The cerebral white matter of premature neonates is particularly vulnerable to injury because of a number of factors: (1) diminished vascularization and subsequent reduced blood flow in the periventricular area; (2) inadequate cerebral vascular autoregulation (with reduced cerebral perfusion in the setting of hypotension); and (3) the susceptibility of preoligodendrocytes (the predominant cell in white matter at early gestational ages and the precursor to normal myelin-producing cells) to injury and cell death from glutamate toxicity, which stems from hypoxia. Maternal infection, which is a risk factor for premature birth itself and lead to umbilical cord funisitis, or neonatal sepsis, is associated with PVL because of cytokines such as interleukin-1 beta, interleukin-6, and tumor necrosis factor- α producing free radicals which then activate astrocytes and microglia, which in turn release reactive oxygen species, toxic to the susceptible preoligodendrocytes.

CLINICAL MANIFESTATIONS

Hypomyelination is seen in periventricular fibers descending from the frontal lobes to the peripheral neurons in the legs. Consequently, the classical presentation is spastic diplegia and cerebral palsy, which may not be present in the newborn period. The involvement of the visual radiations in the posterior white matter can result in visual impairment. There may also be ex vacuo ventriculomegaly, with associated decreased gray matter volume, which may cause behavioral abnormalities and subnormal IQ scores.

DIAGNOSIS

Ultrasonography typically reveals echodensities adjacent to the lateral ventricles, throughout the periventricular region, and usually evolve over time, with potential development of echolucent cysts within weeks and then ventriculomegaly over months. More sensitive is MRI, which can detect more subtle diffuse white matter injuries or noncystic lesions. Diffusion-weighted imaging may allow for earlier detection of PVL or white matter injuries.

TREATMENT

Infants with PVL need to be closely monitored for development of neurologic sequelae, with the appropriate therapy provided for spasticity, cognitive, and visual complications.

OUTCOME

Infants with more extensive injury and ventriculomegaly are more likely to experience more severe motor and cognitive difficulties. Cyst formation is more likely to result in cerebral palsy. White matter injuries are a risk factor for cortical abnormalities and reduction in gray matter volume.

Nervous System Formation and Malformation

Gary D. Clark

INTRODUCTION

Induced by underlying mesodermal structures, such as the notochord, and inhibited by surrounding ectodermal tissue, the nervous system begins as a thickened layer of poorly differentiated cells in the developing ectoderm of a 14-day human embryo. By 21 days, ridge-like structures have formed in the lateral most aspects of the neuroectoderm and begin to appose and to close in multiple closure sites, with the first in the cervical region. This forms a tube-like structure termed the *neural tube*, and this closure is normally complete by 26 days before most women know that they are pregnant. Errors in this process lead to myelomeningoceles (L5 and more rostral) and encephaloceles.

At the most caudal end of this tube is a mixed cell mass of ectoderm and mesoderm termed the *caudal cell mass*, which is induced by the presence of the neural tube to form the sacrum, the filum terminale, the conus medullaris, and the cauda equina. Errors in these processes lead to tethered spinal cords, caudal regression, fatty filum terminale, sacral pits and tracks, and other sacral defects.

The neural crest cells form from the extreme lateral aspects of the neuroectoderm and give rise to many of the sensory ganglia of cranial and spinal nerves in addition to the sympathetic chain and other structures.

Once the neural tube is completely formed, patterning or segmentation of this tube leads to the beginning of the well-described vesicles of the developing nervous system (prosencephalon, mesencephalon, and rhombencephalon). The prosencephalon divides in the midline to two telencephalic vesicles that will become the cerebral hemispheres. Precursors lining the ventricles of the developing nervous systems become postmitotic and migrate radially to populate developing structures such as the cortex. Axons sprout and cross the midline to form the corpus callosum and thereby connect the two developing hemispheres. Neurons extend axons to connect in a very deliberate and use-dependent fashion to the appropriate targets. This is basic nervous system development. To understand nervous system malformations, some additional genetic, molecular, and basic neurobiology insight is needed.

This chapter will summarize normal and abnormal human central nervous system (CNS) formation and describe the genetic aberrations that cause congenital malformations of the CNS. Much of human CNS development is inferred from animal studies and from abnormal developmental processes. Without being exhaustive, the proteins believed to be involved in the individual components of CNS development and those involved in pathologic alterations of normal development will be listed. The functions of some of the genes responsible for abnormal development can be surmised by examining the pathologic consequences. Hence, one is able to correlate genetic abnormalities with developmental neuropathology. Other genes and molecules involved in abnormal human CNS formation have well-studied counterparts in animals that provide insight into their function in humans.

The study of the genetics of human development is rapidly changing, and important new genetic mechanisms are being described often. Although the information regarding human genes involved in normal and abnormal brain formation was as up-to-date as possible at the time that this chapter was written, important new insights into the genetics of human CNS development have likely been made since this was written. Therefore, please visit Online Mendelian Inheritance in Man (OMIM) for more current information (<http://www.ncbi.nlm.nih.gov/omim>). As is the convention for the time that this chapter is written, terms such as *pathogenic variant* for those previously

termed *mutation* will be used herein.

Emphasis is placed on important information for the clinician in this chapter, but there is plenty of knowledge of human nervous system development that could be covered herein. However, the space limitations and lack of current applicability to clinical neurology limit the amount of information that can be communicated here. Instead, the covered pathologic entities are presented in the context of the developmental processes that are believed to have gone awry, disorders previously categorized as migration abnormalities might, on the basis of new genetic insights, be found in the discussion of cellular differentiation or segmentation for example. As further insights are made into human brain developmental disorders leading to neurologic disorders, the following categorization scheme will probably have to be altered.

FORMATION OF NEUROECTODERM

The human brain is formed from the *neuroectoderm*, a placode of cells that are induced by the underlying notochord to differentiate from the ectoderm beginning at 14 days of gestation. The nature of the inducible factor(s) (actually inhibiting factors—bone morphogenic protein 4) involved in this process remain largely unknown. The molecular action of these molecules probably is similar to that of the retinoids that likely bind to a nuclear receptor to promote or suppress specific genes (Fig. 133.1).

NEURAL TUBE CLOSURE

PRIMARY NEURULATION

The neuroectoderm placode develops ridges (folds) laterally and begins to approximate in the region of the future medulla at 22 days of gestation before most women are aware they are pregnant. This closure, a process known as *neurulation*, results in a tube that continues to extend by the process of approximation of the neural folds in multiple locations rostrally and caudally until a complete neural tube is formed at 28 days of gestation, with the latter period marking the end of caudal neural tube closure (future spinal cord). The rostral neural tube, which closes at approximately 24 days of gestation, serves as the foundation for further brain development; the caudal end of the tube forms the spinal cord.

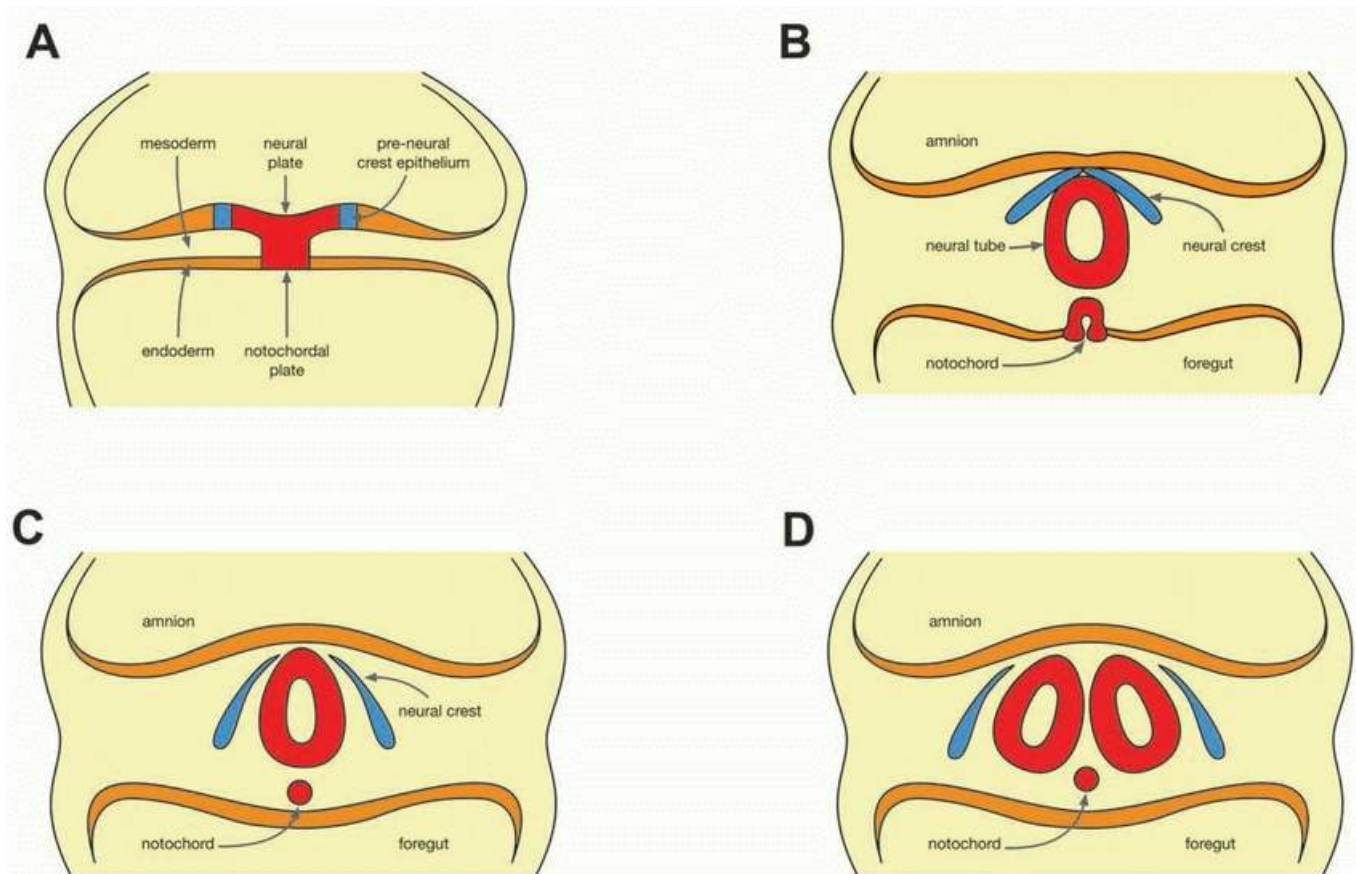

FIGURE 133.1 **A:** Notochord plate induces the neuroepithelium to differentiate from surrounding ectoderm. At the periphery of the neuroepithelium, neural crest forms. **B:** Neural tube closes. **C and D:** Rostral neural tube is induced by ventral notochord (Sonic Hedgehog and other factors) to split into two telencephalic vesicles that will become the cerebral hemispheres. (Drawings by Nathan Licy, <http://www.nathanlucy.com/>.)

Although the specific molecules and genes involved in the processes of neural tube closure in humans are largely unknown, clearly a combination of genetic and environmental factors leads to disorders of these processes. Studies in mice suggest that a codeletion of *Pax1*, a gene for a *transcriptional factor* that mediates notochord signaling, and *Pdgfra*, the platelet-derived growth factor alpha gene, may lead to a spina bifida-like phenotype.

Certain ethnic groups experience a higher incidence of neural tube closure defects than do others, and genetic disorders with an apparent autosomal recessive inheritance that include neural tube defects have been described. In addition, teratogens are involved in neural tube pathology. The most notable teratogens for the neurologist are the anticonvulsants valproate and carbamazepine, each of which imposes a risk of 1% to 6% for a neural tube defect in offspring exposed in utero to these common drugs. Whereas folate supplementation appears to prevent neural tube defects in large population studies, this vitamin may or may not be protective when these disorders are associated with the aforementioned anticonvulsants. Given that short-term treatment with folate is probably benign, it seems prudent to offer this vitamin (400 to 4,000 μg daily, depending on risk factors) to women of childbearing age who are on anticonvulsants.

SPECIFIC NEURAL TUBE DEFECTS

In humans, multiple genes and factors probably are involved in the pathogenesis of disorders of neural tube formation and closure. The human disorders of neural tube closure include craniorachischisis (a complete failure of neural tube closure along the entire neuraxis), anencephaly (a failure of anterior neural tube closure), myeloschisis (a failure of posterior neural tube closure), spina bifida (myelomeningocele, a failure of closure of a portion of posterior neural tube), and encephalocele (a partial defect in anterior neural tube closure). Fetal

recognition of myelomeningocele with correction in utero prior to 26 weeks' gestation can dramatically alter the need for subsequent ventriculoperitoneal shunting (reduced by 42%) and reduces the incidence of intellectual disability. The risk is to the mother.

Encephaloceles

Encephaloceles (brain substance outside of the skull) and meningoceles (meninges and cerebrospinal fluid [CSF] only) vary in location, in the amount of brain involved, and therefore in the clinical manifestations of the lesions. In most cases, the neural tube is closed, and the gyral pattern of the protruding brain appears normal. In the western hemisphere, most encephaloceles are occipital

P.1132

and midline. In the eastern hemisphere, anterior encephaloceles (nasal and frontal) surpasses that of posterior lesions. One should avoid nasogastric tube placement in the situation of a nasal mass in a newborn owing to the possibility of a nasal encephalocele; it is possible in this situation to place the tube in the brain substance.

Meckel Syndrome

Meckel syndrome, a genetic disorder that involves an occipital encephalocele, cerebellar malformations (molar tooth anomaly— see discussion in Joubert syndrome), microcephaly, renal dysplasia (polycystic kidneys), polydactyly, retinal dystrophy, and other malformations, appears to be caused by pathogenic variants in genes involved in ciliary function. Meckel syndrome is allelic with Joubert syndrome and the same genetic aberrations are present in both disorders. Most of these disorders are inherited in an autosomal recessive fashion, although some are inherited in a dominant fashion and others X-linked dominant or recessive. The genes involved are part of a ciliary complex that determines cell polarity and are important for the migration of early neurons in the posterior fossa.

EMBRYONIC NERVOUS SYSTEM SEGMENTATION

Flexures of the rostral neural tube delineate the primary vesicles of the developing nervous system; these are designated as the hindbrain (rhombencephalon), the midbrain (mesencephalon), and the forebrain (prosencephalon). These primary vesicles then further subdivide into the secondary vesicles that later will form the adult brain structures. The hindbrain consists of the metencephalon and myelencephalon; these structures will become the pons, the cerebellum, and the medulla oblongata of the adult. Rostrally, the mesencephalon will become the midbrain of the adult. The forebrain is further divided into the telencephalon and the diencephalon. The telencephalon will become the cerebral hemispheres, and the diencephalon will become the thalamus and hypothalamus of the adult.

TRANSCRIPTIONAL FACTORS AND HOMEBOX GENES

Regional specification of the developing nervous system is an important step in human CNS development and is likely under the control of a number of genes that encode transcriptional factors and of a number of molecules that influence these genes. These genes were first described in *Drosophila* and are involved in the regional specification of the fly embryo. Not surprisingly, the function of the proteins encoded by the comparable genes in mammals differs considerably from that in fruit flies, but the general role of these proteins appears to be that of regional specification of clones of cells destined to form structures in the fully developed nervous system.

Transcriptional factors are proteins with distinct sequences that participate in DNA binding and thus influence DNA. In *Drosophila*, transcriptional factors encoding homeobox genes, empty spiracles, *ems* have been shown to specify head structures. For example, the rudimentary structures of mutant flies that are devoid of *ems* seem to be a result of failure of regional specification of a clone of cells that are destined to form those structures. In humans, pathogenic variants in the comparable gene *EMX2* may result in schizencephaly, cleft in the cortical

mantle. The clefts in this disorder extend from the pia to the ventricle and are lined with a polymicrogyric gray matter (see the discussion in “Polymicrogyria”). The pia and ependyma are usually in apposition, especially in severe cases. The defect is termed *open lipped* if the cleft walls are separated by CSF and *closed lipped* if the walls appose. These clefts may be unilateral or bilateral and the prognosis appears to be dependent on location, bilateral occurrence, or extent of the lesion. Bilateral schizencephaly is associated with mental retardation and spastic cerebral palsy; affected patients often are microcephalic. Seizures almost always accompany severe lesions, especially the openlipped and bilateral schizencephalic clefts. The exact frequency of seizures in patients with the less severe lesions is uncertain, nor is the incidence of asymptomatic schizencephaly. Most patients in whom schizencephaly is diagnosed undergo neuroimaging because of seizure. Therefore, a bias in favor of a universal occurrence of seizure in this disorder is noted. Hence, patients with schizencephaly who do not have epilepsy might exist, but the malformation remains undetected because no imaging is done. With fetal imaging, asymptomatic schizencephaly has been noted (Fig. 133.2).

Seizure type and onset may vary in this disorder. Patients may experience focal or generalized seizures. Some will present with infantile spasms. The onset varies from infancy to the early adult years. Seizures may be easily controlled or may be recalcitrant to standard anticonvulsant therapy.

Improvements in neuroimaging have enhanced the recognition of these disorders and have broadened the spectrum of the radiographic appearance of schizencephalic lesions. The lesions may occur in isolation or may be associated with other anomalies of brain development. An especially common association is made between septo-optic dysplasia and schizencephaly because as many as 50% of patients with septo-optic dysplasia also have schizencephaly.

Other genes for transcriptional factors have been described in the mouse. *Pax3*, *Pax5*, *Pax6*, *Dlx1*, *Dlx2*, *Dbx*, and the *Hox* genes are found in specific brain regions. In general, the *Pax* genes tend to be expressed in midbrain and the *Dlx* genes tend to be expressed in the ventral forebrain, ventral telencephalon, and dorsal telencephalon; *Dlx2* is important for the genesis of GABAergic interneurons from the median ganglionic eminence. The *Hox* genes seem to specify the neuromeres and rhombomeres of the hindbrain.

FIGURE 133.2 Segmentation or patterning defect—schizencephalic cleft in a developing fetus at 21 weeks' gestation. *Arrow* points to the cleft in the developing cortex.

P.1133

Furthermore, in an interesting link to the ventral inductive events described later, when applied to proliferating cells at critical times in development, the protein sonic hedgehog can alter the expression of the homeobox genes. This ties the inductive proteins to the expression of homeobox genes and gives a hint as to the mechanisms involved in inductive processes. Further, a gradient of retinoic acid in a rostral (less) to caudal (more) fashion seems to be important for *Hox* and other patterning gene expression patterns in the hindbrain, neck, and other structures of the head. Retinoic acid activity also decreases the sonic hedgehog signaling (see “[Ventral Induction \[Prosencephalon Cleavage\]](#)”). It is for this reason that retinoids are highly regulated and should not be given to women who may become pregnant.

SEPTO-OPTIC DYSPLASIA

Septo-optic dysplasia (de Morsier syndrome) is a disorder characterized by absence of the septum pellucidum, optic nerve hypoplasia, agenesis of the corpus callosum, and hypothalamic dysfunction. This disorder should be considered in any patient who exhibits at least two of these, and all such patients should have hypothalamic function screening. Fifty percent of patients with septo-optic dysplasia have schizencephaly. Although this is a rare disorder, genetic syndromes with this phenotype and with some risk of recurrence have been described. For instance, pathogenic variants in homeobox gene expressed in ES cells, *HESX1*, have caused a dominantly inherited disorder in siblings. This disorder can be suspected in utero but magnetic resonance imaging (MRI) of the fetus may be necessary to assure a proper diagnosis. The prognosis for development is highly variable, with learning, intellectual, and motor impairments often described. Asymptomatic patients probably only come to

medical attention if there are needs for neuroimaging. Pathogenic variants in *COL11A2* and *PAX6* have also been described. Because most of the genes related to this phenotype are undiscovered and no genetic panels exist, it is recommended that clinicians consider exome sequencing in order to delineate the recurrence risk in a family.

VENTRAL INDUCTION (PROSENCEPHALON CLEAVAGE)

NORMAL PROSENCEPHALON DIVISION

The telencephalon is formed by medial division of a rostral single tube-like structure (prosencephalon); the two vesicles (telencephalon) formed in this division become the two cerebral hemispheres. The ventral and anterior portion of this division is induced by midline facial structures and the notochord via soluble factors. Abnormalities of this induction and division lead to midline abnormalities of the brain such as holoprosencephaly. These disruptions of normal development occur before 42 days of gestation.

FIGURE 133.3 Failure of telencephalic cleavage— holoprosencephaly in a fetus at 32 weeks' gestation. Note the single ventricle with no division of the cerebrum into hemispheres on a coronal view (**left panel**). On a sagittal view (**right panel**), a dorsal cyst is noted that is typical for the alobar holoprosencephaly.

Sonic hedgehog, which was described first in *Drosophila* as a soluble factor (protein) that influences dorsoventral patterning of the developing embryo, is probably the most important of the soluble factors influencing ventral induction. Sonic hedgehog is expressed in the notochord (also in ventral forebrain and floor plate— future facial structures), interacts through a well-defined signaling pathway that includes *PTCH*, a human homolog of *patched*, and alters the expression of transcriptional factors (homeobox and other related gene products).

Other molecules of interest in this inductive process are the retinoids (discussed previously in segmentation), which are lipids capable of crossing membranes and have been shown to exist in gradients across embryos. Retinoic acid can alter the pattern of transcriptional factors in neuroepithelial cells, and it can also downregulate sonic hedgehog, perhaps explaining some of the midfacial defects and holoprosencephaly seen in retinoid embryopathy. Also, cholesterol and cholesterol-derived lipids serve as a cofactor for sonic hedgehog, thus

perhaps explaining telencephalic cleavage issues (holoprosencephaly) in Smith-Lemli-Opitz syndrome (7-dehydrocholesterol reductase deficiency).

DISORDERS OF VENTRAL INDUCTION: HOLOPROSENCEPHALY

The holoprosencephaly syndromes are heterogeneous disorders of ventral induction and telencephalic cleavage that result from a failure of the prosencephalic vesicle to medially cleave normally. At least three forms of this disorder have been described: alobar, semilobar, and lobar. In the alobar form, the telencephalic vesicle completely fails to divide, producing a single horseshoeshaped ventricle, sometimes with a dorsal cyst, fused thalami, and a malformed cortex (Fig. 133.3). In the semilobar form, the interhemispheric fissure is present posteriorly, but the frontal and, sometimes, parietal lobes continue across the midline. In the lobar form, only minor changes may be seen: The anterior falx is absent, the frontal lobes and horns are hypoplastic, there may be partial fusion of the thalami, and the genu of the corpus callosum may be abnormal. Holoprosencephaly is a common human malformation leading to spontaneous abortion.

P.1134

Because sonic hedgehog and patched are expressed in the developing face, it is not surprising that holoprosencephaly is associated with a spectrum of midline facial defects. These include cyclopia, in which there is a single central eye and a supraorbital proboscis; ethmocephali, in which the nose is replaced by a proboscis located above the hypoteloric eyes; cebocephaly, in which hypotelorism and a nose with a single nostril are seen; and premaxillary agenesis, with hypotelorism, a flat nose, a single frontal incisor, and a midline cleft lip.

Only children who have the semilobar and lobar forms are known to survive for more than a few months. An infant affected with the severe form is microcephalic (unless aqueduct stenosis and hydrocephalus are present), hypotonic, and visually inattentive. In infants with the less severe forms of holoprosencephaly, myoclonic seizures frequently develop and, if the infant survives, autonomic dysfunction, failure to thrive, psychomotor retardation, and atonic or spastic cerebral palsy often are present. Some infants with the lobar form may be only mildly affected. Pituitary defects may be associated with these malformations and may result in neuroendocrine dysfunction.

Holoprosencephaly has been reported to be associated with maternal diabetes, retinoic acid exposure, cytomegalovirus, and rubella. Chromosomal abnormalities associated with this disorder include trisomies 13 and 18; duplications in 3p, 13q, and 18q; and deletions in 2p, 7q, 13q, and 18q. Autosomal dominant forms exist in which the pathogenic variant is in *sonic hedgehog* or in *ZIC2*. In this form, the clinical features vary. In their mildest form, presence of a single central incisor, attention deficit disorder, or a choroid fissure coloboma may be the only clinical manifestation of an autosomal dominant disorder.

NEURONAL AND GLIAL PROLIFERATION

NORMAL CELL PROLIFERATION

Lining the interior of the newly developed telencephalic vesicles is a proliferative, primitive neuroepithelium. Neuroepithelial processes extend from the ventricular surface to the pial surface, and the nuclei of the primitive neuroepithelial cells move from the cortical surface in a premitotic phase to a mitotic phase near the ventricle. Cells divide at the most ventricular aspects of the developing telencephalon and, after division, move back toward the pial surface. The pial processes of neuroepithelial cells near the ventricle often will detach from the cortical surface before a new cycle begins.

Neuroepithelial cells divide in so-called proliferative units such that each unit will undergo a specific number of divisions resulting in the appropriate number of cells for the future cortex. Abnormalities in the number of proliferative units or in the total number of divisions can lead to disorders of brain manifested by abnormal brain size and, therefore, an unusually small (microcephaly) or large head (macrocephaly). Disorders in which too

many cells are generated in the proliferative phase result in megalencephaly (large brain) or, if proliferative events go awry on only one side of the developing cortex, hemimegalencephaly. Once the appropriate complement of cells is generated in the proliferative phase, the cells that will become the neurons of the cerebral cortex become postmitotic and are referred to as *neuroblasts*. Others undergo a programmed cell death—apoptosis. The genetics of apoptosis are best characterized in the simple nematode *Caenorhabditis elegans*. Approximately 10% of the cells generated during development of this worm will undergo apoptotic or programmed cell death. Pathogenic variants leading to smaller or larger numbers of surviving cells result in smaller or larger nematodes, respectively. The molecular characterization of these pathogenic variants has led to identification of a number of “death” genes and of genes that prevent apoptosis. The mammalian counterparts of the nematode death genes encode enzymes that are cysteine aspartate-specific proteases, also known as *caspases*. At least one function of such enzymes is that of an interleukin-converting enzyme common in the inflammatory response of the body. These enzymes have been shown to promote neuronal death; in addition, when an animal is produced without caspase 3, a larger than normal brain results.

DISORDERS OF NEURONAL AND GLIAL PROLIFERATION

Microcephaly

Although primary familial microcephaly may be a normal variant, in the classic symptomatic form, clinical and radiologic examinations reveal a receding forehead, flat occiput, early closure of fontanelles, and hair anomalies such as multiple hair whorls and an anterior cowlick. Neuroimaging may show small frontal and occipital lobes, open opercula, and an uncovered cerebellum. The cortex may appear malformed (polymicrogyria, pachygyria, diminished white matter).

Neurologic findings also vary. Only mild psychomotor retardation may be noted, sometimes associated with pyramidal signs, or more severe intellectual disability, seizures, and an atonic cerebral palsy might be present. Primary microcephaly is seen in many genetic syndromes and, in its isolated form, may be autosomal recessive. Autosomal dominant and X-linked transmission has also been reported. *Microcephaly vera* is the term applied to this genetic form of microcephaly. Affected children present with a head circumference that is usually more than two standard deviations below the mean, hypotonia, and intellectual disability. They later show intellectual disability, dyspraxias, motor incoordination, and sometimes seizures.

Destructive lesions of the forming brain, such as those caused by teratogens and by infectious agents, also may result in microcephaly. Teratogens of note are alcohol, cocaine, and hyperphenylalaninemia (maternal phenylketonuria). Intense radiation exposure (such as in a nuclear explosion) in the first trimester can cause microcephaly. Microcephaly and intracranial calcifications are likely due to well-recognized in utero infections caused by cytomegalovirus, toxoplasmosis, or the HIV, among others.

Although now usually recognized in utero, patients with pathologic microcephaly or pathologic macrocephaly have been, in the past, identified by their pediatricians. Neuroimaging may reveal an etiology in such patients. Because multiple genetic or teratogenic etiologies must be considered, one must use neuroimaging as a clue to possible etiologies (presence of malformations, calcifications, etc.). The prognosis varies greatly and depends on the etiology. Familial microcephaly and familial macrocephaly with benign outcomes have been described.

Megalencephaly and Hemimegalencephaly

The terms *megalencephaly* and *hemimegalencephaly* refer to disorders in which the brain volume is greater than normal (not owing to the abnormal storage of material); usually, the enlarged brain is accompanied by macrocephaly or a large head. Although

considered by some to be a migration disorder, the increase in brain size in these disorders appears to be

attributable to errors in neuroepithelial proliferation, as the microscopic appearance of the brain is that of an increase in number of cells (both neurons and glia) and in cell size.

Typically, patients are noted to have large heads at birth and may manifest an accelerated head growth in the first few months of life. Children with megalencephaly or hemimegalencephaly may come to medical attention when presenting with seizures, a developmental disorder (intellectual disability), hemihypertrophy, or a hemiparesis (opposite the affected hemisphere). Seizures vary both in onset and in type and usually are the most problematic symptom, sometimes necessitating hemispherectomy or callosotomy.

Approximately 50% of patients with linear sebaceous nevus syndrome have hemimegalencephaly associated with *HRAS* or *KRAS* somatic-mosaic pathogenic variants. Many patients with hypomelanosis of Ito also have hemimegalencephaly. The neuropathologic and clinical pictures in these conditions appear to be identical to the isolated hemimegalencephalies. Interestingly, the genetic aberrations suggest an upregulation of the mammalian target of rapamycin (mTOR) pathway via a downregulation of phosphoinositol kinase 3 (PI3 kinase).

Microscopic examination of the affected brain usually reveals an increase in cellularity, large bizarre neurons, enlarged glia, cortical lamination defects, and heterotopias. The cortex usually is thickened, and malformed neurons are disturbed in polarity. Interestingly, the cytologic basis for the increase in brain size may be the abundant cytoplasm of individual cells.

NEURONAL DIFFERENTIATION

At the time of neuronal differentiation, the neural tube consists of four contiguous layers: (1) the ventricular zone, which gives rise to neurons and all the glia of the CNS; (2) the subventricular zone, which is the more superficial layer and is the staging area from which postmitotic neurons begin to differentiate and to migrate; (3) the intermediate zone, which is the contiguous, more superficial zone and which is destined to become the cortical plate and the future cerebral cortex; and (4) the marginal zone, which is the outermost zone and is composed of the cytoplasmic extensions of ventricular neuroblasts, corticopetal fibers, and the terminal processes of radial glia (which, at this time, are completely spanning the neural tube).

Differentiation of neuroepithelial cells begins in the subventricular layer at approximately gestational day 26. Neuroepithelial cells were destined to become neurons at the time of the final mitotic division of the neuroepithelial cell precursor before moving to the subventricular zone, the staging area for neuronal migration. At this point, these neuroblasts lack electrically polarized membranes as would commonly be seen in neurons. The fate of the neuroblast probably is determined before this final mitosis has occurred, as the postmitotic neuroblast has the properties of many neuron types. The older, larger pyramidal cells are the first cells to be born and probably differentiate early in order to act as targets or barriers in the migration of the nervous system.

No disorders of solely neuronal differentiation have yet been identified, although some disorders may be found to fit into this category. For instance, premature neuroblast differentiation could result in an inability of these cells to migrate and thus could be manifest as a migration abnormality. The megalencephaly and hemimegalencephaly syndromes may yet be found to be the results of disturbances in differentiation, as discussed earlier. Disorders such as tuberous sclerosis, in which both tumor development and areas of migration abnormalities are seen, seem to be a differentiation disorder due to upregulation of mTOR. The brain manifestations of this disorder include hamartomas of the subependymal layer (tubers), areas of cortical migration abnormalities (cortical dysgenesis), and the development of giant cell astrocytomas in upwards of 5% of patients. Two genes for tuberous sclerosis have been identified: *TSC1* (encodes for hamartin) has been localized to 9q34 and *TSC2* (encodes for tuberin) has been localized to 16p13.3. Both proteins suppress mTOR and when lost or dysfunctional lead to overactivation of this important protein in development. The frequency of gene abnormalities in tuberous sclerosis patients has been estimated to be almost equally distributed between *TSC1* and *TSC2*. Interestingly, recently type IIB cortical dysplasias were found to harbor human papilloma virus 16 and

its oncogenic protein E6, which exerts its effect by upregulating mTOR by, in part, depressing TSC2.

NEURONAL MIGRATION

NORMAL MIGRATION

At the most rostral end of the neural tube in the 40-day-old fetus, the first mature neuron arrives at the developing cortical surface. These first neurons are the *Cajal-Retzius cells*, which are the major neurons of the cortex by day 43. Cajal-Retzius cells, along with corticopetal nerve fibers, form a so-called preplate. These cells will be the major cell type of the most superficial layer of the cerebral cortex, layer I. At the same time that the Cajal-Retzius cells are arriving at the most superficial layer of cortex, other pioneering neurons differentiate and form a so-called subplate. The pioneering neurons of the subplate and the preplate act as the police officers of the developing nervous system and define the limits of the developing cortical plate, which will become the six-layered cortex of the adult brain. Most of the cells of the subplate will die postnatally in a programmed cell death (see earlier discussion of apoptosis).

Near the end of the proliferative phase of neurodevelopment, billions of postmitotic neurons are poised to begin the trip to the cortical surface and to form the cortical plate. This tremendous number of neurons accomplishes this task, for the most part, by attaching to and migrating along radial glia (radially spanning from ventricle to pial surface) in a process known as *radial migration* (Fig. 133.4). In the process of migration, the deepest layer of the cortical plate forms before the other layers. Therefore, the first neurons to arrive at the future cortical plate are layer VI neurons. More superficial layers of cortex then are formed such that the neurons of layer V migrate and pass the neurons of layer VI; the same process occurs for layers IV, III, and II. The cortex therefore is formed in an inside-out fashion (see Fig. 133.4).

The molecules and the interactions between neurons and glia are extremely important in this process of neuronal migration. Reelin, the protein involved in the migration mouse mutant, *reeler*, appears to be one such important molecule. Reelin appears to promote an attachment of neurons to glia and, when abnormal, as in the mouse mutant *reeler*, it leads to an inverted cortex such that the most superficial neurons are the first to arrive and the later-arriving neurons are deeper. This mouse mutant cortex appears to be due to an abnormally adhesive interaction between neurons and glia. Additional molecules that appear to act in an adhesive manner are laminin, astrotactin, L1 antigen, fibronectin, neural cell adhesion molecules (NCAM), and adhesion molecule on glia (AMOG).

FIGURE 133.4 Neuronal radial migration in cortical development—*upper left* depicts a single cortical vesicle stained for glia. Glia radially project from the ventricle to the cortical surface. The *right figure* depicts the apposition of the migrating neuron to a radial glial cell. Cells migrate past their predecessor to deposit in an inside out fashion.

Neuroblast movement on radial glia involves an extension of a leading process, a neural outgrowth having an orderly arrangement of microtubules. *Microtubules* are cytoskeletal elements with a polymerizing (positive) end and a depolymerizing (negative) end. They serve as the major structural element that gives shape to long neural processes. When microtubules depolymerize, or slide, long neural processes are shortened. Shortening of the leading process of migrating neurons has been associated with forward movement of the soma of migrating neurons *in vitro*. Cytoskeletal changes in leading processes have been purported to be responsible for this shortening and somal movement.

A possible mode of movement in neuronal migration on glia would be the attachment of the neuron to a matrix secreted by either the glia or the neurons. This matrix is likely to consist of the aforementioned adhesion molecules. The attachment of the neuron would be through *integrin* receptors, cytoskeletal-linking membrane-bound recognition sites for adhesion molecules. That attachment serves as a stronghold for the leading process

and soma of the migrating neuron. Shortening of the leading process owing to depolymerization or shifts of microtubules results in movement of the soma relative to the attachment points. This theory of movement of neurons also must include a phase of detachment from the matrix at certain integrin receptors so that the neuroblast can navigate successfully along as much as 6 cm of developing cortex (the maximum estimated distance of radial migration of a neuroblast in humans). Finally, the movement of cells must stop at the appropriate location, the boundary between layer I and the forming cortical plate. Therefore, some stop signal must be given in order for the migrating neuroblast to detach from the radial glia and begin to differentiate into a cortical neuron. This is obviously deficient in such disorders as cobblestone lissencephalies (discussed in the following section).

Other forms of neuronal migration occur in brain development. Some evidence exists for a tangential migration of neurons in the cortex and in the early granule cell migration in the cerebellum. A so-called chain migration of neurons on other neurons occurs in the formation of the olfactory bulbs. In this chain migration, neuroblasts from the subventricular zone of the lateral ventricle

P.1137

migrate to the olfactory bulb through a sheath of glial cells, but the actual migration occurs on other neurons.

CORTICAL NEURONAL MIGRATION DISORDERS

Many clinical entities are associated with neuronal migration disorders. In some, abnormalities are limited to the nervous system but, in others, malformations involving other organs also are present. The responsible genetic mechanism has been identified in some of these disorders, and new genetic mechanisms are being identified regularly. Although the role of the gene product in producing many of these migration disorders may not yet be entirely clear, the disorders provide important clues to mechanisms that are responsible for normal brain development.

Modern neuroimaging techniques, particularly MRI, have allowed the recognition of major migration disorders. Some of these disorders are associated with typical clinical features that might alert the clinician to the presence of such abnormalities even before imaging is obtained. In other disorders, the clinical features are so varied that a strong correlation between imaging and clinical presentation does not exist. High-field MRI and other research techniques may further refine the clinician's ability to refine diagnoses.

Lissencephaly

Although the term *lissencephaly* (smooth brain) refers to the external appearance of the cerebral cortex in those disorders in which a neuronal migration aberration leads to improper number of neurons at the surface of the cortex (Fig. 133.5), the most important observation in such cases is the thickened cortex with neurons in what should be white matter. In such deficits of migration, gyri and sulci do not form properly because the cortical-cortical attractive forces that result from strong associations are decreased, owing to improper axon pathways (i.e., the targets for synapses are malpositioned). It is important to note that the term *lissencephaly* is applied to cortical disorders in which there is a thickened cortex (migration deficit) and a cortical surface abnormality; rarely, there is a completely smooth brain. At least two types of lissencephaly have been identified: type I, or classic, lissencephaly and type II, or cobblestone, lissencephaly. This classification is based on both the external appearance of the brain and the underlying histology.

TYPE I (CLASSIC) LISSENCEPHALY

Type I lissencephaly most often accompanies the *Miller-Dieker syndrome*. In this disorder, an inadequate radial migration of neurons appears to have taken place. The cortex is described as being composed of a four-layered abnormal sequence consisting of an outer molecular layer (layer 1), which is similar to normal layer I; a disorganized cellular layer of neurons near the normal location for the outer cortex (layer 2) (cells that should be

in layers II to VI of the normal cortical plate); a cell-sparse zone (layer 3); and a heterotopic zone of neurons that have been arrested in neuronal migration (layer 4). The most extensive layer in this lissencephalic sequence is layer 4, the heterotopic zone. The neurons and cells of this zone have the appearance of cells that would normally be in layers II to IV of the normal cortical plate; however, these neurons are highly disorganized. Therefore, the later waves of neuronal migration that form the outer cortical plate appear to be those most affected by the migration abnormality in this disorder.

Hallmarks on imaging are a lack of opercularization (covering of the sylvian fissure), large ventricles with colpocephaly (fetallike configuration of the occipital horns), and agyria or pachygyria (see [Fig. 133.5](#)). The corpus callosum is almost never absent, and the posterior fossa has a normal appearance on neuroimaging (except in lissencephaly with ambiguous genitalia). Head size typically is in the low-normal range at birth, but most patients develop microcephaly owing to a decreased rate of brain growth over the first year of life. Nearly all patients with this disorder will develop seizures within this first year, and more than 80% of them will have infantile spasms. This seizure frequency is far greater than that seen in other neuronal migration disorders.

In the Miller-Dieker syndrome, facial dysmorphism, cardiac abnormalities (40%), sacral abnormalities (70%), deep palmar creases and, in male patients, genital abnormalities (70%) may be seen. The sacral abnormalities include deep sacral dimples, sacral pits, and sacral tracks. Facial abnormalities include upturned nares; a short nose; a thin, “pouty” upper lip; a long philtrum; micrognathia; and bitemporal hollowing. Although the bitemporal hollowing may be the result of the underlying brain abnormality, the other facial features would be difficult to explain on the basis of the brain abnormality alone. Therefore, these abnormalities are believed to result from deficits of genes near the lissencephaly gene on the 17th chromosome. Larger deletions of the distal short arm of chromosome 17 appear to result in the full Miller-Dieker phenotype, whereas microdeletions of just the lissencephaly gene *LIS1* result in isolated lissencephaly. Therefore, a deletion in the lissencephaly gene appears to be sufficient for the brain abnormalities, but other genes (14-3-3) must be deleted for the full phenotypic manifestations of the Miller-Dieker syndrome to be seen.

Miller-Dieker lissencephaly is one of the migration disorders of brain in which the responsible genetic defect has been identified. By both molecular and cytogenetic techniques, deletions in the terminal portion of one arm of chromosome 17 can be found in approximately 90% of Miller-Dieker lissencephaly cases. These patients typically have dysmorphic features and other congenital anomalies (see earlier discussion). The deletions of the terminal part of chromosome 17 in these cases have included microdeletions, ring 17 chromosome, pericentric inversions, and a partial monosomy of 17p13.3. These genetic abnormalities can be the result of an inherited unbalanced translocation from a parent with a balanced translocation involving this region of chromosome 17; multiple mechanisms of inheritance similar to this have been described for this disorder. Of course, a parent with a balanced translocation of chromosome 17p is at a greatly increased risk of having another child with Miller-Dieker lissencephaly. In families that are affected in this manner, screening with amniocentesis can be performed in subsequent pregnancies.

Current chromosomal microarray testing will detect deletions of *LIS1* and of the neighboring 14-3-3 gene, thus genetically distinguishing Miller-Dieker syndrome from isolated lissencephaly. Some patients with isolated lissencephaly (no facial, skeletal, or cardiac abnormalities) also have deletions (often submicroscopical) of the terminal portion of the short arm of chromosome 17. Therefore, some researchers suspected that within one deleted region of chromosome 17 was a gene that, when deleted, was sufficient to result in the lissencephaly phenotype. In 1993, the human gene for this form of lissencephaly was identified as *LIS1*.

The protein encoded by *LIS1* has 99% homology to a 45-kD subunit of a bovine brain platelet-activating factor acetylhydrolase (in humans PFAH1B1). Subsequently, depletion of this protein has been demonstrated in the brains of patients with Miller-Dieker syndrome and with isolated lissencephaly. Interestingly, whereas the message for *LIS1* in mice is expressed ubiquitously, the *LIS1* protein product has been localized to the neuropile,

ventricular neuroepithelium at the time of human neuronal migration. However, it is not the lack of enzyme activity that leads to the brain malformation; rather, it appears that the catalytic units of this enzyme complex regulate the available level of LIS1 protein.

FIGURE 133.5 Lissencephaly spectrum—**top panels** are from a patient harboring an *LIS1* deletion. To the **left** is an axial T1 magnetic resonance image demonstrating agyria posteriorly and pachygyria anteriorly. To the **right** is a lateral sagittal T1 magnetic resonance image from the same patient demonstrating the same gradient of posterior worse than anterior malformation. **Bottom panels** are from a female with a *doublecortin* (*DCX*) mutation demonstrating the so-called double cortex (subcortical band heterotopia).

The brain malformations in *LIS1* deficiencies are usually worse posteriorly as compared with X-linked lissencephaly, which is worse anteriorly as discussed in the following text (see [Fig. 133.5](#)). However, in Miller-Dieker syndrome the malformation may be equally severe anteriorly and posteriorly, thus making a distinction phenotypically difficult. This lesion can be detected in utero but late and beyond time for termination of a

X-linked lissencephaly looks nearly identical to the LIS1 deletion form of this disorder: Patients have classic lissencephaly, and the neurologic presentation is the same. However, the malformation is usually worse anteriorly, and the skeletal and other anomalies seen in the Miller-Dieker syndrome are not noted in this form of lissencephaly. In addition, X-linked lissencephaly occurs mostly in boys. Females who are heterozygous for the same gene have band heterotopia. Women with band heterotopia have been noted to give birth to boys with lissencephaly (see [Fig. 133.5](#)).

The *X-linked lissencephaly-band heterotopia syndrome* has been linked to Xq22.3. In female patients, the less severe phenotype probably is attributable to random X inactivation, such that in a variable percentage of cells, normal gene expression is seen and, in the remaining cells, the gene for X-linked lissencephaly, doublecortin, is expressed. This protein doublecortin is a microtubule-associated protein that appears to stabilize the cytoskeletal structure. It appears that this is a cell autonomous disorder, in other words, the cell expressing the abnormal X chromosome manifests aberrant migration or disturbed substrate on which cells can migrate.

The band heterotopia or double-cortex syndrome is a unique form of a neuronal migration defect that almost exclusively occurs in girls and is allelic with X-linked lissencephaly in boys. In this disorder, a circumferential, thick band of tissue is isointense with cerebral gray matter located within what should be the white matter of the hemispheres (see [Fig. 133.5](#)). This band is most obvious in the frontocentroparietal regions in keeping with the anterior worse than posterior gradient in disorders associated with *doublecortin* pathogenic variants. The inner and outer margins at its interface with the adjacent white matter usually are smooth. The overlying gyral appearance may vary from normal cortex to a one with abnormal sulcation. This anomaly represents incomplete neuronal migration. The exact mechanism is unclear, but possibilities include a lack of separation of the migrating neuron from the radial fiber or an arrest on the path to a normal cortical location.

Patients with band heterotopia typically present with seizures and a developmental disorder. The seizure type is variable, and the onset of epilepsy usually is between 2 months and 11 years of age. Patients may present with infantile spasms or, even though the migration abnormality is diffuse, some patients may present with focal seizures. Control of the epilepsy varies, some patients being controlled with monotherapy and others being entirely refractory to all agents.

Most patients with the X-linked lissencephaly-band heterotopia syndrome (double cortex) have impaired intellectual development that ranges from severe retardation to low-normal IQs; one girl had an IQ of 91. Generally, individuals with this syndrome are less impaired than are patients with other diffuse neuronal migration defects such as lissencephaly. Patients in whom seizures are of later onset generally have less developmental impairment. Neurologic findings include mild dysarthria and mild bilateral pyramidal syndromes.

Heterozygous pathogenic variants in *TUBA1A* can cause isolated lissencephaly but may cause other malformations such as polymicrogyria. The lissencephaly with cerebellar hypoplasia phenotype may be caused by pathogenic variants in *TUBA1A*.

Lissencephaly with ambiguous genitalia is associated with pathogenic variants leading to loss of function in the X chromosome gene *ARX*. The brain is small in this disorder and there is usually no corpus callosum. The basal ganglia are small or may have cysts. Interestingly, *ARX* poly A expansions may lead to West syndrome (infantile spasms) and *ARX* is responsible for the formation of inhibitory neurons of the cortex. It is important to remember that repeats are not detected well with exome sequencing ([Table 133.1](#)).

TABLE 133.1 Type I (Classic) Lissencephaly Disorders

Gene	Inheritance/Mechanism	Phenotype(s)
LIS1	Hemizygous, de novo deletion 17p13.3, pathogenic variants	Agyria, pachygyria worse posteriorly
LIS1 and 14-3-3	Hemizygous, de novo deletion 17p13.3	Agyria, pachygyria worse posteriorly
Doublecortin (DCX)	X-linked dominant (hemizygous), usually de novo, but germ line inheritance described	Males: lissencephaly, worse anteriorly Females: band heterotopia (double cortex) worse anteriorly
TUBA1A	De novo pathogenic variants	Lissencephaly or lissencephaly with cerebellar hypoplasia
REELN	Recessive pathogenic variants (compound heterozygote or homozygote [with consanguinity])	Lissencephaly with cerebellar hypoplasia
ARX	X-linked de novo pathogenic variants	Lissencephaly, microcephaly, agenesis of the corpus callosum, cysts in basal ganglia, ambiguous genitalia

TYPE II (COBBLESTONE) LISSENCEPHALY

In type II lissencephaly, the brain may have a smooth appearance or may exhibit polymicrogyria and pachygyria. The underlying cortical histology is that of a bizarre arrangement of neurons. Typically, in the most affected areas, normal cortical plate formation is not evident. Rather, bizarre whirls of cells are found. In addition, cells seem to penetrate the molecular layer and may spill into the subarachnoid space as if part of a volcanic eruption. This deposition of neurons in the subarachnoid space imparts a cobblestone street-like appearance to the brain surface; thus, the term *cobblestone lissencephaly* has been used to describe the cortex in these disorders. The Walker-Warburg, muscle-eye-brain, and Fukuyama muscular dystrophy syndromes appear to be genetically distinct. Abnormalities that may or may not be seen in these disorders include muscular dystrophy, ocular anterior chamber abnormalities, retinal dysplasias (abnormal electroretinogram and visual-evoked responses), hydrocephalus (usually of an obstructive type, requiring shunting), and encephaloceles. The Walker-Warburg syndrome or muscle-eye-brain disorder might be diagnosed even if the ocular examination and muscle biopsies are normal. On MRI, an abnormal white matter signal, hypoplastic brain stem and cerebellum, and a thickened falx suggest the Walker-Warburg diagnosis. Neuroimaging of the muscle-eye-brain disorders might

P.1140

reveal focal white matter abnormalities. This disorder and other cobblestone lissencephalies have been diagnosed in utero.

In the cobblestone lissencephaly spectrum, despite the widespread cortical abnormalities, only one-third of patients develop seizures. The typical presentation is that of a child with marked hypotonia, macrocephaly (obstructive hydrocephalus), and eye abnormalities. Depending on the degree of brain and of muscle involvement, this disorder may not be compatible with life. Long-term survival is rare. Syndromes accompanying

type II lissencephaly include the Walker-Warburg syndrome, HARD-1-E (hydrocephalus, agyria, retinal dysplasia, with or without eye [anterior chamber] abnormalities) syndrome, muscle-eye-brain disease, and Fukuyama muscular dystrophy. These are all the result of recessive inheritance of pathogenic variants in extracellular matrix proteins or in the cell receptors for the extracellular matrix.

Fukuyama muscular dystrophy is distinguished from the Walker-Warburg-like syndromes by the severity of the muscular dystrophy, by the cortical malformation that includes polymicrogyria, and by Japanese inheritance. This disorder is seen more often in Japan than in the Western hemisphere, probably because it is the result of a founder pathogenic variant (a viral transposon insertion) in a gene termed *fukutin*. Patients typically present with evidence of a neuronal migration defect (cobblestone lissencephaly with polymicrogyria, hypotonia, and depressed reflexes).

Not surprisingly, patients with other pathogenic variants of *fukutin* have been described to have muscle, eye, brain, and even cardiac abnormal phenotypes. The protein fukutin interacts with laminin, an extracellular protein expressed in brain, muscle, and eyes, and with α -dystroglycans on muscle membranes. There is further interaction with fukutin-related protein (FKRP), which seems to promote glycosylation of α -dystroglycans in coordination with fukutin; FKRP pathogenic variants may cause Walker-Warburg, muscle-eye-brain, HARD-1-E, muscular dystrophy, or may be asymptomatic. [Table 133.2](#) lists known genes involved in cobblestone lissencephalies; only about 50% of patients have genetic aberrations identified. This makes the case for exome sequencing in these disorders.

TABLE 133.2 Cobblestone Lissencephaly Disorders

Gene	Inheritance	Phenotype(s)
<i>POMT1</i>	AR	Cobblestone lissencephaly, muscular dystrophy
<i>POMT2</i>	AR	Intellectual disability, “mild brain malformations,” muscular dystrophy
<i>Fukutin</i>	AR	Fukuyama muscular dystrophy, cobblestone lissencephaly, Walker-Warburg, limb-girdle muscular dystrophy
<i>FKRP</i>	AR	Walker-Warburg, muscle-eye-brain, cardiomyopathy, limb-girdle muscular dystrophy
<i>LARGE</i>	AR	Brain malformations, congenital muscular dystrophy
<i>ISPD</i>	AR	Cobblestone lissencephaly, limb-girdle muscular dystrophy

AR, autosomal recessive.

All these syndromes probably are accompanied by muscle abnormalities; the most extreme muscle involvement is in the Fukuyama muscular dystrophy patients. In the Walker-Warburg syndrome, the muscle abnormalities may or may not be clinically apparent (normal creatinine kinase [CK], no apparent myopathy on clinical exam).

Kallmann Syndrome

The Kallmann syndrome is an X-linked disorder characterized by anosmia and a defect in gonad development. Patients with this disorder may have other neurologic signs and symptoms, including cerebellar dysfunction and eye movement abnormalities. Therefore, abnormalities in other areas of brain, especially cerebellum, have been suspected in this disorder. Gonadal dysfunction is thought to result from a deficiency in gonadotropin-releasing hormone. Because the neurons that produce gonadotropin-releasing hormone are derived from the olfactory plate and actually migrate back into the forebrain via the olfactory nerve, the abnormality of this hormone is likely due to an arrest in migration of the gonadotropin-releasing hormone neurons.

The gene for Kallmann syndrome has been localized to the X chromosome and appears to encode a fibronectin type III-like molecule. Because fibronectin type III has been proposed to be a neural adhesion molecule, the gene for Kallmann syndrome probably also encodes a neural adhesion molecule involved in olfactory and hypothalamic neuron migration.

Zellweger Syndrome

Zellweger syndrome is an autosomal recessive peroxisomal disorder characterized by neuronal migration abnormalities, hepatomegaly, renal cysts, and stippled calcification of the patella. The neuronal migration defects include pachygyria and polymicrogyria, with underlying abnormalities best characterized as a nonlayered appearance of the cortex. Migration abnormalities are also noted in the cerebellum and in the brain stem in this disorder. Children with Zellweger syndrome present in the neonatal period with severe hypotonia, characteristic facies, hepatomegaly, and seizures. A mouse model of Zellweger syndrome has been produced; migration abnormalities were noted in the cerebellum and cortex despite normal-appearing radial glia. Disturbed maturation of neurons and apoptotic neurons also are noted in this mouse model; perhaps similar mechanisms are operative in the comparable Human disorder. More than 12 PEX genes have been implicated in Zellweger or Zellweger-like disorders; all are inherited in an autosomal recessive pattern.

Zellweger syndrome results from the body's inability to make peroxisomes owing to a deficiency of one of the 12 proteins encoded by the *PEX* genes. A number of peroxisomal enzymes are abnormal and lead to the accumulation of very long chain fatty acids. Therefore, testing for this disorder includes an assay of very long chain fatty acids.

Polymicrogyria

Polymicrogyria (many small gyri) is a disorder often considered to be a neuronal migration disorder; it is important to recognize that this malformation may result from both genetic and destructive processes. The microscopic appearance of the lesion is that of too many small abnormal gyri. The gyri may be shallow and separated by shallow sulci, which may be associated with an apparent increased cortical thickness on neuroimaging. The multiple small convolutions may not have intervening sulci, or the sulci may be bridged by fusion of overlying molecular layer, which may give a

P.1141

smooth appearance to the brain's surface; alternatively, the brain may appear to have pachygyria.

Polymicrogyria takes two distinct histologic forms: four-layered and unlayered. The four-layered form consists of an outer layer, a neuronal layer, a cell-sparse layer, and a deeper neuronal layer. One theory is that the lower cell-sparse layer of the four-layered types represents a glial scar from a laminar necrosis. On the basis of examination of fetuses in which the occurrence of the insult causing the malformation has been accurately timed, this pattern is believed to occur as a result of insults late in the first or early in the second trimester. Others believe that this is a postmigration insult resulting from distorted migration of cells through an injured area, the outcome of which is the cell-sparse layer. A cell-sparse layer between the upper and lower neuronal layers is absent from the unlayered form. Insults that occur early in the second trimester before migration is completed are

believed to be the origin of unlayered polymicrogyria. Identical twin pregnancies discordant for polymicrogyria have been described; the theory being that global insults can lead to polymicrogyria. The common association of congenital cytomegalovirus infection with polymicrogyria supports the hypothesis that a destructive process can be involved in these disorders.

Polymicrogyria has also been associated with genetic and chromosomal disorders. It is found in disorders of peroxisomal metabolism such as Zellweger syndrome (see earlier discussion) and neonatal adrenal leukodystrophy. It has also been associated with the Bloch-Sulzberger syndrome, Meckel-Gruber syndrome, thanatophoric dysplasia, and Fukuyama congenital muscular dystrophy. Familial bilateral frontal polymicrogyria and bilateral perisylvian polymicrogyria have been reported. Therefore, if no identifiable cause of the polymicrogyric malformation is found, the recurrence risk may be that of an autosomal recessive disorder (25%) or an X-linked disorder in boys. A bilateral parasagittal parietooccipital polymicrogyria has also been described. Multiple chromosomal deletions and duplications including X-linked potential inheritance have been described. Multiple recessively inherited disorders have also been identified, including GPR56 and WDR62 pathogenic variants in families with recurrences of polymicrogyria with variable phenotypes.

The clinical picture varies depending on the location, extent, and etiology of the abnormality. Microcephaly with severe developmental delay and hypertonia may result when polymicrogyria is diffuse. When polymicrogyria is unilateral, focal deficits might be seen. Epilepsy often is present, characterized by partial complex seizures or partial seizures that secondarily generalize. The age at presentation and severity of seizures depends on the extent of the associated pathology.

The lesions are most clearly recognized by MRI and are best noted on sagittal views. They often are recognized by the rough appearance of the surface of the cortex on a thin-cut T2-weighted image. If MRI cuts are thick, these lesions may be confused with pachygyria. Because the genetic implications of pachygyria and polymicrogyria differ considerably, distinguishing between these two conditions is important.

Congenital Bilateral Perisylvian Syndrome

Advances in neuroimaging have led to the recognition of the congenital bilateral perisylvian syndrome, also known as the *Foix-Chavany-Marie syndrome*. MRI demonstrates bilateral abnormalities in the opercular and perisylvian regions. The cortex is irregular, and the sylvian fissure may be noted to extend to the top of the convexity.

Striking clinical features include a pseudobulbar palsy with abnormal tongue movements, dysarthria, dysphasia, mental retardation, absent or hyperactive gag reflex, drooling, and pyramidal signs in more than 70% of the reported cases. These patients may be intellectually disabled, and nearly all have severe language disorders. Dysphagia can impair proper nutrition. Seizures are present in most of the affected patients. Several patients have had infantile spasms during the first year of life. Seventy percent of the patients experience seizures before the age of 10 years. The etiology of this syndrome is similar to other forms of polymicrogyria (deletions, duplications, insults [cytomegalovirus, twin pregnancies], Aicardi syndrome [see later discussion], and recessively inherited pathogenic variants in genes).

Heterotopias

Heterotopias are collections of normal-appearing neurons in an abnormal location probably secondary to a disturbance in radial migration. The exact mechanism of the migration aberration has not been established. Various hypotheses include damage to the radial glial fibers, premature transformation of radial glial cells into astrocytes, or a deficiency of specific molecules on the surface of neuroblasts or of the radial glial cells (or the receptors for those molecules) that results in disruption of the normal migration process. Heterotopias often occur as isolated defects that may result in only epilepsy. However, when they are multiple, heterotopias might

also be associated with a developmental disorder and cerebral palsy (usually spastic). In addition, if other migration defects such as gyral abnormalities are present, the clinical syndrome may be more profound. Usually, no cause is apparent. Occasionally, heterotopias may be found in a variety of syndromes, including neonatal adrenal leukodystrophy, glutaric aciduria type II, GM₂ gangliosidosis, neurocutaneous syndromes, multiple congenital anomaly syndromes, chromosomal abnormalities, and fetal toxic exposures.

Heterotopias may be classified by their location: subpial, within the cerebral white matter, and in the subependymal region. Leptomeningeal heterotopias often contain astrocytes mixed with ectopic neurons and may resemble a gliotic scar. They may be related to discontinuities in the external limiting membrane and often are associated with type II lissencephaly. These *subarachnoid heterotopias* are responsible for the pebbled appearance of the surface of the brain (therefore the name cobblestone lissencephaly). *White matter heterotopias* may be focal, subcortical, or diffuse. They may cause distortion of the ventricles and may be associated with diminished white matter in the surrounding area. When diffuse, they may take the form of a circumferential subcortical layer of heterotopic gray matter, which has been called *band heterotopia* or the *double-cortex syndrome* (see [previous discussion in "Type I \[Classic\] Lissencephaly"](#)). Laminar heterotopia may consist of sheets of ectopic gray matter that may be split into elongated islands. A central ovoid mass of white matter may be present within the band. Patients with this form of subcortical heterotopia have a high prevalence of developmental delay, hemiplegia, and seizures. Nodular subcortical heterotopias may be seen in association with subependymal heterotopias.

Subependymal heterotopias often are associated only with epilepsy. Most patients will have normal intelligence and no motor deficits. These heterotopias are located just beneath and about the ependymal lining of the lateral ventricles. They may be either bilateral or unilateral and are located most often adjacent to the occipital horns and trigones and, less commonly, within the temporal horns and frontal horns. Seizure onset in patients with

P.1142

subependymal heterotopias is relatively late, often in the second decade, and more often affects women. The seizures may be partial complex, tonic-clonic, or focal motor. Subependymal heterotopias have been identified as an X-linked dominant syndrome linked to markers in the distal Xq28 locus and pathogenic variants in *filaminA* have been found to be causative. Filamin A, a cytoskeletal protein, must be important for the initiation of migration because cells are arrested in the ventricular zone. An increased incidence of spontaneous abortions, patent ductus arteriosus, spontaneous hemorrhage, and a much higher than expected incidence of female offspring are noted in affected women, suggesting that inheritance of *filamin A* pathogenic variants may be lethal for male embryos. Some variants in this gene may result in male phenotypes. A syndrome marked by periventricular heterotopia, mental retardation, and syndactyly has recently been described in male patients.

Patients with diffuse gray matter heterotopias, whether subependymal or in the white matter, usually are candidates for medical treatment of the epilepsies present. Occasionally, patients who are refractory to medical management may be considered for hemispherectomies or focal cortical resections. In the case of bilateral temporal lobe periventricular heterotopias, the prognosis for a surgical cure may be poor.

Cortical Dysgenesis

Cortical dysgenesis refers to disorders of cortical formation. In general, many of the disorders just discussed are considered to be within the spectrum of this entity. In this section, an emphasis on those focal macroscopic and microscopic lesions that do not fit into the preceding classifications will be discussed.

The terms *cortical dysplasia* and *cortical dysgenesis* often are used synonymously for the same disorders. Included in these terms are not only the obvious malformations such as smooth gyri and clefts but also lesions classified as focal cortical dysplasias and microdysgenesis. Focal cortical dysplasia may involve a major part of a lobe and may be characterized by the congregation of large, bizarre neurons and abnormal glial cells in the

subadjacent white matter. *Microdysgenesis*, by definition, can be detected only histologically and is beyond the imaging capability of current MRI scans. It consists of unipolar and bipolar neurons under the pia, increased neurons in the first layer of the cortex, indistinct boundaries between the first and second layers of the cortex, neuronal glial heterotopias in the pia, persistence of columnar architecture of the cortex, and an increased number of neurons in the white matter. Patients with microdysgenesis are reported only in series of patients undergoing epilepsy surgery. Microdysgenesis is not detected in patients with controlled epilepsy and thus the incidences of migration disorders and of microdysgenesis responsible for epilepsy are unknown.

Microdysgenesis was the most common migration disorder noted in a series of pathologic examinations of brain tissue removed from epileptic patients. Malformations of this type were found in 14% of epileptic brains; the frequency of other abnormalities in epileptic brains was microgyria, 4.7%; heterotopia, 15%; and pachygyria, 8%. In patients with microdysgenesis, seizure onset occurs between 2 and 20 years of age.

A surprisingly high incidence of microdysgenesis has been reported in brain tissue removed from adults to treat recalcitrant seizures. The lesions noted included ectopic neurons within the subcortical white matter in 42% of the specimens and neuronal clustering in 28%; in addition, bare areas were present within layers II to VI. Similar findings have been reported in epilepsy surgical specimens from children. Thus, microscopic abnormalities have been found in 20% to 40% of specimens from patients undergoing surgical therapy for intractable epilepsy, the most common lesions being microdysgenesis and cortical dysplasias.

As mentioned earlier, MRI has been useful in detecting migration abnormalities and generally has been found to be more sensitive than computed tomography (CT) scanning. MRI-apparent migration abnormalities have been detected in as many as 50% of patients who underwent epilepsy surgery. Of those patients with epilepsy alone, 6.7% had migration abnormalities; in those who had both mental retardation and epilepsy, such abnormalities were found in 13.7%. The abnormalities included pachygyria or polymicrogyria or both, schizencephaly, heterotopias, and hemimegalencephaly. Of 222 adults with temporal lobe epilepsy studied by MRI, 7.2% were found to have malformations of the temporal lobe. These malformations consisted of heterotopias, focal neocortical dysgenesis, hippocampal malformations, or a combination of various lesions.

Cortical dysgenesis has also been associated with hippocampal sclerosis, leading some to believe that hippocampal sclerosis is a disorder of brain formation. Raymond and colleagues studied 100 patients with hippocampal sclerosis diagnosed by histologic examination or MRI and found that 15 of the patients also had cortical dysgenesis. The most common abnormality was subependymal heterotopia. The cortical dysplasia was, at times, contralateral to the hippocampal sclerosis.

Clearly, migration aberrations need not be manifested by abnormal motor function; rather, epilepsy and mental retardation might be the only clinical symptoms in these disorders.

The severity of the migration disorder correlates with clinical symptoms. Patients with milder forms of neuronal migration defects (i.e., focal cortical dysplasias, heterotopias, microdysgenesis) may appear normal. Most often, migration disorders are diagnosed in patients with epilepsy, as neuroimaging is performed for seizure. These patients generally have partial seizures and normal life expectancies. Some patients with these disorders will have developmental delays, mild intellectual deficits, or spastic or atonic cerebral palsy. Profound defects are associated with more severe symptoms.

Children presenting with intractable epilepsy, significant intellectual disability, and neurologic signs more often have diffuse migration abnormalities on MRI scanning. Therefore, not surprisingly, the degree of abnormality on MRI scans correlates well with the degree of neurologic involvement. The age of onset of seizures varies from early childhood to young adult life. Generally, the severity of the seizures and the severity of the pathology correlate positively. Severe abnormalities are associated with seizures in the first year of life, whereas microdysgenesis may be associated with adult onset of seizures. Later onset seizures also tend to correlate with

subependymal heterotopias.

Although the pathogenic mechanisms involved in focal dysgenesis remain poorly understood, mechanisms similar to those involved in global or more extensive migration disorders probably are operative. Therefore, definition of the pathogenic mechanisms causing these disorders is important. An important insight into the pathogenesis of focal developmental lesions may have come from the observation that the human papilloma virus (HPV) 16 RNA, and its oncogenic protein E6 are present in focal cortical dysplasia type IIB resected for epilepsy. This fascinating observation potentially ties HPV with tuberous sclerosis because the E6 protein encoded by HPV exerts its oncogenic effect via depression of TSC2, thereby upregulating mTOR as occurs in tuberous sclerosis. In support of this hypothesis is the fact that cortical dysplasia type IIB also occurs in tuberous sclerosis. Indeed, other viruses could have

P.1143

similar effects on the developing nervous system and could explain microdysgenesis and other lesions of the nervous system described earlier.

POSTERIOR FOSSA FORMATION AND MALFORMATION

Posterior fossa malformations are best understood in terms of the normal developmental processes that have gone awry. At 4 weeks of human gestation, the hindbrain and/or rhombencephalon bends and divided into two vesicles, the metencephalon and the myelencephalon; the pons develops in the floor of the metencephalon and the lateral walls of the myelencephalon form the medulla oblongata. The cerebellum develops from the dorsal hindbrain (neuromere 1, rhombic lip) with contributions from the lower mesencephalon, which forms the vermis and the metencephalon, which forms the cerebellar hemispheres. As this development progresses, mesenchymal tissue from the forming skull and meninges invade to form the choroid plexus. This invasion of mesenchymal tissue is caudal to the developing rhombic lip and this invasion penetrates the developing fourth ventricle. The roof of the developing fourth ventricle is divided by this invading mesenchymal tissue into two areas, the anterior membranous area and the posterior membranous area. The rhombic lip, the developing cerebellum, grows over the structures as it enlarges to form the cerebellum. As the cerebellum develops, the anterior membranous area involutes and the posterior membranous area protrudes outward from the developing nervous system. This performs the so-called Blake pouch cyst, which may persist normally until 4 months gestation. Eventually, the foramen of Magendie form in this Blake pouch cyst and the protrusion normally involutes. The foramen of Luschka also developed around this time.

A proliferative zone of cells in the ventricular region of the rhombic lip give rise to future Purkinje cells which migrate radially toward the surface of the developing cerebellum. At the tip of the rhombic lip, cerebellar granule cells are born that migrate over the surface of the rhombic lip and then, in a reverse radial migration, penetrate the developing cerebellum, pass Purkinje cells, and deposit in the developing internal granule cell layer. Amazingly, this process of cerebellar granule cell formation is occurring in the first year of human life. Prior to this, other neurons are born in interventricular zone and migrate to the various nuclei of the brain stem.

For the purposes of this chapter, I will divide posterior fossa malformations into predominantly neuronal structural malformations and malformations of the foramina and ventricular and transient cyst structures of the developing brain. This division is in all likelihood further defined by the genetic abnormalities that are involved in neuronal genesis, migration, and patterning (predominantly neuronal structural malformations) and those of mesenchymal support structures that are important in the formation of the transient cyst of the developing posterior fossa.

JOUBERT, MECKEL-GRUBER, AND OTHER CILIOPATHIES

In the classic form, Joubert syndrome is a recessively inherited disorder with clinical features of variable intellectual impairment, respiratory rate dysregulation, oculomotor movement abnormalities (classically oculomotor apraxia), hypotonia, and ataxia. Kidney, liver, renal, and retinal abnormalities may accompany these

symptoms and signs. Radiologically, Joubert syndrome is recognized by the molar tooth anomaly and accompanying vermian hypoplasia or aplasia. The molar tooth malformation results from thin cerebellar peduncles that extend dorsally at right angles to the brain stem and absence or hypoplasia of the vermis giving the appearance of roots of a molar tooth. Absence of the cerebellar peduncle decussation and disturbance of the cortical spinal tract decussation combined with brain stem nuclei abnormalities result in a thinning of the brain stem with a prominent isthmus giving the ventral brain stem the appearance of the crown of a molar tooth. Cerebellar foliation defects may be noted along with other brain stem abnormalities.

The Meckel-Gruber syndrome may include the aforementioned brain stem and cerebellar abnormalities but is distinguished by the presence of an occipital encephalocele that is usually located near the level of the torcula and may contain supratentorial contents or infratentorial contents or both. This may be accompanied by syndactyly and renal, liver, retinal, or kidney problems and the developmental outcomes are more severe than those of Joubert syndrome.

Genetically, Joubert and Meckel-Gruber are caused by recessive loss of function pathogenic variants in primary ciliary genes. The primary cilia are the polarity antenna of many cells, are not motile, nor have motility functions other than to determine directionality in development.

RHOMBENCEPHALOSYNAPSIS

Rhombencephalosynapsis is fusion of the cerebellar hemispheres with absence of the vermis. The development of this lesion is unknown but apparently results from a dorsal lack of division of the developing cerebellum. Clinical manifestations may be developmental or this lesion may be noted in asymptomatic patients. To date, the genetics of this lesion is undetermined with the exception of an implication of *ZIC2* in a combination of holoprosencephaly and rhombencephalosynapsis noted in two half sisters concordant for a pathogenic variant in this gene.

