirth, rapid changes in hormone status that alter hemodynamics and coagulation, and the strain of delivery may predispose to a stroke. The risk of thrombosis in the postpartum period persists until at least 12 weeks after delivery.

ISCHEMIC STROKE

Arterial occlusion resulting in cerebral infarction (see also Chapter 35) accounts for approximately one-half of strokes in pregnant women. Arterial occlusion occurs primarily in the second and third trimesters. Arterial strokes are generally a consequence of identifiable risk factors, including premature atherosclerosis, moyamoya disease, Takayasu arteritis, fibromuscular dysplasia, and primary CNS vasculitis.

CEREBRAL VENOUS THROMBOSIS

Cerebral venous thrombosis (see also Chapter 40) is the second most common cause of stroke in pregnant women, causing approximately one-third of strokes in pregnant women. Cerebral venous thrombosis usually occurs late in pregnancy or in the postpartum period. The pathophysiology of venous infarctions differs from strokes associated with arterial occlusion, as they occur in the setting of venous thrombosis secondary to venous congestion and rise in pressure. Contributing factors include the underlying hypercoagulable state in pregnancy, alterations in platelet function, prothrombotic and antithrombotic proteins, as well as iron deficiency anemia and adaptive response to hemorrhage of labor and delivery. Testing for free protein S deficiency, an acquired hypercoagulable state, is positive in many patients. The clinical presentation is variable, as the woman can present with headaches (the most common presenting symptom), focal neurologic deficits, depressed mental status, or seizures. Hematologic disorders can play an etiologic role in arterial and venous strokes (see Table 124.2). Other causes are cardiogenic and paradoxical emboli.

TABLE 124.2 Medical Conditions that Increase the Risk of Stroke in Pregnancy

Hypertension

Diabetes

Hematologic disorders:

Sickle cell disease

Antiphospholipid syndrome

Thrombotic thrombocytopenic purpura

Hyperhomocysteinemia

Mutations in prothrombin gene

Deficiencies in antithrombin III, protein C, protein S, and factor V Leiden

Cardiac disease

Systemic lupus erythematosus

Smoking

Alcohol use

Recreational drug use (particularly cocaine)

DIAGNOSIS

The key to early diagnosis of stroke in pregnancy is prompt neuroimaging. As with nonpregnant patients, CT and MRI should be done to identify areas of stroke as well as study cerebral vasculature. Angiography including magnetic resonance (MR), CT, or transfemoral catheter angiography may be needed to assess stroke etiology. The current gold standard for diagnosing cerebral venous thrombosis is magnetic resonance venography (MRV) in combination with MRI. Imaging of cerebral venous thrombosis reveals thrombus within cerebral vein or venous sinus either without parenchymal changes or with evidence of cerebral edema, apparent ischemic stroke, or hemorrhage. Hemorrhage occurs in almost half of those with cerebral venous thrombosis (see hemorrhage section for further discussion). Further evaluation such as cardiac ultrasound and serologic studies to evaluate for conditions associated with an increased stroke risk should be pursued. With the exception of protein C, protein S, and antithrombin III deficiency, other hypercoagulable studies can be performed. Evaluation of protein C, protein S, and antithrombin III factors should occur at least 6 weeks after delivery, as they are directly affected by pregnancy itself.

TREATMENT

Treatment of strokes in pregnancy is directed to the specific cause.

Tissue Plasminogen Activator

Intravenous (IV) recombinant tissue plasminogen activator (tPA) is the only U.S. Food and Drug Administration (FDA)-approved thrombolytic drug available for acute ischemic stroke. As pregnant women were excluded from the trials, no controlled studies are available. IV tPA has a short half-life and does not cross the placenta. Potential concern therefore relates to maternal hemorrhage, placental hemorrhage and abruption, fetal loss, and preterm and not increased teratogenicity. In the literature, there are reports of six pregnant women with stroke who received IV tPA. Of those six women, three had no hemorrhagic complications, one had minor hemorrhagic transformation of the stroke, and one had an intrauterine

hematoma. No fetal complications occurred in three, and in two cases, the pregnancy was terminated allowing no further analysis. The sixth patient and fetus died as a result not of a direct effect of the systemic tPA but from arterial dissection complicating angioplasty.

Unfractionated and Low Molecular Weight Heparin

Anticoagulation is a treatment option for prevention of recurrent stroke in patients with stroke due to arterial dissection (see also [Chapter 43](#)). Unfractionated heparin does not cross the placenta.

P.1065

However, long-term use (> 1 month) is associated with osteoporosis and thrombocytopenia. Use of low molecular weight heparin (LMWH) is thus considered to be a more preferable choice than unfractionated heparin, as the development of osteoporosis, thrombocytopenia as well as allergies is less likely. Indeed, LMWH is the drug of choice for treatment of venous thromboembolism from deep vein thrombosis, one of the leading causes of maternal mortality and morbidity in the developed world. Warfarin (Coumadin) crosses the placenta and is a known teratogen. It is therefore recommended only for women who cannot tolerate heparin or who have recurrent thromboembolic events. Aspirin complications in pregnancy include teratogenic effects and bleeding in the neonate. However, low-dose aspirin (<150 mg) is safe in the second and third trimesters, with no increase in maternal or neonatal adverse effects.

Anticoagulation is also the treatment of choice for cerebral venous thrombosis including those with cerebral hemorrhage. Acutely, early anticoagulation with either unfractionated heparin or LMWH is recommended. Studies find that among nonpregnant patients, patients who received heparin had lower mortality when compared to those who did not. In one study, no worsening with anticoagulation occurred in those with hemorrhage (see [Chapter 40](#)). Prolonged anticoagulation is also recommended, typically for 3 to 6 months. Warfarin can be used in the postpartum period. In those cases of cerebral venous thrombosis during pregnancy, LMWH is used and is held during labor and delivery.

CEREBRAL HEMORRHAGE

The risk of cerebral hemorrhage increases in pregnancy. Cerebral hemorrhage occurs in 1 to 5 pregnancies per 10,000, with an associated mortality of 30% to 40%. Factors that predispose to hemorrhage include physiologic changes of pregnancy such as hypertension, high concentrations of estrogens causing arterial dilation, and increases in cardiac output, blood volume, and venous pressure. Pregnancy-related conditions also increase the risk of hemorrhage. These include eclampsia, metastatic choriocarcinoma, cerebral emboli, and coagulopathies.

Subarachnoid hemorrhage accounts for 50% of all intracranial bleeding in pregnancy and carries a high mortality. Cerebral aneurysms and arteriovenous malformations cause most subarachnoid hemorrhages in pregnancy. Other causes include eclampsia, cocaine use, coagulopathies, ectopic endometriosis, moyamoya disease, and choriocarcinoma. Aneurysmal bleeding usually occurs in older patients in the second and third trimesters. In contrast, hemorrhages from arteriovenous malformations (see [Chapter 41](#)) occur in younger women throughout gestation, with the highest risk during labor and the puerperium. A recent large study from China did not, however, find an increased risk of hemorrhage in patients with cerebral arteriovenous malformation during pregnancy and the puerperium.

As discussed previously, cerebral venous thrombosis may also result in cerebral bleeding as a complication of venous infarction. Stasis of flow leads to infarction and secondary hemorrhage. The hemorrhage can extend to multiple areas of the brain including subarachnoid, subdural, and intraventricular spaces.

The diagnosis and treatment of subarachnoid hemorrhage (see [Chapter 39](#)) and intracerebral hemorrhage (see [Chapter 38](#)) in pregnant women are similar to those in nonpregnant patients. Subarachnoid hemorrhage is diagnosed by clinical manifestations and CT. If brain CT is normal and the clinical signs are consistent with

intracranial hemorrhage, lumbar puncture should be performed. Once intracranial hemorrhage is detected, follow-up studies include MRI and four-vessel angiography. Noncontrast CT is also the most sensitive means of diagnosing intracerebral hemorrhage. As previously discussed, cerebral venous thrombosis is best initially diagnosed using MRV in combination with MRI. Digital subtraction angiography with careful venography may be necessary in equivocal cases but is less preferable due to fetal exposure to radiation. Treatment of these conditions is directed to supporting the mother and fetus and preventing complications. Blood pressure should be carefully monitored, and fetal monitoring is indicated. The specific treatment depends on the etiology of the hemorrhage and may require emergent surgery, especially in setting of aneurysmal subarachnoid hemorrhage, when the risk of early rebleeding is high. As in nonpregnant patients, management of intracranial pressure (ICP) is important. Current practice suggests that monitoring ICP and cerebral perfusion pressure (CPP) plays a role in guiding therapy in cerebral hemorrhage, particularly for patients at high risk for developing hydrocephalus (see also [Chapter 107](#)).

MULTIPLE SCLEROSIS

MS affects 1 in 10,000 people in Western countries, primarily women in the childbearing years. MS is classified as either relapsing remitting or chronic progressive with the majority having the relapsing remitting subtype. Pregnancy is common among women with MS, as 20% to 33% of women with MS will have children after being diagnosed. Approximately 97% of these women have the relapsing remitting subtype. Initial presentation of MS during pregnancy is unusual. In contrast, pregnancy may prevent MS. An Australian case-control study of 282 women with a clinically isolated MS attack and 542 controls found that a higher number of pregnancies/births decreased the likelihood of experiencing a first attack. Prospective studies and other surveys find that the relapse rate decreases in pregnancy, especially in the third trimester, and increases in the first 3 months postpartum. A high relapse rate or disability before pregnancy is associated with an increased risk of postpartum attacks. Although prior reports suggested that longterm disability was not affected by pregnancy, studies now suggest that pregnancy may have a protective effect. A recent cross-sectional study of 973 women with relapsing, remitting MS who had two or more pregnancies were less likely to reach a standardized disability marker. A similar outcome was not seen for women with the progressive subtype. The outcome of the pregnancy itself is not affected by MS.

The mechanisms responsible for the change in the rate of relapses include humoral and immunologic changes, as seen also in pregnant women with other autoimmune diseases such as rheumatoid arthritis or systemic lupus erythematosus. There is no correlation of relapse rate with the physical stress of childbirth and caring for the newborn, sleep deprivation, type and dose of anesthesia, breastfeeding, or socioeconomic factors.

Some reports suggest that women with MS are more likely to have inductions and operative interventions during delivery when compared to control groups of women without MS and that MS is associated with lower birth weight. A recent meta-analysis, however, reports that women with MS are not at significant risk for obstetric or neonatal complications.

Treatment of MS is divided into three categories: disease-modulating, acute, and symptomatic therapies. Data regarding pregnancy outcomes and disease-modulating therapies is limited. Among the disease-modulating therapies, glatiramer acetate is currently considered the safest, as it is safe in animal models at doses above

P.1066

those used to treat MS. In a review that included 97 cases, there was no association with low birth weight, congenital anomaly, preterm labor, or spontaneous abortion. The interferon β s are commonly used modulating therapies. They have abortifacient effects in primate models at higher doses than used in humans. Multiple international registry studies have not found an increased risk of birth defects or spontaneous abortions. A systematic review of over 750 pregnancies did find an association with interferon β exposure and lower mean

birth weight, shorter mean birth length, and preterm labor. Natalizumab use in animal studies resulted in decreased survival and hematologic abnormalities. Both a prospective early pregnancy study ($n = 362$) and review of 35 cases found no adverse outcomes. In contrast, eight of nine children born to women with rapidly progressive disease who were treated throughout pregnancy had hematologic abnormalities. Fingolimod and BG-12 are also associated with adverse outcomes in animal studies but human data is lacking. Teriflunomide is FDA category X, as it is teratogenic in animal models. The use of disease-modulating therapies during pregnancy should be limited to cases whereby potential benefits outweigh the risks. If a severe relapse does occur with pregnancy, a short course of corticosteroid therapy is recommended. Use in early pregnancy should be avoided if possible, as it may increase the risk of oral clefts and lower birth weight. In addition, neonatal adrenal suppression may follow maternal corticosteroid use, and large prenatal doses in animals caused growth retardation and compromised development of the CNS. Symptomatic therapies should be minimized in pregnancy. Intrathecal baclofen may be safe for the treatment of severe spasticity due to MS.

MIGRAINE

Migraine is diagnosed in 18% of women of childbearing years, and 60% to 70% of migraine headaches improve during pregnancy, especially for migraines without aura. Women who had migraine onset at menarche or who have had menstrual migraines are more likely to experience improvement, especially in the first or second trimester. Higher levels of estrogen are probably responsible for this improvement during pregnancy. The subsequent fall in estrogen levels may cause postpartum headaches. Postpartum headaches are common, occurring in approximately 30% of women typically during 3 to 6 days postpartum. They are associated with both personal and family histories of migraine headaches.

Migraines may also arise during pregnancy. Studies suggest these headaches are more likely to be with aura. If migraine arises in pregnancy, the differential diagnosis must be considered. A new-onset migraine with aura can be a symptom of vasculitis, brain tumor, or occipital arteriovenous malformation. Subarachnoid hemorrhage can cause headache any time during pregnancy or delivery. Other disorders with headache include stroke, cerebral venous thrombosis, eclampsia, pituitary tumor, and choriocarcinoma.

Medication use during pregnancy should be limited. Acetaminophen is the analgesic of choice, as studies confirm that it is safe at therapeutic doses of 4 g or less per day. If necessary, codeine or other narcotics may be used. Chronic use though can result in neonatal withdrawal. Low-dose aspirin may also be given but should be avoided toward the end of pregnancy because of increased risk of prolonged labor, postpartum hemorrhage, and neonatal bleeding. Ibuprofen is the nonsteroidal anti-inflammatory drug (NSAID) of choice during pregnancy and can be given in the first and second trimesters. Both aspirin and NSAIDs are associated with premature closure of the fetal ductus arteriosus. NSAIDs are also associated with an increased risk of oligohydramnios. Antiemetics such as metoclopramide or prochlorperazine may relieve the headache and associated nausea and vomiting. These agents are generally safe and effective. Ergotamine and dihydroergotamine mesylate (DHE 45) should be avoided. The triptans are effective and widely used for the treatment of headache. Current evidence does not support adverse outcomes associated with their use in pregnancy. However, as limited information is available, their use in pregnancy is not recommended. Sumatriptan has been available the longest and is the most widely used particularly in the first trimester. Current data suggest that first-trimester exposure of sumatriptan is not associated with any significant increase in congenital malformations or poor pregnancy outcomes. For someone with recurrent headaches, a β -adrenergic blocker, such as propranolol, may be used prophylactically. However, adverse effects including intrauterine growth retardation have been reported with β -adrenergic blockers. In addition, treatment should be stopped 2 to 3 days before delivery to reduce risk of fetal bradycardia and reduction in uterine contraction. Other agents used to prophylactically treat migraine headaches include valproate and topiramate. These agents should be discontinued prior to conception, as they are both associated with higher than expected rates of MCMs. In conclusion, the choice of medication for migraine in pregnant

women should balance the mother's comfort with the least fetal risk.

NEOPLASMS

Brain tumors rarely become symptomatic during pregnancy. The types of tumors arising in pregnancy differ from those in nonpregnant women. Glioma is the most common, followed by meningioma, acoustic neuroma, and then a variety of other tumors, including pituitary tumors. Tumor growth may be exacerbated by pregnancy, especially meningioma. Possible mechanisms include increased blood volume, fluid retention, and stimulation of tumor growth by hormones.

Systemic cancer is unusual in young women and rarely begins during pregnancy. Choriocarcinoma is the only systemic tumor specifically associated with pregnancy. Brain metastases are common in choriocarcinoma; among patients diagnosed with choriocarcinoma, 3% to 20% have brain disease at diagnosis.

Cerebral neoplasms cause headaches, seizures, focal signs, or symptoms of increased ICP. The seizures may be partial or generalized. Nausea and vomiting in the first trimester can be confused with morning sickness. All women suspected of having a brain tumor should be examined with MRI. Studies suggest that pregnancy is not a contraindication to biopsy and/or resection. Radiation therapy should be avoided. Chemotherapy is definitely contraindicated. Caesarian section is preferable to vaginal delivery to avoid increased intracranial pressure secondary to Valsalva.

NEUROPATHIES

Women are at an increased risk for peripheral neuropathy during pregnancy and the puerperium. Backache and poorly localized paresthesias are common. At least 50% of pregnant women have back pain. Among the specific rare neuropathies that occur with a higher incidence during pregnancy are carpal tunnel syndrome, facial nerve palsy, meralgia paresthetica, and chronic inflammatory demyelinating polyneuropathy (CIDP).

Carpal tunnel syndrome is the most frequent neuropathy of pregnancy. Estimated incidence ranges from 1% to 60% with approximately 17% described in prospective studies. It usually begins in the third trimester and disappears after delivery. It is

P.1067

attributed to generalized edema. Other potential hypotheses include the effect of hormones such as relaxin on ligamentous laxity, changes in sleep position, and increased adipose tissue. A prospective study found that 30% of women noted resolution of symptoms soon after delivery, 11% during lactation, and 5% after interruption of lactation. Prognosis was better for those who developed symptoms later in pregnancy. *Bell palsy* appears with a slightly higher frequency during pregnancy, mostly in the third trimester. Prognosis for recovery is excellent and is similar to that in nonpregnant women. Corticosteroid use within 3 to 7 days of presentation is the current treatment recommendations for the general population. Steroids are FDA category C and are probably safe in pregnancy. The potential risks in pregnancy particularly if the woman has poorly controlled hypertension or hyperglycemia need to be considered. The AAN guidelines do not find conclusive evidence to support use of antiviral agents; they are, however, safe in pregnancy. As studies suggest that women who develop Bell palsy have an increased incidence of hypertension and preeclampsia, these women should be monitored closely. *Meralgia paresthetica*, a sensory neuropathy of the lateral femoral cutaneous nerve of the thigh, is attributed to compression of the nerve under the lateral part of the inguinal ligament. Swelling during pregnancy, increased body weight, and increased lordosis during pregnancy are possible causes. Numbness, burning, tingling, or pain in the lateral thigh suggests the diagnosis. A local anesthetic with or without steroids is usually all that is necessary. Most women improve in the postpartum period. The incidence of CIDP is slightly higher during pregnancy. As in nonpregnant women, treatment includes plasmapheresis, intravenous immunoglobulin (IVIG), or steroids.

MYASTHENIA GRAVIS

Symptoms of myasthenia gravis (MG) improve in approximately 30% to 40% of patients, remains unchanged in 30% to 40% of patients, and worsen in 20% to 30% of patients. Exacerbations occur more likely in the first trimester, in the final 4 weeks of gestation, or puerperium. The total rate of pregnancy complications particularly preterm rupture of the amniotic membranes is higher among women with MG than in the general population. An association between MG and preeclampsia has been described. Pregnancy does not affect the long-term outcome of MG.

Treatment of myasthenia during pregnancy includes immunosuppressant drugs, plasmapheresis, and MG. Use of prednisone in the first trimester is associated with a small increase in cleft palate, and high doses may lead to premature rupture of membrane. Use of cyclosporine is not recommended because of reported increased risk of spontaneous abortions, prematurity, and low birth weight. Azathioprine and mycophenolate mofetil should not be used, as they can result in significant risk to the fetus and are designated by the FDA as category X. Anticholinesterase drugs are reportedly safe. Thymectomy is deferred until long after delivery. The longterm outcome of MG is not affected by pregnancy. (Myasthenia is also discussed in Chapter 89.)

Neonatal MG affects 12% to 20% of infants born to mothers with MG. The occurrence of neonatal MG does not correlate with maternal disease severity or titer of maternal anticholinesterase receptor antibodies. The symptoms clear within a few weeks.

MOVEMENT DISORDERS

Movement disorders are unusual in young women, but those that specifically occur during pregnancy include the restless legs syndrome, chorea, and drug-induced movement disorders.

The *restless legs syndrome* is the most common movement disorder of pregnancy. It is a chronic condition that has an autosomal dominant pattern of inheritance and is characterized by a crawling, burning, or aching sensation in the calves with an irresistible urge to move the legs. It occurs in 10% to 20% of pregnant women and can occur for the first time in pregnancy, usually in the second and third trimesters. For women with preexisting restless legs syndrome, there can be a worsening of symptoms. In a study of 606 pregnant women, 59 had preexisting restless legs syndrome and among those women, 36 reported worsening of symptoms. Iron deficiency has been found in patients with restless legs syndrome, and treatment of iron deficiency in pregnant women has been advocated but therapeutic trials have yet not been performed. Also, lower folate levels are associated with the restless legs syndrome and treatment recommendations include folate supplementation. Other treatments include massage, flexion and extension, walking, benzodiazepines, opiates, or levodopa.

Chorea gravidarum occurs in pregnancy (see [Chapter 81](#)). Treatment is reserved for those with violent and disabling chorea and includes haloperidol or benzodiazepines.

Drugs that block dopamine receptors are often used to treat the nausea and vomiting of pregnancy. These drugs can cause newonset chorea, tremor, dystonia, or parkinsonism. *Idiopathic Parkinson disease* is uncommon in women younger than 40 years. More common is secondary parkinsonism caused by medication or toxins. There is no definite evidence that Parkinson disease worsens during pregnancy, and there is little information about the toxicity of antiparkinson medications. Successful pregnancies have been reported in women taking levodopa.

Neurologic Complications of Organ Transplantation

Eelco F. M. Wijdicks

INTRODUCTION

Organ transplantation has been associated with a distinct spectrum of neurologic complications. Complications can emerge during pretransplant preparation (e.g., hematopoietic stem cell transplantation and chemotherapy), perioperative support (e.g., cardiac transplantation with cardiopulmonary bypass), and postoperative management (e.g., newly introduced immunosuppression). Some neurologic complications, particularly peripheral nerve injury, are related to the surgical procedure and are less specific.

When large series are reported, neurologic complications from organ transplantation occur in approximately 5% to 10% of patients. Of course, the prevalence depends on the motivation of transplant teams to consult a neurologist and thus is a reflection of how relevant a neurologic complication is when seen in the whole of the clinical picture. Prospective incidence studies may not capture all the postoperative neurologic events if they are not carefully examined by neurologists. Moreover, over the years, there has been a continuous decline in neurologic complications in some types of organ transplantation (e.g., renal, liver).

Neurologic complications are major when they involve recurrent seizures, postoperative failure to awaken, immunosuppression neurotoxicity, or acute disabling neuromuscular disease. Familiarity with the administration and dosing of the main intravenous immunosuppressive drugs has reduced the risk of major neurotoxicity, and extreme cases with coma and seizures and neuroimaging showing diffuse white matter edema are now rarely seen.

This chapter does not attempt to fully discuss all neurologic complications described over the years but will concentrate on the most common considerations ([Table 125.1](#)).

TABLE 125.1 Neurologic Syndromes in Transplant Recipients and Causes

Failure to awaken or acute coma	Hypoxic-ischemic brain injury, brain edema, oversedation, acute graft failure, calcineurin neurotoxicity, intracranial hemorrhage, fulminant CNS infection
Seizures	Calcineurin neurotoxicity, intracranial hemorrhage, new mass (abscess, tumor), posterior reversible encephalopathy syndrome
Aphasia, dysarthria	Calcineurin neurotoxicity, ischemic stroke
Hemiparesis	Brachial plexopathy, ischemic or hemorrhagic stroke, brain tumor, brain abscess
Tremors	Calcineurin neurotoxicity
Myoclonus, asterixis	Acute liver, renal, or pulmonary disease; drug toxicity

GENERAL CONSIDERATIONS

Generally speaking, and not surprisingly, a patient with more elaborate surgery has a higher risk of an early neurologic complication. For instance, liver transplantation carries a much higher risk of early neurologic complications than renal transplantation. Once the patient goes successfully through the first critical weeks, a later phase includes a proclivity for central nervous system (CNS) infections, and much later—although it may be only a few months—serious malignancies may appear. Dramatic is the appearance of posttransplant lymphoproliferative disease (PTLD) and likely explained from introducing genetic material of an Epstein-Barr virus (EBV)-seropositive donor into an EBV-seronegative recipient. It may involve the CNS.

The threshold for cerebral fluid examination should be low even if meningitis is not suspected. Because an infectious mass lesion may be present, a computed tomography (CT) scan may need to be performed to exclude such a lesion. An acutely febrile patient with an abnormal level of consciousness should prompt an aggressive search for a CNS infection. Immunosuppressed transplant recipients have a proclivity for infections with *Listeria monocytogenes*, *Nocardia*, or *Aspergillus*. Infections with *Cryptococcus neoformans* or *Toxoplasma gondii* are rarely seen within 6 months after transplantation. All of these infections present often with meningeal enhancement on a CT or magnetic resonance imaging scan, solitary or multiple abscesses, or ring lesions. None of them are specific and can only be documented by biopsy.

Neurologic complications may result in an increased risk of early demise. Most instructively—when reviewed in more detail—the majority of patients with a lung transplantation were found to have a neurologic manifestation or complication with a third seriously affecting quality of life or resulting in a fatal outcome. That leaves the question of whether neurologic complications are sufficiently recognized.

There are several other considerations. First, neurologic complications may be specific to the type of transplantation. Neurologic complications associated with bone marrow transplantation are quite different than those from organ transplants such as a kidney or liver. Second, seizures are often drug related and less commonly due to a permanent structural lesion. It is a difficult task to implicate certain drugs, but several drugs lower the seizure threshold (i.e., calcineurin inhibitors and antibiotics such as imipenem). Third, any structural lesion in the brain, whether it has the appearance of a cerebritis or ring enhancing, is most often due to an infectious cause and requires immediate treatment. Fourth, major sodium abnormalities and osmotic shifts can be seen after liver transplantation causing osmotic demyelination.

ENCEPHALOPATHY AND DELIRIUM

In actuality, there are particular syndromes that most often present to the neurologist. The most commonly encountered reason

P.1071

for a consultation has to do with assessment of an “altered state of consciousness.” The appearance of a new encephalopathy may be due to rejection causing dysfunction of the graft or may have other causes.

Acute confusional state remains difficult to define in transplant recipients and can be considered if it lasts more than 2 to 3 consecutive days. Postoperative hyperactive delirium associated with hallucinations is common post transplantation, and some circumstances should be recognized. If patients are seen in the immediate postoperative period, both hyperactive and hypoactive delirium after liver transplantation occurs in about a third of the patients. This is more often in patients who had a pretransplant encephalopathy and is more often seen in alcoholic liver disease.

In evaluating patients with impaired consciousness, some guidance can be provided. All potential sedative drugs should be carefully scrutinized, and the time remaining to clearance should be calculated. Physicians should consider administration of flumazenil or naloxone to eliminate the remaining effects. Neurotoxicity of immunosuppressive drugs is frequently implicated, and it continues to be a concern to be dealt with. None of these drugs do cause other structural disease other than a leukoencephalopathy, which cannot be clinically or radiographically distinguished from posterior reversible encephalopathy syndrome (PRES) (see also [Chapter 43](#)).

DRUG TOXICITY

There are many drugs and medications that need to be considered in acute confusion. This includes the use of calcineurin inhibitors, opioid antagonists, β -adrenergic blockers, and high-dose corticosteroids. All of these drugs can be implicated. Other commonly used drugs, such as midazolam and propofol, may impact level of consciousness, particularly because they have different pharmacokinetics in transplant patients. Midazolam, for example, although relatively short acting in comparison with other sedative agents, has a prolonged activity if the liver graft is not functioning fully. It is also highly protein bound, and preexisting low protein levels may increase its sedative effects. Clearance of propofol is dependent on hepatic blood flow and cardiac output; and if both are disturbed, awakening from propofol may be markedly delayed, and the patient may not characteristically awaken as usually anticipated 10 to 15 minutes after discontinuation of infusion. Opioids may continue to linger after cardiac transplantation; typically, very large doses are used during the procedure.

Neurotoxicity associated with cyclosporine or tacrolimus is often considered but less often diagnosed. Breakdown of the blood-brain barrier is needed for cyclosporine to enter because no lipoprotein transport system exists. Cyclosporine is very lipophilic from aliphatic groups but cannot cross the blood-brain barrier because of tight junctions. How crossing occurs remains unknown and perhaps impairment of the blood-brain barrier is facilitated by surgery-associated ischemic insults due to hypotension. The predilection of the posterior areas of the brain may also be related to a less-developed blood-brain barrier that quickly opens when challenged. Oligodendroglia is more susceptible than astrocytes. This characteristic fits nicely with the largely white matter lesions on magnetic resonance imaging.

The pathway of neurotoxicity associated with cyclosporine or tacrolimus has not been resolved at a molecular level. Both immunosuppressive drugs bind to an immunophilin, a protein with an affinity for both drugs, and consequently trigger a cascade of actions that include blockade of calcineurin. Calcineurin is involved in cell signaling and maintenance of cytoskeletal protein function, particularly in oligodendrocytes. Inhibition of calcineurin activity, therefore, may lead to neuronal death or apoptosis. It remains very likely, however, that extremely high doses in the earlier days of transplantation due to unfamiliarity with the drugs has been the major driving factor. This possibility is also supported by the very low incidence of cyclosporine neurotoxicity using oral preparations, resulting in stable blood levels and avoidance of extreme blood levels during intravenous loading. The earliest abnormality seems to be neurotoxicity from fluid extravasation (vasogenic edema) and not cell destruction (cytotoxic edema). Very limited pathology studies are available, and some have suggested demyelination.

One should obtain serum levels of cyclosporine or tacrolimus and trend the values. A marked increase in levels may indicate development of neurotoxicity but such an association is only plausible if it is seen outside of the usual intravenous loading period that is within the first week of treatment. Many transplant surgeons titrate toward increasing plasma levels, and these levels should not be misinterpreted as indicative of neurotoxicity. Recent laboratory values should be obtained and should include electrolyte panel, liver and renal function tests, serum ammonia, arterial blood gas, and where indicated, antiepileptic drug levels.

Finally, a mistake is to label postoperative encephalopathy as multifactorial and it often does nothing to find the

possible triggers. For example, a liver transplant recipient may have severe hyponatremia and rising creatinine and blood urea nitrogen (BUN) and show signs of early rejection. Cefepime toxicity may be the cause of decline in consciousness, and new myoclonus and improvement can be expected when the drug is discontinued.