DANDY-WALKER

Possibly failure to form the foramen of Magendie or failure to involute the anterior membranous area results in an enlargement of the fourth ventricle, thereby lifting, externally rotating, and compressing the vermis. The cerebellar hemispheres are splayed outward and the torcula may be elevated. The posterior fossa is enlarged and in 80% of cases, there is obstructive hydrocephalus requiring postnatal shunting from either failure to form the foramina and therefore outflow from the fourth ventricle or from compression of the aqueduct of Sylvius (Fig. 133.6). Surprisingly, this lesion is associated with good neurologic outcomes if there are no accompanying distinct malformations of the brain or if not accompanying trisomy 9, 13, 18, 21, or other chromosomal aberrations. Some of the genes associated with this disorder are expressed in meninges and developing skull (*FOXC1*) and others in the dorsal cerebellum during development (*ZIC1*, *ZIC4*). The single gene defects thus far associated with this brain lesion are heterozygote deletions or loss of function mutations.

Unfortunately, a rather loose use of the terms *Dandy-Walker* and *Dandy-Walker variant* have made the literature regarding these malformations very difficult to interpret and to the impression that these lesions carry poor prognoses; for the most part, they do not. It is my opinion that the terms *Dandy-Walker* and *Dandy-Walker variant* should be reserved for those malformations that solely involve enlargement of the fourth ventricle with its consequences such that in the case of *Dandy-Walker variant*, the lesion should include at least upward rotation of the vermis.

FIGURE 133.6 Dandy-Walker malformation. **A:** Midsagittal drawing of the posterior fossa with normal fourth ventricle. **B:** Midsagittal drawing of the posterior fossa in Dandy-Walker malformation. The foramen of Magendie has not opened resulting in large fourth ventricle that rotates, compresses, and elevates the vermis and the torcula. **C:** A 21-week-old fetus with Dandy-Walker malformation **D:** Dandy-Walker malformation with obstructive hydrocephalus in a newborn. (A and B by Nathan Lucy, <http://www.nathanlucy.com/>.)

An enlarged cisterna magna forms embryologically in a different fashion, although *FOXC1* is implicated in both enlarged cisterna magna and in Dandy-Walker. Further, arachnoid cysts may form in the posterior fossa resulting in enlargement of the posterior fossa and even compression of developing structures, but because these form distinctly from the dilatation of the fourth ventricle in Dandy-Walker, the term *Dandy-Walker* should not be applied to these lesions nor should the expectations be the same. Similarly, in the earlier described lesions of the posterior fossa that do not expand it, there may be hypoplasia of the brain stem, malformations of the cerebellum, or other malformations that disturb the posterior fossa. The developmental consequences of these lesions are usually dire and to use the term *Dandy-Walker* in any form to describe these is not accurate embryologically and lowers the developmental expectations for true Dandy-Walker patients.

PROCESS OUTGROWTH AND SYNAPSE FORMATION

CORPUS CALLOSUM

Callosal formation begins surprisingly early in human development; the first axons crossing from one developing

hemisphere to the other side is apparent at 6 weeks' gestation. By 11 to 12 weeks, there is an identifiable corpus callosum and by 18 to 20 weeks, all of the structures of the corpus callosum are present (rostrum,

P.1145

body, splenium). Errant formation of this structure can result in complete agenesis, so-called partial agenesis or dysgenesis. The corpus callosum continues to form and differences in appearance may be seen through adolescence owing to myelination and pruning of crossing fibers.

The outcome depends on the genetic disorder and outcome data is heavily biased toward poor outcomes. There is an ascertainment bias in many brain developmental disorders, but perhaps none more than in callosal disorders. Most patients with callosal agenesis/dysgenesis have neuroimaging because they have presented to a neurologist owing to developmental or neurologic issues. Asymptomatic people with callosal agenesis or dysgenesis are therefore not recognized. However, with commonplace fetal imaging, it is possible that more accurate data regarding outcomes in these disorders may be noted. In fact, in a French cohort of 20 patients with agenesis or dysgenesis of the corpus callosum identified in utero (without prejudice), 80% have had normal outcomes up to 10 years later.

Multiple etiologies of agenesis/dysgenesis of the corpus callosum have been described and the potential etiologies are legion and could deserve a chapter. For the clinician, the division into accompanying other brain malformations, isolated and symptomatic seems the most useful. Examples of accompanying other brain malformations include Walker-Warburg and other muscle-eye-brain disorders, ciliopathies (see [“Posterior Fossa Formation and Malformation”](#)), X-linked lissencephaly with ambiguous genitalia (ARX pathogenic variants), and Aicardi syndrome.

Aicardi syndrome occurs mostly in females (in XXY males), is accompanied by other brain anomalies (polymicrogyria, intracranial cysts, nodular heterotopia), and is defined by chorioretinal lacunae; the genetic basis of this disorder is unknown. The prognosis is poor and epilepsy is nearly a certainty.

It is important for the clinician to recognize that structural brain disease can result from metabolic disorders. Nonketotic hyperglycinemia may result in agenesis/dysgenesis of the corpus callosum. With the structural brain disease and lack of acidosis, the neurologist and neonatologist may easily assume that the seizures, hypotonia, and depressed mental status at birth are the result of the brain malformation. Similarly, pyruvate dehydrogenase complex deficiency may result in callosal agenesis/dysgenesis with or without lactic acidosis.

An important review of the genetics of callosal dysgenesis was published as an editorial by Dobyns and nicely catalogs observations with and without other CNS malformations associated with duplications, deletions, trisomies, and point pathogenic variants (recessive, X-linked, and dominant). A reasonable evaluation of a patient symptomatic from a callosal dysgenesis would include an ophthalmologic exam if female to rule out Aicardi, metabolic studies to include CSF glycine to serum glycine ratios, urine organic acids, and chromosomal microarray and if these are negative, consideration for whole exome sequencing should be made.

Fetal recognition of isolated agenesis of the corpus callosum may carry a different prognosis as discussed earlier. Eighty percent of the fetuses so identified will be normal in follow-up. When evaluating the fetus with a corpus callosum malformation, it is important to recognize that Aicardi syndrome, with its poor prognosis, needs to be considered as a possibility for females.

NORMAL SYNAPSE FORMATION

Even as neurons are arriving in the cortical plate, important neural outgrowths and synapses are forming. The process by which neurons sprout new extensions (neurites) that grow impressive distances to make precise synaptic connections is remarkable and has been well studied, although it is still being elucidated. During development, many more synapses are made than are needed; these subsequently are pruned to improve

precision of synaptic connections. Such pruning occurs while other synapses are strengthened. Pruning may be a phenomenon peculiar to the developing nervous system, but synapse strengthening probably continues throughout life.

Most early neurites will form axons. The distance and the terrain that a forming axon must negotiate to reach its target are often formidable, yet this process occurs with little error. Neurites consist of a long shaft of dynamic cytoskeletal elements that terminate in a growth cone, a highly motile structure capable of responding to chemical cues.

The nature of the chemical cues that guide growth cones and, thus, developing axons are threefold: adhesive, chemoattractive, and chemorepulsive. Adhesive molecules, such as those in the NCAM family, line projection pathways; integrin receptors on growth cones and neurites link the internal cytoskeleton of these structures with the extracellular adhesive molecules. These adhesive molecules provide a substrate on which the motile growth cone and neurite can respond to the chemical cues that determine the final synaptic target.

Diffusible cues appear to provide a trophic influence on developing axons through a chemoaffinity mechanism. One hypothesis is that gradients of chemotactic substances, emitted at the targets for synapse formation, interact with receptors on the growth cone that steer the growth cone toward the target.

Although it appears not to play a role in the early stages of synapse formation, synaptic activity is critical for subsequent remodeling. Pathways apparently are overrepresented often in early postnatal life, and “exuberant” projections of axons must be appropriately pruned. This occurs in a use-dependent fashion such that pathways used for neural activity are retained and those not used are eliminated. The classic studies of Hubel and Wiesel have demonstrated that this process is critical in the formation of the proper synaptic connections of the visual cortex. In their studies, the eyelid of one kitten eye was closed temporarily, and the eye deprived of light was underrepresented, whereas the eye that remained open was overrepresented in the visual cortex. This phenomenon is noted in children who have significant amblyopia (so-called lazy eye). If this amblyopia is not recognized during a critical period of synapse remodeling, these children can be cortically blind in the affected eye.

Throughout life, significant synaptic plasticity persists. Memory is believed to result from a strengthening of heavily used synapses, a phenomenon known as *long-term potentiation*. Considering the lessons learned about the role neuronal activity plays in the remodeling of connectivity in sensory systems, one wonders whether early life experiences, such as seizures, could also alter local circuit remodeling for the recurrent axon collaterals of hippocampal pyramidal cells. Hence, during hippocampal development, if repeated seizures occurred, the synchronous discharging of pyramidal cells might prevent axonal remodeling that normally takes place, and so an excess in axonal branching present in early life could be maintained into adulthood. In turn, this consolidation could result in an imbalance between recurrent excitation and inhibition and lead to the production of a chronic epileptic focus in hippocampus.

DISORDERS OF PROCESS OUTGROWTH

The disorders of process outgrowth probably are poorly recognized, given the current limitations of neuroimaging. Many children with cerebral palsy and normal neuroimaging scans likely have disorders

P.1146

involving dendritic branching and axonal growth. Although there are likely many synapse disorders, a number have been well characterized.

Down syndrome (trisomy 21) includes a static encephalopathy characterized by mental retardation and hypotonia. The major neuropathologic changes in Down syndrome are a reduction in both the dendritic spines and the number of synapses.

Rett syndrome is a progressive disorder that affects girls and is due to a loss of function of MECP2. After a normal gestation, normal birth, and normal first 6 months of development, regression in intellect and motor function is seen. Girls affected with this disorder develop a gait and a truncal apraxia, loss of purposeful hand movements, stereotypic hand movements, progressive spasticity, autism-like social withdrawal, and intellectual disability. Accompanying this decline is a deceleration in head growth, which occurs during a time that brain development mainly involves glial proliferation and neuronal process outgrowth. Although patients typically have normal head sizes at birth, they become microcephalic during the time of their decline in function.

Pathologic examinations of the brains of patients with Rett syndrome support a disturbance in neuronal process outgrowth. The size of individual neurons is reduced, which is accompanied by an increase in packing density in the cerebral cortex, thalami, and basal ganglia. Abnormal dendritic branching has been noted in affected brain; this is especially prominent in layers III and V neurons of the frontal, motor, and temporal cortices. Because dendritic branching is believed to occur in response to axonal innervation, an examination of Rett syndrome brains for axonal aberrations was undertaken. This examination revealed significantly lower numbers of axons entering cortex as compared to normal.

Fragile X syndrome is the most common nonchromosomal, genetic form of mental retardation seen in boys and men. The disorder results from the disturbance of the FMR1 gene on the long arm of the X chromosome by a triplicate repeat. The brain in this disorder appears normal but, on microscopic examination, dendritic spine abnormalities are apparent.

Autistic spectrum disorders may turn out to be disorders of synapses. Male patients with autism may have an abnormal acceleration in head growth before age of 2 years. Neuroligins and other synapse-specific targeting proteins are on the X chromosome, perhaps explaining, in part, the increased incidence of autism in boys.

CONCLUSIONS

Exciting, new genetic and molecular insights regarding nervous system development and disturbances in that development have led to this attempt to give the clinician the framework to understand malformations of the human CNS and to evaluate patients afflicted by these disorders. Obtaining an etiology in such situations is of value to the patient, the family, and potentially to society. With new technologies such as exome sequencing, the potential for obtaining an etiology is vastly enhanced.

INTRODUCTION

There are hundreds of inborn errors of metabolism, each individually rare, but collectively sufficiently common to constitute a significant public health burden. Most severe inborn errors of metabolism involve the nervous system, either directly, or by producing neurologic dysfunction through intoxication with toxic substrates, energy deficiency (to which the brain is especially prone), deficiency of essential substrates or neurotransmitters, or combinations thereof. Although the complexity of these disorders defies easy classification, they may be conveniently divided into small and large molecule disorders for clinical purposes. The former group includes amino and organic acidopathies and urea cycle disorders, among others. Most result from enzyme deficiencies that impair the body's ability to cope with substrate loads. In severe forms, they present in neonates exposed to normal substrates for the first time without their mother's metabolic machinery to compensate. Lesser degrees of impairment may present later and intermittently under conditions of unusual stress.

In contrast, large molecule disorders, which include the lysosomal, peroxisomal, and glycogen storage diseases, have a slowly but inexorably progressive course, paralleling the accumulation of macromolecules within cells. The most severe phenotypes exhibit specific patterns of neurodegeneration, reflecting the loci of storage in the nervous system. Thus, predominantly neuronal storage, as seen in the neuronal ceroid lipofuscinoses and neuroaxonal dystrophies, presents as poliodystrophies. Disorders in which white matter bears the major burden of disease are designated as leukodystrophies.

This chapter surveys some of the more prominent of these disorders but cannot be comprehensive. Indeed, the major text of inherited metabolic disease (*Metabolic and Molecular Bases of Inherited Disease* [MMBID]) was last published in print form in 2001 when it was felt that its 4,600 pages spread over four volumes had reached the limits of print publishing. The MMBID is now only available as an electronic text (*Online Metabolic and Molecular Bases of Inherited Disease* [OMMBID]), and the interested reader is referred to it and the recommended reading lists in each of the following sections for more comprehensive data on disorders of interest.

SMALL MOLECULE DISORDERS

GLUCOSE TRANSPORTER TYPE 1 DEFICIENCY SYNDROME

Clinical Syndrome

In 1991, De Vivo et al. described two children with infantile seizures, delayed motor and behavioral development, acquired microcephaly, and ataxia. Lumbar puncture revealed low cerebrospinal fluid (CSF) glucose concentrations (hypoglycorrhachia) and lownormal to low CSF lactate concentrations.

Seizures begin in early infancy, and the seizure types vary with the age of the patient. In infancy, the dominant seizure types include behavioral arrest, pallor and cyanosis, eye deviation simulating opsoclonus, and apnea. The electroencephalogram (EEG) at this stage may be normal or show focal spikes and evolves to a generalized spike-wave pattern in childhood. In childhood, the seizures typically include atstatic seizures, atypical absence seizures, and generalized tonic-clonic seizures. The seizures are refractory to antiepileptic drugs but respond to a ketogenic diet. Other paroxysmal events, including abnormal eye movements, ataxia, paralysis (with or without migraine), and dyskinesias are frequent. Many patients exhibit static defects, of which intellectual disability, ataxia, dystonia, and spasticity are prominent.

Laboratory Data

Diagnosis requires awareness of the clinical manifestations and documentation of hypoglycorrhachia. A low or low-normal CSF lactate concentration strengthens the presumptive diagnosis.

Molecular Genetics and Pathogenesis

D-Glucose is the obligate fuel for brain metabolism under virtually all circumstances. With fasting, the brain adapts to use ketone bodies (β -hydroxybutyrate and acetoacetate) in partial lieu of glucose. The transport of D-glucose across the blood-brain barrier and into brain cells is selectively mediated by glucose transporter 1 (GLUT1), a member of a multigene family of protein transporters that facilitate the diffusion of sugar molecules across tissue barriers. GLUT1 is encoded by SLC2A1 on chromosome 1p34.1 and is present in high abundance in brain capillaries, astroglial cells, and erythrocyte membranes.

The molecular basis of the syndrome is GLUT1 haploinsufficiency; a few patients are hemizygous, but most are heterozygous with a variety of mutations. This syndrome is the first genetically determined abnormality of the blood-brain barrier; it may be familial and transmitted as an autosomal dominant trait.

Diagnosis

Lumbar puncture for measurement of glucose and lactate (with simultaneous serum assays of both) is critical in establishing the diagnosis. Confirmatory evidence is provided by sequencing of the SLC2A1 gene; mutations are found in more than 90% of cases; severe phenotypes have been associated with microdeletions in the SLC2A1 region.

Treatment

Standard treatment is the ketogenic diet, which controls the seizures, at least early in the course, but is less effective in improving cognition and behavior. More recently, anaplerotic therapy with triheptanoin has been studied, with evidence of benefit. Antiepileptic drugs have been uniformly ineffective.

HYPERAMMONEMIA

Introduction

Hyperammonemia has many genetic and acquired causes. The hepatic urea cycle is the major mammalian system for the detoxification of ammonia and defects have been described in all six

P.1151

urea cycle enzymes. The prevalence of these disorders is 1:35,000; two-thirds present after the newborn period. The mortality is 24% in neonates and 11% in older individuals. An additional pathway from arginine to citrulline generates the putative second messenger and neurotransmitter, nitric oxide, catalyzed by nitric oxide synthetase. The enzyme is found in many tissues, including brain. Animal studies suggest that derangement of this pathway, cerebral energy metabolism, amino acid and neurotransmitter pathways, mitochondrial permeability, signal transduction, and oxidative stress all contribute to the brain injury associated with exposure to high levels of ammonia.

Neonatal Hyperammonemia

Transient hyperammonemia is occasionally seen in otherwise well premature infants and rarely requires treatment. Hyperammonemia may reflect liver damage associated with birth asphyxia or congenital hepatic disease; the birth history usually establishes the diagnosis.

The ill neonate with hyperammonemia without other explanation often has an inborn error of metabolism that, directly or indirectly, affects the urea cycle. Marked hyperammonemia causes progressive lethargy, vomiting, poor feeding,

apneic episodes, and seizures. These nonspecific symptoms occur in many disorders, such as sepsis, that can also precipitate hyperammonemia. The age at onset of these symptoms is a useful differential diagnostic point. Infants with hyperammonemia owing to urea cycle enzymopathies or organic acidurias typically are well until they have received 1 to 3 days of protein feeding. In contrast, infants with hyperammonemia secondary to impaired pyruvate metabolism are symptomatic within the first 24 hours. Pyruvate dehydrogenase and (type B) pyruvate carboxylase deficiencies feature lactic acidosis, and these diagnoses can be confirmed by an assay of enzyme activities in fibroblasts.

Organic acidurias lead to ketoacidosis (but maple syrup urine disease does not), which distinguishes them from urea cycle enzymopathies. Severe deficiency of urea cycle enzymes, other than arginase, causes similar clinical syndromes. The affected child is well for the first 24 hours but signs of hyperammonemia appear as protein feedings continue. Respiratory alkalosis with hyperventilation is classic but not always present, and infants with sepsis or vomiting may have metabolic acidosis or alkalosis. Plasma amino acid and orotic acid assays help to distinguish different urea cycle defects (Table 134.1). Direct sequencing of urea cycle genes will make the diagnosis in more than 80% of cases; tissue enzyme analysis is required in the remainder. All of the urea cycle genes are autosomal recessive, except for ornithine carbamyl transferase deficiency, which is X-linked. Prenatal screening is available.

TABLE 134.1 Plasma Amino Acid and Urinary Orotic Acid Findings in Urea Cycle Defects

Enzymatic Deficiency	Citrulline	Argininosuccinic Acid	Orotic Acid	Arginine
Carbamyl phosphate synthetase (CPS deficiency)	0 to trace	0	↓	↓
Ornithine transcarbamylase (OTC deficiencies)	0 to trace	0	↑↑	↓
Argininosuccinate synthetase (citrullinuria)	↑↑	0	↑	↓
Argininosuccinase (argininosuccinic aciduria)	↑	↑↓	nl	↓
Arginase	nl	0	↑	↑↑
Transient hyperammonemia of newborn	nl or slightly ↑	0	nl	nl

↓, decreased; ↑, increased; nl, normal.

Long exposure to high levels of ammonia damages the brain. Thus, acute hyperammonemic coma in the newborn is a medical emergency, and rapid reduction in ammonia levels is necessary. Peritoneal dialysis is more effective than exchange transfusion; hemodialysis may also be effective. Useful adjuncts include intravenous administration of sodium benzoate and sodium phenylbutyrate. A block in the urea cycle (other than at arginase) renders arginine an essential amino acid, which must be supplemented. Protein catabolism should be minimized by temporarily eliminating protein from the diet and by ensuring adequate caloric intake, principally as glucose. Long-term

management depends on the specific enzyme defect.

Hyperammonemia in Older Children and Adults

Primary metabolic disease is much less likely a cause of hyperammonemia in an older child or adult than in neonates. Partial urea cycle defects (as seen in ornithine transcarbamylase [OTC] heterozygotes—i.e., women) may cause episodic hyperammonemia during periods of metabolic stress and should be considered, especially if there are affected relatives. Allopurinol loading, popular historically, has been supplanted by sequencing of urea cycle genes. Heterozygotes for OTC deficiency have impaired neuropsychological function compared to controls; impeccable metabolic control is critical in preserving neurologic function. The older child or adult with hyperammonemia usually has severe liver disease or drug-induced hyperammonemia.

Valproate-Associated Hyperammonemia

Valproate therapy is one of the most common causes of hyperammonemia in clinical neurologic practice. Malnourished patients with carnitine deficiency and those with unrecognized urea cycle and fatty acid oxidation defects seem to be at higher risk of this complication. This dose-related laboratory finding may occur without clinical symptoms. The pathogenesis is disputed but may result from inhibition of hepatic *N*-acetylglutamate synthase activity by valproyl-coenzyme A (CoA). It is unclear whether patients become symptomatic from the increased ammonia under these circumstances.

L-Carnitine supplementation can prevent the development of hyperammonemia in animals and humans receiving valproate; the clinical significance of this reduction is unclear. Some authors routinely supplement L-carnitine in patients with reduced serum carnitine levels. In severe acute valproate hepatotoxicity with hyperammonemia, a disorder with high mortality, intravenous L-carnitine has been shown to improve survival compared to oral therapy with the same agent.

P.1152

DISORDERS OF AMINO ACID METABOLISM

Introduction

Mass screening for disorders of amino acid metabolism has resulted in early biochemical diagnosis of phenylketonuria (PKU) and other aminoacidopathies. In one screening program in New South Wales, Australia, the incidence of PKU was 1:10,000 live births per year, the incidence of defects of amino acid transport was about 2:10,000 live births per year, and the combined incidence of all other aminoacidopathies was less than 8:100,000 live births per year. Although these conditions are rare, they are important because neurologic damage is potentially preventable with early treatment and because they provide information about the development and functions of the brain. PKU is described in some detail as a model for this family of disorders.

Phenylketonuria

INTRODUCTION

Phenylalanine hydroxylase deficiency is an autosomal recessive inborn error of metabolism manifested by impaired hepatic hydroxylation of phenylalanine to tyrosine. Untreated, the disorder causes a clinical picture highlighted by intellectual disability, seizures, and imperfect hair pigmentation.

The disease has been found in all parts of the world. The prevalence in the general population of the United States, as determined by screening programs, is about 1:11,700.

PATHOGENESIS AND PATHOLOGY

The hydroxylation of phenylalanine to tyrosine is an irreversible and complex reaction that requires phenylalanine hydroxylase and five other enzymes, in addition to several nonprotein components. Phenylalanine hydroxylase is normally found in liver, kidney, and pancreas but not in brain or skin fibroblasts.

In classic PKU, enzyme activity is generally less than 5% of normal. More than 40% of PKU subjects and more than 80% of those with mild PKU are tetrahydrobiopterin (BH₄) responsive when challenged with 20 mg/kg BH₄.

In some 1% to 3% of subjects, hyperphenylalaninemia results from a deficiency of BH₄. The BH₄-deficient hyperphenylalaninemias comprise a genetically heterogeneous group of disorders caused by mutations in the genes encoding enzymes involved in the synthesis or regeneration of the coenzyme BH₄. Three genetic defects in the synthesis of BH₄ have been described. These involve guanosine-5'-triphosphate (GTP) cyclohydrolase, 1,6-pyruvoyltetrahydropterin synthase and sepiapterin reductase. In addition, there are two disorders in the regeneration of the aromatic amino acid-hydroxylating system: dihydropteridine reductase and pterin-4a-carbinolamine dehydratase. All these conditions lead to hyperphenylalaninemia associated with progressive neurologic deterioration, along with a variety of dyskinesias.

Children with classic PKU are born with only slightly elevated phenylalanine blood levels, but these rise rapidly on an unrestricted diet. Phenylalanine is converted to phenylpyruvic acid, phenylacetic acid, and phenylacetylglutamine, which impart a characteristic odor to the urine.

Brain changes are nonspecific and diffuse and involve both gray and white matter; they include interference with normal maturation of the brain, defective myelination, and diminished or absent pigmentation of the substantia nigra and locus ceruleus.

SYMPTOMS AND SIGNS

PKU exhibits a wide range of clinical and biochemical severity. In the classic form, untreated infants appear normal at birth. Vomiting and irritability in the first few months is followed by cognitive delay; ultimate intellectual disability may be severe. Seizures, including epileptic spasms, usually present in the first 18 months.

Untreated children are fairer with lighter irides than unaffected sibs and may have eczema and a peculiar musty ("mousey") odor. Focal neurologic abnormalities are rare, but microcephaly, mild spastic paraparesis, and tremor may occur.

Magnetic resonance imaging (MRI) usually shows white matter signal hyperintensity on T2-weighted sequences, mainly in the posterior watershed regions.

DIAGNOSIS

Most PKU patients are identified through newborn screening. If the diagnosis of a case of classic PKU is missed, the most likely reason is laboratory error, rather than insufficient protein intake or too early testing of the infant.

Mutation analysis facilitates carrier detection and the prenatal diagnosis of PKU in families with at least one previously affected child. Newborn screening programs have also detected conditions other than PKU with neonatal hyperphenylalaninemia. Patients with moderate and mild PKU and mild hyperphenylalaninemia, as these entities are termed, have phenylalanine levels that tend to be lower than those seen in classic PKU.

TREATMENT

All infants whose blood phenylalanine concentration is greater than 10 mg/dL (600 μM/L) and whose tyrosine concentration is low or normal (i.e., 1 to 4 mg/dL) should be started on a lowphenylalanine diet immediately. Infants whose blood phenylalanine concentrations remain in the range of 6.6 to 10.0 mg/dL (400 to 600 μM/L) on an unrestricted diet are generally not treated, and on follow-up evaluations, children of this group have normal intelligence and a normal MRI.

Therapy for classic PKU is restriction of the dietary phenylalanine using one of several low-phenylalanine

formulas. Milk is added to the diet in amounts sufficient to maintain blood levels of the amino acid between 2 and 6 mg/dL (120 to 360 μ M/L). Generally, patients tolerate this diet quite well, and within 1 to 2 weeks, the serum concentration of phenylalanine becomes normal.

Weekly serum phenylalanine determinations are essential to monitor dietary adherence for life. Strict dietary control should be maintained for life, and most centers strive to keep levels below 6 mg/dL (360 μ M/L) in all patients with PKU. Dietary lapses are frequently accompanied by progressive white matter abnormalities on MRI. The addition of sapropterin (5 to 20 mg/kg/day), an orally active synthetic form of BH₄, permits a less restrictive diet for those patients who respond to a BH₄ challenge.

Phenylalaninemia caused by BH₄ deficiency requires diet, administration of BH₄ or a synthetic pterin, and replacement of neurotransmitter precursors (L-dopa/carbidopa and 5-hydroxytryptophan), whose synthesis is also impaired.

Early detection and dietary control of PKU has increased the number of homozygous PKU women achieving pregnancy. Maternal hyperphenylalaninemia causes intellectual disability, microcephaly, seizures, and congenital heart defects in affected children. During pregnancy, phenylalanine levels must be monitored as closely as during infancy because the fetus is exposed to even higher phenylalanine concentrations than the mother.

P.1153

OUTCOME

When a child with classic PKU is maintained on a low-phenylalanine diet, seizures disappear and the EEG normalizes. Abnormally blond hair regains natural color, and head growth resumes.

Cognitive effects are less clear cut. In most studies, some deficit in intellectual development has been found, even in infants who had been diagnosed and treated as neonates. This could be a consequence of prenatal brain damage induced by high phenylalanine levels in the fetus.

Although the measured IQ is normal in most, deficits have been noted in executive functioning, attention, verbal memory, verbal fluency, and expressive naming. There is no threshold below which phenylalanine has no effect on cognition. Neurologic deterioration during adult life is generally the consequence of dietary lapses.

Other Amino Acid Disorders

Several other aminoacidopathies have distinguishing features that enable the clinician to suspect the diagnosis. Maple syrup urine disease, a disorder of branched-chain amino acid metabolism, produces a characteristic odor (detectable in cerumen as well as urine) and classically presents in the first week of life with acute encephalopathy and opisthotonic posturing. Isoleucine, leucine, and valine are present in excess in the urine. Emergent diagnosis and management is necessary to preserve life and neurologic function; a few patients are thiamine-responsive. Later onset forms may also occur.

Homocystinuria is manifest as tall stature, dislocated lenses, and varying degrees of intellectual impairment; a subgroup of patients responds to therapy with cobalamin. Thromboembolic episodes may begin in infancy. Disorders of sulfur amino acids are summarized in [Table 134.2](#).

Hartnup disease is a disorder of renal tubular transport of tryptophan and other neutral amino acids; it causes intermittent ataxia with a pellagra-like rash. The disorders of amino acid transport are summarized in [Table 134.3](#).

TABLE 134.2 Disorders of Sulfur Amino Acids

Disorder	Enzyme Deficiency	Neurologic Picture
Homocystinuria	Cystathionine- β -synthase	Multiple thromboembolic episodes starting in first year of life, mental retardation, ectopia lentis
Homocystinuria and mild homocysteinemia	$\Delta^6,10$ -methylenetetrahydrofolate reductase	Seizures, microcephaly, spastic paraparesis, ataxia
Cystathioninuria	γ -Cystathionase	Asymptomatic
Homocystinuria with megaloblastic anemia	—	—
Cbl E	Methionine synthase reductase	Severe developmental delay, lethargy, staring spells, hypotonia
Cbl G	Methionine synthase	Failure to thrive, mental retardation, cerebral atrophy
Cbl C	Synthesis of methyl and adenosyl cobalamin	Marfanoid habitus, mental retardation, acute psychosis, subacute spinal cord degeneration
Cbl D	Synthesis of methyl and adenosyl cobalamin	Acute psychosis, mental retardation, subacute spinal cord degeneration, Marfanoid habitus
Cbl F	Cobalamin lysosomal release	Developmental delay, sudden death in infancy
Sulfite oxidase deficiency	Sulfite oxidase	Seizures starting in neonatal period, profound mental retardation, subluxation of lens
Molybdenum cofactor deficiency	Molybdenum cofactor deficiency	As for sulfite oxidase deficiency

Cbl, cobalamin.

ORGANIC ACIDURIAS

Progress in diagnostic techniques in the 1950s enabled the identification of a family of disorders of distal steps in intermediary metabolism marked by the accumulation of nonamino organic acids, not detectable in bodily fluids by older methods, that are preferentially excreted in the urine. These compounds are mono-, di- and tricarboxylic acids derived from the breakdown of amino acids through the intramitochondrial degradation of CoA-activated carbonic acids. They are separated from the amino acid disorders only because of the analytical methods employed in their diagnosis, not because of any fundamental biologic difference. The classic organic acidurias have a number of common clinical features, including precipitation of acute encephalopathy, acidosis and hyperammonemia, and other multisystem manifestations by an excess substrate load or metabolic stress in the form of fever or other illness. Profound brain and systemic injury follows unless rapid and effective intervention is undertaken. This usually

involves substrate restriction; suppression of aberrant pathways by providing alternate energy sources; and removal of offending metabolites by dialysis, hemofiltration, or by activating alternate pathways. The classical organic acidurias include propionic aciduria, methylmalonic aciduria, and isovaleric aciduria. The first named is associated with a poor long-term neurologic outcome, as assessed by cognitive measures and the presence of basal ganglia lesions; isovaleric aciduria with excellent outcome and methylmalonic aciduria is associated with intermediate impairment of neurologic function. Early diagnosis and tight metabolic control are necessary, but not always sufficient, to achieve the best outcome in these disorders.

Most of these diseases result from deficient activity of enzymes or their cofactors and present as neonatal encephalopathies in their most severe forms; less profound defects may present intermittently in older children. Slowly progressive disorders with predominant or exclusive neurologic manifestations are designated as cerebral organic

P.1154

acidopathies and include glutaric aciduria, type 1, L-2-hydroxyglutaric aciduria, D-2-hydroxyglutaric aciduria, and succinic semialdehyde dehydrogenase deficiency (SSADH) and Canavan disease.

TABLE 134.3 Defects in Amino Acid Transport

Transport System	Condition	Biochemical Features	Clinical Features
Basic amino acids	Cystinuria (three types) Lowe syndrome	Impaired renal clearance, defective intestinal transport of lysine, arginine, ornithine, and cystine Impaired intestinal transport of lysine and arginine, impaired tubular transport of lysine	Renal stones, no neurologic disease Severe mental retardation, congenital glaucoma, cataracts, myopathy
Acidic amino acids	Dicarboxylic aminoaciduria	Increased excretion of glutamic, aspartic acids	Severe mental retardation glaucoma, cataracts, myopathy, sex-linked transmission
Neutral amino acids	Hartnup disease	Defective intestinal and renal tubular transport of tryptophan and other neutral amino acids	Intermittent cerebellar ataxia, photosensitive rash
Proline, hydroxyproline, glycine	Iminoglycinuria	Impaired tubular transport of proline, hydroxyproline, and glycine	Harmless variant
β-Amino acids	None known	Excretion of β -aminoisobutyric acid and taurine in β -alaninemia is increased due to competition at the tubular level	Harmless variant

Glutaric aciduria, type 1, results from glutaryl-CoA dehydrogenase deficiency and manifests as macrocephaly, hypotonia, and mild motor delay; affected children can decompensate suddenly in the face of metabolic stress and

exhibit a hyperkinetic movement disorder that is refractory to most therapy. MRI shows enlarged extra-axial spaces over the frontal and temporal convexities, with widened sylvian fissures. Signal hyperintensity and eventual necrosis occurs in the striatum in untreated cases and corresponds to the presence of movement disorder. Glutaric acid and 3-methylglutaric acid are excreted in excess in the urine, as is glutaryl carnitine. Carnitine supplementation is of proven benefit in preventing neurologic progression but must be introduced before the onset of basal ganglia injury.

L-2-Hydroxyglutaric aciduria is associated with mutations in the L2HGDH gene and presents with progressive ataxia and intellectual disability in children; adult onset with similar, more slowly progressive symptoms also occurs on occasion. MRI shows a characteristic pattern that involves the basal ganglia and dentate nuclei and the subcortical, but not cerebellar, white matter. Patients with this disorder have an increased risk of primary brain tumors, attributed to the putative “oncometabolite” 2-hydroxyglutarate.

D-2-Hydroxyglutaric aciduria (D-2-HGA) is genetically and clinically heterogenous. Some patients who excrete D-hydroxyglutaric acid in the urine are asymptomatic; others exhibit facial dysmorphism, seizures, hypotonia, and developmental delay. About half of the patients have recessive mutations in D2HGDH, designated type 1 D-2-HGA. The remainder, designated type 2 D-2-HGA, harbor dominant mutations in IDH2, a gene which is mutated in some cases of acute myeloid leukemia and gliomas. A few patients have been described with combined D-and L-2-hydroxyglutaric aciduria resulting from mutations in the SLC25A1 gene. The phenotype is severe, with hypotonia, delay, and intractable seizures; it is important to recognize, as it may respond to therapy with citrate.

SSADH deficiency is a disorder of γ -aminobutyric acid (GABA) metabolism that results from mutations in ALDH5A1 and presents with hypotonia, developmental delay, and ataxia. Epilepsy, which may be difficult to control, occurs in more than half of affected children, along with movement disorders and behavioral disturbances. MRI may show hyperintensities in the basal ganglia, specifically the globus pallidus, and less frequently in the dentate nuclei, brain stem, and subcortical white matter. 4-Hydroxybutyric acid is increased in urine and CSF and may be detected by magnetic resonance (MR) spectroscopy. Treatment is symptomatic; vigabatrin (50 mg/kg/day; 500 to 1,500 mg twice daily), which inhibits the production of succinic semialdehyde, is a logical choice as an antiepileptic drug but is not always effective. Valproate (10 to 60 mg/kg/day) is relatively contraindicated but can be cautiously employed if seizures are refractory to other agents. A trial of taurine is currently in progress.

Canavan disease is a spongiform leukodystrophy in which deficient activity of aspartoacylase leads to accumulation of *N*-acetylaspartic acid (NAA) in bodily fluids and the brain. It is commonly manifest as hypotonia and progressive macrocephaly in infants, followed by loss of milestones, spasticity, seizures, and premature death. MRI shows diffuse white matter hyperintensity, and MR spectroscopy demonstrates marked elevation of NAA. The diagnosis is made by demonstrating defective aspartoacylase activity in leucocytes and corresponding mutations in the ASPA gene. Antenatal diagnosis is possible using gene sequencing. Gene therapy using an AAV2 vector has shown reduced NAA levels and evidence of clinical stabilization in an open-label study in humans with Canavan disease.

P.1155

DISORDERS OF PURINE AND PYRIMIDINE METABOLISM

Introduction

Purines and pyrimidines are heterocyclic compounds that participate in nucleotide synthesis, generation of energy compounds (i.e., adenosine diphosphate [ADP] and adenosine triphosphate [ATP]), and in signaling pathways (i.e., cyclic adenosine monophosphate [AMP]). Several disorders of purine and pyrimidine metabolism have been recognized; see [Table 134.4](#). Findings include anemia, immunodeficiency, hypo- or hyperuricemia (i.e., with nephrolithiasis and renal failure in severe cases), and a variety of neurologic phenotypes. The latter range through sensorineural hearing loss, developmental delays, intellectual disability, autism, seizures, and movement disorders. The archetype and most frequently recognized of these disorders is the Lesch-Nyhan syndrome, described in more detail in the following paragraphs.

Lesch-Nyhan Syndrome

In 1964, Lesch and Nyhan described two brothers with hyperuricemia, intellectual disability, choreoathetosis, and self-destructive biting of the lips and fingers. Most cases are boys, but at least one symptomatic female with skewed X-inactivation has been described. The trait is X-linked recessive. The basic defect is the lack of hypoxanthine-guanine phosphoribosyltransferase (HPRT). The enzyme deficiency increases the rate of purine biosynthesis, and uric acid reaches high levels in blood, urine, and CSF. Urate is deposited in the kidneys and joints and may result in nephropathy and gout.

TABLE 134.4 Disorders of Purine and Pyrimidine Metabolism

+, present (or increased for uric acid); -, absent (or decreased for uric acid); 0, unchanged; ID, immunodeficiency; MR, developmental delay, mental retardation; SNHL, sensorineural hearing loss; MD, movement disorder; NT, 5'-nucleotidase; PRPS, phosphoribosyl pyrophosphate synthetase superactivity; ADSL, adenylosuccinate lyase deficiency; AMPD1, adenosine monophosphate deaminase 1; CK, creatine kinase; ADA, adenosine deaminase deficiency; NP, nucleoside phosphorylase deficiency; XDH, xanthine dehydrogenase (= xanthine oxidase) deficiency (xanthinuria; secondary impairment in molybdenum cofactor deficiency); HPRT, hypoxanthine-guanine phosphoribosyltransferase deficiency (Lesch-Nyhan syndrome); APRT, adenosine phosphoribosyltransferase deficiency; UMPS, uridine monophosphate synthase deficiency (hereditary orotic aciduria); UMPH, uridine monophosphate hydrolase (= pyrimidine 5'-nucleotidase) deficiency; DPYD, dihydropyrimidine dehydrogenase deficiency; DPYS, dihydropyrimidinase deficiency; UP, ureidopropionase deficiency.

The neurologic manifestations include severe intellectual disability, spasticity, and choreoathetosis that start in the first year. The characteristic self-mutilating behavior appears in the second year. Death is usually caused by renal failure and may occur in the second or third decade of life. Sudden death may occur at any time because of acute respiratory failure, often related to the motor disorder. Milder variants are recognized, in which self-mutilation may be absent and manifestations may be restricted to cognitive impairment with mild motor symptoms or progressive spastic paraparesis. The pathogenesis of the cerebral symptoms is not known.

Diagnosis depends on recognition of the clinical manifestations and may be made precisely by biochemical assay of the enzyme in erythrocyte hemolysates or cultured fibroblasts. DNA analysis confirms the diagnosis and may be used for prenatal diagnosis and carrier detection; mutations can be detected in most affected individuals. More than 400 mutations have been described.

Gout is treated effectively with allopurinol, but the neurologic disorder is daunting. Restraints may be needed to prevent the child from damaging himself or herself or others; dental extraction is often required to prevent facial mutilation. Diazepam (1 to 2.5 mg by mouth three or four times daily), carbamazepine (10 to 35 mg/kg/day), gabapentin (10 to 40 mg/kg/day), and botulinum

P.1156

toxin are sometimes helpful, but physical restraint is often required in classic cases. Deep brain stimulation surgery, targeted to the globus pallidus, has improved or abolished self-mutilation in some cases. Neither enzyme replacement nor gene therapy is available for Lesch-Nyhan syndrome.

Other Purine Disorders

Neurologic abnormalities are also seen in patients who are without other enzymes of purine-nucleoside metabolism. Adenosine deaminase deficiency causes severe, combined immunodeficiency in infants; some patients have extrapyramidal or pyramidal signs and psychomotor development and may be retarded. Partial exchange transfusion

may be clinically beneficial. Also, a few patients lacking purine-nucleoside phosphorylase with impaired cellular immunity have shown a form of spastic paraparesis in childhood. 5'-Nucleotidase superactivity produces a complex phenotype with all of the features of purine and pyrimidine disorders that responds to oral uridine therapy. These patients may have autistic features that may also be prominent in phosphoribosyl pyrophosphate synthetase (PRPS), adenylosuccinate lyase (ADSL), and dihydropyrimidine dehydrogenase (DPYD) deficiencies.

PORPHYRIA

The porphyrias are a family of disorders in which the synthesis of heme and its precursors are impaired. They are traditionally divided into hepatic and erythropoietic subgroups according to the major sites of gene expression. Acute intermittent porphyria (AIP) is the most frequent of these disorders and the most likely to present to a neurologist.

AIP is an autosomal dominant disorder with low penetrance caused by deficiency of hydroxymethylbilane synthase (HMBS, also known as *porphobilinogen deaminase*), most frequently observed in Sweden and South Africa, which typically presents as an acute encephalopathy with pronounced behavioral changes (including frank psychosis) that may be accompanied by seizures, autonomic neuropathy causing abdominal pain, tachycardia and hypertension, or a painful motor neuropathy that may progress to quadriplegia with respiratory failure in severe cases. Patients may have hyponatremia as a consequence of inappropriate antidiuretic hormone (ADH) secretion. Decompensation may be provoked by fasting or by exposure to alcohol or any one of a number of drugs that interact with this pathway, including older anesthetic agents, barbiturates, and oral contraceptives; pregnancy may also precipitate an attack. Drugs appear to precipitate attacks of AIP by inducing delta-amino levulinic acid synthase, thereby leading to hepatic heme depletion, or by inhibiting the P-450 cytochrome system. Understanding these mechanisms facilitates prediction of the likely toxicity of drugs in affected individuals.

The diagnosis of AIP requires timely assay of urine porphobilinogen, with subsequent confirmation by sequencing of the HMBS gene. Acute management, which must not be delayed for definitive diagnosis, requires the removal of precipitants, careful attention to fluid and electrolyte balance, the administration of intravenous Panhematin or heme arginate to shut down the synthetic pathway, appropriate analgesia with agents such as gabapentin (10 to 40 mg/kg/day), and management of seizures with safe agents such as benzodiazepines that do not exacerbate the metabolic block.

A number of atypical presentations have been reported in AIP, including posterior reversible encephalopathy syndrome, acute cortical blindness, and progressive muscular atrophy.

Long-term management hinges on education of the patients and their medical providers to recognize and avoid situations and agents that provoke decompensation. In rare cases, liver transplantation may be indicated to manage hepatic failure or recurrent attacks when conservative management is ineffective.

Acute variegate porphyria (AVP), a dominant disorder associated with decreased activity of the mitochondrial enzyme protoporphyrinogen oxidase (PPOX), can present in a clinically indistinguishable fashion from AIP because the typical blistering rash may be absent in as many as half of affected individuals in acute crises. It is managed in the same fashion as AIP.

DISORDERS OF METAL METABOLISM

Several inherited neurologic diseases are associated with abnormal handling of metals in the brain. These may be conveniently divided into disorders of copper and iron metabolism.

Disorders of Copper Metabolism

WILSON DISEASE

Kinnier Wilson described his eponymous disease in 1912 as hepatolenticular degeneration, a disorder characterized by progressive dystonia, tremor, and psychiatric disturbances, usually beginning in adolescence, and accompanied by cirrhosis. A decade earlier, Kayser and Fleischer had reported the brown corneal rings now known to represent

the accumulation of copper in Descemet's membrane. These have proven to be an excellent gauge of excess copper stores, which regress in the face of effective copper removal, only to reappear if treatment is discontinued.

Wilson disease is caused by mutations in the transporter, encoded by the ATP7B gene that transports copper from hepatocytes to the bile and blood; its dysfunction leads to accumulation of copper in the liver, where it provokes fibrosis and eventually cirrhosis. When this store is exhausted, copper begins to deposit in the lenticular nuclei, causing extrapyramidal dysfunction and if untreated, destruction of the nuclei.

Neurologic presentations are rare in the first decade of life; Wilson disease is more likely to present in young children with acute or chronic liver failure, hemolytic anemia, or renal tubular dysfunction, reflecting the tissues in which copper is toxic. Affected adolescents have a typical appearance, in which the upper lip is drawn back to expose the teeth, accompanied by a wingbeating tremor and dystonic posturing. Spasticity, dysphagia, and dysarthria are commonly seen, and parkinsonian features are most prominent in some cases. Psychiatric manifestations are frequent and may dominate the clinical picture.

Laboratory tests may show elevated transaminases, low serum uric acid, and elevated urine copper, amino acids, and urate secondary to tubular dysfunction. Serum copper and ceruloplasmin are low. Apart from the demonstration of two mutations *in trans* in the ATP7B gene, no single test is diagnostic for Wilson disease. A diagnostic scoring system has been developed to assist the clinician; this includes presence or absence of Kayser-Fleischer rings or neurologic symptoms, serum ceruloplasmin, liver copper content, urinary copper excretion, and mutation analysis of the ATP7B gene.

Penicillamine (750 to 1,500 mg/day administered in two or three divided doses daily for adults; dosing in children is 20 mg/kg/day rounded off to the nearest 250 mg, given in two or three divided doses) is the traditional chelating agent used in Wilson disease, but its adverse effect profile has led to the employment of zinc (which impairs copper absorption) (150-mg elemental zinc/day for adults; for children, 50 mg in body weight, 75 mg/day,

P.1157

administered in three divided doses, 30 minutes before meals) and trientine (which increases urinary copper excretion) (900 to 2,700 mg/day in two or three divided doses, with 900 to 1,500 mg/day used for maintenance therapy; in children, the weight-based dose is not established, but the dose generally used is 20 mg/kg/day rounded off to the nearest 250 mg, given in two or three divided doses) as preferred treatments today. Vitamin E may have a role as an antioxidant, but no dosage regimen has been widely accepted. If copper stores can be removed before permanent tissue damage has occurred, the prognosis is excellent, provided that treatment is continued lifelong. Liver transplantation is an option in those with irreversible hepatic failure or who cannot tolerate other treatments.

MENKES DISEASE

In contrast to Wilson disease, the manifestations of Menkes disease reflect the effects of copper deficiency on the brain and other tissues. Menkes disease is caused by mutations in the X-linked ATP7A gene that encodes the protein that facilitates transport of copper from the gut to the circulation. The resultant systemic deficiency of copper leads to dysfunction of multiple enzyme systems, including cytochrome c oxidase, lysyl oxidase, and dopamine b-hydroxylase. The disease manifests in boys in the first 2 months with developmental regression; hypotonia; seizures; twisted, sparse, fair hair (often absent through easy breakage); hypothermia; and hypoglycemia. They have a cherubic appearance secondary to abnormal collagen formation, which is also responsible for the bony anomalies (metaphyseal flaring) and dilatation of the urinary collecting system and blood vessels. The latter may rupture spontaneously, leading to intracranial hemorrhage, sometimes mistakenly attributed to child abuse. Without treatment, most boys die by 3 years, although survival into the fourth decade has been reported in one treated patient with a mild phenotype.

The diagnosis is suspected clinically and confirmed by ATP7A mutation analysis. Bypassing the impaired gut absorption by administering subcutaneous copper histidine has shown benefit in morbidity and mortality, provided that treatment is instituted before permanent damage has occurred.

Females with ATP7A mutations can present when X-autosome translocation has occurred or in theory, in cases of Turner syndrome. Their clinical manifestations resemble those in boys.

Two allelic variants have been recognized in patients with ATP7A mutations. The occipital horn syndrome manifests as calcification of the insertions of the trapezius muscles, associated with joint laxity, a dilated urinary collecting system, and tortuous blood vessels, with only mild, if any, cognitive impairment. A distal motor neuropathy resembling Charcot-Marie-Tooth syndrome has also been described in adult males; it lacks any other findings in common with Menkes disease.

Disorders of Iron Metabolism

A family of rare diseases, embraced by the acronym NBIA (neurodegeneration with brain iron accumulation) has been delineated in recent years. All feature varying combinations of basal ganglia dysfunction associated with neuropsychiatric symptoms. Eight of the 10 known subtypes are autosomal recessive disorders; BPAN is X-linked dominant and neuroferritinopathy is autosomal dominant. The core disorders in this family are pantothenate kinase-associated neurodegeneration (PKAN; NBIA 1), formerly known as *Hallervorden-Spatz disease* and *PLA2G6-associated neurodegeneration* (PLAN), or NBIA 2.

PKAN or NBIA 1 is a childhood-onset neurodegenerative disorder that most often presents in the first decade with intellectual delay and progressive gait and oromandibular dystonia; more subtle disturbances of cognitive function and gait may occur with later onset forms of the disease. Saccadic eye movement disorders including vertical supranuclear gaze palsy have been described. The classic phenotype also includes retinal pigmentation, acanthocytes, and deposition of iron in the globus pallidus. This causes signal hypointensity in the globus pallidus on MRI early in the course of the disease; with progression, a central area of hyperintensity appears in the medial globus pallidus, producing the “eye of the tiger” sign. Although highly suggestive of the diagnosis, the absence of this finding does not rule out the diagnosis of PKAN, which is established by sequencing of the PANK2 gene. Although there is no definitive therapy for PKAN, small studies suggest a stabilizing effect of iron chelation using deferiprone.

NBIA 2, PARK14, or PLAN, first recognized as infantile neuroaxonal dystrophy, is associated with mutations in PLA2G6, which encodes calcium-independent phospholipase A2. The key features are the combination of ataxia, truncal hypotonia, spasticity, nystagmus, and optic atrophy with peripheral neuropathy. MRI shows cerebellar atrophy and iron deposition in the globus pallidus—without hyperintensity. Later onset forms may have a dystonia-Parkinson phenotype. Axonal spheroids are the pathologic hallmark of the disease, and their demonstration in biopsies was critical to the diagnosis before mutation analysis was available. Only symptomatic therapy is available.

DISORDERS ASSOCIATED WITH ACANTHOCYTOSIS

Acanthocytes are irregularly shaped red cells with spiny projections whose appearance reflects abnormal membrane structure. They are found in PKAN (see the following text) and in Huntington-like disorder 2 (HDL2), a triplet repeat disease affecting the gene encoding junctophilin-3, a protein involved in sarcoplasmic and plasma membranes.

Chorea-acanthocytosis is an autosomal recessive disorder in which patients experience the onset of a hyperkinetic movement disorder in early adulthood, which eventually evolves into parkinsonism. The movements are often drug resistant but may respond to deep brain stimulation. A neuropsychiatric syndrome, beginning with features of obsessive-compulsive disorder may evolve into dementia; some patients also have an axonal neuropathy and seizures. Death usually occurs within 15 years; there is no disease-modifying therapy. Patients have mutations in CHAC, the human analog of the yeast vacuolar protein sorting 13 (VPS13). The gene product, chorein, interacts with β -adducin and β -actin, membrane cytoskeletal proteins expressed at synapses and red cell membranes.

Two related disorders of lipid metabolism are also associated with acanthocytosis. Abetalipoproteinemia (Bassen-Kornzweig syndrome) is caused by mutations in the gene encoding the microsomal triglyceride transfer protein. This leads to severe diarrhea and almost complete absence of apolipoprotein B (apoB)-containing proteins in the blood,

with very low levels of cholesterol (often <40 mg/dL) and other blood lipids. Fat-soluble vitamins are correspondingly low; perhaps the most significant is vitamin E, whose deficiency causes a spinocerebellar syndrome progressive ophthalmoplegia and pigmentary retinopathy. Vitamin K deficiency may cause serious bleeding. The presence of very low serum cholesterol and acanthocytes should suggest the diagnosis, which can be confirmed by mutation analysis. Treatment with vitamin E and vitamin K is effective if begun early. Hypobetalipoproteinemia results from mutations in the apoB gene itself; the phenotype is indistinguishable from abetalipoproteinemia; the treatment is the same.

P.1158

McLeod syndrome is an X-linked disorder, originally recognized in asymptomatic individuals donating blood. They have abnormal expression of Kell blood group antigens secondary to mutations in the XK gene. A subgroup of people with this finding has a symptomatic neuromyopathy associated with elevated creatine kinase levels, hemolysis, and involuntary movements. Some also have seizures. MRI shows caudate atrophy and increased signal in the putamen. Cardiomyopathy may occur and lead to premature death. Electromyography (EMG) shows axonal degeneration and muscle biopsy may show myopathy and denervation. Complex phenotypes likely result from contiguous gene syndromes; XK is adjacent to CYBB (causing X-linked chronic granulomatous disease), DMD (Duchenne muscular dystrophy), and RPGR (X-linked retinitis pigmentosa) on the X chromosome.

LARGE MOLECULE DISORDERS

LYSOSOMAL AND ASSOCIATED LARGE MOLECULE DISORDERS

Introduction

Lysosomal diseases are characterized by the accumulation of macromolecules within lysosomes because of genetically determined deficiency of a catabolic enzyme or related gene product. The stored materials comprise complex lipids, saccharides, or proteins, and the central nervous system (CNS) is usually affected. Both autosomal and X-linked inheritance occur. Carrier detection and prenatal diagnosis are available for most of these disorders. Specific treatment in the form of enzyme replacement therapy (ERT) for mucopolysaccharidosis (MPS) I, II, and VI; Gaucher, Fabry, and Pompe disease; substrate reduction therapy for Gaucher disease; and hemopoietic stem cell transplantation for several lysosomal storage diseases has now entered practice, albeit with varying evidence of efficacy.

Lipidoses

Lipid storage diseases involve all three major lipid classes: neutral lipids (i.e., cholesterol ester, fatty acid, and triglycerides), polar lipids (i.e., glycolipids and phospholipids), and very polar lipids (i.e., gangliosides).

GM2-GANGLIOSIDOSES

Hexosaminidase-deficiency diseases result from a genetically determined deficiency of the enzyme hexosaminidase, which causes accumulation in cells (especially in neurons) of GM2-ganglioside and other glycosphingolipids.

For full activity, hexosaminidase requires two different subunits: the α -subunit, coded for by the hexosaminidase A locus on chromosome 15, and the β -subunit, coded for by the hexosaminidase B locus on chromosome 5. Three isozymes of hexosaminidase have a defined subunit structure: hexosaminidase A ($\alpha\beta$), hexosaminidase B ($\beta\beta$), and hexosaminidase S ($\alpha\alpha$). Hexosaminidase A is required for cleavage of GM2-ganglioside, but the true substrate is the ganglioside bound to a protein activator whose deficiency also causes a GM2-gangliosidosis (the so-called AB variant). The GM2-gangliosidoses are classified according to the phenotype, the genetic locus, and the allele involved.

Progressive infantile encephalopathy was the most common clinical pattern in the past. The success of carrier screening in the Ashkenazi Jewish community dramatically reduced its incidence, and later onset variants are now seen more commonly. Hexosaminidase deficiencies show diverse phenotypes from infancy to adulthood. This

diagnosis can be suspected with nearly any degenerative neurologic disorder, except demyelinating neuropathy or myopathy. Sensory dysfunction, ocular palsies, neurogenic bladder, and extraneural involvement are not prominent features.

The diagnosis is made by assaying hexosaminidase activity in blood serum and leukocytes and by sequencing the hexosaminidase genes.

Infantile Encephalopathy with Cherry-red Spots

Three disorders in this group are well known: classic infantile Tay-Sachs disease (α -locus), infantile Sandhoff disease (β -locus), and the so-called AB variant (activator locus). Heterozygosity for α -locus mutations occurs in 1 in 30 Ashkenazi Jews (compared with 1 in 300 for the general population), accounting for the ethnic concentration of classic Tay-Sachs disease and genetic compounds containing α -locus mutations.

In all three conditions, the infants appear normal until 4 to 6 months of age. They learn to smile and reach for objects but do not sit or crawl. A myoclonic jerk reaction to sound (traditionally, but misleadingly, termed *hyperacusis*) and the macular cherry-red spot are constant findings. The cherry-red macular spot is a fundoscopic finding reflecting a combination of foveal atrophy and perifoveal lipid accumulation. The former improves visualization of the underlying choroid (whose color may range from bright red to brown in different individuals), which is contrasted with the more opaque surrounding lipid-laden retinal tissue. Cherry-red spots may be seen in GM2 and GM1 gangliosidoses, Niemann-Pick disease types A and B (but not in C), and sialidosis type 1 (cherry-red spot myoclonus syndrome) and has been occasionally reported in Krabbe disease.

Affected infants become floppy and weak but have hyperactive reflexes, clonus, and extensor plantar responses. Visual deterioration, apathy, and loss of developmental milestones lead to a vegetative state by the second year. Seizures and myoclonus are prominent for the first 2 years. The infants eventually become decorticate. They need tube feeding, have difficulty with secretions, and are blind. Head circumference enlarges progressively to about the 90th percentile, from ages 1 to 3 years, and then stabilizes. Death is due to intercurrent infection, usually pneumonia. The disease is confined to the nervous system, apart from variable hepatosplenomegaly in Sandhoff disease.

By light microscopy, grossly ballooned neurons are found throughout the brain, cerebellum, and spinal cord. By electron microscopy, membranous cytoplasmic bodies (i.e., distended lysosomes) are seen, with regularly spaced, concentric, dark, and pale lamellae.

GM2-ganglioside content is markedly increased in the brain and to a much lesser degree, in the viscera. Other glycosphingolipids such as asialo-GM2 and globoside accumulate to a lesser degree.

The storage results from the deficiency of hexosaminidase. In classic Tay-Sachs disease, hexosaminidase A is absent, and hexosaminidase B increased. Heterozygous carriers have a partial decrease of hexosaminidase A.

In infantile Sandhoff disease, hexosaminidases A and B are deficient. Carriers have partially decreased hexosaminidases A and B. In one form of the AB variant, a hexosaminidase A-activating protein is missing. Although levels of hexosaminidases A and B are increased, GM2-ganglioside cannot be cleaved. Diagnosis requires the use of the natural substrate, GM2-ganglioside, or direct testing for the activator or activator mutations. In a second form of the

P.1159

AB variant, the residual hexosaminidase A cleaves artificial but not sulfated-artificial or natural substrate. Although this is detected as an AB variant, it is an α -locus disorder.

Late-Infantile, Juvenile, and Adult GM2-Gangliosidoses

These present with dementia and ataxia with or without macular cherry-red spots. Spasticity, muscle wasting stemming from anterior horn cell disease, and seizures are frequently seen. Hexosaminidase A deficiency or hexosaminidases A and B deficiency are found on biochemical study of serum, leukocytes, and cultured skin

fibroblasts.

Other late-onset forms of GM2-gangliosidosis present as cerebellar ataxia or spinocerebellar ataxia.

Hexosaminidase A or hexosaminidases A and B deficiency are found on biochemical study.

Motor neuron disease resembling spinal muscular atrophy type III may be the first evidence of late-onset GM2-gangliosidosis. Upper motor neuron findings may also be present, giving an amyotrophic lateral sclerosis-like phenotype.

Many, perhaps most, of these late-onset cases are compound heterozygotes. Diagnosis requires both enzyme assay and DNA sequencing.

GM1-GANGLIOSIDOSIS

This group of disorders is characterized by the deficiency of GM1-ganglioside β -galactosidase and storage of GM1-ganglioside, asialo-GM1, keratan sulfate-like oligosaccharides, and glycoproteins. Other β -galactosidases such as those that cleave galactosylceramide and lactosylceramide are not deficient, and these compounds do not accumulate. There are at least three forms of deficiency of this enzyme: primary deficiency of β -galactosidase, causing infantile and late-infantile GM1-gangliosidosis and an adult form; combined neuraminidase and β -galactosidase deficiency, galactosialidosis; and combined deficiency of β -galactosidase and several other lysosomal enzymes in I cell disease, mucopolipidosis II (ML II). The latter two types are discussed under MLs.

Infantile GM1-Gangliosidosis

Infantile GM1-gangliosidosis is earlier in onset, more severe, and more rapidly progressive than infantile Tay-Sachs disease. Soon after birth, these infants become hypotonic, with poor sucking ability and slow weight gain. They have frontal bossing, coarsened features, large low-set ears, and an elongated philtrum. Gum hypertrophy, macroglossia, peripheral edema, and often faint corneal haze are noted. Strabismus and nystagmus may be seen. About half the patients develop macular cherry-red spots. Development is slow, and they do not sit or crawl. By the age of 6 months, liver and spleen are enlarged; joint stiffness and claw-hand deformities may be seen, and the skin is thickened. Seizures may develop. Infants typically die before age 2 years of pneumonia or cardiac arrhythmias.

MRI of the brain may be normal initially, but as the head grows rapidly, diffuse signal hyperintensity appears throughout the white matter (Fig. 134.1). X-rays show changes similar to those of Hurler syndrome after 6 to 12 months, with anterior beaking of vertebral bodies and a J-shaped sella turcica. Peripheral blood smears show vacuolated lymphocytes, and foamy histiocytes are found in the bone marrow.

Diagnosis is suggested by the characteristic oligosaccharide pattern in urine and confirmed by assay of GM1-ganglioside β -galactosidase in blood leukocytes or cultured skin fibroblasts and mutation analysis.

FIGURE 134.1 Sagittal T2-weighted MRI of an infant with GM1-gangliosidosis showing macrocephaly and signal hyperintensity throughout the white matter.

Late-Infantile GM1-Gangliosidosis

Symptoms begin between ages 1 and 3 years, with gait ataxia, hypotonia, hyperreflexia, dysarthria, and speech regression. Seizures, dementia, and spastic quadriplegia lead to death, usually by pneumonia. Optic atrophy and evidence of anterior horn cell disease may be found. Corneas are clear, organomegaly is absent, and bone changes are scanty.

FABRY DISEASE

Fabry disease is an X-linked disorder in which the skin, kidney, peripheral and autonomic nervous systems, and blood vessels store trihexosylceramide, a breakdown product of globoside. Trihexosylceramide accumulates because of a deficiency of β -galactosidase A. Recent studies have found that female heterozygotes are frequently clinically affected, albeit less severely and later than hemizygotes.

Symptoms usually commence in childhood or adolescence, with lancinating pains in the limbs, especially the feet and hands, often brought on by temperature changes and accompanied by paresthesia or abdominal crises. Anhidrosis and unexplained fever are common.

Angiokeratomas, which become more numerous with age, are purple; macular and maculopapular; hyperkeratotic; 1 to 3 mm in size; and with a predilection for the groin, buttocks, scrotum, and umbilicus. Glycolipid storage in the renal

glomeruli and tubules begins with asymptomatic proteinuria in children; it progresses to renal failure and hypertension in the third or fourth decade. Glycolipid storage in blood vessel walls may cause stroke. Edema of the limbs, whorled corneal clouding (cornea verticillata) visible by slit lamp, and myocardial involvement may occur. ERT has been demonstrated to reverse lipid storage in the kidney, heart, and blood vessels and to produce corresponding improvement or reversal of renal impairment, pain, cardiac function, and cerebral

P.1160

blood flow. In some cases, renal transplant may still be required when renal failure supervenes. The lancinating pains may respond to phenytoin (5 to 8 mg/kg/day), carbamazepine (10 to 35 mg/kg/day), or gabapentin (10 to 40 mg/kg/day).

Heterozygous women may also be affected, but manifestations are less marked. Skin lesions are few or absent. Corneal opacity is more common. If renal or cardiac involvement occurs, they are later in onset and less severe. Fabry disease is diagnosed by finding decreased β -galactosidase activity in plasma and leukocytes and a mutation in the β -galactosidase gene.

GAUCHER DISEASE

Gaucher disease is an autosomal recessive sphingolipidosis in which glucocerebroside is stored as a result of deficiency of glucocerebroside β -glucosidase (or glucocerebrosidase). At least four forms have been described: the infantile neuronopathic form, the juvenile neuronopathic form, the adult neuronopathic form, and the adult nonneuronopathic form.

These distinctions seem to be artificial, with overlapping manifestations occurring across a broad spectrum of phenotypes. The adult (nonneuropathic) form (type I) is more common in Ashkenazi Jews than in the general population. Diagnosis of all forms is made by demonstrating reduced glucocerebroside β -glucosidase activity in cultured skin fibroblasts or blood leukocytes and is further refined by demonstrating mutations in the β -glucosidase gene.

Type II (Infantile Neuronopathic) Gaucher Disease

This disease occurs in the first year of life, often in the first 3 months. The course is rapid, with developmental regression and death before age 2 years. Affected infants lose weight, reflecting the mechanical compression of the gut and the hypercatabolic state associated with pronounced hepatosplenomegaly. The neurologic signs reflect severe brain stem dysfunction and include stridor, difficulty in sucking and swallowing, strabismus, retrocollis, spasticity, and hyperreflexia. Bilateral esotropia is typical. Later, they enter a vegetative state, becoming flaccid and weak. Seizures may occur. Macular cherry-red spots and optic atrophy do not occur.

Type III (Juvenile Neuronopathic) Gaucher Disease

The manifestations range from a severe form, presenting in infancy as pulmonary infiltrates, splenomegaly, and cardiorespiratory failure, to a progressive myoclonic dementia in adolescents or adults (common in the northern provinces of Norrbotten and Västerbotten in Sweden). Horizontal supranuclear gaze palsy, with characteristic looping movements, in which the inability to generate horizontal saccades is partially compensated by generating vertical saccades accompanied by a horizontal head thrust, is an important clue to the diagnosis.

Type I (Adult) Gaucher Disease

These patients have visceral (e.g., liver, lymph nodes, lung) and skeletal manifestations without primary neurologic disease. Multiple myeloma may be a late complication. It is most common in Ashkenazi Jews. Type 1 Gaucher disease presents at any age from infancy to the seventh decade. Splenectomy should be avoided unless ERT is not possible or the mechanical and hematologic manifestations are not otherwise controlled. Lesions of long bones, pelvis, or vertebral bodies may be painful. Severe cases may require surgical intervention, including joint replacement. ERT, with purified modified β -glucosidase (i.e., alglucerase) or recombinant β -glucosidase (i.e., imiglucerase), reverses all of the manifestations of type 1 Gaucher disease, provided that treatment begins before

severe tissue damage has occurred.

Adult Neuronopathic Gaucher Disease

Parkinsonism has been found to be more frequent in several studies of adults with Gaucher disease and in heterozygotes for glucocerebrosidase mutations. The relation now appears well established; the mechanism remains uncertain, and nonspecific lysosomal dysfunction may play a role in several neurodegenerative diseases, including parkinsonism.

NIEMANN-PICK DISEASE

This group of disorders includes several diseases that were grouped together in 1958 by Crocker and Farber on the basis of the overlapping pathology (i.e., visceral foam cells) and biochemistry (i.e., lysosomal storage of the glycosphingolipid sphingomyelin). Crocker subsequently proposed four groups. It is now recognized that his groups A and B are primary sphingomyelinase deficiencies, whereas groups C and D are allelic disorders, whose primary defect is not deficiency of a lysosomal hydrolase but in intracellular lipid trafficking. Patients with types A and B Niemann-Pick disease have deficient activity of the sphingomyelin-cleaving enzyme acid, sphingomyelinase. The diagnosis should be suspected in patients with progressive hepatosplenomegaly, with or without cerebral symptoms. The bone marrow contains characteristic mulberry storage cells (i.e., distinct from Gaucher cells). Decreased sphingomyelinase activity may be shown in cultured skin fibroblasts, leukocytes, or tissue.

Infantile Niemann-Pick Disease, Type A

This is the most severe form of Niemann-Pick disease and occurs more commonly in Ashkenazi Jews than in the general population. Transient neonatal jaundice is followed by progressive hepatosplenomegaly; developmental regression and weight loss lead to dementia, hypotonia, and death by age 2 years. About one-half of patients develop macular cherry-red spots. Seizures are uncommon. Bone involvement is mild. Skin often has a brownish-yellow tinge. Most patients have diffuse haziness or patchy infiltrates in the lungs.

Diagnosis is made by the characteristic clinical picture, by demonstration of near-total deficiency of sphingomyelinase in leukocytes or cultured skin fibroblasts, and/or by demonstrating mutations in the acid sphingomyelinase gene.

Juvenile Nonneuronopathic, Type B

This form presents with asymptomatic splenomegaly or hepatosplenomegaly without neurologic disorder in infants, children, or adults, although cherry-red spots may be found. These patients have more residual sphingomyelinase (i.e., 15% to 20% of normal) than those with type A (i.e., up to 10%). ERT is currently in clinical trials for Niemann-Pick disease, type B.

Niemann-Pick Disease, Type C

Niemann-Pick disease, type C (NPC), may arise at any age from fetal life (i.e., with ascites) to the fifth or sixth decades. Early-onset disease is dominated by hepatic and pulmonary failure, which are usually lethal in infancy. Classic childhood-onset disease more often presents insidiously with school failure and clumsiness that evolve into a progressive syndrome of ataxia, dystonia, and dementia. Vertical supranuclear gaze palsy is characteristic and almost invariably presents early, although often unrecognized. About 50%

P.1161

of patients have seizures, and 20% experience gelastic cataplexy. Hepatosplenomegaly is variable, and its absence does not rule out NPC. Genetic isolates have been described in Nova Scotia (i.e., formerly Niemann-Pick disease, type D) and in Hispanics in Colorado and New Mexico.

Most patients with NPC are compound heterozygotes for mutations in NPC1; the gene product is a large transmembrane protein localized to the late endosomal-lysosomal pathway. Dysfunction of this protein is associated with impaired trafficking of large molecules in this pathway, with accumulation of glycolipids, sphingomyelin, and

cholesterol in lysosomes. The diagnosis rests on demonstration of this defect. Direct DNA analysis can be used as a first-line diagnostic test, but false negatives occur owing to the size of the gene and the large number of mutations (more than 300 recognized to date). The standard biochemical test requires demonstration of accumulation of free cholesterol in lysosomes, which is identified by filipin staining. This is an indirect index of the functional defect, with a significant number of variant cases with results that may be difficult to distinguish from heterozygotes. Assay of 3- β , 5- α , 6- β -cholestane triol in blood is a sensitive and specific marker of NPC and is likely to enter clinical practice as a first-line diagnostic test within the lifetime of this text. There is no approved therapy for NPC in the United States, although miglustat has been approved for management of its neurologic manifestations in the European Union and several other countries. Clinical trials are planned or underway for intrathecal cyclodextrin, oral vorinostat, and oral arimoclomol in NPC.

A small number of cases of NPC are associated with mutations in a second gene, *NPC2*, whose gene product is a soluble, lysosomal protein. Recent studies suggest that NPC2 interacts with NPC1 either through transfer of unesterified cholesterol, responding to oxysterol signals, or some combination of both. Hematopoietic stem cell transplantation may be helpful in this disorder.

FARBER DISEASE

Farber disease is caused by deficiency of acid ceramidase. Infants with this disease have profound reduction of enzyme activity and present with painful swollen joints, hoarseness, vomiting, respiratory difficulty, or limb edema in the first few months of life, sometimes as early as 2 weeks of age. Most patients die of pulmonary disease before age 2 years, but some survive into adolescence. Hematopoietic stem cell transplantation has produced improvement in several findings. Children with higher residual acid ceramidase activity (>10%) may present with a spinal muscular atrophyprogressive myoclonic epilepsy phenotype, distinct from that associated with *SMN1* mutations.

CEREBROTENDINOUS XANTHOMATOSIS (CHOLESTANOL STORAGE DISEASE)

Patients with cerebrotendinous xanthomatosis (CTX) often have early cognitive impairment, but cataracts, tendon xanthomas, and progressive spasticity, usually associated with ataxia, commonly do not begin before adolescence or young adulthood. The spasticity and ataxia are severe and progressive. Speech is affected. Neuropathy may appear with distal muscle wasting. Sensory deficits and Babinski signs are seen. Pseudobulbar palsy develops terminally. Death from neurologic disease or myocardial infarction usually occurs in the fourth to sixth decade. Some patients have apparently normal mental function.

Tendon xanthomas are almost always seen on the Achilles tendon and may occur elsewhere. The cerebellar hemispheres contain large (i.e., up to 1.5 cm) granulomatous xanthomas with extensive demyelination. The brain stem and spinal cord may be involved.

Diagnosis is based on demonstration of elevated blood cholestanol levels and mutations in the sterol 27-hydroxylase gene (*CYP27*). Treatment with chenodeoxycholic acid may be beneficial.

Mucopolysaccharidoses

The MPS are defined by a characteristic phenotype and by the tissue storage and urinary excretion of acid mucopolysaccharide. They were originally considered a single disease, but eight clinical types, and numerous subtypes, are now known. Each is caused by deficiency of a lysosomal hydrolase required for degradation of one or more of three sulfated mucopolysaccharides: dermatan sulfate, heparan sulfate, and keratan sulfate.

Diagnosis is suspected based on the clinical picture, the presence of excessive amounts of one or more acid mucopolysaccharides in urine, and is confirmed by demonstrating a specific enzyme defect. Urine screening tests for excess mucopolysaccharides are useful but are subject to false-positive and false-negative results. Positive screening tests require confirmation by quantitative and qualitative determination of urinary mucopolysaccharides and demonstration of the enzyme defect. False negatives are relatively frequent in Sanfilippo and Morquio syndromes. If clinical suspicion for an MPS is high, diagnostic evaluation should be pursued, despite a negative

urine screening test. Prenatal diagnosis of these disorders is available.

HURLER SYNDROME (MUCOPOLYSACCHARIDOSIS I)

This is the most severe of the MPS and is characterized by onset in infancy, progressive disability, and death usually occurring before 10 years of age. Nearly all the features found in other types are present in Hurler syndrome.

Corneal clouding and lumbar gibbus occur in the first year of life, followed by stiff joints with periarticular swelling; short, stubby hands and feet; claw hands; lumbar lordosis; chest deformity; and dwarfing by 2 or 3 years of age. The facies are characteristic, with thickened eyelids and lips; frontal bossing; bushy eyebrows; a depressed nasal bridge; ocular hypertelorism; enlarged tongue; noisy breathing; rhinorrhea; and widely spaced, peg-like teeth. Psychomotor slowing is followed by dementia, but seizures are not typical. Deafness is frequent, and few patients develop speech. Leptomeningeal thickening, arachnoid cysts, and hydrocephalus may occur. Cardiac murmurs resulting from valvular heart disease, coronary occlusion, and cardiac enlargement may occur and cause death. Abdominal distention is common, with inguinal and umbilical hernias and hepatomegaly. Corneal clouding progresses and with retinal degeneration impairs vision. Cervical cord compression with quadriplegia may occur.

Radiographic changes support the diagnosis of MPS but do not reliably distinguish the various types. Findings include ovoid or beaked lumbar vertebrae, peg-shaped metacarpals, a J-shaped sella turcica, and spatulate ribs. Peripheral leukocytes and bone marrow cells contain metachromatic granules. Clear vacuoles are seen in hepatocytes and other cells. Zebra bodies containing lipids occur in the brain. Both dermatan sulfate and heparan sulfate are stored. The diagnosis is made by demonstrating severe deficiency of α -L-iduronidase in cultured skin fibroblasts and leukocytes. Mutation analysis of the α -L-iduronidase gene confirms the diagnosis and permits prenatal diagnosis.

Scheie syndrome (MPS IS), a milder allelic variant of Hurler syndrome, is characterized by juvenile onset of joint stiffness with the development of claw hands and deformed feet. A phenotype intermediate between that of the Hurler and Scheie syndromes is referred to as the *Hurler-Scheie compound* (MPS I HS).

P.1162

HUNTER SYNDROME (MUCOPOLYSACCHARIDOSIS II)

Hunter syndrome includes mild and severe forms. Both are X-linked recessive and show iduronate-2-sulfatase deficiency. A Hunter-like phenocopy in girls with iduronate-2-sulfatase deficiency occurs in the context of total sulfatase deficiency (metachromatic leukodystrophy [MLD], Austin type).

Boys with the severe form experience juvenile-onset joint stiffness, typical facial features (Fig. 134.2), dysostosis multiplex, hepatosplenomegaly, diarrhea, dwarfing, and mental deterioration. Progressive deafness is prominent. Pigmentary retinal deterioration, papilledema, and hydrocephalus may be seen. Nodular or pebbled-skin change over the scapulae and absence of corneal clouding are important features distinguishing Hunter syndrome from Hurler syndrome. Patients usually die as teenagers.

Patients with the mild form of Hunter syndrome may be asymptomatic or have only mild systemic findings

SANFILIPPO SYNDROME (MUCOPOLYSACCHARIDOSIS III)

Patients with this syndrome outnumber all other forms of MPS combined. They exhibit progressive cognitive impairment, mild somatic involvement, and urinary excretion of heparan sulfate alone. Four biochemically distinct forms reflect four metabolic steps required for the degradation of heparan sulfate but not dermatan sulfate or keratan sulfate. Sanfilippo patients have juvenile-onset dementia, with delay or deterioration of speech or school performance. Children presenting with psychiatric disorder, intellectual disability, or dementia should be carefully examined for mild coarsening of facial features, hepatosplenomegaly, hirsutism, joint stiffness, and radiographic changes of dysostosis multiplex. These patients deteriorate neurologically, with progressive dementia, spastic quadriplegia, tetraparesis, athetosis, incontinence, and seizures. Cardiac involvement may occur. Corneal clouding is absent. Bone changes, dwarfing, and organ enlargement are slight. Patients may die in adolescence or survive

into the third decade of life.

The diagnosis is made by the characteristic clinical picture, excess heparan sulfaturia, demonstration of the specific enzyme defect, and mutations analysis. Screening tests for mucopolysacchariduria may be negative in Sanfilippo syndrome.

Mucopolidoses

The MLs resemble the Hurler phenotype but lack excess urinary mucopolysaccharide, having instead, excess urinary oligosaccharides or glycopeptides, most of which are fragments of more complex structures. Urinary thin-layer chromatography for oligosaccharides is a useful screening test.

SIALIDOSIS (MUCOLIPIDOSIS I)

Patients with sialidoses have deficiency of α -L-neuraminidase, also known as *sialidase*. In most forms, sialic acid-containing glycoproteins, oligosaccharides, and glycolipids accumulate in tissue, and sialyloligosaccharides are excreted in urine.

The diagnosis is based on clinical findings, the presence of abnormal sialyloligosaccharides in the urine, and deficiency of the appropriate sialidase in cultured skin fibroblasts, tissue, or leukocytes. There are at least two distinct lysosomal sialidases.

In addition to the isolated sialidase deficiencies, two other groups of MLs have sialidase deficiency. In one, galactosialidosis, both sialidase and β -galactosidase are deficient because a stabilizing protein they share is defective. In the second group, ML II and ML III, sialidase and several other lysosomal hydrolases are deficient owing to deficient activity of the phosphotransferase that is responsible for creating the mannose-6-phosphate motif that targets enzymes to the lysosome.

FIGURE 134.2 Mucopolysaccharidosis type II (Hunter syndrome); note periorbital fullness, increased tissue thickness of the lips and cheeks, and hearing aid.

Sialidoses with isolated sialidase deficiency have a highly variable clinical picture. Neonates with congenital sialidoses have hydrops fetalis, hepatosplenomegaly, and short survival times. Infants with nephrosialidosis resemble the Hurler phenotype and develop macular cherry-red spots and renal disease. Children with ML I (i.e., lipomucopolysaccharidosis), a milder disorder, are similarly affected but develop ataxia, myoclonic jerks, and seizures. The mildest form is the cherry-red spot myoclonus disorder, in which adolescents, who are usually mentally normal, develop macular cherry-red spots, myoclonus, and myoclonic seizures. There is a predilection for individuals of Italian descent.

MUCOLIPIDOSES II AND III

ML II, or I cell disease, and ML III, or pseudo-Hurler polydystrophy, are allelic disorders associated with deficiency of the enzyme, glycoprotein *N*-acetylglucosaminyl phosphotransferase, whose activity is required for mannose-6-phosphate targeting of glycoproteins, including many lysosomal hydrolases, to the lysosome.

ML II is a severe disorder that resembles Hurler syndrome without corneal clouding. Cultured fibroblasts contain coarse inclusions (I cells). Diagnosis is made by finding excess sialooligosaccharides in the urine and deficiencies of multiple lysosomal enzymes in cultured skin fibroblasts, with elevated levels of these enzymes in plasma. In brain and viscera, only β -galactosidase is consistently deficient.

ML III is a milder clinical disorder than ML II that may present with joint stiffness, carpal tunnel syndrome, or mild

intellectual impairment.

MUCOLIPIDOSIS IV

Patients with ML IV present with corneal clouding as early as 6 weeks of age. Mild retardation progresses to severe mental and

P.1163

motor defect. The disease occurs almost exclusively in Ashkenazi Jews. Achlorhydria is universal, and measurement of elevated serum gastrin levels is a convenient and reliable screening test for ML IV. Diagnosis may now be made by mutation analysis of the MCOLN 1 gene, which codes for mucolipin, a protein that may function in cation channels and in membrane trafficking in the endosomal-lysosomal system.

Neuronal Ceroid Lipofuscinoses

The neuronal ceroid lipofuscinoses (NCLs) are a family of lysosomal diseases characterized by varying degrees of progressive dementia, epilepsy, and visual impairment associated with retinal pigmentation and profound cortical atrophy. They were previously defined by histologic and ultrastructural features and a plethora of confusing and inconsistently applied eponyms, but are now classified according to genotypes. The common pathologic features include neurons engorged with periodic acid-Schiff (PAS)-positive and autofluorescent material on light microscopy and typical profiles, including granular osmiophilic deposits, curvilinear and fingerprint bodies (or combinations of these), on electron microscopy. Although the signs and symptoms are confined to the nervous system, the abnormal cytosomes are widely distributed in skin, muscle, peripheral nerves, leukocytes, urine sediment, and viscera.

Thirteen genes have been associated with 14 NCL loci; the gene associated with one locus (CLN9) has not yet been identified. All are autosomal recessive, except for the Parry form of adult NCL, which is associated with dominant mutations in DNAJC5. Some phenotypes may be associated with mutations in several genes (such as adult NCL, associated with mutations in CTSD, PPT1, CLN3, CLN5, CLN6, CTSF, and GRN) and some genes may cause several different phenotypes, such as PPT1, which is associated with infantile, late-infantile, and juvenile NCL.

The diagnosis of PPT1-, TPP1-, and CTSD-deficient forms of NCL may be made by enzyme assay and confirmed by mutational analysis. A database listing NCL mutations is available online at <http://www.ucl.ac.uk/ncl/mutation.shtml>.

Supporting investigations include an abnormal electroretinogram in the infantile, late-infantile, and juvenile forms and electron microscopic examination of tissue (i.e., skin, nerve, muscle, or rectal biopsy for autonomic neurons).

Abnormal autofluorescence is seen on examination of frozen section of biopsied muscle, enabling rapid diagnosis.

The most frequent phenotypes are late infantile (NCL2) and juvenile (NCL3). The former presents between 2 and 4 years with seizures, associated with developmental regression, ataxia, myoclonus, and spasticity. Retinal degeneration occurs later in the course and eventually leads to blindness.

Juvenile NCL begins in the latter half of the first decade with progressive loss of vision and later onset of epilepsy. Patients may survive into the fourth decade.

Leukodystrophies

The leukodystrophies are progressive, genetic metabolic disorders causing dysmyelination, in contrast to leukoencephalopathies that are often acquired.

Disorders such as Krabbe disease, MLD, adrenoleukodystrophy (ALD) (discussed with other peroxisomal disorders), Alexander disease, and classic Pelizaeus-Merzbacher disease were defined by traditional clinical and pathologic investigations. Careful clinical and MR phenotyping combined with molecular biology have led to the identification of a variety of additional leukodystrophies, including childhood ataxia with central hypomyelination or CACH (also known as *vanishing white matter disease*), and megalencephalic leukoencephalopathy with subcortical cysts (MLC), hypomyelination of the basal ganglia and cerebellum (H-ABC), oculodentodigital dysplasia (ODDD), and leukoencephalopathy involving the brain stem and spinal cord with lactate elevation (LBSL). This leaves a

heterogeneous, but shrinking group, of unclassified leukodystrophies, sometimes called *orthochromatic* or *sudanophilic leukodystrophies*. Diffuse sclerosis (Schilder disease) is included in this chapter, although it resembles multiple sclerosis more than traditional leukodystrophies.

METACHROMATIC LEUKODYSTROPHY

MLD is a group of autosomal recessive disorders with degeneration of central and peripheral myelin, striking metachromasia of the stored substances, primarily sulfatides, and deficiency of the sulfatide-cleaving enzyme, sulfatase A, also called *aryl sulfatase A*. Late-infantile-onset disease is most common.

The diagnosis of MLD is complicated by the existence of sulfatase A pseudodeficiency, an autosomal recessive condition in which sulfatase A activity is greatly diminished by the usual enzyme assays, but there is no neurologic disease. An additional complication is the requirement of sulfatase A for the sulfatide-activator protein. Patients with genetic deficiency of sulfatide-activator protein may have MLD, but the commonly used enzyme assays may fail to diagnose normal.

Late-Infantile Metachromatic Leukodystrophy

Affected infants have onset of difficulty in walking after the first year of life, usually between ages 12 and 30 months. Flaccid paresis and diminished, or absent, tendon reflexes are typical, but occasionally, spastic paresis develops. Genu recurvatum, hyperextension of the knee, may be noted. Progressive dementia and dysarthria follow.

Peripheral neuropathy leads to loss of tendon reflexes and may be accompanied by limb pain. Later, patients become bedridden and quadriplegic, with feeding difficulties, bulbar and pseudobulbar palsies, and optic atrophy. Children so affected usually die in the first decade of life, blind and in a vegetative state. Investigations show increased CSF protein content, impaired gallbladder function, metachromatic lipids on sural nerve biopsy, and increased urinary-sulfatide excretion.

Sulfatide accumulates in brain, peripheral nerves, and some extraneural tissues (e.g., kidney). Sulfatide causes brown metachromasia, with acetic acid-cresyl violet staining in glial cells, Schwann cells, myelin lamellae, and neurons. Characteristic “tuffstone” bodies are seen by electron microscopy.

The diagnosis is based primarily on enzyme analysis, supported by ARSA gene sequencing.

Late-onset Metachromatic Leukodystrophy

Juvenile MLD patients resemble those with late-infantile MLD but for the later onset of symptoms (i.e., usually ages 3 to 10 years) and slower progression of the disease. Emotional disturbance and dementia are more common presentations, although gait disorder may be the initial symptom. Nystagmus and tremor may be noted. Nerve conduction velocities are slowed and CSF protein concentrations are elevated. The diagnosis can usually be suspected from MRI of the brain, which shows diffuse, confluent

P.1164

signal hyperintensity in the white matter of the centra semiovale, with a striated “tigroid” appearance (Fig. 134.3).

FIGURE 134.3 Axial T2-weighted MRI of an 18-year-old with metachromatic leukodystrophy, illustrating the characteristic “tigroid” appearance of the white matter.

MLD commonly starts in adults in the third or fourth decade as a psychiatric disorder (mimicking schizophrenia) or progressive dementia. Other findings may include truncal ataxia, hyperactive reflexes, and seizures. Both psychiatric and motor manifestations may coexist in association with certain mutations. CSF protein concentration is usually not elevated. The illness runs a protracted course, averaging 15 years.

KRABBE (GLOBOID CELL) LEUKODYSTROPHY

Patients are normal at birth but may have subtle findings such as fistling in the first few weeks. At 3 to 6 months, irritability, inexplicable crying, fevers, rigidity, seizures, feeding difficulty, vomiting, and slowing of mental and motor development occur. Later, psychomotor regression occurs, accompanied by increasing tone and extensor posturing. Reflexes may be increased before being lost. Optic atrophy is frequent. Patients may develop flaccidity or flexor postures before death, at about 2 years of age.

CSF protein is increased and nerve conduction velocities are slowed. Galactocerebrosidase activity is deficient in serum, leukocytes, and cultured skin fibroblasts. Psychosine, a substrate for this enzyme, is increased at least 200-fold over levels in the normal brain. Psychosine toxicity is probably the cause of the disease, based on studies showing its ability to produce characteristic lesions in animal models.

A few patients with juvenile-onset and slower progression of dementia, optic atrophy, and pyramidal tract signs,

without neuropathy, have had galactocerebrosidase deficiency. An adult-onset disorder with a similar but more slowly progressive course has been described.

Hematopoietic stem cell transplantation in the first 3 weeks of life is effective in prolonging life in infants with early infantile Krabbe disease, although many such children have significant neurologic disabilities. The availability of this therapy has led to the implementation of newborn screening for Krabbe disease in New York and other states.

ALEXANDER DISEASE

Alexander disease is an autosomal dominant progressive leukodystrophy associated with mutations in the GFAP gene that encodes glial fibrillary acidic protein. As such, it is a primary disorder of astrocytes, in contrast to other leukodystrophies, in which the major affected cell type is the oligodendrocyte. The classic presentation occurs in infants, who manifest macrocephaly, developmental regression, seizures, and progressive spasticity. MRI shows a pattern of frontal predominant white matter hyperintensity, sometimes with cavitation, with periventricular hyperintensity with or without enhancement and “garlands” and increased signal in the medulla, middle cerebellar peduncles, and long tracts, with or without atrophy (particularly in later onset cases) (Figs. 134.4 and 134.5). Some patients develop hydrocephalus secondary to compression of the aqueduct of Sylvius by swollen midbrain astrocytes. The affected areas show accumulation of Rosenthal fibers.

In adolescents and adults, Alexander disease is much less likely to be associated with macrocephaly and may be manifest as cognitive and emotional disturbance, with relatively mild long tract signs or ataxia; persistent vomiting may be prominent. Oculopalatal myoclonus has been described as a classical finding in such patients but is often absent. The anatomic and clinical patterns overlap with neuromyelitis optica (NMO), which is an acquired disorder of astrocytes, in which antibodies are directed at aquaporin, expressed in water channels in astrocytes.

There is no disease-modifying therapy available for Alexander disease, but given its prolonged course, particularly in later onset forms, vigorous supportive treatment is strongly encouraged.

FIGURE 134.4 Axial T2 fluid-attenuated inversion recovery (FLAIR) MRI of a 12-year-old with Alexander disease showing frontal predominant white matter hyperintensity with cavitation and periventricular hyperintensity.

FIGURE 134.5 Axial T2 FLAIR MRI of a 12-year-old with Alexander disease showing increased signal in the medulla, middle cerebellar peduncles, and long tracts.

PELIZAEUS-MERZBACHER DISEASE

Pelizaeus-Merzbacher disease (PMD) is an X-linked hypomyelinating disorder associated with duplications, deletions, and point mutations in the gene encoding central proteolipid protein (PLP1). Infantile forms of the disease present with profound hypotonia and unusual pendular nystagmus with gray optic discs. The most severely affected infants do not develop further and succumb to their illness in the first few years of life, but some boys make developmental gains and survive into the second decade, although they rarely walk or talk. In those who survive into childhood, intellectual disability, progressive ataxia, spasticity, and choreoathetosis are often observed. The MRI in PMD shows profound hypomyelination with reduced white matter volume. Some patients with mild mutations in PLP1 have a slowly progressive spastic paraplegia classified as SPG2. There is no established therapy for PMD, but a trial of human CNS stem cells implanted into the cerebral hemispheres is currently in progress.

A number of families, who lack mutations in PLP1, have been recognized with a PMD-like illness. Recessive mutations in GJA12/GJC2, which encodes a protein essential in gap junction formation in myelin, have been identified in some such families; TUBB4A mutations have been identified in another case mimicking PMD.

VANISHING WHITE MATTER DISEASE

In 1994, Schiffmann and colleagues described four girls with progressive ataxic diplegia, whose imaging studies showed confluent white matter disease early in the course of the illness; the peripheral nerves and intellect were spared, and extensive investigation for previously described leukodystrophies was uninformative. Biopsy specimens showed hypomyelination, demyelination, and gliosis and reduced quantities but qualitatively normal lipids. MR

spectroscopy showed reduced NAA, choline, and creatine restricted to the white matter. They named this disorder *childhood ataxia with central hypomyelination*. A year earlier, Hanefeld et al. had described three children with identical features, whose disease they named *myelinopathia centralis diffusa* (MCD).

In 1997, van der Knaap's group described nine more patients with this phenotype. They emphasized the unusual combination of slowly progressive ataxia with episodic decompensation in the face of minor trauma (motor change) or intercurrent infection (coma). They also recognized that the white matter signal eventually disappeared to be replaced by CSF intensity signal. The latter was found to correspond to extensive cystic degeneration of the cerebral white matter with preserved cortex in an autopsied case. Subsequent studies have emphasized the relative preservation of oligodendrocytes with abundant foamy cytoplasm and scarcity of astrocytes as the specific neuropathologic hallmark of the disease.

van der Knaap's descriptive term, *vanishing white matter disease* (VWM), which emphasizes the most dramatic aspect of this illness, has subsequently dominated the literature. MCD was never widely accepted, but CACH is still encountered, most often in tandem with VWM.

VWM is caused by mutations in any one of the genes coding for the subunits of the eukaryotic translation initiation factor 2 b (eIF2B); VWM is the first disease recognized that is associated with mutations in a translation factor. eIF2B is the major regulator of protein synthesis under conditions of mild stress, such as temperatures up to 41°C. The gene is expressed in all tissues, yet VWM is restricted to the cranial white matter. In vitro studies of VWM brain have shown that all three pathways of the unfolded protein response are inappropriately activated but only in white matter. This remarkable specificity remains unexplained, as is the case for other disorders involving mutations of DNA housekeeping machinery that are expressed in specific regions of the nervous systems, such as spinal muscular atrophy.

As has proven to be the case in other inborn errors of metabolism, the appearance and use of a diagnostic test for VWM has been followed by the recognition of a broader range of phenotypes than those originally described. Thus, Cree leukoencephalopathy and ovarioleukodystrophy have both been shown to be associated with mutations in eIF2B. The former is an autosomal recessive leukodystrophy, lethal in the first 2 years, that is observed in the native North American Cree and Chippewyan population where high rates of consanguinity prevail. Death in the context of a common viral infection may be the presenting feature. The latter phenotype can be associated with either primary or secondary amenorrhea and a more indolent neurologic course, with variable dementia, gait ataxia, sphincter dysfunction, optic atrophy, and episodic decompensation. Other unusual features have been reported, including marked macrocephaly in a child with survival into the third decade, adult presentation with psychosis, and precipitation of symptoms after being frightened by a horse.

Despite the availability of DNA diagnostic testing, confirmation of the diagnosis may be technically difficult because VWM can result from mutations in any of the five genes coding for subunits of eIF2B and because there is a high frequency of private and lowfrequency mutations in the cases described to date.

There is, as yet, no specific treatment for VWM. Avoidance of the precipitating factors is obviously advisable but difficult to accomplish in practice, given the propensity of children to bump their heads and catch colds.

DIFFUSE SCLEROSIS

Schilder described new syndromes of diffuse demyelination of the brain in 1912, 1913, and 1924. Later advances identified the 1913 description as one of ALD, and the 1924 patient had subacute sclerosing panencephalitis. Nevertheless, the 1912 case delineated a

P.1166

clinical and pathologic syndrome that is still seen, even though cases of uncomplicated diffuse sclerosis are so few that each encounter results in a case report. In 1994, Afifi and colleagues counted 12 cases since 1912; Yilmaz and others added 16 more between 1998 and 2008.

Schilder disease was and is regarded as a variant of multiple sclerosis, but the etiology and pathogenesis are not

known.

At autopsy, there are large areas of demyelination in the centrum ovale, with relative preservation of axons. Subcortical U-fibers are often spared. In acute lesions, there is perivascular infiltration by CD45-positive lymphocytes and giant cells; there may be necrosis. The lesions are similar to those of multiple sclerosis. In fact, in most cases that include large areas of demyelination, there are also smaller, more typical lesions of multiple sclerosis. For these cases, the term *transitional sclerosis* has been used. It is assumed that the small lesions coalesce to form the large ones. The demyelinating lesions contain CD68-positive macrophages and GFAP-positive astrocytes with long processes.

The clinical syndrome is a leukoencephalopathy, with progressive dementia, psychosis, corticospinal signs, and loss of vision caused by either optic neuritis with papilledema or cerebral blindness. Brain stem signs may include nystagmus and internuclear ophthalmoplegia. The disease is relentlessly progressive, with average survival of about 6 years but sometimes as long as 45 years.

Diagnosis depends on imaging; MRI shows gadolinium enhancement of large white matter lesions. There may be CSF pleocytosis with evidence of intrathecal synthesis of gamma globulin and oligoclonal bands. Brain biopsy may be needed to identify the few cases that simulate mass lesions.

Steroid therapy was followed by complete resolution of lesions or only minor sequelae in 10 of 16 cases reported in the decade up to 2008 (Yilmaz et al.); 9 cases subsequently recurred. Intravenous immunoglobulin has been used successfully; surgical resection is occasionally required to manage herniation complicating a large lesion.

DISORDERS OF CARBOHYDRATE METABOLISM

Glycogen Storage Diseases

Abnormal metabolism of glycogen and glucose may occur in a series of genetically determined disorders, each representing a specific enzyme deficiency (Table 134.5). The signs and symptoms of each disease are largely determined by the tissues in which the enzyme defect is expressed. Virtually all enzymes of glycogen metabolism, including tissue-specific isoforms or subunits, have been assigned to chromosomal loci and the corresponding genes have been cloned and sequenced. Numerous mutations have been identified and genotype-phenotype correlation is taking shape.

Severe fasting hypoglycemia may result in periodic episodes of lethargy, coma, convulsions, and anoxic brain damage in *glucose-6-phosphatase deficiency (glycogenosis type I)* or in *glycogen synthetase deficiency*. The liver is enlarged in both diseases. Clinical manifestations tend to become milder in patients who survive the first few years of life.

The CNS is directly affected by the enzyme defect in generalized glycogen storage diseases, even though neurologic symptoms are lacking in some disorders and in others, it may be ascribed to liver rather than to brain dysfunction. The following enzyme defects seem to be generalized: acid maltase (type II), debrancher (type III), brancher (type IV), and phosphoglycerate kinase (type IX).

Acid maltase (acid α -1,4 and α -1,6 glucosidase) deficiency is a lysosomal disorder due to mutations in the *GAA* gene on chromosome 17. In the infantile form of acid maltase deficiency (Pompe disease), pathologic involvement of the CNS has been documented, with accumulation of both free and intralysosomal glycogen in all cells, especially spinal motor neurons and neurons of the brain stem nuclei. Peripheral nerve biopsy specimens show accumulation of glycogen in Schwann cells. The profound generalized weakness of infants with Pompe disease is probably due to combined effects of glycogen storage in muscle, anterior horn cells, and peripheral nerves. In four patients with the childhood form of acid maltase deficiency, increased glycogen deposition in neurons of the brain stem was related to fatal intractable hyperpyrexia. No morphologic changes were seen in the CNS of a patient with adult-onset acid maltase deficiency despite marked decrease of enzyme activity. However, the enzyme defect predisposes to dilative arteriopathy and cerebral aneurysm formation, sometimes leading to stroke.

Patients with debrancher deficiency (glycogenosis type III, due to mutations in the *AGL* gene on chromosome 1) have hepatomegaly, fasting hypoglycemia, and seizures in infancy and childhood, which usually remit around puberty. Although overt signs of peripheral neuropathy are rare, abnormal deposits of glycogen have been documented both in axons and in Schwann cells and may explain, in part at least, the distal wasting and mixed EMG pattern observed in adult patients with neuromuscular involvement.

In branching enzyme deficiency (glycogenosis type IV, due to mutations in the *GBE1* gene on chromosome 3), the clinical picture is typically dominated by liver disease, with progressive cirrhosis and chronic hepatic failure causing death in childhood. However, the neuromuscular system is involved more often than it was previously realized, with congenital, juvenile, or adult presentations. The severe congenital myopathy, sometime associated with cardiomyopathy, may simulate spinal muscular atrophy type I (Werdnig-Hoffmann disease). Deposits of a basophilic, intensely PAS-positive material that is partially resistant to β -amylase digestion (polyglucosan) have been found in all tissues; in the CNS, spheroids composed of branched filaments were present in astrocytic processes, particularly in the spinal cord and medulla. Ultrastructurally, the storage material was composed of aggregates of branched osmiophilic filaments, 6 nm in diameter often surrounded by normal glycogen particles.

In phosphoglycerate kinase deficiency (glycogenosis type IX, due to mutations in the *PGK1* on the X chromosome), the type and severity of clinical manifestations vary in different genetic variants of the disease and are probably related to the severity of the enzyme defect in different tissues. In several families, the clinical picture was characterized by the association of severe hemolytic anemia, with intellectual disability and seizures.

LAFORA DISEASE AND OTHER POLYGLUCOSAN STORAGE DISEASES

Myoclonus epilepsy with Lafora bodies (Lafora disease) is an autosomal recessive disease that is characterized by the triad of epilepsy, myoclonus, and dementia. Inconstant other neurologic manifestations include ataxia, dysarthria, spasticity, and rigidity. Onset is in adolescence, and the course progresses rapidly to death, which occurs between 17 and 24 years in 90% of patients. Negative criteria or manifestations that imply some other disease include onset before 6 or after age 20 years, optic atrophy, macular degeneration, prolonged course, or normal intelligence. Epilepsy, with predominantly occipital seizures, is the first manifestation in

P.1167

most patients; status epilepticus is common in terminal stages. Myoclonus usually appears 2 or 3 years after the onset of epilepsy, may affect any area of the body, is sensitive to startle, and is absent during sleep. Intellectual deterioration generally follows the appearance of seizures by 2 or 3 years and progresses rapidly to severe dementia. Therapy is symptomatic and is designed to suppress seizures and reduce the severity of myoclonus; some control of myoclonus is achieved with benzodiazepines.

TABLE 134.5 Clasification of Glycogen Storage Disease

Type	Affected Tissues	Clinical Presentation	Glycogen Structure	Enzyme Defect	Mode of Transmission
I	Liver and kidney	Severe hypoglycemia; hepatomegaly	Normal	Glucose-6-phosphatase	AR
II	—	—	—	—	—
Infancy	Generalized	Cardiomegaly; weakness; hypotonia;	Normal	—	AR

death younger than
age 1 yr

Childhood	Generalized	Myopathy-simulating Duchenne dystrophy; respiratory insufficiency	Normal	Acid maltase	AR
Adult	Generalized	Myopathy-simulating limb-girdle dystrophy or polymyositis; respiratory insufficiency	Normal	—	AR
III	Generalized	Hepatomegaly; fasting hypoglycemia; progressive weakness	PLD	Debrancher	AR
IV	Generalized	Hepatosplenomegaly; cirrhosis of liver; neuromuscular disease; APBD	Polyglucosan	Brancher	AR
V	Skeletal muscle	Intolerance to intense exercise; cramps; myoglobinuria	Normal	Muscle phosphorylase	AR
VI	Liver; RBC	Mild hypoglycemia; hepatomegaly	Normal	Liver phosphorylase	AR
VII	Skeletal muscle; RBC	Intolerance to intense exercise; cramps; myoglobinuria	Normal (\pm polyglucosan)	PFK-M	AR
VIII	Liver	Asymptomatic hepatomegaly	Normal	Phosphorylase kinase	XR
—	Liver and skeletal muscle	Hepatomegaly; growth retardation; hypotonia	Normal	Phosphorylase kinase	AR
—	Skeletal muscle	Exercise intolerance; myoglobinuria	Normal	Phosphorylase kinase	XR; AR (?)
—	Heart	Fatal infantile cardiomyopathy	Normal	Phosphorylase kinase	AR
IX	Generalized	Hemolytic anemia;	Normal (?)	PKG	XR

		seizures; mental retardation			
—	—	Intolerance to intense exercise; myoglobinuria	—	—	—
X	Skeletal muscle	Intolerance to intense exercise; myoglobinuria	Normal (?)	PGAM-M	AR
XI	Skeletal muscle	Intolerance to intense exercise; myoglobinuria	Normal (?)	LDH-M	AR
XII	Skeletal muscle RBC	Exercise intolerance	Normal (?)	Aldolase A	AR
XIII	Skeletal muscle	Exercise intolerance	Normal (?)	β -Enolase	AR
—	Generalized	Myoclonus epilepsy (Lafora disease)	Polyglucosan	Laforin	AR
0	Muscle	Cardiomyopathy; exercise intolerance	Glycogen deficiency	Glycogen synthetase	AR
<p>?, not yet definitively documented; AR, autosomal recessive; PLD, phosphorylase-limit dextrin; APBD, adult polyglucosan body disease; RBC, red blood cell; PFK-M, muscle phosphofructokinase; XR, X-linked recessive; PKG, phosphoglycerate kinase; PGAM-M, muscle phosphoglycerate mutase; LDH-M, muscle lactate dehydrogenase.</p>					

Laboratory findings are normal except for EEG changes; bilaterally synchronous discharges of wave-and-spike formations are commonly seen in association with myoclonic jerks. EEG abnormalities may be found in asymptomatic relatives. The pathologic hallmark of the disease is the presence in the CNS of the bodies first described by Lafora in 1911: round, basophilic, strongly PAS-positive intracellular inclusions that vary in size from dust-like bodies less than 3 nm in diameter to large bodies up to

P.1168

30 nm in diameter. The medium and large bodies often show a dense core and a lighter periphery. Lafora bodies are seen only in neuronal perikarya and processes and are most numerous in cerebral cortex, substantia nigra, thalamus, globus pallidus, and dentate nucleus.

Ultrastructurally, Lafora bodies are not membrane bound. They consist of two components in various proportions: amorphous, electron-dense granules and irregular filaments. The filaments, which are about 6 nm in diameter, are often branched and frequently continuous with the granular material.

Irregular accumulations of a material similar to that of the Lafora bodies are found in liver, heart, skeletal muscle, skin, and retina, suggesting that Lafora disease is a generalized storage disease. Both histochemical and biochemical criteria indicate that the storage material is a branched polysaccharide composed of glucose

(polyglucosan) similar to the amylopectin-like polysaccharide that accumulates in branching enzyme deficiency. The activity of branching enzyme, however, was normal in several tissues, including brain, of patients with Lafora disease. About half of the cases of Lafora disease are due to mutations in the *EPM2A* gene, which encodes laforin, a member of the dual-specificity protein phosphatase family that additionally contains a glycogen-binding domain. Lafora disease is genetically heterogeneous, and pathogenic mutations have been identified in a second gene, *EPM2B*, which encodes an E3 ubiquitin ligase called *malin*. Laforin and malin act cooperatively to mediate polyglucosan degradation; the laforin-malin complex also protects against endoplasmic reticulum stress-induced apoptosis. Although over 100 mutations have been identified in these two genes, not all patients have mutations in either one, and there is good evidence for involvement of yet a third gene.

A clinically distinct form of polyglucosan body disease (*adult polyglucosan body disease* or *APBD*) occurs in patients with a complex but stereotyped chronic neurologic disorder characterized by progressive upper and lower motor neuron involvement, sensory loss, sphincter problems, neurogenic bladder, and in about half of the cases, dementia; there is no myoclonus or epilepsy. Onset is in the fifth or sixth decade of life, and the course ranges from 3 to 20 years. Electrophysiologic studies show axonal neuropathy. In some cases, the clinical picture simulates amyotrophic lateral sclerosis. Throughout the CNS, polyglucosan bodies are present in processes of neurons and astrocytes but not in perikarya. There are also polyglucosan accumulations in peripheral nerve and in other tissues, including liver, heart, and skeletal and smooth muscle. As in debranching enzyme deficiency and Lafora disease, the abnormal polysaccharide in APBD seems to have longer peripheral chains than normal glycogen. Branching enzyme activity was significantly decreased in leukocytes from Israeli patients, and this finding was confirmed in both leukocytes and peripheral nerve specimens from American Ashkenazi Jewish patients. Mutations in the gene encoding the branching enzyme (*GBE1*) have been found in both Ashkenazi Jewish families with APBD and in non-Jewish patients, confirming that APBD is a clinical variant of branching deficiency. The observation that APBD is often associated with “mild” *GBE1* mutations or even heterozygous mutations may explain the late onset of symptoms.

Another form of polyglucosan is in *corpora amylacea*, which accumulate progressively and nonspecifically with age. They are more commonly seen within astrocytic processes in the hippocampus and in subpial and subependymal regions; however, they also occur in intramuscular nerves in patients older than 40 years.

PEROXISOMAL DISEASES: ADRENOLEUKODYSTROPHY, ZELLWEGER SYNDROME, AND REFSUM DISEASE

Peroxisomes are ubiquitous cellular organelles that participate in a variety of essential biochemical functions. Peroxisomes are enclosed by a single membrane and contain no DNA, implying that all peroxisomal-associated proteins are encoded by nuclear genes. A complex shuttle system transports peroxisomal enzymes and structural proteins from the cytosolic polyribosomes (where they are made) to the peroxisome. This system involves at least two recognition sequences (peroxisomal targeting sequences) that are embedded in the protein products themselves and several receptors or transporters; the system is ATP dependent.

Peroxisomes participate in both anabolic and catabolic cellular functions, especially in the metabolism of lipids. For example, peroxisomes contain a complete series of enzymes for the β -oxidation of fatty acids. These enzymes are distinct from the mitochondrial enzymes of β -oxidation in both genetic coding and substrate specificity. Because mitochondrial enzymes of β -oxidation cannot metabolize carbon chain lengths greater than 24, the peroxisomal system is required for the degradation of endogenous and exogenous very long-chain fatty acids (VLCFA). The peroxisome is also the site of the initial and rate-limiting steps of the synthesis of plasmalogens, ether-linked lipids that constitute the major portion of the myelin sheath. Other key functions include cholesterol and bile acid biosynthesis, degradation of pipercolic and phytanic acids, and transamination of glyoxylate.

Human diseases caused by disruption of peroxisome function are divided into two broad categories ([Table 134.6](#)). The first category is characterized by abnormalities in more than one metabolic pathway, often accompanied by morphologic changes of the peroxisome. The prototype of this class is the Zellweger syndrome, discussed in the following paragraphs. Milder phenotypes in the Zellweger spectrum include neonatal ALD, infantile Refsum disease,

chondrodysplasia punctata (RCDP), is associated with severe growth failure, profound developmental delay, cataracts, rhizomelia (disproportionate length of proximal limbs, such as short limbs of achondroplasia), epiphyseal calcifications, and ichthyosis. Patients with RCDP have decreased plasmalogen levels and elevated phytanic acid, but unlike the Zellweger spectrum, the β -oxidation pathway and VLCFA levels are normal. In recognition of the similar cellular pathophysiology in these phenotypes, *peroxisome biogenesis disorder* (PBD) is now the preferred term for all Zellweger spectrum and RCDP conditions.

TABLE 134.6 Human Genetic Diseases due to Peroxisomal Dysfunction

Peroxisomal Biogenesis Disorders	Single Peroxisomal Enzyme Disorders
Zellweger syndrome	X-linked adrenoleukodystrophy
Neonatal adrenoleukodystrophy	Oxidase deficiency (pseudoneonatal adrenoleukodystrophy)
Infantile Refsum disease	Bifunctional enzyme deficiency
Hyperpipecolic acidemia	Thiolase deficiency (pseudo-Zellweger)
Rhizomelic chondrodysplasia punctate	DHAP acyl transferase deficiency
	Alky1 DHAP synthase deficiency
	Glutaric aciduria type III (one case only)
	Refsum disease
	Hyperoxaluria type 1
	Acatalsia

The second class of human peroxisomal diseases shows the genetic and biochemical features of single enzyme defects. In addition to X-linked ALD and Refsum disease discussed later in this chapter, this category includes defects in the β -oxidation pathway of VLCFA, which cause a Zellweger-like phenotype, and defects in plasmalogen synthesis, which result in an RCDP-like phenotype.

Zellweger Syndrome

The Zellweger syndrome (*cerebrohepatorenal syndrome*) is an autosomal recessive disease with no ethnic or racial predilection. It results from mutations in any one of a large number of genes named *pexins*, whose gene products are required for normal peroxisome assembly. Affected newborns are strikingly floppy and inactive and lack neonatal reflexes. The characteristic facies includes a high narrow forehead, round cheeks, flat root of the nose, wide-set eyes with shallow orbits, puffy eyelids, pursed lips, narrow high-arched palate, and small chin. The head circumference is normal, but the fontanels and sutures are wide open. Eye findings include pigmentary retinopathy, retinal arteriolar attenuation, and optic atrophy. The pinnae may be abnormal and posteriorly rotated. Affected infants suck and swallow poorly and often require tube feeding. Some have congenital heart disease, notably patent ductus arteriosus or septal defects. The liver is cirrhotic and either enlarged or shrunken; some children are jaundiced, and some develop splenomegaly and a bleeding diathesis. Cystic dysplasia of the kidneys may be palpable and may cause mild renal failure. Genital anomalies include an enlarged clitoris, hypospadias, and cryptorchidism. Minor skeletal anomalies include contractures of large and small joints, polydactyly, low-set rotated thumbs, and clubfeet; there are also stippled calcifications of the patella and epiphyseal cartilage. The children are apathetic, poorly responsive to environmental stimuli, and limp. Tendon reflexes are absent or hypoactive. Many children have seizures and fail to thrive or develop; most succumb within the first few months of life.

Typical but nonspecific laboratory findings include elevated bilirubin levels, abnormal liver enzymes, elevated serum iron, saturated iron-binding capacity, and transferrin. The CSF protein content may be elevated. The EEG is

abnormal, and MRI shows poor myelination, brain atrophy, pachygyria, polymicrogyria, and neuronal heterotopias. Diffusion-weighted and tensor-diffusion MRI identify regions of injury in patients with PBD that are not apparent with conventional MRI.

The hallmark of Zellweger syndrome is dysfunction in multiple enzymatic pathways, including the following:

1. Levels of VLCFA—those with 24 or more carbons—are increased in plasma, fibroblasts, and chorionic villus;
2. In plasma and urine, increased content of intermediates of bile acid metabolism includes trihydroxycholestanoic acid and dihydroxycholestanoic acid;
3. Levels of pipecolic and phytanic acids increase;
4. Plasmalogen levels decrease.

Pathologically, the absence of functional peroxisomes in hepatocytes is a pathognomonic feature of Zellweger syndrome and one that helps distinguish it from other PBDs and from single enzyme disorders such as pseudo-Zellweger disease. Membrane proteins may assemble with membrane lipids to form rudimentary “ghosts” of peroxisomes that seem unable to import enzymes. Secondary abnormalities are also seen in mitochondria that show an abnormally dense matrix and distorted cristae.

Therapy for Zellweger syndrome is primarily supportive and limited because of the multisystem impairment already present at birth. Reliable prenatal diagnosis is available by mutation analysis when the genotype has been established in the proband.

Adrenoleukodystrophy

ALD is an X-linked incompletely recessive disorder with variable expressivity; it is well defined genetically, clinically, and pathologically. The ALD gene has been cloned and encodes a member of the ATP-binding cassette transporter class of proteins (ABCD1). The most common phenotype is the childhood cerebral form, which appears in boys who have normal early development. Behavioral change is the most common initial feature, with abnormal withdrawal, aggression, poor memory, or difficulties in school, ultimately evolving into progressive dementia. Visual loss with optic atrophy reflects demyelination along the entire visual pathway. The outer retina is notably spared. Progressive gait disturbance with pyramidal tract signs is an important feature. Dysphagia and deafness may occur. Seizures are common late in the disease but are occasionally the first manifestation. Some patients have overt signs of adrenal failure, including fatigue, vomiting, salt craving, and hyperpigmentation that is most prominent in skin folds. The course is relentlessly progressive. Patients enter a vegetative state and die from adrenal crisis or other causes 1 to 10 years after onset.

Several other clinical phenotypes have been described. Adrenomyeloneuropathy (AMN) is the most common of the variant phenotypes. Typical features are spastic paraparesis, peripheral neuropathy, and adrenal insufficiency, beginning in the second decade. Hypogonadism, impotence, and sphincter disturbance are also seen. Cerebellar dysfunction and dementia have been reported. A similar syndrome is found in about 15% of women who are heterozygous for mutation at the *ALD* gene. MRI frequently reveals cortical demyelinating lesions in AMN patients, even in those without signs or symptoms of cortical involvement. Pathologic findings in AMN include demyelination and dying-back changes in the cord and lamellar cytoplasmic inclusions in brain, adrenal gland, and testis; the findings are similar to those of ALD.

An adolescent cerebral form of ALD is similar to the childhood form but for its onset. In adults, X-linked ALD may present as dementia, schizophrenia, or focal cerebral syndromes such as aphasia, Klüver-Bucy syndrome, or hemianopia; adrenal insufficiency is usually present. Adult ALD includes spastic paraparesis, frontal lobe syndromes, cerebellar dysfunction, or olivopontocerebellar atrophy. Female heterozygotes may be symptomatic with adult ALD. Adrenal insufficiency can be seen without neurologic disorder; ALD should be considered in any boy with unexplained Addison disease. Finally, children and adults with the biochemical defect may be asymptomatic or presymptomatic. Phenotypic heterogeneity is the rule within families with multiple affected individuals; the disparate

manifestations are probably the result of modifying genetic loci or environmental factors.

Laboratory evaluation of the patient with ALD reveals elevated CSF protein and posteriorly predominant white matter signal hyperintensity with marginal enhancement. Occasionally, the onset

P.1170

is frontal or cerebellar. The corticotropin stimulation test usually shows adrenal insufficiency, even in the absence of clinical signs. Characteristic inclusions, accumulations of lamellar lipid profiles, may be seen in the brain, adrenal glands, sural nerve biopsy, or testis. The primary finding in the brain is extensive diffuse demyelination, sparing U-fibers in the centrum semiovale and elsewhere. In involved areas of white matter, perivascular infiltration of lymphocytes and plasma cells is prominent.

Diagnosis is suggested by the characteristic clinical findings of neurologic deterioration, demonstration of adrenal hypofunction, and MRI abnormalities. The demonstration of elevated VLCFA levels in plasma and cultured skin fibroblasts without disruption of other peroxisomal functions should be followed by ABCD1 mutation analysis.

Several approaches have been taken to treat ALD. Ideally, cases would be detected at birth, which would allow immediate treatment and genetic counseling for parents. A method for newborn screening is under investigation.

Steroid replacement therapy is given during stressful periods, such as intercurrent illness, or if there is evidence of adrenal insufficiency. Dietary avoidance of VLCFA alone does not lead to biochemical change because of endogenous synthesis. Efforts to lower endogenous synthesis using glycerol trierucate oil and glycerol trioleate oil (Lorenzo oil) in conjunction with dietary restriction do produce a fall in VLCFA levels in both affected individuals and female carriers. Unfortunately, this striking biochemical change does not have an equally striking clinical correlate; its use is most likely limited to presymptomatic boys. Bone marrow transplantation cures the biochemical defect in ALD, but the morbidity and mortality are high, and neither neurologic defects nor radiologic abnormalities revert, although favorable outcomes have been reported in boys who are transplanted when few neurologic signs are present. In all cases, radiologic abnormalities and progression almost invariably precede neurologic progression; it is therefore imperative that every child whose family might consider bone marrow transplantation is closely followed radiographically. Immunotherapy has been considered in X-ALD because of the inflammatory component of the central lesions, but β -interferon and thalidomide have not been effective. Finally, the cloning and characterization of the *ALD* locus may lead to a gene or protein product replacement therapy.

Refsum Disease

This autosomal recessive disease (also known as *heredopathia atactica polyneuritiformis*) is unique among the lipidoses because the stored lipid (phytanic acid) is not synthesized in the body, but is exclusively dietary in origin. This has enabled successful therapy by dietary management. Symptoms begin in early childhood in some patients but may be delayed until the fifth decade in others. Progressive night blindness usually appears in the first or second decade, followed by limb weakness and gait ataxia. Symptoms are progressive, but abrupt exacerbations and gradual remissions may occur with intercurrent illness or pregnancy. There are no seizures, but some patients have psychiatric symptoms. Peripheral neuropathy is manifest by loss of tendon reflexes, weakness and wasting, and distal sensory loss. Ataxia may be seen. A granular pigmentary retinopathy is universally present. Other findings include ichthyosis; nerve deafness (often severe); cataracts; miosis and pupillary asymmetry; pes cavus; and bone deformities with shortening of the metatarsal bones, epiphyseal dysplasia, and, in some, kyphoscoliosis. CSF protein content is elevated. Nerve conduction velocities are slowed. ECG changes include conduction abnormalities. Peripheral nerves may feel thickened and, on histologic study, may show hypertrophic interstitial changes and onion-bulb formation. The course is generally progressive with exacerbations and remissions. Peripheral visual fields may ultimately be lost, with resulting telescopic vision. Sudden death may result from cardiac arrhythmia.

The biochemical defect in Refsum disease has been identified as phytanoyl-CoA hydroxylase (PHYH) deficiency; the responsible gene in most cases is *PAHX*. Several kindreds with typical Refsum disease have lacked *PAHX* mutations or linkage to chromosome 10; they proved to be heterozygous for mutations in *PEX 7*. That gene encodes

the receptor for the type 2 peroxisomal targeting signal (PTS2), whose normal function is essential for PHYH import to peroxisomes. Diagnosis is made by the characteristic clinical picture and elevation of phytanic acid levels in the plasma. Studies in rat brain suggest that phytanic acid exerts direct neurotoxic effects by binding to the inner mitochondrial membrane, impairing mitochondrial ATP supply and membrane permeability.

Therapy limits dietary phytanic acid and its precursor, phytol, a branched chain fatty alcohol, which is abundantly present in nature as part of the chlorophyll molecule. When dairy products, ruminant fat, and chlorophyll-containing foods are eliminated, plasma phytanic acid levels are reduced and tissue stores are mobilized, with improvement of symptoms. Paradoxically, symptoms may worsen and plasma phytanic acid levels may rise shortly after institution of dietary therapy, especially if patients reduce caloric intake and lose weight. Increased plasma phytanic acid causes anorexia, increased weight loss, and still more severe symptoms. Adequate caloric intake helps prevent weight loss and abrupt fat mobilization. Plasmapheresis helps to prevent or treat exacerbations. Induction of phytanic acid ω -oxidation might be helpful.

Another rare peroxisomal phenotype can be confused with Refsum disease. Patients with α -methylacyl-CoA racemase (AMACR) deficiency may have retinopathy, peripheral neuropathy plus a variety of cerebral findings, including seizures, progressive cognitive decline, and relapsing encephalopathy.

Chromosomal Disorders and Disorders of DNA

Marc C. Patterson

INTRODUCTION

Rearrangements of the human genome, ranging from grossly disordered chromosome number to submicroscopic variations in copy numbers can profoundly affect development and function of the nervous system. Likewise, defects in the machinery that maintain the integrity and duplication fidelity of DNA lead to a family of rare disorders characterized by varying combinations of neurodegeneration, premature aging, immunodeficiency, and susceptibility to malignancy.

CHROMOSOMAL DISORDERS

Human chromosomal anomalies are manifested as change in the total number of chromosomes, structural rearrangements, imprinting abnormalities, or variations in copy number. Examples of abnormal chromosome number (i.e., aneuploidy) are sex-chromosomal aneuploidy, such as 45,X (Turner syndrome), and autosomal aneuploidy, such as 47,XX × 21 (trisomy 21, Down syndrome). Structural abnormalities include regional deletions or insertions, segmental translocations (i.e., reciprocal or Robertsonian) or inversions (i.e., pericentric or paracentric), duplications, and ring chromosomes. There are many chromosomal syndromes, which result primarily from these numeric or segmental anomalies, producing a functional change of gene dosage; gene imprinting is also recognized as a critical modifier of expression. The most common manifestation of chromosomal anomalies is intellectual disability. Congenital malformations occur with variable frequency and differences in severity. In the sex-chromosome disorders, infertility is the most common feature. [Table 135.1](#) summarizes the features of several classic chromosome disorders as examples: trisomy 21 syndrome, Prader-Willi syndrome (PWS), Angelman syndrome (AS), and a common idiopathic intellectual disability syndrome caused by subtelomeric anomalies of chromosomes. A variety of mechanisms underlie these disorders. Trisomy 21 results from chromosomal nondisjunction (maternal 80%, paternal 20%), an age-related phenomenon in most cases, and unbalanced translocation in the remainder. PWS and AS result from loss of paternally or maternally imprinted alleles in the same chromosomal region (15 q11-13); such loss may reflect abnormal imprinting (methylation— see the following section), chromosomal deletion, translocation or inversion, or point mutations in a specific gene (UBE3A for AS). CATCH-22 is a deletion syndrome—the manifestations are at least in part a reflection of the amount of genetic material that is lost.

GENOMIC IMPRINTING

Genomic imprinting is an epigenetic phenomenon that permits nonmendelian inheritance in the mammalian genome. Several autosomal genes are inherited, in a silent state, on one parental allele and in an active state on the other parental allele. This parent-of-origin-specific gene expression is called *genomic imprinting*. The diseases that arise from these genes are mostly caused by mutation of the active allele, duplication of the nonactive allele, or imprinting errors resulting in silencing of the active allele. Over 20 imprinted genes have now been identified in the mouse genome; many of them have human homologs. For example, the *IGF-2* gene is paternally active, and only when the gene defect is inherited from the father do the offspring express the dwarfing phenotype. In PWS and AS, deletions in the PWS critical region on the paternal chromosome, or maternal uniparental disomy, result in silencing the paternally active allele and the PWS phenotype, whereas deletion of the AS critical region on the maternal chromosome, or paternal uniparental disomy, results in the silencing of the maternal allele and the AS phenotype.

The molecular mechanism of genomic imprinting is incompletely understood. The isolation of a *cis*-acting imprinting center, located upstream to the promoter region of the *SNRPN* gene, has helped us understand the molecular basis of genomic imprinting. Deletions or mutations in this imprinting center have been shown to associate with PWS or AS, depending on the origin of parental germ lines. It is postulated that the imprinting center confers a male or female imprint by use of an imprinting switch during gametogenesis. In the female germ line, the imprinting switch is needed to reset the male chromosome from the maternal grandfather to confer the characteristics of a female chromosome. In the male germ line, the same process is needed to reset the female chromosome from the paternal grandmother to confer the characteristics of a male chromosome. This epigenetic mark is thought to be achieved by DNA methylation. In the case of PWS, the inactive allele on the maternal chromosome is hypermethylated, which suppresses gene transcription. The hypermethylated cytosine residues on the DNA

sequences may repel the transcription factors needed for the activation of gene transcription. In other imprinted genes such as the IGF-2 receptor, DNA methylation is associated with the active allele on the maternal chromosome. Therefore, other factors in addition to DNA methylation may be involved in genomic imprinting.

AUTISM SPECTRUM DISORDER AND GENOMIC IMPRINTING

Autism is a neurodevelopmental disorder characterized by language and social impairments and prominent repetitive, stereotypic behaviors (see also [Chapter 138](#)). Interstitial duplication of maternal chromosome 15q11-13 region is one of the more common chromosomal anomalies in autism. Clinically, there are some phenotypic overlaps between autism spectrum disorders (ASDs) and PWS. Interestingly, among the children with PWS, those who express two maternally imprinted alleles are twice more likely to have ASD than those with PWS caused by deletion of paternally imprinted alleles. The identification of mutations in the methyl CpG-binding protein 2 (*MeCP2*) gene as the major cause of Rett syndrome suggested that DNA methylation (and hence genomic imprinting) may play important roles in other neurodevelopmental disorders.

P.1175

TABLE 135.1 Common Chromosomal Disorders

Genetic Abnormality/Eponym	Key Clinical Features	Diagnosis
Trisomy 21; chromosome 14/21 translocation; Down syndrome	Intellectual disability, hypotonia, atlantoaxial instability, short stature. Characteristic round facies with epicanthal folds. Early-onset dementia. Congenital heart disease, increased risk of leukemia.	Chromosome analysis
Prader-Willi syndrome; 15q11-13 deletion	Neonatal hypotonia and failure to thrive followed by uncontrolled appetite with obesity (hypothalamic dysfunction); characteristic facial features, intellectual disability and behavior (obsessiveness, mood swings, skin picking)	DNA methylation analysis (loss of paternal allele at <i>SNRPN</i> locus: includes 15q11-13 deletion, uniparental disomy, and imprinting defects—detects 99% of cases)
Angelman syndrome; 15q11-13 deletion	Characteristic facies, microbrachycephaly, protruding tongue, jerky limb movements (features may not be apparent until after 1 yr); developmental delays; and intellectual disability	DNA methylation analysis (loss of maternal allele: includes 15q11-13 deletion, uniparental disomy, and imprinting defects—78% of cases); UBE3A mutation analysis 11% of cases; chromosome analysis (translocations, inversions—1% of cases); no diagnostic test findings—10% of cases
22q11 deletion syndrome (CATCH-22; DiGeorge; velocardiofacial syndrome)	Cardiac malformations, facial clefts, other cranial and brachial arch anomalies, dysmorphism, intellectual disability, and psychiatric disorders (schizophrenia, OCD, PDD, and ADHD)	FISH, MLPA, chromosomal microarray (detects 95 + % of cases)

OCD, obsessive-compulsive disorder; PDD, pervasive developmental disorder; ADHD, attention deficit hyperactivity disorder; FISH, fluorescent in situ hybridization; MLPA, multiplex ligation-dependent probe amplification.

Subtle chromosomal anomalies such as subtelomeric and submicroscopic deletion or duplication frequently give rise to neurologic phenotypes, without necessarily causing somatic manifestations. Techniques using subtelomeric probes led the way in improving cytogenetic diagnosis but have been largely supplanted by array comparative genomic hybridization (CGH) in the investigation of idiopathic intellectual disability and cancers.

INTELLECTUAL DISABILITY ASSOCIATED WITH SUBTELOMERIC CHROMOSOMAL DELETION

Telomeres are the chromosome ends that contain complex DNA protein structures. The DNA sequence is a repetitive hexanucleotide motif, TTAGGG, ranging from 2 to 15 kb in length. This repetitive sequence and its specific DNA-binding proteins form a cap structure at the chromosome ends. This cap structure enables cells to distinguish chromosome ends, prevents fusion or degradation of chromosomes, and facilitates chromosomal segregations during cellular divisions. A reverse transcriptase named *telomerase* recognizes this terminal repetitive DNA sequence and works to maintain the chromosomal integrity by adding telomeric DNA onto chromosome ends, when a lagging strand is created during replication. Anomalies of these DNA protein structures change the chromosomal length. Shortening of telomeric length is seen in normal aging of somatic cells, whereas unchecked telomerase activation results in chromosomal fusion, as is often seen in cancer cells. Intellectual disability is a common developmental disorder. The etiology of about 30% to 40% of moderate to severe intellectual disability (IQ <50) remains unknown, despite extensive diagnostic testing. These patients have a normal karyotype using routine- or high-resolution chromosomal-banding techniques.

Since the early 1990s, researchers have developed DNA probes to detect subtle subtelomeric chromosomal anomalies in humans. At least 5% of children with idiopathic intellectual disability harbor subtelomeric chromosomal rearrangements, detected by a set of subtelomeric probes in different fluorescent in situ hybridization (FISH) studies. These rearrangements include subtelomeric deletions, duplications, or derivative chromosomes resulting in partial monosomy-trisomy states. The positive detection rate increases when screening criteria include severe intellectual disability, positive family history of intellectual disability, and at least one physical dysmorphism. These results suggest that subtelomeric FISH study remains a useful tool for identifying the etiology of the disorders of patients with idiopathic intellectual disability. More recently, single nucleotide polymorphism (SNP) arrays have been recommended as an efficient screening test in populations

P.1176

with intellectual disability, with a diagnostic yield greater than 10% in one study.

IDENTIFICATION OF DNA COPY NUMBER VARIATIONS BY ARRAY COMPARATIVE GENOMIC HYBRIDIZATION

Chromosomal disorders arising from segmental deletion or duplication contribute to variations of copy numbers of DNA fragments. These fragments are often not visualized by current high-resolution chromosomal banding. This submicroscopic genomic copy number variation is thought to be the most common cause of idiopathic developmental delay, including intellectual disability. Recent advances in high-throughput microarray technology, coupled with sophisticated data analysis, have allowed rapid and accurate detection of these submicroscopic genomic copy number variations. In CGH, the patient's DNA is hybridized to arrayed genomic DNA targets (genomic clones or oligonucleotides) on a glass slide or gene chip. The signal intensities of each hybridized genomic target are compared with those of the control standards (or the parents). Variation of copy numbers can be readily detected. This new genetic diagnostic tool has led to the identification of an ever-growing family of novel microdeletion syndromes. The repetitive observation of microscopic chromosomal anomalies and their correlation with certain clinical phenotypes is likely to identify the genetic causes of many idiopathic neurodevelopmental disorders whose cause is currently unknown. Investigators have reported relatively high yields of CGH in cohorts with intellectual disability and autism in both children and adults.

DISORDERS OF DNA MAINTENANCE, TRANSCRIPTION, AND TRANSLATION

Except for components of the respiratory chain encoded by DNA, the DNA of the nucleus is responsible for the production of the molecules essential to the cellular economy. Disorders that impair the maintenance of the integrity of DNA, or its timely and accurate transcription and translation, frequently lead to neurodegeneration, impaired growth, premature aging, and a propensity to develop malignancies. The brain is particularly vulnerable to these disorders because cerebral neurons are, for practical purposes, irreplaceable and their high metabolic rate mandates high levels of oxygen consumption; both of these factors render the CNS more susceptible to damage by reactive oxygen species and other metabolites than less richly endowed tissues.

This section provides an introduction to the processes involved and the rare diseases resulting from derangement of these controls. It is likely that the number of these disorders will continue to grow in parallel with the relevant basic science. Neurologists in the 21st century must have a firm grasp of the essential principles to diagnose and manage people with these diseases.

DNA MAINTENANCE AND TRANSCRIPTION

DNA is subject to errors in its duplication during cell division and during the process of repair following exposure to a variety of mutagens (environmental, toxic, and therapeutic). The elaborate machinery includes helicases that unwind the strands of DNA in preparation for transcription into RNA, RNA polymerase, which directs the formation of mRNA on the DNA template, and DNA polymerase, which catalyses the duplication of DNA. The process is fine-tuned by a large family of transcription factors; investigators are constantly adding to their number. This process is highly dependent on sites of replication origin, which change during development and in the face of disease.

A complex system has evolved to correct errors in nucleic acid duplication. When single bases are incorrectly inserted into the new DNA molecules, they are removed by the process of base excision repair, mediated by specific DNA glycosylases and endonucleases and DNA polymerases and ligases. Longer segments of 25 to 32 bases are frequently damaged by exposure to ultraviolet radiation and are removed by nucleotide excision repair, which requires its own family of proteins. Breaks of double-stranded DNA activate a mechanism that requires the participation of DNA protein kinase and recombination proteins. The processes are even more complex than is implied by this brief overview, because many of the involved proteins play multiple, mutually modifying roles in repair and transcription.

Precursor-mRNA (pre-mRNA) is transcribed from the genomic DNA template and includes the sequences of both expressed sequences (exons) and intervening sequences (introns). Introns are removed from pre-mRNA by RNA splicing to produce the mRNA used in translation of the message into protein. This process requires the participation of five additional RNA molecules (small nuclear RNAs or snRNAs) and more than 50 proteins. The snRNAs are added to multiprotein complexes known as *spliceosomes*. The steps involved in pre-mRNA processing into mRNA occur in the nucleus and conclude with export of the mRNA to the cytoplasm via the nuclear pore complex.

DNA TRANSLATION AND MODIFICATION

Translation of mRNA requires intact ribosomal function, factors to control the initiation and duration of translation, and machinery to modify the nascent polypeptide chains by the addition of smaller molecules, particularly oligosaccharides. This modification amplifies the ability of the organism to respond to changing needs at different stages of development (such as differing proportions of enzyme or structural protein isoforms) or in response to external stimuli (as in the modification of T-cell receptor populations and other elements of the immune system to target invading microorganisms). The most important of such processes are *N*- and *O*-linked glycosylation.

CELL CYCLE CONTROL

The activity of the systems responsible for DNA transcription, maintenance, and translation is related to the phase of the cell cycle, which is regulated by a highly conserved family of protein kinases known as *cyclin-dependent kinases* (CDKs). CDKs are themselves regulated by inhibitory phosphorylation (Wee 1), dephosphorylation (Cdc25), the binding of inhibitor proteins (CKIs), and through cyclical proteolysis (ubiquitin ligases and activators—SCF, APC, Cdc20, Hct 1) and gene regulatory proteins (E2F, p53).

SPECIFIC DISORDERS

Table 135.2 summarizes selected monogenic DNA disorders. The categorization of specific disorders in one category is an arbitrary oversimplification because the gene products have multiple actions in many cases.

TABLE 135.2 Selected Disorders of DNA Synthesis, Maintenance, Transcription, and Translation

Disorder	Inheritance	Gene and Protein	Mechanism (Known or Putative)	Specific Features
----------	-------------	------------------	-------------------------------	-------------------

DNA Maintenance and Transcription

Cockayne syndrome, type 1 (CSA)	Autosomal recessive (AR)	<i>CSA (ERCC8)</i> Excision repair crosscomplementing rodent repair deficiency 8 protein	CSA/ERCC8 interacts with p44, CSB, and TFIIH. Mutations thus lead to RNA polymerase II dysfunction and impaired nucleotide excision repair.	Intellectual disability, accelerated aging, pigmentary retinal degeneration, optic atrophy, deafness, marble epiphyses, photosensitivity, and basal ganglia/cerebellar calcification
COFS	AR	<i>CSB (ERCC6)</i> Excision repair crosscomplementing rodent repair deficiency 6 protein	Abnormal nucleotide excision repair resulting from disturbed RNA polymerase I-TFIIH interaction within the CSBIP/150 complex, of which CSB/ERCC6 is a component	Microcephaly, microphthalmia, cataracts, dysmorphism, failure to thrive, recurrent pneumonias, axial hypotonia, appendicular hypertonia, hyperreflexia, and progressive contractures. Calcifications in the periventricular frontal white matter and basal ganglia.
Progeria	AR	<i>LMNA</i> Lamin A	Lamins are structural components of the nuclear membrane. Mutations in LMNA are associated with both defective nuclear mechanics and impaired transcriptional activation.	Postnatal onset of short stature, failure to thrive and accelerated aging, loss of scalp hair and subcutaneous fat, joint stiffness, and early atherosclerosis leading to strokes and myocardial infarcts and premature death. Elevated prothrombin time, platelets, and phosphorous; conductive hearing loss is also reported. Cognition is spared.

Xeroderma pigmentosum (XP) (de Sanctis-Cacchione syndrome — most commonly complementation group D-XPD)	AR	<i>ERCC2</i> Excision repair crosscomplementing rodent repair deficiency 2 protein	Abnormal nucleotide excision repair: XPD (ERCC2) interacts with the p44 subunit of TFIIH stimulating 5-prime-to-3-prime helicase activity. Mutations in XPD prevent the interaction with p44, leading to decreased XPD helicase activity.	Intellectual disability, short stature, facial freckling, spasticity, hypogonadism, and olivopontocerebellar atrophy
Trichothiodystrophy (TTD 1)	AR	<i>ERCC2</i> Excision repair crosscomplementing rodent repair deficiency 2 protein	As for XP, TFIIH also stabilizes thyroid hormone receptors in TTD mouse brain.	Intellectual disability, hair shaft abnormalities, ichthyosis, immature sexual development, short stature, and facial dysmorphism
Rett syndrome	X-linked	<i>MECP2</i> Methyl CpG-binding protein 2	Regulation of gene expression, chromatin composition, and chromosomal architecture through binding to methylated DNA. MeCP2 is expressed ubiquitously by neurons; levels of MeCP2 expression increase during neuronal differentiation and remain at high levels in the adult brain.	Classic phenotype restricted to females. Normal development for first 6 mo, followed by acquired microcephaly, loss of hand skills and replacement by stereotypies, regression of skills, seizures, spasticity, and scoliosis.
Spinal muscular atrophy 1, 2, and 3	AR	<i>SMN1</i> Survival motor neuron protein	SMN1 is a key component of the spliceosome complex; selective vulnerability of anterior horn cells is not yet understood.	Loss of anterior horn cells (and neurons of brain stem and thalami in severe cases)
DNA Translation and Translational Modification				
CACH, Cree	AR	<i>eIF2B</i>	Translation initiation	Slowly progressive

<p>leukoencephalopathy, ovarioleukodystrophy</p>		<p>Eukaryotic translation initiation factor 2B</p>	<p>factor 2B catalyzes exchange of GDP for GTP, an essential stage in recycling of translation initiation factor 2 (eIF2); guanine nucleotide exchange factor (GEF) activity. Mutations in any of the five genes coding for subunits of eIF2B cause loss of normal downregulation of protein translation under stress, resulting in protein denaturation and accumulation of aggregates producing cellular toxicity.</p>	<p>ataxia with diffuse loss of white matter. Episodes of coma with fever and motor impairment with minor trauma.</p>
<p>Congenital disorder of glycosylation 1a (CDG 1a)</p>	<p>AR</p>	<p><i>PMM2</i> Phosphomannomutase 2</p>	<p>PMM2 is one of a family of enzymes catalyzing the assembly of the lipid-linked oligosaccharide (LLO) precursor that is attached to the nascent polypeptide chain during cotranslational modification by <i>N</i>-linked glycosylation.</p>	<p>Intellectual disability, short stature, progressive ataxia, peripheral neuropathy, stroke-like episodes, seizures, immune dysfunction, intermittent hepatic failure, coagulopathies</p>
<p>Cell Cycle Regulation</p>				
<p>Angelman syndrome</p>	<p>Multiple mechanisms, including maternal deletion of 15q11-13, paternal uniparental disomy, imprinting defects, and point mutations or small UBE3A</p>	<p>UBE3A Ubiquitin-protein ligase E3A</p>	<p>The Ube3a gene encodes sense and antisense RNA transcripts in the brain with neuron-specific imprinting of Ube3a in primary brain cell cultures. The maternal UBE3A allele is preferentially expressed in the neuronal nucleus and at synapses;</p>	<p>Psychomotor retardation, ataxia, hypotonia, epilepsy, absence of speech, large mandible, and tongue thrusting. Optic atrophy and albinism in some.</p>

	intragenic deletions. Some patients have MECP2 mutations.		absence of this allele is associated with abnormal dendritic spine morphology.	
Ataxia-telangiectasia	AR	<i>ATM</i> Ataxia-telangiectasia mutated (ATM) protein	The ATM protein is a phosphatidylinositol-3 kinase that phosphorylates key substrates involved in DNA repair and/or cell cycle control	Progressive ataxia, choreoathetosis, anterior horn cell loss, immune deficiency, scleral telangiectasia
Seckel syndrome 1	AR	Ataxia-telangiectasia and Rad3-related (ATR) protein; <i>CEP152</i> Centrosomal protein 152	ATR is a phosphatidylinositol kinase (PIK) involved in cell cycle progression, DNA recombination, and the detection of DNA damage; CEP152 regulates genomic integrity and cellular response to DNA damage.	Short stature, dysmorphism (“bird-headed dwarf”), congenital microcephaly, intellectual disability. No immune deficiency or cancers.