ORGAN-SPECIFIC COMPLICATIONS

LUNG TRANSPLANTATION

Lung transplant patients, due to significant challenges in oxygenation, may have severe neurologic complications in a third of the patients. Most severe complications are perioperative stroke and encephalopathy, and when neurologic complications occur, there is a higher mortality. Acute hyperammonemia—an unexpected and not completely explained metabolic derangement in lung transplant recipients—has also been described causing seizures and profound encephalopathy. Cyclosporin neurotoxicity is not a major cause of complications in lung transplant recipients.

CARDIAC TRANSPLANTATION

Cardiac transplantations are obviously at risk of ischemic injury as a result of embolization from aortic atheroembolism but also perioperative cardiogenic shock requiring extreme measures such as intra-aortic balloon pump support or extracorporeal membrane oxygenation (ECMO). Intracerebral hemorrhage is rarely seen after cardiac transplantation, but poorly controlled hypertension may cause a lobar or basal ganglia hemorrhage.

LIVER TRANSPLANTATION

One relatively uncommon but dramatic clinical scenario is a patient with acute fulminant hepatic failure (FHF) followed by rapid listing for liver transplantation. This condition is very unique with many clinical uncertainties and neurologists and neurosurgeons are often asked to be part of rapidly changing clinical decisions making. There are three immediate concerns. First, the transition of hepatic encephalopathy (basically a metabolic injury) to brain

P.1072

edema (now a structural injury) must be recognized. Second, intracranial pressure may rise steeply and requires prompt treatment. Third, some patients may have already progressed to brain death, which would preclude transplantation.

The mechanism of brain edema in an FHF (see also [Chapter 119](#)) is influenced by multiple factors. Hyperosmolarity due to increased ammonia and also the development of oxidative stress may contribute. Brain edema is mostly vasogenic and is usually first confirmed by the appearance of severe brain swelling on CT. A useful method to identify the development of vasogenic brain edema in encephalopathic patients with FHF is to identify increased cerebral blood flow velocity associated with reduced waveform pulsatility on transcranial Doppler (see [Chapter 23](#)).

Once identified, brain edema requires aggressive treatment to prevent transtentorial herniation and is best guided by an intracranial pressure (ICP) monitor (see [Chapter 107](#)). However, patients who have an ICP monitoring device placed and are treated aggressively do not have a better outcome or higher percentage of liver transplantation and that could question the role of ICPbased management. Most centers place an intraparenchymal ICP in comatose patients with evidence of cerebral edema on CT, but the situation is further complicated by the presence of coagulopathy, which invariably complicated FHF. Use of recombinant factor VII (4 mg intravenous push [IVP]) or prothrombin complex concentrate (25 to 50 U/kg, depending on baseline international normalized ratio [INR]) is an important new development in countering coagulopathy in FHF. Their use has significantly decreased the frequency of bleeding complications, particularly related to ICP monitor insertion.

INTESTINAL TRANSPLANTATION

Intestinal transplantation for a short bowel syndrome due to thrombosis, inflammatory bowel disease, and radiation enteritis has become another “organ” that can be transplanted but experience is only in a few hundred patients. The initial experience is not sufficient to potentially identify specific complications and most reported are in the known categories such as encephalopathy, CNS infection, seizures, stroke, and neuromuscular complications. Early assessment suggests rate of neurologic complications is much higher than solid organ transplants. One possible explanation is the higher immunosuppression as a result of relative lower resistance to rejection of the intestine.

FIGURE 125.1 Magnetic resonance image of PML after liver transplantation.

LONG-TERM EFFECTS OF IMMUNOSUPPRESSION

Any transplant recipient is at risk of developing B-cell lymphomas or glioblastoma multiforme or progressive multifocal leukoencephalopathy (PML). These disorders are extremely uncommon but can present within months after transplantation. Most notorious is the occurrence of CNS lymphoma several weeks after transplantation (may vary from a few weeks to more than two decades after transplantation). Most posttransplantation lymphomas are monoclonal B-cell lymphomas, but multiclonal B-cell lymphomas or T-cell lymphomas have been reported. EBV infection has been linked to B-cell lymphoma. CNS lymphoma debuts with both brain and spinal cord involvement, but presentation is nonspecific with new behavioral changes, visual hallucinations, or focal signs such as hemiparesis. In most patients, a change in personality may be the only key sign. Meningeal involvement may produce headache. The diagnosis can only be considered if the CT scan shows a new mass lesion in the periventricular region and with proportionally large amount of perilesional edema. A biopsy might be necessary to find the lesion followed by aggressive treatment with radiation. Outcome, however, remains very poor with ultimate demise in all patients.

PML is caused by JC virus (see also [Chapter 66](#)), and the disorder is usually relentless ([Fig. 125.1](#)). Withdrawal of immunotherapy or highly active antiretroviral treatment is considered with some good outcomes reported.

CONCLUSIONS

There are early and late neurologic complications after organ transplantation. The nature of neurologic complications may change with new treatment protocols and new drug approaches. Neurotoxicity from immunosuppressive drugs remains commonly implicated but is not common except if the dosing is high. Other complications relate to common operative stressors (hypotension) or perioperative concerns (infections, hemorrhage). This field—neurology of organ transplantation—requires special expertise and frequent reassessment of the spectrum of complications.

Alcoholism

John C. M. Brust

INTRODUCTION

In the United States, 7% of all adults and 19% of adolescents are “problem drinkers”: psychically or physically dependent on ethanol or, even if abstinent most of the time, likely to get into trouble when they drink. Ethanol-related deaths exceed 100,000 each year, accounting for 5% of all deaths in the United States. The devastation is direct (from intoxication, addiction, and withdrawal) or indirect (from nutritional deficiency or other ethanol-related diseases).

ACUTE ETHANOL SYNDROMES

INTOXICATION

Ethanol acts at many levels of the neuraxis. Although specific ethanol receptors comparable to opioid receptors do not appear to exist, ethanol interacts directly with membrane proteins of a number of neurotransmitter systems, and much of its actions depend on facilitation at inhibitory γ -aminobutyric acid (GABA) receptors and inhibition at excitatory glutamate receptors.

To obtain a mildly intoxicating blood ethanol concentration (BEC) of 100 mg/dL, a 70-kg person must drink about 50 g (2 oz) of 100% ethanol. Following zero-order kinetics, ethanol is metabolized at about 70 to 150 mg/kg of body weight per hour, with a fall in BEC of 10 to 25 mg/dL/h. Thus, most adults require 6 hours to metabolize a 50-g dose, and the ingestion of only 8 g of additional ethanol per hour would maintain the BEC at 100 mg/dL.

Symptoms and signs of acute ethanol intoxication are a result of cerebral depression, possibly at first of the reticular formation with cerebral disinhibition and later of the cerebral cortex itself. Manifestations depend not only on the BEC but also on the rate of climb and the person's tolerance, which is related less to increased metabolism than to poorly understood adaptive changes in the brain. At any BEC, intoxication is more severe when the level is rising than when it is falling, when the level is reached rapidly, and when the level has only recently been achieved. A single BEC determination therefore is not a reliable indicator of drunkenness, and the correlations of [Table 126.1](#) are broad generalizations. Death from respiratory paralysis may occur with a BEC of 400 mg/dL, and survival may occur at 700 mg/dL; a level of 500 mg/dL would be fatal in 50% of individuals.

Low to moderate BECs cause slow saccadic eye movements and interrupted jerky pursuit movements that may impair visual acuity. Esophoria and exophoria cause diplopia. With a BEC of 150 to 250 mg/dL, there is increased electroencephalography (EEG) beta activity (“beta buzz”); higher BECs cause EEG slowing. During sleep, suppression of the REM stage is followed by REM rebound after a few hours.

TABLE 126.1 Correlation of Symptoms with Blood Ethanol Concentration

BEC	Symptoms
50-150 mg/dL	<ul style="list-style-type: none">• Euphoria or dysphoria, shyness or expansiveness, friendliness or argumentativeness• Impaired concentration, judgment, and sexual inhibitions

**150-250
mg/dL**

- Slurred speech and ataxic gait, diplopia, nausea, tachycardia, drowsiness, or labile mood with sudden bursts of anger or antisocial acts

**300
mg/dL**

- Stupor alternating with combativeness or incoherent speech, heavy breathing, vomiting

**400
mg/dL**

- Coma

**500
mg/dL**

- Respiratory paralysis

BEC, blood ethanol concentration.

The term *pathologic intoxication* refers to sudden extreme excitement with irrational or violent behavior after even small doses of ethanol. Episodes are said to last for minutes or hours, followed by sleep and, on awakening, amnesia for the events that took place. Delusions, hallucinations, and homicide may occur during bouts of pathologic intoxication. Some cases might be psychological dissociative reactions; others may be owing to the kind of paradoxical excitation that sometimes follows barbiturate administration. These syndromes are more likely to occur in younger people that have had little prior exposure to alcohol.

The term *alcoholic blackout* refers to amnesia for periods of intoxication, sometimes lasting several hours, even though consciousness at the time did not seem to be disturbed. Although sometimes considered a sign of physiologic dependence, blackouts also occur in occasional drinkers. The amnesia is a direct effect of ethanol on memory encoding.

Acute ethanol poisoning causes more than 1,000 deaths each year in the United States. In stuporous alcoholic patients, subdural hematoma, meningitis, and hypoglycemia are important diagnostic considerations, but it is equally important to remember that ethanol intoxication alone can be fatal.

Blood ethanol causes a rise of blood osmolality, about 22 mOsm/L for every 100 mg/dL of ethanol; however, there are no transmembrane shifts of water, and the hyperosmolarity does not cause symptoms.

P.1075

Ethanol overdose should be considered in any comatose patient whose serum osmolality is higher than predicted by calculation of the sum of serum sodium, glucose, and urea.

TABLE 126.2 Treatment of Acute Ethanol Intoxication

For Obstreperous or Violent Patients

- Isolation, calming environment, and reassurance—avoid sedatives.
- Close observation

For Stuporous or Comatose Patients

- If hypoventilation, artificial respiration in an ICU

- If serum glucose in doubt, intravenous 50% glucose with parenteral thiamine 100 mg

- Careful monitoring of blood pressure; correction of hypovolemia or acid-base imbalance

- Consider hemodialysis if patient is severely acidotic, deeply comatose, or apneic.

- Avoid emetics or gastric lavage.

- Avoid analeptics.

- Do not forget other possible causes of coma in an alcoholic.

ICU, intensive care unit.

Patients stuporous or comatose from ethanol intoxication are generally managed similarly to those poisoned by other depressant drugs (Table 126.2). Death comes from respiratory depression, and mechanical ventilation in an intensive care unit is the mainstay of treatment. Hypovolemia, acid-base or electrolyte imbalance, and abnormal temperature require attention, and if there is any uncertainty about the blood glucose level, 50% glucose is given intravenously, along with parenteral thiamine. Because ethanol is rapidly absorbed, gastric lavage does not help unless other drugs have been ingested. In obstreperous or violent patients, sedatives (including benzodiazepines and dopamine-blocking agents) should be used with caution because they may push patients into stupor and respiratory depression. Patients being addressed may appear alert but then lapse into stupor or coma when stimuli are decreased.

In a nonhabitual drinker, a BEC of 400 mg/dL can take 20 hours to return to zero. The only practical agent that might accelerate ethanol metabolism and elimination is fructose, but this causes gastrointestinal upset, lactic acidosis, and osmotic diuresis. Hemodialysis or peritoneal dialysis can be used for BECs greater than 600 mg/dL; for severe acidosis; for concurrent ingestion of methanol, ethylene glycol, or other dialyzable drugs; or for severely intoxicated children. Analeptic agents such as ethamivan, caffeine, or amphetamine have no useful role and can cause seizures and cardiac arrhythmia. Although patients are often depleted of magnesium, administration of magnesium sulfate may further depress the sensorium in intoxicated patients. Anecdotal reports describe temporary reversal of ethanol intoxication with the mu-opioid antagonist naloxone.

ETHANOL-DRUG INTERACTIONS

The combination of ethanol with other drugs, often in suicide attempts, causes 2,500 deaths annually or 13% of all drug-related fatalities. Ethanol is often taken with marijuana, barbiturates, opioids, cocaine, hallucinogens, and inhalants—with varying interactions. Alcoholics often abuse barbiturates, and although ethanol and barbiturates are cross-tolerant, each lowers the lethal dose of the other when they are taken in combination. Ethanol with chloral hydrate (“Mickey Finn”) may be especially dangerous.

Impaired judgment and respiratory depression are also hazards when ethanol is combined with hypnotics, such as methaqualone (Quaalude), sedating antihistamines, antipsychotic agents, and benzodiazepines. Hypnotic drugs with long half-lives may cause potentially dangerous incoordination when ethanol is

consumed the following day.

The cross-tolerance of ethanol with general anesthetics raises the threshold to sleep induction, but synergistic interaction then increases the depth and length of the anesthetic stage reached. Tricyclic antidepressants do not have a consistent effect; desipramine antagonizes the effects of ethanol and amitriptyline potentiates them. Ethanol and morphine, repeatedly used, can increase each other's potency, and methadone addicts not only frequently become alcoholic but also then develop a characteristic encephalopathy. Death has followed ethanol taken with propoxyphene. A mild reaction resembling that caused by disulfiram occurs when patients combine ethanol with sulfonyleureas such as tolbutamide or with some antibiotics, including chloramphenicol, griseofulvin, isoniazid, metronidazole, and quinacrine.

ETHANOL WITHDRAWAL

The term *hangover* refers to the headache, nausea, vomiting, malaise, nervousness, tremulousness, and sweating that can occur in anyone after brief but excessive drinking. Hangover does not imply ethanol dependence, but *ethanol withdrawal* does imply dependence and encompasses several disorders (Table 126.3), which may occur alone or in combination after reduction or cessation of drinking. Severity depends on the length and degree of a particular binge. Withdrawal syndromes are particularly common during hospitalization and can be exacerbated by concurrent illness.

Tremulousness, the most common ethanol withdrawal symptom, usually appears in the morning after several days of drinking. It is usually promptly relieved by ethanol, but if drinking cannot continue, tremor becomes more intense, with insomnia, easy startle, agitation, facial and conjunctival flushing, sweating, anorexia, nausea, retching, weakness, tachypnea, tachycardia, and systolic hypertension. Except for inattentiveness and inability to fully recall the events that occurred during the binge, mentation is usually intact. In some patients, tremulousness can persist for weeks or longer.

Perceptual disturbances, with variable insight, occur in about 25% of ethanol-dependent patients and include nightmares, illusions, and hallucinations, which are most often visual but may be auditory, tactile, olfactory, or a combination of these. Imagery includes insects, animals, or people. Hallucinations are usually fragmentary,

P.1076

lasting minutes at a time for several days. Sometimes, however, auditory hallucinations of threatening content last much longer and may even progress to a persistent state of auditory hallucinosis with paranoid delusions requiring care in a mental hospital. Repeated bouts of acute auditory hallucinosis may predispose to the chronic form.

TABLE 126.3 Ethanol Withdrawal Syndromes

Early (<48 hours after last drink)

Tremulousness

Hallucinosis

Seizures

Late (>48 hours after last drink)

Delirium tremens

Ethanol can precipitate *seizures* in any epileptic; seizures usually occur the morning after weekend or even single-day drinking rather than during inebriation. Alcohol-related seizures affecting alcoholics not otherwise epileptic have traditionally been considered a withdrawal phenomenon, usually occurring within 48 hours of the last drink in persons who have abused ethanol chronically or in binges for months or years. The minimal duration of drinking sufficient to cause seizures is uncertain, but the risk is dose-related, beginning at only 50-g absolute ethanol daily. (In the United States, a “standard drink” usually means 12 ounces of beer, 5 ounces of wine, or 1.5 ounces of 80 proof spirits, each containing 14 g of absolute ethanol.) Seizures usually occur singly or in a brief cluster; status epilepticus is infrequent. Focal features are present in 25% and do not consistently correlate with evidence of previous head injury or other structural cerebral pathology. Alcohol seizures sometimes accompany tremulousness or hallucinosis, but they may occur in otherwise asymptomatic individuals. Their frequent appearance during active drinking or after more than 1 week of abstinence is consistent with mechanisms other than withdrawal per se.

The diagnosis of alcohol-related seizures depends on an accurate history and exclusion of other cerebral lesions. Workup should include brain computed tomography (CT) or magnetic resonance imaging (MRI) and consideration of lumbar puncture. Alcohol withdrawal can trigger new-onset seizures in patients with intracranial hemorrhage, central nervous system (CNS) infection, or brain neoplasm. Fewer than 10% of patients with alcohol-related seizures have spontaneous EEG abnormalities, compared with 50% of those with idiopathic epilepsy.

Transient *parkinsonism* during alcohol withdrawal is described in older patients. Transient chorea and dystonia are described in younger patients.

In contrast to tremor, hallucinosis, or seizures, which usually occur early and within 48 hours of abstinence, *delirium tremens* usually begins from 48 to 72 hours after the last drink. Patients with delirium tremens are often hospitalized for other reasons. Delirium tremens may follow withdrawal seizures either before the postictal period has cleared or after 1 or 2 asymptomatic days, but when seizures occur during a bout of delirium tremens, some other diagnosis (e.g., meningitis) should be considered.

Symptoms of delirium tremens typically begin and end abruptly, lasting from hours to a few days. There may be alternating periods of confusion and lucidity. Infrequently, relapses may prolong the disorder for a few weeks. Patients are typically agitated, inattentive, and grossly tremulous, with fever, tachycardia, and profuse sweating. They pick at the bed clothes or stare wildly about and intermittently shout at or try to fend off hallucinated people or objects. “Quiet” delirium is infrequent. Mortality is as high as 15%; death is usually owing to other diseases (e.g., pneumonia or cirrhosis), but it may be attributed to unexplained shock or lack of response to therapy or have no apparent cause.

The pathophysiologic basis of ethanol withdrawal in its several forms is probably a combination of glutamate receptor upregulation and GABA receptor downregulation. Neuronal excitotoxicity during withdrawal could then set the stage for a kindling pattern of repeated withdrawal episodes, further excitotoxicity, a permanently lowered seizure threshold, and the occurrence of seizures temporally independent of withdrawal.

Treatment of ethanol withdrawal includes prevention or reduction of early symptoms, prevention of delirium tremens, and management of delirium tremens after it starts (Table 126.4). Benzodiazepines, which have cross-tolerance with ethanol, are appropriately given to recently abstinent alcoholics or those with mild early withdrawal symptoms. Lorazepam (Ativan) 2 to 4 mg every 4 hours is a reasonable starting agent and dose. It is important to adjust the dose to symptom response, level of consciousness, and respiratory status after initiating therapy. A

loading dose may cause symptoms of mild intoxication (calming, dysarthria, ataxia, fine nystagmus); dosage can then be adjusted to avoid both intoxication and tremulousness, and after 1 or 2 days, it can be gradually tapered, with reinstitution should withdrawal symptoms reappear.

Compared to fixed dose schedules, symptom-triggered pharmacotherapy more effectively decreases the likelihood of progression to delirium tremens and is less likely to result in sedative accumulation. Among standard protocols for symptom-triggered therapy, the Clinical Institute for Withdrawal Assessment for Alcohol (CIWA-Ar) scale assesses at regular intervals vital signs, nausea/vomiting, tremor, paroxysmal sweating, anxiety, agitation, tactile, visual or auditory disturbances, headache, and orientation/clouding of consciousness.

β -Adrenergic blockers such as propranolol and α -2 agonists such as clonidine or dexmedetomidine are helpful as adjunctive therapy to help control symptoms of sympathetic overdrive, but they are not cross-tolerant with alcohol and have reportedly triggered hallucinosis. Phenobarbital, which has a different GABAergic mechanism of action than benzodiazepines, has also been used as add-on treatment.

TABLE 126.4 Treatment of Ethanol Withdrawal

Prevention or Reduction of Early Symptoms

- Lorazepam 1-4 mg PO or IV; diazepam 5-20 mg; or chlordiazepoxide 25-100 mg repeated hourly until sedation or mild intoxication; successive daily doses tapered with resumption of higher dose if withdrawal symptoms recur
-
- Thiamine 100 mg and multivitamins IM or IV
-
- Magnesium, potassium, and calcium replacement as needed
-

Delirium Tremens

- Lorazepam 2-4 mg IV or IM or diazepam 10 mg IV, repeated every 5-15 min until calming; maintenance dose every 1-4 h p.r.n.
-
- If refractory to benzodiazepines, phenobarbital 260 mg IV repeated in 30 min p.r.n.
-
- If refractory to phenobarbital, propofol 25-100 μ g/kg/min, with endotracheal intubation and repeated doses to produce general anesthesia
-
- Careful attention to fluid and electrolyte balance; several liters of saline per day, or even pressors, may be needed.
-
- Cooling blanket for high fever
-
- Prevent or correct hypoglycemia.
-

- Thiamine and multivitamin replacement

- Consider coexisting illness (e.g., liver failure, pancreatitis, meningitis, subdural hematoma).

PO, by mouth; IV, intravenous; IM, intramuscular; p.r.n., as needed.

P.1077

Numerous anticonvulsants, especially those with GABAergic actions, have been subjected to randomized trials comparing them to benzodiazepine or placebo. A Cochrane review of 56 such trials concluded that evidence was insufficient to recommend their use. Similar conclusions were reached in Cochrane reviews of baclofen or γ -hydroxybutyric acid compared to benzodiazepines in the treatment of alcohol withdrawal.

Intravenous parenteral ethanol solutions have been used to treat delirium tremens. Treating with parenteral ethanol has the disadvantage of a low therapeutic index, and because ethanol is directly toxic to many organs, it should be avoided during hospitalization, even though most patients resume drinking on discharge. Haloperidol and phenothiazines are less likely to prevent hallucinosis or delirium tremens than drugs cross-tolerant with ethanol, and they can lower seizure threshold, prolong the QT interval, cause hypotension, and impair thermoregulation. They are appropriately considered in patients whose only symptoms are hallucinations or in whom hallucinations have outlasted other withdrawal symptoms.

Parenteral lorazepam given to patients following an ethanol withdrawal seizure reduces the likelihood of recurrence. Status epilepticus during ethanol withdrawal is treated as in other situations. Long-term anticonvulsants are not indicated in patients whose seizures occur only during withdrawal; abstainers do not need them, and drinkers do not take them. Alcoholics whose seizures occur independent of withdrawal and epileptics whose seizures are exacerbated by ethanol unfortunately do need anticonvulsant prophylaxis even though compliance is unlikely.

Hypomagnesemia is common during early ethanol withdrawal, and although it may not be the primary cause of symptoms, magnesium sulfate should be given to hypomagnesemic patients. Hypokalemia and hypocalcemia may also be present, and the latter may respond to treatment only when hypomagnesemia is corrected. Parenteral thiamine and multivitamins are given even if there are no clinical signs of depletion.

Delirium tremens, once it appears, cannot be abruptly reversed by any agent, and the mainstay of treatment is a parenteral benzodiazepine in dosage sufficient to produce adequate sedation. The required doses might be fatal in a normal person (see [Table 126.4](#)), but one cannot predict in any individual patient how high the tolerable dose is. Liver disease decreases the metabolism of benzodiazepines, and patients with cirrhosis are more vulnerable to the depressant effects of sedatives; as delirium tremens clears, hepatic encephalopathy can take its place.

General medical management in delirium tremens is intensive. Although dehydration may be severe enough to cause shock, patients with liver damage may retain sodium and water. Hypokalemia can cause cardiac arrhythmias. Hypoglycemia may be masked, as may other serious coexisting illnesses, such as alcoholic hepatitis, pancreatitis, meningitis, or subdural hematoma.

CHRONIC ETHANOL SYNDROMES

WERNICKE-KORSAKOFF SYNDROME

Although they share the same pathology, Wernicke and Korsakoff syndromes are clinically distinct. Wernicke syndrome, when fullblown, consists of mental, eye movement, and gait abnormalities. Korsakoff syndrome is a

mental disorder that differs qualitatively from Wernicke syndrome (Table 126.5). Both are the result of thiamine deficiency.

In acute Wernicke syndrome, mental symptoms most often consist of a global confusional state that appears over days or weeks; there is inattentiveness, indifference, decreased spontaneous speech, disorientation, impaired memory, and lethargy. Selective amnesia is unusual. Disordered perception is common; a patient might identify the hospital room as his or her apartment or a bar. In fewer than 10%, mentation is normal.

TABLE 126.5 Major Nutritional Disturbances in Alcoholics

Disorder	Clinical Disorder	Deficiency
Wernicke syndrome	Dementia with lethargy, inattentiveness, apathy, and amnesia Ophthalmoparesis Gait ataxia	Thiamine
Korsakoff syndrome	Dementia, mainly amnesia, with or without confabulation	Thiamine
Cerebellar degeneration	Gait ataxia; limb coordination relatively preserved	Probably thiamine plus other vitamins plus ethanol neurotoxicity
Polyneuropathy	Distal limb sensory loss and weakness; less often autonomic dysfunction	Probably thiamine plus other vitamins plus ethanol neurotoxicity
Amblyopia	Optic atrophy, decreased visual acuity, central scotomas; total blindness rare	Probably thiamine plus other vitamins plus ethanol neurotoxicity

Abnormal eye movements include nystagmus (horizontal with or without vertical or rotatory components), lateral rectus palsy (bilateral but usually asymmetric), and conjugate gaze palsy (horizontal with or without vertical), progressing to complete external ophthalmoplegia. Although sluggishness of pupillary reaction is common, total loss of reactivity to light and ptosis are rare. Mental symptoms, including progression to coma, can occur without evident abnormal eye movements in patients with pathologically verified acute Wernicke syndrome.

Truncal ataxia, present in more than 80% of patients, may prevent standing or walking. Dysarthria and limb ataxia, especially in the arms, are infrequent. Peripheral neuropathy, which occurs to some degree in most patients, may cause weakness sufficient to mask the ataxia. Abnormalities of vestibular caloric testing are common, with gradual improvement, often incomplete, over several months.

Patients with the Wernicke syndrome frequently have signs of nutritional deficiency (e.g., skin changes, tongue redness, cheilosis) or liver disease. Autonomic signs are common. Although beriberi heart disease is rare, acute tachycardia, dyspnea on exertion, and postural hypotension unexplained by hypovolemia are common, and sudden circulatory collapse may follow mild exertion. Hypothermia is less frequent; fever usually indicates infection.

In acute Wernicke syndrome, the EEG may show diffuse slowing or it may be normal. Cerebrospinal fluid (CSF) is normal except for occasional mild protein elevation. Elevated blood pyruvate, falling with treatment, is not

(which requires thiamine pyrophosphate as cofactor) and serum thiamine level may be depressed, but in most centers, the diagnosis depends on history and examination (and thiamine and multivitamins should be given to any alcoholic patient, symptomatic or not).

In most patients, the more purely amnesic syndrome of Korsakoff emerges as the other mental symptoms of Wernicke syndrome respond to treatment. How often Korsakoff syndrome occurs without a background of Wernicke syndrome is disputed and bound up with the question of "alcoholic dementia" (see later in the text). Pathologic changes of Wernicke-Korsakoff are sometimes encountered unexpectedly at autopsy, suggesting the presence of subclinical or atypical forms, including unexplained coma.

The amnesia of Korsakoff syndrome is both anterograde, with inability to retain new information, and retrograde, with rather randomly lost recall for events months or years old. Alertness, attentiveness, and behavior are relatively preserved, but there tends to be a lack of spontaneous speech or activity. Confabulation is not invariable and, if initially present, tends gradually to disappear. Insight is usually impaired, and there may be flagrant anosognosia for the mental disturbance.

The histopathologic lesions of Wernicke-Korsakoff syndrome consist of variable degrees of neuronal, axonal, and myelin loss; prominent blood vessels; reactive microglia, macrophages, and astrocytes; and, infrequently, small hemorrhages. Nerve cells may be relatively preserved in the presence of extensive myelin destruction and gliosis, and astrocytosis may predominate chronically.

Lesions affect the thalamus (especially the anterior and dorsomedial nuclei and the medial pulvinar), the hypothalamus (especially the mammillary bodies), the midbrain (especially the oculomotor and periaqueductal areas), and the pons and medulla (especially the abducens and medial vestibular nuclei). Such lesions sometimes produce abnormal signals on MRI, including diffusion-weighted imaging (DWI). Diffusion tensor imaging reveals disruption of the fornix. In the anterior-superior vermis of the cerebellum, severe Purkinje cell loss and astrocytosis accompany lesser degrees of neuronal loss and gliosis in the molecular and granular layers.

Memory impairment in Korsakoff syndrome correlates best with lesions involving the anterior nuclei of the thalamus; other components of the so-called Papez circuit (e.g., the mammillary bodies) probably contribute. The global confusion of Wernicke syndrome can occur without visible thalamic lesions and may be a biochemical disorder. Periaqueductal, oculomotor, or abducens nucleus lesions probably explain ophthalmoparesis. Both cerebellar and vestibular lesions likely contribute to ataxia.

Experimental and clinical evidence ascribes a specific role to thiamine in the Wernicke-Korsakoff syndrome. A genetic influence is implied because only a few alcoholic or otherwise malnourished people are affected, and whites seem more susceptible than blacks.

Untreated Wernicke-Korsakoff syndrome can be fatal, and the mortality rate is 10% among treated patients. Concomitant liver failure, infection, or delirium tremens often makes the cause of death unclear. Postural hypotension and tachycardia call for strict bed rest; associated medical problems may require intensive care. The cornerstone of treatment is thiamine, 1,000 mg daily, until a normal diet can be taken; intramuscular or intravenous administration is preferred because thiamine absorption is impaired in chronic alcoholics. Hypomagnesemia may retard improvement after thiamine treatment; magnesium is therefore replaced, along with other vitamins. Protein intake may have to be titrated against the patient's liver status.