CSB, Cockayne syndrome group B; TFIH, transcription factor II H; COFS, cerebro-oculo-facio-skeletal syndrome; CACH, childhood ataxia with central nervous system hypomyelination.

The Floppy Infant

Darryl C. De Vivo

Jahannaz Dastgir

INTRODUCTION

Tone opposes gravity and maintains postural attitude. The term *hypotonia* refers to a state of low muscle tone. Infants who are hypotonic are often referred to as *floppy* because their limbs and head hang limply rather than firmly extended when held by an examiner in the prone position. These infants also may show a diminished resistance to passive limb movement when examined. The floppy infant seems to be weak, but the examiner may find it difficult to distinguish between true weakness and apparent weakness due to hypotonia and/or hyperlaxity.

Causes for hypotonia in infants are many, and it is the responsibility of the clinician to create a relevant differential diagnosis for the clinical presentation (Fig. 136.1). The clinician should first focus on the presenting history, noting weeks of gestation, intrauterine drug exposure, perinatal ultrasound abnormalities (e.g., cerebral dysgenesis, reduced fetal movements, oligohydramnios, or polyhydramnios), intrauterine infections (herpes simplex, cytomegalovirus, toxoplasmosis, rubella), and perinatal drug exposure or trauma (global or focal). A notation also should be made on whether the infant had low tone, limb contractures, difficulty breathing, or a weak cry at birth. This information helps determine whether the condition began before, at, or after birth. Hypotonia, emerging days after birth suggests an inborn error of metabolism. Additional history, when evaluating an infant in the first month of life, should include the strength of the infant's suck and whether the infant chokes with feeds. Potential exposures to *Clostridium botulinum* (via honey or corn syrup consumption or dirt) are important. Family history may reveal an inherited risk for hypercoagulability (including prior maternal spontaneous abortions), immune-mediated conditions, genetic syndromes (premature death may suggest a metabolic syndrome), neuropathies, myasthenia gravis, or myopathies/muscular dystrophies (developmental delay and weakness).

The aforementioned history will complement a careful neurologic exam that identifies (1) unique dysmorphic features; (2) a highly arched palate or tenting of the mouth (suggestive of congenital tongue weakness); (3) respiratory distress; (4) heart, abdominal, genitourinary, skin (birthmarks, doughy quality), or musculoskeletal abnormalities (congenital scoliosis, kyphosis, contractures, hip dysplasia, torticollis, hyperextensibility of joints); (5) level of alertness; (6) quality of cry; (7) cranial nerve dysfunction (facial weakness, ptosis, limited extraocular movements, tongue fasciculations, tongue atrophy, strength of suck); (8) focal or diffuse weakness; (9) evidence of hypertonicity (increased jitteriness and rigidity of the limbs) or hypotonicity (frog-legged posture while supine, lack of spontaneous movement, scarf sign, tendency to keep the trunk flexed while held in horizontal suspension, slip through); and (10) tendon reflex responses. The pertinent findings on examination, in conjunction with a thorough history, will guide the clinician to whether the infant's presentation is related to a nonneurologic (structural, toxic, or genetic syndrome) or neurologic etiology that may be central (brain and spinal cord) or peripheral (peripheral nerves, neuromuscular junction, or muscle).

If the clinician believes that the hypotonia is neurologic and central in nature, additional workup would include brain imaging (magnetic resonance imaging [MRI] or computed tomography [CT] scan), electroencephalography (EEG), and cerebrospinal fluid (CSF) studies. If the hypotonia is neurologic and peripheral, confirmatory studies may include electromyography (EMG), nerve conduction studies (NCS), serum creatine kinase (CK) levels, muscle ultrasound or MRI, and muscle and/or nerve biopsy. If the findings from these tests raise concerns for a dystrophy or myopathy, additional processing of the muscle for electron microscopy (to identify distinctive

ultrastructural abnormalities), immune staining, or biochemical assays for specific enzyme deficiencies should be performed.

If the clinician finds that the hypotonia is nonneurologic, confirmatory diagnostic workup should address a particular genetic syndrome (chromosomal microarray, whole exome sequencing, or targeted gene sequencing), inborn error of metabolism (blood studies—e.g., glucose, electrolytes, blood gas, ammonium, lactate and pyruvate, carnitine profile, liver function testing, very longchain fatty acids, plasma amino acids, 7-dehydrocholesterol, isoimmune electrophoresis for transferrin; urine studies—e.g., urinalysis, urine amino acids, urine organic acids; CSF studies— e.g., amino acids, lactate, pyruvate, neurotransmitters, pterins, and 5-methyltetrahydrofolate), or structural abnormality (bone films, spinal MRI). These studies complement the newborn screening.

CAUSES OF CENTRAL HYPOTONIA

Central hypotonia refers to decreased tone due to lesions above the anterior horn cells of the spinal cord. Such hypotonia is often symmetric and affects the upper and lower limbs equally. It may also present with additional features of developmental delay (speech, motor, or global), seizures, and/or brisk reflexes.

HYPOXIC-ISCHEMIC ENCEPHALOPATHY

Hypoxic-ischemic encephalopathy (HIE) develops in the setting of perinatal hypoxia. The initial presentation of HIE in the newborn period may be hypotonia in addition to seizures, decreased level of alertness, and/or irritability. Over time, the initial presentation of hypotonia may evolve into increased tone and spasticity.

NEURONAL MIGRATION DISORDERS

Neuronal migration disorders include holoprosencephaly, anencephaly, lissencephaly, pachygyria, polymicrogyria, and/or heterotopias. It should be noted that neuronal migration disorders might be part of a larger syndrome, and some of these syndromes also present with peripheral hypotonia either in the form of myopathy, muscular dystrophy, or neuropathy (e.g., merosindeficient congenital muscular dystrophy, Fukuyama congenital muscular dystrophy, Walker-Warburg syndrome, or muscle-eye-brain disease).

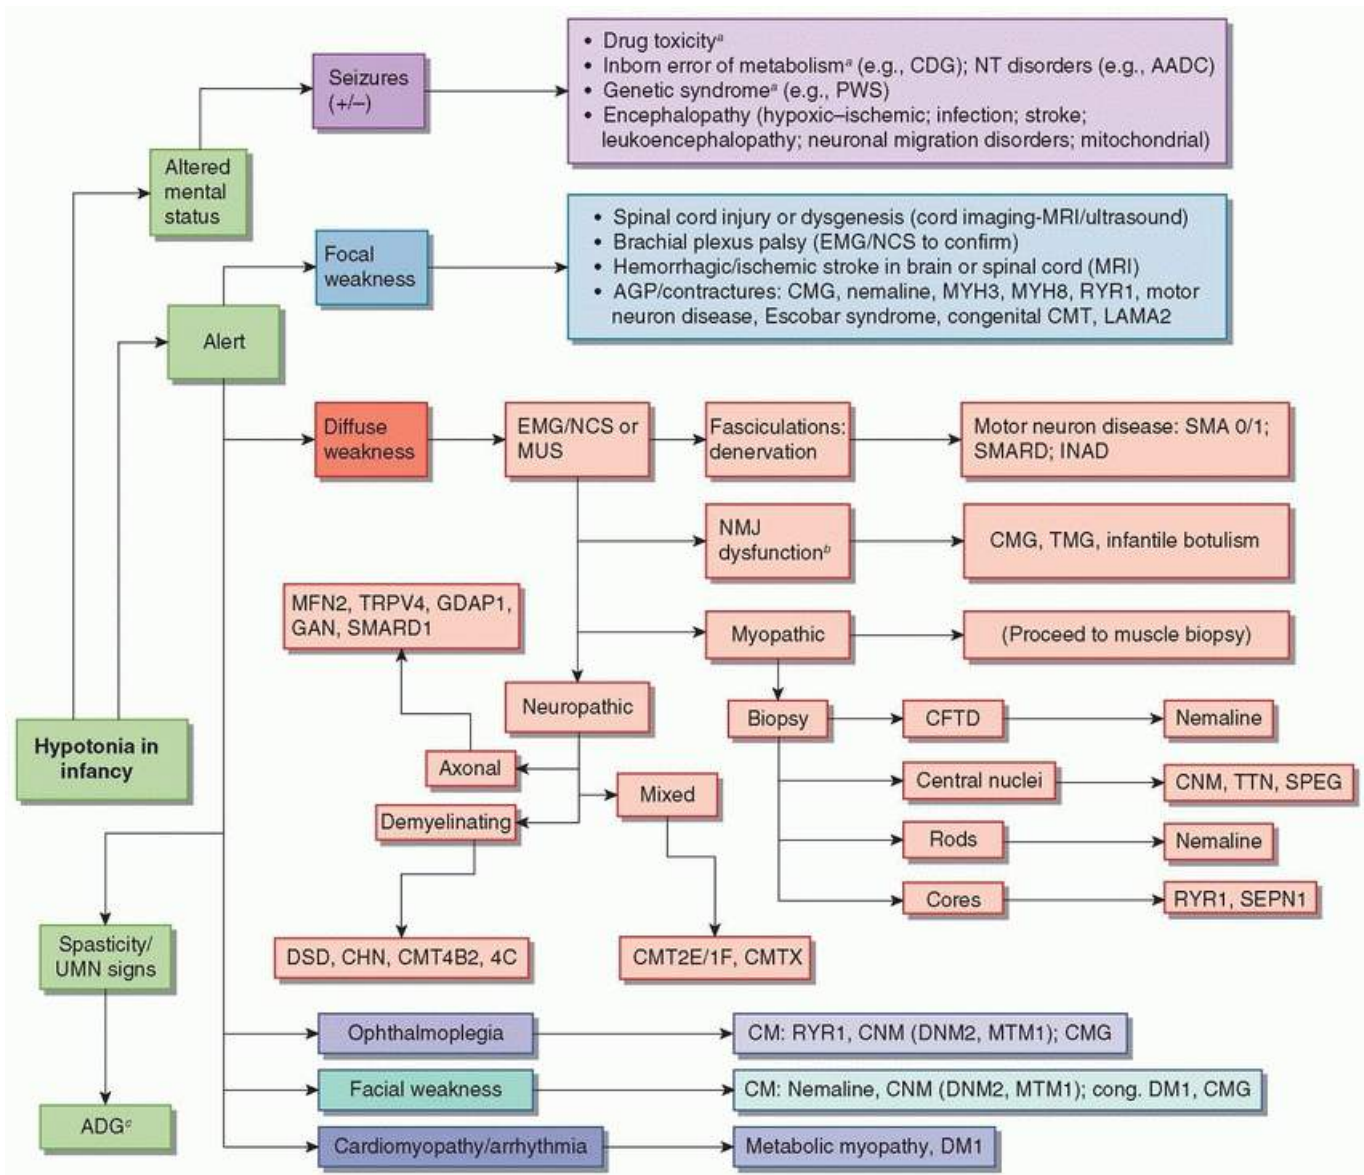

FIGURE 136.1 Differential diagnosis for hypotonia in infants. ^aMay be associated with pathognomonic dysmorphic features. ^bMuscle ultrasound (MUS) is not diagnostic for neuromuscular junction dysfunction but can visualize fasciculations and fibrofatty replacement in muscle either due to myopathy, neuropathy, or motor neuron disease. ^cMay also present with seizures.

AADC, aromatic L-amino acid decarboxylase deficiency; ADG, α -dystroglycanopathy; AGP, arthrogryposis; CDG, congenital disorder of glycosylation; CFTD, congenital fiber-type disproportion; CHN, congenital hypomyelinating neuropathy; CM, congenital myopathy; CMG, congenital myasthenia gravis; CMT, Charcot-Marie-Tooth; CNM, centronuclear myopathy; DM1, myotonic dystrophy; DNM2, dynamin 2 gene; DSD, Dejerine-Sottas disease; EMG, electromyography; GAN, giant axonal neuropathy; GDAP1, ganglioside induced differentiation associated protein 1; INAD, infantile neuroaxonal dystrophy; LAMA2, laminin α -2 gene; MFN2, mitofusin 2 gene; MRI, magnetic resonance imaging; MTM1, myotubularin 1 gene; MUS, muscle ultrasound; MYH, myosin heavy chain; MYH3, myosin heavy chain 3 gene; MYH8, myosin heavy chain 8 gene; NCS, nerve conduction studies; NMJ, neuromuscular junction; NT, neurotransmitter; PWS, Prader-Willi syndrome; RYR, ryanodine receptor 1 gene; SEPN1, selenoprotein 1 gene; SMA, spinal muscular atrophy; SMARD1, spinal muscular atrophy and respiratory distress type 1; SPEG, striated muscle preferentially expressed protein kinase; TMG, transient myasthenia gravis; TRPV4, transient receptor potential cation channel, subfamily V, member 4; TTN, titin gene; UMN, upper motor neuron.

LEUKODYSTROPHIES

Leukodystrophies may also present with a concomitant demyelinating neuropathy (see “[Peripheral Neuropathy](#)” section).

Leukodystrophies are disorders of central nervous system (CNS) myelin development and maintenance (divided into disorders of dysmyelination, hypomyelination, or demyelination). They are genetically determined and may present in infancy with hypotonia, encephalopathy, and/or developmental delays.

VASCULOPATHIES: ISCHEMIC OR HEMORRHAGIC

Neonatal stroke may initially present as hypotonia and later evolve into hypertonia with spasticity.

CONGENITAL INFECTIONS

Congenital infections include toxoplasmosis, *Treponema pallidum*, rubella, cytomegalovirus, herpesvirus, hepatitis B and C viruses, HIV, varicella, and parvovirus B19. These may present with hypotonia in addition to other features of intracranial calcifications or cysts, abnormal liver function, skin rash, hearing loss, encephalopathy, seizures, and/or retinitis or optic nerve atrophy.

INBORN ERRORS OF METABOLISM

Refer to Chapters 134 and 139. Some inborn errors of metabolism may also cause peripheral neuropathy.

GENETIC SYNDROME

Genetic syndromes that most commonly present with hypotonia include Down syndrome, Prader-Willi syndrome, fragile X syndrome, trisomy 18, 1p36 deletion, 22q13 deletion syndrome, 22q11.2 deletion syndrome, DiGeorge/velocardiofacial syndrome, Williams syndrome, trisomy 13, Smith-Magenis syndrome, Sotos syndrome, Lowe syndrome, Smith-Lemli-Opitz syndrome, Wolf-Hirschhorn syndrome, Kabuki syndrome, Cri-du-chat syndrome.

TOXICITY

Intrauterine exposure to drugs such as lamotrigine, lithium, and benzodiazepines have been associated with hypotonia. Antepartum or peripartum maternal exposure to high levels of magnesium sulfate for the treatment of eclampsia and prevention of cerebral palsy has also been associated with congenital hypotonia.

NERVE/CORD INJURY OR STRUCTURAL ABNORMALITY

For discussion of spinal dysraphism/spina bifida, refer to Chapter 133.

Spinal cord injury may be secondary to intrauterine malpositioning or trauma/severe asphyxia during birth (via hypoperfusion between the anterior spinal artery and paired spinal arteries) that subsequently damages the lower motor neurons of the spinal cord. Autopsy studies of fatally asphyxiated neonates demonstrate prominent, ischemic necrosis of anterior spinal cord gray matter. Infants with spinal cord injury often present with hypotonia, weakness, and absent tendon reflexes only in the regions distal to the site of injury. Ultrasound/MRI of the spine also may be used to identify cord ischemia or spinal dysraphism.

CAUSES OF PERIPHERAL HYPOTONIA

Peripheral hypotonia refers to disorders of the motor unit/anterior horn cell, peripheral nerve, neuromuscular junction, and/or muscle. Identifying whether or not there is focality to the weakness often helps with diagnosing its etiology.

FOCAL WEAKNESS: BRACHIAL PLEXUS INJURY

Epidemiology

Brachial plexus injury is variable and ranges from 0.38 to 3 per 1,000 live births in industrialized countries. Birth incidence depends on the type of obstetric care and the average birth weight (strongest predictor) of infants in different geographic regions.

Pathobiology

Shoulder dystocia is a strong predictor for brachial plexus palsy. Vaginal deliveries associated with vacuum extraction or direct compression of the fetal neck during delivery by forceps can cause stretching of the cervical nerve roots (via misdirected traction or hyperextension of the arms) and eventually, brachial plexus injury. A prolonged second stage of labor may also increase the risk.

Clinical Features

Brachial plexus palsies are divided into four categories based on location of injury: (1) upper (Erb palsy, C5-C7, most common palsy presenting with adducted arm that is internally rotated at the shoulder; wrist is flexed and fingers are extended in a “waiter’s tip” posture), (2) intermediate (C7 and sometimes C8 and T1), (3) lower (Klumpke paralysis—C8, T1—poor hand grasp with more intact proximal muscles), and (4) total plexus palsy (C5-C8 and sometimes T1—second most common and the most devastating—claw hand and flaccid arm with no sensation). Additional finding that may be associated with a poor prognosis is Horner syndrome.

Diagnosis

X-rays of the chest, spine, and upper limbs are most important for brachial plexus palsies because they reveal associated injuries (fracture of ribs, transverse process, clavicle, humerus, or phrenic nerve injury). MRI of the upper limb/shoulder and spinal MRI also should be performed to rule out nerve root evulsion. CT myelography may be used if MRI is not possible. EMG/NCS may identify the severity of the neural lesion and detect signs of reinnervation. Serial EMG/NCSs within the first 48 hours after birth will distinguish between prenatal and obstetric causes of brachial plexus palsy. Sensory-evoked potentials can be used to assess the integrity of sensory conduction.

Treatment

For brachial plexus palsy, supportive therapy to maintain passive range of motion and muscle strength is recommended. The optimal timing of surgical exploration remains controversial but most recommend intervention in the first 6 months of life if there is no evidence of clinical recovery.

Outcome

The majority (70% to 95%) of patients with brachial plexus palsy make complete spontaneous recovery, but both the extent (upper, lower, total) and the severity (avulsion, rupture) of the injury influence the prognosis (lower plexopathies tend to be more severe). A small proportion of infants, managed conservatively, have severe permanent disability.

For motor neuron disease, refer to Chapter 141. For congenital myopathies and muscular dystrophies, refer to Chapter 142. For metabolic myopathies, refer to Chapter 134.

Peripheral Neuropathy

Peripheral neuropathies in infancy are rare and can present with hypotonia, weakness, sensory alteration, areflexia, ataxia, contractures, congenital hip dysplasia, and predominantly distal muscle wasting. They may be described according to neurophysiologic findings (via EMG/NCS) and/or findings on nerve biopsy. Inherited neuropathies of the demyelinating or axonal type are described in the following text. Acquired causes are less common in infants and include Guillain-Barré syndrome, nutritional deficiencies (B₁₂, thiamine, or vitamin E), and toxic or infectious (e.g., diphtheria) causes. These will not be discussed in this section (see [Chapter 88](#)).

DEMYELINATING NEUROPATHIES

Dejerine-Sottas Disease (Also Known as CMT3 or HMSN Type III)

Pathobiology: Dejerine-Sottas disease (DSD) may be due to PMP22 point mutations, duplications, or deletions. Mutations in myelin protein zero (MPZ), EGR2, NEFL, periaxin, frabin (FGD4 gene/also referred to as *CMT4H*), and FIG4 (also referred to as *CMT4J*) have also been noted. PMP22 is a glycoprotein with four putative transmembrane domains and accounts for 2% to 5% of compact myelin of the peripheral nervous system. It may play a role in the proliferation and differentiation of Schwann cells. MPZ is a member of the immunoglobulin gene superfamily that functions as a hemophilic adhesion molecule playing an important role in myelin adhesion and compaction. EGR2 is a zinc finger transcription factor, which binds regulatory domains of target genes, including those critical for myelin formation and maintenance. Periaxin is a cytoskeleton-associated protein expressed exclusively in myelinating Schwann cells. It is important for the elongation of Schwann cells and myelination during development. FGD4 is a Rho GDP/GTP nucleotide exchange factor expressed in the peripheral nerve. FGD4 induces changes in Schwann cell shape.

Clinical Features: DSD presents around 6 months with motor delays, hypotonia, and areflexia. Weakness is more distal than proximal. Most patients acquire the skill of walking. Cases associated with PMP22 point mutations may also have sensorineural hearing loss, facial weakness, rarely nystagmus, vestibular dysfunction, ptosis, limited extraocular movements, and bladder symptoms. Adie pupil may be associated with MPZ mutations. EGR2-related neuropathies have a high frequency of cranial nerve involvement. FIG4-related neuropathies have the unusual features of asymmetric involvement and sometimes rapid progression of muscle weakness precipitated by trauma.

Diagnosis: Profound slowing of motor conduction velocities (<10 to 12 m/s) supports the diagnosis. Nerve biopsies show significant reduction in density of myelinated fibers with hypomyelination and/or demyelination and extensive onion bulb formations. In periaxin mutation-related cases, immunohistochemistry demonstrates absent C-terminal L-periaxin staining.

Congenital Hypomyelinating Neuropathy

Pathobiology: Congenital hypomyelinating neuropathy (CHN) is due to PMP22 point mutations (autosomal dominant [AD] or autosomal recessive [AR]), MPZ (AD, AR), or EGR2 (AD, AR) mutations. It is thought to reflect a defect in myelin synthesis.

Clinical Features: Severe cases of CHN present at birth with profound weakness, hypotonia, arthrogryposis, and respiratory insufficiency. Tongue fasciculations may be present. Less severe cases may present in infancy with hypotonia and motor delay.

Diagnosis: NCSs demonstrate very slow or absent responses. Nerve biopsies show complete absence of peripheral nerve myelin without classic onion bulb formations, although some may have unusual “basal lamina

onion bulbs” consisting of concentric whorls of double-layered Schwann cell basement membrane. Evidence of myelin degeneration is absent on pathology.

CMT4B2

Pathobiology: CMT4B2 is due to mutations in the myotubularin-related protein (MTMR13) gene (also known as *SET binding factor 2* [SBF2]).

Clinical Features: Some children present with early-onset glaucoma that precedes the onset of neuropathy and delayed motor milestones.

Diagnosis: NCSs show slowing of motor nerve conduction velocities.

CMT4C

Pathobiology: CMT4C is due to mutations in SH3TC2 or KIAA1985 gene. SH3TC2 is expressed exclusively in Schwann cells and is thought to play a role in endosomal recycling and membrane trafficking processes that are required for normal myelin formation.

Clinical Features: Early-onset severe spinal deformities are often the presenting symptom. Hypotonia is noted in the first few months of life with delayed motor development. Most children achieve walking. Foot deformity is common and may precede weakness. Hearing loss is the most common form of cranial nerve involvement, although facial weakness, nystagmus, and tongue atrophy/fasciculations are also reported. Respiratory insufficiency or hypoventilation may also occur.

Diagnosis: NCSs confirm a demyelinating neuropathy. Nerve biopsy shows loss of myelinated fibers, thinly myelinated fibers, basal lamina onion bulbs, and large cytoplasmic Schwann cell processes surrounding multiple unmyelinated axons.

Infantile Demyelinating Neuropathies with Central Nervous System Involvement

- CNS hypomyelination
 - Hypomyelination with congenital cataracts/DRCTNNBIA gene
 - Peripheral demyelinating neuropathy, central dysmyelinating leukodystrophy, Waardenburg syndrome, and Hirschsprung disease (PCWH)/SOX10 gene
 - Pelizaeus-Merzbacher disease/PLP1
 - Pelizaeus-Merzbacher-like disease/GJA12
 - Cockayne syndrome/ERCC6 and ERCC8 genes
- CNS white matter changes
 - Metachromatic leukodystrophy/ARSA gene
 - Krabbe disease/GALC gene
 - Niemann-Pick disease, type C/NPC1 and NPC2 genes
 - Merosin-deficient congenital muscular dystrophy/LAMA2 gene
 - Navajo neurohepatopathy/MPV17 gene
- Other CNS involvement
 - Congenital disorders of glycosylation/multiple genes

- Congenital cataracts, facial dysmorphism, and neuropathy (CCFDN)/CTP1 gene
- POLG-related hepatocerebral mtDNA deletion syndromes/POLG1 gene
- Leigh syndrome/multiple genes

AXONAL NEUROPATHIES

CMT2A/Mitofusin 2 Mutations

Pathobiology: Mitofusin 2 (MFN2) is a transmembrane GTPase located in the outer mitochondrial membrane. It is important for mitochondrial fusion, axonal mitochondrial transport, and tethering of the mitochondria to the endoplasmic reticulum. Most mutations are dominant (30% to 40% de novo), and some are compound heterozygous and homozygous.

Clinical Features: CMT2A may start in early childhood with distal weakness. Most children reach ambulation, but progression is rapid and usually leads to wheelchair dependence by the end of the second decade. Children may have complete distal paralysis and claw hands. Planus foot is universal in all cases. Early proximal weakness of the lower limbs is also noted and may produce a waddling gait with foot drop. Optic atrophy is noted in 10% to 20% of cases.

Diagnosis: NCSs show axonal and sensory neuropathy with normal velocities. Motor and sensory responses may be unrecordable. Nerve biopsy shows severe loss of large, myelinated fibers and abnormal aggregations of small round mitochondria on electron microscopy.

CMT2C/TRPV4 Mutations

Pathobiology: TRPV4 is a Ca²⁺ permeable nonselective cationic channel widely expressed in a number of tissues (cartilage, motor neurons, and dorsal root ganglia). Mutations result in neurotoxic gain of function effect from increased Ca²⁺ influx. How this translates to a neuromuscular disorder is unknown.

Clinical Features: Those who present in infancy usually have a congenital distal spinal muscular atrophy phenotype presenting with congenital foot deformities (often talipes equinovarus) and contractures of the hips, knees, and Achilles tendons. Congenital hip dysplasia and scoliosis are also common. CMT2C may be associated with vocal cord paresis presenting as stridor or respiratory distress due to diaphragmatic involvement. Additional features include hearing loss, mild sensory loss, hand tremor, and bladder dysfunction.

Diagnosis: NCSs show motor and sensory axonal neuropathy. Findings on biopsy include moderate loss of myelinated fibers and clusters of regenerating axons.

CMT4A/GDAP1 Mutations

Pathobiology: The GDAP1 protein is expressed in axons localized to the outer mitochondrial membrane and involved in mitochondrial fission and regulation of the mitochondrial network.

Clinical Features: CMT4A presents in the first year of life with prominent foot deformities, gait difficulties, and distal weakness. Some children are hypotonic at birth, but many have normal early motor development and walk by 2 years. Hand weakness develops in the first decade and rapidly evolves to “claw hands.” Progressive proximal weakness renders patients wheelchair dependent by the second decade. Vocal cord paresis or hoarseness is a frequent feature. Diaphragmatic dysfunction and restrictive lung disease is also very common. Optic atrophy has been noted.

Diagnosis: Both axonal and demyelinating features are present on NCSs. On nerve biopsy, the most common finding is axonal degeneration, regeneration, and pseudo-onion bulbs. Some patients have a predominantly

demyelinating process with a decrease in the number of myelinated fibers and segmental demyelination.

Giant Axonal Neuropathy

Pathobiology: Giant axonal neuropathy is due to recessive mutations in the gigaxonin (GAN) gene, which is ubiquitously expressed and involved in the maintenance of microtubule networks. Mutations are thought to cause defective ubiquitin-mediated degradation of microtubule-related proteins leading to neuronal toxicity and impaired retrograde axonal transport.

Clinical Features: Children with GAN have severe, early-onset motor and sensory neuropathy with CNS involvement and characteristic “kinky” hair. Most present with delayed development and gait difficulties. Additional CNS involvement (cerebellar signs and/or spasticity) may or may not present early or throughout the course of the disease. The clinical course is progressive with most kids being wheelchair dependent in the second decade.

Diagnosis: NCSs show an axonal sensorimotor neuropathy sometimes with mild slowing of nerve conduction. Visual, somatosensory, and auditory brain stem-evoked potentials are abnormal. EEG may show diffuse slowing with occasional sharp waves. MRI may show periventricular and cerebellar white matter signal abnormalities and/or cerebral, cerebellar, and brain stem atrophy. Biopsy shows characteristic giant axons (large axonal swellings in thinly myelinated/unmyelinated nerve fibers) with densely packed structurally normal bundles of neurofilaments.

Spinal Muscular Atrophy with Respiratory Distress Type I

This is also known as *SMARD1* or *infantile axonal neuropathy with respiratory failure*.

Pathobiology: SMARD1 is due to mutation in the IGHMBP2 gene.

Clinical Features: Children with SMARD1 present with respiratory failure and progressive distal weakness.

Diagnosis: NCSs show absent responses in most cases. Nerve biopsy demonstrates decreased myelinated fibers, active axonal degeneration or active evidence of regeneration, and no onion bulb formations.

Infantile Neuroaxonal Dystrophy/Neuronal Brain Iron Accumulation Syndrome

Pathobiology: Infantile neuroaxonal dystrophy (INAD) is due to recessive mutations in the PLA2G6 gene.

Clinical Features: INAD present with early-onset hypotonia and psychomotor regression. Onset is between 6 months and 3 years after a period of normal development. Children evolve from hypotonia to a spastic tetraparesis, although some children have obvious features of a neuropathy with amyotrophy and areflexia. Gait ataxia, ophthalmologic abnormalities (optic atrophy, nystagmus, and strabismus), and dystonia are frequent. Seizures are rare. Mean age of death is 9 years.

Diagnosis: NCSs shows a sensorimotor axonal neuropathy and EMG evidence of denervation. Abnormal visual-evoked potentials may also be noted. Muscle ultrasound may show fasciculations. Almost all children have cerebellar atrophy on MRI along with T2/fluid-attenuated inversion recovery (FLAIR) hyperintensities in the cerebellum. Around 50% have abnormal iron accumulation in the globus pallidus. Nerve biopsy electron microscopy shows dystrophic axons.

MIXED AXONAL AND DEMYELINATING NEUROPATHY

CMT2E/1F

Pathobiology: CMT2E is due to NEFL mutations (also seen in DSD). Severe, early-onset cases can be caused by dominant or

recessive mutations. NEFL assembles into heteropolymers with heavy and medium neurofilaments forming the major intermediate filament in axons. Neurofilaments determine axonal diameter and thus conduction velocity. NEFL mutations disrupt neurofilaments assembly and axonal transport resulting in decreased axonal diameter and contributing to slowed conduction.

Clinical Features: CMT2E presents in infants with hypotonia, delayed motor development, and/or foot deformity (e.g., pes cavus). Distal weakness and wasting may be severe, and proximal weakness may be present. Additional features include intellectual disability, pyramidal signs, hearing loss, ataxia, and tremor.

Diagnosis: NCSs show mixed axonal and demyelinating features. Compound motor action potentials (CMAPs) are usually moderately to severely reduced and distal motor latencies may be significantly prolonged. Nerve biopsy shows loss of large myelinated fibers with regenerating clusters. Some individuals have giant axons containing accumulations of irregularly oriented neurofilaments.

CMTX

Pathobiology: CMTX is due to mutations in the gap junction protein beta-1 (GJB1 or connexin 32). This is an X-linked CMT. CMTX2 is associated with cognitive impairment. CMTX4 is associated with hearing loss and cognitive deficits.

Clinical Features: CMTX presents with delayed motor development in infancy. Neuropathy is slowly progressive and most patients remain ambulant. Sensorineural hearing loss may occur.

Diagnosis: NCS velocities are in the intermediate range and CMAP amplitudes are usually low. Demyelinating and axonal features are present on nerve biopsies with reduced myelinated fiber density, thinned myelin sheaths, and onion bulb formations. Paranodal abnormalities are also described.

Disorders of the Neuromuscular Junction

For congenital myasthenia, please refer to Chapter 89.

BOTULISM

Epidemiology

As of 2006, infant botulism was reported in at least 26 different countries around the world, with the largest number of cases in the United States (mainly California, Utah, and Eastern Pennsylvania).

Pathobiology

Infant botulism results from the ingestion of *C. botulinum* spores. This bacterium is a gram-positive spore that produces seven different toxins (A→G), and only types A, B, E, and F are known to cause disease in humans. Upon ingestion of *C. botulinum* spores, colonization occurs in the infant's intestinal tract, which lacks the competitive microbial flora that normally inhibits growth of ingested spores. The spores then produce neurotoxins that are absorbed into the blood and eventually bind to the presynaptic nerve terminals. This prevents the binding, fusion, and release of acetylcholine and causes a symmetric, descending motor weakness and flaccid paralysis with autonomic dysfunction.

Clinical Features

Botulinum toxicity often presents with rather acute manifestations of feeding difficulties, decreased gag, ileus, constipation, hypotonia, weakness, pupillary dilation and paralysis, ophthalmoplegia, decreased tendon reflexes, bulbar palsy, and apneic spells.

Diagnosis

Botulism diagnosis may be confirmed by the recovery of the bacterium and the exotoxin in the feces.

Treatment

Treatment for infant botulism is highly dependent on early clinical diagnosis (examination and EMG/NCS) confirmed with identification of the *C. botulinum* organism in the patient's stool. Stool samples should be collected carefully, as the botulinum toxin is poisonous. Baby botulism immune globulin is available only to infants who are diagnosed with suspected botulism within 7 days of hospital admission and after consultation with an Infant Botulism Treatment and Prevention Program (IBTPP) physician.

Outcome

Patients diagnosed with infant botulism are expected to make a complete recovery if spared any secondary complications. Botulism immune globulin intravenous (BIG-IV) shortens hospital stays.

Disorders of Motor and Mental Development

Toni S. Pearson

Reet K. Sidhu

INTRODUCTION

Infancy and early childhood are marked by rapid brain growth and development. A wide variety of genetic and nongenetic factors may affect the immature brain during this period and manifest as a delay in the acquisition of milestones in one or more developmental domains: motor (gross and fine), speech/language, social, and cognitive. The delay may be isolated to one domain. When development in more than one domain is significantly delayed in children younger than the age of 5 years, the term *global developmental delay* applies.

Developmental delay is a common reason for referral to a child neurologist. The aims of the initial neurologic evaluation of a child with developmental delay are, first, to confirm the nature and severity of the suspected delay and second, to characterize any specific findings that may provide a clue to the underlying diagnosis. A detailed history is the key starting point. Items of particular importance include the family history (presence of neurologic or developmental disorders in the siblings, parents, grandparents, aunts, or uncles), perinatal history (complications during pregnancy, birth, or the neonatal period, including prematurity), and history of any coexisting medical problems. With regard to the presenting problem (e.g., motor delay), important items include the age at which the initial concern arose, the child's developmental progress over time, and whether or not there has been developmental regression. On general examination, the child's head circumference, height and weight, and the presence of any dysmorphic features should be noted. The eyes and optic fundi should be thoroughly examined, and skin should be checked for stigmata of neurocutaneous syndromes. Specific features of interest in the neurologic examination will be outlined in the relevant sections below.

DISORDERS OF MOTOR DEVELOPMENT

The acquisition of motor skills features prominently in the first year of life ([Table 137.1](#)). As a result, conditions that affect the motor system often present during infancy with motor developmental delay. Motor delay may also be the first manifestation of a condition that affects development globally because impaired motor function becomes apparent earlier than impairments in other domains such as cognition and language. Motor delay may be accompanied by specific motor symptoms such as stiffness, floppiness, and involuntary movements.

APPROACH TO THE CHILD WITH MOTOR DELAY

The neurologic examination begins with observation, particularly in the infant or toddler. Observe the child's spontaneous posture and movements for asymmetry, paucity of movement that may hint at weakness, abnormal postures, and excessive or involuntary movements. On cranial nerve examination, look for eye movement abnormalities including restricted range of movement and nystagmus. If the child can speak, note whether speech is clear or dysarthric. Turning attention to the body, assess muscle tone in the trunk and limbs. Low truncal tone is common to many disorders that present with motor delay in infancy. Are the limbs hypotonic or spastic? Check whether tendon reflexes are abnormally brisk, suggesting an upper motor neuron lesion, or reduced, suggesting a neuromuscular abnormality. Assess coordination on targeted reaching movements (looking for dysmetria) and, in an older child, rapid alternating movements such as repetitive hand tapping. If the child is able, ask them to rise to standing from the floor (looking for a Gowers sign, which indicates proximal lower limb weakness). Note whether the gait is narrow or wide based and steady or unsteady. If involuntary movements are present, note their body distribution, their quality (e.g., sustained, writhing, or jerky), whether

they are random or repetitive and stereotyped, and in what contexts they appear (e.g., at rest, during movement).

Following the clinical evaluation, brain imaging may be considered. Magnetic resonance imaging of the brain is indicated if there is a history of developmental regression, marked micro- or

P.1189

macrocephaly (>2 standard deviations from the mean), abnormal rate of head growth, or any abnormalities on neurologic examination including cranial nerve dysfunction, focal weakness, spasticity, abnormally brisk reflexes, or involuntary movements. Other investigations, such as genetic testing, may be indicated by the clinical syndrome or brain imaging results. In all cases, the aim is to determine a specific etiologic diagnosis whenever possible in order to guide the most appropriate management strategy. If the clinical syndrome and brain imaging findings are compatible with a developmental malformation or static brain lesion, then symptomatic management will be the most important consideration (see "*Cerebral Palsy*" below). On the other hand, several individually rare genetic and metabolic disorders may present with motor delay and mimic cerebral palsy. It is vital that the child neurologist be alert to signs that may indicate one of these conditions (Table 137.2). Making the correct diagnosis in these selected cases has important implications for management. In some cases, there is a disease-specific treatment that may dramatically improve the clinical course. Even if no disease-specific treatment yet exists, accurate diagnosis makes it possible to provide prognostic information and genetic counseling regarding recurrence risk in future pregnancies to the family.

TABLE 137.1 Motor Developmental Milestones in the First 5 Years

Gross Motor	Age Range
Hold head steady	2-4 mo
Roll over	2-5 mo
Sit without support	5½-7 mo
Pull to stand	8-10 mo
Walk	11-15 mo
Run	14-20 mo
Jump	21-28 mo
Hop	3-4 yr
Balance on one foot for 4 s	3½-5 yr
Fine Motor	Age Range
Grasp rattle	3-4 mo

Reach	4-6 mo
Transfer objects	5-8 mo
Pincer grasp	7-10 mo
Scribble	12-17 mo
Feed self with spoon	13-18 mo
Stack two blocks	13-21 mo
Hold crayon using fingers (not fist)	2-3 yr
Copy a circle	3-4 yr
Refined tripod pencil grip, print own name, copy a square	4-5 yr

Age range indicates approximately the 25th to 90th percentile for each milestone according to the Denver II Developmental Screening Tool.

TABLE 137.2 Features that Should Prompt Evaluation for a Possible Genetic or Metabolic Disorder in a Child Presenting with Symptoms of Cerebral Palsy

- Parent or sibling with a neurologic disorder

- Absent history of perinatal complications

- Normal brain imaging

- Developmental regression

- Progressive neurologic symptoms

- Ataxia or involuntary movements

- Signs of peripheral neuromuscular disease (reduced or absent reflexes, sensory loss)

- Fluctuating motor symptoms, for example, diurnal variation, worsening during fasting or exercise (may be symptoms of a treatable condition, e.g., a neurotransmitter disorder or Glut1 deficiency syndrome)

CEREBRAL PALSY

Cerebral palsy (CP) is an umbrella term that describes a group of disorders characterized by motor impairment due to a developmental anomaly or nonprogressive lesion that arose in the developing fetal or infant brain. CP is not a specific disease and does not imply any one specific etiology. The term remains useful if considered not as a diagnosis in itself, but rather as a descriptive term which has widespread familiarity and conveys a recognized set of clinical characteristics and physical needs.

CP is common, with a birth prevalence of 2 or 3 per 1,000 live births in developed countries. Risk factors include a perinatal history of prematurity, intrauterine growth retardation, multiple gestation, and antepartum hemorrhage. One common misconception is that CP is usually caused by birth asphyxia, but in fact, fewer than 20% of patients with CP have documented perinatal asphyxia in many studies, and the actual proportion may be less than 10%. Other causes of CP include periventricular leukomalacia (the most common form of ischemic brain injury in very preterm infants), cerebral malformations, stroke, and infection. The etiology is usually, but not always, evident on brain imaging.

CP may be classified according to the predominant motor abnormality: spasticity, dyskinesia (involuntary movements including dystonia, chorea, or athetosis), or ataxia. In some cases, there is a mixture of more than one motor feature, such as spasticity and dystonia. Spastic CP may be further classified according to the affected body regions: diplegia (both legs), quadriplegia (all four limbs), and hemiplegia (one side of the body). An accurate characterization of the motor syndrome is important for two reasons. First, it assists the interpretation of the clinical history and brain imaging findings in establishing the etiology of a child's CP. Second, it guides management decisions.

Spastic Diplegia

Approximately one-third of children with CP have spastic diplegia (or diparesis), in which spasticity is predominantly found in the legs. The arms may be mildly affected or unaffected. Parents may notice leg stiffness and a tendency for the legs to cross ("scissoring") due to increased tone in the hip adductor muscles. The increased lower limb tone may lead an infant to roll over or bear weight through the legs at an atypically early age. An older child with mild to moderate symptoms may have a narrow-based, scissoring gait and toe walking. On examination, there is increased tone in the lower limb muscle groups, particularly hip adductors, hamstrings, and calves. Tendon reflexes are brisk and plantar responses are extensor. The most commonly associated brain imaging abnormality is bilateral periventricular white matter lesions, particularly in children with a history of prematurity. The white matter lesions may be periventricular leukomalacia, consequences of intraventricular hemorrhage, or both.

Spastic Quadriplegia

Spastic quadriplegia (found in 20% to 25% of children with CP) is the most severe form. It is frequently associated with diffuse brain injury or dysgenesis. Brain imaging may demonstrate abnormalities in both gray and white matter, such as cystic encephalomalacia resulting from diffuse hypoxic injury. Severe limb hypertonia is often associated with hypotonia in the neck and trunk. A subset of patients has lesions in the deep gray nuclei (basal ganglia or thalamus) and may have a coexisting movement disorder. Most children with spastic quadriplegia are unable to walk and are dependent on a wheelchair for mobility and on support from caregivers for routine daily activities. Due to the diffuse nature of the cerebral insult, a number of comorbidities are often present, including seizures, cognitive impairment, and swallowing and speech difficulties. If swallowing is impaired, a feeding gastrostomy is often required to ensure adequate nutrition. For children who have both the inability to speak and limited voluntary control of hand movements, communication can be very challenging. Effective use of a communication device such as a board or tablet to which the child can point, or devices with eye tracking capability, may vastly improve the quality of life for both the child and their caregivers.

Spastic Hemiparesis

Spastic hemiplegia is found in about one-third of children with CP and results from a unilateral corticospinal tract lesion, such as a cerebral infarct (often in the territory of the middle cerebral artery), focal malformation (e.g., schizencephaly, cortical dysplasia), or posthemorrhagic porencephalic lesion in the white matter.

P.1190

Such lesions may have been acquired prenatally or perinatally, but symptoms tend to manifest around age 6 months, when parents notice that the child exhibits a strong preference to use one hand over the other. Handedness normally develops at age 2 to 3 years, and so an obvious hand preference younger than 12 months of age should prompt clinical evaluation for a hemiparesis.

The hemiparesis usually affects the arm and hand more than the leg. Children with spastic hemiplegic CP are able to walk, although walking may be delayed, and an asymmetric gait pattern with toe walking and circumduction of the affected leg on the affected side is observed. In mild cases, upper limb weakness may only be evident as a subtle loss of hand dexterity or abnormal arm posturing during running. On the other hand, large lesions that involve both the white matter and the cortex can be associated with pronounced weakness as well as cortical sensory loss, leading to little or no functional hand use. Speech and language development is often delayed in the setting of a unilateral lesion of either hemisphere, but most children develop age-appropriate spoken language by the time they enter school. Longitudinal follow-up studies describe the emergence of subtle cognitive weaknesses in school-aged children with a history of perinatal stroke. Seizures are an additional factor that may adversely impact long-term cognitive outcome.

Dyskinetic Cerebral Palsy

Involuntary movements are the predominant motor finding in 5% to 10% of children with CP. The majority of children with dyskinetic CP have a history of term birth. Several types of involuntary movements may occur either alone or in combination. *Dystonia* describes stereotyped, abnormal twisting postures that may be fixed or intermittent. When severe dystonia causes fixed postures that make the limb appear hypertonic, it may be difficult to distinguish from severe spasticity. *Athetosis* refers to continuous writhing or wriggly movements, whereas *chorea* appears as discrete, random-appearing, jerky movements. Children with dyskinetic CP often have a history of hypotonia during early infancy, and their underlying muscle tone also tends to be low. A key feature of the involuntary movements is their tendency to worsen with increased activity or attempts to initiate voluntary movement. Often, muscles of the face and neck are involved in addition to the trunk and limbs.

TABLE 137.3 Selected Genetic Conditions that May Mimic Dyskinetic and Ataxic Cerebral Palsy

Condition	Features
Neurotransmitter disorders	Hypotonia, dystonia with diurnal variation (better in morning and after sleep), oculogyric crises. Diagnosed by CSF neurotransmitter metabolite assay, genetic testing. Many forms respond to levodopa treatment.
Glut1 deficiency syndrome	Seizures, acquired microcephaly, ataxia, spasticity, dystonia, paroxysmal dyskinesia (may be triggered by exercise, fasting); treatment: ketogenic diet
Creatine deficiency	Intellectual disability, seizures, autism, progressive dystonia in guanidinoacetate methyltransferase (GAMT) deficiency. Treated with creatine monohydrate

supplementation.

Benign hereditary chorea	Hypotonia, chorea, dystonia, myoclonus; may be associated with hypothyroidism, neonatal respiratory distress, or asthma.
Lesch-Nyhan syndrome	Hypotonia, dystonia, self-injurious behavior, elevated plasma urate
Ataxia-telangiectasia	Slowly progressive ataxia; chorea; dystonia (involuntary movements may precede onset of ataxia); oculocutaneous telangiectasia; immunodeficiency; elevated serum α -fetoprotein; reduced levels of serum IgA, IgE, IgG ₂
Pelizaeus-Merzbacher disease	Initial hypotonia then spastic quadriplegia, ataxia, \pm dystonia and chorea, nystagmus (in classic form)
Niemann-Pick disease type C	Initial hypotonia followed by vertical supranuclear gaze palsy, slowly progressive ataxia, dystonia; \pm hepatosplenomegaly

CSF, cerebrospinal fluid; Ig, immunoglobulin.

Basal ganglia lesions are the most common abnormality seen on brain imaging in children with dyskinetic CP. These lesions may result from hypoxic-ischemic injury (in which cortical injury is also often seen) or neonatal hyperbilirubinemia (*kernicterus*, usually caused by maternal-fetal blood group incompatibility and now rare in developed countries). In instances where the cortex is spared, children may have good cognitive function despite severe motor disability and speech impairment.

Ataxic Cerebral Palsy

Ataxic CP is the least common form of CP (<5%) and is characterized by hypotonia, trunk and gait ataxia, and limb ataxia (intention tremor, dysmetria). If speech is affected, dysarthria with a slow and scanning quality is typical. Brain imaging may demonstrate a cerebellar malformation or lesion, although it is often normal. Both dyskinetic and ataxic CP are associated with normal brain imaging in a significant proportion of children (approximately one-third and one-half, respectively). In these cases, it is important to consider further investigation for an underlying treatable or neurodegenerative condition ([Table 137.3](#)).

Management of Cerebral Palsy

Children with CP should be referred to a multidisciplinary specialty center and to an early intervention program for therapy services as soon as they are identified. Hearing and vision should both be assessed early. Interventions are directed toward: (1) spasticity management; (2) management of involuntary movements; and (3) improvement of strength, motor abilities, function, and self-care. Effective management requires ongoing regular follow-up as the child grows and develops so that realistic expectations and achievable goals can be set and periodically reevaluated.

Spasticity management aims to reduce hypertonia in order to maximize the child's ability to gain muscle strength and range of movement through physical therapy, and to prevent long-term complications such as joint

contractures and deformity. Functional goals depend on the severity of the child's impairment. For example, the goal for a child with moderate spastic diparesis may be to achieve independent ambulation. In a child with severe spastic quadriplegia, seizures, and intellectual disability, the goal may be to improve comfort and ease the caregivers' burden of care during daily activities such as dressing and bathing. The effect of spasticity on a child's posture and motor function can change over time, often increasing noticeably during periods of rapid growth.

Botulinum toxin injections are an effective tool for reducing spasticity, particularly when targeted toward a limited number of muscle groups. The toxin's effect lasts approximately 3 to 4 months, so injections typically need to be repeated up to three times per year. Sometimes, injections may be combined with serial casting to treat mild contractures. Oral medications such as baclofen (starting dose: 2.5 to 5 mg/day) and diazepam (starting dose: 1 to 5 mg/day depending on age and size) are useful when symptoms are generalized and offer modest benefit, but side effects such as sedation often limit the dose and efficacy.

Neurosurgical options for the management of spasticity include placement of an intrathecal baclofen pump and selective dorsal rhizotomy. Compared to oral baclofen, intrathecal baclofen may achieve a greater reduction in spasticity, particularly in the lower limbs, with fewer side effects. However, this potential benefit must be weighed against the long-term effort needed to maintain the pump and risk of complications. Rhizotomy aims to produce a permanent reduction in tone and is a good treatment option for some patients. Traditionally, the "ideal" rhizotomy candidate has been an ambulating child aged 3 to 8 years with spastic diparesis, in whom the goal of surgery is to optimize gait and independent function. Rhizotomy may also be appropriate in selected patients with spastic quadriplegia in order to ease caregivers' burden of care and reduce the need for future botulinum toxin injections and orthopedic procedures. If musculoskeletal complications such as joint contractures develop despite medical and surgical attempts to control spasticity, orthopedic surgery (such as tendon release procedures) may be indicated.

Children with dyskinetic CP often benefit from symptomatic treatment of their involuntary movements. For dystonia, trihexyphenidyl, starting at a low dose (1 to 2 mg/day) and titrated gradually to the point of tolerance (with common side effects being sedation, constipation, and urinary retention), may reduce abnormal posturing. Levodopa (starting dose: 25 to 50 mg/day) is beneficial in some children with dystonic CP. Hyperkinetic movements, such as chorea or athetosis, may respond to tetrabenazine (starting dose: 6.25 to 12.5 mg/day). Deep brain stimulation, with electrodes placed in the globus pallidus pars interna, may be a surgical option in severe, treatment-refractory cases of dyskinetic CP, although experience regarding efficacy and long-term outcome remains limited.

The rehabilitation team, composed of a physiatrist; orthotist; and physical, occupational, and speech/language therapists, plays an essential role in the care of a child with CP. Physical therapy aims to improve strength and range of movement, train ambulation, and stretch muscles to prevent joint deformity. Occupational therapy focuses on upper limb function and gaining independence with practical skills. Speech and language therapy focuses on communication. It is important to assess the child's home and school environments and determine equipment to facilitate mobility and daily activities.

Although diagnosed during childhood, CP is a lifelong condition, and all interventions made early in life are performed with an eye to the child's future as an adult. Children with severe motor and intellectual disability will require lifelong care, either from a parent or relative or in a nursing home setting. Less affected children need a school and therapy program targeted to their abilities, aiming to maximize their potential for future independence and well-being.

DEVELOPMENTAL COORDINATION DISORDER

Developmental coordination disorder (DCD) affects about 5% to 6% of children and is characterized by subtle

impairments in gross and fine motor skills that typically manifest as difficulties in daily activities such as dressing, writing, or learning to ride a bike. Affected children are often described as “clumsy.” In contrast to CP, the neurologic examination in DCD is normal apart from subtle signs such as mild hypotonia and dysdiadochokinesia. The underlying neurophysiologic basis remains poorly understood. DCD often co-occurs with other developmental disorders including attention deficit hyperactivity disorder, learning disabilities, and speech/language impairment.

DISORDERS OF HIGHER CEREBRAL FUNCTIONS

Assessment of speech and language, cognitive, academic, and reciprocal social abilities is an essential component of the evaluation of a child with developmental delay. The disorders that affect these domains of development are all defined behaviorally, lacking a single biologic marker or gold standard diagnostic instrument. Consequently, thorough assessment is crucial for proper diagnosis and effective management. The groups of developmental disorders of higher cerebral development under consideration are listed in [Table 137.4](#).

APPROACH TO THE CHILD WITH LANGUAGE, COGNITIVE, OR ACADEMIC DELAYS

The age and manner in which children acquire speech and language varies considerably. Knowledge of normal developmental language milestones is essential in order to properly assess a child ([Table 137.5](#)). Speech and/or language delays are one of the most common presenting complaints to a child neurologist, especially in toddlers and preschool children. Hearing impairment must be excluded in all children with speech and language delays. The main diagnostic considerations in toddlers/preschoolers are developmental language disorders, autism spectrum disorders, intellectual disability, and attention deficit hyperactivity disorder (ADHD), although a definitive diagnosis of the latter may be postponed until a child is older if symptoms are not severe.

The mental status examination is the most informative part of the neurologic examination in the evaluation of a developmental disability involving higher cerebral function. The mental status exam in the toddler/preschooler relies heavily on observation. Watch the child play with representational toys (e.g., tiny dolls in a dollhouse, cars and trucks at a fire station, people and animals at a farm), assess his or her ability to talk to and play with the examiner or parent, and observe his or her interest and ability to focus on an activity introduced by another person (playing ball, looking at pictures, drawing). Particular attention should be paid to

P.1192

the child's ability to engage in creative/imaginative play, imitation, behavioral flexibility (ability to switch activities), attention span, and joint attention (the ability to draw another person's attention to an object of interest through the use of eye gaze and gestures, such as pointing).

TABLE 137.4 Developmental Disorders of Higher Cerebral Functions

Disorder	Function Affected	Location of Brain Dysfunction
Intellectual disability	Cognition	Diffuse or multifocal
Dysphasia (developmental language disorder)	Oral language	Language systems
Dyslexia (reading disability)	Written language (phonologic processing)	Language systems (left perisylvian)

Dyscalculia (math disability)	Math (spatial cognition)	Posterior right hemisphere
Nonverbal learning disability (NVLD)	Visuospatial, math, social cognition	Right parietal
Attention deficit hyperactivity disorder (ADHD)	Focused attention (executive functioning)	Prefrontal
Autism spectrum disorders (ASDs)	Social cognition	Connectivity

Speech and/or language disorders can be subdivided based on the area of deficit: expressive or receptive. Expressive disorders can exist in isolation, but receptive disorders always coexist with expressive deficits. Speech and language skills should be assessed in the following areas: (1) production: amount of speech and its intelligibility, fluency, length and syntactic complexity of sentences, and richness of vocabulary; (2) pragmatics: knowing how to engage another person in conversation, turn taking, topic maintenance, appropriate eye gaze, awareness of tone of voice, facial expression, gestures, and body postures; (3) comprehension: following commands, answering simple questions (e.g., what's that? where is_?), answering complex, open-ended questions (e.g., why? when? how?); and (4) abnormal features: immediate echolalia, delayed echolalia (overlearned scripts), perseveration, abnormal prosody, and narrow range of topics.

In school-age children, school failure or underachievement is a common presenting complaint. In this age group, the differential diagnosis includes those disorders under consideration in the toddler/preschool years but expands to include disorders affecting academic achievement, for example, learning disabilities. Thus, the evaluation of the older child must include an assessment of academics in the areas of reading, writing, spelling, and mathematics. An assessment of cognitive ability is the first step, as the diagnosis of learning disability implies at least average intelligence. Attention should also be evaluated, as attention deficit hyperactivity disorder can now be diagnosed more reliably than in the toddler/preschooler. Language screening in the office is best done through a combination of informal assessment (as described for the preschooler) and standardized measures to assess vocabulary, word retrieval, word fluency, and automaticity of retrieval. General fund of knowledge, reading, spelling, writing, arithmetic, drawing (visuospatial skills), attention, and social reciprocity should also be evaluated. These skills can be assessed qualitatively; however, standardized screening tests are advisable to increase reliability.

Many children will come to the office with a detailed quantitative report generated by a psychologist or neuropsychologist detailing the strengths and weaknesses in cognitive, linguistic, and academic domains. It is important to be knowledgeable in the interpretation of these tests, and their scores as parents rely on neurologists to synthesize the findings for diagnostic clarification and developing an effective management plan. If a child has not had a formal assessment, it is advisable to have a comprehensive evaluation by a psychologist (preferably a neuropsychologist) and speech language pathologist to assess the child's cognitive and linguistic strengths and weaknesses. This should include a report of school achievement tests when learning disabilities are suspected. Attention disorders (with or without hyperactivity) frequently co-occur with learning disability; therefore, it is essential to diagnose these conditions accurately, as management strategies are quite different (i.e., educational vs. pharmacologic).

DEVELOPMENTAL LANGUAGE DISORDERS

Developmental language disorders (DLI), often lumped under the umbrella term *specific language impairment* (SLI) or *developmental dysphasias*, are a heterogeneous group of disorders characterized by inadequate

language acquisition at the expected age despite otherwise normal development. The diagnostic criteria remain controversial, but DLD is usually ascribed when there is evidence that expressive and/or receptive language deficit is not attributable to inadequate hearing, intellectual disability, extreme and prolonged social deprivation (not simply social impoverishment), or a known brain lesion. Dysphasias can affect phonology (speech sounds) and syntax (word order, grammar) or higher order language processing skills, for example, semantic (word meaning) and pragmatics (communicative and conversational use of language). Genetics is the major cause of the developmental dysphasias, which occur more frequently in boys than girls.

Autism spectrum disorder (ASD) is an important diagnostic consideration in any child with a speech and/or language delays. Children with ASDs differ from children with DLD in their lack of drive to communicate. Unlike ASD, children with DLD use gestures, such as pointing and head nodding, which are usually well coordinated with eye gaze and facial expressions. Children with ASD have abnormal features such as echolalia, overlearned scripts, and perseverative language, in addition to the hallmark of impaired social reciprocity (see [Chapter 138](#)).

The occurrence of language regression in a child raises alarm in most families and sets off a cascade of neurodiagnostic testing that usually involves performing an electroencephalography (EEG). The exceptionally rare acquired epileptic aphasia or *Landau-Kleffner syndrome* (LKS) refers to previously normal children who lose their language skills, usually due to word deafness (i.e., auditory verbal agnosia), in the setting of clinical seizures or an epileptiform EEG, activated in sleep. Electrical status epilepticus during slow-wave sleep (ESES) is the electroencephalographic pattern seen in LKS. Similarly, approximately one-third of children with ASDs experience regression during

P.1193

the first 1 to 3 years of life, commonly referred to as *autistic regression*. EEGs in these children can be epileptiform. Children with autistic regression, however, undergo a more global loss of skills involving language, nonverbal communication, and sociability, unlike those with LKS who tend to maintain nonverbal communication skills and reciprocal social capabilities. The degree of overlap between LKS, ESES, and autistic regression with epileptiform EEG is currently poorly understood, although it is known that ESES is rarely seen in children with a more global autistic regression.

TABLE 137.5 Language and Social//Emotional Milestones

Age	Receptive Skills	Expressive Skills	Social/Emotional
0-2 mo	Startle, eye widening to sound	Range of cries (from hunger to pain)	Smiles spontaneously
2-4 mo	Quiets to voice, eye blinking to sound	Coos in response to voice	Smiles responsively
4-9 mo	Head turns to sound, responds with raised arms when mom says "up" and reaches for child, responds appropriately to friendly or angry voices	Babbling, repeats self-initiated sounds	Laughs to social attentions
9-	Listens selectively to	Repeats parent-initiated sounds,	Responds and

12 mo	familiar words, begins to respond to “no” and to one-step commands (usually accompanied by gesture), understands 10 words	symbolic gestures, jargoning, says “mama/dada” nonspecifically	plays social games: pat-a-cake, peek-a-boo. Joint attention emerges.
12-18 mo	Points to three body parts, understands up to 50 words, recognizes common objects by name, follows one-step commands accompanied by gestures	Uses words to express needs, 10 words by 18 mo, word usage may be inconsistent and mixed with jargon	Responds to name, joint attention established, functional play
18 mo-2 yr	Points to pictures when asked “show me,” begins to distinguish “you” from “me”	Telegraphic two-word phrases “go bye-bye,” “mama up,” “baby go,” 2 yr: vocab of at least 50 words and 50% intelligible by strangers	Symbolic play (feed baby, mix food in bowls)
2½ yr	Follows two-step commands, can identify actions in pictures and objects by use	2-3-word sentences develop, adjectives and adverbs appear, begins to ask questions	Imaginative play
3 yr	Knows several colors, knows what to do when we are hungry, thirsty, or sleepy; aware of past and future, understands “today” and “not today”	Uses pronouns and plurals, sentence length increases to 3-5 words, can tell stories that begin to be understood; uses negatives “I can’t” and “I won’t”; verbalizes toileting needs; tells full name, age, and gender	Starts to join in play with other children, begins dramatic play
3 ½ yr	Answers questions as “do you have a doll?” and “what toys do you have?”	Can relate experiences in sequential order, asks for permission	More independent in play with other children, shares toys and takes turns with assistance
4 yr	Understands same versus different, can follow three-step commands, understands why we have houses, umbrellas ...	Can tell a story, uses past tense, names primary colors, asks many questions, nearly all speech understood by strangers	Fully plays and interacts with other children, improving in turn taking and cooperation, very imaginative with self and others
5 yr	Understands what we do with eyes and ears; understands “if,” “because,”	Asks definition of specific words, makes serious inquiries (“how does this work?” “what does it mean?”),	Respects reasonable authority, wants to

“when,” “why”; understands differences and comparisons; begins to understand left and right

language is now complete in structure and form, all parts of speech are used as well as all types of sentences and clauses

do what is expected, plays games with rules

INTELLECTUAL DISABILITY

Intellectual disability (ID), also known as *intellectual developmental disorder*, requires limitations in both intellectual ability and deficits in adaptive skills relative to the child's age, experience, and environment. The onset of both deficits must occur during the

P.1194

developmental period. Deficits in intellectual functioning must be confirmed through clinical evaluation and standardized IQ testing. The IQ definition of ID uses 100 as the mean and 15 as the standard deviation. An IQ score of 65 to 75 (approximately 2 standard deviations below the mean, with a variation of +/- 5 points) is the demarcation point. The level and severity of ID (mild, moderate, severe, and profound) is defined on the basis of adaptive skills rather than the IQ score. The definition links the severity of ID to the degree of community support required to achieve optimal independence. Mild ID indicates the need for intermittent support, moderate ID for limited support, severe ID for extensive support, and profound ID for pervasive support. Although both intellectual and adaptive functioning are pertinent in defining ID, impairment of adaptive function is more likely to be the presenting feature than low IQ; however, it is expected that there is an association between intellectual functioning and adaptive skills.

The term *global developmental delay* (GDD) is used to describe children younger than the age of 5 years with significant delays in developmental milestones in several areas of functioning. GDD can be diagnosed using a standardized test, which shows performance at least two standard deviations below the mean in at least two developmental domains: motor, speech and language, cognition, personal-social, and/or adaptive (daily living). The diagnosis of ID is not used for children younger than 5 years old because IQ scores are not reliable until after 5 years and because some children with GDD will not meet criteria for ID as they get older.

The prevalence of ID varies due to differences in diagnostic approach, population characteristics, and study design but is generally considered to be 1%. Mild ID represents the majority (85%) and severe ID the minority (0.5% to 1%). Those with severe ID are more likely to have a definable etiology, whereas those with mild ID tend to come from socially disadvantaged backgrounds, often with a family history of mild ID or borderline intellectual function. The prevalence of GDD (in children younger than 5 years) is estimated at 1% to 3%.

The yield of diagnostic testing in determining a cause for GDD/ID is quite variable. The diagnostic evaluation should focus on clues for a genetic versus acquired etiology for ID. Recent years have seen important progress in identifying the genes involved in ID and currently, genetic defects are found in approximately 25% to 50%. A history of consanguinity, pregnancy losses/stillbirths, postnatal deaths of prior offspring, or birth defects should raise suspicion for a genetic etiology. If there is a family member known to have GDD/ID, testing specific to the known disorder should be performed, and if not known, a comprehensive genetics evaluation should be initiated. Observed dysmorphic features may prompt specific testing (e.g., Down syndrome, fragile X syndrome).

Other neurodiagnostic investigations should be undertaken based on the clinical picture. Inherited metabolic diseases are responsible for 1% to 5% of unspecified ID, and testing should be undertaken if clinical indicators are present. An EEG is appropriate if an underlying epilepsy syndrome is suspected or when there are paroxysmal behaviors concerning for seizures. Neuroimaging is recommended as part of the diagnostic evaluation of a child with GDD. Magnetic resonance imaging is more sensitive than computed tomography (CT), with abnormalities found in approximately one-half to one-third of children with global delay. The chance of detecting an abnormality increases if physical abnormalities, particularly CP, are present.

The management of children with ID focuses on finding the appropriate educational setting for children with mild ID, vocational training for those with moderate ID, and determining home or institutional placement for those with severe and profound ID. Available evidence demonstrates the benefits of early intervention through a variety of programs, at least with respect to short-term outcomes, and suggests that early diagnosis of a child with global delay may improve long-term outcome.

LEARNING DISABILITIES

Learning disabilities (LDs) occur in approximately 10% to 15% of school-aged children and can affect one or more academic skills. LDs involve reading (dyslexia), spelling (dysorthographia), writing (dysgraphia), mathematics (dyscalculia), and visuospatial skills (nonverbal learning disability [NVLD]). Executive functioning deficits are seen in LDs and also in disorders of attention, for example, attention deficit hyperactivity disorder. Specific learning disabilities do not refer to those children whose learning problems result from visual, hearing, or motor handicaps or are a consequence of emotional disturbance, environmental, cultural, or economic disadvantage. The term *learning disability* implies at least average intelligence.

DYSLEXIA

Developmental dyslexia is the most widely recognized and most common LD. It occurs in as many as 10% of school-aged children and comprises 80% of LDs. Boys are more often affected than girls. Dyslexia is characterized by an unexpected difficulty learning to read despite at least average intelligence, adequate instruction, and sociocultural opportunity. Major sensory functions must be normal. Dyslexia has a significant genetic component with heritability estimated at 54% to 84%. Dyslexia-susceptibility-1-candidate-1 (DYX1C1) was the first gene reported to be associated with dyslexia. Numerous candidate dyslexia susceptibility genes have subsequently been identified including several that affect neuronal migration.

There are different subtypes of dyslexia but the most common involves impaired phonologic processing. Children with dyslexia have difficulties with accurate and/or fluent word recognition, poor spelling, and decoding abilities. They have problems segmenting and sequencing speech into phonemes (e.g., speech sounds). Measures that assess phonologic functioning (e.g., segmenting words [say *cowboy* without the *boy*, say *smack* without the *m*], word and nonword blending, sound matching of first and last syllables) best differentiate dyslexic from normal readers.

A history of language delay and/or a family history of reading disabilities are often found in those with dyslexia. The elemental neurologic examination is normal. Routine imaging is normal and unnecessary, except perhaps in children with abnormalities on neurologic examination, seizures, or large discrepancies between verbal and spatial skills. All children with dyslexia should have a formal neuropsychological evaluation to determine their cognitive abilities (strengths and weaknesses) and to determine if there are co-occurring conditions that might affect treatment (e.g., ADHD).

Dyslexia is a lifelong disorder; however, most children with early reading problems learn to read at average to above-average levels if they are diagnosed by age 8 to 9 years (i.e., third or fourth grade) and evidence-based reading instruction is provided. Early diagnosis is essential, as children diagnosed late are likely to continue to have reading problems, even if remediated. Large population studies suggest that some degree of reading disability persists into adulthood in most, and occupational attainment may be lower in some.

NONVERBAL LEARNING DISABILITIES

Mycklebust and Johnson coined the term *nonverbal learning disabilities* in 1967. It described a predominantly social emotional disorder that in many ways resembled the current concepts of the ASDs but included some

spatial difficulties as well. The distinction between NVLDs and high-functioning ASD is widely debated. Some differentiate NVLD from ASD based on the lack of restrictive behaviors and the presence of greater verbal than performance IQ in the former. Subtypes of NVLD were subsequently described that involved varying degrees of social cognitive impairments, visuospatial skills, math difficulties, attention, and executive functioning relative to average or above-average reading (decoding) and spelling. NVLD does not appear in the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*), but is referred to by various other names, including *right hemisphere syndrome* and *visuospatial learning disability*. The exact prevalence is unknown largely due to varying definitions but it is generally thought to account for approximately 10% of all LDs.

The basis for the identification of children with NVLDs is usually their higher verbal as compared with performance IQ scores on neuropsychological assessment batteries. This is an indicator of their visuospatial and visuomotor difficulties, which are a core feature of the disorder. A complete neuropsychological evaluation is required for diagnosis. Suggested management for NVLDs often trades on developing verbal strengths to compensate for the nonverbal deficits.

DYSCALCULIA

Developmental dyscalculia involves any or all aspects of mathematics from difficulties representing and manipulating numeric information to learning and remembering arithmetic facts to executing arithmetic procedures. The prevalence of dyscalculia is approximately 3% to 6%, affecting both genders equally. A developmental Gerstmann syndrome (right/left disorientation, finger agnosia, dysgraphia, dyscalculia, and sometimes constructional apraxia) occurs in as many as 2% of school-aged children. ADHD co-occurs in one-fourth of individuals and approximately one-fifth have dyslexia.

Comprehensive neuropsychological evaluations are recommended in individuals suspected of having dyscalculia. Children with neuropsychological signs of both left and right hemisphere dysfunction can have dyscalculia. Both groups have similar problems on arithmetic batteries, but those with left hemisphere dysfunction seem to perform significantly worse in addition, subtraction, complex multiplication, and division and also make more visuospatial errors. Math remediation is appropriate for the child with isolated difficulties or with mathematics difficulties in combination with other learning difficulties.