With thiamine treatment, the ocular abnormalities (especially abducens and gaze palsies) improve within a few hours and usually resolve within 1 week; in about 35% of patients, horizontal nystagmus persists indefinitely. Global confusion may improve in hours or days and usually resolves within 1 month, leaving Korsakoff amnesia

in more than 80%. In less than 25% of these patients, there is eventual clearing of the memory deficit. Ataxia may improve in a few days, but recovery is complete in less than 50% of patients, and nearly 35% do not show improvement at all.

Nonalcoholics who develop Wernicke encephalopathy (e.g., as a result of starvation or hyperemesis gravidarum) are less likely to have Korsakoff amnesia following treatment, consistent with a contributory role for alcohol itself in the pathogenesis of Wernicke-Korsakoff syndrome.

ALCOHOLIC CEREBELLAR DEGENERATION

Cerebellar cortical degeneration may occur in nutritionally deficient alcoholics without Wernicke-Korsakoff syndrome (see [Table 126.5](#)). Instability of the trunk is the major symptom, often with incoordination of leg movements. Arm ataxia is less prominent; nystagmus and dysarthria are rare. Symptoms evolve in weeks or months and eventually stabilize, sometimes even with continued drinking and poor nutrition. Ataxia without Wernicke disease is less likely to appear abruptly or to improve.

Pathologically, the superior vermis is invariably involved, with nerve cell loss and gliosis in the molecular, granular, and especially the Purkinje cell layers. There may be secondary degeneration of the olives and of the fastigial, emboliform, globose, and vestibular nuclei. Involvement of the cerebellar hemispheric cortex is exceptional and limited to the anterior lobes. Pathologic evidence of Wernicke disease may coexist, even though it is unsuspected clinically. CT and autopsies, moreover, have revealed cerebellar atrophy in alcoholics who were not clinically ataxic.

Although similar cerebellar lesions occur in malnourished nonalcoholics, most patients with alcoholic cerebellar degeneration do not have clinical or pathologic evidence of Wernicke disease. The disorder is probably the result of both nutritional deficiency and ethanol toxicity, perhaps involving glutamate.

ALCOHOLIC POLYNEUROPATHY

Alcoholic polyneuropathy is a sensorimotor disorder that stabilizes or improves with abstinence and an adequate diet (see [Table 126.5](#)). Neuropathy is found in most patients with Wernicke-Korsakoff syndrome but more often occurs alone. Paresthesia is usually the first symptom; there may be burning or lancinating pain and exquisite tenderness of the calves or soles. Impaired vibratory sense is usually the earliest sign; proprioception tends to be preserved until other sensory loss is substantial. Loss of ankle jerks is another early sign; eventually, there is diffuse areflexia. Weakness appears at any time and may be severe. Distal leg muscles are affected first, although proximal weakness may be marked. Radiologically demonstrable neuropathic arthropathy of the feet is common, as are skin changes (e.g., thinning, glossiness, reddening, cyanosis, hyperhidrosis). Peripheral autonomic abnormalities are usually less prominent than in diabetic neuropathy but may cause urinary and fecal incontinence, hypotension, hypothermia, cardiac arrhythmia, dysphagia, dysphonia, impaired esophageal peristalsis, altered sweat patterns, or abnormal Valsalva ratio. Pupillary parasympathetic denervation is rare. The CSF is usually normal except for occasional mild elevation of protein content.

Pathologically, the neuropathy is axonal, and clinical and experimental evidence suggests that it is both toxic and nutritional

P.1079

in origin. A clinical and pathologic study found that pure thiamine deficiency neuropathy (TDN) differs from pure alcoholic neuropathy (ALN); ALN is sensory dominant, slowly progressive, and painful and causes predominantly small-fiber axonal loss, whereas TDN is motor dominant and acutely progressive and causes predominantly large-fiber axonal loss.

Peripheral nerve pressure palsies, especially radial and peroneal, are common in alcoholics. Nutritional polyneuropathy may increase the vulnerability of peripheral nerves to compression injury in intoxicated

individuals, who tend to sleep deeply in unusual locations and positions. Recovery usually takes days or weeks; splints during this period can prevent contractures.

ALCOHOLIC AMBLYOPIA

Alcoholic amblyopia is a visual impairment that progresses over days or weeks, with development of central or centrocecal scotomas and temporal disc pallor (see [Table 126.5](#)). Demyelination affects the optic nerves, chiasm, and tracts, with predilection for the maculopapular bundle. Retinal ganglion cell loss is secondary. Although amblyopia improves in patients who receive dietary supplements but continue to smoke and drink ethanol, direct toxicity from ethanol and from compounds in tobacco smoke (perhaps cyanide) could be contributory. Alcoholic amblyopia does not progress to total blindness; it may remain stable without change in drinking or eating habits. Improvement, which is often incomplete, nearly always follows abstinence and nutritional replacement.

PELLAGRA

Nicotinic acid deficiency in alcoholics causes pellagra, with dermatologic, gastrointestinal, and neurologic symptoms. Altered mentation progresses over hours, days, or weeks to amnesia, delusions, hallucinations, or delirium. Nicotinic acid therapy (plus other vitamins, deficiency of which can be contributory) usually results in prompt improvement.

ALCOHOLIC LIVER DISEASE

Alcoholic liver disease, progressing from reversible steatosis through steatohepatitis to cirrhosis, is a major cause of death among alcoholics. Altered mentation in an alcoholic always raises the possibility of hepatic encephalopathy, which may accompany intoxication, withdrawal, Wernicke syndrome, meningitis, subdural hematoma, hypoglycemia, or other alcohol states. Hepatic encephalopathy is discussed in detail in Chapter 119. Other neurologic disorders encountered in alcoholic cirrhotics include a poorly understood syndrome of altered mentation, myoclonus, and progressive myelopathy following portacaval shunting, as well as acquired chronic hepatocerebral degeneration, a characteristic syndrome of dementia, dysarthria, ataxia, intention tremor, choreoathetosis, muscular rigidity, and asterixis, which usually occurs in patients who have had repeated bouts of hepatic coma. Heavy ethanol use greatly increases the risk for acetaminophen hepatotoxicity and for cirrhosis and hepatocellular carcinoma in patients with hepatitis C infection.

HYPOGLYCEMIA

Metabolism of ethanol by alcohol dehydrogenase and of acetaldehyde by mitochondrial aldehyde dehydrogenase uses nicotinamide adenine dinucleotide (NAD). The resulting elevated NADH-to-NAD ratio impairs gluconeogenesis, and if food is not being eaten and liver glycogen is depleted, there may be severe hypoglycemia with altered behavior, seizures, coma, or focal neurologic deficit. Residual symptoms are common, including dementia. Even after appropriate treatment with intravenous 50% dextrose, these patients require close observation; blood glucose may fall again, with the return of symptoms and possibly permanent brain damage. Ethanol stimulates intestinal release of secretin, which aggravates reactive hypoglycemia, especially in children, by enhancing glucosestimulated insulin release.

ALCOHOLIC KETOACIDOSIS

In alcoholic ketoacidosis, β -hydroxybutyric acid and lactic acid accumulate in association with heavy drinking. The mechanism relates to starvation, increased lipolysis, and impaired fatty acid oxidation. Typical patients are young binge drinkers who stop drinking when they are overcome by anorexia. Vomiting, dehydration, confusion, obtundation, and hyperventilation ensue. Blood glucose may be normal, low, or moderately elevated, with little or no glycosuria. A large anion gap is accounted for by β -hydroxybutyrate, lactate, and lesser amounts of pyruvate

and acetoacetate. Serum insulin levels are low, and serum levels of growth hormone, epinephrine, glucagon, and cortisol are high, but glucose intolerance usually clears without insulin and is not demonstrable on recovery. It is not unusual for patients to have repeated attacks of alcoholic ketoacidosis.

Alcoholics may have other reasons for metabolic acidosis with a large anion gap (e.g., methanol or ethylene glycol poisoning). When β -hydroxybutyrate is the major ketone present, the nitroprusside test (Acetest) may be negative. Treatment includes infusion of glucose (and thiamine), correction of dehydration or hypotension, and replacement of electrolytes such as potassium, magnesium, and phosphate. Small amounts of bicarbonate may be given. Insulin is usually not needed.

INFECTION IN ALCOHOLICS

Alteration of white blood cell (WBC) function contributes to the alcoholic's predisposition to infection (e.g., bacterial and tuberculous meningitis). Infectious meningitis must always be considered in alcoholics with seizures or altered mental status, even when the clinical picture seems to be that of intoxication, withdrawal, thiamine deficiency, hepatic encephalopathy, hypoglycemia, or other alcoholic disturbances. Alcoholic intoxication is a risk factor for HIV infection.

TRAUMA IN ALCOHOLICS

Thrombocytopenia, a direct effect of ethanol and a consequence of cirrhosis, increases the likelihood of intracranial hematomas after head injury. Abnormalities of clotting factors also increase the possibility of intracranial hematomas. Experimentally, moreover, acute ethanol enhances blood-brain barrier leakage around areas of cerebral trauma. Close observation is essential after even mild head injury in intoxicated patients; an abnormal sensorium must not be dismissed as drunkenness.

ALCOHOL AND CANCER

Independently of tobacco, ethanol in moderate amounts increases the risk of carcinoma of the mouth, esophagus, pharynx, larynx, liver, and, probably, large bowel and breast.

ALCOHOL AND STROKE

As with coronary artery disease, epidemiologic studies suggest that low to moderate amounts of ethanol decrease ischemic stroke risk, whereas higher amounts increase it. Although reports have been inconsistent, meta-analysis of rigorously designed cohort and

P.1080

case-control studies found a J-shaped association between ethanol consumption and the risk of ischemic stroke and a linear association between ethanol consumption and the risk of hemorrhagic stroke. In the United States, the relationship holds for men and women; for blacks, whites, and Hispanics; and for spirits, beer, and wine. Whether extra risk is temporally associated with binge drinking and whether special benefit is conferred by wine (especially red wine) is less clear. In asymptomatic subjects, moderate ethanol consumption reduces the risk of both carotid atherosclerosis and leukoaraiosis. Ethanol could either prevent or cause stroke by several mechanisms. Acutely and chronically, ethanol causes hypertension. It reportedly lowers blood levels of low-density lipoproteins, raises levels of high-density lipoproteins, decreases fibrinolytic activity, increases or inhibits platelet reactivity, increases or decreases C-reactive protein, dilates or constricts cerebral vessels, and indirectly reduces cerebral blood flow through dehydration. The antioxidant properties of flavonoids in red wine might confer special protection. Alcoholic cardiomyopathy predisposes to embolic stroke.

ALCOHOLIC MYOPATHY

Alcoholic myopathy is of two types. Chronic myopathy produces painless proximal weakness; serum creatine kinase (CK) can be elevated or normal, and pathologically, there is atrophy affecting especially type 2 fibers (a

nonspecific finding also seen with disuse or glucocorticoid toxicity). Cardiomyopathy may be present. Acute alcoholic myopathy consists of rhabdomyolysis, painful swelling, and myoglobinuria with renal injury. Both types of myopathy are attributed to direct effects of ethanol on muscle independent of malnutrition. Acute rhabdomyolysis often occurs hours or days after binge drinking. Workup includes checking for potassium or phosphate depletion, which are common in alcoholics. Treatment is supportive, and symptoms improve with abstinence.

CENTRAL PONTINE MYELINOLYSIS AND MARCHIAFAVA-BIGNAMI DISEASE

Central pontine myelinolysis occurs in both alcoholics and nondrinkers and is a consequence of overvigorous correction of hyponatremia. Marchiafava-Bignami disease is nearly always associated with alcoholism (including wine, beer, and whiskey). It is of unknown origin and causes symptoms, including death, that are scarcely explained by the characteristic callosal lesions. Marchiafava-Bignami disease and central pontine myelinolysis are discussed in detail in Chapter 70.

ALCOHOLIC DEMENTIA

Whether ethanol, as a direct neurotoxin, can cause progressive mental decline in the absence of nutritional deficiency, brain trauma, or other indirect mechanisms has been controversial for decades. Properly controlled animal studies reveal dose-related impaired learning and neuropathologic changes in hippocampus and other brain regions. Brains of alcoholics without evident nutritional deficiency have reduced volume especially affecting white matter; reports of cortical or hippocampal neuronal loss are less consistent, but neuropathologic changes appear to correlate with memory and other cognitive impairment. A plausible mechanism is inhibition of glutamate neurotransmission with receptor upregulation and rebound excitotoxicity. It is possible that ethanol neurotoxicity and thiamine deficiency are synergistic in this regard.

Numerous cohort and case-control studies addressing dose-related effects of ethanol on cognition have found that compared to nondrinking, low to moderate alcohol intake actually reduces the risk of dementia. As with ischemic stroke, a J-shaped curve reflects ethanol's long-term effects on cognition: Compared to nondrinking, moderate intake reduces the risk of dementia and heavy intake increases it. Ethanol's protective effect is independent of its benefit on cerebrovascular disease. Wine, beer, and spirits are each protective, with some studies finding special benefit in red wine (perhaps related to antioxidant polyphenols such as resveratrol). The mechanism of ethanol's protective effects against nonvascular dementia is otherwise unclear.

FETAL ALCOHOL SPECTRUM DISORDERS

Ethanol ingestion during pregnancy causes congenital malformations and delayed psychomotor development. Major clinical features of the *fetal alcohol syndrome* (FAS) include cerebral dysfunction, growth deficiency, and distinctive facies ([Table 126.6](#)); less often, there are abnormalities of the heart, skeleton, urogenital organs, skin, and muscles. Neuropathologic abnormalities include absence or displacement of the corpus callosum, hydrocephalus, cerebellar dysplasia, abnormal neuronal migration, heterotopic cell clusters, and microcephaly. These changes occur independently of other potentially incriminating factors, such as maternal malnutrition, smoking, other drug use, or age. Binge drinking, which may produce high ethanol levels at a critical fetal period, may be more important than chronic ethanol exposure, and early gestation appears to be the most vulnerable period.

The face of a typical patient with FAS is distinctive and as easily recognized at birth as that of an infant with Down syndrome. Irritability and tremulousness with poor suck reflex and hyperacusis are usually present at birth and last weeks or months. Of these children, 85% perform more than two standard deviations below the mean on tests of mental performance; those who are not grossly retarded rarely have even average mental ability. Older children are often hyperactive and clumsy, and there may be hypotonia or hypertonia. Except for neonatal

seizures, epilepsy is not a component of the syndrome.

Some children of alcoholic mothers have milder cognitive or behavioral features—for example, depression, anxiety, or hyperactivity. The broad continuum of ethanol's fetal effects is referred to as *fetal alcohol spectrum disorders* (FASDs), comprising mental, emotional, craniofacial, physiologic, and immunologic abnormalities that occur alone or in combination. Dysregulation of the hypothalamic-pituitary-adrenal (HPA) axis, with hyperstress responses, is a major feature in many subjects.

Ethanol is directly teratogenic to many animals. Proposed mechanisms include apoptosis secondary to blockade of *N*-methyl-D-aspartate (NMDA) glutamate receptors during a critical period of synaptogenesis, toxicity to adhesion molecules essential for neuronal migration, and fetal vasospasm and CNS ischemia. Twin studies show genetic vulnerability to FASD (100% concordance in monozygotes, 63% in dizygotes), and ethanol has epigenetic effects which in animals are transgenerational. Epigenetics might explain observations that paternal drinking also carries risk for FASD.

In humans, the risk of alcohol-induced birth defects is established with more than 3 oz of absolute alcohol daily. Below that, the risk is uncertain; a threshold of safety has not been defined. As rates of ethanol use in the United States rose during the 1990s, so did the incidence of FAS. On the basis of data from the United States and France, it was estimated that the incidence of FASD is nearly 1% of all live births. FASD may affect 1% of infants born to women who drink 1 oz of ethanol daily early in pregnancy. More than 30% of the offspring of heavy drinkers are affected by FAS,

P.1081

P.1082

which thus may be the leading teratogenic cause of mental retardation in the Western world.

TABLE 126.6 Clinical Features of Fetal Alcohol Syndrome

Feature	Majority	Minority
CNS	Mental retardation Microcephaly Hypotonia Poor coordination Hyperactivity	—
Impaired growth	Prenatal for length and weight Postnatal for length and weight Diminished adipose tissue	—
Abnormal face	Short palpebral fissures	Ptosis
Eyes	—	Strabismus Epicanthal folds Myopia Microphthalmia Blepharophimosis Cataracts Retinal pigmentary abnormalities

Nose	Short, upturned Hypoplastic philtrum	—
Mouth	Thin vermilion lip borders Retrognathia in infancy Micrognathia or prognathia in adolescence	Prominent lateral palatine ridges Cleft lip or palate Small teeth with faulty enamel
Maxilla	Hypoplastic	—
Ears	—	Posteriorly rotated Poorly formed concha
Skeletal	—	Pectus excavatum or carinatum Syndactyly, clinodactyly, or camptodactyly Limited joint movements Nail hypoplasia Radioulnar synostosis Bifid xiphoid Scoliosis Klippel-Feil anomaly
Cardiac	—	Septal defects Great vessel anomalies
Cutaneous	—	Abnormal palmar creases Hemangiomas Infantile hirsutism
Muscular	—	Diaphragmatic, inguinal, or umbilical hernias Diastasis recti
Urogenital	—	Labial hypoplasia Hypospadias Small rotated kidneys Hydronephrosis
CNS, central nervous system.		

TREATMENT OF CHRONIC ALCOHOLISM

The literature on the treatment of alcoholism is voluminous, and strong opinions outweigh scientific data. Not all problem drinkers consume physically addicting quantities of ethanol, no personality type defines an alcoholic,

and the relative roles of genetics and social deprivation vary from patient to patient. (Animal and human studies indicate polygenetic influences in alcoholism.) Of course, such variability of alcoholic populations means that no treatment modality (e.g., psychotherapy, group psychotherapy, family or social network therapy, drug therapy, behavioral [aversion] therapy) or no single therapeutic setting (e.g., general hospital, halfway house, vocational rehabilitation clinic, Alcoholics Anonymous) is appropriate for all. For example, the success rate of Alcoholics Anonymous has been estimated to be 34%.

Use of tranquilizing and sedating drugs is especially controversial because they may lead to switching of dependency or to drug-ethanol interactions. Some clinicians espouse short-term use of these drugs in doses high enough to reduce the psychological tensions that lead to ethanol use but low enough not to block symptoms of ethanol withdrawal.

Disulfiram inhibits aldehyde dehydrogenase and reduces the rate of oxidation of acetaldehyde, accumulation of which accounts for the symptoms that appear soon after someone taking disulfiram drinks ethanol. Within 5 to 10 minutes, there is throbbing headache, dyspnea, nausea, vomiting, sweating, chest pain, palpitations, hypotension, anxiety, and confusion. The severity and duration of these symptoms depend on the amount of ethanol drunk; severe reactions can last hours or be fatal and require hospital admission, with careful management of hypotension and cardiac arrhythmia.

Taken in the morning, when the urge to drink is least, disulfiram, 0.25 to 0.5 g daily, does not alter the taste for ethanol and helps only patients who strongly desire to abstain. Side effects of disulfiram that are unrelated to ethanol ingestion include drowsiness, psychiatric symptoms, and cardiovascular problems. Paranoia, impaired memory, ataxia, dysarthria, and even major motor seizures may be difficult to distinguish from ethanol effects. So may peripheral neuropathy, which can be fulminant. Hypersensitivity hepatitis also occurs.

Naltrexone and acamprosate are both U.S. Food and Drug Administration (FDA) approved for treatment of alcoholism. Naltrexone might work by decreasing dopaminergic activity in reward circuits. Acamprosate might work by modulating glutamate neurotransmission and resetting a disrupted balance between GABA and glutamate systems. Placebo-controlled trials suggest that acamprosate (1,332 to 3,000 mg/day) is more effective than naltrexone in maintaining abstinence, whereas naltrexone (50 to 100 mg/day) is more effective in reducing heavy drinking and craving should drinking be resumed.

Topiramate affects both dopaminergic and glutamatergic pathways, and placebo-controlled trials demonstrate benefit (at doses ranging from 50 to 300 mg/day) both for maintaining abstinence and for reducing heavy drinking.

Drug Intoxication and Withdrawal

John C. M. Brust

INTRODUCTION

There are two kinds of drug dependence. *Psychic dependence* leads to craving and drug-seeking behavior. *Physical dependence* produces somatic withdrawal symptoms and signs. Depending on the particular drug and the circumstances of its administration, psychic and physical dependence can coexist or occur alone. *Addiction* is psychic dependence.

In the United States, dependence of one or both types is encountered with a variety of agents, licit and illicit (Table 127.1). Different classes of drugs produce diverse symptoms of intoxication and withdrawal as well as medical and neurologic complications.

DRUGS OF DEPENDENCE

OPIOIDS

Opioids include agonists, antagonists, and mixed agonist-antagonists (Table 127.2). Heroin, the opioid most often abused, is illegal in the United States. During the past decade, however, escalation in the use of prescription opioids for noncancer pain resulted in an epidemic of prescription opioid recreational use, especially oxycodone, hydrocodone, methadone, morphine, fentanyl, and hydromorphone. During the same period, heroin use also increased sharply, in many cases representing escalation from prescription opioid use.

Desomorphine, a reduction of codeine that is more potent but also often contains more impurities, is termed *crocodile* for the green-black skin lesions found on parenteral users.

At desired levels of intoxication, agonist opioids produce drowsy euphoria; analgesia; cough suppression; miosis; and often nausea, vomiting, sweating, pruritus, hypothermia, postural hypotension, constipation, and decreased libido. Taken parenterally or smoked (often in combination with alkaloidal crack cocaine), heroin produces a “rush,” a brief ecstatic feeling followed by euphoria and either relaxed “nodding” or garrulous hyperactivity. Overdose causes coma, respiratory depression, and pinpoint (but reactive) pupils. For adults with respiratory depression, treatment consists of respiratory support and naloxone, 2 mg intravenously, repeated as needed up to 20 mg; for those with normal respirations, smaller doses (0.4 to 0.8 mg) are given to avoid precipitation of withdrawal signs. Naloxone is short acting, and so patients receiving it require admission and close observation.

TABLE 127.1 Drugs of Dependence

Opioids

Psychostimulants

Sedatives/hypnotics

Marijuana

Hallucinogens
Inhalants
Phencyclidine
Anticholinergics
Ethanol
Tobacco

Opioid agonist withdrawal symptoms include irritability, lacrimation rhinorrhea, sweating, yawning, mydriasis, myalgia, muscle spasms, piloerection, nausea, vomiting, abdominal cramps, fever, hot flashes, tachycardia, hypertension, and orgasm. In adults, seizures and delirium are not features of opioid withdrawal, which is rarely life threatening and can usually be prevented or treated with 20 mg of methadone taken once or twice daily. By contrast, untreated opioid withdrawal in newborns is severe and protracted, probably causes seizures, and is often fatal. Treatment is with titrated doses of methadone or paregoric; a barbiturate can be added if additional drug withdrawal is suspected or if seizures require treatment.

Effective pharmacotherapy for opioid dependence consists of substitution with oral methadone or buprenorphine. Treatment failure is usually attributable to inadequate dosage. Antagonist therapy with naltrexone proved disappointing.

TABLE 127.2 Commonly Used Opioids
Agonist

Pseudoephedrine

Methylphenidate

Pemoline

Phenmetrazine

Phentermine

Phenylpropanolamine (no longer produced in the United States)

Methylenedioxymethamphetamine (MDMA; ecstasy)

Cocaine
Cathinone, methcathinone

PSYCHOSTIMULANTS

Psychostimulants include amphetamine-like agents and cocaine (Table 127.3). 3,4-methylenedioxymethamphetamine (MDMA; “ecstasy”) appears to combine the psychostimulant properties of amphetamine with the hallucinogenic properties of lysergic acid diethylamide (LSD). An East African-Arabian shrub, khat (*Catha edulis*), is chewed for the effects of its psychoactive ingredient cathinone. A related and easily manufactured compound, methcathinone, as well as numerous designer analogs, are marketed as “bath salts” in Europe and North America. Also available are designer psychostimulants chemically characterized as aminoindanes, piperazines, and pipradol.

Desired effects of psychostimulants include alert euphoria with increased motor activity and physical endurance. Taken parenterally or smoked as alkaloidal cocaine (“crack”) or methamphetamine (“ice”), psychostimulants produce a rush clearly distinguishable from that of opioids. With repeated use, there is stereotypic activity progressing to bruxism or other dyskinesias and paranoia progressing to frank hallucinatory psychosis. Overdose causes headache, chest pain, tachycardia, hypertension, flushing, sweating, fever, and excitement. There may be delirium, cardiac arrhythmia, myoclonus, seizures, myoglobinuria, shock, coma, and death. Malignant hyperthermia and disseminated intravascular coagulation are described. Treatment includes benzodiazepine sedation, oxygen, bicarbonate for acidosis, anticonvulsants, cooling, an antihypertensive (preferably an α -blocker such as phenoxybenzamine or a direct vasodilator such as sodium nitroprusside), respiratory and blood pressure (BP) support, and cardiac monitoring.

Psychostimulant withdrawal produces fatigue, depression, and increased hunger and sleep. Objective signs are few, but depression or somnolence can require treatment or even hospitalization.

An effective pharmacotherapy for psychostimulant dependence does not exist.

SEDATIVES

Sedative agents include barbiturates, benzodiazepines, and miscellaneous products (Table 127.4). Desired effects and overdose both resemble ethanol intoxication, although respiratory depression is much milder with benzodiazepines. Treatment is supportive; for severe benzodiazepine poisoning, there is a specific antagonist, flumazenil. Withdrawal causes tremor and seizures, which can be prevented or treated with titrated doses of a benzodiazepine such as lorazepam 5 mg every 4 hours. Delirium tremens is a medical emergency requiring intensive care.

γ -Hydroxybutyric acid (GHB) and two of its precursors, γ -butyrolactone and 1,4-butanediol, are notorious as “date rape” drugs. Often taken with ethanol, they cause sedation and respiratory depression. Treatment is supportive. Dependence occurs and withdrawal signs resemble those of other sedatives and ethanol, including seizures and delirium tremens.

MARIJUANA

Marijuana, from the hemp plant *Cannabis sativa*, contains many cannabinoid compounds, of which the principal psychoactive

agent is δ -9-tetrahydrocannabinol (THC). Hashish refers to preparations made from the plant resin, which

contains high concentrations of psychoactive cannabinoids. δ -9-THC acts at cannabinoid receptors in the brain, and the pharmaceutical development of synthetic receptor agonists was soon followed by their availability as recreational agents. Marketed as “Spice” or “K2,” they are often many times more potent than δ -9-THC.

TABLE 127.4 Sedative//Hypnotic Drugs

Barbiturates

-

- Diphenhydramine
-

- Ethchlorvynol
-

- Glutethimide
-

- Hydroxyzine
-

- Meprobamate
-

- Methaqualone (no longer produced in the United States)
-

- Zolpidem
-

- Zaleplon
-

- γ -Hydroxybutyric acid

Usually smoked, marijuana produces a relaxed dreamy euphoria, often with jocularity, disinhibition, depersonalization, subjective slowing of time, conjunctival injection, tachycardia, and postural hypotension. High doses cause auditory or visual hallucinations, confusion, and psychosis, but fatal overdose has not been documented. Withdrawal symptoms, other than craving, are minimal; there may be jitteriness, anorexia, and headache. Psychic dependence is common, however.

HALLUCINOGENS

Hallucinogenic plants are used ritualistically or recreationally around the world. In the United States, the most popular agents are the indolealkylamines psilocybin and psilocin (from several mushroom species), the phenylalkylamine mescaline (from the peyote cactus), and the synthetic ergot compound LSD. Increasingly popular is the herb *Salvia divinorum*, which contains the kappa-opioid receptor agonist salvia A. Other synthetic hallucinogens carry such street names as “fly” and “dragonfly.”

The acute effects of hallucinogens are perceptual (distortions or hallucinations, usually visual and elaborately formed), psychologic (depersonalization or altered mood), and somatic (dizziness, tremor, and paresthesia). Some users experience paranoia or panic and some, days to months after use, have flashbacks, the spontaneous recurrence of drug symptoms without taking the drug. High doses of LSD cause hypertension, obtundation, and seizures, but fatalities are usually the result of accidents or suicide. Treatment of overdose consists of a calm environment, reassurance, and, if necessary, a benzodiazepine. Withdrawal symptoms do not occur.

INHALANTS

Recreational inhalant use is especially popular among children and adolescents, who sniff a wide variety of products, including aerosols, spot removers, glues, lighter fluid, fire-extinguishing agents, bottled fuel gas, marker pens, paints, and gasoline. Compounds include aliphatic hydrocarbons such as *n*-hexane, aromatic hydrocarbons such as toluene, and halogenated hydrocarbons such as trichloroethylene; in addition, nitrous oxide is sniffed from whipped-cream dispensers and butyl or amyl nitrite from room odorizers. Despite such chemical diversity, desired subjective effects are similar to those of ethanol intoxication. Overdose can cause hallucinations, seizures, and coma; death has resulted from cardiac arrhythmia, accidents, and aspiration of vomitus. Symptoms tend to clear within a few hours, and treatment consists of respiratory and cardiac monitoring. There is no predictable abstinence syndrome other than craving.

PHENCYCLIDINE

Developed as an anesthetic, phencyclidine hydrochloride (PCP or “angel dust”) was withdrawn because it caused psychosis. As a recreational drug, it is usually smoked. The related agents ketamine, dextromethorphan, and methoxetamine are also used recreationally. Low doses of PCP cause euphoria or dysphoria and a feeling of numbness; with increasing intoxication, there is agitation, nystagmus, tachycardia, hypertension, fever, sweating, ataxia, paranoid or catatonic psychosis, hallucinations, myoclonus, rhabdomyolysis, seizures, coma, respiratory depression, and death. Treatment includes a calm environment with benzodiazepine sedation and restraints as needed, gastric suctioning, activated charcoal, forced diuresis, cooling, antihypertensives, anticonvulsants, and monitoring of cardiorespiratory and renal function. Neuroleptics, which can aggravate seizures, hypotension, and myoglobinuria, are best avoided. Symptoms can persist for hours or days. Psychic dependence to PCP occurs, but withdrawal signs are infrequent, usually consisting of nervousness, tremor, and upset stomach.

ANTICHOLINERGICS

The recreational use of anticholinergics includes ingestion of the plant *Datura stramonium*, popular among American adolescents, as well as use of antiparkinson drugs and the tricyclic antidepressant amitriptyline. Intoxication produces decreased sweating, fever, tachycardia, dry mouth, dilated unreactive pupils, and delirium with hallucinations. Severe poisoning causes myoclonus, seizures, coma, and death. Treatment includes intravenous (IV) physostigmine, 0.5 to 3 mg, repeated as needed every 30 minutes to 2 hours, plus gastric lavage, cooling, bladder catheterization, respiratory and cardiovascular monitoring, and, if necessary, anticonvulsants. Neuroleptics, which have anticholinergic activity, are contraindicated. There is no withdrawal syndrome.

COMPLICATIONS OF DRUG TOXIDROMES

TRAUMA

Trauma may be a consequence of a drug's acute effects, for example, automobile and other accidents during marijuana, inhalant, or anticholinergic intoxication; violence in psychostimulant or PCP users; and self-mutilation during hallucinogen psychosis. Trauma among users of illicit drugs, however, is most often the result of the illegal activities necessary to distribute and procure them. Overprescribing of sedatives is a major contributor to falls in the elderly.

INFECTION

Parenteral users of any drug are subject to an array of local and systemic infections, which in turn can affect the nervous system. Hepatitis leads to encephalopathy or hemorrhagic stroke. Cellulitis and pyogenic myositis produce more distant infection, including vertebral osteomyelitis with myelopathy or radiculopathy. Endocarditis, bacterial or fungal, leads to meningitis, cerebral infarction or abscess, and septic ("mycotic") aneurysm. Tetanus, often severe, affects drug injectors, and botulism occurs either at injection sites or, among cocaine snorters, in the nasal sinuses. Malaria affects heroin users in endemic areas. Anthrax has affected users of contaminated heroin.

Parenteral drug use is a major risk factor for HIV infection. Users are subject to the same neurologic complications that affect nondrug users, especially syphilis and tuberculosis, including drug-resistant forms. Because of promiscuity and associated sexually transmitted diseases, nonparenteral cocaine users are also at increased risk for AIDS. Heroin and cocaine are themselves immunosuppressants (heroin users were vulnerable to unusual fungal infections before the AIDS epidemic), yet their use in HIVseropositive individuals does not seem to accelerate the development of AIDS.

Progressive myelopathy occurs in parenteral drug users infected with either human T-lymphotropic virus (HTLV)-I or HTLV-II.

P.1087

SEIZURES

Seizures are a feature of withdrawal from sedatives, including, infrequently, benzodiazepines. Methaqualone (no longer legally available in the United States) and glutethimide have reportedly caused seizures during intoxication. Opioids lower seizure threshold, but seizures are seldom encountered during heroin overdose. Myoclonus and seizures more often occur in meperidine users, a consequence of the active metabolite normeperidine. Seizures may occur in cocaine users without other evidence of overdose. In animals, repeated cocaine administration produces seizures in a pattern suggestive of kindling. Amphetamine and other psychostimulants are less epileptogenic than cocaine, but seizures did affect users of the no longer legal over-the-counter anorectic phenylpropanolamine. A case-control study found that marijuana was protective against the development of new-onset seizures. In animal studies, the nonpsychoactive cannabinoid compound cannabidiol is anticonvulsant.

STROKE

Illicit drug users frequently abuse ethanol and tobacco, increasing their risk for ischemic and hemorrhagic stroke. Parenteral drug users are subject to stroke through systemic complications such as hepatitis, endocarditis, and AIDS. Heroin users develop nephropathy with secondary hypertension, uremia, and bleeding. Heroin has also caused stroke in the absence of other evident risk factors, perhaps through immunologic mechanisms.

Amphetamine users are prone to intracerebral hemorrhage following acute hypertension and fever. They are also at risk for occlusive stroke secondary to cerebral vasculitis affecting either medium-sized arteries

(resembling polyarteritis nodosa) or smaller arteries and veins (resembling hypersensitivity angiitis). Ischemic and hemorrhagic stroke is also a frequent consequence of cocaine use, regardless of route of administration. Over 600 cases have been reported, roughly half hemorrhagic and half ischemic. Most hemorrhagic strokes are probably consequent to acute surges of hypertension; most ischemic strokes are probably secondary to cocaine's vasoconstrictive actions on cervical and intracranial circulation. Cerebral saccular aneurysms and vascular malformations are often found in patients undergoing angiography for cocaine-related intracranial hemorrhage.

Because of their association with stroke, diet pills and decongestants containing phenylpropanolamine were banned by the U.S. Food and Drug Administration (FDA). Similar association led to a number of states banning dietary supplements containing ephedra. Intracerebral and subarachnoid hemorrhages are described in MDMA users.

Anecdotal and epidemiologic reports describe marijuana use as a risk factor for ischemic stroke. A proposed mechanism is reversible cerebral vasoconstriction. Ischemic stroke was reported in young smokers of the synthetic cannabinoid Spice.

LSD and PCP are vasoconstrictive, and occlusive and hemorrhagic strokes have followed their use.

ALTERED MENTATION

Dementia in illicit drug users may be the result of concomitant ethanol abuse, malnutrition, head trauma, or infection. Parenteral drug users are at risk for HIV encephalopathy. Whether the drugs themselves cause lasting cognitive or behavioral change is more difficult to establish, for predrug mental status is nearly always uncertain and many drug users are probably self-medicating preexisting psychiatric conditions (e.g., cocaine for depression).

Clinical studies describe significant impairments in working memory, verbal fluency, and "cognitive impulsivity" among users of opioids, including prescription opioids and methadone maintenance therapy. Functional imaging studies demonstrate reduced cerebral gray matter density, decreased white matter fractional anisotropy, and abnormal connectivity patterns.

Controversy exists over whether psychostimulants predispose to lasting depression or if PCP predisposes to schizophrenia. In animals and humans, methamphetamine damages both dopaminergic and serotonergic nerve terminals and MDMA destroys serotonin nerve terminals. Impaired memory is described in abstinent methamphetamine users, and among MDMA users followed prospectively, only a few years of use was associated with cognitive decline and abnormal fractional anisotropy in multiple brain areas.

Cocaine is not neurotoxic to axon terminals, but impaired cognition is described as well as morphologic abnormalities in hippocampus, frontostriatal and limbic systems, and cerebral white matter.

Clinical, imaging, and animal studies convincingly demonstrate that marijuana use, especially during adolescence, causes lasting behavioral and cognitive alteration. Long-term marijuana users demonstrate axonal microstructural alterations and volume reductions in brain regions rich in cannabinoid receptors. Epidemiologic studies provide persuasive evidence that marijuana is a significant risk factor for schizophrenia.

Sedatives can cause reversible dementia in the elderly and delayed learning in small children.

Lead encephalopathy is described in gasoline sniffers, and cerebral white matter lesions with dementia are described in toluene sniffers.

FETAL EFFECTS

The effects of illicit drugs on intrauterine development are also difficult to separate from damage secondary to

ethanol, tobacco, malnutrition, and inadequate prenatal care or home environment. Infants exposed in utero to heroin have reportedly been small for gestational age, at risk for respiratory distress, and cognitively impaired later in life.

Prenatal methamphetamine exposure is an independent risk factor for fetal growth restriction. Studies of cocaine's fetal effects, including cognitive, are conflicting. Studies have described impaired memory and language and brain morphologic abnormalities. A 10-year prospective study controlling for such confounders as additional drugs and environmental influences concluded that first-trimester cocaine exposure confers risk for reduced height, weight, and head circumference and for abnormal behavior. Animal studies demonstrate that in utero cocaine exposure detrimentally affects learning.

Long-term cohort studies of in utero marijuana exposure have demonstrated impaired attention and memory and smaller head size. Animal studies show abnormal axonal connectivity. Organic solvents are teratogenic in animals.

MISCELLANEOUS EFFECTS

Guillain-Barré-type neuropathy and *brachial or lumbosacral plexopathy*, probably immunologic in origin, have been associated with heroin use. (Brachial plexopathy has also resulted from septic aneurysm of the subclavian artery.) Severe sensorimotor polyneuropathy occurs in sniffers of glue containing *n*-hexane. *Myoglobinuria* and renal failure have followed use of heroin, amphetamine, cocaine, and PCP.

P.1088

Myeloneuropathy indistinguishable from cobalamin deficiency occurs in nitrous oxide sniffers. Anemia is absent, and serum vitamin B₁₂ levels are usually normal. The mechanism is inactivation of the cobalamin-dependent enzyme methionine synthetase.

Possibly vascular in origin, acute myelopathy occurs in parenteral heroin users.

Severe irreversible parkinsonism developed in Californians exposed to a meperidine analog contaminated with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a metabolite of which is toxic to neurons in the substantia nigra. Symptoms responded to levodopa.

Dementia, ataxia, quadriparesis, blindness, and death occur in smokers of heroin pyrolysate ("chasing the dragon"). Autopsies show spongiform changes in the central nervous system (CNS) white matter. The responsible toxin has not been identified.

Parenteral methcathinone users are subject to *extrapyramidal gait disturbance* and *hypophonia*, a consequence of hypermagnesemia following the use of potassium permanganate in the preparation of the drug.

Blindness developed in a heroin user whose mixture contained large quantities of quinine.

Chronic cocaine users experience *dystonia* and *chorea*, and cocaine can precipitate symptoms in patients with *Tourette syndrome*.

Marijuana inhibits luteinizing and follicle-stimulating hormones, causing *reversible impotence* and *sterility* in men and *menstrual irregularity* in women.

Ataxia and *cerebellar white matter* changes have occurred in toluene sniffers.

Hallucinogen users not only experience flashbacks but, in some cases, visual phenomena persist for years (*hallucinogen-persisting perception disorder*).

U.S. cocaine is frequently adulterated with the immunomodulatory drug levamisole, complications of which include leukopenia, vasculitis, and leukoencephalopathy.

INTRODUCTION

Xenobiotics are substances within an organism that are not normally found in or produced by that organism. *Neurotoxicology* refers to the adverse effects of xenobiotics, or poisons, on the nervous system. This is a massive field with well over 350 documented neurotoxic xenobiotics. To facilitate digestibility and clinical use of the topic, this chapter will focus on acute neurotoxicology. Chronic neurotoxic associations and syndromes will be listed and briefly described. Neurotoxicology with reference to neurodevelopment, withdrawal syndromes, and psychiatric disorders, such as psychosis and mood disorders, will be minimally discussed.

Xenobiotics can include medications; industrial chemicals such as heavy metals, air pollution, solvents, and vapors; substances produced by other organisms (e.g., marine toxins, snake venom); food additives; herbal products and botanicals; recreational drugs; and insecticides, herbicides, rodenticides, and other household products. Acute neurotoxic events have been better described and causal links are more convincing. Neurotoxic effects from chronic exposures are more challenging to prove, as the clinical symptoms may be temporally distant from the exposure or the concentration of the xenobiotic in the organism is so low that it may be difficult to detect.

EPIDEMIOLOGY

The specific incidence, prevalence, and demographics of specific neurotoxins, where available, will be mentioned individually in the following sections. Age, gender, and certain comorbidities have been associated with the occurrence and severity of various toxicity syndromes.

Clinical toxicity is more commonly seen in older patients for several reasons. Age-related decrements in renal and hepatic function impair the ability to clear and eliminate xenobiotics. Reductions in neuronal quantity increase the sensitivity to the presence of xenobiotics. Finally, changes in mitochondrial function are known to occur with advanced age, increasing the possibility of excitotoxicity.

Gender has been associated with certain clinical manifestations in the setting of xenobiotics. Bruxism and dystonia are more prevalent in males, whereas tardive dyskinesia and parkinsonism are more frequently observed in females.

Comorbidities can increase the risk of neurotoxicity if they impair elimination of the xenobiotic (e.g., renal insufficiency or cirrhosis) or facilitate its entry into the central nervous system (CNS) via disturbance of the blood-brain barrier (e.g., meningitis, encephalitis). The presence of or prior exposure to other nonneurotoxic xenobiotics (e.g., prescription medications) can influence the relative neurotoxicity of a xenobiotic by impairing its metabolism or elimination; hastening its conversion to a neurotoxic metabolite; and altering gene expression, neurotransmitter production, release, breakdown, and neurotransmitter receptor density or function. Efflux transporters on the blood-brain barrier, such as P-glycoproteins and organic acid transport proteins, are typically responsible for shuttling xenobiotics out of the CNS. Some medications and conditions are known to inhibit the function of P-glycoproteins ([Table 128.1](#)), increasing the concentration of the neurotoxic xenobiotics in the CNS. Some nutrition inadequacies, such as heavy metal deficiencies, can enhance the uptake of neurotoxic xenobiotics. Lastly, some neurologic disorders can be unmasked with the introduction of a xenobiotic ([Table 128.2](#)).

PATHOBIOLOGY

For neurotoxicity to occur, a xenobiotic must come into contact with the nervous system. CNS toxicity occurs when certain xenobiotics cross the blood-brain barrier via endocytosis, transport proteins, or diffusion. Lipophilic xenobiotics gain entry via diffusion, whereas hydrophilic ones must engage with one of the two other mechanisms.

Neurotoxicity occurs through a variety of mechanisms that are summarized in [Table 128.3](#). The most elusive mechanism to associate with a xenobiotic are those that alter gene expression, as the appearance of clinical toxicity may not occur until the xenobiotic has been eliminated from the system. *Excitotoxicity* is a common end point for several of the neurotoxic xenobiotics whether it is through activation of excitatory pathways or via retarded energy production, which leads to metabolic failure in the setting of neuroexcitation.

Neurotoxicity can manifest pathophysiologically as central or peripheral demyelination, neuronal death, clinical syndromes

TABLE 128.2 Neurologic Disorders Unmasked by Xenobiotics

Xenobiotic	Neurologic Disorder
Aminoglycosides	Myasthenia gravis
Vincristine	Charcot-Marie-tooth
Antiretrovirals	HIV-related peripheral neuropathy

CLINICAL FEATURES

Neurotoxic presentations are protean and may include seizures or status epilepticus, ataxia, tremor, encephalopathy, movement disorders, peripheral neuropathies, lethargy, stupor, coma, cognitive impairment, neuropsychiatric behavioral disturbances, or diffuse weakness. Lateralization of neurologic deficits is uncommon unless the toxicity is unmasking a prior neurologic insult.

Seizures are a not uncommon neurotoxic presentation. [Table 128.4](#) lists some xenobiotics known to cause seizures. A variety of movement disorders have been reported to be caused by xenobiotics, including dyskinesias, akathisia, chorea, parkinsonism, dystonias, myoclonus, and asterixis ([Table 128.5](#)). Tremors associated with xenobiotics, which can be resting, sustentation, or kinetic, are summarized in [Table 128.6](#). Medications and toxins known to cause ataxia are listed in [Table 128.7](#). Cranial and/or peripheral neuropathies can be the result of demyelination, axonal injury, or failed transmission at the neuromuscular junction (NMJ) or of the action potential and present with diffuse weakness, autonomic dysfunction, and/or sensory disturbances. [Tables 128.8](#) and [128.9](#) summarize xenobiotics associated with each of these mechanisms. Lastly, [Table 128.10](#) lists xenobiotics associated with myopathies, which present with diffuse myalgias and weakness.

- Mimics neurotransmitter, stimulating receptor

- Altered protein function or structure

DIAGNOSIS

Many of the neurotoxic xenobiotics or their metabolites can be detected in the serum, urine, or other body tissues or fluids. Of note, the detection of a neurotoxic xenobiotic should not universally lead the clinician to conclude that it is the culprit for the clinical complaint or ailment. The clinical symptoms should be consistent with a well-documented neurotoxicity or syndrome in a patient with a known exposure to the toxin. Otherwise, a neurotoxin can be suspected to be the cause of the clinical symptoms, but other etiologies should be excluded. Improving symptoms in the setting of neurotoxin elimination serves to increase confidence in the diagnosis of neurotoxicity. Additional diagnostic clues can be obtained when certain odors are perceived that are suggestive of a particular xenobiotic ([Table 128.11](#)).

TREATMENT

In any acute neurotoxic presentation, the first steps are to rule out hypoglycemia and remove the victim from the exposure. If the toxin is on the patient's clothing or skin, they should be promptly decontaminated. Health care workers should employ universal precautions when approaching such patients to prevent self-exposure. Entry into an enclosed environment should be delayed until decontamination can be performed so as to not poison other patients or health care providers. If providing glucose, *thiamine* 100 mg intravenous (IV) should be considered prior to doing so as to not induce Korsakoff syndrome in those with a (relative) thiamine deficiency. In hypopneic or apneic patients with miotic pupils, *naloxone* 0.4 to 2.0 mg IV can be administered to reverse a potential opiate overdose.

The core components of treating any neurotoxic presentation include reducing absorption of the toxin, enhancing its elimination, provision of an antidote, and supportive care. Performing gastric lavage, administering activated charcoal, and/or providing whole bowel irrigation (WBI) has the potential to reduce the absorption of an ingested xenobiotic.

Gastric lavage has largely become antiquated, as it is resource intensive, often requires endotracheal intubation, and has not been objectively shown to be beneficial. However, it still has a role in the hyperacute ingestions (within 1 hour) of highly toxic substances that are not effectively absorbed by activated charcoal and do not have an effective antidote. Due to the risk for inadvertent aspiration, hydrocarbons and alkaline caustics should not be lavaged.

Similarly, the use of activated charcoal has decreased over the years, as published evidence has failed to demonstrate appreciable efficacy. It is not to be used in those with a depressed level of consciousness, at risk for aspiration, and after some ingestions ([Table 128.12](#)). WBI can be considered in those with an ingestion of a highly toxic sustained-release medication or xenobiotics that are not absorbed by activated charcoal.

Options for enhanced elimination include the provision of hemodialysis, hemoperfusion, urinary alkalinization, and rarely, exchange transfusion. The elimination of protein-bound xenobiotics is not

appreciably enhanced with dialysis.

Table 128.13 summarizes some neurotoxins and their antidotes. Benzodiazepines are the preferred treatment for neurotoxin-induced seizures. Ion channel dysfunction is a not uncommon mechanism for several of the seizure-inducing neurotoxins, which may be made worse with the administration of many of the commonly used antiepileptics (e.g., phenytoin or valproic acid).

TABLE 128.4 Xenobiotics Known to Induce Seizures

Xenobiotic Category	Specific Agents
Antihistamines	Diphenhydramine, doxylamine
Anticholinergics	Benztropine mesylate, scopolamine
Antibiotics	Isoniazid, beta-lactams (penicillins, cephalosporins, carbapenems), ciprofloxacin
Antivirals	Acyclovir, valacyclovir, amantadine
Antimalarials	Chloroquine, mefloquine, pyrimethamine
Nonsteroidal antiinflammatories	Mefenamic acid, phenylbutazone (veterinary NSAID), ibuprofen, naproxen, salicylates
Opioids	<i>Meperidine</i> , propoxyphene, tramadol
Local anesthetics	Bupivacaine, lidocaine, procaine, tetracaine
Antiepileptics	Phenytoin, carbamazepine, valproic acid, ethosuximide
Antineoplastics	Bleomycin, busulphan, carmustine, chlorambucil, cisplatin, cytarabine, mechlorethamine, methotrexate, vinblastine, vincristine
Antidepressants	<i>Bupropion</i> , fluoxetine, maprotiline, mianserin, trazodone
Tricyclic antidepressants	All of them
Antipsychotics, mood stabilizers	All antipsychotics, especially <i>chlorpromazine</i> , <i>clozapine</i> , and <i>phenothiazines</i> , lithium
Stimulants	Methylphenidates, pemoline
Antiemetics	<i>Prochlorperazine</i> , metoclopramide, <i>promethazine</i> , droperidol

Cardiovascular drugs	Propranolol, flecainide, digoxin
Ergotamines	Dihydroergotamine, ergotamine
Methylxanthines	Caffeine, theophylline
Other medications	Levodopa, baclofen, levothyroxine, allopurinol, bromocriptine, colchicine, corticosteroids
Alcohols	Ethylene glycol, methanol
Recreational drugs	Cocaine, MDMA (ecstasy or molly), amphetamines, phencyclidine, nicotine
Rodenticides	Tetramethylenedisulfotetramine (TETS), thallium, zinc phosphide, arsenic
Pesticides/insecticides	Pyrethrins (insecticides), organochlorines (e.g., Lindane), organic phosphorus compounds (e.g., Malathion)
Botanicals	Cicutoxin (water hemlock), picrotoxin (<i>Anamirta cocculus</i> , plant and performance enhancers), ackee fruit, daphne, rhododendrons
Heavy metals	Thallium, arsenic, copper, lead, nickel, manganese
Household and industrial toxins	Carbon monoxide, camphor, cyanide, fluoride, phenols (e.g., paint strippers), 1,4-dichlorobenzene (e.g., mothballs), monomethylhydrazine (rocket fuel), carbon disulfide, hydrogen sulfide, methyl bromide, triazine, various hydrocarbons, chlorophenoxy herbicides
Ingestion	Domoic acid (amnesic shellfish poisoning), ciguatera (moray eels, barracuda, red snapper) tetrodotoxin (puffer fish species, blue-ringed octopus, horseshoe crab), gyromitrin (<i>Gyromitra</i> fungus species), herbals (lobelia, passion flower, periwinkle, wormwood, <i>Galega</i> , mandrake, jimson weed).
Envenomations	Pit viper, tick bite, scorpion

The xenobiotics in bold are reported to have caused status epilepticus, and those in *italics* frequently cause seizures. Strychnine poisoning causes nonepileptic convulsions and is intentionally excluded from these lists.

MDMA, 3,4-methylenedioxyamphetamine.

OUTCOME

Outcomes following a neurotoxin exposure are dependent on the pathophysiology of the neurotoxic insult. Mechanisms that lead to neuronal injury or death are more likely to produce permanent deficits than mechanisms that interfere with the functioning of neurotransmitters or cell signaling. In some circumstances, toxins that alter cell signaling or action potential propagation can lead to permanent changes in the structure, function, or density of neurotransmitter receptors or ion channels, increasing the possibility of lasting effects. Many of the toxicities are dependent on the peak concentration of the toxin in the patient and its concentration over time. Clinical outcomes can be worsened with delays in toxic elimination or the provision of an antidote. Reexposure tends to produce exponentially severe clinical symptoms, which are more likely to be permanent.

COMMON NEUROTOXIDROMES

Neurotoxins with similar mechanisms of action typically produce distinct syndromes that allow for their clinical recognition and commonalities in their treatment. This section will summarize several syndromes, provide lists of known culprit neurotoxins, outline treatment options, and describe their expected clinical outcomes.

ANTICHOLINERGIC TOXICITY

Approximately 20,000 patients are exposed to anticholinergic xenobiotics per year. This is likely an underestimate, as this only accounts for the recognized and reported cases. To be specific, these substances have antimuscarinic properties that produce their characteristic clinical symptoms. Xenobiotics with antinicotinic actions are separate and distinct from those mentioned here. Hundreds of medications have anticholinergic properties, which

P.1093

places many patients at risk for subtle toxicities that may manifest in mild behavioral or cognitive disturbances.

MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine; AMPT, alpha-methyl-p-tyrosine.

Clinical Features

Clinical symptoms of anticholinergic toxicity are summarized in [Table 128.14](#) and are secondary to antimuscarinic actions. Patients rarely have all of the associated symptoms; tachycardia and dry mucous membranes are the most commonly seen. The most severe exposures produce hyperthermia, coma, and/or seizures. Xenobiotics with antimuscarinic activity are summarized in [Table 128.15](#). Note that ophthalmic drops are absorbed systemically and therefore can produce anticholinergic symptoms in the setting of liberal administration. Additionally, recreational drugs have been contaminated with anticholinergic adulterants on more than one occasion (e.g., heroin tainted with scopolamine).

Treatment

Treatment is largely supportive. Hyperthermia should be rapidly corrected with conductive and evaporative measures. Agitation and seizures should be controlled with benzodiazepines such as *lorazepam* 2-4 mg IV repeated as needed. Antipsychotics should be avoided, as they lower the seizure threshold and nearly all of them have antimuscarinic actions as well (see [Table 128.15](#)). Antiepileptics are typically not effective in the treatment of anticholinergic-induced seizures and their action on ion channels may increase the risk for cardiac arrhythmias. Status epilepticus is rarely the result of antimuscarinic toxicity; if present, other etiologies should be considered.

Physostigmine is an acetylcholinesterase inhibitor that has been used to treat anticholinergic toxicity and is the only acetylcholinesterase inhibitor that crosses the blood-brain barrier. A dose of 0.02 mg/kg can be given over 5 minutes and repeated every 10 to 15 minutes. It has a rapid onset and short duration of action (~1 hour). Extreme caution must be exercised when using physostigmine, as it may produce symptoms of cholinergic toxicity, severe bradycardia, and even asystole. Anticholinergic toxicity is quite rarely fatal with supportive therapy; therefore, the use of physostigmine is rarely justified, given its associated risks. It is contraindicated in atrioventricular and intraventricular conduction delays and in tricyclic antidepressant toxicity.

SYMPATHOMIMETIC TOXICITY AND ACUTE EXCITED STATE

The clinical presentation of patients with a toxin-induced excited delirium and those with sympathomimetic toxicity is largely indistinguishable. The risk factors, patient characteristics, and management are largely the same as well, so they will be discussed together. Some pertinent idiosyncrasies of some of the xenobiotics will be mentioned. [Table 128.16](#) summarizes the various agents known to cause excited delirium.

Widespread use of prescription, botanical, and recreational stimulants and hallucinogens has brought the neurotoxic effects of these substances into daily clinical conversation. There are well over 100,000 presentations to emergency departments each year in the United States related to these xenobiotics. Their neurotoxic effects are exerted through manipulation of the mechanisms carried out by the central monoamine neurotransmitters (serotonin, norepinephrine, and dopamine). This includes increased neurotransmitter release, exaggerated effects at its postsynaptic receptor, decreased neurotransmitter breakdown, and receptor agonism or antagonism, among other mechanisms. In several cases, the culprit xenobiotic's effects are not isolated to one neurotransmitter or receptor, making their clinical manifestations less predictable and reliable.

TABLE 128.7 Medications and Toxins Associated with Ataxia

- **Antiepileptics:** phenytoin, carbamazepine, oxcarbazepine, gabapentin, levetiracetam, lamotrigine, valproate sodium

- **Antineoplastic agents:** cytarabine, methotrexate, 5-fluorouracil, asparaginase

- **Heavy metals:** methylmercury, arsenic, lead, thallium, manganese

- **Lithium**

- **Hydrocarbons:** toluene, benzene, *n*-hexane, carbon tetrachloride

- **Amiodarone**

- **Carbon disulfide**

- **Cyclosporine**

- **Tacrolimus**

- **Metronidazole**

- **Bismuth**

- **High-dose corticosteroids**

Clinical Features

Clinically, these patients will present with hypervigilance, agitation, paranoia, hallucinations, stereotyping, dyskinesias, choreoathetoid movements, tachycardia, hypertension, mydriasis, and/or diaphoresis. More severe toxicity can cause delirium, combativeness, severe hyperthermia (>40°C), and seizures. Wide complex tachycardia can be seen in the setting of cocaine- (due to its sodium channel blockade) or rhabdomyolysis-induced hyperkalemia. The patient may have a depressed level of consciousness due to other co-ingested intoxicants. Diaphoresis is absent in anticholinergic toxicity, making this finding suggestive of excited delirium. However, it can be absent in sympathomimetic toxicity if the patient is volume depleted.

Diagnosis

Diagnosis is largely based on the clinical presentation and history. When the circumstances are unknown, the provider must exclude lifethreatening, treatable etiologies, such as an intracranial hemorrhage, status

epilepticus, or CNS infection. Urine drug screens are frequently performed, but they are fraught with false positives and negatives. Furthermore, a positive finding on a urine drug screen may be the result of a prior exposure and is not the cause of the patient's current

P.1095

P.1096

symptoms. A basic metabolic panel should be obtained. Hyponatremia has been known to occur in 3,4-methylenedioxymethamphetamine (MDMA) ingestions causing status epilepticus.

Treatment

Treatment is largely supportive. Agitation should be treated with liberal *benzodiazepine* administration with the goal of minimizing muscle activity to prevent hyperthermia. Antipsychotics are not typically used so as to avoid administering drugs with anticholinergic actions that may increase the risk for seizures, delirium, and hyperthermia. If they are used, the *butyrophenones* (haloperidol, droperidol) are the best option, so long as the patient's QTc interval is normal. Antiepileptics are best avoided, as these patients frequently have electrolyte abnormalities and are at higher risk for complications when they are given. Benzodiazepines, propofol, or barbiturates are preferred for seizure management. Hyperthermia must be avoided or rapidly corrected. IV hydration should be provided to prevent rhabdomyolysis-induced kidney injury and hyperkalemia. Cocaine-induced wide complex tachycardia may be treated with sodium bicarbonate. Persistent hypertension despite adequate sedation can be treated with *phentolamine* 5 mg IV repeated as needed or nitroglycerine IV 5 to 20 μ g/min. β -Blockers are best avoided given the potential for worsened vasospasm due to unopposed α -agonist activity. With optimal acute management, outcomes are typically outstanding.

CHOLINERGIC TOXICITY: ORGANOPHOSPHATES AND CARBAMATES

Organophosphates (OPs) and carbamates are acetylcholinesterase (AChE) inhibitors that have been recognized and used since the mid-19th century. OPs are used as weapons of war (e.g., sarin gas), insecticides, and for medicinal purposes. Carbamates have medical applications (e.g., physostigmine) and are used as insecticides. Some xenobiotics that are carbamates do not inhibit AChE.