ATTENTION DEFICIT HYPERACTIVITY DISORDER

Attention deficit hyperactivity disorder begins in childhood with symptoms of hyperactivity, impulsivity, and/or inattention. For children younger than 17 years of age, the *DSM-5* diagnosis requires six or more symptoms of hyperactivity and impulsivity and six or more symptoms of inattention. For individuals 17 years and older, five or more symptoms per category are required. Depending on the predominance of symptoms, ADHD is divided into three subtypes: predominantly inattentive, predominantly hyperactive/impulsive, and combined type. Symptoms of hyperactivity/impulsivity and inattention must occur often; be present in more than one setting, such as school or work and home; persist for at least 6 months; be present before age 12 years; impair academic, social, or occupational functioning; and be excessive for the developmental level of the child.

The reported prevalence of ADHD in school-aged children ranges from 1% to 20%. The *DSM-5* conservatively estimates the prevalence of ADHD as about 5% of children and 2.5% of adults in most cultures. The variation in prevalence is secondary to differing techniques of ascertainment and invariably reflects the lack of a biologic marker for the disorder. ADHD occurs approximately twice as often in males. Affected females are more likely to present primarily with inattentive features.

ADHD occurs and can be diagnosed in the toddler (although the false-positive rate is relatively high). The diagnosis is more reliably made when a child reaches 4 years old. Hyperactive and impulsive symptoms typically increase during the next 3 to 4 years, peaking at age 7 to 8 years. By adolescence, hyperactivity symptoms

diminish, although symptoms of impulsivity and feelings of restlessness persist. Symptoms of inattention usually are not obvious until the child is 8 to 9 years old. ADHD persists into adulthood in two-thirds to three-fourths of people diagnosed with ADHD in childhood.

Attention disorders (with or without hyperactivity) are diagnosed based on history obtained from parents, observations of the child, questionnaires from parents and teachers, and in some instances, computerized tests of attention. As the disorder must affect functioning in at least two settings (i.e., school and home), it is advisable to obtain some written or verbal report from the child's teacher or school personnel. Given the high rate of psychiatric comorbidities in ADHD (e.g., anxiety and mood disorders, oppositional defiant disorder, conduct disorder), both narrow-band questionnaires that specifically assess for ADHD and broad-band questionnaires that assess for ADHD as well as other psychiatric comorbidities should be used. The elemental neurologic examination is generally normal, although minor findings are common (e.g., synkinesis during repetitive finger tapping and sequencing tasks). Neuropsychological testing is not absolutely necessary unless comorbid learning disabilities are suspected. The neuropsychological profile usually reveals average intelligence, but low scores are common on the Wechsler IQ subtests that demand attention or rapid processing (e.g., digit span, coding, arithmetic, symbol search) and intratest scatter often is found, reflecting variability in attention. Executive frontal lobe functioning, the ability to initiate, inhibit, sustain, and shift attention, working memory, and organizational skills, is often impaired.

ADHD has a substantial genetic component. Reported heritability of ADHD ranges from 0.70 to 0.88 in twins. ADHD frequently co-occurs with other neurobehavioral disorders such as Tourette syndrome, obsessive-compulsive disorder, anxiety, and learning disabilities, raising the question of possible shared susceptibility genes.

Dopamine appears to be the primary neurotransmitter involved in ADHD. Medications that increase levels of dopamine, in particular psychostimulants, are the mainstay of treatment. The National Institutes of Health (NIH)-sponsored Multimodal Treatment Study of ADHD (MTA) has shown both behaviorally and by neuropsychological testing that stimulants work and that they work better than behavioral modification [Level 1].¹ Approximately 75% of children respond to stimulants initially. Side effects may limit treatment (e.g., weight loss, rebound depression or irritability, flat affect) in 5% to 10%. Many different formulations of the stimulants exist, with different durations of action. Tics are not a

P.1196

contraindication to stimulant use in ADHD, although they may affect medication choices. Comorbid mood or anxiety disorders also influence medication choice. Medications other than stimulants can be used to treat ADHD. Atomoxetine (starting dose: 0.5 mg/kg q.d.) and α -agonists clonidine (starting dose: 0.05 to 0.1 mg q.d.), guanfacine (starting dose: 0.5 to 1 mg q.d.), Intuniv (starting dose: 1 mg q.d.), and Kapvay (starting dose: 0.1 mg q.h.s.) are accepted nonstimulant medication choices. Tricyclic antidepressants, selective serotonin reuptake inhibitors, serotonin-norepinephrine reuptake inhibitors, bupropion, and modafinil have all been used generally in those who failed to respond to stimulants. In addition to medication, treatment should focus on parent skills training, educational accommodations (preferential seating, extended time/separate testing site for testing, organizational supports), and behavioral modification.

LEVEL 1 EVIDENCE

Autism Spectrum Disorders

Reet K. Sidhu

INTRODUCTION

Autism spectrum disorders (ASD) are a heterogeneous group of biologically based neurodevelopmental disorders of brain function. They are a behaviorally defined group of disorders that are characterized by impairments in two areas: (1) deficits in social communication and social interactions and (2) restricted and repetitive patterns of behavior, interests, and activities. The term *autism* (originating from the Greek word *autos* meaning *self*) was adopted by Leo Kanner in 1943 to describe children whose behavior was “governed rigidly and consistently by the powerful desire for aloneness and sameness.”

The ASDs have been defined in the *Diagnostic and Statistical Manual of Mental Disorders (DSM)* of the American Psychiatric Association under many different names including the umbrella term *pervasive developmental disorder* or PDD, causing much confusion for both families and professionals. With the most recent 2013 revision, *Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5)*, ASD now subsumes what were previously separate diagnostic categories of autistic disorder (also referred to as *classic autism* or *early infantile autism*), pervasive developmental disorder not otherwise specified (PDD-NOS), and Asperger syndrome. These changes are based on research results which have failed to document these categories as separate biologic entities.

Under the *DSM-5*, a diagnosis of ASD requires an individual to exhibit three deficits in social communication and at least two symptoms in the category of restricted range of activities/repetitive behaviors. The prior version of the diagnostic manual also included deficits in language expression as a separate criterion, but this is no longer the case, as not all children with ASD have specific language disorders. Pragmatic language skills, however, are incorporated into the social domain, as all individuals with ASD have deficits in this domain of language. Within the second category, a new symptom is included: hyper- or hyporeactivity to sensory input or unusual interests in sensory aspects of the environment. Deficits in social communication and interactions include those in social reciprocity; nonverbal communication; and skills in developing, maintaining, and understanding relationships. Symptoms must be present in early development but need not be shown until social demands exceed the individual's capacity. Furthermore, *DSM-5* specifies three levels of severity (mild, moderate, severe) rated separately for social communication and restricted, repetitive behaviors based on what level of support the individual requires. In addition to the diagnosis, individuals are also described in terms of any known genetic cause (e.g., fragile X syndrome, Rett syndrome), level of language and intellectual disability, and presence of medical conditions such as seizures, psychiatric disorders (e.g., anxiety, depression), and/or gastrointestinal disorders. The variability in severity and range of disabilities seen in children with ASD cannot be overemphasized. A full description of the *DSM-5* criteria for ASD can be found in the American Psychiatric Association, *Diagnostic and Statistical Manual of Mental Disorders, 5th edition*.

EPIDEMIOLOGY

There has been a significant increase in the prevalence of ASD in the United States, particularly since the late 1990s when the estimated frequency was about 1 per 1,000 for autism and 2.8 per 1,000 for all ASD subtypes (autistic disorder, Asperger syndrome, and PDD-NOS). The estimated prevalence is much higher now. The Autism and Developmental Disabilities Monitoring Network (2010, 2014) that identifies ASD through screening and review of health and education records that document behaviors associated with ASD in 11 sites in the United States most recently reported a prevalence rate of 14.7 per 1,000 (1 in 68) among 8-year-olds, with

prevalence estimates varying from 5.7 to 21.9 per 1,000 in the different sites. Non-Hispanic white children were approximately 30% more likely to be identified with ASD than non-Hispanic black children and almost 50% more than Hispanic children. ASDs are four times more likely in males than in females.

Factors such as increased awareness among parents and professionals, broadening of the diagnosis with emphasis on the spectrum aspect of the disorder, including mildly affected individuals, change in referral patterns, and using the diagnosis as a basis for intervention services may account for increased prevalence rates. The theory that vaccines, in particular the measles, mumps, rubella (MMR) vaccine, play any role in the increased prevalence of autism has been completely discredited.

PATHOBIOLOGY

NEUROPATHOLOGY

ASDs are characterized as neurodevelopmental disorders because their signs and symptoms have been demonstrated to be the result of alterations in brain structure and function. Although much remains to be discovered, a great deal is now known about the fundamental alterations in the brain in ASD. ASDs are now considered disorders of the development of connectivity of neurons of cerebral cortex, which results in disturbances in the highly specialized connections that provide for uniquely human abilities. Studies of brain structure have implicated multiple events in prenatal and postnatal brain development, particularly neuronal organizational events. The generalized enlargement of the brain resulting from premature overgrowth attests to the broadness of the involvement of the brain, precluding focal brain theories and single primary deficit theories. The occurrence of mutations in genes that act on molecular signaling pathways involved in the development and maintenance of neuronal and synaptic connections have reinforced the centrality of disruption of cortical connectivity in ASD.

The most consistent abnormality seen on neuroimaging studies and in postmortem examination is an increase in brain weight and volume in children with ASDs compared to controls. Very young children with ASD (18 months to 4 years) have a 5% to 10% increase in brain volume, especially in the frontal lobe, which

P.1198

parallels the increasing head circumference during this period. By adolescence and adulthood, however, brain volumes seem to be lower than in controls, suggesting brain overgrowth within the first few years of life followed by volume loss. Increased brain volume in childhood is attributed primarily to enlargement of white matter, specifically the corona radiata and U-fibers, whereas the size of the corpus callosum is reduced, perhaps resulting in decreased interhemispheric communication. The white matter abnormalities result in abnormality of connectivity. At the cytoarchitectonic level, minicolumns that determine connectivity are abnormal, especially in the dorsolateral prefrontal cortex. As a result, and well delineated on diffusion tensor (DT) imaging, short-range connectivity is increased, and long-range connectivity is decreased. The hyperconnected local networks may become partially isolated and acquire novel functional properties. By contrast, the decrease in long-range connections could explain the problems with top-down control and integration.

Imaging studies also highlight the dissociation between white matter tract overgrowth and gray matter dendritic and synaptic underdevelopment. Also found is an enlargement of the cerebellum and caudate nuclei. Larger caudate volumes are associated with more severe stereotyped motor mannerisms. Volumes of the amygdala and hippocampus have been more variable. In addition to showing an increase in short-range connectivity and decrease in long-range connectivity, DT imaging also demonstrates an alteration of white matter tracts in brain regions implicated in social cognition, including the fusiform gyrus, superior temporal gyrus, ventromedial prefrontal cortex, anterior cingulate, and temporoparietal junction. Magnetic resonance (MR) spectroscopy studies suggest that gray matter is abnormal and dendritic arborization and synaptosome density reduced with lower levels of neuronal *N*-acetylaspartate and alterations in choline and creatinine metabolism.

Positron emission tomography (PET) and single-photon emission computed tomography (SPECT) suggest reduced brain perfusion and abnormalities of serotonin synthesis. Functional imaging studies (functional magnetic resonance imaging [fMRI]) have shown atypical patterns of brain activation during tasks of face processing, language, and emotional understanding. Activation of the mirror neuron system—a network within the inferior frontal gyrus and posterior parietal lobe that is thought to subserve imitation and understanding of intentions of other people—is reduced in individuals with ASDs, suggesting a role for this network in the pathogenesis of autism.

Neuropathologic studies have generally consisted of few subjects, but postmortem abnormalities include inflammatory changes and reduced width and increased number of cortical minicolumns compared with controls. A recent postmortem study supports a prenatal onset of ASD occurring during the second and third trimester of pregnancy. Focal patches of abnormal laminar cytoarchitecture and cortical disorganization of neurons, but not glia, were found in the prefrontal and temporal cortical tissue from 10 of 11 children with autism and from 1 of 11 unaffected children, supporting a probable dysregulation of layer formation and layerspecific neuronal differentiation prenatally.

GENETICS

ASDs are clinically and etiologically heterogeneous. Twin and family studies provide evidence for ASD as a highly genetic disorder with heritability estimates of 85% to 92%. Genetic heterogeneity is suspected. Using currently available technology, a genetic cause can be identified in 30% to 40% of children with ASD. This number has increased with the use of chromosomal microarrays (CMAs).

Known genetic causes of ASD include cytogenetically visible chromosomal abnormalities (5%), copy number variants (CNVs) (e.g., submicroscopic deletions and duplications) (10% to 20%), and single gene disorders in which neurologic findings are associated with ASD (5%). CMA is rapidly replacing high-resolution chromosomes as the initial test of choice to evaluate children with ASD. CMA has identified clinically relevant de novo genetic imbalances in up to 20% of individuals with autism of unknown cause. The most common autism-related CNVs are the 15q11.2-11.3 duplications, reciprocal 16p11.2 microdeletions and duplications, and the 7q11.23 duplication. Taken together, these CNVs seem to confer susceptibility to ASD in up to 1% of individuals. A number of other CNVs have been described in a few autism families, and although none seems to be particularly common, they highlight the potential of array-based techniques to point autism researchers toward specific autism genes within the CNVs.

The microarray technology is evolving with more advanced types of arrays, including those used in research studies, picking up more and smaller CNVs. Unfortunately, it is often not possible to know whether many of the small CNVs are pathologic or benign. In some cases, a variant might be reported that has no known phenotypic consequence or that the consequence is not known to be related to the ASD. Parental testing is frequently performed to assist in interpretation of abnormal findings. Informed genetic counseling is very important in this context. Children identified with CNVs of unclear significance should be followed periodically by the geneticist so new information can be shared with the family as it becomes available. It should be noted that CMA will not detect balanced translocations or low-level mosaicism; a karyotype should be done when there is a family history of multiple miscarriages or there is high suspicion of mosaic aneuploidy.

For individuals with ASD in whom the etiology is known, genetic counseling and risk assessment are based on the genetics of that specific disorder. For ASD of unknown cause, the empiric aggregate risk to siblings is 5% to 10% for autism and 10% to 15% for milder conditions including language, social, and psychiatric disorders. For families with two or more affected children, the recurrence risk approaches 35%. Recurrence risk may be up to 20% for families who have one autistic child plus another child or relative with mild autistic symptoms. The amount of weight to place on mild autistic symptoms in siblings, parents, and other relatives when estimating

recurrence risk for families is unknown. Families contemplating additional pregnancies should be offered genetics evaluation and counseling by a medical geneticist.

In addition to clinically identifying known genetic disorders which may predispose to ASD, intense efforts have been directed to identifying genes that specifically cause or increase the risk of developing ASD. Methods used include both large genome-wide association studies and investigation of candidate genes. A number of genes of interest, including neuroligin 3 and 4, neuroligin 1, contactin 4, contactin-associated protein-like 2, and SHANK 3, play a role in synapse formation and function. Other genes have a role in serotonin, glutamate, or γ -aminobutyric acid (GABA) neurotransmission. This is an area of tremendous interest in the scientific community and is rapidly evolving.

CLINICAL FEATURES

Social communication dysfunction is the hallmark of ASDs. Deficits in sociability are variable but an essential and defining feature. Early signs include failure to respond to name, abnormal eye gaze (gaze aversion), paucity of gestures, and impairment of

P.1199

joint attention (the ability to draw another person's attention to an object of interest through the use of eye gaze and gestures, such as pointing). Children appear aloof with a lack of interest in others and mainly interact with others when they need something rather than to share their interests, enjoyment, and achievements. As children age, a lack of empathy becomes apparent along with difficulty interpreting and reciprocating the social and emotional behaviors of others. Pragmatic language skills are always impaired, that is, the social rules for communicating are not well understood. These individuals have a hard time taking turns in conversations, talk only about topics of their interest or knowledge, talk *at* people without checking to see if anyone is listening or interested, fail to maintain appropriate interpersonal distance, and are inappropriately intrusive or persistent. There is an impaired ability to read facial expressions, body language, and tone of voice of others, which contributes to these deficits. They are often described as "odd" or "annoying," as their social approaches are peculiar.

Another cardinal feature of ASD is a restricted range of behaviors, interests, and activities that are often repetitive or stereotyped. These include motor stereotypies such as hand flapping or licking, finger flicking, spinning, and body rocking. They may have unusual preoccupations and interests and play skills are impaired. These children can watch the same video for hours, play with unusual objects (e.g., a piece of string), or line up toys instead of playing with them imaginatively. Some children have routines or rituals that need to be followed and many such children have difficulty making transitions. Overall, there is a tolerance for monotony and a resistance to change.

Although no longer a criterion for a diagnosis of ASD, verbal communication disturbances are commonly found. The most common presenting complaint is a delay in language development. Despite this delay, there is a lack of compensation through nonverbal modes of communication, such as gesture and imitation. Spoken language is often echolalic with repetitive and stereotyped phrases. Some children will recite scripts from television or videos. Some children fail to process language and despite normal hearing, appear deaf (verbal auditory agnosia). Abnormalities in syntax (word order), semantics (word meaning), and most prominently pragmatics are present in higher functioning individuals. These children are often extremely literal and concrete and have difficulties understanding jokes, humor, or sarcasm. Speech prosody (melody of language) is impaired, as evidenced by mechanical, monotonous, excessively rapid, high-pitched, and high-volume speech. There can be a fascination with letters and numbers in the early toddler years and some children may learn to read without instruction, e.g. hyperlexia, although comprehension is limited.

Intelligence is not a defining feature but strongly influences prognosis. Intellectual disability (IQ <70) occurs in

approximately 55% of individuals with ASD, although many have average or even superior intellectual ability. Prodigious or savant skills can be seen in visuospatial ability, memory, calculation, or music ability. IQ is a key predictor of long-term outcome in autism, especially for those with an IQ of less than 50 who generally fare poorly. Average to superior IQ is a positive prognostic sign. Having a higher verbal IQ at 2 to 3 years of age appears to predict better outcome, particularly if intervention is delivered early.

Developmental regression or loss of previously established skills during the first 1 to 3 years of life has been estimated as occurring in approximately one-third of children with ASD. There is debate as to whether children with ASD and regression develop better, worse, or the same on IQ, language, and social functioning than those with no regression, but good recovery in children with regressive symptoms is rare.

MEDICAL COMORBIDITIES

Medical comorbidities frequently occur in ASD. Among them include epilepsy, gastrointestinal dysfunction, sleep disorders, and psychiatric conditions (e.g., anxiety, depression, obsessive-compulsive disorder [OCD]). It is important to consider medical causes for any change in behavior, especially in those individuals who are nonverbal or with limited language capability. Examples of such medical conditions include, but are not limited to, the following: pain (due to migraine headaches, ear infection, fractures, etc.), gastrointestinal disorders (e.g., gastroesophageal reflux disease [GERD], constipation), genitourinary conditions (e.g., urinary tract infection [UTI]), hormonal imbalance/endocrine dysfunction (e.g., menstruation), and sleep disturbance (e.g., sleep apnea).

EPILEPSY

The association of epilepsy with autism provided one of the first clues to suggest that autism was a neurodevelopmental disorder of brain function. It is now well established that individuals with ASD have a higher risk of epilepsy as compared with the general population. Epilepsy is commonly reported to occur in approximately one-third of individuals with ASD but the exact prevalence is unknown with reports in the literature ranging from 5% to 50%. Variation in estimates is likely related to multiple factors such as sample ascertainment, degree of intellectual disability, age, gender, and type of ASD (idiopathic vs. complex). Intellectual disability and motor impairments (e.g., cerebral palsy) have been identified most commonly as significant risk factors for epilepsy in ASD, with higher rates in those with more severe cognitive impairments. A community-based study of ASD in children with epilepsy has found that only 5% to 15% of children with epilepsy have autism.

Age of onset of epilepsy in ASD has generally been thought to occur in two peaks, one in early childhood (0 to 5 years) and the other in adolescence (10 to 15 years). The peak before age 5 years, however, includes those children with ASD secondary to infantile spasms (frequently as part of tuberous sclerosis) and other epileptic encephalopathies.

Given the prevalence of epilepsy in autism, it is important to consider the possibility of seizures when evaluating an individual with autism but currently, there is inadequate evidence to recommend electroencephalogram (EEG) in all individuals with autism. Although all seizure types are present in ASD, the most commonly observed are complex partial seizures (85%) and generalized tonic-clonic seizures (7%). Absence and myoclonic seizures occur less commonly (1% to 4%).

ASD can occur in the context of other comorbid medical conditions. Some of the most widely recognized syndromes associated with ASD and epilepsy include tuberous sclerosis, fragile X syndrome, Rett syndrome, Angelman syndrome, and 15q duplication syndrome. A targeted physical examination should consider other risk factors for epilepsy including head circumference (microcephaly), dysmorphism, skin lesions (tuberous sclerosis, neurofibromatosis type 1 [NF-1]), and focal neurologic findings. It is crucial to assess for medical comorbidities, which may mimic seizures including sleep disorders, gastroesophageal reflux and other gastrointestinal

disorders, and psychiatric disorders including attention deficit hyperactivity disorder (ADHD).

Epileptiform EEG abnormalities are frequently seen in children with ASD, with or without epilepsy. Because these background or epileptiform EEG abnormalities can occur in ASD individuals without a clinical history of seizures, they are not to be considered evidence for epilepsy. The significance of these abnormalities,

P.1200

especially in the absence of clinical seizures, is quite unclear. At the present time, there are no data to support the use of antiepileptic drugs or epilepsy surgery in the treatment of these abnormalities in the absence of clinical seizures.

The relationship of autistic regression to epilepsy and epileptiform EEG abnormalities is unclear. Findings in the literature are inconsistent with some studies reporting higher rates of epilepsy in children with ASD and regression and others showing no relationship. However, language regression is a hallmark of Landau-Kleffner syndrome (LKS), a rare childhood-onset epileptic encephalopathy in which loss of previously acquired language skills occurs in the context of an epileptiform EEG, activated in sleep. Electrical status epilepticus during slow-wave sleep (ESES) is the electroencephalographic pattern seen in LKS. The degree of overlap between LKS, ESES, and autistic regression with epileptiform EEG is currently poorly understood, although it is known that this ESES is rarely seen in children with a more global autistic regression. At the current time, there are no data to support the use of LKS- or ESES-specific treatment regimens in those with more classic autistic regression and epileptiform EEG without clinical seizures.

DIAGNOSIS

EVALUATION

ASDs are diagnosed based on clinical history and observations of the child. Research indicates that ASDs may be identified as young as 18 months of age or younger. By age 2 years, it is expected that a qualified professional can reliably make the diagnosis. The American Academy of Pediatrics recommends screening all children at wellchild visits at 18 months and at 24 months of age. A number of questionnaires and observation measures are available to screen for ASDs. Probably the most commonly used is the Modified Checklist for Autism in Toddlers-Revised (M-CHAT-R), which is a parent-completed questionnaire designed to identify children at risk for autism in the general population. The Social Communication Questionnaire (SCQ) is another commonly used screening questionnaire that has established validity against the Autism Diagnostic Interview-Revised (see ADI-R in the following text) in children 4 years or older. It is a parent questionnaire that can be completed and scored easily.

There are a number of tools used to assess ASDs, but experts believe that no single tool should be used to make a diagnosis. The Autism Diagnostic Observation Schedule-2 (ADOS-2) is considered the “gold standard” in diagnosing ASD. It consists of a semistructured, standardized assessment of social interaction, play, and imaginative use of material for individuals suspected of having ASDs from toddlers through adults. A recent toddler module was designed to assess children who are 18 months of age onwards. The ADOS often is used in conjunction with the ADI-R, a clinical diagnostic interview for diagnosing autism in children and adults with mental ages of 18 months and older that focuses on assessing reciprocal social interactions, communication, and language and restricted and repetitive, stereotyped interests and behaviors. Both the ADOS and ADI-R are time consuming and require special training to administer and score, making them less practical for the average office setting. Other well-known assessments include the Childhood Autism Rating Scale-2nd edition (CARS-2) that is appropriate for children older than age 2 years and draws from observations on different areas of behavior associated with ASDs and can be helpful to quantify office observations in addition to the Gilliam Autism Rating Scale-3rd edition (GARS-3), which helps teachers, parents, and clinicians in diagnosis of the disorder.

NEUROLOGIC EXAMINATION

Observations of the child are the key aspect of the neurologic examination. The remainder of the examination is fairly unremarkable. Motor findings include mild hypotonia with incoordination and motor apraxia. Toe walking and motor stereotypies are very common. Many children have a constellation of symptoms that are referred to as *sensory deficits*; however, the neurologic basis for this is unclear. These include a preoccupation with sensory features of objects, over- or underresponsiveness to environmental stimuli, or paradoxical responses to sensory stimuli (e.g., excessive sniffing or licking, oral aversions, intolerant to loud noises, or tactile contact). Macrocephaly (occipitofrontal circumference [OFC] >2 standard deviations [SD] above mean) occurs in approximately 30% of children with autism and usually becomes apparent between the age of 2 and 4 years, reflecting an increase in brain volume. Macrocephaly in adults with autism is less common than in children with ASD, suggesting volume loss. Microcephaly is not a common finding and should prompt neuroimaging. The skin examination requires careful attention, especially given the high co-occurrence with tuberous sclerosis. Examination for dysmorphology is important for making genetic diagnoses (e.g., fragile X, velocardiofacial syndrome, and Smith-Magenis syndrome).

NEURODIAGNOSTIC TESTING

There are many different causes of ASD. The purpose of performing neurodiagnostic testing is to potentially identify any diagnosable or treatable condition. A clinical rationale for performing diagnostic testing is advisable. There are clinical practice guidelines for performing genetic testing but other diagnostic investigations, such as neuroimaging, EEGs, or metabolic laboratory investigations follow “best practice” recommendations, as evidenced-based guidelines are not available.

All children with ASD should have a comprehensive medical history and examination to assess for symptoms or signs of an underlying genetic disorder. Having an etiologic diagnosis offers clinicians the opportunity to provide better guidance regarding recurrence risks as well as prognostic information and obviates the need for additional testing. Furthermore, a specific diagnosis can alert clinicians to be aware of other comorbidities associated with certain genetic syndromes. CMA and fragile X are considered first tier testing in the diagnostic workup of ASD. MECP2 sequencing for Rett syndrome and phosphatase and tensin homolog [PTEN] testing for those with head circumferences greater than 2.5 SD above the mean are recommended second-tier testing. See [Table 138.1](#) for genetic disorders associated with an ASD phenotype.

The clinical rationale for neuroimaging in children with ASD is an attempt to determine a specific etiopathologic diagnosis for an individual. In a minority of cases, the detection of an abnormality of the brain may lead to determination of a specific cause for the child's ASD. This is true especially if the lesion is pathognomonic for a given disorder, for example, a neurocutaneous syndrome. However, it should be noted that abnormalities on neuroimaging are not necessarily causally related to the ASD. In many cases, the etiology of the brain abnormality is still unknown and the relationship to the ASD unclear. Nonetheless, the MRI may help guide more focused etiologic investigations that could further lead to specific diagnoses in a limited number of cases. For these reasons, imaging is not a routine part of the evaluation of individuals with ASD. See [Table 138.2](#) for clinical indicators to consider neuroimaging in ASD.

Trisomy 21

Turner syndrome (45,X)

Copy Number Variants (CNVs)

15q11.2-11.3 duplications

Reciprocal 16p11.2 microdeletions and duplications

7q11.23 duplication

PTEN, phosphatase and tensin homolog.

Hearing impairment should be excluded by a formal audiology assessment. EEG, including a sleep record or overnight video-EEG monitoring, is appropriate when seizures occur or if developmental regression has occurred (see “Epilepsy” section).

There are multiple metabolic causes of ASD, many of which are not usually associated with any dysmorphism. The diagnosis of a primary inborn error of metabolism in simple autism is a rare occurrence. On careful history taking and examination, usually one or more “red flags” is identified in children whose ASD is part of a presentation of an inborn error of metabolism (Table 138.3). Treatable conditions include phenylketonuria (PKU), hyperammonemia/urea cycle defects, and creatine synthesis/creatine transporter defects. Other conditions include purine and pyrimidine abnormalities, Smith-Lemli-Opitz syndrome, and lysosomal storage disorders. Primary mitochondrial disease and ASD is a subject of much debate. Some investigators report a significant incidence of mitochondrial DNA changes or functional disturbances in children with ASD but whether these are the primary cause of ASD remains to be defined. The extent of the evaluation for an underlying metabolic disorder depends on clinical suspicions and the relevance to family counseling. Table 138.4 lists metabolic disorders that can be associated with an ASD phenotype.

TABLE 138.2 Clinical Indicators that Might Prompt Neuroimaging with Brain Magnetic Resonance Imaging

- Seizures or history of focal EEG

- Microcephaly

- Extreme (≥ 3 SD above mean) or progressive macrocephaly

- Neurocutaneous lesions

- Suspicion of CNS structural abnormality

- Focal motor findings or a change in motor examination

- Active or recurrent regression

EEG, electroencephalogram; CNS, central nervous system.

TABLE 138.3 Red Flags that Might Indicate a Metabolic Etiology for Autism Spectrum

Disorders

History or symptoms of any of the following:

-
- Active or recurrent regression
-
- Profound intellectual disability or global developmental delay
-
- Severe growth retardation
-
- Deafness
-
- Unexplained intractable seizures
-
- Fatigue with daily activities or exercise
-
- Recurrent or relapsing history of decompensation with illness
-
- Family history suggestive of metabolic disease

Any of the following *physical* or *laboratory* findings:

-
- Objective neurologic abnormalities (e.g., significant hypotonia with gross motor delay, muscle weakness, microcephaly, macrocephaly, dystonia/chorea)
-
- Multiple organ system involvement
-
- Unrelated signs suggesting an inborn error of metabolism (e.g., hypoglycemia, metabolic acidemia)
-
- MRI abnormality suggestive of metabolic disease

List is not meant to be exhaustive.
MRI, magnetic resonance imaging.

TREATMENT

There are no known cures for ASDs; however, early and intensive behavioral and educational interventions are highly effective in most individuals and provide the best chance for a favorable outcome. Both behavioral and educational interventions target the core symptoms of ASDs. Usually, children with ASD

require a combination of therapies and interventions to address their individual groups of symptoms. It is recommended that children receive educational intervention as soon as they are suspected of having ASD, with services being provided a minimum of 20 to 25 hours a week on a yearly basis.

Intensive behavioral interventions, such as applied behavior analysis (ABA), based on the work of Lovaas, uses multiple prompting paradigms, reinforcement schedules, and imitation and modeling. Another type of intervention, the Treatment and Education of Autistic and Related Communication-Handicapped Children (TEACCH) method uses structured teaching to help improve skills, with the therapist functioning as a generalist in treating the whole child.

P.1202

Developmental and relationship-based models, such as the Developmental Individual Difference Relationship approach (DIR or Floortime) focus on teaching skills, such as social communication and interpersonal skills. The Early Start Denver Model (ESDM) is considered an integrative approach as it uses a combination of intensive ABA and developmental and relationship-based intervention and includes parents as therapists. A randomized controlled trial that compared the ESDM program with interventions commonly available in the community demonstrated significant gains in language, cognitive, and adaptive functioning in toddlers over a 2-year period [Level 1].¹

TABLE 138.4 Metabolic Disorders Associated with Autism Spectrum Disorders

Phenylketonuria

Mitochondrial disorders

Mucopolysaccharidosis, including Sanfilippo

Smith-Lemli-Opitz syndrome

Urea cycle disorders

Adenylosuccinate lyase deficiency

Cerebral folate deficiency

Disorders of creatine transport or metabolism

Succinic semialdehyde dehydrogenase deficiency

Dihydropyrimidinase deficiency

Cystathionine β -synthase deficiency

Homocysteine

Biotinidase deficiency

Parental involvement is considered an important part of the treatment program. Social skills training programs are very helpful, especially in higher functioning individuals. Maladaptive behaviors can develop and become extremely challenging to manage. It is very important to evaluate and treat problem behaviors appropriately. Medical causes need to be excluded (see “[Medical Comorbidities](#)” section). Functional behavioral analysis is important to identify the antecedents, consequences, and functions of behaviors. A combined approach of pharmacotherapy and behavioral modification therapy is often necessary. Medications are used to treat comorbid symptoms/conditions such as irritability, aggression, self-injury, inattention, hyperactivity/impulsivity, OCD, anxiety, depression, sleep disturbance, and seizures.

OUTCOME

The symptoms of ASD, like other developmental disorders, often change with age. Outcome studies of children diagnosed with ASD suggest that although 40% show overall improvement during adolescence, as many as a third may deteriorate. The onset of seizures can contribute to this decline. In addition, psychiatric comorbidities commonly develop in adolescence and adulthood: depression, anxiety, and even catatonia. A minority of patients, usually the higher functioning group, improve significantly during adolescence. Approximately two-thirds of adults with autism show poor social adjustment (limited independence in social relations), and half require institutionalization. Autistic adults who are not intellectually impaired tend to improve more than those who are intellectually impaired. Even though higher functioning individuals with ASD (including those previously diagnosed as Asperger syndrome) have the best outcome, only 15% to 30% have fair to good outcomes, and only 5% to 15% become competitively employed, lead independent lives, marry, and raise families. Probably, some “odd” adults go undiagnosed in childhood and adolescence, thus increasing the proportion of those with ASD who ultimately function in the mainstream.

Mitochondrial Encephalomyopathies

Salvatore DiMauro

Michio Hirano

INTRODUCTION

Mitochondria are uniquely intriguing organelles, not only for the variety of biologic functions that they perform but also because of their regulation by two genomes—their own DNA (mtDNA) and that of the nucleus (nDNA). Accordingly, mitochondrial diseases can be due to mutations in either genome (Table 139.1). The main function of mitochondria is aerobic production of adenosine triphosphate (ATP) energy through oxidative phosphorylation. Because brain and muscle have high-energy requirements, mitochondrial disorders frequently manifest as encephalomyopathies. Advances in this rapidly expanding field have been covered extensively in recent reviews, but here we provide general overview of the genetically and clinically heterogeneous mitochondrial diseases.

TABLE 139.1 Genetic Classification of Mitochondrial Diseases with Representative Clinical Syndromes

1. Defects of mitochondrial DNA

A. Single deletions (usually sporadic)

a. Kearns-Sayre syndrome (KSS)

b. Chronic progressive external ophthalmoplegia (CPEO) and CPEO-plus

c. Pearson syndrome

B. Point mutations (maternal transmission)

a. Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS);

b. Myoclonus epilepsy with ragged red fibers (MERRF);

c. Leber hereditary optic neuropathy (LHON);

d. Neuropathy, ataxia, and retinitis pigmentosa (NARP)

2. Defects of nuclear DNA (mendelian or X-linked transmission)

A. “Direct hits”: mutations in genes encoding subunits of the respiratory chain enzyme complexes with biochemical defects of complex I, II, III, or IV presenting as Leigh syndrome or a multisystemic disorder

B. “Indirect hits”: defects of respiratory chain enzyme complex assembly factors with biochemical defects of complex I, II, III, or IV presenting as Leigh syndrome or a multisystemic disorder

C. Defects of mitochondrial transcription

D. Defects of mitochondrial translation

E. Defects of mitochondrial lipid composition

F. Defects of mitochondrial dynamics (fusion, fission, movement)

G. Defects of mitochondrial DNA maintenance

H. Defects of mitochondrial importation

I. Defects of mitochondrial metal metabolism

HISTORY

In 1962, the first human disease attributed to mitochondrial dysfunction was described as a hypermetabolic state in a patient with normal thyroid function and excessive number of abnormally large mitochondria in skeletal muscle. Biochemical studies showed “loose coupling” of oxidative phosphorylation. This syndrome was named after the endocrinologist Rolf Luft. Since then, however, there has been only one other known case of Luft syndrome and its etiology remains unknown.

Later in the 1960s, mitochondrial diseases were brought to prominence by Milton Shy and Nicholas Gonatas, who defined this new organellar disorder by the electron microscopic appearance of overabundant or enlarged mitochondria with paracrystalline inclusions. Soon thereafter, W. King Engel noted that abnormal proliferation of mitochondria could be identified under the light microscope as *ragged red fibers* (RRF) with a modified Gomori trichrome stain. For the next two decades, this histologic hallmark was the basis for recognition of mitochondrial diseases based on an initial biochemical classification.

The molecular era of mitochondrial disease began in 1988 when the first two pathogenic mutations in mtDNA were described: a point mutation in Leber hereditary optic neuropathy patients and single large deletions causing mitochondrial myopathy.

EPIDEMIOLOGY

Although mitochondrial diseases have been detected worldwide, epidemiologic data are limited. The prevalence of mitochondrial diseases has been estimated to be 7.6 per 100,000 births per year in Southern Australia whereas the prevalence in the working age adult population has been assessed to be 9.6 per 100,000 in the northeast of England.

PATHOBIOLOGY

We will consider separately the pathobiology associated with mtDNA mutations and with nDNA mutations.

PATHOBIOLOGY OF mtDNA MUTATIONS: MITOCHONDRIAL GENETICS VERSUS MENDELIAN INHERITANCE

Human mtDNA is a small (16.6 kb) circle of double-stranded DNA ([Fig. 139.1](#)) comprising only 37 genes. Of

these, 13 encode polypeptides, all subunits of the respiratory chain: 7 subunits of complex I (NADH-ubiquinone oxidoreductase), 1 subunit of complex III (ubiquinone-cytochrome c oxidoreductase), 3 subunits of complex IV (cytochrome c oxidase [COX]), and 2 subunits of complex V (ATP synthase). The other 24 genes encode 22 transfer RNAs (tRNAs) and 2 ribosomal RNAs (rRNAs) that are required for translation of messenger RNAs on mitochondrial ribosomes

P.1205

(mitoribosomes). The subunits of complex II (succinate dehydrogenase [SDH]-ubiquinone oxidoreductase) and the enzymes required for synthesis of small electron carriers (coenzyme Q₁₀ [ubiquinone] and cytochrome c) are encoded exclusively by nDNA.

FIGURE 139.1 The respiratory chain (**top**) and mitochondrial DNA (mtDNA; **bottom**). Genes and corresponding gene products are similarly color-coded. ND denotes the subunits of NADH-coenzyme Q oxidoreductase (complex I); cyt *b*, cytochrome *b*; subunits of cytochrome *c* oxidase are labeled CO in the mtDNA scheme and COX in the respiratory chain rendition; A6 and A8 indicate subunits 6 and 8 of ATP synthase. The 22 tRNA genes are denoted by one-letter amino acid nomenclature, whereas 12S and 16S denote ribosomal RNAs (rRNAs). O_H and O_L are the origin of heavy- and light-strand replication; HSP and LSP are the promoters of heavy- and light-strand transcription.

The following main principles distinguish mitochondrial genetics from mendelian genetics and help explain many of the clinical peculiarities of mtDNA-related disorders.

1. *Polyplasmcy*. Most cells contain multiple mitochondria and each mitochondrion contains multiple copies of mtDNA so that there are thousands of mitochondrial genomes in each cell.

2. *Heteroplasmy*. When an mtDNA pathogenic mutation affects some but not all genomes, a cell, a tissue, indeed a whole individual will harbor two populations of mtDNA, normal (or wild-type) and mutant, a condition known as *heteroplasmy*; in normal tissues, all mtDNA were considered identical, a situation called *homoplasmy*. However, highly sensitive next-generation sequencing has revealed the coexistence of mutated mtDNA variants (0.2% to 2.0% heteroplasmy) and wild-type mtDNA within a cell in blood and skeletal muscle of clinically unaffected individuals (a phenomenon termed *universal heteroplasmy*).
3. *Threshold effect*. The functional impairment associated with a pathogenic mtDNA mutation is largely determined by the degree of heteroplasmy, and a minimal critical number of mutant genomes (the mutation load) is required before tissue dysfunction becomes evident (and related clinical signs become manifest), a concept aptly termed *threshold effect*. This is, however, a relative concept: Tissues with high metabolic demands, such as brain, heart, and muscle, tend to have lower tolerance for mtDNA mutations than do metabolically less active tissues.
4. *Mitotic segregation*. Both organellar division and mtDNA replication are apparently stochastic events unrelated to cell division: Thus, the number of mitochondria (and mtDNA) can vary not only in space (i.e., among cells and tissues) but also in time (i.e., during development or aging). Moreover, at cell division, the proportion of mutant mtDNAs in daughter cells may drift, allowing for relatively rapid changes in genotype; therefore, if and when the threshold is exceeded, a clinical phenotype may manifest.
5. *Maternal inheritance*. At fertilization, all mitochondria (and all mtDNA) in the zygote are derived from the oocyte. Therefore, a mother carrying an mtDNA pathogenic mutation will pass it on to all her children, males and females, but only her daughters will transmit to their progeny, in a vertical matrilineal line. When maternal inheritance is evident in a clinical setting, it provides strong evidence that an mtDNA mutation must underlie the disease in question. However, the other features of mitochondrial genetics (e.g., heteroplasmy degree and

P.1206

the threshold effect) often mask maternal inheritance by causing striking intrafamilial clinical heterogeneity.

Thus, when suspecting an mtDNA-related disorder, it is crucial to collect the family history meticulously, paying special attention to “soft signs” (such as short stature, hearing loss, or migraine headache) in potentially oligosymptomatic maternal relatives.

More than 250 point mutations of mtDNA have been identified (Fig. 139.2). Ten pathogenic mutations in mtDNA have been observed frequently in neonatal cord blood of over 3,000 well babies, and a surprisingly high frequency, 1 in 200, harbored a pathogenic mtDNA mutation. The frequent occurrence of mtDNA mutations leads to a correspondingly high prevalence of mtDNA-related diseases: In the northeast of England, for example, 1 in 10,000 people are clinically affected by mtDNA-related disorders, and 1 in 6,000 individuals are considered at risk.

FIGURE 139.2 Morbidity map of the human mtDNA. Disorders caused by mutations in protein-coding genes are shown in *red*. Disorders caused by mutations in gene controlling protein synthesis are shown in *blue*. FBSN, familial bilateral striatal necrosis; LHON, Leber hereditary optic neuropathy; LS, Leigh syndrome; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes; MERRF, myoclonus epilepsy with ragged red fibers; MILS, maternally inherited Leigh syndrome; NARP, neuropathy, ataxia, and retinitis pigmentosa; PEO, progressive external ophthalmoplegia.

MENDELIAN INHERITANCE

The identification of nDNA mutations for mitochondrial diseases has accelerated rapidly since the discovery in 1995 of the first “direct hit” mutation in an nDNA-encoded gene for one of four subunits of complex II, exclusively controlled by nuclear genetics. These advances have been made possible by rapidly evolving technologies, from linkage analysis, homozygosity mapping, sequencing of candidate genes, and—ultimately—to next-generation genome-wide (whole-exome) sequencing (WES) or to screening of the portion of the genome that encodes the approximately 1,700 mitochondrial

proteins in a process known as *mito-exome sequencing*. The advantages of high-throughput DNA sequencing

are eminently practical, enabling rapid diagnosis of puzzling cases and informing genetic counseling.

Direct Hits Mutations

“Direct hits” refer to pathogenic mutations that directly affect nDNA-encoded respiratory chain subunits in all five complexes but most commonly affecting the 16 of the 45 structural subunits of the gigantic complex I. In contrast, only a few direct hits affect complex II (affecting any of the four subunits), complex III (2 of the 11 subunits harbor damaging mutations, UQCRB and UQCRCQ), complex IV (COX), of which only COX subunits 6B1 and 7B harbor deleterious mutations, and complex V (ATP synthase, containing a direct hit in a single gene, *ATP5E*). In keeping with the all-or-none effect of mostly recessive mendelian mutations, as opposed to the variegated effect of heteroplasmic mtDNA mutations, disorders to direct hits to the mitochondrial respiratory chain generally manifest at or soon after birth and are severe, often being lethal in infancy, most often associated with Leigh syndrome.

Indirect Hits Mutations

Even when all nDNA-encoded subunits of the various complexes are expressed correctly, they must be translated, imported into mitochondria, and directed to the inner mitochondrial membrane (IMM). At this site, they assemble with their mtDNA-encoded counterparts, acquire prosthetic groups, if necessary multimerize, and further assemble into supercomplexes (respirasomes). Mutations in these pathways are referred to as *indirect hits*, as they indirectly affect the mitochondrial respiratory chain.

In 1998, the search for the molecular basis of COX-deficient Leigh syndrome led to simultaneous discovery by two groups of the first mutant mitochondrial assembly gene, *SURF1*. Mutations in *SURF1* are among the most common causes of Leigh syndrome. Mutations in at least seven more COX assembly factors (*SCO1*, *SCO2*, *COX10*, *COX14*, *COX15*, *COA5*, *FAM36A*, and *TACO1*) have been associated with various human diseases, predominantly encephalopathy, but cardiopathy often occurs with some mutations (*SCO2*, *COX10*, *COX15*, and *COA5*), whereas hepatopathy is associated with the *SCO1* mutations.

In patients with complex I deficiencies that are difficult to define molecularly, mutant assembly factors have been identified through next-generation sequencing of DNA. The clinical manifestations of these indirect hits tend to be more clinically heterogeneous than those associated with direct hits; all described patients have had encephalopathy resembling Leigh syndrome, but many have had leukodystrophy rather than gray matter involvement. Cardiomyopathy is often the dominating feature, presenting in infancy or in early childhood and early death.

The first assembly defect in complex III was identified in 2002 in Finnish infants with an extremely severe syndrome named GRACILE, an acronym aptly summarizing the symptoms and signs: *g*rowth *r*etardation, *a*minoaciduria, *c*holestasis, *i*ron *o*verload, and *e*arly death. The mutated protein was the mitochondrial chaperone *BCSL1*, needed for insertion of the iron-sulfur (Fe-S) subunit into complex III.

A new group of disorders attributed to deficiency of coenzyme Q₁₀ (CoQ₁₀) can be related to indirect hits that consist of mutations in a cascade of biosynthetic enzymes. They result in deficiency of this relatively simple component, CoQ₁₀, which is an integral part of the respirasome, where it shuttles electrons from complex I and complex II to complex III, acts as an antioxidant and modulates apoptosis. Molecular defects in genes encoding CoQ₁₀ biosynthetic enzymes (*PDSS2* and *COQ2*) were initially discovered in 2006, but mutations in other biosynthetic genes (*PDSS1*, *COQ6*, *ADCK3*, and *COQ9*) followed. Five clinical syndromes are attributed to CoQ₁₀ deficiency and they will be considered in the following section.

Defects of mtRNA Translation

The mitochondrial genome is transcribed into 13 mRNAs, which are translated by mitoribosomes into the 13 mtDNA-encoded respiratory chain subunits. As described in a comprehensive review, this process can be divided

into two phases: a posttranscriptional phase (involving tRNA modifications, aminoacyl-tRNA synthetases, and processing of ribosomal proteins) and mtRNA translation (initiation, elongation, termination, and recycling). Representative examples of defects of each step of the mitochondrial translation process are briefly highlighted.

ABNORMAL tRNA MODIFICATIONS

Pseudouridylation modification is thought to promote stability and conformation of mitochondrial and nuclear tRNAs. Mutations in pseudouridine synthase 1 (*PUS1*) differentially impair nuclear and mitochondrial tRNA maturation causing mitochondrial myopathy, lactic acidosis, and sideroblastic anemia (*MLASA*); in addition, psychiatric symptoms and facial dysmorphism are likely due to abnormal cytosolic protein synthesis.

The conundrum of spontaneous improvement in *infantile reversible COX-deficient myopathy* (more accurately designated reversible infantile respiratory chain deficiency [RIRCD]) was resolved by elucidation of the tRNA modification processes in this disorder. RIRCD is due to homoplasmic mutations in *MT-TE*, which encodes mt-tRNA^{Glu}. Pathogenesis of the disease became more complex when patients in two families were found to harbor mutations in the *TRMU* gene, which modifies a wobble uridine base in mt-tRNA^{Glu}. Skeletal muscle from infants in the initial symptomatic phase showed significantly decreased 2-thiouridylation due to defective TRMU activity, which exacerbated the effect of the mtRNA^{Glu} mutation and triggered the mitochondrial translation defect, thus demonstrating an nDNA-modifying effect on the mtDNA mutation.

Mutations in nine highly specialized aminoacyl-tRNA synthetases (ARs), which covalently link an amino acid to its cognate tRNA (tRNA charging), are associated with multiple specific clinical syndromes. Mitoribosomes consist of two mRNA components (12S and 16S rRNAs) and of novel about 30 and 50 nDNA-encoded proteins. Of the roughly 80 ribosomal proteins, 3 have been firmly linked to mitochondrial diseases: MRPS16, MRPS22, and MRPL3. Patients with defects of mitochondrial elongation factor genes (*GFM1* encoding EFG1; *TUFM*, EF-T_u^{mt}; and *TSMF*, EF-TS_{mt}) typically present with infantile-onset multisystemic diseases. Of the three known mitochondrial translation termination factors, which catalyze release of fully synthesized polypeptides, mutations have only been identified in a poorly characterized ribosome-recycling factor encoded by *C12orf65* in two unrelated families with LS, optic atrophy, and ophthalmoplegia. Mutations in two mitochondrial translation activators, both required for COX, have been linked to human diseases. Mutations in the gene *TACO1* (encoding translational activator for COX I), cause late-onset Leigh syndrome and COX deficiency, whereas mutations in *LRPPRC* (which encodes a leucine-rich pentatricopeptide repeat-containing protein) have been identified as the cause of a distinctive Leigh syndrome prevalent in French Canadians. Mutations of *RMND1* cause mitochondrial translational defects affecting multiple organs; however,

P.1208

the function of the encoded protein, which contains a domain of unknown function (DUF 155), remains a mystery.

Defects of the Inner Mitochondrial Membrane Lipid Milieu

The respiratory chain resides in the phospholipid component of the IMM and alterations in the lipid milieu are increasingly associated with mitochondrial encephalomyopathy. Cardiolipin, a dimeric molecule composed of two phosphatidylglycerol moieties connected by a glycerol group, is the signature mitochondrial phospholipid and a major component of the IMM, where it is synthesized. Cardiolipin deficiency was first documented—together with mutations in the gene encoding tafazzin (*TAZ*)—in patients with Barth syndrome, an X-linked mitochondrial myopathy and cardiomyopathy, with neutropenia and stunted growth.

Similar to Barth syndrome, Sengers syndrome affects primarily heart and muscle, with the distinctive additional clinical feature of congenital cataracts. Whole exome sequencing revealed mutations in the acylglycerol kinase (*AGK*) gene. Notably, lack of phosphatidic acid is a precursor of cardiolipin, thus providing a point of convergence in Sengers syndrome and Barth syndrome, which could account for the clinical similarities between

the two disorders.

The mitochondrial-associated endoplasmic reticulum (ER) membrane (MAM) is the close physical and functional association between ER and mitochondria. MAMs are involved in multiple functions, including lipid transport, cholesterol metabolism, calcium signaling, energy metabolism, apoptosis, and mitochondrial dynamics.

New diseases have been associated with MAM dysfunction, including the MEGDEL syndrome (3-methylglutaconic aciduria type IV, deafness, and Leigh syndrome), in which the SERAC protein is located in the MAM and controls exchange of phospholipids between the ER and mitochondria. Interestingly, a central role of MAM in the pathogenesis of Alzheimer disease has been well documented.

Defects of Mitochondrial Dynamics

Mitochondria are highly dynamic organelles that move around the cell on microtubular tracks and, similar to their bacterial precursors, they fuse and divide, thus forming tubular networks that favor a balanced distribution of energy throughout the cell. Impairment of mitochondrial motility, fusion, or fission causes the nervous system particularly susceptible, as it is highly dependent on oxidative energy, and mitochondria must travel long distances along central axons and peripheral nerves.

Mitochondrial fusion requires coordinated action of multiple guanosine triphosphatases (GTPases) in the outer mitochondrial membrane (OMM), namely mitofusins MFN1 and MFN2, and in the IMM, namely OPA1.

Mitochondrial fission requires cytosolic dynamin-related protein 1 (DRP1; also a GTPase), which is recruited to the OMM together with two partners, mitochondrial fission (FIS1) and mitochondrial fission factor (MFF). Once recruited to the OMM, DRP1 forms a spiral that wraps around the mitochondrion like a noose and severs the mitochondrial membrane using guanosine triphosphate (GTP) hydrolysis.

DEFECTS OF MITOCHONDRIAL MAINTENANCE

These disorders have been traditionally subdivided into two groups: (1) mtDNA depletion syndromes manifesting early in life and presenting as myopathy, hepatocerebral disease, or encephalomyopathy and (2) multiple mtDNA deletions, usually associated with chronic progressive external ophthalmoplegia with other manifestations that are predominantly neurologic (progressive external ophthalmoplegia [PEO]-plus).

The disorders of intergenomic communication are usually caused either by defects of mtDNA replication that are catalyzed by polymerase γ (genes *POLG* and *POLG2*) and by the helicase Twinkle (*PEO1*) or by altered homeostasis of the intramitochondrial deoxynucleoside triphosphates (dNTPs) pool that is controlled by multiple genes including *TK2* (encoding thymidine kinase 2), *DGUOK* (encoding deoxyguanosine kinase), and *TYMP* (encoding thymidine phosphorylase). In addition, the gene encoding adenine nucleotide translocase 1 (*ANT1*) causes autosomal dominant progressive external ophthalmoplegia (adPEO). Another mutant gene (*OPA1*), which is required mitochondrial fusion, has curiously been associated with autosomal dominant PEO-plus.

It is evident that mtDNA depletion and multiple mtDNA deletions often coexist in the same patient and are often caused by the same genes that cause either isolated depletion or multiple deletions of mtDNA (Table 139.2). A peculiarity of these disorders is that—although they are unequivocally mendelian—they share many features of mitochondrial genetics, including heteroplasmy and the threshold effect.

DISORDERS OF MITOCHONDRIAL PROTEIN IMPORTATION

A prerequisite for the assembly of any respiratory chain complex is the import of nDNA-encoded subunits from the cytoplasm into mitochondria, thus adding one more category to the indirect hits, namely defects in the mitochondrial importation machinery.

CLINICAL FEATURES

mtDNA-RELATED DISEASES

Mitochondria and mtDNA are ubiquitous, which explains why every tissue in the body can be affected by mtDNA mutations. This is illustrated in [Figure 139.2](#) depicting mtDNA as a veritable Pandora box (abbreviated morbidity map). [Table 139.2](#) is a compilation of symptoms and signs reported in patients with three different types of mtDNA mutations, including single deletions, point mutations in two distinct tRNA genes, and point mutations in a protein-coding gene. As shown by the boxes, certain constellations of symptoms and signs are sufficiently characteristic to make the diagnosis relatively easy in typical patients. On the other hand, because of the peculiar rules of mitochondrial genetics, different tissues harboring the same mtDNA mutation may be affected to different degrees or not at all, which explains the sometimes puzzling variety of syndromes associated with carriers of mtDNA mutations, even within a single pedigree.

Among the maternally inherited encephalomyopathies, four syndromes are more frequent. The first is *MELAS* (*mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes*), which usually presents in children or young adults after normal early development. Symptoms include seizures, migraine-like headache, and stroke-like episodes causing cortical blindness, hemiparesis, or hemianopia. Magnetic resonance imaging (MRI) of the brain shows “infarcts” that do not correspond to the distribution of major vessels, raising the question of whether the strokes are vascular due to

P.1209

mitochondrial microangiopathy ([Fig. 139.3](#)). The most common cause of MELAS is *m3243A> G* in the *tRNA^{Leu(UUR)}* gene, but more than 20 other mutations have been associated with this disorder.

TABLE 139.2 Paradigms of mtDNA-mutation Disorders

Tissue	Symptom/Sign	mtDNA Single Deletions		tRNA		ATPase6	
		KSS	Pearson	MERRF	MELAS	NARP	MILS
CNS	Seizures	-	-	+	+	-	+
	Ataxia	+	-	+	+	+	±
	Myoclonus	-	-	+	±	-	-
	Psychomotor retardation	-	-	-	-	-	+
	Psychomotor regression	+	-	±	+	-	-

GI	Exocrine pancreas dysfunction	±	+	-	-	-	-
	Intestinal pseudo-obstruction	-	-	-	-	-	-

Typical features are highlighted in red for each disorder except MILS, which is diagnosed neuropathologically.

KSS, Kearns-Sayre syndrome; MERRF, myoclonus epilepsy with ragged red fibers; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes; NARP, neuropathy, ataxia, and retinitis pigmentosa; MILS, maternally inherited Leigh syndrome; CNS, central nervous system; PNS, peripheral nervous system; GI, gastrointestinal.

The second syndrome is *MERRF* (*myoclonus epilepsy with ragged red fibers*), characterized by myoclonus, seizures, myopathy, and cerebellar ataxia. Less common signs include dementia, hearing loss, peripheral neuropathy, and multiple lipomas. The typical mtDNA mutation in MERRF is the m.8344A>G in the *tRNA^{Lys}* gene, but other mutations in the same gene have been reported.

The third syndrome has two clinical presentations. The first is *NARP* (*neuropathy, ataxia, and retinitis*

pigmentosa), which usually affects young adults and causes retinitis pigmentosa, dementia, seizures, ataxia, proximal weakness, and sensory neuropathy. The second is maternally inherited Leigh syndrome (*MILS*), a more severe infantile encephalopathy with characteristic symmetric lesions in the basal ganglia and the brain stem (see Fig. 139.3). As noted by the late Anita Harding in her original description of this syndrome, the two major causative mutations (m.8993G>T or m.8993C>T, both affecting the same gene *MTATP6*) affect maternal relatives in the same family with those afflicted with *MILS* having higher mutation loads than individuals with *NARP*.

The fourth syndrome, *Leber hereditary optic neuropathy* (*LHON*), is characterized by acute or subacute loss of vision in young adults, more frequently males, due to bilateral optic atrophy. Mutations in three genes of complex I (ND genes) have been associated with *LHON*, m.11778G>A in *ND4*, m.3460G>A in *ND1*, and m.14484T>C in *ND6*. Epidemiologic studies have shown that *LHON* is the most common mtDNA-related disorder in adults. Epigenetic factors contribute to disease expression in homoplasmic patients by virtue of increased penetrance due to the European mtDNA haplogroup J and a protective effect of estrogens in women who are less frequently affected than men.

Three sporadic conditions are associated with mtDNA single deletions, *Kearns-Sayre syndrome* (*KSS*), *chronic progressive external ophthalmoplegia* (*CPEO*), and *Pearson syndrome* (*PS*). All three conditions are typically sporadic; however, a few cases of maternal

P.1210

transmission have been reported. A multicenter retrospective study of 226 families has confirmed that women carrying single mtDNA deletions have a low risk of having affected children (1 in 24).

FIGURE 139.3 Characteristic brain MRI abnormalities in mitochondrial encephalomyopathies. These T2-weighted images show bilateral putaminal hyperintensities in a child with cytochrome c oxidase (COX)-associated Leigh syndrome (**top left panel**), bilateral globus pallidus hyperintensities in a child with a familial Leigh

syndrome phenotype (**top right**), a left posterior cerebral hyperintense stroke-like lesion in a child with MELAS (**bottom left**), and bilateral white matter hyperintensities in a child with Kearns-Sayre syndrome (KSS) (**bottom right**).

KSS is a multisystem disorder with the obligate triad of onset before age 20 years of impaired eye movements (PEO and ptosis), pigmentary retinopathy plus heart block (requiring installment of a pacemaker), ataxia, or markedly elevated cerebrospinal fluid (CSF) protein (>100 mg/dL). Frequent additional signs include dementia, endocrinopathies (diabetes mellitus, growth hormone deficiency, and hypoparathyroidism), and lactic acidosis.

CPEO is a relatively benign disorder characterized by ptosis, PEO, and proximal myopathy. In addition, patients often develop dysphagia and ataxia.

PS, characterized by sideroblastic anemia and exocrine pancreatic dysfunction, is usually a fatal disorder of infancy. Due to *mitotic segregation* of deleted mtDNAs resulting in loss of the mutant mtDNA from blood cells but increased mutation burden in muscle and other postmitotic cells, the phenotype often evolves into CPEO or KSS in some surviving babies.

It is often stated that any patient having multiple organ involvement and evidence of maternal inheritance should be suspected of harboring a pathogenic mtDNA point mutation until proven otherwise. Although this “rule of thumb” has some practical value, it is also important to keep in mind that patients with involvement of a single tissue can still have pathogenic point mutations of mtDNA. This is especially true for skeletal muscle. As described earlier, isolated myopathy with PEO can be due to single large-scale mtDNA deletions, but isolated myopathy without PEO has been associated with point mutations in several tRNA genes, which can be due to generalized but skewed heteroplasmy in muscle. However, a simple nonmaternal inherited rule can be applied to pure mitochondrial myopathies due to somatic mutations in protein-coding mtDNA genes, including subunits of complex I, complex III (including cytochrome *b*, *MTCYB*), or complex IV, accompanied by severe exercise intolerance, myalgia, and myoglobinuria.

MENDELIAN INHERITANCE

Leigh syndrome (LS) is the most important mitochondrial disease affecting infants and children, and reflecting the ravages of energy shortage on the developing nervous system, LS is a defined neuropathologically or neuroradiologically entity by bilateral symmetric lesions all along the neuraxis but especially in the basal ganglia, thalamus, brain stem, and cerebellar roof nuclei. Microscopically, there is neuronal loss, proportionate loss of myelin, reactive astrocytosis, and proliferation of cerebral microvessels. Clinically, these children have psychomotor retardation or regression, respiratory abnormalities, hypotonia, failure to thrive, seizures, and optic atrophy. Although we have highlighted mtDNA mutations in complex V genes causing LS (NARP/MILS), several other defects in mtDNA-encoded complex I (ND) genes as well as mutations in nuclear encoded subunits of complexes I, II, and IV frequently cause LS.

Besides LS, four distinct presentations have been attributed to direct hits in complex I deficiency: fatal infantile lactic acidosis (FILA), neonatal cardiomyopathy with lactic acidosis, leukodystrophy with macrocephaly, and hepatopathy with renal tubulopathy. Likely, these disorders represent variations of the common LS theme rather than separate clinical entities: Usually, these children are fine at birth or early in life, but disease progression is rapid and relentless, leading to death often before 1 year of age.

It has long been known that complex IV deficiency is a common cause of LS, but years went by before a mutated gene (*SURF1*) was associated with LS, the first example of an “indirect hit.” Mutations in the COX assembly gene *SCO2* cause a severe combination of neonatal cardiomyopathy with encephalopathy, which is fatal in the first weeks or months of life. Importantly, *SCO2* mutations can simulate spinal muscular atrophy (SMA); therefore, it is important to consider *SCO2* mutations in patients with the clinical picture of SMA but without mutations in the

SMN gene and with cardiomyopathy and COX-deficiency in muscle histology. Mutations in several other genes encoding COX assembly proteins have been associated with encephalopathy resembling LS together with involvement of other tissues. However, mutations in *SCO1* cause encephalohepatopathy, mutations in *COX10* cause encephalonephropathy, and mutations in *COX15* cause encephalocardiopathy as do mutations in *C2orf64*. Additional disorders due to indirect hits and resulting in generalized COX deficiency, including an unusual “toxic” mechanism of COX inhibition, have been reported. Indirect hits in complex V are rather frequently associated with mutations in the gene *TMEM70*, resulting in defective assembly of ATP synthase. Most patients harboring *TMEM70* mutations were severely affected with neonatal hypotonia, apneic spells, psychomotor delay, hypertrophic cardiomyopathy, and profound lactic acidosis, whereas a minority presented with additional infantile-onset cataracts, early-onset gastrointestinal dysfunction, and multiple joint contractures.

Indirect hits include those encompassing five major phenotypes due to CoQ₁₀ deficiency. These disorders are important to diagnose, as they often respond to CoQ₁₀ supplementation. The first patients reported in 1989 were a pair of sisters, ages 12- and 14-year-old with a mitochondrial disorder characterized by encephalopathy (mental retardation, seizures, and mild ataxia) and myopathy with recurrent myoglobinuria. The triad of mitochondrial myopathy, myoglobinuria, and encephalopathy has been reported in a few

P.1211

other patients. The second syndrome is childhood-onset cerebellar atrophy and ataxia, with variable additional symptoms, including neuropathy, seizures, mental retardation, and muscle weakness. The molecular basis of this phenotype was identified in some but not all patients, and the mutated gene was *ADCK3/CABC1*. The third syndrome was an infantile multisystemic disease, which typically manifests as encephalopathy and nephropathy (particularly steroid-resistant nephrotic syndrome). This syndrome was initially associated with mutations in *COQ2* and *PDSS* and subsequently in additional genes required for CoQ₁₀ biosynthesis including *PDSS1*, *PDSS2*, and *COQ9*. The fourth syndrome, dominated by severe nephropathy and typically leading to end-stage renal disease, was originally attributed to *COQ2* gene mutations, whereas steroid-resistant nephrosis and end-stage renal failure associated with sensorineural deafness was linked to *COQ6* mutations. The fifth syndrome is isolated myopathy and, in a few cases, has been due to multiple acyl-CoA dehydrogenases deficiency causing secondary CoQ₁₀ deficiency.

Defects of the Inner Mitochondrial Membrane Lipid Milieu

Phospholipid metabolism and the lipid composition of the IMM were relatively neglected in the study of mitochondrial diseases, but there was a recent awakening of this subject and several new disorders were discovered, thanks in part to whole exome sequencing.

Barth syndrome is an X-linked disorder characterized by mitochondrial cardiac and skeletal myopathy, cyclic neutropenia, and growth retardation and, as previously noted, is due to *TAZ* mutations that alter cardiolipin, the most abundant phospholipid component of the IMM.

Sengers syndrome, an autosomal recessive disorder, was described in 1975 and consisted of congenital cataracts, hypertrophic cardiomyopathy, skeletal myopathy, exercise intolerance, and lactic acidosis. This syndrome was ultimately attributed through exome sequencing to mutations in the gene (*AGK*) encoding acylglycerol kinase.

A third disorder of the mitochondrial lipid milieu was identified in 15 patients with a *congenital myopathy* characterized by early-onset muscle weakness and mental retardation with protracted course (most patients were alive at the time of publication and only four had died between the ages of 2½ and 28 years). The hallmark of the disease was the presence in muscle of greatly enlarged mitochondria (megaconial disease) displaced at the periphery of the fibers and the genetic cause was due to mutations in the gene (*CHKB*) encoding choline kinase beta.

A genetic alteration of phospholipid metabolism explained a syndrome characterized by 3-methylglutaconic aciduria (3-methylglutagonic aciduria type IV, deafness, and Leigh-like encephalopathy, which was dubbed *MEGDEL*). This syndrome was caused by mutations in the phospholipid remodeling gene *SERAC1*, a key player in intracellular cholesterol trafficking and a member of the MAMs.

Defects of Mitochondrial Translation

Mitochondrial translational defects typically present with diverse clinical phenotypes with multisystemic disease and LS being the most prevalent; however, a few distinct phenotypes have emerged in this group of heterogeneous disorders. As previously noted, MLASA can be caused not only by *PUS1* mutations but also *YARS* mutations. RIRCD to a homoplasmic tRNA^{Glu} is particularly important to diagnose because, with proper supportive care, children typically improve spontaneously and eventually become clinically normal. Pathogenic mutations in the gene *DARS* (encoding aspartyl-tRNA synthetase) cause brain stem and spinal cord involvement and lactate elevation (*LBSL*) in affected children with cerebellar ataxia, spasticity, dorsal column dysfunction, and mild cognitive decline. Equally severe mutations in the gene *RARS2* (encoding arginyl-tRNA synthetase) have been identified in three patients with severe infantile encephalopathy with *pontocerebellar hypoplasia*. Mutations in *EARS2*, encoding glutamyl-tRNA synthetase, were identified by whole exome sequencing in a cohort of 11 unrelated cases with symmetric cerebral white matter abnormalities and signal abnormalities of the thalami, midbrain, pons, medulla oblongata, and cerebellar white matter. All patients share an infantile-onset and rapidly progressive disease with severe lactic acidosis. Mutations in *MARS2*, encoding the methionyl-tRNA synthetase, were found to be responsible for *autosomal recessive spastic ataxia with leukoencephalopathy* (*ARSAL*).

Defects of mitoribosomes have been associated with complex multisystemic disorders; however, in one family with *MPRL3* mutations, four siblings manifested fatal infantile-onset hypertrophic cardiomyopathy and psychomotor retardation. Similarly, patients with abnormal mitochondrial translational elongation factors typically present with fatal infantile diseases with early hepatoencephalopathy with *GFM1* (*EFG1*) mutations and macrocytic leukodystrophy and micropolygyria due to *TUFM* (*EF-Tu_{mt}*) defects.

Defects of Mitochondrial Dynamics

There is a group of disorders due to numerous mutations in mitochondrial fusion proteins and, less commonly, in fission proteins. Mutations in fusion proteins, such as *OPA1*, result in a dominantly inherited optic atrophy (*DOA* or *Kjer disease*), the nDNA blindness corresponding to the mtDNA disorder *LHON*. Other mutations in fusion proteins, such as *MFN2* or *GADP1*, result in *Charcot-Marie-Tooth neuropathies* (types 2A and 4A).

Two infants with distinct mutations in fission genes (*DRP1* and *MFF*) showed both mitochondrial and peroxisomal abnormalities, and they were severely affected with rapidly fatal encephalopathy and lactic acidosis.

DEFECTS OF mtDNA MAINTENANCE

Here, we consider the main clinical phenotypes associated with mtDNA depletion syndromes (*MDS*), with multiple mtDNA syndromes (*PEO-plus*), and, finally, with combined appearance of mtDNA depletion and of multiple mtDNA deletions.

mtDNA Depletion Syndromes

MYOPATHIC mtDNA DEPLETION SYNDROMES

Patients usually present in the first year of life with failure to thrive, hypotonia, weakness, and sometimes *PEO*. They usually die in childhood from pulmonary insufficiency but severity of weakness and survival vary considerably. The myopathic *MDS* is most commonly due to mutations in the gene (*TK2*) encoding mitochondrial

thymidine kinase 2. About 20 mutations have been reported in as many patients. Notably, mutations in *TK2* can also cause a phenocopy of SMA; therefore, it is of practical importance to screen for *TK2* mutations in patients with SMA but without mutations in the *SMN1* gene.

ENCEPHALOMYOPATHIC mtDNA DEPLETION SYNDROMES

Two variants of this condition are both due to a defect of succinyl-CoA lyase activity in the Krebs cycle. Mutations in the gene (*SUCLA2*)

P.1212

encoding the ATP-dependent succinyl-CoA lyase *SUCLA2* cause severe psychomotor retardation, muscle hypotonia, hearing loss, generalized seizures, knee and hip contractures, mild ptosis, lactic acidosis, and methylmalonic aciduria. There is only moderate mtDNA depletion (about 30%) in muscle, whereas MRI of the brain is suggestive of LS. Mutations in the gene (*SUCLG1*) encoding the GTP-dependent isoform *SUCLG1* cause a much more severe and rapidly fatal phenotype with mtDNA depletion in both muscle and liver, characterized clinically by dysmorphic features, congenital lactic acidosis, and methylmalonic aciduria. A less dismal course, more like the *SUCLA2* phenotype, is correlated to the degree of residual activity.