Epidemiology

Exposure to OPs and carbamates has been on the decline in the United States, falling to less than 10,000 reports per year in the mid-2000s. This is in contrast to the hundreds of thousands of deaths that occur each year in rural Asia. Chronic and delayed sequelae are subject to underreporting, as the association between the exposure and clinical event may go unrecognized.

Pathobiology

OPs and carbamates are highly lipophilic xenobiotics that penetrate tissues with ease. Systemic toxicity occurs following dermal

P.1097

exposure via cutaneous absorption, inhalation, or less commonly, ingestion. The initial binding of AChE by OPs is reversible and then becomes irreversible, a process termed *aging*. The time to “aging” varies by OP and ranges from a few hours to a couple of days, with the weapons of war having the shortest time to aging. Once the bond is “aged,” the antidote *pralidoxime* (2-PAM) is not effective. Carbamates, on the other hand, do not age, and their effects dissipate upon their clearance.

Clinical Features

The clinical manifestations of OP or carbamate exposure are the result of increased acetylcholine (ACh) in all neuronal junctions (i.e., parasympathetic and sympathetic postganglionic muscarinic, parasympathetic and sympathetic preganglionic nicotinic, CNS, and NMJ nicotinic; [Fig. 128.1](#)). Symptom onset ranges from a few minutes to several hours. The high lipophilicity of the compounds causes them to be absorbed in adipose tissues; delayed effects can be seen when they diffuse into the circulation. A syndrome of OP-induced delayed axonal neuropathy is the result of inhibition of a neuronal lysophospholipase neuropathy target esterase (NTE).

Clinical full range of manifestations of OP or carbamate exposure are summarized in [Table 128.15](#). The most common presentation includes miosis, diaphoresis, and dyspnea due to bronchorrhea. CNS manifestations range from restlessness and confusion to stupor, coma, and seizure activity. The increased ACh at the NMJ leads to muscle fasciculations, weakness, and finally, paralysis. A syndrome of delayed NMJ dysfunction seen in

25% of patients 1 to 4 days after OP exposures, characterized by muscle weakness without fasciculations and respiratory insufficiency, has been called *intermediate syndrome*. Some patients experience an OP-induced delayed polyneuropathy (OPIDN) that involves the upper and lower motor neurons days to weeks after exposure.

Diagnosis

The diagnosis of OP/carbamate toxicity is best made based on known exposure and subsequent symptoms. In cases of uncertain exposure or atypical or subtle presentations, measurement of plasma and red blood cell (RBC) *cholinesterase levels* can assist in the diagnosis. There are several caveats to their interpretation that are beyond the scope of this text. Spontaneous repetitive potentials

P.1098

on single-nerve electromyography (EMG) are a sensitive finding of AChE inhibition.

TABLE 128.10 Xenobiotics Associated with Myopathy

Xenobiotic Category	Specific Agents
Antiretrovirals	Azidothymidine, zidovudine
Antibiotics	Penicillin, D-penicillamine, rifampin, sulfonamides
Antimalarials	Chloroquine, hydroxychloroquine
Lipids-lowering medications	Clofibrate, HMG-CoA reductase inhibitors (statins), niacin
Immunosuppressives and antineoplastics	Cyclosporine, vincristine, glucocorticoids (especially when combined with a neuromuscular blocker)
Other medications	Amiodarone, cimetidine, colchicine, doxylamine, ϵ -aminocaproic acid, ipecac, procainamide, propylthiouracil, suxamethonium (succinylcholine)
Recreational drugs	Ethanol, heroin, phencyclidine
Envenomations	Snakes: <i>Bothrops asper</i> (pit viper), <i>Agkistrodon</i> (pit viper), <i>Acanthophis</i> (elapid snakes), other crotaline snakes Spider: <i>Loxosceles</i> sp. (recluse spider)

HMG-CoA, hydroxymethylglutaryl-coenzyme A.

Treatment

Patients with OP exposure must be rapidly decontaminated by removing all clothing and liberally irrigating the skin. The initial treatment begins with liberal amounts of *atropine* (starting dose 1 to 2 mg IV doubled

every 5 minutes until respiratory secretions are ceased). It is not uncommon for patients to require nearly 500 mg of atropine during the initial hour of care. Additionally, an oxime, typically *pralidoxime* (2-PAM), should be administered as soon as the syndrome is suspected (1 to 2 mg IV every 4 hours for at least 24 hours) to prevent aging and irreversible inhibition of AChE. Of note, the evidence supporting oxime use is conflicting. Benzodiazepines, particularly *diazepam* 5 to 10 mg IV every 4 to 6 hours, have been observed to decrease cerebral injury resulting from OP-induced seizures and mitigate OP-induced respiratory depression. *Ketamine* (1 to 4 mg/kg loading dose followed by 0.1 to 0.5 mg/min IV infusion) and other

P.1099

P.1100

P.1101

N-methyl- D -aspartate (NMDA) receptor antagonists have been shown to reduce OP-induced seizures and enhance survival in mice. When endotracheal intubation is being performed, succinylcholine is best avoided.

TABLE 128.11 Smells and Odors Suggestive of Neurotoxic Xenobiotics

Odor or Smell	Xenobiotic
Mothballs	Camphor
Garlic	Organophosphates, arsenic, thallium
Peanuts	Vacor
Carrots	Cicutoxin (water hemlock)

TABLE 128.13 Neurotoxins and Their Antidotes/Specific Treatments

Neurotoxin/Toxidrome	Antidote/Treatment
Arsenic, lead, mercury	BAL
TCA's	Bicarbonate
Rattlesnake envenomation	CroFab antivenin
Serotonin syndrome	Cyproheptadine
Arsenic, lead, mercury	D-Penicillamine
NMS, sympathomimetic hyperpyrexia	Dantrolene
Iron	Cefuroxime
Digoxin	Digoxin-specific Fab
Lead	DMSA
Lead	EDTA
Methanol, ethylene glycol	Ethanol
Benzodiazepines	Flumazenil
Methanol, methotrexate	Folate/folinic acid

Ethylene glycol, methanol	Fomepizole
Cyanide, hydrogen sulfide	Hydroxycobalamin, sodium thiosulfate, sodium nitrite
Local anesthetics, TCAs	Intralipid 20%
Valproic acid	L-Carnitine
Black widow spider envenomation	Lactrodectus antivenin
Opioids	Naloxone
Anticholinergics	Physostigmine
Organophosphates, carbamates	Pralidoxime (2-PAM)
Isoniazid, monomethylhydrazine, ethylene glycol	Pyridoxine

BAL, dimercaprol; TCAs, tricyclic antidepressants; NMS, neuroleptic malignant syndrome; DMSA, dimercaptosuccinic acid; EDTA, ethylenediaminetetraacetic acid.

TABLE 128.14 Clinical Findings of Neurotoxic Syndromes

Anticholinergic

- Flushed skin
- Anhidrosis
- Dry mucus membranes
- Urinary retention
- Constipation/ileus/decreased bowel sounds
- Hyperthermia
- Mydriasis
- Blurred vision (impaired accommodation)
- Agitation, confusion, delirium, psychosis
- Visual hallucinations
- Myoclonus, choreoathetosis, picking behavior
- Stupor/coma (higher doses)
- Seizures (very rarely status epilepticus)

Sympathomimetic

- Diaphoretic
- Hypertensive
- Tachycardic
- Hyperthermia
- Agitation, combativeness, psychosis

- Hallucinations
- Mydriasis
- Seizures

Organophosphate and carbamate toxicity

- Restlessness
- Diarrhea
- Lacrimation
- Salivation
- Urination
- Bronchorrhea
- Diaphoresis
- Muscle fasciculations
- Seizures/convulsions
- Confusion to stupor/coma
- Blurred vision/miosis^a
- Bronchospasm^a
- Bradycardia^a
- Hypotension^a

Neuroleptic malignant syndrome

- Confusion/delirium
- Catatonia/mutism
- Stupor/coma
- Lead pipe rigidity
- Hyperthermia
- Tachycardia
- Hypertension
- Tachypnea

Serotonin syndrome

- Agitation, hypervigilance
- Confusion, delirium
- Hyperthermia
- Tachycardia
- Hypertension
- Diaphoresis
- Diarrhea
- Ocular clonus
- Mydriasis
- Akathisia
- Tremor
- Rigidity
- Hyperreflexia^b
- Clonus^b

^aCholinergic activity at the preganglionic sympathetic fibers leads to increased release of norepinephrine at the postganglionic nerve terminals in the target organs. Clinically, this results in activation of the sympathetic and parasympathetic pathways, which may lead to normocardia,

tachycardia, normotension, bronchodilation, or mydriasis.

^bMore pronounced in the lower extremities.

TABLE 128.15 Xenobiotics with Anticholinergic Properties

Category	Specific Agents
Antihistamines	Cetirizine, chlorpheniramine, cimetidine, diphenhydramine, doxylamine, hydroxyzine, loratadine, ranitidine
Antipsychotics	Chlorpromazine, clozapine, olanzapine, quetiapine, risperidone, ziprasidone
Antiemetics	Doxylamine, metoclopramide, promethazine, scopolamine
Antivertigo	Meclizine, scopolamine
Tricyclic antidepressants	Amitriptyline, desipramine, doxepin, imipramine, nortriptyline
Antidepressants	Mirtazapine, paroxetine
Antiparkinsonian	Benzotropine, biperiden, carbidopa/levodopa, procyclidine, selegiline, trihexyphenidyl
Ophthalmic	Atropine, cyclopentolate, homatropine, tropicamide
Bronchodilators	Ipratropium, tiotropium
Antispasmodics	Dicyclomine, hyoscyamine, loperamide, oxybutynin ^a , propantheline
Muscle relaxants	Baclofen, carisoprodol, cyclobenzaprine, methocarbamol
Others	Amantadine, glycopyrrolate ^a , trazodone
Botanicals	Deadly nightshade (atropine, <i>Atropa belladonna</i>), henbane (<i>Hyoscyamus niger</i>), jimson weed (scopolamine, <i>Datura stramonium</i>), mandrake (<i>Mandragora officinarum</i>)

^aDoes not cross blood-brain barrier.

TABLE 128.16 Xenobiotics Causing Sympathomimetic Toxicity/Acute Excited State

Category	Source	Specific Agents	Comments
Cocaine	Coca plant (<i>Erythroxylum coca</i>)	Cocaine hydrochloride, methylecgonidine, and ecgonidine (“crack”)	WCT/arrhythmias and local anesthetic due to Na channel blockage
Methamphetamines	Synthetic	“crank,” “crystal,” “chalk,” “ice,” etc.	Lead toxicity can be seen due to contamination.
Designer (recreational) amphetamines	Synthetic	MDMA (“ecstasy,” “XTC,” or “Adam”), MDA, MDEA (“Eve”), PMA (“death”), DOM (“STP”), DOI, DOB, others	Hyponatremia not uncommonly seen that may be due to ADHlike action with MDMA; irreversible damage to serotonergic neurons seen on MRI
Prescription amphetamines	Synthetic	Dextroamphetamine, lisdexamfetamine	
Prescription piperazine compounds	Synthetic	Methylphenidate	
NMDA receptor antagonists	Synthetic	PCP, ketamine, dextromethorphan	
Synthetic cannabinoid	Synthetic	HU-210, JWH-018, JWH-073, JWH-200, CP-47, and cannabicyclohexanol (all largely referred to as <i>K2</i> or <i>spice</i>)	New compounds rapidly cycled in as DEA adds them to controlled substances lists.
Ephedrine	Ephedra (<i>ma-huang</i>)	Various recreation, herbal, and weight loss compounds	
Cathinone	Khat (<i>Catha edulis</i>)	Consumed by chewing or in teas	Manganese toxicity from contamination has produced EPS.

Cathinone derivatives	Synthetic	Mephedrone, methylone, ethylone, butylone, pyrovalerone, MDPV, methcathinone, ethcathinone, others (“bath salts” marketed under many names)	
Methylxanthines	<i>Coffea arabica</i> , many other botanicals	Caffeine	
N-substituted piperazine compounds	Synthetic	“Legal E,” “legal X,” BZP (“A2”), TFMPP (“Molly”), CPP, 25I-NBOMe (“N-bomb”)	
Mescaline	Cacti (<i>Lophophora williamsii</i> , <i>Lophophora diffusa</i> , <i>Trichocereus pachanoi</i>)	“Peyote”	
LSD	Synthetic		
LSD-like substances	Hawaiian baby woodrose (<i>Argyreia nervosa</i>), Hawaiian woodrose (<i>Merremia tuberosa</i>), morning glory (<i>Ipomoea violacea</i>), oliliuqui (<i>Rivea corymbosa</i>)		
Hallucinogen: tryptamines (indole alkaloids)	<i>Psilocybe</i> , <i>Panaeolus</i> , and <i>Conocybe</i> mushrooms Various plants and organisms Synthetics	Psilocybin and psilocin “magic mushrooms” DMT, 5-MeO-DMT AMT, DiPT, 5-MeO-DiPT (“foxy” or “foxy-methoxy”)	Drank as <i>ayahuasca</i>
Hallucinogens: botanicals	<i>Salvia divinorum</i> <i>Mitragyna speciosa</i> Korth tree African rain forest shrub (<i>Tabernanthe iboga</i>) Wormwood tree	Salvinorin A or divinorin A Kratom, specific compound uncertain, suspect mitragynine Iboga (ibogaine) Thujone (“absinthe”)	Ion channel effects, 11 deaths reported from cardiac arrest Inhibitor of GABA-A receptor → seizures

extract (*Artemisia absinthium*)
 Isoxazole mushrooms
 (*Amanita muscaria*,
Amanita pantherina,
Amanita gemmata,
 and *Amanita cothurnata*)

Ibotenic acid and
 muscimol

WCT, wide complex tachycardia; MDMA, 3,4-methylenedioxyamphetamine; MDA, 3,4-methylenedioxyamphetamine; MDEA, 3,4-methylenedioxyamphetamine; PMA, paramethoxyamphetamine; DOM, 4-methyl-2,5-dimethoxyamphetamine; DOI, 2,5-dimethoxy-4-iodoamphetamine; DOB, 2,5-dimethoxy-4-bromoamphetamine; STP, serenity, tranquility, and peace; PCP, phencyclidine; EPS, extrapyramidal symptoms; MDPV, methylenedioxypropylamphetamine; BZP, 1-benzylpiperazine; TFMPP, 1-(trifluoromethylphenyl)piperazine; CPP, 1-(chlorophenyl)piperazine; 25I-NBOMe, 2-(4-iodo-2,5-dimethoxyphenyl)-N-[(2-methoxyphenyl)methyl]ethanamine; LSD, lysergic acid diethylamide; DMT, dimethyltryptamine; 5-MeO-DMT, 5-methoxy-dimethyltryptamine, diisopropyl; 5-MeO-DiPT, 5-methoxy-tryptamine; DiPT, diisopropyltryptamine; AMT, alpha-methyltryptamine.

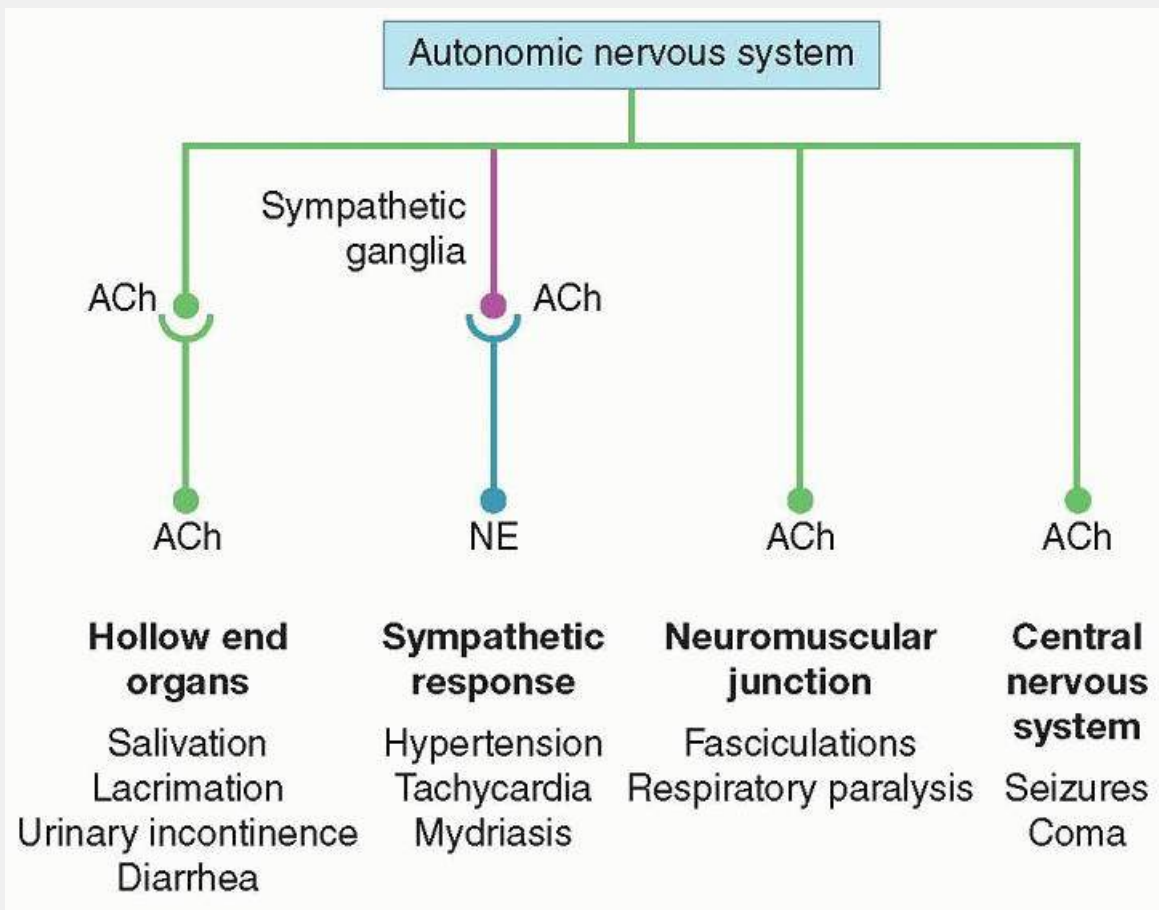

FIGURE 128.1 Sites of action of organophosphates and carbamates. ACh, acetylcholine; NE, norepinephrine.

Outcome

The case fatality rate ranges from 10% to 40%. Evidence is lacking that describes neurologic outcomes with precision following acute and chronic poisoning. Residual deficits with an incomplete recovery are common in those with OPIDN. Cognitive deficits have been observed after acute OP exposure.

NEUROLEPTIC MALIGNANT SYNDROME

Neuroleptic malignant syndrome (NMS) is an idiosyncratic lifethreatening neurologic emergency seen in those on neuroleptic (antidopaminergic) agents or after withdrawal of dopaminergic medications (Table 128.17). Precise estimates of its incidence are lacking. It can occur at any age of life and is seen more often in men, but this is proportional to the increased use of neuroleptics in the male gender. NMS is frequently seen within the first 2 weeks of treatment with a neuroleptic, but it may occur at any time even in those on antipsychotics for years. The risk of NMS is higher with rapid dose escalation, parenteral administration, switching of agents, and when higher doses are used. The precise pathophysiology is not known, but it is believed to be the result of a relative dopamine deficit in the CNS. Genetic studies have identified a specific allele of the D2 receptor that results in a decreased amount and function of dopamine receptors to be a risk factor.

TABLE 128.17 Examples of Medications that Cause Neuroleptic Malignant Syndrome

Dopaminergic Agents (Discontinuation)	Antipsychotics	Antiemetics
Bromocriptine	Aripiprazole	Droperidol
Amantadine	Chlorpromazine	Metoclopramide
Rimantadine	Clozapine	Prochlorperazine
Memantine	Haloperidol	Promethazine
Levodopa	Olanzapine	
Cabergoline	Quetiapine	
Dihydroergocryptine (DHEC)	Risperidone	
Pergolide	Thioridazine	
	Ziprasidone	

Clinical Features

Clinical features include mental status changes, muscular rigidity, hyperthermia, and autonomic dysfunction; symptoms typically present in this sequence. Mental status changes may precede the other symptoms by 24 hours or more. Mental status changes range from confusion and delirium to catatonia, mutism, stupor, and coma. Cogwheeling, dystonia, and other dyskinesias can be seen in addition to the lead pipe rigidity. The majority of patients will have a temperature higher than 38°C, with nearly half exceeding 40°C. Autonomic dysfunction

manifests as tachycardia, hypertension, and tachypnea. Laboratory abnormalities may include an elevated creatine kinase (>4× normal), transaminitis, and leukocytosis.

Diagnosis

The diagnosis is clinical. A scoring system has been proposed, but it has not been validated. The evaluation is typically targeted toward identifying metabolic derangements that require correction and the exclusion of other differential diagnoses. Cerebral edema has been observed on magnetic resonance imaging (MRI). Seizures are not typically seen in NMS. Cerebral spinal fluid evaluation may reveal a mild protein elevation without pleocytosis or hypoglycorrhachia.

Treatment

Treatment includes aggressive supportive therapy, temperature correction, and cessation of any possible offending agent (or resumption of a discontinued one). *Dantrolene* (1 to 2.5 mg/kg IV), a skeletal muscle relaxant that works by inhibiting calcium release from the sarcoplasmic reticulum, maybe used to reduce rigidity and help to correct hyperthermia and rhabdomyolysis. It should not be used if there is a significant transaminitis. *Amantadine* (100 mg orally [PO] every 12 hours) and *bromocriptine* (2.5 mg PO every 6 hours) are dopamine agonists that may be considered in the treatment of NMS. Summated evidence from retrospective observations and cases suggests that they may hasten recovery and reduce mortality, but this is far from conclusive. There are reports of electroconvulsive therapy (ECT) being used, but its true efficacy is far from clear. In fact, several patients are reported to have gone into cardiac arrest during ECT.

OUTCOME

Recovery typically occurs within 2 weeks of stopping the neuroleptic (or resuming the dopamine agonist), with some exceptions being reported. The mortality ranges from 5% to 20%. Relapse upon resumption of neuroleptics is very difficult to predict. If they must be resumed, lower potency agents should be selected at the lowest possible dose. Weak evidence suggests lithium therapy may increase the risk of developing NMS; therefore, it is best avoided if possible.

P.1102

TABLE 128.18 Xenobiotics Known to Potentially Cause Serotonin Syndrome

Category	Specific Examples
SSRIs	Citalopram, escitalopram, fluoxetine, paroxetine, sertraline
SNRIs	Desvenlafaxine, duloxetine, milnacipran, venlafaxine
TCA's	Amitriptyline, clomipramine, desipramine, doxepin, imipramine, nortriptyline, protriptyline, trimipramine
MAOIs	Isocarboxazid, moclobemide, phenelzine, tranylcypromine

DNRIs	Bupropion
SARIs	Nefazodone, trazodone, and vilazodone
Recreational drugs	Cocaine, methamphetamine, designer amphetamines (e.g., MDMA ["ecstasy"], see Table 128.16), LSD
AEDs	Carbamazepine, valproate
Triptans	Almotriptan, eletriptan, frovatriptan, rizatriptan, sumatriptan, zolmitriptan
Ergots	Ergotamine, methylergonovine
Amphetamines	Dextroamphetamine, lisdexamfetamine
Opioids	Meperidine, tramadol, pentazocine, fentanyl
Appetite suppressants	Fenfluramine, phentermine, dexfenfluramine, sibutramine
Parkinson medications	Levodopa, carbidopa/levodopa, rasagiline, selegiline
5-HT ₃ receptor antagonists	Dolasetron, granisetron, ondansetron, palonosetron
Antibiotics	Linezolid, tedizolid
Others	Tryptophan, St. John's wort, cyclobenzaprine, dextromethorphan, buspirone, lithium, methylene blue, procarbazine

SSRIs, selective serotonin reuptake inhibitors; SNRIs, serotonin-norepinephrine reuptake inhibitors; TCAs, tricyclic antidepressants; MAOIs, monoamine oxidase inhibitors; DNRIs, dopamine-norepinephrine uptake inhibitors; SARIs, serotonin antagonist and reuptake inhibitors, AEDs, antiepileptic drugs; MDMA, 3,4-methylenedioxymethamphetamine; LSD, lysergic acid diethylamide.

SEROTONIN SYNDROME

Serotonin syndrome is a life-threatening neurologic emergency resulting from a relative serotonin excess. The death of Libby Zion at New York Hospital in 1984, which was reported in the mainstream media and eventually led to the creation of the contemporary laws that limit resident work hours, was suspected to be the result of serotonin syndrome. The syndrome can be precipitated when two or more serotonergic medications are coadministered but can occur with monotherapy as well (see [Table 128.18](#) for a list of serotonergic xenobiotics). There are over 25,000 reported cases of potential toxic exposure to serotonergic agents annually in the United States, with nearly 10,000 of them suspected to cause serotonin syndrome resulting in nearly 100 deaths.

Serotonin syndrome occurs on a spectrum. Mild symptoms are likely to go unrecognized and are underreported.

TABLE 128.19 Hunter Serotonin Toxicity Criteria

Any of the following are present after a serotonergic agent is introduced:

-
- Spontaneous clonus
-
- Inducible or ocular clonus with agitation or diaphoresis
-
- Inducible or ocular clonus with hypertonicity and fever
-
- Tremor with hyperreflexia

Pathobiology

Serotonin receptors are primarily found in the CNS in the brain stem (midline raphe nuclei) and peripherally in the gastrointestinal tract, vasculature, and platelets. Rapid increases in serotonin concentration at these sites produce the symptoms of serotonin syndrome. Mild symptoms include tremor, diarrhea, and restlessness or hypervigilance. More severe symptoms result in further autonomic dysfunction, hyperthermia (>40°C), and more significant deficits in mental status (see [Table 128.14](#)). Clonus (ocular, spontaneous, and induced) and hyperreflexia are specific for serotonin syndrome and are more pronounced in the lower extremities. The onset is typically within minutes to hours of exposure to the serotonergic agent.

Diagnosis

[Table 128.19](#) outlines the Hunter Serotonin Toxicity Criteria, which have a sensitivity of 84% and specificity of 97% for diagnosing serotonin syndrome. The diagnosis is completely clinical. Laboratory and imaging investigations are done to evaluate for metabolic derangements and to exclude alternative diagnoses.

Management

Symptoms resolve promptly upon the cessation of all serotonergic agents, making this the cornerstone of treatment. Unfortunately, some selective serotonin reuptake inhibitors (SSRIs) have long half-lives (e.g., fluoxetine's half-life is 1 week). In such cases, prolonged supportive therapy is necessary. Agitation should be treated with benzodiazepines. If agitation persists or if autonomic dysfunction persists despite control of agitation, *cyproheptadine*, a histamine and serotonin antagonist, maybe used. It is only available for oral administration. The initial dose is 12 mg followed by 2 mg every 2 hours. There is little evidence beyond case reports to confirm that it has any therapeutic benefit. Outcomes can be expected to be excellent with optimal supportive care and prompt withdrawal of the serotonergic agent(s).

CARBON MONOXIDE POISONING

Carbon monoxide (CO) intoxication is a common cause of neurotoxic damage and death. Deaths averaged 5,600 annually over a 10-year period in the United States and split between accidental and intentional. Statistics on nonfatal CO encephalopathy and the delayed CO-induced neuropsychiatric syndrome are imprecise. CO

competes with oxygen for binding to hemoglobin, myoglobin, and cytochrome c oxidase resulting in tissue hypoxia and disordered cellular energy generation.

Clinical Features

Clinical presentations range from mild, viral syndrome-like symptoms, such as headache, malaise, dizziness, nausea, difficulty

P.1103

concentrating, and dyspnea, to coma, particularly in the setting of smoke inhalation. In survivors, neurologic symptoms include dementia, cerebellar dysfunction, and parkinsonism. A delayed neuropsychiatric syndrome may follow acute exposure by 3 to 240 days with cognitive and personality changes and psychotic behavior. This syndrome occurs in 10% to 30% of CO poisonings. Although up to 10% of victims show gross neurologic or psychiatric impairment, more frequently there is only a subtle, persistent neuropsychiatric deficit. Computed tomography (CT), MRI, magnetic resonance spectroscopy (MRS), and isotopic imaging can disclose the brain damage. Postmortem findings include multifocal necrosis and myelinopathy with discrete lesions in the globus pallidus, cortex, and white matter.

Diagnosis

The diagnosis is made by measuring the serum carboxyhemoglobin (COHb) level. Normal levels are less than 5% in nonsmokers and can be as high as 12% in two-pack-per-day smokers. Although serious toxicity is often associated with levels greater than 25%, neurologic damage is not always directly related to the COHb level. Furthermore, serum levels may have fallen by the time the patient reaches the emergency department such that a normal COHb level does not rule out CO poisoning. Blood taken at the scene by emergency technicians can be used. Measurement of CO in expired air and in the exposure area's ambient air can also be useful. The U.S. government standard for CO prohibits exposure to more than 35 ppm, averaged over an 8-hour workday.

Treatment

Initial treatment is 100% oxygen by a nonrebreather face mask, which will reduce the elimination half-life of COHb from 4 to 5 hours to 1 to 2 hours. Treatment continues until the COHb levels are below 10%. Most experts advocate hyperbaric oxygen (HBO) for treatment of symptomatic CO poisoning. It enhances elimination of COHb with an average half-life of 20 minutes at three atmospheres, but randomized trials have not clarified whether it hastens recovery or reduces the rate of late sequelae. Coma, ischemic symptoms, acidosis, levels over 25%, and pregnancy with levels over 20% are indications for HBO.

MALIGNANT HYPERTHERMIA

Malignant hyperthermia (MH) is a life-threatening reaction that occurs in approximately 1/100,000 exposures to volatile anesthetics or succinylcholine. It results from the improper opening of the ryanodine receptors on the sarcoplasmic reticulum in skeletal muscle. Its presentation is on a spectrum, with the most pronounced episodes being characterized by diffuse muscle rigidity despite neuromuscular blockade. The first signs are an elevation of the end-tidal CO₂ and tachycardia. Fever develops later, with the temperature being prone to rapid elevations. Untreated, rhabdomyolysis and hyperthermia and their associated complications lead to death. Rapid treatment with *dantrolene* (2.5 mg/kg IV followed by 1 mg/kg IV until symptoms resolve) is the cornerstone of treatment. Epidemiologically, MH is most commonly the result of a mutation of the ryanodine receptor or dihydropyridine

receptor. Additional cases are seen in those with several hereditary myopathies. Population-based screening is not justifiable. Genetic testing is specific but not sensitive. Contracture testing is much more sensitive, but it is invasive and only available at select centers. Additionally, contracture testing has a 20% false-positive rate.

STRYCHNINE POISONING

Strychnine, a competitive antagonist of glycine, causes involuntary tonic-clonic activity in otherwise awake individuals. It is derived from the seeds of the tree *Strychnos nux vomica*. Contemporary poisonings are usually the result of the adulteration of recreational drugs and less commonly in herbal medications. It is absorbed through all routes, including dermal, with an onset of 10 to 20 minutes. It is largely eliminated by the liver with a half-life of approximately 12 hours. The diagnosis is clinical. Rhabdomyolysis and its associated complications are a significant threat as well as respiratory arrest from an inability to properly ventilate. Treatment is supportive with benzodiazepine or propofol use.

METHANOL (METHYL ALCOHOL)

Methanol ingestion occurs when it is substituted for ethanol or in suicide attempts. Poisoning is related to the conversion of methanol to formaldehyde and formic acid, which results in a severe metabolic acidosis. The initial clinical presentation is similar to acute ethanol intoxication with gastrointestinal symptoms, drunkenness, and coma. The mortality rate is approximately 35%. Visual loss is common and attributed to retinal metabolism of methanol to formic acid. Cerebral imaging has demonstrated petechial hemorrhages and edema. Inhibitors of aldehyde dehydrogenase (ethanol and fomepizole) block the conversion of methanol to formaldehyde, allowing it to be excreted in the urine.

VOLATILE ORGANIC COMPOUNDS

Neurologic syndromes caused by volatile organic compounds (VOC) (*solvents*) occur after either occupational or deliberate exposure by inhalation abuse. The agents include aromatic and aliphatic hydrocarbons, alcohols, esters, ketones, aliphatic nitrates, anesthetic agents, halogenated solvents, and propellants. Aromatic hydrocarbons, especially *toluene*, produce cerebral and cerebellar damage. Aliphatic hydrocarbons caused outbreaks of peripheral neuropathy in industrial or recreational exposures to *n*-hexane or methyl-*n*-butyl ketone, which begin in the lower extremities and ascend, resembling Guillain-Barré syndrome. Pathophysiologically, neurofilamentous axonal swelling and distal axonal degeneration are seen.

Other organic compounds that induce axonal neuropathy by industrial exposure are acrylamide, carbon disulfide, methyl bromide, and triorthocresyl phosphate. Halogenated hydrocarbons are toxic for the CNS by damaging nerve cell membranes and altering neurotransmission; an excitatory phase is rapidly followed by CNS depression. The compounds include chloroform, methylene chloride, and tetrachloroethane. The neurotoxic potential of one substance is sometimes facilitated by others in the same commercial product.

NITROUS OXIDE MYELOPATHY

Nitrous oxide (NO), commonly known as *laughing gas*, is used as an inhaled anesthetic. Chronic exposure to NO, also known as *Layzer syndrome*, was described in the last 1970s in a series of dentists with occupational exposure or chronic NO abuse. It has also been described in those with a vitamin B 12 deficiency that are exposed to NO. Because NO interferes with the action of vitamin B 12, symptoms mimic its deficiency and include paresthesias, Lhermitte symptoms, ataxia, leg weakness, impotence, and sphincter disturbances. Examination showed signs of sensorimotor polyneuropathy, often implicating the posterior and lateral columns of the spinal cord, which can be confirmed on MRI. Electrodiagnostic tests showed

axonal polyneuropathy. Animal studies have suggested that methionine has a protective role. Improvement has been reported to occur over weeks to months after exposure ceased.

HEAVY METALS

Lead

Acute lead encephalopathy in children is typically attributed to pica or ingestion of flaking lead-containing paint. Children with blood levels above 80 µg/dL are more susceptible than adults to overt lead encephalopathy with delirium, ataxia, seizure, stupor, or coma with associated cerebral edema. Adults with chronic lead exposure yielding blood lead levels of 25 to 60 µg/dL may experience irritability, headache, myalgias, anorexia, nausea, crampy abdominal pain, and depression with signs of impaired visualmotor dexterity and reaction times. Objective neuropathies that manifest in muscle weakness and atrophy occur with long-term levels of 60 µg/dL or more. Because of links between lead and cognitive dysfunction, behavioral problems, as well as stunted growth in children, the Centers for Disease Control and Prevention has declared levels exceeding blood concentration of 5 µg/dL to be abnormal and requiring case management. Periodic screening of children aged 9 to 36 months is advocated, especially because the symptoms are nonspecific, including lethargy, anorexia, intermittent abdominal pain with vomiting, or constipation. Testing blood lead levels is recommended for children with presumed autism, attention deficit disorder (ADD), pervasive development disorder, mental retardation, or language problems.

A diagnosis of lead intoxication is supported if blood zinc protoporphyrin exceeds 100 µg/dL or if urinary aminolevulinic acid excretion is more than 15 mg/L. With blood lead levels of 10 µg/dL, the activity of aminolevulinic acid dehydratase is low. At higher lead levels, the activities of coproporphyrinogen oxidase and ferrochelatase are also low. Anemia and basophilic stippling of erythrocytes are characteristic. Nerve conduction velocities are nonspecifically slow in lead and other neuropathies.

Treatment combines decontamination, supportive care, and the judicious use of chelating agents. In affected people, chelation therapy commences with levels of 40 to 45 µg/dL. Supportive care may include treatment of increased ICP by standard use of IV mannitol and glucocorticoids, the latter because the pathophysiology of lead encephalopathy involves capillary leak. In patients with lead encephalopathy, calcium disodium edetate or calcium ethylenediaminetetraacetic acid (EDTA) should be administered at 30 mg/kg every 24 hours. Some advocate initiating chelation with a single dose of dimercaprol (British anti-Lewisite [BAL]) 4 to 5 mg/kg deep intramuscularly. Alternatively, meso-2,3-dimercaptosuccinic acid (DMSA or succimer) is advocated for treatment of moderately severe chronic lead intoxication. Childhood lead exposure carries a risk of long-lasting health impairment, especially with neurocognitive and neurobehavioral sequelae, emphasizing the need for primary prevention and for obtaining occupational and environmental information.

Mercury

The relations between elemental, inorganic, and organic forms of mercury involve transformations from one form to another. Modern epidemics include Minamata disease from fish contaminated by methyl mercury (MeHg), which affected 2,500 people in Japan, and erethism (abnormal sensitivity to stimulation of any type)—also known as the *mad hatter syndrome*—from mercuric nitrate used in the hatting industry. Acute toxicity from elemental mercury may include encephalopathy and seizures, whereas its chronic toxicity includes peripheral sensorimotor neuropathy, dysarthria, and parkinsonism. Subclinical nerve conduction and neuropsychiatric abnormalities have been documented in the modern workplace.

Organic mercury includes MeHg, the cause of Minamata disease, and ethyl mercury. Excessive MeHg intake has been reported in fish-eating communities in Greenland, the Faroe Islands, the Seychelles, the Madeira Basin of the Amazon River, and New Zealand. Symptoms of organic mercury toxicity include tremor; ataxia; dysarthria; paresthesias of the hands, feet, and mouth; visual field constriction; erethism; and spasticity. Prenatal exposure to MeHg can cause severe congenital abnormalities such as micrognathia, microcephaly, mental retardation,

blindness, and motor deficits. Minamata disease produces neuropathologic abnormalities in the cerebral cortex, cerebellum, and peripheral nerves.

The 24-hour urine mercury concentration may assess both recent exposure and elimination of tissue burden. The normal blood concentration is less than 10 to 20 $\mu\text{g/L}$, and the urinary level is less than 20 $\mu\text{g/L}$. Treatment consists of decontamination and chelation with established guidelines. If the person is symptomatic, dimercaprol is given intramuscularly 3 to 5 mg/kg every 4 hours on day 1, every 12 hours on day 2, and then once a day for the next 3 days followed by a 2-day interruption. Other agents are DMSA and 2,3-dimercapto-propane-1-sulfonate, a water-soluble form of BAL. All agents are somewhat effective for organic and inorganic mercury poisoning.

Arsenic

Arsenic toxicity is a global health problem. It is estimated that tens of millions of people, for example, in Bangladesh, are at risk of excessive arsenic levels from natural geologic sources leaching into aquifers, contaminated drinking water, mining, and other industrial processes. Arsenicosis can result in cancer at various sites, encephalopathy, and axonal peripheral neuropathy. The chronic version is “blackfoot disease” with vascular changes, gangrene, and a less severe peripheral neuropathy. The use of arsenic trioxide to treat leukemia may cause arsenic neuropathy.

Vomiting, bloody diarrhea, myoglobinuria, renal failure, arrhythmias, hypotension, seizures, coma, and death characterize acute arsenic poisoning. In survivors, *Mees lines* on the fingernails and sensorimotor neuropathy appear in 7 to 14 days. Slow and incomplete recovery takes years. Cognition may be impaired in some survivors depending on the severity of the acute encephalopathy.

The diagnosis of arsenic intoxication is confirmed by urinary levels more than 75 $\mu\text{g/dL}$. Hair analysis has been used but is not reliable. BAL therapy is also used for acute arsenic poisoning. It is most effective before symptoms of neuropathy appear. BAL is considered more effective than penicillamine in treating the chronic neuropathy. Hemodialysis is another treatment for an acute episode.

Thallium

Despite the ban on manufacture of thallium rodenticides in the United States, accidental and suicidal exposures still occur because the poisons are available in other countries. After an acute exposure, gastrointestinal symptoms occur first with paresthesias occurring a few weeks later with the onset of a neuropathy. The encephalopathy presents with cognitive impairment and choreoathetosis, myoclonus, or other involuntary movements. Alopecia, which is unique to thallium toxicity, begins 1 to 3 weeks after exposure.

P.1105

After acute exposure, blood tests are not useful for detecting thallium because it is rapidly taken up by the cells. Normal urinary thallium values are 0.3 to 0.8 $\mu\text{g/L}$. Levels of 200 to 300 $\mu\text{g/L}$ are seen in overt poisoning. A provocative test uses potassium chloride (KCl), which is given orally in a dose of 45 mEq. Potassium displaces thallium from tissue stores, blood levels rise, and urinary content can be followed serially.

Treatment of acute poisoning depends in part on enhancing urinary and fecal excretion of thallium by giving laxatives and using Prussian blue or activated charcoal to retard absorption. Urinary excretion is enhanced by forced diuresis and administration of KCl. Hemodialysis may be effective.

Manganese

Manganese intoxication, still a threat in industrial settings, reproduces the essential motor features of parkinsonism but with sufficient clinical and pathologic differences to indicate the conditions are not identical; for instance, exaggerated tendon reflexes and behavioral features occur early in manganese toxicity. The outlook is

gloomy, including severe cognitive loss. Responses to levodopa and to chelation therapy are limited.

Aluminum

Dialysis dementia (see also [Chapter 120](#)) has been attributed to aluminum in the dialysis water and also in ingested phosphate binders used to control blood phosphorus levels. Treatment of the water and avoidance of the binders have decreased the incidence. Encephalopathy, however, has also occurred in uremic patients dialyzed with deionized water and also in those that ingest the phosphate binders without dialysis. Paresthesias and weakness were part of “potroom palsy,” a complex syndrome in workers in a smelter who were exposed to pots that had not been vented properly. Other manifestations included ataxia, tremor, and memory loss.

PLANT, ANIMAL, AND MARINE NEUROTOXINS

Ciguatera poisoning or the *marine neurotoxic syndrome* is the most common nonbacterial form of food poisoning in the United States and is endemic in subtropical regions. Toxins are found in tropical reef fish, which acquire them when they consume dinoflagellates. Initial symptoms are gastrointestinal followed by sensory symptoms, paresthesias, and pruritus. *Sensory inversion*, manifested as cold feeling hot and vice versa, dysuria, and dyspareunia are particular to this poisoning. Myalgia, fasciculations, areflexia, trismus, and carpopedal spasm are also reported. Respiratory failure is uncommon. There is no formal laboratory or clinical criteria for diagnosis. Mechanistically, most associated toxins open sodium channels. Treatment is symptomatic, with a randomized trial of mannitol showing no advantage.

Shellfish poisoning can result from contamination of mollusks by saxitoxin, which blocks sodium channels. The symptoms are similar to ciguatera but more severe, and respiratory depression is a greater risk. Cerebellar ataxia was the dominant finding and hypertension is common. Binding assays and liquid chromatography identify the toxin in serum and urine. In Japan, the agent of puffer fish poisoning is tetrodotoxin. Treatment of these conditions is symptomatic.

Amnesic shellfish poison is due to consuming domoic acid, a glutamate receptor agonist, in mussels, which can result in a transient encephalopathy. There is no specific treatment.

Many plants contain pharmacologically active substances that cross the blood-brain barrier with resulting delirium, hallucinations, seizures, and sedation. *Cicutoxin*, from *water hemlock*, produces a clinical state of agitation and confusion followed by sedation. *Andromedotoxin* from *rhododendron* is a depressant. Over 100,000 potential toxic exposures to botanicals are reported per year.

Neurolathyrism presents with spastic paraparesis in impoverished countries and is seen during times of drought when the *Lathyrus* plant is consumed. *Konzo* is a disease due to prolonged consumption of the bitter cassava *Manihot esculenta* prevalent in sub-Saharan Africa with a similar presentation. Cassava contains a cyanoglucoside linamarin, which is enzymatically converted to cyanide, which then damages neural cells. The clinical picture is a sudden, symmetric, and permanent spastic paraplegia. Males are predominately affected in both conditions. Hearing loss, visual impairment, and dysarthria may be seen in cassavaism but not neurolathyrism.

Radiation Injury

Christopher Zammit

Edward (Mel) J. Otten

INTRODUCTION

The first known description of nervous system injury by radiation was in 1930 by Fischer and Holfelder. Contemporary medicine's use of radiotherapy to treat malignancies has brought radiation injury into daily clinical discussion. The expansion of nuclear energy programs during the 1970s increased the risk for widespread radiation injury in the event of nuclear plant failure. The Three Mile Island accident in 1979 and disasters at the Chernobyl Nuclear Power Station in 1986 and the Fukushima Nuclear Power Plant following a tsunami in 2011 have provided real reminders of the ongoing risk.

Radiation injury is the result of exposure to ionizing radiation. Nonionizing radiation does not cause neurologic injury; its biologic injury is limited to thermal surface injury. Nervous system injury results from x-rays or gamma rays; alpha and beta particles also produce ionizing radiation, but they do not penetrate tissue by more than 8 mm and therefore do not reach the central or peripheral nervous system. Internal injury can result when alpha or beta particles are ingested, but even in such cases, their proximity to central neurologic structures limits their ability to produce significant neurologic injury.

The amount of radiation absorbed is described in terms of *gray* (Gy), where one Gy is equal to one joule of radiation absorbed per kilogram of tissue. A *radiation-absorbed dose* (rad) is equal to 100th of a Gy (i.e., 100 rad = 1 Gy). One rad is also equal to one *roentgen equivalent man* (rem), that is, 1 rad = 1 rem. In contrast, the dose of radiation delivered is described in sieverts (Sv), where 1 Sv is equal to 100 rem. To provide context, we are exposed to approximately 3 millisieverts (mSv) per year from natural radioactive material and cosmic radiation. Furthermore, one head computed tomography (CT) delivers 2 mSv of radiation.

Radiation effects on the nervous system and other organ systems ([Table 129.1](#)) can be difficult to predict, as the amount of radiation delivered is not necessarily equal to the amount absorbed, particularly when considering occupational or environmental exposures. The clinical effects of radiation are related to the individual susceptibility, dose rate, dose absorbed, and distribution of the dose.

TABLE 129.1 Radiation Effects

- Acute cerebral edema

- Early-delayed leukoencephalopathy or demyelination

- Late-delayed radiation necrosis

- Myelopathy

- Vasculopathy

- Plexopathy

- Neuropathy (including cranial and optic neuropathy)

- Neuroendocrine disorders

- Radiation-induced tumors

- Neuropsychiatric, behavioral, and cognitive disturbances

EPIDEMIOLOGY

As mentioned earlier, the incidence of radiation injury is related to individual patient characteristics, the dose amount, dose rate, and distribution of the exposure. Hypertension and diabetes mellitus increase the risk of radiation injury. Radiation injury may occur after scalp radiation for tinea capitis, radiotherapy to the head or neck for malignancy, whole-brain radiation for acute lymphoblastic leukemia (ALL) or small cell carcinoma, brachytherapy, or radiotherapy for intracranial malignancies.

Acute cerebral edema may occur days to weeks after radiation. It rarely occurs at doses below 2 Gy and is seen in about half of the time after doses over 7.5 Gy. Delayed leukoencephalopathy and/or demyelination typically occur between 1 and 6 months after exposure. Radiation necrosis is seen between 6 months and 7.5 years after radiotherapy, with a median onset of 14 months, and 75% of patients experience symptoms within 3 years. The cumulative dosing threshold for necrosis is reported as being 50 to 60 Gy, with a 5% incidence in those receiving a total of 50 Gy in daily doses of 2 Gy.

Myelopathy occurs 1 to 3 years after radiation, with peaks in incidence at 12 to 14 months and 24 to 28 months. Similar to radiation necrosis, 5% of patients receiving total doses of approximately 60 Gy to the spinal cord have been reported to develop myelopathy, but this is not consistent.

Intracranial and extracranial vasculopathy have been seen over 20 years after radiation exposure. Stroke-like migraine attacks after radiation therapy (*SMART*) syndrome has been reported many years after whole-brain radiation. It is rare with an incidence and risk factors that are not well described.

Plexopathy and neuropathy (including cranial and optic neuropathy) are typically seen after radiation directed at the affected region. Brachial plexopathy after radiation for breast cancer has a median onset of 4.5 months. Transient symptoms are seen in 1% to 2% of those receiving doses of 50 Gy. Lumbosacral plexopathy is rarely seen, even at doses of up to 70 to 80 Gy. Neuropathy is rarely seen at doses under 60 Gy. Optic neuropathy is seen within 3 years of exposure when it occurs.

The radiation dose threshold associated with neuroendocrine disorders in children is less than that for the previously mentioned injuries. Growth hormone (GH) deficiency is seen in fractionated doses of less than 20 Gy. Sixty-five percent of children undergoing prophylactic cranial radiation for ALL in a total dose of 20 to 30 Gy are observed to have a GH deficit. Other neuroendocrine disorders occur at total doses over 40 to 50 Gy, including gonadotropin deficiency, thyrotropin deficiency, adrenocorticotrophic hormone deficiency, and hyperprolactinemia.

Cognitive and neuropsychiatric disturbances are all too common in children receiving radiation for malignancies, with some series reporting rates of 100%. Radiotherapy that traverses the hippocampus or frontostriatal brain

circuitry is felt to increase the risk of occurrence.

Radiation-induced tumors include meningiomas, sarcomas, gliomas, and peripheral nerve tumors. Meningiomas have a latency of up to 37 years at doses of 8.5 Gy and as short as 18 months after 20 Gy. Sarcomas are seen about 10 years after doses of 50 Gy with an unclear frequency. The relationship between glioma occurrence and radiation therapy is not agreed upon. However, high-volume cell phone use has been associated with the occurrence of gliomas (and meningiomas) and the risk appears to be related to the “dose” of cell phone use. Peripheral nerve tumors are seen in about 10% of patients receiving radiation therapy directed through a peripheral nerve.

PATHOBIOLOGY

Ionizing radiation causes biologic injury by damaging the most basic elements that make up cellular structures and conduct cellular processes. The x-rays and/or gamma rays collide with electrons, causing elements to become ionized that were not otherwise, altering their ability to conduct cellular functions. This will damage DNA, leading to mutations that contribute to the increased malignancy risk. Cells that have high rates of turnover are the most vulnerable to this damage (e.g., hematopoietic, mucosal, endothelial, and gastrointestinal cells).

The early cerebral edema is suspected to be secondary to vascular endothelial dysfunction, causing vasogenic edema (hence its clinical response to corticosteroids). The latently observed leukoencephalopathy is thought to be the result of a transient demyelination due to oligodendrocyte dysfunction, as the time frame corresponds with expected myelin turnover.

Radiation necrosis is predominately a white matter process that may occur by one or more of the following mechanisms: glial dysfunction, vasculopathy, or immunologic. Glial dysfunction is supported by histologic changes including white matter necrosis, cystic cavitation with gliosis, and patchy demyelination suspected to be the result of oligodendrocytes injury. Alternatively, vascular injury has been observed histologically as perivascular lymphocytic infiltration, endothelial proliferation, fibrinoid degeneration, capillary occlusion, and intraluminal thrombosis of medium- and small-sized arteries. Endothelial cell injury then causes vasogenic edema. A *mineralizing microangiopathy* is seen in nearly 20% of patients at autopsy and can be appreciated clinically as calcifications at the gray-white junction on head CT. Lastly, an *immunologic mechanism* is suspected to occur when irradiated glial cells release antigens that induce an autoimmune reaction.

TABLE 129.2 Acute Radiation Syndrome Prognosis Based on Acute Symptoms and 48-Hour Absolute Lymphocyte Count

Radiation Dose (Gy)	Acute Symptoms	24-hour CNS Symptoms	48-hour Absolute Lymphocyte Count	Prognosis/Mortality
0-0.4	None to very mild, onset ~6 h	None to very mild headache	1,400-3,000 (normal)	Excellent, <5%
0.5-2	None to mild, onset 2-6 h	None to headache	1,000-1,399	Good, <5%
2-4	Mild to moderate, onset 1-2 h	Brief cognitive impairments	500-999	Fair, 5-50%

4-8	Moderate to severe, onset 10-60 min	Drowsy to confused	100-499	Poor, 50-100%
>8	Severe, onset within 10 min	Immediate lethargy, coma, seizures	100	Dismal, 100%

CNS, central nervous system.

In myelopathy, white matter necrosis is seen after higher radiation doses, whereas lower doses are observed to cause vascular damage, with a more delayed presentation. Asymptomatic animals are found to have a spongy vacuolation of the spinal cord white matter. In contrast, the animals with paralysis were found to have tissue destruction and vascular changes, predominately in the posterior and lateral columns.

Plexopathies and neuropathies can be the result of an occlusion of an artery (e.g., subclavian artery stenosis causing a brachial plexopathy) or radiation fibrosis, producing external compression around the nerve. Peripheral nerve ischemia due to radiation injury to the vasa nervorum is also suspected. Autopsies of those with radiation vasculopathy reveal myointimal proliferation, hyalinization, and occlusion.

CLINICAL FEATURES

Acutely radiated victims of an occupational or environmental event or accident typically do not know the dose of radiation they were exposed to. Symptoms of acute radiation sickness (ARS) on presentation include nausea, vomiting, diarrhea, or headache. The onset, persistence, and severity of symptoms are used to gage the dose and therefore prognosis of the victim. If neurologic symptoms are present acutely and are not the result of an injury sustained from a blast or other traumatic force, such as a decreased level of consciousness, ataxia, and seizures, the estimated radiation exposure is greater than 10 Gy and mortality is 100%. Those with a moderate radiation dose (2 to 6 Gy) may develop some mild transient cognitive impairment. Those with a higher dose (~6 to 10 Gy) will have more significant disturbances in cognition and consciousness that persist beyond 24 hours and have an expected survival of less than 5%. If the radiation dose remains uncertain due to confounders or an ambivalent presentation, the absolute lymphocyte count at 48 hours can provide further insight into the estimated radiation dose absorbed (Table 129.2).

Symptoms of cerebral edema from radiation injury following therapeutic radiotherapy with high daily dose fractions appear within a few days to weeks and include headache, nausea, and vomiting. Alopecia and scalp erythema may also be seen. Injury to

P.1109

the pharyngeal mucosa may cause pharyngitis and eustachian tube dysfunction leading to otitis media. A delayed leukoencephalopathy can present 4 to 10 weeks after radiation with somnolence and headache. A posterior fossa syndrome of ataxia, dysarthria, and nystagmus may follow radiation to the middle ear area for glomus jugulare tumors.

Radiation necrosis is a delayed-late consequence of radiation that presents between 6 months and 7.5 years after radiotherapy with clinical manifestations that may mimic the original tumor. Other presentations may include seizures, headaches, or increased intracranial pressure (ICP). Focal or lateralizing neurologic deficits can be neuroanatomically linked to the site of the treated malignancy or distant from it.

Early-delayed radiation myelopathy is transient and presents within 6 months of radiotherapy. Lhermitte sign (i.e., flexion of the neck causes an electric shock sensation down the spine) is reported in up to 15% of those

receiving radiation for Hodgkin lymphoma. Delayed radiation myelopathy presents 1 to 3 years following radiotherapy and presents with painless numbness and paresthesias, which then progress to include a spastic gait, sphincter symptoms, and limb weakness. Less commonly, acute paraplegia occurs acutely over a few hours and in this instance is thought to be the result of vascular injury causing infarction. Also worth mentioning is a syndrome that simulates motor neuron disease, which progress over 1 to 2 years and then plateaus.

Radiation-induced vasculopathy typically presents as a transient ischemic attack and/or ischemic stroke. Cerebrovascular malformations have been reported in the field of irradiated tissue as well. This time course to onset can be short or several decades after radiotherapy. SMART syndrome presents many years after wholebrain radiation and presents with seizures, headaches, and strokelike symptoms.

Radiation plexopathy is observed in three distinct clinical syndromes. A transient plexus injury presents 3 to 6 months following radiotherapy with paresthesias, pain, or weakness. Acute ischemic brachial neuropathy has an acute presentation that does not progress and is painless. Radiation fibrosis presents with painless paresthesias involving the upper (brachial) plexus +/- swelling of the arm about 4 years after radiotherapy. Tumor recurrence can also present in a delayed fashion with paresthesias, but there is typically no swelling, it is painful, and it affects the lower plexus.

Optic neuropathy presents with painless visual loss, decreased visual acuity, and/or abnormal visual fields within 3 years of radiotherapy. Exam demonstrates papilledema followed by optic atrophy and hemorrhagic exudates.

Endocrine dysfunction presents with growth arrest in children, a decrease in muscle mass, and an increase in adipose tissue in adults. Gonadotropin deficiency manifests as a failure to enter puberty in children and with amenorrhea, infertility, sexual dysfunction, and decreased libido in adults. Thyrotropin deficiency presentations may include weight gain and lethargy. Adrenocorticotrophic hormone deficiency is uncommon and presents with lethargy, fatigue, fasting hypoglycemia, and hyponatremia. Hyperprolactinemia is featured by delayed puberty, galactorrhea, and amenorrhea in women and decreased libido and impotence in men.

Neuropsychological sequela of radiation is most conspicuous when it manifests with a delayed IQ decline, learning disability, or academic failure. Detailed neuropsychiatric testing can reveal deficits in memory, executive function, processing speed, and verbal selective reminding. A syndrome of ataxia, cognitive disturbance, and urinary incontinence has been described that resolves with ventriculoperitoneal shunting.

DIAGNOSIS

The diagnosis for many of the aforementioned clinical sequela rests on the identification of their clinical features, time frame between radiation exposure and onset of symptoms, and exclusion of other conditions or inflictions that can produce the same symptoms. The early onset of cerebral edema after radiotherapy can be appreciated on head CT and brain magnetic resonance imaging (MRI) (T2 or fluid-attenuated inversion recovery [FLAIR]), but the clinical diagnosis is often assumed if there is improvement in symptoms after the administration of corticosteroids. Early-delayed leukoencephalopathy is suspected by the time between radiation exposure and symptom onset. T2 and FLAIR sequences on MRI may demonstrate hyperintensities, which are not specific for the condition. Confidence in the diagnosis of early-delayed leukoencephalopathy is strengthened by the gradual improvement in symptoms without treatment or intervention.

Radiation necrosis is suspected when symptoms begin more than 6 months after radiotherapy.

Neuroradiologic abnormalities range from focal mass lesions to diffuse white matter changes. Mass lesions are typically at the site of the original tumor/malignancy or in the path of delivered radiotherapy. CT and/or MRI may demonstrate ringlike or heterogeneous enhancement mimicking the original neoplasm.

Angiography will demonstrate that the lesion is avascular. Initially, changes are typically seen in the white

matter but may progress to involve the gray matter over a period of 6 months to 2 years. Diffuse white matter changes are seen as areas of hypodensity on CT or increased signal intensity on T2/FLAIR on MRI (with MRI being more sensitive), do not necessarily correlate with clinical symptoms, and are typically not reversible. Mild or early changes are seen adjacent to the frontal and occipital horns of the lateral ventricles. More extensive or progressive changes extend to include the centrum semiovale. The most advanced show diffuse lesions with a characteristic scalloped configuration. Accompanying changes include cortical atrophy or ventricular dilatation. In all stages, mass effect is rare, and if seen an alternative process or focal necrosis should be considered.

Distinguishing tumor recurrence from radiation necrosis may be difficult. Single-photon emission computed tomography (SPECT) and positron emission tomography (PET) may be helpful. Hypometabolic areas on PET are suggestive of radiation necrosis. A reduction in choline levels on *magnetic resonance (MR) spectroscopy* suggests tumor necrosis (and therefore radiation necrosis), whereas an increase could suggest tumor recurrence. Lactate elevations are suggestive (but not diagnostic) of necrosis due to vasculopathy. The clinicians should avoid anchoring themselves to a diagnosis based on neuroimaging alone and should have a low threshold for performing a biopsy to increase their diagnostic certainty.