Patients with mtDNA depletion are due to mutations in *RRM2B* (encoding the small subunit, p53R2, of the p53-inducible ribonucleotide reductase protein). Infants are hypotonic and children are weak but may also manifest nephropathy and central nervous system involvement with microcephaly, seizures, and developmental delay.

HEPATOCEREBRAL mtDNA DEPLETION SYNDROMES

Mutations in three other genes, *DGUOK*, *MPV17*, and *POLG* also cause liver and brain involvement. Mutations in *DGUOK*, encoding the mitochondrial deoxyguanosine kinase (dGK), were first reported in 2001. Severe mutations cause fatal infantile hepatopathy and brain involvement, whereas milder mutations cause isolated liver disease and are compatible with longer survival.

Mutations in *MPV17*, which encodes a small mitochondrial membrane protein of unknown function, cause a rather typical hepatocerebral syndrome in Caucasian children but is associated with a peculiar neurohepatopathy that is prevalent in the Navajo population due to a founder *MPV17* mutation. The clinical features of NNH include peripheral and central nervous system involvement, acral mutilation, corneal scarring or ulceration, liver failure, and immunologic derangement.

Alpers-Huttenlocher syndrome (AHS) is the most important form of hepatocerebral MDS and it has been attributed to mutations in *POLG*. AHS is defined as a disorder of childhood by the tetrad of refractory seizures, episodic psychomotor regression, cortical blindness, and hepatopathy with micronodular cirrhosis. It is crucially important not to expose these children to valproate, which often precipitates fulminant hepatic failure.

Syndromes due to Multiple mtDNA Deletions

MUTATIONS IN *ANT1*

Mutations in the gene for one isoform of the adenine nucleotide translocator (*ANT1*) have been identified in patients with autosomal dominant PEO, sometime associated with psychiatric disorders. In a seminal paper, multiple mtDNA deletions were most abundant in brain, followed by cardiac and skeletal muscle. Sporadic PEO may also infrequently be due to mutations in *ANT1* and the association of mitochondrial myopathy and cardiomyopathy, even in patients with recessive inheritance and without PEO, should raise the question of *ANT1* mutations.

MUTATIONS IN *PEO1*

In 2001, autosomal dominant PEO with multiple mtDNA deletions was associated with mutations in the gene

(*PEO1*), encoding a mitochondrial helicase called *Twinkle*, an essential factor for mtDNA maintenance and for the regulation of mtDNA copy number. A review of 33 patients from 26 families showed that the most common symptoms were ptosis (97%) and ophthalmoparesis (94%), followed by exercise intolerance (52%) and mild proximal weakness. (33%). Central nervous system involvement was infrequent and included visual impairment, migraine, lethargy, hearing loss, and epilepsy. Cardiac problems were noted in 24% of the patients. A relatively benign long-term progression was noted in a large family with autosomal dominant isolated PEO.

MUTATIONS IN POLG

Mutations in the gene encoding the only mitochondrial polymerase, polymerase γ (*POLG*) have emerged as major causes of a vast array of mitochondrial disorders. Over 150 mutations have been described in all three domains of the gene, exonuclease, linker, and polymerase and may cause either autosomal dominant or autosomal recessive PEO, a syndrome comprising autosomal recessive sensory ataxic neuropathy, dysarthria, and ophthalmoparesis (SANDO), mitochondrial recessive ataxia syndrome (MIRAS), or parkinsonism with or without PEO.

MUTATIONS IN OPA1

One unexpected gene was recently added to those described earlier and associated with myopathy and PEO, *OPA1*. This was unexpected because mutations in *OPA1* had been initially associated with a purely ophthalmologic condition, dominant optic atrophy (DOA) or Kjer disease, and because the gene product is a mechanoenzyme associated with mitochondrial fusion rather than with mitochondrial maintenance.

However, a syndromic disorder, often dubbed DOA-plus, has emerged, which is characterized more or less sequentially by optic atrophy with visual failure, sensorineural deafness, ataxia, myopathy, axonal sensory motor polyneuropathy, and PEO. Muscle biopsy in these patients shows scattered ragged blue, COX-negative fibers and multiple mtDNA deletions. The relationship between this defect of mitochondrial dynamics and altered mitochondrial maintenance is intriguing. Two explanations have been proposed: decreased ability by the organelles to repair stress-induced mtDNA damage or accelerated accumulation of preexisting age-associated somatic mtDNA mutations.

Coexistence of mtDNA Depletion and mtDNA Multiple Deletions

MITOCHONDRIAL NEUROGASTROINTESTINAL ENCEPHALOMYOPATHY

One of the disorders in which the coexistence of multiple mtDNA deletions and mtDNA depletion was first recognized is mitochondrial neurogastrointestinal encephalomyopathy (MNGIE). This autosomal recessive multisystemic syndrome is characterized by mitochondrial myopathy with ptosis and PEO, peripheral neuropathy, gastrointestinal dysmotility causing severe cachexia, and leukoencephalopathy without cognitive impairment. MNGIE is due to mutations in the gene (*TYMP*) encoding thymidine phosphorylase (TP), resulting in elevated levels of thymidine and deoxyuridine in plasma and tissues. The disease starts in young adults and is relentlessly progressive, with an average age of death at 37 years. Molecular analysis has shown over 50 *TYMP* mutations resulting in mtDNA multiple deletions, depletion, and site-specific somatic mtDNA point mutations in multiple tissues. A mouse model has demonstrated that increased levels of thymidine and deoxyuridine imbalance mitochondrial deoxynucleotide triphosphate pools, resulting in mtDNA instability.

P.1213

Infantile-onset spinocerebellar ataxia (IOSCA) was described in the 1970s in Finland. Between 9 and 18 months, children develop acutely or subacutely ataxia, hypotonia, athetosis, and areflexia, and by teenage years, they lose independent ambulation. Additional symptoms include PEO, optic atrophy, sensorineural hearing loss, cognitive impairment, sensory neuropathy, and autonomic nervous system dysfunction. In 2005, this autosomal recessive disorder was attributed to mutations in *PEO1*. Both brain and liver showed mtDNA depletion.

In addition to causing early childhood-onset myopathic mtDNA depletion, mutations in *TK2* can also cause adult-onset myopathy with mtDNA depletion and even late-onset PEO with multiple mtDNA deletions rather than mtDNA depletion.

Mutations in *RRM2B* can also be associated with autosomal dominant or recessive PEO and multiple mtDNA deletions.

Exome sequencing revealed *DGUOK* mutations in five adult patients with PEO and mitochondrial myopathy with multiple mtDNA deletions: Only one of these patients had had liver problems in childhood. Mutations in *MPV17*, in addition to causing juvenile-onset mtDNA depletion, can also cause adult-onset PEO-plus with multiple mtDNA deletions in muscle.

DIAGNOSIS

LABORATORY

Lactic acidosis is a common finding in defects of the respiratory chain, and the lactate-to-pyruvate ratio is usually elevated (>20:1). Information about CSF lactate and pyruvate is important because CSF values can be increased in children with encephalopathy and normal blood lactate. However, lack of lactic acidosis does not exclude the diagnosis. For example, in patients with NARP or MILS, blood lactate and pyruvate can be normal or only mildly elevated. Serum creatine kinase (CK) levels are usually normal or modestly increased except, of course, in patients with myopathy during episodes of myoglobinuria. As another exception to this rule, and a useful diagnostic clue, serum CK values can be markedly elevated in children with the myopathic form of mtDNA depletion, such as those with mutations in the gene (*TK2*) encoding mitochondrial thymidine kinase. Another important laboratory test is plasma thymidine, which is greatly increased in patients with MNGIE, an autosomal recessive disease due to mutations in *TYMP* encoding thymidine phosphorylase.

NEURORADIOLOGY

Bilateral MRI T2 signal hyperintensities in basal ganglia and brain stem are indicative of LS. Stroke-like lesions predominantly affecting the cortex, often in the posterior cerebral hemispheres, are typically seen in patients with MELAS. Increased MRI T2 signal abnormality of the central white matter is sometimes observed in KSS, whereas basal ganglia calcifications are common in both MELAS and KSS syndrome (see [Fig. 139.3](#)). White matter signal abnormalities are distinctively seen in patients with complex I deficiency or in children with mtDNA translation defects or in several patients with problems of mtDNA maintenance. Proton magnetic resonance spectroscopy reveals lactate accumulation in the CSF and in specific areas of the brain, where lactate concentration can be compared to the concentration of *N*-acetylaspartate (NAA), an indicator of cell viability.

EXERCISE PHYSIOLOGY

Impaired oxygen extraction by exercising muscle can be detected by near-infrared spectroscopy, which measures the degree of deoxygenation of hemoglobin. A simpler test is based on the measurement of the partial pressure of oxygen (PO₂) in cubital venous blood after forearm aerobic exercise. PO₂ rises paradoxically in patients with mitochondrial myopathy or PEO, and the degree of rise reflects the severity of oxidative impairment. By ³¹P-magnetic resonance spectroscopy, the ratio of phosphocreatine to inorganic phosphate (PCr to Pi) can be measured in muscle at rest, during exercise, and during recovery. In patients with mitochondrial dysfunction, PCr to Pi ratios are lower than normal at rest, decrease excessively during exercise, and return to baseline more slowly than normal.

PATHOLOGY

SKELETAL MUSCLE

Muscle biopsy has a central role in the diagnosis of primary mtDNA-related disorders but is equally important in diagnosing patients with defects of mtDNA maintenance, who have strictly mendelian inheritance and secondary mtDNA alterations. In both types of disorders, abnormal mitochondrial proliferation, a hallmark of mitochondrial dysfunction, can be revealed with the modified Gomori trichrome stain (RRF) or better with the SDH reaction (ragged blue fibers) (Fig. 139.4). RRF are present in muscle biopsies from patients with most disorders due to mtDNA mutations although rare exceptions include NARP/MILS and LHON. Most cases of mendelian inheritance rarely are diagnosable by the presence of RRF or ragged blue fibers, but these types of fibers are exceptionally detectable in patients with either mtDNA depletion or mtDNA multiple deletions.

FIGURE 139.4 Serial sections from the muscle biopsy of a patient with MERRF syndrome. With the modified Gomori trichrome stain (**A**), two ragged red fibers are evident. The same fibers appear *ragged-blue* with the succinate dehydrogenase (SDH) stain (**B**), are pale with the cytochrome c oxidase (COX) stain (**C**), and appear more or less intensely blue with the combined COX/SDH stain (**D**). In contrast to the checkerboard appearance of the muscle biopsy in an mtDNA-related disease, the biopsy from a patient with mutations in *SCO2*, an nDNA assembly gene of COX, shows normal fiber type-related variability in SDH staining intensity (**E**) but uniform lack of COX activity (**F**).

MELAS syndrome and (2) mutations in mtDNA genes encoding cytochrome *b* or complex I subunits. To confirm the pathogenicity of an mtDNA mutation, single fibers can be dissected out of thick cross-sections of muscle and used to determine the levels of a given mutation by polymerase chain reaction (PCR). Finding higher levels of the mutation in affected (ragged red or COX-negative fibers) than in unaffected (non-ragged red, COX-positive fibers) is strong evidence that the mutation in question is pathogenic.

Electron microscopy has lost much of its historical diagnostic value but it can reveal focal accumulations of mitochondria or mitochondria with paracrystalline inclusions in cases in which histochemical results are equivocal.

NEUROPATHOLOGY

The major neuropathologic findings in mitochondrial encephalomyopathies consist of four histologic lesions: spongy degeneration, neuronal loss, gliosis, and demyelination. Although these lesions are nonspecific, their distribution patterns vary in patients with different mtDNA-related disorders. Thus, the neuropathology of KSS is characterized by spongiform degeneration, which is usually generalized and affects both gray and white matter. In MELAS, multifocal necrosis predominates, affecting not only the cerebral cortex or the subcortical white matter but also the cerebellum, thalamus, and basal ganglia. Calcification of basal ganglia is also common. In MERRF, neuronal degeneration, astrocytosis, and demyelination affect preferentially the cerebellum (especially the dentate nucleus), the brain stem (especially the olivary nucleus), and the spinal cord. In LS, due to either mtDNA-related diseases or to mendelian conditions, there are symmetric, bilateral foci of necrosis in the basal ganglia, thalamus, midbrain, and pons. Microscopically, the lesions show vascular proliferation, gliosis, neuronal loss, demyelination, and cystic cavitation.

BIOCHEMICAL FINDINGS

All 13 proteins encoded by mtDNA are components of the mitochondrial respiratory chain. Seven (ND1 to ND5, ND4L, ND6) are subunits of complex I, one (cytochrome *b*) is part of complex III, three (COX I, COX II, and COX III) are subunits of complex IV, and two (adenosine triphosphatase [ATPase] 6 and ATPase 8) are subunits of complex V (see [Fig. 139.1](#)). Therefore, disorders owing to mutations of mtDNA are usually associated with biochemical defects of oxidative phosphorylation. Skeletal muscle is the preferred tissue for biochemical analysis because it is rich in mitochondria, it is invariably affected in multisystem disorders (mitochondrial encephalomyopathies), and it is the most common tissue affected in isolation (mitochondrial myopathies). There is some controversy about whether fresh muscle tissue is needed or frozen tissue suffices. It is our view that—except for the rare cases in which freshly isolated mitochondria for polarographic analyses are required—frozen specimens provide adequate biochemical information. Because mitochondrial proliferation in muscle (RRF) is a common occurrence, activities of respiratory chain complexes should be referred to the activity of citrate synthase, a nuclearencoded enzyme of the mitochondrial matrix that is a good marker of mitochondrial abundance.

Biochemical studies in muscle extract from patients with mtDNA-related disorders yield two main types of results. The first pattern consists of partial defects in the activities of multiple complexes containing mtDNA-encoded subunits (I, III, and IV) contrasting with normal or increased activities of SDH (complex II) and citrate synthase. The second pattern is a severe deficiency in the activity of one specific respiratory complex. As a rule, the first pattern is found in patients with single mtDNA deletions (e.g., KSS) or mutations in tRNA genes (e.g., MELAS, MERRF) because these genetic errors impair mitochondrial protein synthesis *in toto*. The second pattern is typical of mutations in mtDNA protein-coding genes. For example, mutations in the cytochrome *b* gene cause isolated complex III deficiency. However, mutations in ND genes, which are encountered with increasing frequency in patients with MELAS, LS, LHON, or overlap syndromes, cause inconsistent and often modest impairment of complex I activity.

Specific enzyme defects are documentable in mendelian conditions, especially clear in “direct” and “indirect” hits of complex I and complex IV. However, universal decrease of all respiratory chain enzymes (except for complex II) typically appears in conditions of mtDNA depletion syndromes and—equally devastating—it typically also characterizes most disorders due to mtDNA translation syndromes. Occasionally, defects in Fe-S assembly proteins show biochemical decreases of three specific respiratory chain enzymes (complex I, complex II, complex III) and of one specific enzyme of the Krebs cycle (aconitase) of which Fe-S are components.

TREATMENT

No panacea for respiratory chain dysfunction and no universal therapy for mitochondrial disorders currently exist. Nevertheless, symptomatic pharmacologic treatments (e.g., antiepileptic drugs) and surgical remedies (such as blepharoplasty) are useful in prolonging and improving the lives of patients with mitochondrial disease. Exercise therapy has been demonstrated to improve exercise tolerance and quality of life in patients with mitochondrial diseases. Several strategies aimed at curing (or even preventing) mitochondrial diseases have shown promise *in vitro* or in animals or have produced encouraging preliminary results in humans and are briefly reviewed in the following sections.

MITOCHONDRIAL TRANSFER

For mtDNA-related diseases, many of which are devastating and undiagnosable prenatally, the ultimate goal is to prevent their occurrence altogether via mitochondrial replacement. In this approach, the nucleus of an *in vitro*-fertilized oocyte from an mtDNA mutation carrier is transferred to an enucleated oocyte from a normal donor: The embryo will have the nDNA of the biologic parents but the mtDNA of a normal mitochondrial donor. In nonhuman primate experiments using oocyte spindle-chromosomal complex transfer, the infants were healthy and devoid of original maternal mtDNA. The same technique was applied to fertilized and unfertilized but parthenogenetically activated human oocytes, and the cells were found to develop into normal blastocysts and contain virtually exclusively donor mtDNA. Moreover, only donor mtDNA was detected after stem cell lines from blastocysts were differentiated into neurons, cardiomyocytes and β cells. Similar results were obtained in the United Kingdom after pronuclear transfer in abnormally fertilized human oocytes developed to the blastocyst stage. Despite some concerns, the stage seems set for approval of this technique for therapeutic application both in the United Kingdom and the United States.

P.1215

SHIFTING HETEROPLASMY

For mtDNA-related disorders, an obvious but challenging goal is to shift heteroplasmy in patients, thereby lowering the mutation load to subthreshold levels. When deprived of glucose and exposed to ketogenic media, cybrids harboring single mtDNA deletions shifted their heteroplasmy level and recovered mitochondrial function, probably through selective mitochondrial autophagy (mitophagy). A genetic approach to heteroplasmic shifting involves use of restriction endonucleases to eliminate specific pathogenic mutations.

ENHANCEMENT OF RESPIRATORY CHAIN FUNCTION

The most obvious therapeutic approach to mitochondrial disorders is to enhance respiratory chain function, thereby mitigating both energy crisis (ATP deficit) and oxidative stress (toxic buildup of reactive oxygen species [ROS]). The compound used almost universally in patients with mitochondrial disease is CoQ₁₀, given the pivotal role of this molecule in electron transport, its antioxidant properties, and its safety even at high doses. Two synthetic analogs of CoQ₁₀ — idebenone and parabenzoquinone—seem more promising. Idebenone, a short-chain benzoquinone, has shown positive results at 900 mg daily in two studies of patients with LHON. The second compound, a parabenzoquinone labelled EPI-743, has so far been tested

only in open studies: This compound at 100 to 400 mg three times daily reversed vision loss in four of five patients with LHON, produced clinical improvement in 12 children with various mitochondrial disorders, and arrested or reversed disease progression in 13 children with genetically proven LS.

ELIMINATION OF NOXIOUS COMPOUNDS

The second logical therapeutic approach to mitochondrial disease is to eliminate the noxious compounds that accumulate in these disorders. To decrease brain lactate in patients with MELAS, we used dichloroacetate (DCA), which keeps pyruvate dehydrogenase in the active form and favors lactate oxidation. Unfortunately, this agent had unacceptable neurotoxicity and treatment had to be discontinued. A more promising “detoxifying therapy” seems to be allogeneic hematopoietic stem cell transplantation (AHSCT) aimed at restoring sufficient thymidine phosphorylase activity in patients with MNGIE to normalize the circulating toxic levels of thymidine and deoxyuridine. As of 2012, 9 of 24 patients with MNGIE who had undergone AHSCT were alive and had normal blood thymidine phosphorylase activity, virtually undetectable levels of thymidine and deoxyuridine, and mild clinical improvements. A safety study of AHSCT in patients with MNGIE is under way to assess if transplants can be performed with low morbidity in mildly to moderately affected individuals.

ALTERATION OF MITOCHONDRIAL DYNAMICS

Mitochondrial dynamics could be exploited therapeutically in two opposing ways. We could enhance mitochondrial fission and favor mitophagy, a natural “quality control” function that sequesters and eliminates dysfunctional mitochondria, perhaps sensing their abnormally low membrane potential. Alternatively, enhancement of mitochondrial fusion and “networking” would allow complementation of “bad” and “good” mitochondria and normalization of overall mitochondrial function.

Although natural mitochondrial proliferation (e.g., RRF) is a futile compensatory mechanism, preliminary studies indicate it may be possible to improve on nature's strategy by enhancing mitochondrial biogenesis through activation of the transcriptional coactivator PGC-1 α AMPK pathway or Sirtuin1. The advantage over disease-induced mitochondrial proliferation, which appears to favor mutated mtDNAs, is that upregulation of mitochondrial biosynthesis increases numbers of all mtDNAs, allowing wild-type genomes to compensate for mutated ones. Encouraging results have been obtained in four mouse models of COX deficiency.

Neurocutaneous Syndromes

Marc C. Patterson

INTRODUCTION

Several genetic diseases involve both the skin and nervous system. These are called *neurocutaneous disorders* or *neuroectodermatoses*. In the past, they were referred to as the *phakomatoses* (*phakos* is the Greek word for lentil, flat plate, or spot).

Any part of the central nervous system (CNS) or peripheral nervous system can be affected by these hereditary diseases; their expressivity is quite variable both between and within kindreds.

NEUROFIBROMATOSIS

INTRODUCTION

Although neurofibromatosis (NF) was first described at least as early as the 17th century and a comprehensive clinical review was published in 1849, the clinical and pathologic phenotypes were first linked by von Recklinghausen in 1882. NF is one of the most common single-gene disorders of the CNS. Cardinal features include multiple cutaneous hyperpigmented marks (*café au lait spots*); multiple neurofibromas; and lesions in bone, CNS, peripheral nervous system, or other organs. The best characterized forms are neurofibromatosis type 1 (NF-1; *von Recklinghausen disease* or *peripheral NF* [MIM 162200]), neurofibromatosis type 2 (NF-2; *central NF* or the *bilateral acoustic neuroma syndrome* [MIM 101000]) and schwannomatosis, a phenotype characterized by the presence of multiple schwannomas, associated with intractable pain, without vestibular involvement. The three conditions differ in genetics, pathogenesis, and clinically.

EPIDEMIOLOGY

Both sexes are affected equally, and the condition is found worldwide in all racial and ethnic groups. Incidence figures must be a minimal estimate, because mild cases are often unrecognized.

MOLECULAR GENETICS AND PATHOBIOLOGY

NF-1, NF-2, and schwannomatosis are autosomal dominant conditions; penetrance of NF-1 is almost 100%, but expressivity varies. Mutations account for 50% of new cases. The *NF-1* gene has been mapped to chromosome 17q11.2. The gene product is called *neurofibromin*, a tumor suppressor gene that acts through the RAS/MAPK pathway. Translocations, large megabase deletions, large internal deletions, small rearrangements, and point mutations all occur in the *NF-1* gene. Although the genotypes differ, the phenotypes are indistinguishable. The marked clinical variability within families having an identical *NF-1* gene mutation equals the variability among families with different *NF-1* gene mutations. The exception occurs with large megabase deletions associated with cognitive dysfunction and more severe clinical manifestations generally. Mutation inactivates the gene, and, by analogy with other oncogenes, loss of the allelic gene later in life could result in tumor formation. It is not known how the other manifestations of the disease arise. Several potential genetic modifiers in associated signalling pathways have been identified in screening studies.

The *NF-2* gene maps to chromosome 22q12. The gene product is similar to that of the moezin-ezrin-radixin-like protein gene; for this reason, it is called *merlin*. Deletions of the gene have been found in schwannoma and meningioma cells, the major tumors in NF-2 patients. NF-2 inhibits the Rac/CDC42-dependent Ser/Thr kinase PAK1, which activates both Ras transformation and NF-1 through two separate domains. Specific inhibitors of

PAK1 selectively inhibit the growth of NF-2-deficient cancer cells, suggesting that PAK1 is essential for the malignant growth of NF-2-deficient cells. Inhibitors of PAK1 might have a future role as therapies for these tumors.

Schwannomatosis has been linked to mutations in three genes: SMARCB1, LZTR1, and COQ6. The SMARCB1 gene product is a subunit of the SWI/hSHNF chromatin remodeling complex. Mutations in this gene account for about half of familial schwannomatosis but only about 10% of sporadic cases. LZTR1 encodes a protein that acts as a tumor suppressor; COQ6 mutations impair the synthesis of coenzyme Q10.

NEUROPATHOLOGY

Dysplasia, hyperplasia, and neoplasia of neural-supporting tissues involves the central, peripheral, and autonomic nervous systems. Visceral manifestations result from hyperplasia of the autonomic ganglia and nerves within the organ. Dysplastic and neoplastic changes also affect skin, bone, endocrine glands, and blood vessels. Developmental anomalies include thoracic meningocele and syringomyelia. Patients affected by NF-1 are more likely than others to have neoplastic disorders, including neuroblastoma, Wilms tumor, leukemia, pheochromocytoma, and sarcomas.

Neoplasms involving the peripheral nervous system and spinal nerve roots include schwannomas and neurofibromas. Intramedullary spinal cord tumors include ependymomas (especially of the conus medullaris and filum terminale) and astrocytomas (although some of these may actually be ependymomas when electron microscopy is used); gliomas are rare. The most common intracranial tumors are hemispheric astrocytomas of any histologic grade from benign to highly malignant; posterior fossa tumors are rare. Pilocytic astrocytic gliomas of the optic nerve and optic chiasm are also characteristic and generally progress very slowly. Bilateral acoustic neuromas and solitary or multicentric meningiomas occur in adults with NF-2.

CLINICAL MANIFESTATIONS

There are at least four forms of NF. *Peripheral NF* (NF-1) as described by von Recklinghausen is most common. *Central NF* (NF-2) is manifested by bilateral acoustic neuromas with mild cutaneous changes. *Segmental NF* arises from mosaic-type microdeletions in NF-1; it is characterized by café au lait spots and neurofibromas that are limited, usually affecting an upper body segment. The lesions extend to the midline and include the ipsilateral arm but

P.1219

spare the head and neck. *Cutaneous NF* is limited to pigmentary changes; there are numerous café au lait spots but no other clinical manifestations. One percent to 4% of patients with a mild NF phenotype (café au lait spots only) have a related disorder, Legius syndrome, which is associated with mutations in the SPRED1 gene.

NF-1-Noonan syndrome has the clinical manifestations of NF-1 coupled with a Noonan syndrome phenotype. The clinical features of the Noonan syndrome include ocular hypertelorism, downward-slanting palpebral fissures, webbed neck, low-set ears, and pulmonic stenosis.

NF-1 has protean and progressive manifestations. Families and physicians often anticipate a fate like that of Joseph Merrick (the Elephant Man, who almost certainly had the Proteus syndrome, not NF-1). In reality, many patients with the disease are functionally indistinguishable from normal. Often, they have only cutaneous lesions and are not diagnosed until they see a physician because of a learning disability, scoliosis, or another problem.

Cutaneous Manifestations

The café au lait macule is the pathognomonic lesion, being present in almost all patients (Figs. 140.1 and 140.2). Six or more café au lait spots larger than 5 mm in diameter before puberty and greater than 15 mm in diameter after puberty are diagnostic. The spots are usually present at birth but may not appear until age 1 or 2 years.

Increasing in both size and number during the first decade of life, the macules tend to be less evident after the second decade because they blend into the surrounding hyperpigmented skin. These discrete, tan macules involve the trunk and limbs in a random fashion but tend to spare the face.

Other cutaneous manifestations may include freckles over the entire body, but freckles usually involve the axilla and other intertriginous areas. Larger, darker hyperpigmented lesions are often associated with an underlying plexiform neurofibroma if this involves the midline, it may indicate the presence of a spinal cord tumor.

Ocular Findings

Pigmented iris hamartomas (Lisch nodules) (Fig. 140.3) are pathognomonic and consist of small translucent yellow or brown elevations on slit lamp examination. The nodules increase in number with age and are present in almost all patients older than 20 years.

FIGURE 140.1 Café au lait patches and neurofibromas on the back. (Courtesy of Suresh Kotagal, MD.)

FIGURE 140.2 Café-au-lait patches on the abdomen. (Courtesy of Marc C. Patterson, MD.)

Neurologic Symptoms

Neurofibromas are highly characteristic lesions and usually become clinically evident at age 10 to 15 years. They always involve the skin, ultimately developing into sessile, pedunculated lesions. The nodules are found on deep peripheral nerves or nerve roots and on the autonomic nerves that innervate the viscera and blood vessels. The lesions increase in size and number during the second and third decades. There may be a few or many thousands. These benign tumors consist of neurons, Schwann cells, fibroblasts, blood vessels, and mast cells. They rarely give rise to any symptoms other

P.1220

than pain as a result of pressure on nerves or nerve roots; however, they may undergo sarcomatous degeneration in the third and fourth decades of life. Neurofibromas involving the terminal distribution of peripheral nerves form vascular plexiform neurofibromas that result in localized overgrowth of tissues or segmental hypertrophy of a limb. Spinal root or cauda equina neurofibromas are often asymptomatic when

they are small, but large tumors may cause myelopathy. The number and size of neurofibromas may increase during pregnancy.

FIGURE 140.3 Lisch nodules.

Optic gliomas, astrocytomas, acoustic neuromas, neurilemmomas, and meningiomas have a combined frequency of 5% to 10% in all patients with NF. Optic nerve gliomas and other intracranial neoplasms are often evident before age 10 years; acoustic neuromas become symptomatic at about age 20 years. When optic glioma is associated with NF, it commonly involves the optic nerve or is multicentric; less frequently, it involves the chiasm. Optic nerve glioma must be distinguished from the commonly observed nonneoplastic optic nerve hyperplasia. The optic glioma of NF is slowly progressive and has a better prognosis than similar tumors without this association.

NF-2 is clinically evident at about age 20 years; symptoms include hearing loss, tinnitus, imbalance, and headache. Only a few café au lait spots and neurofibromas are seen. Intracranial and intraspinal neoplasms include meningiomas, schwannomas, and gliomas.

CNS involvement in NF is highly variable. Macrocephaly, a common clinical manifestation of postnatal origin, is an incidental finding not related to academic performance, seizures, or neurologic function. Specific learning disabilities or attention deficit disorder, with or without impaired speech, are the most common neurologic complications of NF. Intellectual disability or convulsive disorders each occur in about 5% of the patients. Brain stem tumors associated with NF-1 have a more indolent course than those without NF.

Occlusive cerebrovascular disease is rare but is sometimes seen in children, resulting in acute hemiplegia and convulsions. Magnetic resonance angiography (MRA) or conventional angiography may demonstrate tapering occlusion of the supraclinoid portion of the internal carotid artery at the origin of the anterior and middle cerebral arteries with associated collaterals in the adjacent basal ganglia (moyamoya disease).

A more severe form of NF-1, often clinically apparent in young children, is due to a contiguous gene deletion on chromosome 17q11 that includes neurofibromin. In addition to the clinical features of NF-1, there are dysmorphic features, major malformations, and intellectual disability.

Skeletal and Limb Manifestations

Skeletal anomalies characteristic of NF include (1) unilateral defects in the posterosuperior wall of the orbit, with pulsating exophthalmos, usually associated with dural ectasia; (2) a defect in the lambdoid with underdevelopment of the ipsilateral mastoid; (3) dural ectasia with enlargement of the spinal canal and scalloping of the posterior portions of the vertebral bodies (also seen in connective tissue disorders such as Marfan and Ehlers-Danlos syndromes); (4) scoliosis, affecting between 21% and 49% of patients with NF-1; (5) pseudarthrosis, especially involving the tibia (5% of cases) and radius; (6) “twisted ribbon” rib deformities; and (7) enlargement of long bones.

Miscellaneous Features

Pheochromocytomas occur in 0.1% to 5.7% of patients with NF-1; they are rare in children. Hypertension may be due to a pheochromocytoma (20% to 50% of cases) or a neurofibroma of a renal artery. Malignant tumors occurring less frequently in NF include sarcoma, leukemia, Wilms tumor, ganglioglioma, and neuroblastoma. Medullary thyroid carcinoma and hyperparathyroidism are rare. Precocious puberty and, less commonly, sexual infantilism result from involvement of the hypothalamus by glioma or hamartoma. Cystic lesions, malignancy, and interstitial pneumonia are pulmonary complications.

DIAGNOSIS

Diagnosis of NF-1 or NF-2 is based on clinical, radiologic, and pathologic findings, as well as the family history. Diagnostic criteria were established by a National Institutes of Health consensus conference ([Table 140.1](#)). Some investigators have suggested updating the criteria to account for new knowledge regarding “anaemic nevi, unidentified bright objects, choroidal hamartomas, and a typical neuropsychological phenotype” in NF-1.

Laboratory Data

Diagnosis is usually made by clinical presentation and family history. Molecular genetic studies are available, but many subjects who meet consensus diagnostic criteria do not have detectable mutations in the NF-1 gene. Most affected individual have de novo mutations.

All patients and those at risk should receive a tailored evaluation to confirm the diagnosis and assess the extent of disease. A comprehensive evaluation may include psychoeducational and psychometric testing; electroencephalogram (EEG); ophthalmologic and audiologic testing; cranial computed tomography (CT), including orbital views; CT of the spine and internal auditory foramina; magnetic resonance imaging (MRI) of brain and spine; and quantitative measurement of 24-hour urinary catecholamines.

TABLE 140.1 Diagnostic Criteria for Neurofibromatosis

Neurofibromatosis 1 (Any Two or More)

Six or more café au lait macules

Before puberty >5-mm diameter

After puberty >15-mm diameter

Freckling in the axillary or inguinal areas

Two or more neurofibromas or one plexiform neurofibroma

A first-degree relative with NF-1

Two or more Lisch nodules (iris hamartomas)

Bone lesion

Sphenoid dysplasia

Thinning of the cortex of long bones with or without pseudarthrosis

Neurofibromatosis 2

Bilateral eighth nerve tumor (MRI, CT, or histologic confirmation)

A first-degree relative with NF-2 and a unilateral eighth nerve tumor

A first-degree relative with NF-2 and any two of the following: neurofibroma, meningioma, schwannoma, glioma, or juvenile posterior subcapsular lenticular opacity

NF-1, neurofibromatosis type 1; MRI, magnetic resonance imaging; CT, computed tomography; NF-2, neurofibromatosis type 2.

TREATMENT

There is no specific treatment for NF, but its manifestations may be ameliorated with early recognition and prompt therapeutic intervention. Learning disabilities should be considered in all children with NF-1 and may be complicated by comorbid conditions (such as attention deficit hyperactivity disorder) that warrant educational therapy or behavioral modification, psychotherapy, and pharmacotherapy. Speech problems require a language evaluation and formal speech therapy, and seizures should be managed with appropriate antiepileptic drugs. Progressive kyphoscoliosis usually requires surgical intervention. Surgery may be necessary for removal of pheochromocytomas and intracranial or spinal neoplasms; cutaneous neurofibromas require extirpation when they compromise function or are disfiguring. Preliminary data suggest that thalidomide might have a role in treating neurofibromas. Radiation therapy is reserved for some CNS neoplasms, including optic glioma. Genetic counseling by a qualified geneticist or genetic counselor is essential, and psychotherapy with family counseling is often indicated.

TUBEROUS SCLEROSIS COMPLEX

INTRODUCTION

Tuberous sclerosis complex (TSC) was first described by von Recklinghausen in 1863. In 1880, Bourneville coined the term *sclérose tubéreuse* for the potato-like lesions in the brain. In 1890, Pringle described the facial nevi or *adenoma sebaceum*. Vogt later emphasized the classic triad of seizures, intellectual disability, and adenoma sebaceum. TSC (MIM 191400) is a progressive genetic disorder characterized by the development in early life of hamartomas, malformations, and congenital tumors of the CNS, skin, and viscera.

EPIDEMIOLOGY

Incidence figures are considered minimal because milder varieties are often unrecognized. Clinical surveys suggest a prevalence between 1 in 10,000 and 1 in 170,000. Pulmonary lymphangiomyomatosis, progressive and often fatal, occurs almost exclusively in young women.

GENETICS

Tuberous sclerosis is an autosomal dominant trait, with a high incidence of sporadic cases and protean clinical expression. This variability is attributed to modifier genes. The defective genes map to chromosome 9q34 (TSC1) and chromosome 16p13.3 (TSC2). TSC1 or TSC2 is mutated in 75% to 85% of TSC patients; no mutation is found in 15%. *Hamartin* is the gene product for TSC1, and *tuberin* is the gene product for TSC2. Hamartin and tuberin form heterodimers that inhibit the mammalian target of rapamycin (mTOR); phosphorylation is an important aspect of this complex process, which involves over 50 interacting proteins.

PATHOLOGY AND PATHOBIOLOGY

The pathologic changes are widespread and include lesions in the nervous system, skin, bones, retina, kidney, lungs, and other viscera. Multiple small nodules often line the ventricles.

TSC is characterized by the presence of hamartias and hamartomas. Hamartias (from the Greek for “flaw”) are malformations in which cells native to a tissue display abnormal architecture and morphology. These lesions do not grow disproportionately for the tissue or organ in which they are found. Hamartomas have the same characteristics but grow excessively for their site of origin. This old concept is valuable in recognizing the proliferative potential of lesions found in TSC. Thus, cortical tubers are hamartias and do not grow excessively, whereas angiomyolipomas are hamartomas that grow disproportionately and may produce symptoms as a consequence.

The brain is usually normal in size, but variable numbers of hard nodules occur on the surface of the cortex. These nodules are smooth, round, or polygonal and project slightly above the surface of the neighboring cortex. They are white, firm to the touch, and of various sizes. Some involve only a small portion of one convolution; others encompass the convolutions of one whole lobe or a major portion of a hemisphere. In addition, there may be developmental anomalies of the cortical convolutions in the form of pachygyria or microgyria. On sectioning of the hemispheres, sclerotic nodules may be found in the subcortical gray matter, the white matter, and the basal ganglia. The lining of the lateral ventricles is frequently the site of numerous small nodules that project into the ventricular cavity. Sclerotic nodules are less frequently found in the cerebellum. The brain stem and spinal cord are rarely involved.

Histologically, the nodules are characterized by a cluster of atypical glial cells in the center and giant cells in the periphery. Calcifications are relatively frequent. Other features include heterotopia, vascular hyperplasia (sometimes with actual angiomatous malformations), disturbances in the cortical architecture, and, occasionally, development of subependymal giant cell astrocytomas (SEGAs). Intracranial giant aneurysm and arterial ectasia are uncommon findings.

The skin lesions are multiform and include the characteristic facial angiofibromas and fibrous plaques, typically localized to the frontal area. The facial lesions are not adenomas of the sebaceous glands but small hamartomas arising from nerve elements of the skin combined with hyperplasia of connective tissue and blood vessels (angiofibromas) (Fig. 140.4). In late childhood, lesions similar to those on the face are found around or underneath the nails (*periungual* or *subungual fibromas*). Circumscribed areas of

P.1222

hypomelanosis or depigmented nevi are common in tuberous sclerosis and are often found in infants. Although these depigmented nevi are less specific than the angiofibromas, they are important signals of the diagnosis in infants with seizures. Histologically, the skin appears normal except for the loss of melanin, but ultrastructural studies show that melanosomes are small and have reduced content of melanin. The retinal lesions are small congenital tumors composed of glia, ganglion cells, or fibroblasts. Glioma of the optic nerve has been reported.

FIGURE 140.4 Facial angiofibromas.

Other lesions include cardiac rhabdomyoma; renal angiomyolipoma, renal cysts, and, rarely, renal carcinoma; cystic disease of the lungs and pulmonary lymphangiomyomatosis; hepatic angiomas and hamartomas; skeletal abnormalities with localized areas of osteosclerosis in the calvarium, spine, pelvis, and limbs; cystic defects involving the phalanges; and periosteal new bone formation confined to the metacarpals and

metatarsals.

CLINICAL MANIFESTATIONS

The cardinal features of tuberous sclerosis are skin lesions, convulsive seizures, and intellectual disability. The disease is characterized by variable expressivity of the clinical manifestations and is often age related: the symptomatic neonate with cardiac rhabdomyoma and heart failure; the infant with hypomelanotic macules and infantile spasms; preschool and school-age children with angiofibromas, developmental delay, learning disability or intellectual disability, and seizures; and adults with dermatologic lesions, subungual fibromas, seizures, and often intellectual disability.

Cutaneous Findings

Depigmented or hypomelanotic macules are the earliest skin lesion (Fig. 140.5). They are present at birth, persist through life, and may be found only with a Wood lamp examination. The diagnosis is suggested if there are three or more macules measuring 1 cm or more in length. Numerous small macules sometimes resemble confetti or depigmented freckles. Most macules are leaf shaped, resembling the leaf of the European mountain ash tree and sometimes following a dermatomal distribution. Facial angiofibromas never present at birth but are clinically evident in more than 90% of affected children by age 4 years. At first, the facial lesion is the size of a pinhead and red because of the angiomatous component. It is distributed symmetrically on the nose and cheeks in a butterfly distribution. The lesions may involve the forehead and chin but rarely involve the upper lip. They gradually increase in size and become yellowish and glistening. *Shagreen patches*, connective tissue hamartomas, are also characteristic. Rarely present in infancy, the patches become evident after age 10 years. Usually found in the lumbosacral region, shagreen patches are yellowish-brown elevated plaques that have the texture of pigskin (from which the name originated in French). Other skin lesions include café au lait spots, small fibromas that may be tiny and resemble coarse gooseflesh, and unguinal fibromas that appear after puberty.

FIGURE 140.5 Hypomelanotic or ash leaf macules under UV light. (Courtesy of Suresh Kotagal, MD.)

Neurologic Findings

Infantile spasms are the characteristic seizures in young infants and, when associated with hypopigmented

macules, are diagnostic of tuberous sclerosis. The older child or adult has generalized tonic-clonic or focal seizures. There is a close relationship between the onset of seizures at a young age and intellectual disability. Intellectual disability rarely occurs without clinical seizures, but intellect may be normal despite seizures. Other than delayed acquisition of developmental milestones, intellectual impairment, or nonspecific language or coordinative deficiencies, the formal neurologic examination is typically nonfocal. TSC is a major cause of autism.

Ophthalmic Findings

Hamartomas of the retina or optic nerve are observed in about 50% of patients. Two types of retinal lesions are seen on funduscopy: first, the easily recognized calcified hamartoma near or at the disc with an elevated multinodular lesion that resembles mulberries, grains of tapioca, or salmon eggs and second, the less distinct, relatively flat, smooth-surfaced, white or salmon-colored, circular or oval lesion located peripherally in the retina. Nonretinal lesions may range from the specific depigmented lesion of the iris to nonspecific, nonparalytic strabismus; optic atrophy; visual field defects; or cataracts.

Visceral and Skeletal Findings

Renal lesions include hamartomas (angiomyolipomas) and hamartias (renal cysts). Typically, both are multiple, bilateral, and usually innocuous and silent. Renal angiomyolipomas grow and occasionally bleed, but most can simply be followed with annual CT scans. Renal cell carcinoma is a rare complication in the older child or adult. In one series, 50% of patients with cardiac rhabdomyoma had tuberous sclerosis. Often asymptomatic, this cardiac tumor may be symptomatic at any age and in infancy can (rarely) result in death.

Pulmonary hamartomas consisting of multifocal alveolar hyperplasia associated with cystic lymphangiomyomatosis occur in fewer than 1% of patients. These become symptomatic (often with a spontaneous pneumothorax) in women in the third or fourth decade and are progressive and often lethal. Hamartomatous hemangiomas of the spleen and racemose angiomas of the liver are rare and usually asymptomatic. Sclerotic lesions of the calvarium and cystic lesions of the metacarpals and phalanges are asymptomatic. Enamel pitting of the deciduous teeth and gingival fibromas may aid in diagnosis.

DIAGNOSIS

Clinical diagnosis is possible at most ages. In infancy, three or more characteristic depigmented cutaneous lesions suggest the diagnosis, and this is reinforced by the presence of infantile myoclonic spasms. In the older child or adults, the diagnosis is made by the triad of tuberous sclerosis: facial adenoma sebaceum, epilepsy, and intellectual disability. Retinal or visceral lesions may be diagnostic. The disease, however, is noted for its protean manifestations, and the family history may be invaluable in establishing the diagnosis,

P.1223

which is often reinforced by CT or MRI lesions. Antenatal diagnosis of TSC by fetal ultrasound and MRI is suggested by the presence of a cardiac rhabdomyoma and cortical tubers. Prenatal molecular diagnosis is available for both TSC1 and TSC2.

The differential diagnosis includes other neurocutaneous syndromes that are differentiated by their characteristic skin lesions. Multisystem involvement may complicate the diagnosis of tuberous sclerosis. The Tuberous Sclerosis Complex Consensus Conference has published updated diagnostic criteria ([Table 140.2](#)).

Laboratory Data

MRI of the brain is the cornerstone of diagnosis of TSC. Cortical tubers may be hypo- or isointense on T1-weighted images and show varying patterns of hyperintensity on T2 and fluid-attenuated inversion recovery (FLAIR) sequences; calcification may occur over time. Subependymal nodules are common and most calcify

over time; radial bands of hyperintense signal from the ventricles to the cortex are characteristic of TSC. SEGAs arise from the caudothalamic groove and may obstruct the ipsilateral foramen of Monroe; these tumors most often present in the second decade. Positron emission tomography (PET) often reveals hypometabolic regions that are not obviously abnormal on MRI, indicating a more extensive disturbance of cerebral function.

Visceral lesions are best assessed with imaging studies. Cardiac rhabdomyomas, easily visualized on echocardiography, are frequent in neonates and typically regress over time, whereas renal angiomyolipomas may gradually enlarge and produce symptoms by obstructing the collecting system or bleeding. They are best monitored with ultrasound or CT. Pulmonary lymphangiomyomatosis may be detected on routine chest x-rays, but chest CT is more sensitive.

The EEG is often abnormal, especially in patients with clinical seizures. Abnormalities include slow-wave activity and epileptiform discharges such as hypsarrhythmia, focal or multifocal spike or sharp-wave discharges, and generalized spike-and-wave discharges.

Routine laboratory tests of blood and urine are usually normal, except if there is renal dysfunction, including bleeding from angioliipomas.

TREATMENT

Everolimus, a derivative of rapamycin, has been approved for the treatment of SEGAs that are not suitable for surgery. The drug is also being used for off-label indications including topical application for angiofibromas and for adjunctive treatment of intractable epilepsy. The efficacy of the agent for these purposes has not yet been established in clinical trials. Everolimus has a number of adverse effects related to its immunosuppressive actions and so should be administered with careful monitoring. The cutaneous lesions do not compromise function, but cosmetic surgery may be indicated for facial adenoma sebaceum or large shagreen patches. Infantile spasms respond to corticosteroid or corticotropin therapy; currently, vigabatrin is the drug of choice. Focal and generalized seizures are treated with antiepileptic drugs. Patients with focal seizures and minimal developmental delay may experience long-term seizure control following surgical resection of epileptogenic tubers. Progressive cystic renal disease often responds to surgical decompression, but with renal failure, dialysis or renal transplantation may be necessary. Cardiac rhabdomyomas are rarely symptomatic but may be managed medically with standard therapy for arrhythmias or cardiac failure. Surgery is rarely required. Progressive pulmonary involvement is an indication for respiratory therapy, but response is poor and most patients die a few years after the onset of this complication without lung transplantation.

TABLE 140.2 Diagnostic Criteria for Tuberous Sclerosis Complex

A. Genetic Diagnostic Criteria

The identification of either a TSC1 or TSC2 pathogenic mutation in DNA from normal tissue is sufficient to make a definite diagnosis of tuberous sclerosis complex (TSC). A pathogenic mutation is defined as a mutation that clearly inactivates the function of the TSC1 or TSC2 proteins (e.g., out-of-frame indel or nonsense mutation), prevents protein synthesis (e.g., large genomic deletion), or is a missense mutation whose effect on protein function has been established by functional assessment (www.chromium.liacs.nl/LOVD2/TSC/home.php?select_db=TSC1; www.chromium.liacs.nl/LOVD2/TSC/home.php?select_db=TSC2). Other TSC1 or TSC2 variants

whose effect on function is less certain do not meet these criteria and are not sufficient to make a definite diagnosis of TSC. Note that 10%-25% of TSC patients have no mutation identified by conventional genetic testing, and a normal result does not exclude TSC or have any effect on the use of clinical diagnostic criteria to diagnose TSC.

B. Clinical Diagnostic Criteria

Major features

1. Hypomelanotic macules (three or more, at least 5-mm diameter)

2. Angiofibromas (three or more) or fibrous cephalic plaque

3. Ungual fibromas (two or more)

4. Shagreen patch

5. Multiple retinal hamartomas

6. Cortical dysplasias^a

7. Subependymal nodules

8. Subependymal giant cell astrocytoma

9. Cardiac rhabdomyoma

10. Lymphangiomyomatosis (LAM)^b

11. Angiomyolipomas (two or more)^b

Minor features

1. "Confetti" skin lesions

2. Dental enamel pits (more than three)

3. Intraoral fibromas

4. Retinal achromic patch

5. Multiple renal cysts

6. Nonrenal hamartomas

Definite diagnosis: two major features or one major feature with two or more minor features

Possible diagnosis: either one major feature or two or more minor features

^aIncludes tubers and cerebral white matter radial migration lines.

^bA combination of the two major clinical features (LAM and angiomyolipomas) without other features does not meet criteria for a definite diagnosis.

OUTCOME

Mild or solely cutaneous involvement often follows a static course, whereas patients with the full-blown syndrome have a progressive course with increasing seizures and cognitive impairment. The child with infantile spasms that are not promptly controlled is at

P.1224

great risk of intellectual disability. Brain tumor, status epilepticus, renal insufficiency, cardiac failure, or progressive pulmonary impairment can lead to death.

ENCEPHALOTRIGEMINAL ANGIOMATOSIS

INTRODUCTION

Encephalotrigeminal angiomasia (*Sturge-Weber-Dimitri syndrome*; MIM 185300) is manifested by a cutaneous vascular portwine nevus of the face, contralateral hemiparesis and hemiatrophy, glaucoma, seizures, and intellectual disability. The condition is attributed to partial persistence of a primitive embryonic vascular plexus that develops around the cephalic portion of the neural tube 6 weeks after conception and under the ectoderm in the region destined to become facial skin. In encephalotrigeminal angiomasia, the vascular plexus persists beyond the ninth week, when it normally regresses. Variability in this process accounts for unilateral or bilateral involvement and also for an incomplete syndrome characterized by leptomenigeal angiomasia without facial involvement.

EPIDEMIOLOGY

The syndrome occurs in 1:20,000 to 1:50,000 live births.

GENETICS

Almost all patients with encephalotrigeminal angiomasia, and with nonsyndromic port-wine stains, carry somatic mosaic activating mutations in the GNAQ gene. Mutations in this gene lead to abnormal signaling between G-protein-coupled receptors and downstream effectors. Similar mechanisms have been described in the Proteus and McCune-Albright syndromes.

NEUROPATHOLOGY

The occipital lobe is most often affected, but lesions may involve the temporal and parietal lobes or the entire cerebral hemisphere. Atrophy is characteristically unilateral and ipsilateral to the facial nevus. Leptomenigeal angiomasia with small venules fills the subarachnoid space. Calcification of the arteries on the surface of the brain and intracerebral calcifications of small vessels are seen. Recent studies have associated focal cortical

dysplasia with medically intractable epilepsy in encephalotrigeminal angiomatosis, with important implications for early surgical intervention.

CLINICAL MANIFESTATIONS

Facial nevus and a neurologic syndrome of seizures, hemiplegia, intellectual disability, and glaucoma are characteristic. Typically, other than the facial nevus, the child has normal function for months or years. The subsequent clinical course is highly variable.

Cutaneous Manifestations

The port-wine facial stain, or nevus flammeus, involves variable portions of the face and neck ([Fig. 140.6](#)). Most commonly involving the forehead, the nevus may involve one-half of the face and may extend to the neck. The nevus may cross or fall short of the midline. Bilateral facial lesions are seen in about 15% of cases. Recent studies have suggested that the distribution of the nevus flammeus conforms more closely to the embryonic circulation than the divisions of the trigeminal nerve; a nevus involving any part of the forehead is the best clinical indicator of adverse outcome, including glaucoma, seizures, and abnormal development.

FIGURE 140.6 Facial nevus flammeus. (Courtesy of Suresh Kotagal, MD.)

Neurologic Manifestations

Epilepsy is the most common neurologic manifestation, usually starting in the first year of life with focal or generalized motor or focal dyscognitive seizures. Often refractory to anticonvulsants, the focal motor seizures, hemiparesis, and hemiatrophy are contralateral to the facial nevus. Onset of seizures before age 2 years and refractory epilepsy has prognostic significance; these patients are more likely to be intellectually impaired. Intellectual disability often becomes more marked over time.

Ophthalmologic Manifestations

Raised intraocular pressure with glaucoma and buphthalmos occurs in approximately 30% of patients. Buphthalmos, congenital enlargement of the eye, is more common than glaucoma and results from antenatal intraocular hypertension. Homonymous hemianopia, a common visual field complication, is invariable when the occipital lobe is affected. Other congenital anomalies include coloboma of the iris and deformity of the lens.

DIAGNOSIS

The diagnosis is based on the facial vascular port-wine nevus flammeus and one or more of the following: seizures, contralateral hemiparesis and hemiatrophy, intellectual disability, and ocular findings of glaucoma or buphthalmos. Meningeal involvement is usually obvious on MRI. Rarely, Sturge-Weber-Dimitri syndrome may occur with the neurologic syndrome and the typical meningeal involvement, absent the facial nevus. Encephalotrigeminal angiomas must be distinguished from other vascular malformation syndromes, including Klippel-Trenaunay and Parkes Weber syndromes, both

P.1225

of which feature combined vascular malformations, in contrast to the pure capillary lesions of encephalotrigeminal angiomas. The identification of GNAQ mutations provides a means of molecular confirmation in biopsies of affected tissue.

Laboratory Data

MRI with contrast-enhanced FLAIR sequences is the most sensitive noninvasive technique to identify leptomeningeal involvement and cortical atrophy. ¹⁸F-fluorodeoxyglucose positron emission tomography (FDG-PET) may be helpful in predicting seizure control and cognitive outcome. In a study of 13 children, patients with mild asymmetry of glucose uptake had worse cognitive function than those with marked asymmetry, suggesting that functional reorganization of the cortex is more effective in the latter situation. The capillaries over the affected hemisphere are homogeneously increased, the superficial cortical veins are markedly decreased, and the superior sagittal sinus may be diminished or not seen.

EEG shows low amplitude over the affected areas, and this electrical suppression correlates with the degree of intracranial calcification. The remainder of the hemisphere may show epileptiform activity. The EEG evolves over time, with increasing epileptiform activity, but these electrical changes do not correlate with clinical or seizure severity.

TREATMENT

The facial nevus rarely requires early cosmetic therapy. Later, this blemish can be covered with cosmetics or permanently treated with laser therapy. Seizures may be difficult to control with anticonvulsants. Children with medically intractable seizures often respond to hemispherectomy, even when surgery is delayed. Physical and occupational therapies are indicated for the hemiparesis. Educational therapy and placement

in a special school are important for learning-disabled or intellectually impaired patients; vocational training is essential in affected older children and young adults. Behavioral problems are common and include mood disorder, disruptive behavior disorder, and adjustment disorder in children and substance-related disorder in adults. Prophylactic daily low-dose aspirin to prevent venous thrombosis is controversial but can be considered if there are recurrent transient ischemic attacks (TIAs). Yearly monitoring for glaucoma is recommended for all patients and, if present, should be treated aggressively.

INCONTINENTIA PIGMENTI

INTRODUCTION

Incontinentia pigmenti (IP; MIM 308300), described by Bloch and Sulzberger, is a genetic disorder affecting the skin in a characteristic manner and also involving the brain, eyes, nails, and hair.

GENETICS

IP is an X-linked dominant condition that is lethal in males. Mutations in the *NEMO/IKK γ* gene at Xq28 cause the disease. *NEMO/IKK γ* is an essential component of the newly discovered nuclear factor kappa B (NF- κ B) signaling pathway. When activated, NF- κ B controls the expression of multiple genes, including cytokines and chemokines, and protects cells against apoptosis. *NEMO/IKK γ* deficiency causes the phenotypic expression of the disease via the NF- κ B pathway.

Sporadic disease has also appeared in girls with no family history of the disease. In these cases, there is a translocation with a breakpoint at Xp11.21. Some patients and some families do not map to either site, implying *locus heterogeneity*, with still more gene loci to be discovered.

Incontinentia pigmenti achromians (IPA or hypomelanosis of Ito; MIM 146150) resembles IP in that the pigmentary changes respect the lines of Blaschko, but it is otherwise an unrelated syndrome. Blaschko lines are not ordinarily visible, but several cutaneous disorders follow parallel linear streaks. A pregnant woman with IP runs a 25% risk of a spontaneous miscarriage (the affected son); 50% of her infant daughters will be affected and will have the disease. Daughters are likely to be more severely affected than their mothers.

NEUROPATHOLOGY

The neuropathologic findings are nonspecific and include cerebral atrophy with microgyria, focal necrosis with formation of small cavities in the central white matter, and focal areas of neuronal loss in the cerebellar cortex.

CLINICAL MANIFESTATIONS

One-half of affected infants have the initial linear vesicobullous lesions at birth, and most of the remaining children show the lesions in the first 2 weeks of life. About 10% are delayed, appearing as late as age 1 year. The skin lesions can recur and ultimately may undergo a characteristic change to linear verrucous and dyskeratotic growth, usually between the second and sixth weeks of life; pigmentary changes appear between 12 and 26 weeks. Some infants may show the pigmentary lesions at birth without further cutaneous progression. The pigmentation involves the trunk and limbs, is slate gray-blue or brown, and is distributed in irregular marbled or wavy lines (Fig. 140.7). With age, the pigmentary lesions fade and become depigmented with atrophic skin changes.

FIGURE 140.7 Incontinentia pigmenti. (Courtesy of Suresh Kotagal, MD.)

P.1226

Neurologic, Ophthalmic, and Other Symptoms

About 20% of affected children have a neurologic syndrome that may include slow motor development; pyramidal tract dysfunction with spastic hemiparesis, quadriplegia, or diplegia; intellectual disability; and convulsive disorders.

Strabismus, cataracts, and severe visual loss occur in about 20% of affected children. Retinal vascular changes may result in blindness with ectasia, microhemorrhages, avascularity, and later, retinal pigmentation and atrophy.

Partial or total anodontia and peg-shaped teeth are characteristic of IP. Partial or complete diffuse alopecia with scarring and nail dystrophy may also occur.

LABORATORY DATA

Eosinophilia as high as 65% is often seen in infants younger than 1 year, together with an associated leukocytosis. Eosinophils are also found in the vesicobullous lesions and in affected dermis.

TREATMENT

There is no specific treatment for IP, and management is directed at complicating problems, such as anticonvulsants for seizures. Awareness of the ocular manifestations is essential because laser coagulation in retinal ectasia prevents blindness.

INCONTINENTIA PIGMENTI ACHROMIANS (HYPOMELANOSIS OF ITO)

INTRODUCTION

IPA is a syndrome of regions of cutaneous hypopigmentation that conform to the lines of Blaschko, first described by the German dermatologist in 1901, which define the cutaneous distribution of many hereditary dermatoses and acquired inflammatory disorders. The pattern is believed to result from functional autosomal mosaicism transmittable through the action of retrotransposons. IPA is associated with variable involvement of other body systems, particularly the nervous system.

EPIDEMIOLOGY AND GENETICS

IPA is found in all races and sexes and is a syndrome with multiple etiologies. Mutations in the inhibitor of kappa light polypeptide gene enhancer in B-cells gamma kinase (IKBKG), which is also called *NEMO*, gene are the most common single cause of IP in infant girls and anhydrotic ectodermal dysplasia with immunodeficiency (EDA-ID) in infant boys.

Most cases of IPA with an identifiable cause are associated with somatic mosaicism for chromosomal trisomies. Families with IPA have been reported linked to Xp11, but most cases are sporadic.

PATHOBIOLOGY

The pathogenesis of this disease is similar to that of other neurocutaneous disorders. Migration of neural cells to the brain and melanoblasts to the skin from the neural crest occurs between 3 and 6 months' gestational age. A disturbance of this migration results in both brain and cutaneous pigmentary disease.

The hypopigmented skin lesions are characterized by a decrease in the number of dopa-positive melanocytes and decreased pigment production in the basal layer of the epidermis.

CLINICAL MANIFESTATIONS

In infancy, hypopigmented skin lesions appear as whorls or streaks that follow the lines of Blaschko. This lesion is the negative image of IP. In later childhood, affected areas tend to return to normal skin color. The cutaneous lesion is often associated with developmental and neurologic abnormalities with hypotonia, pyramidal tract dysfunction, intellectual disability (approximately 80%), and seizures. Ophthalmologic disorders, including strabismus, optic atrophy, microphthalmia, tessellated fundus (a normal fundus with a pigmented choroid that creates the appearance of dark polygonal areas between choroidal blood vessels), eyelid ptosis, and heterochromia iridis, are also present. Hair, teeth, and the musculoskeletal system may also be affected.

DIAGNOSIS AND LABORATORY DATA

Because there is no pathognomonic laboratory test, diagnosis is clinical. Investigation for chromosomal mosaicism, with karyotyping of blood, fibroblasts, and hair bulbs, should be considered in all cases.

TREATMENT

The whorled, marble-cake hypopigmented skin lesions do not require any treatment. Therapy is directed toward the associated complications, such as anticonvulsants for seizures and specialized educational facilities for the learning-disabled or retarded child.

Spinal Muscular Atrophies of Childhood

Petra Kaufmann

Darryl C. De Vivo

SPINAL MUSCULAR ATROPHY RELATED TO CHROMOSOME 5 MUTATIONS

GENETIC ETIOLOGY

Spinal muscular atrophy is a motor neuron disease that manifests with muscle atrophy and weakness. Although there are several genetic etiologies, more than 95% of spinal muscular atrophy (SMA) patients carry a homozygous deletion in the *survival motor neurons* (SMN) gene on chromosome 5q11-q13. Based on age at onset and severity of symptoms, three SMA types have historically been described; all are autosomal recessive. The three SMA types are allelic and clinically on a continuous spectrum with SMA1 being the most severe, and SMA3 the milder phenotype. The SMN gene has two almost identical forms on chromosome 5, one telomeric (SMN1) and one centromeric (SMN2). The phenotypic severity of SMA is associated with the SMN2 copy number. SMN1 gene mutation is embryonic lethal in the absence of SMN2 gene. A quantitative study of SMN2 copy number in 375 patients with SMA types 1, 2, and 3 showed that 80% of SMA1 patients had one or two SMN2 copies, 82% of SMA2 patients had three SMN2 copies, and 96% of SMA3 patients had three or four SMN2 copies. In theory, SMA carriers have approximately 50% SMN protein. A mouse model for SMA was made by knocking out the SMN1 gene and introducing the human SMN2 transgene. The murine SMA phenotype is mitigated by increasing the SMN2 copy number, confirming the observation in humans. These findings have become the basis for attempted treatment to increase SMN2 expression in children with SMA.

Direct deletion analysis has high sensitivity and specificity and can be used for diagnosis without muscle biopsy in suspected cases; it is also effective in antenatal diagnosis in an at-risk fetus. Point mutations are found in the few who lack a deletion. The SMN protein is depleted in the spinal cords of patients. How absence of SMN leads to the disease, however, still has to be elucidated.

TABLE 141.1 Spectrum of Phenotypic Severity in Spinal Muscular Atrophy

	SMA 1	SMA 2	SMA 3
Type	Infantile	Intermediate	Mild
Eponym	Werdnig-Hoffmann disease	Dubowitz disease	Kugelberg-Welander disease
Age at onset	0-6 mo	6-18 mo	older than 18 mo
Highest motor milestone achieved	Never able to maintain a sitting position	Sitting	Walking
Life	Without respiratory and	Normal or	Normal

expectancy	nutritional support typically younger than 2 yr	slightly reduced	
Typical number of SMN2 copies	2	3	3-4
Notes	Onset may be in adulthood, when it is sometimes referred to as <i>SMA type 4</i> .		
SMA, spinal muscular atrophy; SMN, centromeric survival motor neurons.			

CLINICAL MANIFESTATIONS

Infantile SMA type I (*Werdnig-Hoffmann syndrome*; MIM 253300) is evident at birth or soon thereafter, always before age 6 months (Table 14.1). Mothers may notice that intrauterine movements are decreased. In the neonatal period, nursing problems may occur and limb movements are feeble and decreased; this is one of the most common causes of the *floppy infant syndrome* (see also Chapter 136). Proximal muscles are affected before distal muscles, but ultimately, flaccid quadriplegia results. The tongue is often seen to fasciculate, but twitching is seen only rarely in limb muscles, presumably because of the ample subcutaneous fat. Sooner or later, respiration is compromised and paradoxical movements of the chest wall are seen. Tendon reflexes are absent. Without ventilatory and nutritional support, most infants die before age 2 years. The others may survive but never sit; their condition may remain stable for many years.

SMA type II (MIM 253550) patients have clinical onset from 6 months to 1 year and learn to sit but never walk. Respiratory insufficiency and scoliosis are dreaded complications. With proactive pulmonary and rehabilitation management, most patients can lead productive lives and have a normal life expectancy.

Kugelberg-Welander syndrome or SMA type III (MIM 253400) patients learn to walk but have varying degrees of weakness. Symptoms begin with a slowly progressive gait disorder in late childhood or adolescence. The onset is followed by proximal arm weakness and wasting; tendon reflexes are lost. Fasciculations of

P.1230

limb muscles, as well as of the tongue, and a tremor of the outstretched limb may be visible. This condition is relatively benign and associated with a normal life span. Others may be handicapped with scoliosis, but serious dysphagia or respiratory compromise is rare. Sensation is spared, and no other organ systems are affected.

DIAGNOSIS

Diagnosis now depends on DNA analysis. Muscle biopsy and electromyography (EMG) are not necessary if a deletion or mutation of SMN is found.

When performed, electrodiagnostic studies show evidence of denervation with normal nerve conduction. Muscle biopsy similarly shows a neurogenic picture. The CSF shows no characteristic changes. Serum levels of sarcoplasmic enzymes, such as creatine kinase, may be increased; in the Kugelberg-Welander type, the increase may be 20 times normal in the range of many myopathies.

TREATMENT

There are promising leads for specific therapy, and clinical trials are underway. Classical gene therapy experiments now can target the SMN1 and SMN2 genes; splice-site enhancers can focus on SMN2 trying to increase the percentage of full-length transcript, and pharmacologic strategies may upregulate the SMN2 transcripts. Histone deacetylase inhibitors are a promising class of compounds that increase full-length SMN protein in vitro. Current treatment is analogous to that described for children with muscular dystrophy using rehabilitative measures, bracing, attention to scoliosis, and assistance in education and social adaptation. Some authorities believe that children with SMA are characteristically of high intelligence; academic programs are important. There is no level 1 evidence to date for an effective treatment of SMA.

OTHER SPINAL MUSCULAR ATROPHIES (NOT RELATED TO CHROMOSOME 5)

SYNDROMES

These syndromes do not map to 5q11 and differ in the focal distribution of symptoms and signs. Most are autosomal recessive, but some families show dominant inheritance.

Fazio-Londe Syndrome

In contrast to the sparing of cranial nerve functions in most juvenile SMA, selective dysarthria and dysphagia in Fazio-Londe syndrome (MIM 211500) begin in late childhood or adolescence. Wasting of the tongue with visible fasciculation occurs. Symptoms may be restricted for years, but weakness of the arms and legs may occur later, and respiration may be affected. It is caused by homozygous or compound heterozygous mutation in the SLC52A3 gene on chromosome 20p13 and may respond to riboflavin.

Scapuloperoneal and Facioscapulohumeral Forms of Spinal Muscular Atrophy

Scapuloperoneal (MIM 271220, 181400) and facioscapulohumeral (FSH; MIM 182970) forms of SMA have been reported. Some may actually have had FSH muscular dystrophy with ambiguous results on EMG and biopsy that led to incorrect classification as a neurogenic disorder. The distinction now depends on DNA analysis.

Childhood Spinal Muscular Atrophy with Known Biochemical Abnormality

Hexosaminidase deficiency (MIM 272800) may cause a syndrome of SMA starting in childhood or adolescence. The pattern of inheritance is autosomal recessive. Some patients also have upper motor neuron signs, as in ALS. Associated psychosis, dementia, or cerebellar signs may appear. Other rare biochemical abnormalities seen with SMA are lysosomal diseases, phenylketonuria, hydroxyisovaleric aciduria, mutations of mtDNA, peroxisomal disease, and ceroid lipofuscinosis.

DIAGNOSIS

Most of the childhood SMAs can be identified by the history and clinical examination. They must be differentiated from muscular dystrophies by DNA analysis, EMG, or muscle biopsy; the family history aids in classification. Hexosaminidase deficiency is suspected in families of Ashkenazi Jewish background, especially if there are known cases of Tay-Sachs disease in the family or if some family members are known to be carriers of the gene. Kennedy syndrome is recognized by onset after age 40 years, distribution of weakness, and gynecomastia.

TREATMENT

For most forms of SMAs, there is no specific treatment. Support and comfort are therefore the goals of

treatment, which may include nutritional support, respiratory support, physical and occupational therapy, rehabilitation devices, and other measures as needed.

Progressive Muscular Dystrophies

Mathula Thangarajh

Petra Kaufmann

Louis H. Weimer

Michio Hirano

Lewis P. Rowland

DEFINITION

A muscular dystrophy has five essential characteristics:

1. It is a myopathy, as defined by clinical, histologic, and electromyographic (EMG) criteria. No signs of denervation or sensory loss are apparent unless there is a concomitant and separate disease.
2. All symptoms are effects of limb or cranial muscle weakness. (The heart and visceral muscles may also be involved.)
3. Symptoms become progressively worse.
4. Histologic changes imply degeneration and regeneration of muscle, but no abnormal storage of a metabolic product is evident.
5. The condition is recognized as heritable, even if there are no other cases in a particular family.

Although not part of the definition, there are two further characteristics, which we hope will be reversed in the future:

1. It is incompletely understood why muscles are weak in any of these conditions, even when the affected gene product is known.
2. There is no curative therapy for any of the dystrophies yet, and gene therapy has not yet been successful.

Improvements in medical care and modern rehabilitation measures have improved the life expectancy and opportunities for children with muscular dystrophy. Furthermore, prednisone has been established as a disease-modifying agent for Duchenne muscular dystrophy (DMD) because it delays the loss of ambulation. Newer treatment strategies are currently entering clinical trials.

Prevention is another important strategy because genetic counseling and prenatal testing allow parents to make informed choices.

The definition of muscular dystrophies requires qualifications. For instance, some familial myopathies manifest by symptoms other than limb weakness, but those conditions are not called dystrophies. Familial recurrent myoglobinuria, for example, is considered a metabolic myopathy. The several forms of familial periodic paralysis do not qualify as dystrophies even if there is progressive limb weakness because the attacks of weakness are the dominant manifestations in most patients. Syndromes that include myotonia incorporate that word in the name of the disease, as in myotonia congenita, but are called *muscular dystrophy* only when there is progressive limb weakness, as in myotonic muscular dystrophy (MMD). In addition, static conditions, such as congenital myopathies, are not called dystrophies because the weakness does not become progressively more severe. This distinction allows some exceptions: A slowly progressive dystrophy may seem static, and some congenital myopathies slowly become more severe. Another exception is the term *congenital muscular dystrophy* (CMD), which may be severe and static from birth.

CLASSIFICATION

The classification of muscular dystrophies is based on both clinical and genetic characteristics, starting with three main types: DMD, facioscapulohumeral muscular dystrophy (FSHD), and MMD. Each type differs from others in age at onset, distribution of weakness, rate of progression, presence or absence of calf hypertrophy, or high serum levels of creatine kinase (CK), and pattern of inheritance ([Table 142.1](#)).