Radiation myelopathy is diagnosed via exclusion of other processes and its time of onset in relation to the radiation administration (~1 to 3 years after radiotherapy). MRI may demonstrate cord swelling, atrophy, or complete subarachnoid block, but it also may be normal. Signal changes on T1 (low intensity) or T2 (high intensity) and contrast enhancement may appear 1 month after the onset of clinical symptoms. Beginning about 1 year after onset of symptoms, cord atrophy is seen and there is no further contrast enhancement. The diagnostic approach should seek to exclude other possible etiologies of the patient's myelopathy, such as extra- or

P.1110

intramedullary tumors, leptomeningeal metastases, or cord compression due to vertebral body abnormalities.

Unilateral gyriform enhancement on MRI many years after whole brain radiation in a patient with headaches, seizures, and/or focal neurologic findings is suggestive of SMART syndrome. Radiation vasculopathy is suspected based on history, location of the vasculopathy, and region of prior radiotherapy. Radiation plexopathy due to fibrosis is favored with electromyography (EMG) demonstrates myokymia. CT and MRI changes consistent with fibrosis increase the likelihood of a causal link but are not conclusive. Endocrinopathies and pituitary dysfunction are diagnosed as described elsewhere in this text. Cognitive and neurobehavioral disturbances are detected through neuropsychiatric assessment.

TREATMENT

The nervous system effects from ARS do not have specific therapies. The treatment of ARS is described in other texts and largely includes supportive care and granulocyte-stimulating drugs when significant lymphopenia is seen. Corticosteroids do not have a role in ARS, as immunosuppression is one of the most feared and deadly consequences of high-dose ionizing radiation exposures.

Cerebral edema, early-delayed leukoencephalopathy, late-delayed radiation necrosis, myelopathy, plexopathies, and neuropathies are often treated with corticosteroids. Among these afflictions, only cerebral edema seems to have an appreciable clinical response. Not uncommonly, there is a transient improvement with corticosteroids in radiation necrosis and myelopathies, but they are not expected to alter the ultimate course of the disease. Surgical resection should be considered when focal radiation necrosis produced marked mass effect, as it can be lifesaving and mitigate further neurologic injury from herniation syndromes.

There are no known effective treatments for radiation myelopathy. Large artery vasculopathy has been treated successfully with stenting. Treatments for plexopathy include the prevention of shoulder subluxation, treating lymphedema, and providing analgesia.

SMART syndrome does not have any proven or specific treatments; patients often receive a course of corticosteroids and antiepileptics. Some authors advocate for antiplatelet agents and/or statins.

OUTCOME

Outcomes after acute radiation syndromes are displayed in [Table 129.2](#). Early cerebral edema and early delayed leukoencephalopathy/demyelination are nearly always self-limited and reversible. Radiation necrosis can be progressive and fatal and is typically not reversible. Symptoms of radiation myelopathy are also not expected to improve. Outcomes after vasculopathy are related to the efficacy and timing of revascularization efforts. Outcomes after SMART syndrome have only been described in case series, but up to 50% appear to have residual neurologic deficits. Radiation plexopathy, neuropathy, and optic neuropathy are usually irreversible. Cognitive deficits are typically not reversible and not uncommonly progressive, resulting in death or permanent disability and dependence.

Electrical and Lightning Injury

Christopher Zammit

Edward (Mel) J. Otten

INTRODUCTION

Electrical injuries (EI) and lightning strikes (LS) have been reported to cause a variety of neurologic injuries. Interestingly, although some of the associated neurologic sequelae are seen acutely, others develop in a delayed fashion. Although both EI and LS produce injury via the creation of an electrical current, the neurologic complications of each can be quite different.

Low-voltage electrical injuries (LVEI) are defined as resulting from exposures of less than 1,000 V, whereas greater exposures are termed *high-voltage electrical injuries* (HVEI). They are to be further distinguished as being the result of a direct current (DC) or alternating current (AC), with the latter producing approximately three times as much injury as the former. LS are exceptionally brief, with voltages on the order of the millions, and produce a unique constellation of immediate and delayed injuries.

EPIDEMIOLOGY

The first death in the United States related to an artificial electrical source occurred in front of a crowd in Buffalo, New York in 1881 when an intoxicated man came into contact with a generator. His death was seen as being quite painless, leading to the use of electrocution as a humane method of capital punishment. Formal reporting of electrical and lightning injuries is not required, limiting the accuracy of existing epidemiologic data.

There are an estimated 3,000 EI per year in the United States, including 1,000 deaths. Children are more likely to suffer LVEI, whereas adolescents and adults more commonly experience HVEI, which are frequently occupationally related.

Over 15,000 police departments across the United States use conducted energy weapons (CEW), such as stun guns and TASER devices to restrain suspects. Cardiac arrests have occurred after the uses of CEW, but a causal link has been proposed in only a minority of cases. In the majority of circumstances, excited delirium and/or intoxicates ingested by the victim are blamed for causing the arrest.

Three hundred to 1,000 lightning injuries occur per year in the United States, with an estimated mortality rate of 10%. Many victims either do not seek care at the time of the injury, and half of the immediate deaths are transported directly to the coroner and never reported. Victims are usually men (4.5:1 male-to-female ratio) in their second to third decade of life and are performing outdoor recreational or occupational activities.

PATHOBIOLOGY

ELECTRICAL INJURIES

The severity of LVEI is subject to the pathway of the current and proportional to the duration of exposure and amount of current (milliamperes [mA]). Low-voltage AC, in contrast to low-voltage DC, can produce continuous involuntary muscle contractions. If the victim grips an AC electrical source with their hand, tetany of the flexors of the upper extremity prove stronger than the extensors, causing the victim's grasp of the source to be strengthened. Currents of 6 to 9 mA or greater, which can be achieved via exposure to a standard 110-V household outlet, exceed the "let-go threshold," rendering the victim incapable of dissociating himself/herself from the source. If the current flows through the thorax, tetany of the muscles of respiration can occur, causing

the victim to suffocate. Currents of approximately 50 to 100 mA can cause ventricular fibrillation; the current threshold is inversely proportional to the duration of exposure.

Direct contact with a high-voltage electrical source more commonly produces diffuse, sudden, and violent muscle contractions that thrust the victim away from the source, causing traumatic insults in addition to the EI. Even with brief exposures, the high voltages convey a tremendous amount of energy, which is released via electrothermal heating at points of high resistance (e.g., the skin, where full-thickness burns are seen). Internally, the current is carried along tissues of low resistance, such as the nerves, muscles, and blood vessels. Immediate effects include muscle necrosis and small-vessel thrombosis, resulting in threats to extremity viability and peripheral nerve integrity through compartment syndromes and limb ischemia.

In contrast to a direct contact injury, a spark can jump from a highly charged source to a ground source, forming an electrical arc, where temperatures can reach 2,500°C. When a victim is caught in the path of the arc, he or she suffers cutaneous thermal burns and blast injuries when the suddenly heated air rapidly cools, in addition to a HVEI by becoming part of the conduction pathway of the current.

CEWs are reported to be high voltage (with an initial charge of ~50,000 V). However, the victim does not experience this voltage. Instead, it allows for an arc to be created if the barbs do not make contact with the skin, which happens about 30% of the time. Once contact is made, the voltage immediately decreases to provide a current of approximately 2 mA in brief pulses at a rate of 20 times per second, producing involuntary muscle clonus (much like an AC circuit), preventing the suspect from resisting. Because of the low current, EI is rare with CEWs, and most injuries, when they do occur, are traumatic and related to when the victim falls to the ground.

LIGHTNING STRIKES

Lightning victims can be directly struck with the discharge, receive current via an adjacent object that was directly struck (side flash), become part of the ground current when their feet are apart (step voltage), be the conduit for currents that originate from the ground and discharge toward the clouds (upward stream), and/or experience a concussive or blast injury from the rapid heating and cooling of the air (thunder). Curiously, some of the injuries typically seen with direct contact HVEI are not found in lightning injuries and entry and exit wounds are only seen in a minority

P.1114

of cases, suggesting that most, if not all, of the current flows external to the victim. This is thought to result in a powerful magnetic field being created over the victim, causing electrical currents to flow internally through low-resistance tissues (i.e., nerves, muscles, blood vessels), resulting in powerful muscle contractions and medullary dysfunction leading to apnea, asystole, and a tremendous catecholamine surge.

Ball lightning (BL) is a poorly understood, spherical, mobile electrical field observed floating along power lines, down aisles of airplanes, or through the air during lightning storms. Neurologic sequela has been reported in those that have come into contact with BL.

The pathophysiology of neuronal injury after EI and LS is not clear and several plausible mechanisms have been reported. The low resistance of nerves makes them a conduit for the electrical current, causing tremendous excitatory discharges, which result in microglia activation, electroporation, and chromatolysis. Electroporation is the destabilization of neuronal cell membranes from electrical current-induced changes in cellular proteins, resulting in their dysfunction and perhaps ultimate death. Microglia activation produces an inflammatory response suspected to result in injury to neurons and oligodendrocytes. Upregulation of postsynaptic cortical γ -aminobutyric acid (GABA)-B receptors is also a suggested consequence of the excitatory impulse based on the results of experiments using transcranial magnetic stimulation in patients with HVEI. Axonal injury and demyelination have been observed in EI and LS victims on MRI, nerve conduction studies, and autopsy.

Blood vessels similarly conduct electrical current, which has been observed to cause microvascular thrombosis and large vessel vasospasm, with some case reports of cerebral thrombosis. Endothelial cell dysfunction at the capillary level resulting in tissue ischemia is a proposed etiology for some of the delayed clinical consequences.

Muscles are also low resistance and therefore conduct a great deal of electrical current. Sarcolemmal injury is a proposed cause of the protracted fatigue reported by many victims of HVEI.

CLINICAL FEATURES

The immediately clinical presentation of EI and LS can range from a minor contact burn to a victim in cardiac arrest. In EI due to direct contact, particularly HVEI, there are often significant cutaneous burns with much more extensive internal burn injuries, particularly involving muscles, small vessels, and tendons. Limb amputation is not uncommonly required and rhabdomyolysis is frequent in HVEI. Traumatic injuries to the head and spinal cord are also common. Vasospasm and cerebral arterial thrombosis, both immediate and delayed, have been reported. Myelopathy is frequently reported and occurs at a spinal level consistent with the path of the electrical current. Contact injuries to the head and LS may cause a multiple-level myelopathy when the current exits through the foot. Myelopathy is not uncommonly delayed in presentation, with a time period that is inversely proportional to the patient's age. Curiously, peripheral neuropathy is not commonly seen, but when it does occur, it tends to affect motor nerves more than sensory and recently has been described to be axonal.

Neuropsychiatric symptoms, cognitive and memory impairment, autonomic dysfunction, fatigue, chronic headaches, and sleep disturbances are quite common among survivors. The constellation of symptoms is quite similar to those seen after a traumatic brain injury.

Cherington has divided the neurologic complications of lightning injury into four categories. Category I are temporary and benign, category II are prolonged and permanent, category III includes delayed symptoms, and category IV are traumatic neurologic injuries that occur secondary to falls, sudden violent muscle contractions, or blast effects. [Table 130.1](#) summarizes these injuries.

TABLE 130.1 Neurologic Complication in Victims of Lightning Strikes

Category I	Headache, numbness, weakness, depressed level of consciousness, keraunoparalysis (Charcot paralysis)
Category II	Hypoxic encephalopathy; cognitive deficits; memory and attention impairment; mood, behavioral, and sleep disturbances; fatigue; autonomic dysfunction; cold insensitivity; acute ischemic stroke; intracerebral hemorrhage (basal ganglia or brain stem); myelopathy
Category III	Parkinsonism, progressive motor disease, focal dystonia, and tics
Category IV	Traumatic intracranial hemorrhage, spinal cord injury due to fractures, or hemorrhages

Keraunoparalysis, or Charcot paralysis, is an immediate, transient paralysis seen in some LS victims. It involves the lower extremities more than the upper, lasts for less than an hour, and is characterized by pale limbs with diminished or absent pulses, sensory symptoms, and hypertension. A catecholamine surge has been suspected, but not proven, to be the cause.

Several case reports have attempted to suggest a link between EI/LS and amyotrophic lateral sclerosis; however, several recent reviews have summarized the available data and reports and concluded that any link is quite unlikely.

DIAGNOSIS

Victims of EI or LS with an altered level of consciousness, focal deficit, or paralysis on presentation should have emergent diagnostic imaging of the head and/or spine performed to evaluate for traumatic injuries or acute ischemia, which may warrant prompt interventions. Acute cerebral ischemia may be secondary to thrombosis or vasospasm; emergent computed tomography (CT) or conventional angiography should be considered.

TREATMENT

Specific treatments for the neurologic sequela of electrical and lightning injuries have not been described. Intravenous thrombolytics and/or endovascular therapy (clot retrieval if thrombosis or angioplasty/intra-arterial therapy if vasospasm) should be considered in patients presenting with a sudden onset of focal neurologic deficits after an EI or LS. Victims who are resuscitated after a cardiac arrest and not following commands should be considered candidates for targeted temperature management, barring other contraindications. Similarly, if the victim remains comatose for longer than 2 hours without an alternate explanation, it may suggest he or she was transiently asystolic and/or apneic, particularly in the setting of an LS. Cardiac automaticity and ventilation may have spontaneously resumed but not without suffering a hypoxic-ischemic cerebral injury. The astute clinician should consider targeted temperature management in this setting as well

P.1115

because the event is the equivalent of return of spontaneous circulation in a cardiac arrest patient who received an active resuscitation. Traumatic injuries should be treated accordingly. Survivors of EI and LS may be referred to an international support group, Lightning Strike and Electric Shock Survivors International, Inc. (<http://www.lightning-strike.org>).

OUTCOME

The neuropsychiatric complications, cognitive deficits, and autonomic disturbances seen after EI and LS are most commonly permanent and at times progressive. Myelopathy may improve, and recovery has been seen in some victims, but most are left with persistent symptoms. Cardiopulmonary resuscitation (CPR) success rates have been higher in victims of electrical and lightning injuries than from other causes even when the interval from injury has been prolonged. Outcomes after EI or LS complicated by a cerebral infarction or hypoxic-ischemic injury are only found in case reports or case series, making accurate estimations impossible.

Decompression Illness

Christopher Zammit

Edward (Mel) J. Otten

INTRODUCTION

The symptoms of decompression illness (DCI) have been observed in underwater and caisson workers since the early 1800s, when it was coined “caisson disease.” Today, DCI refers to the sequela that result from arterial gas embolism (AGE) and decompression sickness (DCS). Both conditions are the result of rapid changes in ambient pressure that cause dissolved inert gases to emerge in the circulation as bubbles. The rapid growth in popularity of underwater diving with a self-contained underwater breathing apparatus (SCUBA), particularly by travelers, has made DCS a diagnostic possibility even in land-locked areas. Although this chapter focuses on DCI, other dysbaric conditions with neurologic inflections or complaints are also briefly discussed, which include middle ear barotrauma (MEBT), inner ear barotrauma (IEBT), alternobaric vertigo (ABV), carbon monoxide poisoning, nitrogen narcosis, oxygen toxicity, and swallow water blackouts.

EPIDEMIOLOGY

DCS has been observed in those who perform submersion activities (e.g., SCUBA, saturation, or breath-hold diving), high-altitude aviation (e.g., U-2 pilots), and simulated altitude ascents. AGE can occur after resurfacing from depths of only 1 to 1.5 m, whereas DCS is never seen after surfacing from depths of less than 6 m and very rarely occurs after dives less than 10 m in depth. AGE can occur if the diver rapidly ascends to the surface, holds his or her breath during ascent, or has intrinsic lung disease, particularly those with blebs and asthmatics. DCS risk factors include longer submersion times, deeper submersions, high exertion and warm temperatures during the dive, cold temperatures after the dive, older age, obesity, dehydration, and male gender. Divers with a patent foramen ovale (PFO) appear to be at increased risk (odds ratios of 2.6 to 5.6) for neurologic DCI when compared with divers without a PFO. Dive computers and tables are available to advise whether “decompression stops” are required during ascent to mitigate the DCS risk.

DCI is estimated to occur in 3 out of every 10,000 dives, with higher rates in U.S. Navy and commercial divers and the lower rates in recreational divers. The Divers Alert Network produces an annual report, which profiles diving-related complications. Data from the most recent report are outlined in [Table 131.1](#).

DCS is less commonly seen in high-altitude flying, when compared with submersion activities, and when observed, the symptoms are typically less severe and rarely include neurologic manifestations. A notable recent exception are Air Force U-2 pilots who fly at altitudes of up to 70,000 ft in suits that are pressurized to approximately 30,000 feet above sea level.

PATHOBIOLOGY

DCI is believed to result from bubbles of inert gas, particularly nitrogen, being formed in the circulation during decompression. In the case of submersion, at increasing pressures, inert gases, mostly nitrogen, become intensely dissolved in the blood and tissues of the body. The amount dissolved will increase if the temperature rises. Upon ascent (whether that is resurfacing from a dive or ascending in elevation, as in aviation), these inert gases come out of solution. Ideally, the gas is delivered to the alveoli, where it is expired. In reality, gas bubbles can be observed in the blood of all divers via ultrasound upon emergence from a dive. Typically, the pulmonary circulation filters the bubbles and the diver does not experience any symptoms. However, if the quantity of

bubbles is too great, they will buildup and occlude small veins and lymphatic vessels. At high bubble loads, the pulmonary vasculature also develops occlusions, increasing right heart pressures and raising the possibility of opening an otherwise closed PFO through which bubbles can pass into the arterial circulation.

In addition to vessel occlusion, intravascular bubbles are known to irritate the endothelium, causing capillary leakage, and platelet, complement, and cytokine activation, leading to third spacing, hemoconcentration, small-vessel thrombosis, and eventually hypotension. The occlusive action in the venules combined with small-vessel thrombosis is hypothesized to be the cause of the cerebral, vestibular, and spinal cord injuries and dysfunction in neurologic DCS. Inert gases preferentially dissolve in tissue with a high lipid content, such as the central nervous system (CNS), where the emergence of nitrogenous bubbles are suspected to contribute to neurologic dysfunction and injury.

AGE has a slightly different pathophysiology. Alveolar gas that abruptly expands on decompression (Boyle law) and is not ventilated appropriately will force itself through the alveolar-capillary membrane and directly enter the arterial circulation, where it produces mechanical obstructions. The most notable clinical sequela occur when the cerebral or coronary vessels are occluded, producing ischemic strokes and myocardial infarctions.

TABLE 131.1 2008 Diving-Related Deaths and Morbidity in the United States

Condition	Confirmed	Suspected
Fatalities	144 ^a	—
Decompression sickness (DCS)	122	209
Cerebral DCS	16	10
Spinal DCS	28	15
Arterial gas embolism	—	11
Middle ear barotrauma	—	344
Inner ear barotrauma	—	26
Alternobaric vertigo	—	6

^a83 U.S./Canadian residents.

Data from the Divers Alert Network annual report.

MEBT and IEBT occur during compression when the eustachian tube collapses and the middle ear cannot equalize its pressure with the ambient pressure. In MEBT, the tympanic membrane ruptures, exposing the middle ear to the water, causing vertigo and, at times, a seventh cranial nerve palsy. IEBT is the result of a sudden

equalization of pressure in the inner ear, causing injury to the cochleovestibular system. In contrast, ABV occurs during ascent when gases expand in the middle ear but cannot escape to allow equalization.

Nitrogen narcosis is a result of high concentrations of dissolved nitrogen that can occur at depth of greater than 100 ft. CNS oxygen toxicity can occur when the partial pressure of oxygen exceeds 1.4 atm. Compressed air tanks can be contaminated with carbon monoxide or carbon dioxide if the compressor's exhaust is too close to the air intake, causing carbon monoxide poisoning. Symptoms would be expected to occur during descent or at depth, in contrast to DCI that occurs with ascent or after surfacing. Swallow water blackouts occur in divers who hyperventilate ambient air prior to a dive, driving their arterial carbon dioxide levels very low without increasing their arterial oxygen content. During the dive, carbon dioxide levels do not increase sufficiently to increase respiratory drive, whereas oxygen levels fall, causing a loss of consciousness.

CLINICAL FEATURES

DCS has been divided into two clinical categories, type 1 (DCS1) and type 2 (DCS2). The majority of the time, DCS presents within 24 hours of decompression, but delayed presentation have been seen, particularly in those that have flown or ascended in altitude shortly after decompression. DCS1 includes signs and symptoms related to the integumentary, lymphatic, or musculoskeletal system. The patient will describe joint aches and pains, itching, or extremity edema, and a lenticular skin rash believed to be due to venous stasis, known as *cutis marmorata*, can be observed.

DCS2 can include features of DCS1 with additional symptoms related to the CNS, lungs, or vestibular system. The pulmonary symptoms, which include a cough, dyspnea, or chest pain, have been called *the chokes*. Vestibular symptoms, also known as the *staggers*, manifest as vertigo, nystagmus, nausea, or vomiting and can be difficult to differentiate from ABV because both can occur on ascent. The symptoms of cerebral DCS can include headache, diplopia, dysarthria, personality changes, disorientation, fatigue, ataxia, drowsiness, and even lethargy. Visual disturbances include optic neuropathy, homonymous hemianopsia, and central retinal artery occlusion. Spinal cord DCS presents with limb weakness, numbness, paresthesias, incontinence, priapism, urinary retention, or back/pelvic pain.

AGE has a dramatic and abrupt presentation, occurring during ascent or within 10 minutes of surfacing, and is commonly found to be the cause of death in diving fatalities. The presentation can include a variety of neurologic changes, including stroke syndromes, and may include pulmonary symptoms in about half of the cases. It can be difficult to distinguish AGE from DCS2. Alas, their treatment is the same, so sorting out the diagnosis is of academic interest only.

MEBT, IEBT, and ABV all have similar symptoms. MEBT will often include a ruptured tympanic membrane. IEBT should be distinguished, as the symptoms will be persistent and often require referral to an otolaryngologist. IEBT and vestibular DCS may be difficult to distinguish as well. A history of a sudden symptom onset upon equalization of pressures suggests IEBT. Cerebellar infarcts have been seen as a result of DCS and should be treated the same as vestibular DCS.

DIAGNOSIS

The diagnosis of DCS is clinical. Any symptoms upon decompression consistent with DCS should be treated as such. There are sporadic reports of carotid artery dissection and one report of an epidural spinal hematoma in a breath-hold diver, but these cases are the exception, and recompression should not be delayed. Magnetic resonance imaging (MRI) lesions have been seen in cerebral and spinal DCS, but they lack sensitivity, as even those with incomplete recovery have been observed to have normal serial imaging. Spinal cord MRI lesions have been observed in the white and gray matter. Cerebral MRI findings include

foci of ischemia and T2 hyperintensities, which have been found in the anterior and posterior circulations and in the subcortical white and cortical gray matter. Divers without a history of neurologic DCS have rarely been reported to have abnormal MRIs, but there are only a handful of controlled studies to fully describe the specificity of neuroimaging. Spinal canal stenosis has been associated with the occurrence of spinal DCS and MRI lesions, but it is not associated with clinical outcomes.

TREATMENT

DCI is a medical emergency that calls for the immediately administration of 100% oxygen and recompression. Large-scale observational evidence suggests that timely recompression optimizes outcomes and hastens recovery. More recent publications challenge whether time to recompression impacts the rates of recovery in those with neurologic DCS, but the datasets are small and limited to observations. Therefore, expeditious recompression remains the standard of care, and DCS must be considered a medical emergency.

Hyperbaric therapy (HBT) can be provided in monoplace or multiplace chambers, with the later allowing for hands-on treatment of the patient, if needed. HBT recommendations for DCS and AGE can be found in the U.S. Navy Diving Manual (see “Suggested Readings”). Serial HBT dives are performed until benefit is not seen with consecutive treatments. Patients requiring air transport to HBT should be flown at the lowest safe altitude (recent recommendations are <500 ft above surface level) or in a pressurized aircraft. Portable chambers that allow for partial recompression are available. For chamber locations and emergency information, U.S. physicians should contact the Divers Alert Network, at 919-681-4326, a 24-hour hotline.

Isotonic, non-dextrose-containing intravenous fluids should be administered, as many of these patients are hemoconcentrated. If AGE is suspected, intravenous lidocaine is commonly provided, as randomized evidence from the cardiac surgery literature, where AGE and cerebral injury are commonly seen, suggests it has neuroprotective benefits. Aspirin is considered by many, without evidence to support its use. An randomized controlled trial (RCT) of tenoxicam for DCS demonstrated that it hastened recovery and reduce the number of required recompressions from 3 to 2, but clinical outcomes were no different [**Level 1**].¹ Preliminary evidence is promising for perfluorocarbons, but clinical trials are needed. A small study from the 1990s suggested that a helium-oxygen mixture might be superior to an air-oxygen mixture during recompression, but the results have not been reproduced. A recent study of PFO closure in divers suggests it reduces the incidence of DCS and the quantity of ischemic brain lesions on MRI.

P.1118

OUTCOME

Cerebral DCS outcomes are similar to ischemic stroke survivors, as one series found the National Institutes of Health Stroke Scale (NIHSS) to have a similar ability to predict outcomes in both conditions. Spine DCS outcomes have been found to be worse in those older than 42 years of age, with bladder symptoms, with progressive symptoms upon decompression, with initial severe symptoms, and with MRI abnormalities. One-quarter to one-third of spinal cord DCS victims will make an incomplete recovery.

INTRODUCTION

Pediatric neurologists treat many children with brain injuries that originate in the perinatal period and cause mental retardation, cerebral palsy, and/or seizures. This chapter will focus on some of the most common disease processes affecting neonates.

PERIVENTRICULAR-INTRAVENTRICULAR HEMORRHAGE

EPIDEMIOLOGY

Premature, low birth weight neonates are especially at risk for periventricular-intraventricular hemorrhage, and the incidence and severity of intraventricular hemorrhage (IVH) increases with earlier prematurity and lower birth weight. The prevalence of periventricular IVH in newborns weighing less than 1,500 g has declined, falling from approximately 40% in 1980 to 20% since the late 1990s. Corticosteroid therapy prenatally and surfactant use after birth have contributed to the decline of IVH. However, with the increased survival rate of extremely low birth weight infants, there are more infants at highest risk, with a risk of 45% in infants less than 1,000 g. In a population-based study in Switzerland, IVH decreased by 3.5% with each added week of gestation.

Additionally, severe IVH increases with decreasing gestational age. In a large, multicenter registry of infants of very low gestational age (22 to 28 weeks) and birth weight (401 to 1,500 g), born between 2003 and 2007 in the United States, 16% overall had severe IVH, and the prevalence increased with decreasing gestational age, from 38% at 22 weeks to 7% at 28 weeks.

PATHOBIOLOGY

In premature neonates, the vascular germinal plate near the foramen of Monro, in the region of the caudate, is friable and susceptible to hemorrhage. The risk for hemorrhage is further exacerbated by disturbances in cerebral blood flow, either through hypotension and lower cerebral perfusion, possibly lowered further by positive pressure ventilation through endotracheal intubation, and/or through hypoperfusion-reperfusion coupled with immaturity of intrinsic cerebral vasoreactivity and autoregulatory mechanisms. Other factors potentially increasing risk of IVH during prematurity are metabolic (hypoglycemia, hypernatremia), hematologic (anemia, thrombocytopenia), and immunologic (chorioamnionitis, immaturity of antioxidant responses, or other immune responses).

The Papile grading system, with some modification, is the most commonly used scale to describe the severity of the IVH (Fig. 132.1). The IVH may remain in the matrix area (grade I), but 50% can rupture into the lateral ventricles (grade II), which can result in ventricular enlargement or distension (grade III). Grade IV, now termed *periventricular hemorrhagic infarction* (PVHI), refers to extensive IVH with parenchymal involvement, likely due to terminal venous occlusion, venous infarction, and subsequent secondary hemorrhage.

Late in the course after IVH (1 to 3 weeks after the initial hemorrhage), especially with more severe IVH, there can be posthemorrhagic hydrocephalus (PHH), or progressive ventricular dilatation (PVD), thought to result from impaired reabsorption of cerebrospinal fluid (CSF) because of inflammation of the subarachnoid villi. Usually, impaired reabsorption results in a communicating hydrocephalus, although there can also be a noncommunicating hydrocephalus due to localized obstruction or scarring.

CLINICAL MANIFESTATIONS

Most IVH in premature infants occurs within the first 5 postnatal days. Late IVH is associated with low cerebral blood flow, usually from systemic processes.

The clinical presentation of IVH varies depending on severity. Grade I IVH is usually asymptomatic. Many grade II and some III hemorrhages are clinically silent, but there may be a saltatory course evolving over hours to days, characterized by nonspecific findings of altered level of consciousness, hypotonia, eye movement changes, subtle changes in movement, decreased spontaneous movements, and disturbed respiratory function. Some grade III hemorrhages produce hydrocephalic symptoms of varying severity, and if seen in combination with PVHI, there may be signs of severe apnea, bradycardia, extensor posturing, and opisthotonus. There also may be flaccid weakness, cranial nerve abnormalities including fixed pupils to light, most likely leading to unresponsiveness and death within hours. There may be clonic limb movements, which some clinicians have labeled as seizures, although there is usually little electroencephalogram (EEG) correlation. Most infants who die have other lesions, such as periventricular leukomalacia (see the section “Periventricular Leukomalacia”), brain stem necrosis, or cerebellar necrosis.

DIAGNOSIS

Cranial ultrasonography is the preferred imaging modality because of its portability, its ability to delineate blood in the parenchyma and ventricles as well as ventricular size, and its lack of ionizing radiation. Routine ultrasound screening should be performed in all infants with a gestational age younger than 30 weeks and should be strongly considered in infants with abnormal clinical signs such as changes in neurologic or respiratory status or with systemic conditions which can predispose to IVH.

FIGURE 132.1 Papile grading system for neonatal IVH, shown by head ultrasonography. Echodensities are seen in periventricular region (I, grade I), with rupture into the lateral ventricles (II, grade II) and with ventricular enlargement (III, grade III). PVHI (IV) has parenchymal involvement. (From El-Dib M, Massaro AN, Bulas D, et al. Neuroimaging and neurodevelopmental outcome of premature infants. *Am J Perinatol.* 2010;27[10]:803-818.)