Early investigators recognized that these three types did not include all of the common muscular dystrophies, so they included a fourth subtype of muscular dystrophy, namely, limb-girdle muscular dystrophy (LGMD). Patients with LGMD often have weakness of the shoulder and pelvic girdle muscles. In some forms of LGMD, cardiac and respiratory involvement can be prominent. The identification of several genes associated with LGMD-like phenotype has resulted in a newer classification of LGMD based on whether the disease is inherited in an autosomal dominant or recessive pattern.

Progressive muscular dystrophies result from diverse defects in muscle proteins associated with the extracellular matrix (collagen type VI, merosin); cell membrane and associated proteins (dystrophin, sarcoglycans, caveolin-3, dysferlin, integrins); cellular enzymes (calpain-3), organelle, or sarcomere function (telethonin, myotilin, titin); and nuclear envelope (lamins, emerin) ([Fig. 142.1](#)).

LABORATORY DIAGNOSIS

DNA analysis in leukocytes now often obviates the need for EMG and muscle biopsy. Commercially available genetic testing is available for Duchenne, Becker, facioscapulohumeral, scapuloperoneal, myotonic dystrophies, and LGMDs.

The identification of a genetic cause of dystrophinopathy has revolutionized our diagnostic approach to this disorder. In a young boy with gross motor delay and elevated CK and clinical examination suggestive of proximal muscle weakness, the initial testing should focus on large deletions and duplication mutations in the dystrophin gene. Sequencing of the dystrophin gene may be necessary in select cases to confirm diagnosis. Should gene testing in a patient with presumed dystrophinopathy be negative or ambiguous, a muscle biopsy may be performed to establish the diagnosis. Immunocytochemistry and/or Western blot to quantify dystrophin protein may be required. For patients in whom there is mismatch between the clinical phenotype of dystrophinopathy and genetic phenotype, sequencing mRNA from muscle can be performed.

A muscle biopsy can be useful in identifying the appropriate gene for testing in LGMD patients. Histochemical analysis and electrophoretic studies of dystrophin, the associated dystrophin glycoproteins, and other possibly abnormal proteins may be needed for final diagnosis. If unique features are encountered in the biopsy, a regional research center can be consulted. Muscle biopsy is needed to characterize most congenital and metabolic myopathies. Measuring serum CK level and electrocardiogram (ECG) should be included in the workup of all patients with suspected myopathy.

Muscle ultrasound and magnetic resonance imaging (MRI) of skeletal muscle are increasingly used in the diagnostic evaluation.

P.1232

Muscle ultrasound is painless, less expensive compared to MRI, and offers dynamic images. Muscle imaging can show the selective pattern of muscle involvement associated with some of the muscular dystrophies. For example, there is selective involvement of sartorius and adductor longus in selenoprotein N1 (SEPN1) myopathy with sparing of the gracilis. MRI also offers good delineation between fatty infiltration and skeletal muscle and may guide the choice of the muscle to biopsy.

TABLE 142.1 Features of the Most Common Muscular Dystrophies

	Duchenne (DMD)	Facioscapulohumeral (FSHD)	Myotonic Dystrophy (DM 1) and Proximal Myotonic Myopathy (PROMM, DM 2)
MIM number	310200	158900	DM 1: 16090; DM 2: 60268
Incidence estimates	1 in 3,500 live male births	1 in 20,000 births	1 in 8,000 births
Mode of inheritance	X-linked recessive	Autosomal dominant	Autosomal dominant
Gene defect	Deletion or point mutation in dystrophin gene	FSHD 1: reduced number of tandem repeats in D4Z4: 1-8 repeats (normal 10 to >100 repeats) FSHD 2: mutations in chromatin modifier SMCHD1 causing chromatin relaxation at D4Z4	DM 1: CTG expansion in protein kinase gene; 50 to >2,000 repeats (normal 5-37 repeats) DM 2: CCTG repeat expansion in zinc finger protein 9 gene
Gene location	Xp21.2	4q35	DM 1: 19q13; DM 2: 3q21
Expressivity	Complete	Variable	Variable
Age of onset	Childhood	Adolescence, rarely childhood	DM 1: broad range (infancy to adult life) DM 2: adolescence to adult life
Site of onset	Pelvic girdle	Shoulder girdle	DM 1: face and distal limbs; congenital form: hypotonia, clubfeet, dysphagia, dysmorphism, respiratory distress, mental retardation

DM 2: pelvic girdle, neck flexors DM 1 compared to PROMM patients usually have more: facial weakness, dysphagia, and distal weakness and wasting

Calf hypertrophy	Common	Never	DM 1: never DM 2: some
Rate of progression	Relatively rapid	Slow	Variable
Facial weakness	Rare and mild	Common	Common
Contractures	Common	Rare	Rare
Cardiac disease	Usually late (cardiomyopathy)	None	Common (conduction defect)
Other clinical features	Respiratory insufficiency; scoliosis; cognitive function variably impaired (sometimes high function)	High-frequency hearing loss and retinal vasculopathy (rare)	Cataracts, endocrine dysfunction
Genetic heterogeneity	Duchenne and Becker allelic; Becker resembles Duchenne but onset later and less severe	Not all FSHD phenotypes linked to 4q35	Some PROMM patients not linked to 3q21

X-LINKED MUSCULAR DYSTROPHIES

DEFINITIONS

Duchenne and Becker muscular dystrophies (MIM 310200) are dystrophinopathies and are due to mutations in the dystrophin gene located at Xp21. Out-of-frame large deletion or duplication mutations result in the absence of dystrophin protein leading to the severe clinical phenotype (Duchenne), whereas in-frame deletion or duplication mutations in which some dystrophin protein occurs result in the milder clinical phenotype (Becker) (see [Table 142.1](#)). Point mutations can cause either Duchenne or Becker muscular dystrophy. There is often overlap in the clinical phenotype, and these children can be classified as having an “intermediate” phenotype. Boys are affected and females are carriers of the mutations. Nondystrophin diseases that map to the same position are called *Xp21 myopathies*.

PREVALENCE AND INCIDENCE

The incidence of DMD is about 1 in 3,500 male births, with no geographic or ethnic variation. Approximately one-third of the

cases are caused by de novo mutations; the others are more clearly familial. Because the life span of patients with DMD is shortened, the prevalence is less—about 1 in 18,000 males. Becker muscular dystrophy (BMD) is much less common, with a frequency of about 1 in 20,000.

FIGURE 142.1 Skeletal muscle proteins and muscular dystrophies. The dystrophin-glycoprotein complex (DGC) comprises dystrophin, the dystroglycans (α , β), the sarcoglycans (α , β , γ , δ), sarcospan, the syntrophins (α , β_1), and dystrobrevin (α). The complex stabilizes the sarcolemma and protects surface membranes in muscle contraction. Nitric oxide synthetase (nNOS) interacts with the syntrophin complex and laminin- α 2, one of many extracellular ligands of α -dystroglycan. Disease-causing mutations are cited in the text and [Table 142.3](#). LGMD, limb-girdle muscular dystrophy; CMD, congenital muscular dystrophy; DMD, Duchenne muscular dystrophy; BMD, Becker muscular dystrophy; EDMD, Emery-Dreifuss muscular dystrophy. (From Mathews KD, Moore SA. Limb-girdle muscular dystrophy. *Curr Neurol Neurosci Rep.* 2003;3:78-85, with permission.)

Duchenne and Becker Muscular Dystrophies

DUCHENNE MUSCULAR DYSTROPHY

The condition may become evident in infancy if serum enzymes are coincidentally measured, for example, for an incidental respiratory infection. A positive family history may also alert an astute physician to the early recognition of motor delay. Authorities often state that symptoms do not begin until age 3 to 5 years but that view may be a measure of the crudeness of muscle evaluation in infants. Infants with DMD score less on scales that evaluate gross motor function. Many boys have hypertrophied calf muscles. Walking is often delayed, and the boys probably never run normally; toe walking and waddling gait are evident. Then, the condition progresses to overt difficulty in walking, climbing stairs, and rising from chairs. An exaggerated lordosis is assumed to maintain balance. The boys tend to fall easily if jostled and then they have difficulty rising from the ground. In doing so, they use a characteristic maneuver called the *Gowers sign* ([Fig. 142.2](#)). They roll over to kneel, push down on the ground with extended forearms to raise the rump and straighten the legs, then move the hands to the knees and push up to a standing position. The process has been called *climbing up himself*. It is also seen in other conditions that include proximal limb and trunk weakness, such as spinal muscular atrophy. At this stage, the knee jerks may be lost, whereas ankle jerks are still present; this discrepancy is a measure of the proximal accentuation of weakness.

As the disease progresses, the arms and hands are affected. Slight facial weakness may be seen, but speech, swallowing, and

P.1234

ocular movements are spared. Iliotibial contractures limit hip extension; heel cord contractures are partly responsible for toe walking. Loss of ambulation occurs between ages 9 and 12 years or later when treated with steroids. Boys then become wheelchairbound. Scoliosis may then become serious and may compromise limb and respiratory function. Elbow and knee contractures contribute to disability. Respiratory muscle weakness causes progressive decline in lung capacity beginning at about age 8 years. Nocturnal hypoventilation may occur and cause morning headaches and daytime fatigue if untreated. By about age 20 years, respiration is severely compromised that respiratory support is needed. Life expectancy in DMD has improved greatly in the last three decades, probably because of better coordinated medical care and home nocturnal ventilation. Some attribute the improvement to prednisone therapy.

FIGURE 142.2 Gowers sign in a patient with DMD or BMD. Postures assumed in attempting to rise from the supine position.

The heart is usually spared clinically until late in the disease when congestive heart failure (CHF) and arrhythmias may develop. The ECG is abnormal in most patients, with increased QRS amplitude in lead V1 and deep, narrow Q waves in left precordial leads. Echocardiography shows progressively diminished contractility. Signs of cardiomyopathy may not be apparent because of the inability to exercise but may supervene in a few cases. The gastrointestinal system is usually spared, but intestinal hypomotility and acute gastric dilatation are uncommon complications probably related to dystrophin deficiency in smooth muscle. Osteoporosis begins in the ambulatory years, is more severe in the legs, and may contribute to fractures. Intellectual impairment with predominantly verbal difficulties is seen in one-third of boys with DMD, and the average IQ is shifted approximately 1 standard deviation below normal. Therefore, some boys with DMD have average or below average intelligence.

Anesthetic catastrophes may occur with hyperkalemia, extremely high CK levels (even more than 20 times the normal maximum), acidosis, cardiac failure, hyperthermia, and rigidity. The risk can be decreased by avoiding inhaled general anesthetics and depolarizing muscle relaxants, especially succinylcholine. This vulnerability can be considered a form of malignant hyperthermia.

BECKER MUSCULAR DYSTROPHY

This condition is defined by milder skeletal muscle weakness compared to DMD. Calf hypertrophy is present, weakness is greatest proximally, and serum CK levels are high. EMG is myopathic and muscle biopsy reveals some staining of dystrophin. The two clinical features that distinguish it from DMD are differences in age at onset (typically after age 10 years) and rate of progression (still walking after age 16 years, often later). Cognitive impairment is less common than in DMD. Cardiomyopathy usually develops later but may overshadow limb weakness. Cardiac complications contribute to 50% of BMD deaths compared with 20% with DMD. However, some patients have severe cardiomyopathy and mild muscle weakness. Another allelic disorder, X-linked dilated cardiomyopathy, demonstrates little to no skeletal muscle weakness.

INTERMEDIATE PHENOTYPE

Some patients show an intermediate phenotype that can be considered either severe BMD or mild DMD. They remain ambulatory after age 12 years but use wheelchairs before age 16 years. They have preserved antigravity strength in the neck flexors longer than typical DMD patients.

MANIFESTING CARRIERS

DMD is an X-linked recessive condition. Female mutation carriers are usually asymptomatic, but “manifesting carriers” can have limb weakness, calf hypertrophy, cardiomyopathy, or high serum CK levels.

DIAGNOSIS

The diagnosis of Duchenne dystrophy is usually evident from clinical features. In sporadic and atypical cases, spinal muscular atrophy might be mistaken for DMD. Fasciculations and EMG evidence of denervation, however, identify the neurogenic disorder. High CK values are sometimes encountered in screening blood chemistry analysis done for some other purpose; regardless of the clinical findings, this may lead to the erroneous diagnosis of Duchenne dystrophy. However, typical DMD or BMD CK values are at least 20 times normal; few other conditions attain these values, not even interictal phosphorylase deficiency or acid maltase

deficiency. Similarly, when a child with an incidental infection has routine blood tests, increased serum liver enzyme values may lead to diagnosis of suspected hepatitis; serum CK should then be assayed, and if it is elevated, a myopathy should be suspected, not a liver disease. In DMD, serum CK levels are highest in the presymptomatic years and then gradually decrease with age.

Increased CK levels are also seen in girls and women who carry the dystrophin mutations, in some patients with spinal muscular atrophy, and, for unknown reasons, in some otherwise

P.1235

asymptomatic individuals (idiopathic or asymptomatic hyperCK-emia). Even before myopathic symptoms begin, high CK values are seen in the dysferlinopathies (LGMD2B or Miyoshi myopathy), which are discussed later in the chapter. Similarly, caveolin-3 mutations (LGMD 1C) may cause hyperCKemia before symptoms of limb-girdle dystrophy become evident.

MOLECULAR GENETICS

The dystrophin gene is involved in both Duchenne and Becker dystrophies, which are allelic diseases. Dystrophin is a cytoskeletal protein located at the plasma membrane. Brain and other organs contain slightly different isoforms. In muscle, dystrophin is associated with membrane glycoproteins that link the cytoskeleton with membrane proteins and then to laminin and the extracellular matrix (see Fig. 142.1). The protein probably plays an essential role in maintaining muscle fiber integrity. If dystrophin is absent, as in Duchenne dystrophy, or is abnormal, as in Becker dystrophy, the sarcolemma becomes unstable in contraction and relaxation, and the damage results in excessive calcium influx, thereby leading to muscle cell necrosis. If specific glycoproteins are abnormal or missing, the same problems arise, as in some LGMDs (described later in the chapter).

These findings have been put to practical use in the diagnosis of Duchenne and Becker dystrophies and in genetic counseling. DNA analysis demonstrates a deletion or duplication at Xp21 in about 65% of DMD and 85% of BMD patients. Patients with DMD typically have “frameshift” mutations that alter the DNA reading frame and consequently change amino acids downstream of the mutation, whereas individuals with BMD have milder “in-frame” rearrangements that maintain the sequence of amino acids flanking the mutation. Point mutations or small rearrangements account for the remainder and can be detected by gene sequencing. The presence of a deletion or point mutation in a patient with compatible clinical findings is diagnostic. Carriers can be similarly identified, and the test can also be used for prenatal diagnosis (Fig. 142.3).

The initial evaluation of a boy suspected to have dystrophinopathy includes a serum CK followed by genetic screening for dystrophin mutations performed on peripheral blood leukocytes. Mutations that interfere with the expression of dystrophin cause DMD and those that leads to abnormal quality or quantity of dystrophin cause BMD. Muscle biopsy is sometimes performed in sporadic cases of unclear phenotype, even when a deletion has been identified, because immunocytochemistry for dystrophin and Western blot for quantitative dystrophin analysis can confirm and refine the diagnosis in these questionable cases. If no deletion is found and if dystrophin sequencing is not available, muscle biopsy is needed.

FIGURE 142.3 Prenatal diagnosis in DMD. A: Autoradiograph of Southern blot of 1% agarose gel with DNA samples from each individual

digested with the restriction enzyme XmnI and probed with pERT87-15. The affected male is deleted (no signal). His sister who was pregnant has a deleted X and an X chromosome with the 1.6/1.2 allele. Her husband's X chromosome contains the 2.8 allele. The fetus contains the husband's X and the deleted X. **B:** Diagram of the four possible outcomes of the prenatal diagnosis. The fetus is a carrier female. (Courtesy of A. D. Roses.)

In Duchenne dystrophy, dystrophin staining is absent by both immunocytochemistry and Western blot. In Becker dystrophy, immunocytochemistry shows an interrupted pattern of staining on the surface membrane, and the Western blot shows decreased dystrophin levels or abnormal protein size. Carriers show a mosaic pattern; some fibers contain normal dystrophin staining and others show no dystrophin staining. The most widely used animal model of DMD is the *mdx-23* mouse, which has a spontaneous mutation in the exon 23 of the murine dystrophin gene.

TREATMENT

Oral corticosteroids are standard of care in DMD. Prednisone (0.75 mg/kg/day) or deflazacort (0.9 to 1.2 mg/kg/day) can be used in DMD. Prednisone therapy improved function and strength in placebo-controlled trials, but the side effects of chronic administration—in particular, weight gain, growth retardation, and behavioral changes—may limit the use of steroids. If not prohibited by side effects, prednisone is usually offered to ambulatory patients older than 5 years of age and may be continued until the patient enters the wheelchair stage. Data on the use of prednisone before age 5 years or during the wheelchair years are insufficient.

Experimental attempts at gene replacement through implanted myoblasts were unsuccessful to date. Drugs encouraging “reading through” nonsense mutations are under investigation as possible treatment for the minority of DMD patients with a point mutation resulting in a premature stop codon. Other treatment approaches currently under investigation include exon skip-mediated correction and gene therapy.

Supportive management is aimed at maintaining function and independence, avoiding complications, and improving quality of life.

Orthopedic and rehabilitation measures include stretching exercises and ankle-foot orthoses during sleep to prevent contractures. Later, standing and walking can be maintained with ankle-foot

P.1236

orthoses or knee-ankle-foot orthoses combined with standing devices or walkers. Surgical release of contractures is only occasionally used for functional reasons, such as maintaining standing or ambulation. During the wheelchair years, surgical scoliosis stabilization can help maintain a comfortable sitting position and may reduce the risk of atelectasis and pneumonia.

Pulmonary function should be monitored regularly in patients with respiratory symptoms and in those who are nonambulatory to detect declines in respiratory muscle strength or ability to cough. Reduced cough strength increases the risk of atelectasis and respiratory infections. Therefore, chest physical therapy and mechanical insufflators/exsufflators are useful. When symptoms of sleep-disordered breathing are suspected, overnight in-home oximetry or laboratory-based sleep studies can confirm nocturnal hypoventilation. Noninvasive nighttime mechanical ventilation should then be considered. Later in the disease when respiratory muscle weakness progresses, continuous noninvasive ventilation is often needed, and sometimes the difficult decision whether to do a tracheostomy arises.

Cardiac function should be assessed prior to any major surgery in those with respiratory insufficiency or cardiac symptoms and, at least annually, in the later stages of the disease. Perindopril (2 to 4 mg/day) is thought to slow the progression of cardiac disease in DMD. Cardiac transplantation has been performed in select BMD patients.

Other measures include precautions with general anesthesia, influenza and pneumococcal vaccinations, weight control, neuropsychological evaluation to guide in educational issues, and social support to aid emotionally and financially. Genetic counseling for families is crucial.

OTHER XP21 MYOPATHIES

Dystrophinopathies

A deletion in a neighboring gene can extend into the dystrophin gene and produce myopathy. The resulting syndrome may be dominated by other neighboring gene changes, including congenital adrenal insufficiency or glycerol kinase deficiency, as well as a myopathy, which may range from mild to severe. These syndromes are customarily called *Becker variants* if appropriate dystrophin abnormalities are found. That nomenclature may be confusing, however, because the original definition of Becker dystrophy was based on clinical criteria, and these syndromes are clinically different. Among them are myopathies that affect girls or women, not only manifesting carriers but also girls with Turner syndrome or balanced translocations that involve Xp21, as well as syndromes of atypical distributions of weakness, such as distal myopathy or quadriceps myopathy. Some syndromes lack limb weakness but are manifested by other symptoms, such as recurrent myoglobinuria or X-linked cramps without weakness. Each of these atypical syndromes warrants studies of dystrophin.

Nondystrophin-Related Xp21 Myopathies

McLeod syndrome (MIM 300842) is a multisystemic disorder first discovered in blood banks because the donors lacked a red cell antigen, the Kell antigen. These individuals were found to have abnormally shaped red blood cells (acanthocytes), and serum CK values were often 29 times normal or even higher. In addition, some had myopathic limb weakness, and the condition mapped to Xp21. Dystrophin is normal in these patients. Deletions in the XK gene cause McLeod syndrome and a chromosomal microarray analysis may be helpful. It is also described in Chapter 134 (acanthocytes).

EMERY-DREIFUSS MUSCULAR DYSTROPHY

Emery-Dreifuss muscular dystrophy (EDMD) is a muscular dystrophy with several distinct manifestations:

1. The characteristic humeroperoneal distribution of weakness is unusual. That is, the biceps and triceps are affected rather than shoulder girdle muscles, and distal muscles are affected more than proximal muscles in the legs. The limb weakness may be mild or severe.
2. Contractures are disproportionately severe and are evident before much weakness is noted. The contractures affect the elbows, knees, ankles, fingers, and spine. A rigid spine develops, and neck flexion is limited.
3. Heart block, atrial paralysis, and atrial fibrillation are found in 95% of patients by age 30 years and lead to placement of a pacemaker. Dilated cardiomyopathy occurs in about 35% of all cases.

EDMD has been associated with six genes. It is characteristically an X-linked recessive disease (MIM 310300) and is linked to mutations in the *EMD* or *emerin* gene on Xq28. Emerin is localized to the nuclear membrane in muscle and other organs. Alternatively, the phenotype is inherited in an autosomal dominant (MIM 181350) or recessive pattern (MIM 604929) linked to the *LMNA* gene on 1q21, encoding lamin A/C. Lamin A/C is located in the inner nuclear lamina and has also been linked to several allelic disorders, as discussed later in the chapter. Mutations in *FHL1* encoding four-and-a-half LIM protein 1 also cause X-linked EDMD. Autosomal dominant EDMD can also be caused by the following genes: *SYNE1*, *SYNE2*, and *TMEM43*.

Symptoms of EDMD often start before age 5 years with difficulty walking. Examination typically shows symmetric contractures and weakness without pseudohypertrophy. Tendon reflexes are hypoactive or absent, and there may be mild facial weakness. Serum CK activity can be mildly elevated to levels less than 10 times normal. The diagnosis is usually confirmed by DNA testing. Absence of emerin can be demonstrated by immunocytochemical study of a muscle biopsy. Emerin staining is absent not only in muscle nuclei but also in circulating white blood cells (WBCs) and skin. As a result, skin biopsy, leukocytes, or inner cheek swabs for exfoliated mucosal cells can be examined diagnostically instead of muscle biopsy. However, DNA or gene product analysis is preferred to establish accurate diagnosis. Cardiac surveillance (including 24-hour ECG and echocardiography) is crucial.

EDMD must be distinguished from other conditions. The rigid spine syndrome includes vertebral and limb contractures but not cardiomyopathy or muscle wasting. Because the cardiac abnormality may not be evident in childhood, some patients with a rigid spine might be expected to have EDMD. Collagen type VI-related disorders (Bethlem myopathy/Ullrich CMD—MIM 158810/254090) include contractures and myopathy but not cardiomyopathy, as discussed later in the chapter.

Management is symptomatic and may include physical therapy and surgical tendon release for contractures. Pacemaker implantation and treatment of cardiomyopathy is often crucial. Female carriers are at risk of arrhythmias and should have regular cardiac evaluations.

FACIOSCAPULOHUMERAL MUSCULAR DYSTROPHY

DEFINITION

FSHD (MIM 158900) is defined by clinical and genetic features that differ from those of DMD. Inheritance is autosomal dominant.

P.1237

The name designates the characteristic distribution of weakness, which causes symptoms that differ from those of DMD. The face is almost always affected. Severity varies, and some of those affected are asymptomatic but show diagnostic signs. Progression is slow. Symptoms usually begin in adolescence, but signs may be evident in children. Serum CK levels are normal or minimally elevated.

MOLECULAR GENETICS

The disease is autosomal dominant with nearly complete penetrance. Almost all FSHD patients have deletion of the subtelomeric array of 3.3-kilobase repeat elements, termed *D4Z4*, on chromosome 4q35. Normal individuals have 11 to 150 repeats; FSHD patients usually have fewer than 11. The deletion results in inappropriate expression of the double homeobox-containing gene *DUX4* in muscle cells. This common form is referred to as *FSHD1*. About 5% of FSHD patients have chromatin relaxation at *D4Z4* without *D4Z4* contraction and are due to mutations in the chromatin modifier gene *SMCHD1*. This rare form is referred to as *FSHD2*.

CLINICAL MANIFESTATIONS

The following features are characteristics of FSHD:

1. Facial weakness is evident not only by limitation of lip movements but also in the slightly everted lips and wide palpebral fissures. Patients may state that they have never been able to whistle or blow up a balloon. Some are said by relatives to sleep with eyes open.
2. Scapular winging is prominent. Protrusion of the scapulae is more evident when the patient tries to push against a wall with elbows extended and hands at shoulder level. The winging becomes more evident when the patient tries to raise the arms laterally. The patient cannot raise the arms to shoulder level even though there is no weakness of the deltoids on manual testing. This limitation is caused by inadequate fixation of the scapulae to the chest wall.
3. The shoulder girdle has a characteristic appearance. Viewed from the front, the clavicles seem to sag and the tips of the scapulae project above the supraclavicular fossa. This abnormality becomes more marked when the subject tries to raise the arms laterally to shoulder level. Smallness of the pectoral muscles affects the anterior axillary fold, which is ordinarily diagonal but assumes a vertical position. Abdominal muscle weakness may cause abdominal protrusion and exaggerated lumbar lordosis. The lower abdominal muscles are weaker than the upper causing a positive "Beevor" sign with the navel moving toward the head upon neck flexion in a supine position. The limb muscle weakness is often asymmetric.
4. Leg weakness may affect proximal muscles or, more often, the tibialis anterior and peroneals, resulting in footdrop.

In family studies, asymptomatic individuals can be identified by mild versions of these signs. Within a single family, the condition may vary markedly. Progression is slow, however, and the condition may not shorten longevity. About 20% of patients eventually use a wheelchair. Respiratory insufficiency is rare. Men may be more severely affected than women.

ASSOCIATED DISORDERS

Mild sensorineural hearing loss and vascular retinopathy as well as oropharyngeal symptoms, Coats disease (exudative telangiectasia of the retina), and, possibly, mental retardation are occasionally seen in children with FSHD. However, these findings are not consistent, and it is not known how they relate to the genetic abnormality. Cardiac arrhythmias are rarely seen in FSHD.

LABORATORY STUDIES

In most cases, the diagnosis can be confirmed by leukocyte DNA testing for a contraction of the subtelomeric repeat array on 4q35. Presymptomatic diagnosis is possible in families with more than one affected member, but testing should be done only with appropriate counseling. EMG and muscle biopsy, by definition, should show a myopathic pattern. The histologic changes are mild and nonspecific. Inflammatory cells are found in some patients, raising the question of polymyositis, but immunosuppressive therapy has always failed in these patients. DNA diagnosis resolves this possible confusion and may obviate muscle biopsy. Some patients with typical manifestations do not show the characteristic mutation, which may imply locus heterogeneity (mutation at some other locus) or could exceed the limits of sensitivity of current tests for the mutation.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes uncommon myogenic and neurogenic scapuloperoneal syndromes, especially when facial weakness is absent. Additionally, EDMD is sometimes confused with FSHD, but the essential clinical features are different. The increasing availability of genetic testing for FSHD, LGMD, and EDMD is likely to clarify these diagnostic problems. Infantile onset of FSHD is rare, but facial weakness may be severe enough to simulate the Möbius syndrome of congenital facial diplegia.

MANAGEMENT

Albuterol, a β_2 -agonist sympathomimetic drug, was evaluated in an open-label pilot study followed by a randomized clinical trial of 90 FSHD patients for 12 months comparing two dose levels (8 and 16 mg of albuterol twice daily) to placebo. The primary end point, a difference in global strength, was not reached, but albuterol increased two of the secondary end points: grip strength and muscle mass.

Supportive treatment includes physical therapy, analgesics for joint pain, and ankle-foot orthoses for footdrop. Wiring the scapulae to the chest wall has been used to facilitate use of the arms, but the data seem insufficient to warrant widespread use.

MYOTONIC MUSCULAR DYSTROPHY AND PROXIMAL MYOTONIC MYOPATHY

DEFINITION

Myotonic dystrophy (DM 1, MIM 160900) is an autosomal dominant, multisystem disease of unique distribution that includes muscular dystrophy, myotonia, cardiomyopathy, cataracts, and endocrinopathy. Proximal myotonic myopathy (PROMM, DM 2; MIM 602668) shares many characteristics with DM 1 but differs genetically.

EPIDEMIOLOGY

DM 1 is compatible with long life, and gene penetrance is almost 100%. Because of these characteristics, DM 1 is a disease of high prevalence, about 5 per 100,000 throughout the world, with no specific geographic or ethnic variation. It is probably the most common form of muscular dystrophy. The incidence is about 13.5 per 100,000 live births.

FIGURE 142.4 Myotonic dystrophy. Atrophy of facial, temporal, neck, and hand muscles.

CLINICAL MANIFESTATIONS

In DM 1, as in many other autosomal dominant diseases, variation in age at onset and severity are characteristic. Some affected people are asymptomatic but show signs of the disease on examination. The myopathy is distinctive in distribution ([Fig. 142.4](#)). Unlike any of the other major forms of muscular dystrophy, it affects several cranial muscles. Ptosis is common; eye movements may be impaired; and dysarthria and dysphagia may be problems. The temporal muscles are small, and the resulting appearance is distinctive, with a long lean face and ptosis. In men, frontal baldness contributes to the impression. Insensitive clinicians perpetuate unkind words to describe this facial appearance. The sternomastoid muscles are characteristically small and weak. Limb weakness is most pronounced distally and affects the hands and feet equally. This dystrophy is one of the few neuromuscular disorders in which weakness of the finger flexors is prominent. Distal leg weakness may cause a footdrop or steppage gait. Most patients are generally thin, and focal wasting is not prominent. The tendon jerks are lost in proportion to the weakness.

Muscles of respiration may be affected even before there is much limb weakness; this symptom may contribute to the hypersomnia seen in MMD. Sensitivity to general anesthesia may be increased, with prolonged hypoventilation in the postoperative period. MMD, however, is not a muscle disease likely to cause alveolar hypoventilation. The rate of progression is slow and longevity may not be affected, but variation is evident; some people are almost asymptomatic and some become disabled.

Myotonia has a dual definition. First, clinically, it is a phenomenon of impaired relaxation. Second, the EMG shows a distinctive pattern of waxing and waning high-frequency discharges that continue after relaxation begins, thus prolonging and impeding the effort. The EMG pattern is essential to the definition because there are other forms of impaired relaxation (see [Chapter 94](#)). Myotonia is most evident in the hands. Symptomatically, it may impair skilled movements or may embarrass the patient by complicating the attempt to shake hands or

turn a doorknob because it is difficult to let go. As a sign on examination, the slow relaxation can be elicited by tapping the thenar eminence or, in the forearm, the bellies of the extensors of the fingers. Eliciting percussion myotonia in other limb muscles may be difficult for reasons unknown, but lingual myotonia may be present. Myotonia can also be evoked by asking the patient to grasp forcefully and then relax, which a normal person can do rapidly. In someone with myotonia, however, the grasp is followed by slow relaxation. The abnormal activity arises in the muscle because the response to percussion persists in curarized muscle of these patients; that is, the activity persists after neuromuscular transmission has been blocked.

Cataracts are almost universal but take years to appear. Early findings include characteristic iridescent opacities and posterior opacities.

Endocrinopathy is most readily seen in men. Frontal baldness is almost universal, and testicular atrophy is common; fertility is little diminished, however, so that the disease continues to be propagated in the family. Menstrual irregularities and ovarian failure are not nearly so frequent, and fertility is little decreased in women. Diabetes mellitus may be more common than in the general population, and therefore, annual measurements of glucose and glycosylated hemoglobin should be considered. Hypothyroidism is rare but should be considered so that untreated hypothyroidism does not contribute to muscle weakness.

The *cardiac disorder* is manifested by conduction disturbances, atrial fibrillation and flutter, and ventricular tachyarrhythmias. More than half of the adult patients have abnormalities in the ECG. However, these are often asymptomatic, and pacemakers are needed in only about 5% of patients. CHF and syncope or sudden death may be more common in affected individuals.

Gastrointestinal disorders include impaired swallowing, pseudoobstruction, or megacolon. *Cognitive impairment* is common in the congenital form of DM 1, but many patients with adult-onset DM 1 are socially well-adjusted. However, mild cognitive and neuropsychiatric impairment may be evident. *Excessive daytime somnolence* is attributed to nocturnal hypoventilation and may be helped by treatment with modafinil or methylphenidate. *Respiratory difficulties* may occur owing to diaphragmatic and intercostal muscle weakness as well as impaired respiratory drive. *Pilomatrixomata* and *epitheliomas* have been associated with DM 1.

Congenital Myotonic Dystrophy

About 5% of children born to a person with DM 1 have symptoms at birth, a condition termed *congenital myotonic dystrophy*. It affects children of either sex who are born to a woman with the usual adult form of the disease, which is often so mild that the woman may be asymptomatic but shows signs of the condition; the mother is the affected parent in almost all cases, but paternal transmission has been reported. The infants have difficulty feeding and breathing in the newborn period, develop slowly, are often mentally retarded, and show developmental anomalies of the face and jaws, as well as severe limb weakness and clubfeet. The genetic basis for the syndrome is discussed later in the text. The clinical syndrome can be confused with other congenital anomalies, and identification of the disease in the mother is therefore essential; this may be difficult because the mother may be asymptomatic or mildly affected. The child may not show EMG evidence of myotonia, but the mother does.

P.1239

Proximal Myotonic Myopathy

When the mutation causing DM 1 was discovered in 1992, it became evident that some patients did not carry the mutation. Their symptoms and signs are similar to those of DM 1 in many respects, including autosomal dominant myopathy, myotonia, cataracts, and weakness of the sternocleidomastoids. It differs in the distribution of limb weakness because DM 1 is primarily a distal myopathy, and in DM 2, weakness of pelvic girdle muscles is more pronounced than the distal leg weakness. Other differences are less conspicuous. For instance, myotonia is more difficult to elicit, symptoms are less severe, and there may be calf hypertrophy. Congenital DM 1 has not been reported in DM 2 families. Most important, the syndrome does not map to chromosome 19 but maps to chromosome 3q.

LABORATORY STUDIES

EMG shows evidence of myopathy and the characteristic myotonic discharges. Muscle biopsy shows mild and nonspecific changes. Serum CK level may be normal or slightly increased. DNA analysis is now obligatory for precise diagnosis but may raise sensitive questions in a family, and individuals at risk may not wish to be tested. When tested, they should be offered adequate genetic counseling and psychosocial support.

MOLECULAR GENETICS AND PATHOPHYSIOLOGY

The gene for *DM 1* maps to 19q13.2. The mutation is an expansion of a CTG triplet repeat within the DMPK gene. Unaffected people have 5 to 30 CTG repeats; affected individuals have more than 50. Infants with congenital DM 1 have more than 800 repeats, but there is otherwise no strict relation between the number of repeats and clinical severity. Two patients with the same number of repeats may differ in severity. However, the larger the number of repeats, the younger the age at onset, a phenomenon referred to as *anticipation*, and the more severe the syndrome is likely to be (potentiation).

It is not known how the repeat expansion causes the disease. There is no deficiency of the DMPK gene, but mutant mRNA may be retained in the nucleus in structures called *ribonuclear inclusions*. This may reduce the expression of DMPK, but knockout mice do not show a myopathy or myotonia. It has therefore been suggested that the mutant mRNA itself may be toxic, a suspicion confirmed

by transgenic mice that show expanded CUG repeats and ribonuclear inclusions and myotonia. The mutant mRNA may bind and sequester essential proteins, such as “muscleblind,” which is found in the inclusions of patient's cells. The knockout mouse lacking that gene shows muscle, eye, and RNA splicing abnormalities characteristic of DM.

Locus heterogeneity indicates that a different gene must be involved in *DM 2*, which maps to chromosome 3q21. An expanded CCTG repeat has been found in the gene encoding a zinc finger protein, ZNF9, which is an RNA-binding protein.

Whatever the fundamental fault in these diseases, it must explain how the mutation could cause such a *pleiotropic* disorder, with manifestations in so many different organs.

DIAGNOSIS

The clinical features of DM 1 are so characteristic that the diagnosis is often evident at a glance by noting the long lean face, baldness in men, small sternocleidomastoids, distal myopathy, and myotonia. Early footdrop may lead to confusion with Charcot-Marie-Tooth disease but EMG patterns distinguish the two. Noting an autosomal dominant familial pattern is helpful in general, and diagnosing the mother is especially important in congenital DM 1, which can be mistaken for other causes of mental retardation or chromosome abnormalities. DNA analysis can confirm the diagnosis in most cases.

“Nondystrophic myotonias” are described in other chapters: hyperkalemic periodic paralysis and paramyotonia congenita in Chapter 93 and myotonia congenita and the Schwartz-Jampel syndrome in Chapter 94. “Pseudomyotonia,” or impaired relaxation without true myotonic discharges, is seen in the Isaac syndrome or neuromyotonia (see [Chapter 94](#)). Myotonic-like discharges, but not clinical myotonia, are seen in patients with acid maltase deficiency. Inclusion body myopathy with both Paget disease and frontotemporal dementia can be associated with myotonia. However, none of these other myotonic syndromes has the characteristic myopathy and multisystem involvement of DM 1 and therefore rarely cause diagnostic confusion.

MANAGEMENT AND GENETIC COUNSELING

Myotonia can be ameliorated with mexiletine (150 to 1,000 mg/day), phenytoin sodium (Dilantin) (300 to 400 mg/day), or other anticonvulsant drugs. However, myotonia is only rarely a bothersome symptom in contrast to other myotonic syndromes; it is the weakness that is disabling. Rehabilitation measures are helpful in keeping the muscles functioning as best as they can and in assisting the patient in the activities of daily living. Orthoses help the footdrop. Ocular and cardiac symptoms are treated as they would be in any patient. An ECG should be recorded annually for adults, and slit lamp examination is also carried out periodically. Glucose metabolism, thyroid function, and, in symptomatic males, testosterone levels should be periodically monitored and when abnormal, treated. Fatigue is common and often responds to pharmacologic treatment such as modafinil (200 to 400 mg/day). Pain is a frequent symptom and should be managed with pharmacologic and other approaches. General anesthesia should be avoided if possible because of increased postoperative pulmonary complications. In congenital DM 1, respiratory support and feeding tubes are often needed. Early intervention with physical, occupational, and speech therapy and special education are indicated to address the problems associated with global developmental delay. The families are educated about the nature of the disease, inheritance, and the availability of DNA diagnosis for adults and for prenatal testing.

LIMB-GIRDLE MUSCULAR DYSTROPHY

HISTORY AND DEFINITION

Limb-girdle muscular dystrophy is a term originally conceived to separate progressive muscular dystrophies that were not X-linked (Duchenne/Becker) or otherwise clinically distinct dystrophies, such as FSHD or DM 1. The group comprises a heterogeneous collection of other progressive muscular dystrophies primarily involving shoulder and pelvic girdle muscles, autosomal dominant or recessive inheritance, and a normal dystrophin gene product. Metabolic myopathies have been separated, especially acid maltase and debrancher enzyme deficiencies; other limb-girdle syndromes proved to be Becker dystrophy, mitochondrial myopathies, polymyositis, inclusion body myositis, or other diseases ([Table 142.2](#)). The remaining group was expected to have diverse genetic causes, and in the last 15 years, specific gene defects or chromosomal locations have been discovered for most of the remaining entities; the count currently stands at 27. The disorders are usually not

P.1240

clinically distinguishable because of marked variability in severity and age onset, even in a single family. However, some characteristic features are seen with specific defects ([Table 142.3](#)). The identification of new gene defects has led not only to refinement of this category but has also advanced the understanding of basic muscle cellular biology. The newly identified proteins include many not previously known to play a role in normal muscle function.

TABLE 142.2 Conditions Simulating Limb-Girdle Muscular Dystrophy

Acquired Diseases

Inflammatory

Polymyositis, dermatomyositis, inclusion body myositis, sarcoidosis

Toxic myopathies

Chloroquine, steroid myopathy, vincristine, lovastatin, ethanol abuse, phenytoin

Endocrinopathies

Hyperthyroidism, hypothyroidism, hyperadrenocorticism (Cushing syndrome), hyperparathyroidism, hyperaldosteronism

Vitamin deficiency

Vitamin D and vitamin E malabsorption

Paraneoplastic

Lambert-Eaton syndrome, carcinomatous myopathy

Heritable Diseases

Becker muscular dystrophy

Manifesting carrier of Duchenne or Becker gene

Emery-Dreifuss muscular dystrophy

Facioscapulohumeral or scapulohumeral dystrophy

Myotonic muscular dystrophy

Congenital myopathies (centronuclear, central core, nemaline, tubular aggregates, cytoplasmic body, collagen VI-related muscular dystrophy)

Metabolic myopathies: glycogen storage diseases (phosphorylase deficiency, acid maltase deficiency, debrancher deficiency), lipid storage diseases (carnitine deficiencies), mitochondrial myopathies

Myopathy of periodic paralysis

Modified from Jerusalem F, Sieb JP. The limb girdle syndromes. In: Vinken PJ, Bruyn GW, Klawans HL, eds., *Handbook of Clinical Neurology*, Vol. 62. Amsterdam: Elsevier, 1992:179-195.

CLINICAL MANIFESTATIONS

The diseases are separated into autosomal dominant (type 1) and autosomal recessive (type 2) groups. Individual protein defects are given an additional letter designation in order of discovery. In general, recessive forms are more common, more severe, and of earlier onset. Some have characteristic manifestations but none can be conclusively diagnosed on clinical grounds alone. All of the disorders are characterized by proximal weakness of the pelvic or shoulder girdle muscles and dystrophic signs on muscle biopsy; some include cardiomyopathy. Disorders with primarily distal myopathic weakness are grouped separately as *distal myopathies*. Severity may vary between and within families. Proximal muscle weakness manifesting as difficulty climbing stairs or arising from a deep-seated chair are common early symptoms. A waddling gait then develops. Difficulty raising the arms and scapular winging may be seen. Knee jerks tend to

be lost before ankle jerks. Cranial muscles are usually spared. Serum CK levels are almost always high in recessive types and are often elevated in dominant forms. The progression of disease is slow. Needle examination shows myopathic changes, and muscle biopsy is remarkable for inflammation and dystrophic changes.

MOLECULAR GENETICS

Availability of specific protein antibody markers for muscle biopsy immunohistochemistry and molecular genetic analysis varies for each LGMD, but some are commercially available. A nonprofit federally supported database for both current commercial and research testing can be found at the Web site <http://www.genetests.org>. Many of the entities, especially dominant ones, have one or more allelic disorders, in some cases with identical gene defects with multiple manifestations (see [Table 142.3](#)). Allelic disorders include several with isolated hyperCKemia without muscular weakness (caveolin-3, calpain-3, dysferlin, ANO5), some with neurogenic weakness (lamin A/C), and others with other muscle disorders such as rippling muscle disease (CAV3), autosomal dominant EDMD (lamin A/C), and distal myopathy (dysferlin, ANO5). The functions of the altered proteins span far wider than maintenance of the sarcolemma as initially postulated. Correlation of genetic defects and clinical manifestations is still in progress.

Autosomal Recessive Limb-Girdle Muscular Dystrophy

Now that specific proteins are recognized with varying manifestations, disorders based on the proteins rather than phenotype may emerge, as in the dystrophinopathies. Currently, the following LGMD classification is still in use (see [Table 142.3](#)).

LIMB-GIRDLE MUSCULAR DYSTROPHY 2A

Mutations in the calpain-3 (*CAPN3*) gene on chromosome 15q are among the most common causes of LGMD, and over 130 distinct mutations spanning numerous countries are known. In some populations, these mutations account for 28% to 50% of LGMD cases if sarcoglycanopathies and dystrophinopathies are excluded. The protein is a calcium-sensitive protease that is activated through autolysis. Calpain-3 is a muscle cytoskeletal regulator through cleavage of titin and filamin C. Disease severity varies from asymptomatic hyperCKemia to severe weakness. Onset ranges from 2 to 45 years; some have predominantly distal myopathy. Pelvic weakness initially sparing hip adductors and extensors, scapular winging, abdominal laxity, and contractures are characteristic. CK is moderately elevated. At present, immunostaining of calpain-3 on muscle biopsy is not reliable, and therefore, immunoblotting or Western blot is needed for a definitive diagnosis. Sequencing of the coding region is available for a genetic diagnosis.

LIMB-GIRDLE MUSCULAR DYSTROPHY 2B

Dysferlin mutations are seen in LGMD2B and this disorder is allelic with distal Miyoshi myopathy. Both forms prominently affect the gastrocnemius muscles, but the LGMD2B form progresses proximally. Onset is later than most recessive LGMDs, usually after age 15 years and occasionally much later. CK is elevated more than most LGMDs, likely because dysferlin appears to play an important role in muscle membrane repair. Muscle cell injury induces membrane patches enriched in dysferlin. Muscle immunostaining

P.1241

P.1242

P.1243

or blood immunoblot for dysferlin as well as DNA sequencing of the coding region are available.

TABLE 142.3 Limb-Girdle Muscular Dystrophies

MIM No.	Name	Map Position	Gene Product	Clinical Features	Allelic Disorders	Comment/Diagnosis Method
Autosomal Dominant						
159000	LGMD1A	5q31	Myotilin	Nasal speech, proximal weakness	Myofibrillar myopathy	Rare

LIMB-GIRDLE MUSCULAR DYSTROPHY 2C THROUGH LIMB-GIRDLE MUSCULAR DYSTROPHY 2F (SARCOGLYCANOPATHIES)

Sarcoglycans are dystrophin-associated glycoproteins (DAGs) integral to sarcolemmal stability. The four primary protein subunits (α , β , γ , and δ) form a complex that provides support and signaling functions for the muscle membrane. These four DAGs have been implicated in specific forms of LGMD. A distinct ϵ subunit replaces α -sarcoglycan in smooth muscle and in some striated muscle cells; ϵ mutations lead to a myoclonus-dystonia syndrome, not LGMD. A mutation in any of the four main subunits typically disrupts the complex as a whole, leading to decreased function and typically loss of muscle immunostaining. α -Sarcoglycan (adhalin) is most commonly screened on muscle biopsy, but DNA analysis is needed to confirm the mutant subunit. Sequencing is commercially available for all four subunits associated with LGMD. Cases with complete complex loss manifest from 3 to 15 years of age and are typically wheelchair users by age 15 years. Partial loss delays onset until the teens or early adulthood. γ -Subunit defects are more severe, often with congenital onset. Duchenne dystrophy can result in secondary DAG deficiency, and dystrophin must be proved normal before a sarcoglycanopathy can be diagnosed by muscle biopsy. Combined mutations in these four subunits represent roughly only 10% of teen- or adult-onset cases; LGMD2D (α -sarcoglycanopathy) is most common. Associated cardiomyopathy is seen more in β and γ and less in α forms, perhaps due to vascular smooth muscle disease that causes vascular constrictions and ischemia. The LGMD, however, appears to be a primary myopathy and not a vasculopathy.

LIMB-GIRDLE MUSCULAR DYSTROPHY 2G THROUGH LIMB-GIRDLE MUSCULAR DYSTROPHY 2Q

The remaining known recessive forms are considerably rarer. LGMD2G is a very rare disorder linked to defects in *telethonin*, which is a muscle-specific protein localized to the Z-disc, associated with *titin*, and likely affects sarcomere structure. LGMD2H is a relatively mild LGMD seen in Canadian Hutterites owing to a defect in *TRIM32*, which is likely involved in targeting proteins for proteasome degradation. LGMD2I is one of a growing number of dystrophies caused by abnormal α -dystroglycan glycosylation and disruption of the link between dystroglycan and laminin. This form is a result of a defect in the fukutin-related protein (FKRP), which also causes CMD 2C, discussed later, but can cause LGMD of variable severity and age of onset. Accurate prevalence data are not yet known, but this form is relatively common in some populations. Muscle hypertrophy and cardiomyopathy may be present. LGMD2J is a rare form of LGMD also known as *tibial muscular dystrophy*; it is caused by defects in the very large *titin* gene. This sarcomeric protein has multiple proposed roles and directly interacts with numerous other proteins discussed in this section. Distal myopathy and familial dilated cardiomyopathy are other titinopathies. Few cases of LGMD2K have been described to date. This condition is associated with mutations in the *POMT1* gene encoding protein O-mannosyl-transferase. Affected individuals have early childhood onset of muscle weakness and global developmental delay with CK levels 20 to 40 times above normal. LGMD2L is due to *ANO5* mutations, which presents with late-onset leg weakness, with mean age of onset being approximately 35 years. Patients with LGMD2L have markedly elevated CK levels, typically 10 to 50 times the upper limit of normal. In the U.K. population, about 25% of LGMD cases are due to *ANO5* mutations. LGMD2M, 2N, and 2O have defects of dystroglycan glycosylation due to mutations in *FKTN*, *POMT2*, and *POMGNT1*, respectively. In the Turkish population, an ancestral founder mutation in *PLEC* causes LGMD2Q, which presents in early childhood as muscle weakness. Other *PLEC* mutations, however, cause epidermal bullosa simplex with late-onset muscular dystrophy or myasthenic syndrome with late-onset myopathy. *PLEC* encodes a scaffold protein critical for myofiber structure.

Autosomal Dominant Limb-Girdle Muscular Dystrophy

Dominant forms are less common (10% of LGMD) but are associated with greater clinical heterogeneity.

LIMB-GIRDLE MUSCULAR DYSTROPHY 1A

LGMD1A is rare and linked to defects in *myotilin*, localized to the Z-disc near *telethonin*. Affected members are described as having a distinctive, dysarthric speech pattern. Myofibrillar myopathy also occurs with myotilin defects; overexpression in a mouse model causes both pathologies.

LIMB-GIRDLE MUSCULAR DYSTROPHY 1B

LGMD1B is a result of mutations in the LMNA gene that encodes both lamin A and lamin C, which are alternative splice forms. Mutations in this gene lead to multiple distinct phenotypes, including autosomal dominant EDMD, hypertrophic cardiomyopathy, familial partial

lipodystrophy, mandibuloacral dysplasia, Hutchinson-Gilford progeria, as well as LGMD. Lamins A and C are found on the inner nuclear membrane and interact with integral nuclear membrane proteins, including *emerin*, as discussed earlier. The LGMD phenotype is relatively mild but often has significant cardiomyopathy and cardiac conduction disease similar to X-linked EDMD; some also have contractures but less severely than EDMD. To add to the heterogeneity and confusion, this gene is also mutated in a form of axonal Charcot-Marie-Tooth disease (2C).

LIMB-GIRDLE MUSCULAR DYSTROPHY 1C

Caveolins are plasma membrane vesicular invaginations important in cellular trafficking and signaling. Caveolin-3 (CAV3) is a muscle-specific caveolin-related protein in skeletal, smooth, and cardiac muscles. In addition to LGMD, mutations of this gene can produce nondystrophic rippling muscle disease, idiopathic and familial asymptomatic hyperCKemia, and a form of distal myopathy. LGMD often begins around age 5 years with cramping, mild weakness, and calf hypertrophy, but mild cases without clinical weakness are also seen. Caveolin-3 appears to interact with dysferlin, and in some patients with LGMD 2B (dysferlin), there is a secondary reduction in CAV3 levels.

LIMB-GIRDLE MUSCULAR DYSTROPHY 1D

LGMD1D (or 1E) (6q) was previously named *familial dilated cardiomyopathy with conduction disease and myopathy* and is due to mutations in the *DES* gene encoding the desmin protein. *DES* mutations more typically cause myofibrillar myopathy or dilated cardiomyopathy.

LIMB-GIRDLE MUSCULAR DYSTROPHY 1E

In two families with autosomal dominant LGMD and vacuoles in skeletal muscles, mutations have been identified in *DNAJB6*, which encodes a molecular cochaperone involved in protecting proteins from irreversible aggregation.

P.1244

LIMB-GIRDLE MUSCULAR DYSTROPHY 1F

In a large Spanish family with variable juvenile to adult-onset muscular dystrophy and a sporadic LGMD patient, mutations in *TNPO3* were identified. Transportin 3 is a nuclear protein that is a member of the importin-beta/transportin family. Muscle biopsies in the Spanish patients showed abnormally enlarged nuclei.

LIMB-GIRDLE MUSCULAR DYSTROPHY 1G THROUGH LIMB-GIRDLE MUSCULAR DYSTROPHY 1H

These disorders are chromosomally mapped forms awaiting gene identification.

Oculopharyngeal muscular dystrophy (OPMD) is a late-onset autosomal dominant disorder with progressive ptosis, dysphagia, and late-onset proximal limb weakness. Autosomal recessive forms are known. Although originally recognized in French Canadian families, cases have been recognized worldwide. The bulbar onset, however, is usually confused more often with myasthenia gravis than other myopathies. Muscle filamentous intranuclear inclusions are a pathologic hallmark, but rimmed vacuoles are also prominent. The CK is normal or mildly elevated. The disease maps to 14q11.2-q13 and is caused by an expanded GCG repeat in the polyadenylationbinding protein 2 (PABP2). The disease-producing repeat number is unusually short. The normal repeat length is 6, and disease results from lengths of 7 to 13, with 9 and 10 repeats being most common. A more severe autosomal recessive phenotype with earlier onset is described in homozygous patients. *Oculodistal muscular dystrophy* is even less common than OPMD and differs in the distribution of limb weakness but has not yet been mapped.

Collagen type VI-related disorders include a phenotypic spectrum ranging from Bethlem myopathy (MIM 158810) to *Ullrich CMD* (MIM 254090). *Bethlem myopathy* is an autosomal dominant, progressive muscular dystrophy with onset in infancy or childhood. Contractures are prominent, but CK is only mildly elevated and, in contrast to EDMD, cardiomyopathy is not seen. *Ullrich CMD* is an autosomal recessive collagen type VI-related disorder. It is characterized by congenital hypotonia, proximal weakness and joint contractures, and hyperlaxity of distal joints. Skin biopsy analysis for collagen type VI may be diagnostic.

TABLE 142.4 Distal Myopathies

Type	Heritance	Map/Gene Site	Phenotype	CK	Vacuoles	MIM No.
Onset after Age 40 Yr						
Welander	AD	2p13, TIA1	Hands	Normal	Sometimes	604454

Markesberry-Griggs-Udd	AD	2q31, titin	AC	Normal	Yes	600334
Onset before Age 40 Yr						
Nonaka	AR	9p1-q1, GNE	AC	Normal to 5× normal	Yes	605820
Miyoshi	AR	2p13, dysferlin	PC	Elevated 10 to 150×	No	254130
Nebulin	AR	2q23, nebulin	Toe and finger extensors	Normal	No	—
Gowers-Laing	AD	14q11.2, MYH7	AC	Normal to 3× normal	No	160500
Myopathy with anterior leg sparing	AD	7q32, filamin	Hands and legs	Normal to mild elevation	No	609524
HIBM1	AD	2q35, desmin	Legs, quadriceps	Normal to mild elevation	Yes	—

CK, creatine kinase; MIM, mendelian inheritance in man (McKusick); AD, autosomal dominant; AC, anterior compartment of legs; AR, autosomal recessive; GNE, UDP-*N*-acetylglucosamine-2-epimerase/*N*-acetylmannosamine kinase; PC, posterior compartment.

OTHER RARE DYSTROPHIES

Several forms of scapuloperoneal weakness with dystrophic muscle pathology are not linked to the FSHD site. Some show hyaline bodies. Autosomal dominant and recessive and X-linked-dominant inheritance patterns are described. A similar phenotype is neurogenic (scapuloperoneal muscular atrophy). Mutations in the *FHL1* gene cause X-linked dominant scapuloperoneal myopathy; desmin and myosin heavy-chain 7 gene mutations have been identified in autosomal dominant cases. Other rare discrete entities include epidermolysis bullosa simplex with late-onset muscular dystrophy linked to plectin gene mutations and desmin-related myopathy, one with a defect in the α - β crystalline gene on 11q as well as dominant and recessive forms linked to the desmin gene on 2q. Despite all of the identified genetic defects, additional forms of LGMD will be linked to yet unidentified chromosomal loci and novel pathogenic genes.

DISTAL MYOPATHIES (DISTAL MUSCULAR DYSTROPHIES)

Distal myopathies (distal muscular dystrophies) are defined by clinical manifestations in the feet and hands before proximal limb muscles are affected. As heritable diseases with features of myopathy and slow progression, they are properly considered muscular dystrophies. The distinction from hereditary neuropathies is supported by spared sensation and histologic and electrodiagnostic features of myopathy. Most distal myopathies have been assigned to different map positions, confirming the clinical differences in patterns of inheritance, onset in leg or hands, predominant leg weakness in anterior or posterior compartments, presence or absence of vacuoles, and rise in serum CK (Table 142.4).

P.1245

The most common form is *Welander distal myopathy* (MIM 604454), which was first described in Sweden; inheritance is autosomal dominant. Symptoms begin in adolescence or adult years and progress slowly. The legs are affected before the hands. Histologic changes are mild, but filamentous inclusions may resemble those seen in oculopharyngeal dystrophy or inclusion body myositis. Serum CK is only slightly elevated. The gene maps to chromosome 2p13 but may not be owing to the nearby dysferlin gene.

In the autosomal recessive *Nonaka* variant (MIM 605820), a vacuolar myopathy is seen, the gastrocnemius muscles are spared, and serum enzyme values are only slightly increased. *Nonaka* distal myopathy and hereditary inclusion body myopathy share clinical and morphologic similarities; both conditions are a result of defects in the UDP-*N*-acetylglucosamine 2-epimerase/*N*-acetylmannosamine kinase (GNE) gene. *Miyoshi* (MIM 254130) distal myopathy is also autosomal recessive but differs from *Nonaka* in that the histologic changes are nonspecific (without vacuoles), the gastrocnemius muscles are affected first, and serum CK values are notably high; hyperCKemia may be noted before symptomatic weakness. *Miyoshi* myopathy and LGMD type 2B (proximal limb weakness) are allelic, map to 2p17, and are associated with mutations in dysferlin (see Fig. 142.1). *Miyoshi* type 3 is due to *ANO5* mutations. Some *Miyoshi* families do not have mutations in either gene, which implies further locus heterogeneity. Other variants of distal myopathies have been

described and more are likely to be identified.

Seizures in Children

James J. Riviello Jr

Douglas R. Nordli Jr

INTRODUCTION

A seizure is a paroxysmal neurologic event resulting from excessive central nervous system (CNS) excitation, the hypersynchronous neuronal discharge. Management begins with evaluating the event, formulating a differential diagnosis, selecting appropriate diagnostic studies, and determining treatment, including the need for anticonvulsant medications. Seizures may be precipitated by an acute CNS insult, such as infection, stroke, intracranial hemorrhage, or traumatic brain injury; may result from a primary systemic disorder with secondary effects on the CNS, such as hypoglycemia; or occur with epilepsy, a condition in which recurrent, unprovoked seizures occur. However, many paroxysmal disorders in children are also referred to as *seizures* but are more properly called *nonepileptic paroxysmal events* (NEPE). It is important to consider the differential diagnosis of a seizure because NEPE are not treated with anticonvulsant medications. Seizures and epilepsy are similar in adults and children but certain seizure types and epilepsy syndromes are either peculiar to or more common in children.

The evaluation must determine if the seizure results from an acute CNS insult or if it is the initial presentation of epilepsy. A specific treatment may be needed if the seizure occurs during an intercurrent illness. Benign febrile seizures are frequently encountered in children (see the following text), but a seizure with fever (fever lowers seizure threshold) may occur at any age. In discussing seizures and epilepsy, several terms require definition: seizure, epilepsy, epilepsy syndrome, focal onset, generalized onset, status epilepticus, and refractory status epilepticus ([Table 143.1](#)).

EPIDEMIOLOGY

The incidence of unprovoked seizures varies from 42.3 to 61.0 per 100,000 population per year and the incidence of acute symptomatic seizures varies from 20 to 39.0 per 100,000 population per year. In the developed world, the annual incidence of epilepsy is about 46 per 100,000 population per year.

For specific childhood epilepsy syndromes, childhood absence epilepsy is the most common syndrome, occurring in 12% overall in several series, followed by benign rolandic epilepsy, 11.5%, and childhood epilepsy with occipital discharges, 9% (now Panayiotopoulos syndrome). In this series, myoclonic atonic epilepsy occurred in 6%; infantile spasms, 4.1%; and the epileptic encephalopathies, electrical status epilepticus of sleep, 1.1%; and Landau-Kleffner syndrome or epileptic aphasia, 0.5%.

CLASSIFICATION

The classification of the seizure and the actual epilepsy syndrome guides management. The first step is to consider the differential diagnosis because not all events referred to as seizures are epileptic events, such as the NEPE ([Table 143.2](#)). The seizure refers to the actual clinical manifestations and the epilepsy syndrome is the constellation of signs and symptoms that cluster around the seizure type. Three major classification systems are used: (1) the location of the seizure onset in the brain, either focal or generalized; (2) the seizure duration; and (3) seizure etiology.

TABLE 143.1 Terms from International League Against Epilepsy Task Force on

Classification and Terminology

Seizure: sudden clinical event with outward change in neurologic function; etiology from the Greek, “to take hold”

Ictus: a neurologic event, including stroke, epileptic seizure, or an anoxic event

Convulsion: excessive, abnormal muscle contractions, usually bilateral, which may be sustained or interrupted

Epileptic seizure: refers to the clinical manifestations of an epileptic pathophysiology (transient hypersynchronous neuronal discharge), usually self-limited, neuronal activity. Adding the descriptor epileptic to seizure clearly signifies an epileptic etiology separating an epileptic from a nonepileptic seizure.

Epilepsy refers to (1) an **epileptic disorder:** a chronic neurologic condition characterized by recurrent epileptic seizures, and (2) **epilepsies:** conditions involving chronic recurrent epileptic seizures.

Epileptic syndromes: a complex of signs and symptoms that define a unique epilepsy condition

Focal: indicates a seizure in which the initial clinical manifestations suggest activation of only one part of a cerebral hemisphere

Febrile seizures: refers to a seizure that occurs in association of a febrile illness

Simple febrile seizures are isolated, brief generalized convulsions.

Complex febrile seizures are those that are focal or followed by a postictal deficit (Todd paresis), last >10-15 min, or occur more than once within 24 h.

Generalized: indicates a seizure whose initial clinical manifestations are consistent with more than minimal involvement of both cerebral hemispheres

Status epilepticus: The operational definition of status epilepticus, used for treatment, is a seizure or recurrent seizure without return of consciousness lasting >5 min.

Refractory status epilepticus is now defined as failure to respond to the first two antiepileptic drugs used.

The International League Against Epilepsy (ILAE) developed the International Classification of Epileptic Seizures (ICES), last revised in 2010. The ICES classifies the seizure type, referred to as the *semiology*, the *signs*, and the *epilepsy syndrome*. Seizures are divided into the location of the cortical onset: either focal or

P.1248

generalized. A focal seizure is defined as one whose initial clinical manifestations indicate activation of only a focal area, or one part of the cortex, or in other words, the initial activation of a focal group of neurons. A generalized seizure is one with “more than minimal involvement of both cerebral hemispheres” or in other words,

the initial activation of neurons throughout both hemispheres. A generalized seizure may not simultaneously involve every neuron. This is an important dichotomy because the clinical manifestations of the seizure depend on where the seizure starts and where it spreads and the antiepileptic drugs (AEDs) used to prevent seizure recurrence typically have efficacy for either focal or generalized seizures. The definitions of focal or generalized were revised to emphasize the concept of epileptic networks.

TABLE 143.2 Differential Diagnosis of Seizures

Syncope, convulsive syncope, pallid infantile syncope, breathholding attacks
Cardiac arrhythmias (prolonged QT syndrome)
Narcolepsy, cataplexy, hypersomnia
Hyperekplexia (startle disease)
Rage attacks, episodic dyscontrol, panic attacks
Migraines, especially benign paroxysmal vertigo, acute confusional state, basilar artery migraine
Movement disorders, paroxysmal dystonia, paroxysmal choreoathetosis, tics (especially ocular tics)
Munchausen syndrome, Munchausen by proxy
Night terrors, somnambulism, parasomnias
Sandifer syndrome, gastroesophageal reflux, esophageal spasm
Ocular movements (nystagmus, spasms, spasmus nutans, ocular tics)
Infantile self-gratification
Nonepileptic seizures (pseudoseizures)
Transient ischemic events

Seizure duration is important because aggressive treatment is needed for longer seizures. Status epilepticus, defined as a prolonged seizure lasting greater than 30 minutes or serial seizures without return of consciousness for 30 minutes, is a medical emergency that requires immediate termination. Five minutes of a continuous seizure or serial seizures without return of consciousness is the operational definition of status epilepticus for the purpose of treatment. Most seizures usually have a short duration, lasting less than several minutes, but status epilepticus is more likely to occur in the critically ill. The staging of status epilepticus has been used to guide treatment ([Table 143.3](#)), although the recent guideline from the Neurocritical Care Society defines refractory status epilepticus as failure to respond to the first two AEDs given rather than a stage of status epilepticus.

The third system classifies seizures and epilepsy by etiology, dividing them into symptomatic, cryptogenic, and idiopathic (Table 143.4). A symptomatic seizure is one for which the exact cause is identified. A cryptogenic seizure is one in which an underlying specific etiology is presumed because the neurologic state is abnormal (abnormal development or examination) but is not yet identified. The idiopathic seizure is one in which the etiology is not known, meaning that it arises spontaneously or from an obscure unknown cause. Many of the seizures identified as idiopathic are now identified as being associated with an abnormal gene or a channelopathy. A patient presenting with a new-onset seizure or status epilepticus from a specific cause would have an acute symptomatic seizure (review paper). If a past known CNS insult has caused the seizure, this is called a *remote symptomatic seizure*. However, a patient with epilepsy may have a seizure precipitated by an acute illness, referred to as a *remote symptomatic seizure with an acute precipitant* or an *acute on chronic seizure*.

TABLE 143.3 Stages of Status Epilepticus

Incipient stage (0-5 min)

Early stage (5-30 min)

Special circumstances of the early stage: situations that need immediate seizure control

Transition stage (from early to late; time is variable, depends on underlying condition; e.g., a patient with a brain tumor and increased intracranial pressure may have no remaining compensatory mechanisms)

Late stage (established) (30-60 min)

Refractory stage (>60 min)

Postictal stage

The 2010 classification revision replaces the categories symptomatic; cryptogenic; and idiopathic with genetic, structural/metabolic, and unknown. The distinction between complex partial and simple partial seizures is also eliminated. However, it is important to be familiar with both systems because the terms symptomatic, cryptogenic, and idiopathic are still in common clinical use.

SPECIFIC PEDIATRIC SEIZURES AND EPILEPSY SYNDROMES

Space limitations preclude an all-inclusive review of pediatric seizures and pediatric epilepsy syndromes. We shall therefore summarize the seizure types and epilepsy syndromes that are peculiar

P.1249

to the younger child. These include febrile seizures, both benign and complex, the most common seizure type and syndrome in childhood, and the severe childhood epilepsy syndromes including infantile spasms and the epileptic encephalopathies. These benign and severe syndromes are distinct from the seizures and epilepsy syndromes that occur in the adult.

TABLE 143.4 Classification of Seizure Etiology

Symptomatic seizure: The exact cause of the seizure has been identified.

Cryptogenic seizure: A specific etiology is presumed because the neurologic state is abnormal (abnormal development or examination) but has not yet identified.

Idiopathic seizure: There is no identifiable cause other than a possible hereditary predisposition.

Genetic cause: The concept of genetic epilepsy is that as best understood, the epilepsy is the result of a known genetic defect.

Structural/metabolic cause: There is a distinct structural or metabolic condition or disease that has been demonstrated to be associated with a substantially increased risk of developing epilepsy: stroke, trauma, infection.

Unknown cause: The nature of the underlying cause is not known.

FEBRILE SEIZURES

The ILAE defines a febrile seizure as “a seizure in association with a febrile illness in the absence of a CNS infection or acute electrolyte imbalance in children older than 1 month of age without prior afebrile seizures.” Febrile seizures are the most common cause of convulsions in children: Between 2% and 4% of all children in the United States and Europe and 9% to 10% of children in Japan have at least one febrile seizure before age 5 years. Hauser (1994) estimated that in 1990, there were 100,000 cases of newly diagnosed febrile seizures in the United States. Genetic predisposition is an important factor. Overall, siblings and offspring of affected probands have a two- to threefold increased risk of seizures with fever. Based on studies of large families with simple febrile seizures, various genetic loci have been mapped. The literature on the genetics of febrile seizures is substantial and it continues to grow. Linkage analysis has implicated many different chromosomes including 1q, 2q, 2p, 5q, 6q, 8q, 12q, 19p, and 19q. An important linkage has been with genes residing on 2q, which is the location of sodium channel genes, including SCN1A. Recently, another gene, SEZ-6, located on chromosome 17q, has been implicated. Some families have a susceptibility to febrile seizures that persists to an unusually late age, and some of these family members later develop epilepsy. These traits are inherited in an autosomal dominant fashion, and the condition has been termed *genetic epilepsy febrile seizures plus* (GEFS+). Mutations in the voltage-gated sodium channel genes SCN1A, SCN1B, and SCN2A are involved as well as the GABRG2 gene.

About two-thirds of febrile seizures occur in the first 24 hours of illness. Indeed, in some children, the seizure is the first indication of illness. Febrile seizures are subdivided into simple and complex types. Simple febrile seizures are most common, representing 80% to 90% of all febrile seizures. Simple febrile seizures are isolated, brief generalized convulsions. Parents commonly report diffuse stiffening followed by rhythmic jerking of all limbs lasting less than 1 to 2 minutes. Complex febrile seizures are those that are focal or followed by a postictal deficit (Todd paresis), last more than 10 to 15 minutes, or occur more than once within 24 hours. Factors predisposing to febrile status epilepticus include a younger age (mean age 15 months vs. 19 months for benign febrile seizures), a lower temperature (102.3°F vs. 103.6°F), female gender, first-degree family history of febrile seizures, and structural temporal lobe abnormalities.

About one-third of children with febrile seizures have more than one attack. Independent risk factors for recurrence are first febrile seizure before the age of 18 months, a family history of febrile seizures, a low peak temperature, and a short duration of fever before the seizure. Febrile seizures represent acute symptomatic seizures, also referred to as *reactive seizures*, and even when recurrent, do not warrant the designation of epilepsy. However, they do have an epileptic pathophysiology.

Children who have an isolated febrile seizure have a risk of developing epilepsy that is similar to that of the general population. This risk increases if simple febrile seizures recur (2% to 3%), if the febrile seizures are complex, there is a family history of afebrile seizures, or neurologic abnormalities were detected before the first febrile convulsion (10% to 13%). When all three features of complex febrile seizures are present (prolonged, focal, repeated), the risk of subsequent epilepsy may be as high as 49%. Mortality is not increased in children with febrile seizures who are neurologically normal.

Simple febrile seizures have not been associated with, nor do they lead to, mental retardation, low IQ, poor school achievement, or behavioral problems. Most studies have also failed to demonstrate any cognitive or behavioral consequences of complex febrile seizures, although some differences have been reported. In children with prolonged febrile convulsions, nonverbal intelligence measures may be slightly lower compared with children with simple febrile seizures and normal controls. Children with complex febrile seizures are also more likely to require special schooling than those with simple febrile seizures.