Computed tomography (CT) or magnetic resonance imaging (MRI) have limited usefulness as routine screening tools because of their lack of portability, exposure to ionizing radiation (CT), and a longer examination time (MRI). However, these modalities may be helpful in documenting other lesions, such as parenchymal abnormalities or subdural or posterior fossa hemorrhages. CT scanning is generally avoided because of the exposure to ionizing radiation, if MRI is available.

Lumbar puncture may be helpful if ultrasonography is unavailable. The red blood cell count is typically high, with a protein concentration of 250 to 1,200 mg/dL. Later, the CSF becomes xanthochromic, and glucose concentration frequently decreases.

TREATMENT

Prevention

The most effective prevention strategy is avoidance of premature birth. When preterm birth is inevitable, there are some prenatal and delivery room practices associated with a lowered risk of IVH. Corticosteroids given antenatally, at a dose of two 12-mg

P.1121

intramuscular injections of betamethasone at 24-hour intervals, reduce risk of IVH. Delayed clamping of the umbilical cord (30 to 60 seconds) has been associated with a reduction in the relative risk of IVH, although it is not clear whether there is a correlative decrease in severe IVH. Maternal transport to a perinatal center before delivery reduces risk of IVH in very low birth weight infants as compared with infant transport after delivery.

General measures of neonatal care are widely accepted to reduce risk of IVH in the postnatal period. Resuscitation should be prompt and hemodynamic instability, hypoxia, hypercarbia, hyperoxia, and hypocarbia should be avoided. Hypotension and hypertension should be avoided and corrected (in a gradual fashion to avoid large acute changes in blood pressure). Coagulopathies and metabolic abnormalities should be corrected. Bicarbonate therapy is associated with an increased risk of IVH and should be avoided.

Medical Therapies

There are no medical interventions that have been shown to safely reduce the long-term effects of IVH. Indomethacin, usually administered as three 0.1 or 0.2 mg/kg doses beginning 6 or 12 hours after birth, with a dosing interval of 12 or 24 hours, may reduce the rate of severe IVH but has not been shown to affect long-term outcomes such as death or severe neurologic impairment.

Procedural or Surgical Intervention

In general, no treatment is needed for grade I and II hemorrhages, although they should be followed for progression by regular cranial ultrasonography. For grade III hemorrhage or PVHI, ongoing monitoring should be performed, with weekly head ultrasounds with daily head circumference measurement and frequent clinical assessment for increased intracranial pressure (ICP). If there is evidence of significant lateral ventricular dilatation or increased ICP, intervention may be needed. Serial lumbar punctures can be done, although they should be coupled with cranial ultrasonography to ensure that there is a resultant decrease in ventricular size. As a temporizing measure, ventricular drainage with a direct extraventricular drain or with a subcutaneous drain to a subcutaneous reservoir or a ventriculosubgaleal shunt may be helpful. Usually, if a drain is needed, eventually, a permanent ventricular shunt, usually a ventriculoperitoneal shunt, will be needed, although a third ventriculostomy may be effective as well in some cases. Every attempt should be made to delay shunting until the newborn attains as much somatic growth as possible.

TABLE 132.1 Intraventricular Hemorrhage Clinical Features, Treatment, and Outcome

IVH Grade	Clinical Syndrome	Treatment	Outcome
-----------	-------------------	-----------	---------

I	Usually asymptomatic	Follow clinically and with cranial ultrasound.	Usually normal; may have long-term behavioral/learning problems if low birth weight
II	Frequently asymptomatic, may display subtle neurologic signs affecting mental status, tone, eye or muscle movements, or respiration		
III PVHI	May show signs of hydrocephalus; may show other neurologic signs similar to grade II May show more severe neurologic signs including apnea, bradycardia, opisthotonus, posturing	If signs of increased intracranial pressure, may require intervention: serial lumbar punctures, ventricular drainage, ventricular shunt, or third ventriculostomy	20% mortality; 75% show PHH. May progress to developmental delay, cerebral palsy, bilateral deafness, especially with bilateral blindness associated with more severe bleeds and extreme prematurity. May be normal if small hemorrhage.

IVH, intraventricular hemorrhage; PHH, posthemorrhagic hydrocephalus; PVHI, periventricular hemorrhagic infarction.

OUTCOME

Grades I and II IVH usually has a good short-term outcome, with an 80% to 90% survival rate without an obvious neurologic abnormality (Table 132.1). However, there may be long-term disorders of learning and behavior, especially with extremely low birth weight neonates (<1,000 g).

The mortality rate of grade III IVH and PVHI is approximately 20%, with 75% of the surviving infants developing PHH. Long-term prognosis worsens with decreasing gestational age and increasing severity of IVH, with higher rates of developmental delay, cerebral palsy, bilateral deafness, and bilateral blindness associated with more severe bleeds and extreme prematurity. Some infants with PVHI survive without disability, especially when the infarctions are small.

HYPOXIC-ISCHEMIC ENCEPHALOPATHY

EPIDEMIOLOGY

In developed countries, birth asphyxia affects 3 to 5 newborns per 1,000 live births and causes moderate to

severe hypoxic-ischemic encephalopathy (HIE) in 0.5 to 1 per 1,000 live births. Globally, 10% to 60% of neonates with HIE die, and 25% have long-term neurodevelopmental difficulties.

PATHOBIOLOGY

HIE is most commonly associated with severe maternal hypotension, uterine rupture, placental abruption, and placental or umbilical cord dysfunction. In addition, there may be associated hypoxic cardiopulmonary, hepatic, or renal injury.

Brain pathology depends on the level of maturity at the time of the insult, as well as the duration and location of the insult. In infants injured younger than 32 weeks' gestation, periventricular leukomalacia (PVL) is commonly seen because of the vulnerability of late oligodendroglial precursors. After 36 weeks' gestation, hypoxic lesions are frequently located in the cerebral gray matter, deep gray nuclei, brain stem, and Purkinje cells of the cerebellum.

P.1122

On a cellular and molecular level, hypoxia-ischemia acutely causes neuronal loss in the cerebral sulci, often with edema and infarction. Chronically, there is neuronal loss and astrocytosis, with possible atrophy, cystic encephalomalacia, ulegyria, status marmoratus, and cerebellar atrophy. Energy failure from hypoxia stems from loss of mitochondrial function, which can be confirmed by measuring increased lactic acid levels in the CSF or by magnetic resonance spectroscopy (MRS). There is accompanying membrane depolarization and an increase in neurotransmitter release, as well as excessive activation of glutamate receptors. Resultant is excitotoxic cellular injury, leading to an increase in intracellular calcium that leads to a cascade of pathologic pathways leading to secondary cell death. In addition, there is oxidative stress, which produces reactive oxygen species and subsequent reactive nitrogen radicals, also contributing to cell toxicity. After the anoxic insult, many cells undergo reoxygenation and reperfusion. Reperfusion contributes further to oxidative stress by producing more reactive oxygen species and further cellular injury.

CLINICAL MANIFESTATIONS

HIE initially presents with low Apgar scores, which translate into bradycardia, depressed respiration, diminished responsiveness, and decreased muscle tone ([Table 132.2](#)). One of three clinical patterns then evolves: (1) mild: awake, irritable, hyperalert, with jitteriness, dilated pupils, increased deep tendon reflexes, and normal muscle tone; (2) moderate: lethargy with depressed deep tendon reflexes, frequently with seizures; and (3) severe: apathy, with severe hypotonia, poorly reactive pupils, an absent Moro reflex, depression or coma, and seizures. There is usually clinical improvement with the mild and moderate cases as the newborns become more alert, improve their tone, and are able to feed. Seizures or therapy for seizures may delay recovery. Newborns with severe encephalopathy will usually become stuporous; develop frequent seizures, respiratory depression, or brain stem abnormalities; and may show signs of decerebration. They become unresponsive and lose sucking reflexes and the Moro response, and even with vigorous supportive and anticonvulsant therapy, 20% to 30% of these newborns die. If the neonate survives, seizures usually stop after 48 to 72 hours, and there is usually some recovery.

DIAGNOSIS

HIE should be distinguished from other causes of encephalopathy in the newborn period. Strict diagnostic criteria for HIE includes the presence of a sentinel obstetric event in the immediate prenatal or perinatal period, nonreassuring fetal heart rate tracing in the prenatal or perinatal period, fetal umbilical artery acidemia with a pH less than 7.0 and/or a base deficit greater than or equal to 12 mmol/L, Apgar scores of 0 to 3 for 5 minutes or longer, and imaging evidence of acute multifocal or diffuse cerebral injury. There may be multisystem organ failure consistent with HIE, such as renal, hepatic, or cardiac dysfunction; hematologic

abnormalities; metabolic derangements such as low serum glucose or sodium or elevated CSF lactate; and/or gastrointestinal injury. All of these criteria lie on a continuum, so, for example, more severe acidemia increases the likelihood of an intrapartum hypoxic injury.

TABLE 132.2 Apgar Scores

	Score of 0	Score of 1	Score of 2
Color	Blue or pale, entire body	Blue at extremities, body pink	No cyanosis
Heart rate	Absent	<100	>100
Reflex irritability	No response to stimulation	Feeble cry or grimace when stimulated	Cry or pull away when stimulated
Muscle tone	None	Some flexion	Flexed arms and legs
Respiratory effort	Absent	Weak, gasping, irregular	Strong, lusty cry

Adapted from Apgar V. A proposal for a new method of evaluation of the newborn infant. *Curr Res Anesth Analg.* 1953;32(4):260-267.

Certain patterns of brain injury seen in neuroimaging of late preterm or term infants are commonly seen in HIE, including parasagittal injury in an arterial watershed distribution and/or injury to the deep gray nuclei (Figs. 132.2 and 132.3). Neuroimaging, alternatively, may reveal another cause of encephalopathy, such as a developmental brain malformation or a focal area of infarction. Brain MRI is the most sensitive imaging modality for most lesions and usually yields the most useful information, although it requires transport, monitoring, and support. MRS, if available, can be useful for diagnosis of HIE if a lactate peak is seen. Head CT is useful for detecting intracranial hemorrhage and brain calcifications but is less sensitive for detecting mild brain edema or white matter injury, which is somewhat obscured because of the high water content of the newborn white matter. The posterior fossa is not adequately imaged with CT because of bony artifact. Cranial ultrasonography can be done at the bedside but is not very sensitive for detection of white matter abnormalities or lesions in the outer cerebral cortex.

Along with revealing seizure activity that may be inapparent clinically, EEG can be helpful to indicate the degree of HIE: Indications of severity include a burst-suppression pattern and/or a relatively inactive background. Amplitude-integrated EEG, although not as sensitive as standard EEG, may show low voltage in the setting of severe HIE and is able to detect some but not all seizure activity.

TREATMENT

Because multiple organ systems are involved in addition to the brain, management and therapeutic measures include maintenance of physiologic homeostasis, including providing adequate ventilation,

maintenance of perfusion and metabolism, avoidance of brain edema, and seizure control. Therapeutic hypothermia has been shown in multiple randomized controlled trials to lower mortality and major neurodevelopmental disability in term

P.1123

and late preterm infants with moderate or severe HIE [Level 1].¹ There are some adverse effects of hypothermia, including an increase in sinus bradycardia and in thrombocytopenia, but the benefits of cooling outweigh these short-term adverse effects. Questions still remaining are the optimal timing of the cooling after birth (research protocols have started cooling before 6 hours of age), the duration of cooling needed (most research protocols have cooled for 72 hours), the level of hypothermia required, and the method (selective head cooling vs. whole body cooling).

FIGURE 132.2 MRI of full-term infant with birth asphyxia (from ruptured uterus). **A:** Inversion recovery sequence shows increased intensity within thalami and basal ganglia. Diffusionweighted imaging (**B-D**) shows restricted diffusion in the ventrolateral thalami, lentiform nuclei, cerebral peduncles, and perirolandic cortex. (From de Vries LS, Groenendaal F. Patterns of neonatal hypoxic-ischaemic brain injury. *Neuroradiology*. 2010;52[6]:555-566.)

FIGURE 132.3 MRI of full-term infant born with severe anemia, showing watershed pattern of injury. **A:** T2-weighted sequence shows loss of cortical ribbon, with increased signal intensity in corpus callosum. **B:** Apparent diffusion coefficient (ADC) map shows decreased signal intensity in posterior watershed areas, splenium of corpus callosum, and optic radiation. (From de Vries LS, Groenendaal F. Patterns of neonatal hypoxic-ischaemic brain injury. *Neuroradiology*. 2010;52[6]:555-566.)

OUTCOME

Long-term prognosis of HIE remains a challenge for the neonatal neurologist, especially with the relatively recent introduction of therapeutic hypothermia. Most infants with mild HIE have a normal outcome. Children with severe HIE who survive the neonatal period usually have low cognitive ability and scholastic achievement, serious motor disability, and epilepsy. Children with moderate HIE form a heterogeneous group, depending on how the outcomes are measured and how the degree of encephalopathy is defined.

P.1124

NEONATAL SEIZURES

EPIDEMIOLOGY

Neonatal brains are particularly susceptible to seizures because of a relative abundance of excitatory neurotransmitters and the relative underdevelopment of inhibitory systems. Seizures occur in 1 to 3.8 per 1,000 newborns and are often an urgent clinical problem requiring prompt diagnosis and treatment.

PATHOBIOLOGY

The vast majority of neonatal seizures are due to specific etiologic causes rather than epileptic syndromes (Table 132.3). The most common causes are encephalopathy (often HIE) in term infants and IVH in premature babies. Other important causes include other hemorrhage (intracerebral, subdural, subarachnoid), infection (meningitis, encephalitis, or intrauterine), infarction, metabolic (hypoglycemia, hypocalcemia, hypomagnesemia),

chromosomal anomalies, cerebral malformations, neurodegenerative disorders, inborn errors of metabolism (nonketotic hyperglycinemia, urea cycle defects, phenylketonuria, maple sugar urine disease, lactic or organic acidurias), and maternal drug withdrawal or intoxication. Some seizures are responsive to vitamin treatment, including B 6, pyridoxal phosphate, and folinic acid. There has been a decrease in seizure frequency from transient metabolic causes or infection, most likely because of the advances in neonatal care over the past few decades.

There are three well-recognized neonatal epilepsy syndromes as classified by the International League Against Epilepsy: benign neonatal familial convulsions (BFNS), early myoclonic encephalopathy (EME), and early infantile epileptic encephalopathy (EIEE or Ohtahara syndrome). (The formerly recognized syndrome of benign idiopathic neonatal convulsions has been eliminated because of its diminished occurrence since the 1970s, when it was first described.) BFNS is a dominantly inherited condition, and diagnosis depends on a family history of neonatal seizures. There are two identified genes: *KCNQ2* and *KCNQ3*, which are voltage-gated potassium channel genes. EME and EIEE may be secondary to multiple etiologies, usually a severe metabolic cause for EME or a structural lesion for EIEE.

TABLE 132.3 Etiology of Neonatal Seizures

Cause	Examples
Encephalopathy	HIE
Hemorrhage	IVH, also intracerebral, subdural, subarachnoid
Infarction	Embolic stroke
Infection	Meningitis, encephalitis, intrauterine
Metabolic	Hypoglycemia, hypocalcemia, hypomagnesemia
Genetic	Chromosomal anomaly, neonatal epilepsy syndrome (EME, EIEE, BFNS)
Structural	Heterotopia or other migrational anomaly
Inborn error of metabolism	Nonketotic hyperglycinemia, urea cycle defect, maple syrup urine disease, lactic aciduria, organic aciduria
Maternal	Drug withdrawal, intoxication

Vitamin dependency

B₆, pyridoxal phosphate, folic acid

HIE, hypoxic-ischemic encephalopathy; IVH, intraventricular hemorrhage; EME, early myoclonic encephalopathy; EIEE, early infantile epileptic encephalopathy; BFNS, benign neonatal familial convulsions.

On a molecular level and cellular level, both animal models and human studies indicate that the developmental regulation of excitatory and inhibitory synaptic networks play a crucial role in the greater susceptibility of neonates to seizures. In particular, both AMPA and N-methyl-D-aspartate (NMDA) subtypes of glutamate receptors, which are excitatory, have high expression and are expressed with subunit composition enhancing excitability of neuronal networks in the period around birth in humans and in animal models. Additionally, the inhibitory class of γ -aminobutyric acid (GABA) receptors is underexpressed during this time period.

CLINICAL MANIFESTATIONS

Seizure semiology and EEG features of neonatal seizures differ from those of older children and adults. Consequently, classification schemes for seizures in older children and adults are not appropriate for neonates. Neonatal seizure classification schemes most often rely on dominant clinical features. Focal clonic, focal tonic, and some myoclonic seizures have associated ictal EEG discharges. Other paroxysmal movements, such as generalized tonic posturing, and motor automatisms (mouthing, pedaling, and rotatory arm movements) have unreliable or inconsistent EEG equivalents and may reflect etiologies other than seizures such as HIE. Generalized tonic-clonic seizures do not occur in newborns because of the immaturity of the cerebral white matter.

DIAGNOSIS

As with older patients with seizures, history is essential, especially details about the pregnancy, delivery, and family history. Head circumference, the presence of congenital anomalies, neurocutaneous markings, and organomegaly are all relevant findings. The neurologic exam should also note any abnormal posturing or unusual movements.

Laboratory evaluation should focus first on common metabolic or infectious disorders that are treatable—serum should be studied for levels of glucose, calcium, magnesium, sodium, and acid-base levels, as well as culture. CSF should be evaluated for meningitis and hemorrhage. EEG should be done promptly if there are abnormal movements or unexplained behavioral changes. Continuous EEG should be done if available, as there can be seizures without clinical manifestations. Ultrasound may identify hemorrhage and hydrocephalus. Amplitude-integrated EEG may be able to detect seizures, although localization is limited and some seizures may be missed. CT also shows hemorrhage and hydrocephalus and, in addition, demonstrates parenchymal calcifications and major cerebral malformations. MRI is usually necessary to detect more subtle developmental abnormalities, such as partial lissencephaly, polymicrogyria, or cortical dysplasia.

Timing of the first seizure may aid in the diagnosis. Seizures due to severe brain malformations, intracerebral hemorrhage, and hypoxic-ischemic injury occur within 24 to 48 hours. Seizures caused by infection and inborn errors of metabolism typically begin later in the first week of life. Seizures due to drug withdrawal usually occur in the first 3 days (e.g., alcohol or short-acting barbiturates) but may not appear for 2 to 3 weeks (e.g., methadone).

TABLE 132.4 Treatments for Metabolic Causes of Seizures

Cause	Treatment	Maintenance
Hypoglycemia	10% glucose IV 2 mL/kg	8 mg/kg/min
Hypocalcemia	10% calcium gluconate (100 mg/kg or 1 mL/kg IV) infused over 5-10 min, checking HR and infusion site, repeated in 10 min if no response <i>OR</i> Calcium chloride (20 mg/kg or 0.2 mL/kg)	Add calcium gluconate to IV solution.
Hypomagnesemia (may be associated with hypocalcemia)	50% solution IM 0.25 mL/kg or 125 mg/kg, repeat every 12 h until normalized	
Pyridoxine-responsive seizures	Pyridoxine 100 mg IV or pyridoxal phosphate 30 mg/kg/day divided t.i.d.	Pyridoxine 15-18 mg/kg/day and folic acid 3-5 mg/kg/day
Pyridoxal phosphate-responsive seizures	Pyridoxal phosphate 30 mg/kg/day divided t.i.d. or q.i.d. for 3-5 days and folic acid 3-5 mg/kg/day	Pyridoxal phosphate 30 mg/kg/day divided q.i.d.

IV, intravenous; HR, heart rate; IM, intramuscular.

Seizures must be distinguished from other paroxysmal phenomena that occur in newborns, including jitteriness, which can be triggered or stopped by manipulation of a limb, benign sleep myoclonus, dyskinesias (e.g., seen commonly with severe bronchopulmonary dysplasia), and the movements that occur during rapid eye movement (REM) sleep. Brief, generalized, tonic postures that occur with poor cerebral perfusion or with resolving encephalopathies are usually not epileptic seizures, and they respond poorly or not at all to antiepileptic drugs.

TREATMENT

Etiology of seizures is a crucial determinant for choosing an appropriate treatment protocol. If there is a metabolic or infectious cause, for example, there may be specific therapies to address the seizures. Treatment of metabolic causes of neonatal seizures is presented in [Table 132.4](#).

TABLE 132.5 Treatment of Acute Symptomatic Neonatal Seizures

Medication	Dosage	Notes
Phenobarbital	Load: 20 mg/kg IV, repeated once as needed. Daily dosing: 5 mg/kg/day (target serum level 40-60 µg/mL)	Side effects: respiratory depression, depressed level of consciousness, hypotension, hypotonia, hepatotoxicity, blood dyscrasia, skin rash
Fosphenytoin (and phenytoin)	Load: 20 mg/kg IV. Daily dosing 5 mg/kg/day (target level 10-20 µg/mL)	Cardiovascular, CNS, cutaneous side effects, which are less often seen with fosphenytoin compared with phenytoin. Variability in pharmacokinetics may result in inconsistent serum levels.
Levetiracetam	Load: 40-60 mg/kg IV. Daily dosing 30 mg/kg/day	Optimal dosing regimen not known
Lorazepam	Load: 0.05-0.1 mg/kg IV	Side effects: respiratory depression, depressed consciousness, hypotension
Midazolam	Load: 0.2 mg/kg IV, then continuous infusion (1 µg/kg/min), increasing by 0.5-1 µg/kg/min every 2 min to 2-5 µg/kg/min	Side effects: respiratory depression, depressed consciousness, hypotension
Lidocaine	Load: 2 mg/kg over 10 min, then continuous infusion 6 mg/kg/h during first 12 h, then 4 mg/kg/h for next 4 h, then 2 mg/kg/h. Lower doses when infant is being treated with therapeutic hypothermia.	Side effect: arrhythmia. Should only be given in ICU setting with continuous cardiac monitoring. Avoid concurrent treatment with proarrhythmic drugs such as phenytoin. Avoid in patient with congenital heart disease.

IV, intravenous; CNS, central nervous system; ICU, intensive care unit.

Adapted from Glass HC. Neonatal seizures: advances in mechanisms and management. *Clin Perinatol.* 2014;41(1):177-190.

First-line anticonvulsant therapy for seizures in most nurseries is phenobarbital, and other agents are fosphenytoin (preferred over phenytoin because of fewer cardiac side effects) and benzodiazepines such as lorazepam and midazolam. There are some initial indications of the use of other agents such as levetiracetam, lidocaine, topiramate, and bumetanide. Recommendations are to start with one anticonvulsant and increase levels to maximum tolerance if needed, before starting with another anticonvulsant. Treatment of acute symptomatic neonatal seizures is presented in [Table 132.5](#).

Goals of treatment remain an open question for certain clinical scenarios. Certainly, electroclinical seizures should be treated

as long as there are no compromises in respiratory or circulatory function. Subclinical seizures may result in long-term behavioral or cognitive effects.

OUTCOME

Prognosis usually depends on etiology, and, as discussed earlier, it is essential to address and remedy the underlying cause of the seizures if possible. HIE, severe IVH, and cerebral malformations are particularly associated with poor outcomes. An interictal EEG showing a suppression-burst pattern, a low-voltage background, and/or continuous multifocal epileptiform discharges frequently correlates with disabling brain damage.

Approximately 15% to 30% of neonates with seizures will develop epilepsy. There has been a decrease in overall mortality during the past few decades from neonatal seizures, from approximately 40% to 20%, although the prevalence of long-term neurodevelopmental sequelae has been unchanged at approximately 30%, perhaps because sicker infants are surviving the acute illness but then developing chronic manifestations. There is also some question about whether seizures directly cause brain injury, in particular when there is already an underlying defect in energy metabolism such as in HIE.

STROKE AND SINUS VENOUS THROMBOSIS

EPIDEMIOLOGY

Acute symptomatic perinatal stroke can be classified into three clinical groups (with incidence): arterial-ischemic stroke (70%), sinus venous thrombosis (20%), and hemorrhagic stroke (10%). The incidence is approximately 10-fold higher than in childhood stroke in general. In retrospective studies, the prevalence of perinatal ischemic stroke has been found to be approximately 1 per 3,500, but this prevalence is undoubtedly an underestimate because it is based in part on database searches, which may not account for all cases.

PATHOBIOLOGY

Pathophysiologic mechanisms leading to neonatal ischemic stroke include embolism, arteriopathy, or thrombosis. Most commonly, there is an infarction in the distribution of the middle cerebral artery (MCA), usually on the left. Neonates are at particular risk for thromboembolism because of multiple factors, including placental pathology or the normal thrombosis of placental vessels seen at birth; right-to-left shunts that may result from a patent foramen ovale or another congenital heart lesion; or indwelling umbilical vessel catheters, commonly used in neonatal intensive care units. Prothrombotic states, either from a systemic condition such as infection or from an inherited coagulation disorder may also play a contributory role.

Sinus venous thrombosis may also result from placental conditions resulting in a prothrombotic state or from a prothrombotic disorder. Most occur in the superior sagittal or transverse sinus, and there is frequently infarction, which may be hemorrhagic.

CLINICAL MANIFESTATIONS

In arterial ischemic stroke, seizures are frequently seen, with contralateral focal seizures if there is unilateral cerebral infarction. There may also be hemiparesis, which may appear as a subtle asymmetry of spontaneous movements. There may be a normal neonatal course, however, with hemiparesis presenting only after many months. Sinus venous thrombosis usually presents with seizures and/or alteration of consciousness.

DIAGNOSIS

CT or, preferably, MRI/magnetic resonance angiography (MRA) will show complete or branch infarcts, usually in the MCA distribution. An infarct may be detected early with diffusion-weighted imaging. MRA can also be helpful if there are congenital vascular anomalies or carotid artery dissection. In sinus venous thrombosis, MRI/magnetic resonance venography (MRV) or CT may show the “empty delta” sign and/or associated stroke or hemorrhage (Fig. 132.4).

If the infant presents with seizures, a thorough evaluation for systemic causes, such as infection, inborn errors of metabolism, or toxicity should be performed. EEG may show focal attenuation, slowing, and/or epileptiform discharges. An echocardiogram should be done to evaluate for a congenital anomaly or a thrombus.

Hypercoagulability should be evaluated in the setting of ischemic stroke (Table 132.6). The workup includes maternal studies for lupus anticoagulant, anticardiolipin antibody, and antinuclear antibodies. The placenta should be examined for infarcts or clots. Protein S, protein C, and antithrombin III are usually tested at 3 to 4 months of age because newborns normally have low values of these proteins. Genetic analysis can be performed for factor V

P.1127

Leiden and prothrombin G20210A mutations. Homocystinuria, if not part of regular newborn screening, can be assessed with the maternal homocysteine concentration or methylene tetrahydrofolate reductase mutations.

FIGURE 132.4 Sagittal venous sinus thrombosis in a near-term neonate, as shown by head computed tomography. “Empty delta sign” of the torcular herophili and associated posterior fossa hemorrhage, ventriculomegaly. (From Fumagalli M, Ramenghi LA, Mosca F. Palpebral ecchymosis and cerebral venous thrombosis in a near term infant. *Arch Dis Child Fetal Neonatal Ed.* 2004;89:F530.)

TABLE 132.6 Hypercoagulability Workup for Ischemic Stroke

Test	Comment
Lupus anticoagulant	
Anticardiolipin antibody	
Antinuclear antibodies	

Protein S, protein C, antithrombin III	Examine at age 3-4 mo.
Factor V Leiden	
Prothrombin G20210A	
Homocystinuria	Test for maternal homocysteine concentration or methylene tetrahydrofolate reductase mutations.
Placenta	Examine for infarct or clot.

TREATMENT

Supportive care for stroke includes maintenance of adequate oxygenation; treatment of acidosis, electrolyte disturbances, dehydration, and anemia; and antibiotic or anticonvulsant treatment if needed. For arterial ischemic stroke, treatment with anticoagulants or antiplatelet agents is restricted to patients with a documented cardioembolic source or recurrent arterial ischemic stroke or patients who are at risk for recurrent stroke because of severe thrombophilic disorders.

Historically, there has been some controversy regarding anticoagulation therapy for sinus venous thrombosis, although there is now growing evidence supporting its safety, and there is some evidence that treatment reduces the occurrence of clot propagation. Current recommended guidelines suggest anticoagulation for 6 weeks if there is no significant intracerebral hemorrhage, to continue for 6 more weeks unless there is complete recanalization, and to consider anticoagulation in the setting of significant hemorrhage, beginning anticoagulation if there is thrombus propagation at 5 to 7 days.

OUTCOME

Long-term prognosis for ischemic stroke depends on the location and extent of the ischemic injury. Hemiparesis occurs in 25% to 30% of infants with unilateral infarction and is more often seen when there is infarction of the entire MCA territory. Milder neuromotor dysfunction occurs in another 30% with unilateral damage. Epilepsy occurs in 10% to 30% of patients with acute perinatal stroke. Cognitive impairment occurs in 20% to 25% of patients with unilateral infarction, with a worse risk if there is bilateral infarction or a large injury. The involvement of deep gray nuclei worsens cognitive outcome.

Outcome of sinus venous thrombosis varies. Most neonates (80% to 97%) survive the immediate neonatal period. Motor deficit occurs in approximately 60% of survivors, with cognitive impairment in approximately 25% to 50% and epilepsy in 20% to 40%.

PERIVENTRICULAR LEUKOMALACIA

EPIDEMIOLOGY

PVL is a focal injury, usually from infection or ischemia, to the cerebral white matter, in the periventricular region,

occasionally with more diffuse injury. It is more commonly seen in premature infants, especially in infants younger than 32 weeks' gestational age, although it can be seen in term infants as well. Prevalence based on ultrasound diagnosis ranges from 5% to 15% of very low birth weight infants, but the prevalence is higher when MRI, which is a more sensitive imaging modality, is used.

PATHOBIOLOGY