Whether prolonged febrile seizures cause mesial temporal sclerosis and refractory partial seizures is controversial. Large prospective studies have failed to find an association, but experience in adult epilepsy surgical centers suggests otherwise because many adults with mesial temporal sclerosis have had a prolonged febrile convulsion as a child. Furthermore, magnetic resonance imaging (MRI) in some children with prolonged febrile seizures has shown acute changes in the mesial temporal region that progress over time to mesial temporal sclerosis. There is accumulating evidence that febrile status epilepticus may have long-term consequences. This issue is currently being studied in the United States in a prospective multicenter research effort. The first phase consists of identifying the patients and biomarkers and the next phase will identify who ultimately develops mesial temporal sclerosis.

There are several epilepsy syndromes in pediatric epileptology, besides benign febrile seizures, that must be included: infantile spasms, now called *epileptic spasms*, and epileptic encephalopathy and electrical status epilepticus of sleep with its two major epilepsy syndromes: Landau-Kleffner syndrome and the continuous spikes and waves of sleep. Genetics is very important in many of the epileptic encephalopathies.

INFANTILE SPASMS, WEST SYNDROME

Infantile spasms are an age-dependent epileptic syndrome characterized by the triad myoclonic or tonic seizures, hypsarrhythmia, and mental retardation, referred to as *West syndrome*. The peak onset is between 4 and 7 months and always before 12 months of age. The current classification system now uses the term *epileptic spasms* because spasms may continue or develop after infancy.

Epileptic spasms are divided into symptomatic, cryptogenic, and idiopathic forms. Symptomatic epileptic spasms are secondary to a known neurologic disorder, such as tuberous sclerosis; cryptogenic refers to a suspected but not definitely identified neurologic disorder; idiopathic refers to a case in which no specific disorder has been identified. The etiology must be identified because there are treatable causes and prognosis is worse when the spasms are either symptomatic as opposed to cryptogenic or idiopathic.

The spasms themselves consist of sudden tonic and myoclonic phenomena, including brief head nods, with quick extension and flexion movements of the trunk, arms, and legs, occurring in clusters and especially during transitions from sleeping to awaking. These are also described as flexor, extensor, or mixed. The actual spasms

may resolve, but other seizure types occur later.

The classic interictal electroencephalogram (EEG) finding is the hypsarrhythmia pattern, which refers to the high-voltage, disorganized EEG background with multifocal spike and sharp waves. The ictal pattern typically consists of a high-amplitude vertex slow wave, the electrodecremental event (sudden EEG suppression lasting for several seconds), or fast activity and high-voltage spikes or polyspikes and slow waves.

P.1250

Treatment for epileptic spasms has typically been with steroids or vigabatrin. The American Academy of Neurology (AAN) and Child Neurology Society practice parameter from 2004 concluded that ACTH is probably effective and that vigabatrin was possibly effective for infantile spasms associated with tuberous sclerosis [Level 1].¹ A United Kingdom study showed that oral prednisolone was possibly effective.

EPILEPTIC ENCEPHALOPATHY

The ILAE defines an epileptic encephalopathy as a condition in which:

The epileptic activity itself may contribute to severe cognitive and behavioral impairments above and beyond what might be expected from the underlying pathology alone (such as a cortical malformation), and that these may worsen over time. Certain syndromes may be referred to as epileptic encephalopathies, but the encephalopathic effects of seizures and epilepsy may potentially occur in association with any form of epilepsy (Berg et al., 2010).

Electrical status epilepticus of sleep is the term used to describe the extreme form of sleep-activated EEG activity: a spike-wave index (SWI), the number of seconds of non-rapid eye movement (NREM) sleep with spikes/the number of seconds of NREM sleep. The Landau-Kleffner syndrome (LKS) and epileptic encephalopathy with continuous spike and wave during sleep (CSWS) are two of these epileptic encephalopathies that may have electrical status epilepticus of sleep (Fig. 143.1). LKS consists of an acquired epileptic aphasia, typically starting with a receptive aphasia in which the patient first doesn't understand language and then loses expressive language. Children with CSWS typically have seizures, but the hallmark is regression in cognitive functioning and behavior, but not primarily language, as occurs in LKS.

INITIAL MANAGEMENT

Evaluation depends in part on the setting. Is the seizure an acute, new-onset seizure, with the child admitted to the emergency department or is the family reporting the seizure later in an outpatient visit? With an acute presentation, management starts with initial patient stabilization, starting with the airway, breathing, and circulation (ABCs), and then assessing whether the child is acutely ill. Persistent altered awareness could indicate the postictal state or nonconvulsive status epilepticus, with emergent EEG needed to differentiate these.

FIGURE 143.1 EEG of electrical status epilepticus of sleep.

The specific treatable causes for seizures must always be considered in the first-time seizure, especially in infants and younger children who have a greater incidence of symptomatic seizures. Meningitis and encephalitis must always be excluded, especially in the febrile infant, in whom the classic signs of meningitis may not occur. Fever itself may reduce the seizure threshold in infants and young children, as in the benign febrile seizures.

DIAGNOSTIC EVALUATION

The history and physical examination are important [Level 1].² Has there been fever, vomiting, diarrhea, or recent trauma? The physical examination includes both a general and neurologic examination, paying particular attention to signs of increased intracranial pressure, such as papilledema, herniation, or focality. For febrile seizures, the diagnosis is made by excluding other possible causes of convulsions, such as meningitis, metabolic abnormalities, or structural brain lesions. Depending on the clinical appearance of the child and the clinician's experience, laboratory tests are not always necessary. Usually, a clinically identifiable illness such as otitis media, upper respiratory infection, or gastroenteritis is present. Fever after immunization may also trigger a febrile seizure. Any suspicion of meningitis, however, mandates lumbar puncture. The typical indicators of meningeal irritation, such as nuchal rigidity and the Brudzinski sign, are not reliable in young infants. Practice guidelines of the American Academy of Pediatrics (1996, 2011) recommend that lumbar puncture be strongly considered if the child is younger than 12 months or if aged between 12 and 18 months, especially if the child has not been immunized or has been pretreated with antibiotics [Level 1].^{3,4} Although a pleocytosis may occur with a seizure, especially status epilepticus, in 200 children with pure febrile status epilepticus, the cerebrospinal fluid (CSF) cell count was less than 3 in 85%.

ELECTROENCEPHALOGRAPHY

If the seizure has focal features, or if the examination elicits focal neurologic abnormalities, brain imaging is necessary. EEG is not useful in children with simple febrile seizures because it does not provide information regarding either the risk for recurrence of febrile seizures or later development of epilepsy. The role of EEG in the evaluation of children with complex febrile seizures, including febrile status epilepticus, is not yet fully determined.

The EEG is especially useful in the evaluation and management of seizures and epilepsy syndromes. The AAN practice parameter in 2000 for evaluating a first nonfebrile seizure in children does recommend a routine EEG [Level 1].² There is controversy regarding the need for EEG after a first afebrile seizure, but EEG findings may help differentiate an epileptic from a nonepileptic event. Syncope can be associated with myoclonus and various

motor movements that are thought to be seizures, and cardiac disorders such as the prolonged QT syndrome may present with a “seizure.” However, a normal EEG does not exclude the diagnosis of epilepsy, and an abnormal EEG does not, in itself, establish a diagnosis of epilepsy. In a longitudinal study of 3,726 normal children aged 6 to 13 years, 3.5% had epileptiform patterns. The EEG is “diagnostic” of a seizure only when actual clinical manifestations occur at the time of the electrographic discharge.

NEUROIMAGING

Neuroimaging is not mandatory in every child with a seizure. The practice parameter from the AAN in 2000 on the first afebrile seizure recommended that neuroimaging be done based on the specific circumstances. In general, children with focal seizures should have neuroimaging done. Proper classification of the seizure type and epilepsy syndrome is important in determining this. Regarding specific epilepsy syndromes, the generalized syndrome, childhood absence epilepsy, and the focal syndrome “benign rolandic epilepsy” are extremely unlikely to have abnormal neuroimaging and MRI is not recommended. Neuroimaging should be done in every patient with an abnormal neurologic examination, particularly if it is focal or if there is evidence for increased intracranial pressure, with a change in type or severity of seizures, or when seizures are intractable or associated with headaches [Level 1].⁵

MRI is now the preferred neuroimaging study for seizures because it is more sensitive than cranial computerized axial tomography (CAT) scan, especially for disorders of neuronal migration. The AAN has produced a practice parameter in 2007 on the use of emergent neuroimaging for seizures [Level 1].⁶ A study on emergent neuroimaging (cranial CAT scan) in children with new-onset afebrile seizures found that an abnormal CAT scan was more likely in those with underlying disorders or age younger than 33 months with a focal seizure.

GENETIC TESTING

Genetic disorders are a very important cause of seizures in children, both febrile and nonfebrile. These may cause specific genetic syndromes with seizures, such as Rett syndrome or Angelman syndrome, or genetic variants causing seizures. Many of the epilepsies classified previously as idiopathic are now known to result from these variants. Genetic testing includes karyotyping, chromosomal microarray, single gene testing, gene panel testing, whole exome sequencing, and whole genome sequencing. Genetic testing is not typically done for new-onset seizures but can be useful in identifying the etiology of recurrent seizures and the epileptic encephalopathies.

TREATMENT

An important management point is the identification of the child with benign febrile seizures versus the child with epilepsy.

Because most children with simple febrile seizures have no longterm consequences, prophylactic treatment using AEDs should be avoided, even after two or three isolated convulsions. Although both phenobarbital and valproate are effective in reducing recurrence, evidence does not show that treatment alters the risk of later epilepsy. In addition, adverse drug effects occur in as many as 40% of infants and children treated with phenobarbital, and valproate carries a risk of idiosyncratic fatal hepatotoxicity and pancreatitis. Phenytoin and carbamazepine are ineffective.

If treatment is considered at all, it should be reserved for children with a high risk of developing epilepsy or a history of prolonged febrile seizures. A reasonable alternative to chronic drug therapy is abortive treatment using rectal diazepam or intranasal midazolam in children with prolonged seizures. Several studies have shown that administration of diazepam during febrile illnesses is safe and as effective in reducing seizure recurrence as chronic phenobarbital. Although intermittent oral diazepam during acute illnesses has also been shown to be effective, as many as 30% of children experience adverse effects,

including ataxia, lethargy, or irritability. Antipyretics may improve the child's comfort during the febrile illness, but they have been shown to be only slightly effective in preventing the recurrence of febrile convulsions.

Watching their child have a convulsion is a frightening experience for parents. The physician therefore must provide reassurance to dispel any myths the family may have, emphasizing in particular that simple febrile seizures are neither life threatening nor damaging to the brain. The American Academy of Pediatrics offers copies of its guidelines and an information sheet for parents through its Web site (www.aap.org), and the Epilepsy Foundation Website (www.epilepsyfoundation.org) provides information about febrile seizures.

RECURRENT SEIZURES

Recurrent seizures raise different questions. Recurrent seizures in infancy require an evaluation to exclude a specific cause. If the child has not been treated with an AED, this decision may need reconsideration. The first step in the treatment of seizures is to establish the diagnosis of epilepsy. Again, there are many nonepileptic disorders that resemble epileptic seizures. If the diagnosis is uncertain, it is better to withhold the diagnosis of epilepsy and not treat with AEDs. Because the overall risk of recurrence of a first seizure varies, these are not usually treated. Although there is agreement that recurrent seizures need treatment with AEDs, after how many seizures should treatment be started remains in question. The decision to treat must be made taking into account the risk-to-benefit ratio: the risk of a recurrent seizure versus the risk of an adverse effect from chronic AED treatment [**Level 1**].⁷

Once the diagnosis of epilepsy has been established and the need for treatment established, the next decision is which AED to use. The choice of an AED is based on the seizure type, the epilepsy syndrome, and the efficacy and toxicity profile of various AEDs ([Table 143.5](#)). In general, treatment starts with a single AED; the initial dosing is based on weight, aiming for a specific target dose, and doses increased in increments over several weeks until either complete seizure control is achieved or side effects occur. At this point, another AED is considered. If the first AED does not work, another AED is introduced and the first AED is slowly tapered. AEDs should never be abruptly stopped due to concern for withdrawal seizures unless a major adverse effect occurs. The treatment goal should be monotherapy initially, which results in higher blood levels, fewer side effects, and ultimately, better seizure control. However, polytherapy is frequently used when seizures are hard to control (medically resistant or medically refractory).

If the child is on an AED, management questions include the following: Is the AED dose appropriate, should the AED level be checked, and is it the appropriate AED?

P.1252

TABLE 143.5 Choice of Antiepileptic Drugs for Seizure Prophylaxis

Drug (Generic)	Brand Name	Dose Range (mg/kg/day)	Target Drug Level
Carbamazepine	Tegretol/Carbatrol	10-30	4-12 µg/mL
Clobazam	Onfi	Up to 40	Not done
Ethosuximide	Zarontin	15-40	40-100 µg/mL
Felbamate	Felbatol	15-45	30-100 µg/mL

Gabapentin	Neurontin	30-45	4-20 µg/mL
Lacosamide	Vimpat	5	5-10 µg/mL
Lamotrigine	Lamictal	2-8	2-20 µg/mL
Levetiracetam	Keppra	20-60	10-60 µg/mL
Oxcarbazepine	Trileptal	20-40	10-40 µg/mL
Phenobarbital	Luminal	5	10-45 µg/mL
Phenytoin	Dilantin, fosphenytoin	5	10-20 µg/mL
Primidone	Mysoline		5-10 mg/mL
Rufinamide	Banzel	10-45	3-30 µg/mL
Tiagabine	Gabitril	1-2	20-200 ng/mL
Topiramate	Topamax	5-10	2-25 µg/mL
Valproate	Depakene/Depakote	10-45	50-100 µg/mL
Vigabatrin	Sabril	100-200	Not done
Zonisamide	Zonegran	5-20	10-40 µg/mL

Therapeutic ranges are just guidelines for dosing. Seizures may respond to a low level and toxicity may occur at low levels. Levels above “normal” may be needed to control seizures and can be used if tolerated. It is important to treat the patient and not the “level.”

INTRODUCTION

There are two classifications for pediatric stroke: by age and by stroke subtype. By age, a perinatal stroke occurs during gestation through 28 days of life. Often, a child is discovered to have a chronic infarct in infancy that is presumed to have occurred during the perinatal period. These are referred to as *presumed perinatal strokes*. A stroke that occurs after 28 days through 18 years is a *childhood stroke*. Childhood stroke can be further subdivided into *infancy* (older than 28 days to younger than 2 years), *childhood* (2 to 11 years), and *adolescence* (12 to 18 years). By subtype, pediatric stroke is subdivided as arterial ischemic stroke (AIS), cerebral venous thrombosis (CVT), and hemorrhagic stroke. Hemorrhagic stroke includes intracranial hemorrhage (ICH), intraventricular hemorrhage (IVH), and subarachnoid hemorrhage (SAH). This chapter will begin with a discussion of stroke subtypes, will continue by looking at the unique features of stroke related to sickle cell anemia (SCA) and perinatal and presumed perinatal stroke, and will conclude with a brief review of genetics of pediatric stroke.

ARTERIAL ISCHEMIC STROKE

EPIDEMIOLOGY

Annual incidence for childhood AIS is 1.2 to 7.9 per 100,000 children. After the neonatal period, pediatric AIS peak among school-aged children. From the first 676 patients in the International Pediatric Stroke Study (IPSS) registry, the largest registry of all pediatric stroke, the median age at first AIS presentation was 5.7 years (interquartile range, 1.7 to 11.6 years).

For all childhood stroke, there is a predominance of affected males. In the California discharge database, the relative risk (RR) for ischemic and hemorrhagic stroke was higher among boys than girls: for AIS, RR 1.25 (confidence interval [CI] 1.11 to 1.40); SAH, RR 1.24 (CI 1.00 to 1.53); and ICH, RR 1.34 (CI 1.16 to 1.56). Mortality after AIS was also higher among boys (17% vs. 12%). The ratio of boys-to-girls is generally estimated to be 6:4. IPSS found that 59% of children with AIS are male.

Recent studies in the United States are reporting racial and ethnic disparities in childhood stroke where black children are at higher risk for ischemic and hemorrhagic stroke than white children. Pediatric stroke mortality was found to be higher in stroke belt states (southeastern United States), compared with other U.S. states.

PATHOBIOLOGY

Arteriopathy (50% of Arterial Ischemic Stroke)

Arteriopathy in pediatric stroke is presumed to be nonatheromatous and instead due to inflammation, infection, and inherited disorders of tissue stability and repair. Arteriopathy is found in approximately 50% of childhood AIS, and discrete radiographic and clinical subtypes have begun to be described. Two reported predictors of arteriopathy are a recent upper respiratory infection and SCA. The traditional nomenclature for AIS arteriopathy subtypes are *focal cerebral arteriopathy* (FCA), *moyamoya*, *intracranial and extracranial arterial dissection*, *vasculitis*, *sickle cell arteriopathy*, *postvaricella arteriopathy*, and other unspecified forms of arteriopathy (Fig. 144.1). (Frequencies of arteriopathy subtypes are as reported in the IPSS registry.)

1. **FCA** (25% of arteriopathy). FCA is typically characterized by unilateral mainstem arterial disease with

lenticulostriate infarction. An East Asian study found that FCA was reversible in 68%, progressive in 20%, and stable in 12%. Of the patients with reversible arteriopathy, 53% had early worsening. In European cohorts, the course of unilateral arteriopathy was progressive in only 6%, stabilized in 32%, improved in 45%, and completely normalized in 23%. Among patients with a nonprogressive arteriopathy, 44% had an antecedent varicella infection, and 18% had a recurrent stroke or transient ischemic attack (TIA).

2. **Moyamoya** (22% of arteriopathy). Moyamoya arteriopathy is the progressive development of bilateral occlusive disease of the terminal internal carotid arteries (ICAs) with basal collaterals (see also [Chapter 43](#)). There may also be involvement of the mainstem branches of the terminal ICA. Moyamoya syndrome is used when there is an accompanying condition known to be associated with moyamoya arteriopathy and moyamoya disease when the disease is idiopathic. Moyamoya arteriopathy is commonly progressive. In a single-center series, progression developed in 45% over 5.4 ± 3.8 years. Stroke recurrence is also high from 20% over 4 years to 38% over 10 years.
3. **Cranio cervical arterial dissection (CCAD)** (20% of arteriopathy). CCAD in childhood includes intracranial and extracranial dissections. In a meta-analysis of arterial dissection in children younger than 18 years, males were affected considerably more than females: 74% male in anterior circulation dissections and 87% male in posterior circulation dissections. This predominance persisted even for nontraumatic dissections. Of dissection involving the anterior circulation, 40% were extracranial and of dissections involving the posterior circulation, 79% were extracranial. One-third of dissections are spontaneous, but less than a fifth are associated with significant trauma. The mean age of presentation is older than all AIS at 8 to 10 years. Common presenting symptoms are hemiparesis and headache. Neck pain was less common in children. Follow-up after an average of 5.2 years showed moderate or severe deficits in 14%, recurrent strokes in 9%, and recurrent dissections only after anterior circulation dissection and in 10% of those patients.
4. **Vasculitis** (12% of arteriopathy). Cerebral vasculitis is rare and can be difficult to diagnose in children (see also [Chapter 42](#)). Vasculitis due to systemic inflammatory conditions, viral, fungal, mycobacterial, and even parasitic infections is more likely than primary central nervous system (CNS) angiitis.

P.1255

P.1256

Consider vasculitis where there are infarcts in multiple vascular territories with microhemorrhages.

FIGURE 144.1 Progressive arteriopathy of the posterior circulation. **A and B:** Subacute images after initial stroke: MRA, occlusion of the left superior cerebellar artery with distal posterior cerebral artery (PCA) stenosis. **C:** MRI T2, left cerebellar encephalomalacia. **D and E:** Six months later, postural lightheadedness, nausea, fatigue, and left-sided paresthesia: MRA, tip of the basilar and left vertebral stenosis.

5. **Sickle cell arteriopathy** (8% of arteriopathy). (See later discussion on SCA, and [Chapter 118](#))
5. **Post-varicella angiopathy** (7% of arteriopathy) traditionally stenosis of the distal internal carotid and mainstem branches with lenticulostriate infarction. (See [later discussion on “Risk Factors, Infection.”](#))

Cardiogenic (30% of Arterial Ischemic Stroke)

Cardiogenic causes of stroke include congenital heart disease, valvular heart disease, arrhythmias, cardiomyopathy, cardiac surgery and catheterization, extracorporeal membrane oxygenation, and Kawasaki disease.

Congenital heart disease is the most common cardiac risk factor, reported in 59% of those with a cardiogenic stroke. An isolated patent foramen ovale (PFO) was reported in 15% and cardiac catheterization in 8%.

Thromboembolic (15% of Arterial Ischemic Stroke)

Thromboembolic stroke may be due to an indwelling catheter, infection, or a hypercoagulable state that is inherited or acquired. (See “[Risk Factors, Thrombophilia Traits.](#)”)

Cryptogenic Stroke

Cryptogenic stroke is reported in approximately one-fifth of children.

RISK FACTORS FOR ARTERIAL ISCHEMIC STROKE

Infection (25% of Arterial Ischemic Stroke)

The earliest reports suggesting an association between infection and stroke are in children. Stroke as a complication of bacterial meningitis was thought to be due to inflammation of the vessels traversing infected meninges involving perforating and pial arteries. Subsequently, large-artery involvement and recovery-phase large-artery stenosis was recognized.

Varicella-zoster virus (VZV) was the first viral infection associated with cerebral vasculopathy and ischemia after it was described in a 5-year-old boy following a primary VZV infection. Among young children with AIS, a VZV infection in the preceding year was at least three times more frequent compared with published population rates and controls. On imaging, vascular stenosis in the proximal portion of major arteries was seen in 20 of 22 children with AIS and VZV in the preceding year.

Recently, minor infection is found in association with AIS. In the northern Californian Kaiser Pediatric Stroke Study (1993 to 2003), a minor infection (acute fever, upper respiratory tract infection, pneumonia, acute otitis media, pharyngitis, urinary tract infection, or acute gastroenteritis) independently predicted stroke risk in the month that followed the infection. Similarly, chronic inflammatory conditions such as autoimmune disease were highly associated with stroke risk.

Acute Head and Neck Disorders (25% of Arterial Ischemic Stroke)

Acute head and neck disorders include head trauma, pharyngitis, meningitis, intracranial surgery, otitis media, sinusitis, and mastoiditis.

Acute Systemic Conditions (20% of Arterial Ischemic Stroke)

Acute systemic conditions includes fever longer than 48 hours, sepsis, shock, dehydration, acidosis, and anoxia.

Chronic Systemic Conditions (20% of Arterial Ischemic Stroke)

Chronic systemic conditions include SCA, indwelling catheter, genetic disorders, malignancy, and connective tissue disorders.

Chronic Head and Neck Disorders (10% of Arterial Ischemic Stroke)

Chronic head and neck disorders most commonly refer to migraine, brain tumor, and ventriculoperitoneal (VP) shunt.

Thrombophilia Traits

Most thrombophilic states contribute only a small component to an individual's risk for stroke, but these tendencies are prevalent in the population and may be more important with other risk factors in children with stroke. The largest systematic review to date of thrombophilia risk factors in childhood, AIS and CVT found that in children with first AIS compared with healthy children, there was a significantly greater odds of having an MTHFR C677T, factor V G1691A, or factor II G20210A mutation; antithrombin deficiency; protein C deficiency;

protein S deficiency; elevated lipoprotein(a); and antiphospholipid antibodies. The American Heart Association Stroke Council suggests that it is reasonable to test for the more common prothrombotic states even when another stroke risk factor has been identified (Class IIa, Level of Evidence C).

CLINICAL FEATURES

The most common symptoms of an AIS in children is hemiparesis and a speech disturbance. In a single-center pediatric stroke registry, 22% of children with acute AIS presented with seizures. Similarly, an inpatient database in Taiwan found that early symptomatic seizures occurred in 26% of children with AIS.

DIAGNOSIS

Imaging

Patients who present with new focal neurologic deficits should undergo an urgent computed tomography (CT) scan of the head to rule out acute hemorrhage. Early ischemic stroke may not be seen on head CT and should be confirmed with magnetic resonance imaging (MRI). In children with moyamoya disease, transcranial Doppler (TCD) may be useful to follow for stability or progression of vascular disease. (Class IIb, Level of Evidence C).

Stroke Classifications

A new classification system for childhood AIS was recently proposed, the Childhood AIS Standardized Classification and Diagnostic Evaluation (CASCADE) criteria. The system is divided into acute classifications with arteriopathy subdivided by location: small-vessel arteriopathy of childhood, unilateral FCA of childhood, bilateral cerebral arteriopathy of childhood, aortic/cervical arteriopathy, cardioembolic, other, and multifactorial and chronic classifications: progressive, stable, reversible, and indeterminate arteriopathy. These classifications are not yet evidence-based.

P.1257

TREATMENT

Acute care after AIS begins with maintenance of normal oxygenation, normothermia, normoglycemia, and control of systemic hypertension (Class I, Level of Evidence C). It is reasonable to treat dehydration and anemia (Class IIa, Level of Evidence C). There is no evidence that in children with normal oxygenation, supplemental oxygen provides benefit, and in children without clinical or electrographic seizures, prophylactic administration of antiepileptic medications is not necessary (Class III, Level of Evidence C). There is no data confirming the safety and efficacy of hypothermia as an acute treatment for stroke (Class III, Level of Evidence C). The use of thrombolysis (tissue plasminogen activator [tPA]) is not recommended outside research protocols (Grade 1B). When treatable stroke risk factors are discovered, those conditions should be treated (Class I, Level of Evidence C).

Initial therapy in children without SCA should be unfractionated heparin (UFH) or low molecular weight heparin (LMWH) or aspirin (1 to 5 mg/kg/day) until dissection and embolic causes have been excluded. Once excluded, daily aspirin prophylaxis (1 to 5 mg/kg/day) for a minimum of 2 years should be continued (Grade 1B). In children receiving aspirin who have recurrent AIS or TIAs, consider changing to clopidogrel or an anticoagulant (Grade 2C).

Craniocervical Arterial Dissection

The American Heart Association Stroke Council recommends beginning treatment of an extracranial CCAD with UFH or LMWH and to continue subcutaneous LMWH or bridge to warfarin for 3 to 6 months of treatment (Class IIa, Level of Evidence C). The American College of Chest Physicians recommends

anticoagulant therapy for at least 6 weeks, with ongoing treatment dependent on radiologic assessment (Grade 2C). One can also consider using an antiplatelet agent instead of LMWH or warfarin. Beyond 6 months, for recurrent symptoms, it is reasonable to continue anticoagulation or an antiplatelet agent. If symptoms have resolved but there is residual abnormality of the dissected artery on imaging, it is also reasonable to continue an antiplatelet agent beyond 6 months (Class IIa, Level of Evidence C). Surgical procedures may be considered for symptoms due to CCAD despite optimal medical therapy (Class IIb, Level of Evidence C). For an intracranial dissection and for SAH resulting from CCAD, anticoagulation is not recommended (Class III, Level of Evidence C).

Moyamoya Arteriopathy

With moyamoya disease, surgical revascularization can effectively reduce the risk of stroke (Class I, Level of Evidence B). Children with moyamoya should be referred to an appropriate center for consideration of revascularization (Grade 1B). There is less literature to recommend one surgical procedure over another, but indirect revascularization may be preferred in younger children whose small-caliber vessels make direct anastomosis difficult, and direct bypass techniques may be preferable in older individuals (Class I, Level of Evidence C). Indications for revascularization surgery include progressive ischemic symptoms, evidence of inadequate perfusion, or collateral reserve (Class I, Level of Evidence B). After revascularization surgery or in asymptomatic individuals with moyamoya disease, aspirin may be considered (Class IIb, Level of Evidence C). In general, anticoagulants are not recommended with moyamoya disease because of the risk of hemorrhage and the difficulty of maintaining therapeutic levels in children (Class III, Level of Evidence C). Supportive care in children with moyamoya disease includes techniques to reduce anxiety and pain that could lead to hyperventilation-induced vasoconstriction (Class IIb, Level of Evidence C). Perioperative and intraoperative avoidance of hypotension, hypovolemia, hyperthermia, and hypocarbia may reduce the risk of perioperative stroke (Class IIb, Level of Evidence C).

Cardiogenic Stroke

Treatment for congestive heart failure and congenital heart lesions is recommended and may reduce the likelihood of cardiogenic embolism. This includes resection of an atrial myxoma and does not yet apply to PFOs (Class I, Level of Evidence C). It is reasonable to begin anticoagulation following a cardiac embolism in children who are judged to have a high risk for recurrence. UFH or LMWH can be introduced as a bridge to warfarin (Class IIa, Level of Evidence B). LMWH can be continued instead of warfarin, and it is reasonable to continue either LMWH or warfarin for at least 1 year or until the lesion responsible for the risk has been corrected (Class IIa, Level of Evidence C). For a suspected cardiac embolism with an unknown or lower risk of stroke and that is unrelated to a PFO, it is reasonable to treat with aspirin for at least 1 year (Class IIa, Level of Evidence C). It is reasonable to close large atrial septal defects (excludes PFOs) to prevent stroke (Class IIa, Level of Evidence C).

In patients with endocarditis of a prosthetic valve, it may be reasonable to continue long-term anticoagulation (Class IIb, Level of Evidence C). Anticoagulation should not be used for native valve endocarditis, and it is not necessary to remove a cardiac rhabdomyoma in an individual who has been asymptomatic (Class III, Level of Evidence C).

Inherited Thrombophilic State

In children with AIS or CVT, it is reasonable to measure the serum homocysteine level and to introduce therapies such as diet and supplementation of folate, vitamin B₆, or vitamin B₁₂ to lower elevated homocysteine values (Class IIa, Level of Evidence B). In an adolescent with AIS or CVT, it is reasonable to discontinue oral contraceptives (Class IIa, Level of Evidence C).

Other Causes

Children with Fabry disease should receive α -galactosidase replacement therapy (Class I, Level of Evidence B).

REHABILITATION

A child who has suffered a stroke should be enrolled in ageappropriate rehabilitation and therapy program (Class I, Level of Evidence C). Cognitive and behavioral performance is especially important in school-aged children. The pediatric stroke outcome measure (PSOM) is based on a detailed age-appropriate, neurologic exam and scored for four domains: sensorimotor deficit, language deficit—production (excludes dysarthria), language deficit—comprehension, and cognitive or behavioral deficit. The weight of language and cognitive and behavioral deficits is considerably greater and motor deficits are less weighty compared with similar adult stroke outcome measures. Neuropsychological assessment is useful for planning therapy and educational programs and monitoring cognitive, behavioral, and language deficits after a stroke (Class I, Level of Evidence C).

OUTCOME

Neurologic Deficits

In one single-center series of 90 children followed for a mean of 2.1 years after an AIS, 49% were either normal or mildly impaired by PSOM.

P.1258

Recurrence

In northern California, the 5-year cumulative recurrence rate was 19% after childhood AIS. All of the recurrences occurred among children with a vascular abnormality. In a large single-center series, 37% of children had a recurrent AIS or TIA at a median of 267 days (range 1 day to 11.5 years). Of the 84% of patients who had reimaging, 11% had clinically silent recurrent ischemia. Among children with arteriopathy in northern California, the 5-year cumulative recurrence rate was 66%. Factors associated with silent reinfarction and clinical recurrences were moyamoya, low birth weight, genetic thrombophilia, previous TIA, bilateral infarction, preexisting condition, and leukocytosis.

Epilepsy

Poststroke seizures and epilepsy is considerable in children. A population-based retrospective study of children with AIS found an average annual incidence rate of first unprovoked seizure of 4.4% (95% CI, 3.3 to 5.8), 16% (95% CI, 12 to 21) at 5 years, and 33% (95% CI, 23 to 46) at 10 years. The risk of epilepsy was 13% (95% CI, 9 to 18) at 5 years and 30% (95% CI, 20 to 44) at 10 years. An inpatient database in Taiwan found epilepsy in 17% of children after AIS.

CEREBRAL VENOUS THROMBOSIS

EPIDEMIOLOGY

Population-based incidence studies report that less than 1 per 100,000 children per year are diagnosed with CVT (see also [Chapter 40](#)). Many stroke providers believe true incidence is significantly higher and diagnoses are missed. Among patients with a presumed diagnosis of idiopathic intracranial hypertension (IIH), routine imaging discloses CVT in as many as 26%. CVT also peaks in school-aged children. The mean age of children at the time of diagnosis is 5 to 9 years.

PATHOBIOLOGY

The cerebral veins and sinuses are thin-walled and without valves. Cerebral veins drain into the sinuses that

form from dural pockets around the brain. Unlike arterial vascular territories, thrombosis of particular veins does not present with well-defined clinical syndromes. The venous system has considerable anatomic variability, flow can be reversed, and there may be collateral drainage pathways such as through occipital sinuses.

The cerebral veins and sinuses are positioned for thrombotic complications. Venous drainage is slow; it follows a tortuous route and the walls easily distend. A combination of local inflammation in the vessel wall, systemic thrombophilia, hyperosmolality, reduced blood flow, and injury to the vessel wall all work to tip the balance toward cerebral thrombosis. When a thrombus obstructs venous outflow, the pressure becomes high in the venous system. Edema and hemorrhage can develop from high pressure in the capillaries with plasma and red blood cell diapedesis or frank rupture, and the high pressure can exceed arterial perfusion pressure resulting in ischemic infarction. Hydrocephalus with intracranial hypertension will occur when cerebrospinal fluid reabsorption through arachnoid villi and pacchionian body granulations in the dural sinuses becomes impaired. A large thrombus in the superior sagittal sinus, the sinus where most of the reabsorption occurs, will generally lead to a communicating hydrocephalus.

In children, the superior sagittal and lateral sinuses are most often affected, and two or more sinuses or veins are involved. Sinus occlusion may present with intracranial hypertension, whereas an isolated cerebral vein thrombosis may present with focal neurologic signs.

CVT is a complication of many chronic inflammatory, infectious, and prothrombotic states. Inflammatory states and conditions that are recognized to be associated with increased risk for CVT include inflammatory bowel disease, systemic lupus erythematosus, Behçet disease, celiac disease, multiple sclerosis, head injury, brain neoplasm, and a hematologic malignancy. Infectious conditions include mastoiditis, otitis, sinusitis, meningitis, the postoperative period, and postcatheterization. Prothrombotic inherited tendencies and states may be due to nephrotic syndrome, homocystinuria, oral contraceptive use, pregnancy, or exposure to asparaginase. Other conditions associated with CVT are anemia, hydrocephalus, dehydration, and hypoxia.

Prothrombotic tendencies may be present in half of children tested, and more than one abnormality is not uncommon. The meta-analysis of prothrombotic traits in childhood stroke also found a positive association for all of the thrombophilia traits studied with CVT: antithrombin deficiency, protein C deficiency, protein S deficiency, factor V G1691A mutation, and prothrombin G20210A mutation. An antithrombin deficiency was 18-fold higher in children with CVT compared to a control population and protein C or S were six and five times higher in a cohort of children with CVT.

CLINICAL FEATURES

Presenting symptoms are often diffuse and nonspecific. In series of children with CVT, the most common presenting symptoms are headache, vomiting, and visual symptoms. Presenting symptoms may overlap with traditional symptoms of IIH. Other presenting symptoms are lethargy, malaise, irritability, poor appetite, limb weakness, unsteady gait, and seizures.

Common clinical signs on presentation are papilledema, seizure, fever, sixth nerve palsy, and hemiparesis. Other signs include a decreased level of consciousness, visual field defects, cranial nerve palsies, ataxia, speech impairment, and hemisensory loss.

DIAGNOSIS AND IMAGING

The diagnosis is often delayed. A retrospective chart review of 21 children treated from 1997 to 2005 found that there was a mean of 6.3 (range 0 to 26) days from onset of symptoms to hospital presentation, and from hospital presentation to diagnosis, there was a mean of 2.9 (0 to 12) days.

There are pathognomonic imaging signs for CVT. The cord sign is due to dense cortical veins or thrombosed sinuses. The dense-triangle sign due to acutely congealed blood is a very early and transient sign. The delta- or

empty-triangle sign is a late finding and is the result of venous flow in the collateral veins in the walls of the sinus compared with absent flow within the sinus.

CT scan is widely available and can be obtained rapidly. At many centers, good quality images can now be obtained with low radiation. In one study, unenhanced CT scan was 73% sensitive for CVT, and there were no false-positive results. CT venogram increases the sensitivity of the study to detect thrombus in the vein and may be superior to magnetic resonance venogram (MRV) in visualization of cerebral veins but requires skilled technicians for appropriate timing of the contrast bolus to avoid arterial contamination. It is also affected by poor cardiac output and conditions associated with increased circulation time.

MRI is superior for the evaluation of parenchymal abnormalities. MRI and MRV do not require contrast but contrast can be

P.1259

helpful to distinguish between a hypoplastic sinus and thrombosis in the lumen. Flow voids can be mistaken for thrombosis where there is slow cerebral flow.

In children with CVT, approximately one-quarter have no parenchymal involvement, one-third have ischemic infarcts, and one-third have ICH. Intraventricular and SAHs are seen in less than 10%.

TREATMENT

Recommendations on anticoagulant use are based on retrospective analysis. While we await a prospective study on anticoagulant use in neonates, a large single-center retrospective analysis of 162 neonates and children from 1992 to 2005 suggests benefit for anticoagulant use even with preexisting hemorrhage. The study was conducted at an institution where a protocol was initiated in 1995 and was practiced. All neonates and children without significant ICH received anticoagulation. If anticoagulation was not started because of significant ICH, a follow-up study was done at 5 to 7 days for clot stability. If the follow-up imaging showed clot propagation, these patients were treated with anticoagulation despite significant ICH. Within 2 weeks of diagnosis, the thrombus propagated in 7% of treated children and 37% of untreated children. Propagation was symptomatic in 60% of children and associated with more severe deficits at discharge. Anticoagulant-related ICH occurred in 5% of treated children and 98% of ICH with anticoagulation occurred in patients with pretreatment ICH. ICH as a complication of anticoagulation was most commonly a subdural hemorrhage and almost all bleeds occurred with additional factors such as supratherapeutic anticoagulation, hypertension, thrombocytopenia, VP shunt surgery, and cerebral atrophy. The acute management of children with CVT should include hydration, control of clinical and subclinical seizures, and treatment of elevated intracranial pressure (Class I, Level of Evidence C). With severe or long-standing increased intracranial pressure, there is a risk for vision loss. Visual fields and visual acuity should be periodically assessed and appropriate measures to control elevated intracranial pressure should be instituted (Class I, Level of Evidence C). Monitoring the intracranial pressure may be considered during the acute phase of CVT (Class IIb, Level of Evidence C).

Bacterial infection and anemia are treatable causes of CVT, so children with a suspected bacterial infection should receive appropriate antibiotics and a complete blood count should be performed (Class I, Level of Evidence C). There may be benefit to diagnostic testing for underlying infections with blood cultures and sinus radiographs (Class IIb, Level of Evidence B). Performing a thorough thrombophilic screen may be beneficial, and its results could affect the risk of rethrombosis and influence therapeutic decisions (Class IIb, Level of Evidence B). In children who have an impaired mental status and are paralyzed or sedated, subclinical seizures are not uncommon. Continuous electroencephalography monitoring may be considered for these patients (Class IIb, Level of Evidence C).

The American Heart Association Stroke Council suggests that it is reasonable to institute either UFH or LMWH whether or not there is secondary hemorrhage, followed by warfarin therapy for 3 to 6 months. Follow-up neuroimaging studies in children with CVT to confirm vessel recanalization or recurrence of the thrombus may be beneficial (Class IIa, Level of Evidence C). The American College of Chest Physicians recommends initial anticoagulation with UFH or LMWH only in children without significant ICH, followed by LMWH or a vitamin K antagonist for a minimum of 3 months (Grade 1B). If after 3 months of therapy there is incomplete radiologic recanalization of CVT or ongoing symptoms, anticoagulation should be continued for an additional 3 months (Grade 2C). In children with significant hemorrhage, there is a suggestion to repeat the radiologic evaluation at 5 to 7 days and if there is propagation of thrombus, institute anticoagulation (Grade 2C).

There are case series describing local cerebral thrombolysis for CVT. Reported cases suggest that there may be benefit in the hands of experienced interventionalists but there may also be a considerable risk for hemorrhagic complications. The American Heart Association Stroke Council suggests that in selected children, administration of a thrombolytic agent can be considered (Class IIb, Level of Evidence C). The American College of Chest Physicians suggests thrombolysis, thrombectomy, or surgical decompression only in children with severe CVT in whom there is no improvement with initial UFH therapy (Grade 2C). In children with CVT and ongoing risk factors for thrombosis, such as nephrotic syndrome, or L-asparaginase therapy, prophylactic anticoagulation is suggested (Grade 2C).

OUTCOME

In large-center series, anticoagulation is not associated with increased mortality and severe neurologic outcomes.

Recanalization

At 3 months, more than half of children have recanalization of thrombosed vein. A prothrombotic disorder is associated with nonrecanalization.

Recurrence

Recurrence occurs in 5% to 17% of children. This may depend on the course of the underlying risk factors and residual patency of the cerebral venous system.

Neurologic Deficits

Poor neurologic outcomes after CVT include chronic intracranial hypertension, frequent headaches, cognitive difficulties, hemiparesis, reduced visual acuity, isolated sixth nerve palsy, and epilepsy in 5% to 8%. Predictors for good outcome are anticoagulation, older age, no parenchymal abnormality on imaging, and lateral sinus involvement.

In a small cohort of children followed for a mean of 2.1 years after a CVT, 79% were either normal or mildly impaired by PSOM. In a larger series of children, outcome was unfavorable in 37%.

Mortality

Mortality is reported between 5% and 12%. In one series of children, 88% of whom were not treated with anticoagulation, early mortality was 18%.

HEMORRHAGIC STROKE

ICH, IVH, and SAH (excludes traumatic hemorrhage and germinal matrix hemorrhages)

EPIDEMIOLOGY

In children, approximately half of all strokes are hemorrhagic. The annual incidence rate ranges from 0.63 to 5.11 per 100,000 children without SCA. ICH affects school-aged children. The median age of affected children is 7 to 10 years.

P.1260

PATHOBIOLOGY

ICH in children is most often intraparenchymal hemorrhage or intraparenchymal hemorrhage with IVH extension. Isolated IVH is rare. Hematoma expansion may occur in one-third of children and the expansion may be significant, requiring urgent evacuation.

Causes of ICH from three pediatric tertiary care centers in the United States are arteriovenous malformations (37%), unknown (17%), cavernous malformations (13%), coagulopathy (11%), anticoagulation (9%), aneurysm (9%), developmental venous anomaly (2%), and moyamoya (2%). In the Baltimore-Washington Cooperative Young Stroke Study, ICH was due to arteriovenous malformations (29%), hematologic causes (23%), vasculopathy (18%), surgical complications (12%), coagulopathy (6%), and indeterminate causes (12%).

CLINICAL FEATURES

Presenting symptoms are headache, focal deficits, altered mental status, and seizures in approximately one-third of children.

DIAGNOSIS AND IMAGING

Children with nontraumatic brain hemorrhage should undergo a thorough risk factor evaluation. When noninvasive imaging does not demonstrate a nidus, conventional cerebral angiography should be performed (Class I, Level of Evidence C). For a patient who presents with symptoms that could be explained by an aneurysm, computed tomography angiography (CTA) or conventional angiography (CA) may be considered even if the patient's magnetic resonance angiography (MRA) fails to show evidence of an aneurysm (Class IIb, Level of Evidence C).

TREATMENT

Children with a severe coagulation factor deficiency should receive appropriate factor replacement therapy, and children with less severe factor deficiency should receive factor replacement after trauma (Class I, Level of Evidence A). There is a recommendation to identify and correct, where clinically feasible, congenital vascular anomalies (Class I, Level of Evidence C). Recently, A Randomised trial of Unruptured Brain Arteriovenous malformations (ARUBA) in adults found that medical management alone was superior to medical management with interventional therapy. This study is changing treatment practice for unruptured arteriovenous malformations.

The child with an acute brain hemorrhage requires urgent care. Attention should be toward assessment of respiratory effort, control of systemic hypertension, control of clinical and subclinical seizures, and managing increased intracranial pressure (Class I, Level of Evidence C). In general, surgical evacuation of a supratentorial intracerebral hematoma is not recommended (Class III, Level of Evidence C). Surgery is reasonable in selected patients at risk for cerebral herniation or who have extremely elevated intracranial pressure; however, it is not clear whether this improves the outcome (Class IIa, Level of Evidence C). Acute hydrocephalus with an ICH requires ventricular drainage. If hydrocephalus persists beyond the acute period, shunting may be indicated (Class I, Level of Evidence B). Low platelet counts should be corrected, and vitamin K should be administered for vitamin K-dependent coagulation disorders (Class I, Level of Evidence B). In the ongoing acute care of patients with SAH, measures to control cerebral vasospasm may be beneficial (Class IIb, Level of Evidence C).

It is reasonable to follow up asymptomatic individuals who have a condition that predisposes them to intracranial aneurysms with a cranial MRA every 1 to 5 years, depending on the perceived level of risk posed by an underlying condition (Class IIa, Level of Evidence C). Given the possible need for repeated studies over a period of years, CTA may be preferable to conventional angiogram for screening individuals at risk for aneurysm (Class IIb, Level of Evidence C).

OUTCOME

Neurologic Deficits

Disability is more prevalent after childhood ICH than other forms of stroke. In a single-center prospective cohort study at a median follow-up of 3.5 months, 71% of survivors had neurologic deficits and 55% had clinically significant disability. A prospective cohort from three centers found severe disability in 12%, moderate disability in one-half, and good recovery in only one-third.

Recurrence

In a population-based study from northern California, the 5-year cumulative recurrence rate was 10%. Sixty-four percent of recurrences were within the first 6 months. Children with idiopathic hemorrhage had no recurrences, compared with children with a structural lesion such as a vascular malformation or tumor who had a 5-year cumulative recurrence rate of 13%.

Epilepsy

In one study, at 2 years, epilepsy developed in less than 15%. A risk factor for late seizures and epilepsy was elevated intracranial pressure requiring acute intervention.

Mortality

Childhood ICH confers mortality in approximately 5%.

SICKLE CELL ANEMIA

The process of neurologic injury that confers long-term cognitive and focal impairment in SCA begins in childhood. Neurologic complications of sickle cell disease include cognitive deficit, ischemic and hemorrhagic stroke due to arterial and venous thrombus, sickle cell arteriopathy, and white matter T2 hyperintensity on brain imaging (see also [Chapter 118](#)).

EPIDEMIOLOGY

The Cooperative Study of Sickle Cell Disease, the largest series of stroke in SCA, showed that by the age of 20 years, the risk of stroke was 11% and peak incidence was from 2 to 5 years. There were no gender differences in stroke incidence. In SCA, the annual incidence of stroke is orders of magnitude greater than other childhood stroke. The Baltimore-Washington Cooperative Young Stroke Study found an annual incidence of 285 per 100,000. Ischemic stroke is more common than hemorrhagic stroke in older than 20 years, but in young adults, this trend reverses.

PATHOBIOLOGY

At low oxygen tension, sickle cell hemoglobin (HgbS) polymerizes to form an elongated and rigid sickle shape. This translates to high blood viscosity and the potential for endothelial damage. Sickle cell arteriopathy may be the most important determinant of stroke risk. Over time, arteriopathy tends to progress. Children with a history of stroke were more likely to have progressive vasculopathy

than children with abnormal TCDs but no history of stroke. Silent ischemia is twice as common as clinical strokes and confers a high risk for recurrent stroke. Sickle-related arteriopathy more often takes the form of moyamoya arteriopathy with high-grade internal carotid and proximal circle of Willis artery occlusive disease and collateral formation. Older children and adults are at risk for aneurysms, dolichoectasia, and SAH.

RISK FACTORS

The combination of risk factors that result in vascular disease and stroke are still not fully understood. Risk factors such as infection, elevated leukocyte count, acute chest syndrome, inflammation, low hemoglobin concentration, and nocturnal desaturations may all contribute to the risk for stroke in SCA.

Single-nucleotide polymorphisms in genes for a tumor necrosis factor (TNF) promoter, interleukin 4 receptor, adrenoceptor beta 2, leukotriene C4 synthase, vascular cell adhesion molecule 1, and low-density lipoprotein receptor are all reported in association with stroke in children with SCA. These genes are involved in inflammatory pathways.

DIAGNOSIS AND IMAGING

The American Heart Association/American Stroke Association (AHA/ASA) guidelines (2011) recommend TCD for selection of children for primary stroke prevention. MRI and MRA are not similarly established (Class III; Level of Evidence B).

TREATMENT

The only class I recommendations for primary pediatric stroke prevention is in SCA. The recommendations largely derive from the STOP I and II randomized controlled trials. The STOP I trial enrolled children with SCA, mean TCD velocity in the ICA or middle cerebral artery of 200 cm/s or greater, and no history of stroke. Patients were randomized to periodic blood transfusions versus standard of care. The study was terminated early at 130 subjects. In the standard of care arm, there were 10 ischemic and 1 hemorrhagic strokes, compared with the transfusion arm where there was 1 ischemic stroke. Periodic transfusions reduced the risk of stroke by 92%. There is a recommendation to begin TCD screening at 2 years (Class I; Level of Evidence B) TCD should be performed annually and abnormal studies should be repeated in 1 month (Class IIa, Level of Evidence B). Borderline and mildly abnormal TCD studies may be repeated in 3 to 6 months. For TCD velocity greater than 200 cm/s, even in children without a clinical stroke, regular transfusions to reduce the percentage of sickle hemoglobin is recommended to reduce the risk of stroke in children 2 to 16 years of age (Class I, Level of Evidence A) (Grade 1B) (Class I; Level of Evidence B). Children with a confirmed infarction should also receive regular red cell transfusion in conjunction with measures to prevent iron overload (Class I, Level of Evidence B). Prior to undergoing a cerebral angiogram, all children with SCA should be treated with a red blood cell transfusion to reduce sickling precipitated by the procedure (Class I, Level of Evidence C).

When routine transfusions became accepted clinical practice for abnormal TCDs or history of a stroke, the question of when one could safely stop transfusions became widely relevant. Seven years after STOP I, STOP II published its findings. Patients with greater than 30 months on transfusion therapy, no history of a clinical stroke, and reversion to a low-risk TCD (<170 cm/s) were randomly assigned to continuation or discontinuation of transfusions. Again, the trial was stopped early. Of 41 patients in the discontinuation group, 14 developed a high-risk TCD over a mean of 4.5 months and 2 had a stroke. Neither outcome occurred in the continuation group. A long-term transfusion program is currently recommended (Grade 1B) (Class IIa; Level of Evidence B).

There is ongoing research on hydroxyurea as an alternative to routine transfusions. Hydroxyurea increases fetal hemoglobin (HgbF) and mean corpuscular volume (MCV) and it decreases reticulocytes, white blood

cells, and platelets. Trials on transition from transfusion to hydroxyurea therapy have not found similar efficacy but are ongoing. Myeloablative stem cell transplantation if successful could reverse high TCD velocities and almost eliminate the risk of stroke in children. Transplantation requires a matched donor, and even if one is identified, rejection and morbidity are considerable. The AHA/ASA guidelines suggests that in children at high risk for stroke, who are not candidates for transfusion, it might be reasonable to consider hydroxyurea or bone marrow transplantation (Class IIb; Level of Evidence C).

In children without SCA and moyamoya arteriopathy, revascularization is an effective treatment for prevention of recurrent stroke. The data in children with SCA and moyamoya arteriopathy is more limited but suggests benefit. The AHA/ASA recommendation is to consider surgical revascularization as a last resort in cases where there is cerebrovascular dysfunction despite optimal medical management (Class IIb, Level of Evidence C).

Acute management of ischemic stroke should include hydration, correction of hypoxemia, and correction of systemic hypotension (Class I, Level of Evidence C). An exchange transfusion to reduce sickle hemoglobin to less than 30% of the total hemoglobin is reasonable (Class IIa, Level of Evidence C) (Grade 1B). A vascular lesion should be considered when there is an ICH (Class IIa, Level of Evidence B). There are no data to indicate that periodic transfusions reduce the risk of ICH caused by SCD (Class III, Level of Evidence B).

OUTCOME

Neurologic Deficits

Compared with healthy children, children with SCA have deficits in working memory and processing speed on neurocognitive testing.

Recurrence

Untreated, the risk of recurrent stroke may be 50%.

Mortality

Overall stroke-related mortality is approximately 10%, and in the 2 weeks after a hemorrhagic stroke, mortality is as high as one-quarter.

PERINATAL AND PRESUMED PERINATAL STROKE: ARTERIAL ISCHEMIC STROKE AND HEMORRHAGIC STROKE

Perinatal stroke is defined as signs and symptoms referable to a vascular event with radiologic or pathologic confirmation of the vascular event. A presumed perinatal stroke is diagnosed when neuroimaging shows a chronic stroke with or without delayed focal neurologic signs referable to the vascular lesion. Perinatal stroke most often affects term infants but it includes strokes that occur from 20 weeks of gestation through 28 postnatal days.

P.1262

EPIDEMIOLOGY

In the National Hospital Discharge Survey (1980 to 1998), the rate of neonatal ischemic stroke was 17.8/100,000, and hemorrhagic stroke was 6.7/100,000. The overall incidence of neonatal stroke incidence was 26.4/100,000, or 1/4,000 live births, per year. This does not account for infants who present after the first few days of life, children who are diagnosed with a presumed perinatal stroke and undiagnosed hemiplegic cerebral palsy. In northern California, the population prevalence of perinatal AIS was 20 per 100,000 live births. A

population-based study from Estonia accounted for neonates diagnosed acutely and retrospectively. Incidence was higher at 63 per 100,000 live births.

PATHOBIOLOGY

The majority of perinatal strokes likely occur in the few days before and after delivery. A nationwide Swedish cohort study showed that the risk of maternal embolism and hemorrhage increased more than 10 times in the 2 days before and 1 day after delivery compared with women in their third trimester. AIS is most common in the anterior circulation and on the left, specifically involving a middle cerebral artery distribution. Bilateral AIS is seen in approximately one-quarter.

Peripartum Factors

Pregnancy and delivery complications have been loosely associated with perinatal stroke. In the Kaiser Permanente Medical Care Program (1997 to 2002), a nested case-control study found that primiparity, history of infertility, preeclampsia, intrauterine growth restriction, oligohydramnios, prolonged rupture of membranes, chorioamnionitis, fetal heart rate abnormality, emergency cesarean delivery, prolonged second stage of labor, vacuum extraction, cord abnormality, 5-minute Apgar less than 7, and resuscitation at birth were more likely in infants with perinatal stroke. In an international series, maternal conditions were uncommon except for gestational hypertension or preeclampsia seen in 10%. Perinatal factors included maternal fever, prolonged rupture of membranes, presence of meconium, a prolonged second stage of labor, and emergent cesarean section seen in 26%. Among neonates, 30% required resuscitation.

Prothrombotic Factors

The meta-analysis on thrombophilia in pediatric stroke showed that neonates with a stroke were more likely to have a factor V Leiden (FVL) mutation (odds ratio [OR] 3.56; 95% CI, 2.29 to 5.53) and a prothrombin 20210 gene mutation (OR, 2.02; 95% CI, 1.02 to 3.99) compared with controls. In a study of mother-infant pairs, 64% of infants and 68% of mothers had evidence of thrombophilia. Compared with controls, infants were more likely to have FVL mutation, protein C deficiency, and antiphospholipid antibodies, and mothers were more likely to have FVL and antiphospholipid antibodies. Most mother-infant pairs were mismatched in their thrombophilia trait.

Infection

Sepsis and meningitis have long been associated with large-artery ischemic strokes and CVT. In an international series of neonates, 23% had a systemic illness around the time of stroke.

Congenital Heart Disease

Intracardiac thrombi due to congenital heart disease are a source of embolic stroke in the newborn. Approximately one-fifth of neonates have a cardiac risk factor most often in the form of congenital heart disease. At one institution, over almost a decade, the risk for AIS or CVT in children with congenital heart disease was 5.4 strokes per 1,000 children undergoing a cardiac surgery. In the Canadian Pediatric Ischemic Stroke Registry, 27% of patients with congenital heart disease had a recurrent stroke within 10 years of the original stroke, and 50% of patients with recurrence were on anticoagulation at the time of recurrence. Aside from inherited heart disease, there is limited data on other cardiac causes of perinatal stroke. In two series of neonates without known congenital heart disease, echocardiography was not informative.

Despite a recent expansion of research in this field, there are no strong predictors of perinatal stroke. Placental abnormality is suspected to be a source of systemic emboli. Research is sparse but ongoing to address this question. Little is known about pathophysiologic mechanisms of perinatal stroke.

CLINICAL FEATURES

Neonatal seizures are the most common presenting sign of a stroke. In one international series on ischemic stroke, 72% of neonates presented with seizures. Other common presenting signs are changes in tone and level of consciousness. More than 50% of neonates with ICH also present with seizures. Neonates are more likely than children to present with diffuse signs of encephalopathy such as lethargy, hypotonia, feeding difficulties, and apnea. In the same series, 63% presented with nonfocal neurologic signs most commonly respiratory and feeding difficulties. An infant with a presumed perinatal stroke may present with delayed milestones, an early hand preference, focal seizures, and hemiparesis.

DIAGNOSIS AND IMAGING

Ultrasound is safe, widely available, and does not require transport of the neonate to an imaging suite. It is sensitive for intraventricular and periventricular blood and chronic infarction, but sensitivity is low for AIS. In one study, only 30% of perinatal AIS was detected on ultrasound. CT scan is often avoided in the neonate because of the availability of ultrasound and in order to avoid exposure to radiation, but where indicated, CT will accurately show superficial ischemic and hemorrhagic lesions. MRI is safe, more sensitive for early ischemic strokes and superficial lesions, and can often be done without anesthesia in newborns.

TREATMENT

Where there is no cardiac indication for aspirin or anticoagulation, there is a recommendation against its use after a first neonatal AIS (Grade 1B). For recurrent AIS, aspirin or anticoagulation are suggested (Grade 2C). Neonates with ICH resulting from coagulation factor deficiency require replacement of the deficient coagulation factors (Class I, Level of Evidence B). Neonates born to mothers exposed to warfarin, phenytoin, or barbiturates may require higher doses of vitamin K. Supportive measures such as treatment of dehydration and anemia should be considered (Class IIa, Level of Evidence C). After a stroke, if there is delayed acquisition of milestones, hypotonia, spasticity, or focal deficits, it is reasonable to institute multispecialty therapy (Class IIa, Level of Evidence B). If an MTHFR mutation with elevated homocysteine levels is discovered, it is reasonable to give folate and B vitamins to normalize homocysteine levels for secondary stroke prevention (Class IIa,

P.1263

Level of Evidence C). Anticoagulation with LMWH and UFH can be considered in selected neonates with severe thrombophilic disorders and multiple cerebral or systemic emboli (Class IIb, Level of Evidence C). Thrombolytic agents are not recommended in neonates until more information about safety and effectiveness is known (Class III, Level of Evidence C).

OUTCOME

Neurologic Deficits

A review of studies over 30 years on perinatal stroke outcome found that 57% of survivors were neurologically abnormal. In an international series, approximately half of newborns had neurologic deficits at discharge. A small cohort, followed for a mean of 2.1 years, found that by PSOM, children were normal or had only a mild impairment after AIS in 61% and after CVT in 84%. Perinatal stroke is presumed to be the most common cause of hemiplegic cerebral palsy.

Cognitive and Behavioral Deficits

After a unilateral infarction, IQ is generally preserved. Among 46 survivors of a perinatal ischemic stroke, followed for a mean of 42.1 (range 18 to 164) months, neurodevelopmental outcome was abnormal in 67%; multiple disabilities were present in 50%, cerebral palsy in 48%, and cognitive impairment in 41%.

Seizures and Epilepsy

In a single-center prospective stroke registry, at a mean follow-up of 31.3 (*SD* 16.1) months, 24% of patients with perinatal AIS had at least one seizure and 13% had epilepsy. In a single-center retrospective review, at a median follow-up age of 43 (range, 9 to 197) months, 67% of perinatal stroke survivors had epilepsy.

Recurrence

In northern California, the 5-year cumulative recurrence rate was only 1.2% after perinatal stroke. In another large study from Germany, among 215 neonates followed for median of 3.5 (range, 1 to 8) years, 3.3% experienced a second thromboembolic event including 1.8% who experienced a recurrent AIS.

PERINATAL CEREBRAL VENOUS THROMBOSIS

EPIDEMIOLOGY

Incidence of CVT in neonates is 2 to 3 per 100,000. CVT typically occurs in term or near-term infants. In one study, the mean gestational age was 37 weeks (*SD* 4 weeks, range 25 to 41 weeks), and 19% of the neonates were preterm. The mean birth weight was 2,720 g (range 770 to 3,960 g).

PATHOBIOLOGY

The deep venous system is more prone to thrombosis in the neonatal period compared with childhood. In one study, involvement of the straight sinus, vein of Galen, or internal cerebral veins was seen in more than two-thirds of neonates.

In neonates, hemorrhagic infarcts are seen in 35% to 50%. MH is more prevalent than in children and is found in 19% to 38% of neonates. AIS has been reported in 10% and SAH in 5%.

CLINICAL FEATURES

Neonates are more likely to present with seizures and generalized encephalopathy compared with children. Typical neonatal diffuse signs are depressed level of consciousness, jitteriness, irritability, apnea, poor feeding, and low tone.

DIAGNOSIS

Symptoms may begin around the time of birth but diagnosis may be delayed. In one study, the mean age at diagnosis was 9 days.

Doppler ultrasound is portable and well tolerated, but in one neonatal study, only 48% of CVT was detected.

TREATMENT

In the large single-center retrospective analysis, 25% of the neonates were anticoagulated only after thrombus propagation. Within 2 weeks of diagnosis, thrombus propagation occurred in 4% of treated neonates and 28% of untreated neonates. Propagation was asymptomatic but was associated with new venous infarcts in 10%. Anticoagulant-related ICH occurred in 8% and only occurred when there was pretreatment ICH.

Anticoagulation can be considered in neonates with clinical or radiologic evidence of propagating CVT despite supportive therapy (Class IIb, Level of Evidence C). There is insufficient evidence to recommend

the initial routine use of anticoagulation in neonates with CVT. Despite this recommendation, at many stroke centers, anticoagulation is started with initial CVT diagnosis when there is not significant hemorrhage.

OUTCOME

Anticoagulation may be safe even in neonates. In the large singlecenter review, there were no deaths related to anticoagulation in neonates. Recurrence is seen in 8% of neonates. Recanalization may be better in neonates than in older children. In one study at 3 months, 85% of neonates had complete recanalization. Outcome is more likely to be normal in neonates without parenchymal involvement due to CVT. In neonates with infarction, outcome was normal in only 41% to 43%, and 29% had severe disability at follow-up. The risk of an unfavorable outcome was similar even among neonates with major anticoagulant-related hemorrhage.

Poor outcome includes epilepsy (38% in one series), spastic hemiplegia or tetraplegia, and intellectual disability or developmental delay. A predictor of poor neonatal outcome was absence of anticoagulant treatment.

GENETICS OF STROKE

Study of the genetic association in pediatric stroke may reveal important contributors to stroke mechanism. An excellent review of monogenic disorders associated with childhood AIS and arteriopathy was recently published (Munot et al.). Numerous genetic disorders are associated with an increased risk for stroke. Some of these to consider in patients with additional signs are the hereditary dyslipoproteinemia and hypercholesterolemias, inherited disorders of connective tissue such as Ehlers-Danlos syndrome (type IV) and Marfan syndrome, metabolic disorders such as Menkes syndrome and organic acidemias including glutaric aciduria type II, and disorders of energy metabolism such as mitochondrial encephalomyopathies and Leigh disease.

Congenital and Childhood Central Nervous System Tumors

James H. Garvin Jr

INTRODUCTION

Childhood brain tumors range from benign congenital lesions to aggressive, infiltrative cancers. Cure rates for malignant brain tumors are lower than those of most other common childhood cancers, and treatment sequelae may seriously compromise quality of survival. Nonetheless, research advances and refinement of treatment techniques continue to give a sense of cautious optimism. Current research focuses on validating experimental models and identifying molecular targets for novel therapies. An emerging concept is that malignant brain tumors are propagated from stem-like progenitor cells, which may be intrinsically resistant to standard radiation and chemotherapy but could be eliminated by targeted therapy with agents, which disrupt critical signaling pathways or induce differentiation.

EPIDEMIOLOGY

Malignant and benign central nervous system (CNS) tumors may arise at any time in infancy and childhood. Categorization as malignant or benign does not always reflect clinical behavior. Certain benign lesions such as craniopharyngioma can cause extensive damage, whereas low-grade astrocytomas, although classified as malignant, are rarely life-threatening. The peak age for malignant brain tumors is 3 to 4 years. Location is predominantly cerebral or ventricular in infants, cerebellar or brain stem in young children, and midbrain or cerebral in older children and adolescents. Astrocytomas are the largest group, mostly of low-grade histology; pilocytic astrocytomas (World Health Organization [WHO] grade I) account for 24% of all childhood brain tumors. Next in frequency are medulloblastomas, the most common high-grade malignant tumor (16%). After these are a diverse group of congenital and acquired lesions, including high-grade astrocytomas (14%), ependymomas (10%), craniopharyngiomas (5.6%), germ cell tumors (2.5%), and choroid plexus tumors (0.9%). Neuronal tumors (gangliocytoma) and mixed glioneuronal tumors (ganglioglioma, dysembryoplastic neuroepithelial tumor) are relatively uncommon. The principal primary brain tumors of adults (glioblastoma multiforme, meningioma, oligodendroglioma, pituitary adenoma) are rarely seen in children. Moreover, tumorigenesis of high-grade astrocytomas in children differs from that in adults, as deduced from comparative genomic hybridization studies. CNS metastases from solid tumors are also uncommon in children compared to adults. Cerebral metastases are occasionally seen in pediatric germ cell tumors (13.5% incidence), osteosarcoma (6.5%), neuroblastoma (4.4%), melanoma (3.6%), Ewing sarcoma (3.3%), rhabdomyosarcoma (1.9%), and Wilms tumor (1.3%).

Primary CNS malignancies account for about 20% of all childhood cancers, second only to leukemia.

Approximately 2,200 cases are diagnosed annually in the United States in children and adolescents age 0 to 19 years, an incidence of 2.9 per 100,000 population in this age group. When nonmalignant lesions are added, the total annual incidence is about 3,750 cases. The reported annual incidence of childhood brain tumors in the United States increased by 35% between 1973 and 1994, led mainly by supratentorial low-grade gliomas and brain stem tumors diagnosed by magnetic resonance imaging (MRI), which became widely available in the mid-1980s. The reported incidence of brain tumors in infants below 12 months of age increased between 1973 and 1986 but has remained stable since then; leading histologies in infants are gliomas, medulloblastoma/primitive neuroectodermal tumor (PNET), and ependymoma.

The causes of congenital and childhood CNS tumors remain unknown. A meta-analysis from 16 international surveys revealed a male-to-female ratio of 1.29. Increased head circumference at birth is positively associated with brain cancer in childhood, with a relative risk of 1.27 per 1-cm increase after adjustment for birth weight,

gestational age, and gender, suggesting brain pathology may originate in fetal development. The most common CNS tumors diagnosed in the first year of life are low-grade glioma, medulloblastoma, ependymoma, and choroid plexus tumors.

Most CNS tumors are sporadic, but some are seen in inherited disorders, especially neurocutaneous syndromes. Individuals with *neurofibromatosis type 1* (NF-1) have a 10% chance of developing an intracranial tumor, including optic pathway gliomas and astrocytomas elsewhere in the brain and spinal cord. The NF-1 gene maps to chromosome 17q11.2, and loss of one NF-1 allele is evident in nearly all NF-1-associated pilocytic astrocytomas but only rarely in sporadic pilocytic astrocytomas, suggesting different mechanisms of tumor formation. In the less common *neurofibromatosis type 2* (NF-2), there is a predisposition to bilateral vestibular schwannomas, with chromosome 22q deletions and NF-2 gene mutations in at least half of cases. NF-2 also predisposes to ependymomas, which commonly show a chromosome 22q deletion, but analysis of the NF-2 gene in ependymomas has revealed only a single mutation in a tumor that had lost the remaining wild-type allele.

Children with *tuberous sclerosis* may have a subependymal giant cell astrocytoma or ependymoma. Tuberous sclerosis genes map to chromosomes 9q and 16p, and allelic loss at these loci has been found in some subependymal giant cell astrocytomas, suggesting a tumor suppressor function. Hemangioblastomas of the cerebellum, medulla, and spinal cord are associated with *von Hippel-Lindau disease*, and choroid plexus tumors have occasionally been reported. Loss of chromosome 3p sequences has been described in one choroid plexus tumor, suggesting involvement of the VHL gene. There is an increased risk of brain tumors, particularly choroid plexus carcinoma, in the *Li-Fraumeni syndrome*, involving germ line mutations in *p53* on chromosome 17. *Gorlin syndrome* (*nevroid basal cell carcinoma syndrome*), resulting from *PTCH1* gene mutation, predisposes to medulloblastoma, specifically sonic hedgehog (Shh) subtype (see the following discussion).

Combined cytogenetic and molecular studies of the common sporadic childhood brain tumors have identified genomic alterations that may lead to the identification of genes contributing to tumorigenesis. Isochromosome 17q is found in half of all medulloblastomas implicating a tumor suppressor gene. Clinical outcome is now

P.1266

predictable by gene expression profiles. For example, overexpression of *p53* in malignant gliomas of childhood is associated with adverse outcome. In medulloblastoma, low *MYC* oncogene mRNA expression and high *TrkC* neurotrophin receptor mRNA expression identify a good outcome; the desmoplastic subtype of medulloblastoma is specifically associated with the *basal cell nevus syndrome* (BCNS) (*Gorlin syndrome*), in which the molecular defect is thought to be a mutation in the human homologue of the *Drosophila* patched gene. Identification of a novel polymorphism in this gene allows direct detection of allelic loss in BCNS. Desmoplastic medulloblastoma in infants from affected families is reported to have a good prognosis. Conversely, the large cell, anaplastic variant of medulloblastoma and the atypical teratoid/rhabdoid tumor (ATRT) have an unfavorable prognosis. Diagnosis of these variants is based on light microscopic and immunohistochemical findings, and ATRT is further distinguished by chromosome 22q11 deletion with inactivation of the *hSNF5/INI1* gene.

Environmental risk factors for CNS tumors include ionizing radiation, which in the distant past was given even for benign conditions such as tinea capitis. In children treated for acute lymphoblastic leukemia, there is a 1.39% cumulative incidence of secondary brain tumors (gliomas and meningiomas) at 20 years, and cranial irradiation is a dose-dependent predisposing factor. Cerebral PNETs may also follow cranial irradiation. Another study with 30-year follow-up found a 3.0% cumulative incidence of brain tumors (excluding meningioma) following *all* treatment. There is no conclusive evidence of risk from prenatal x-ray exposure, prenatal ultrasound, or from electromagnetic fields (from electric blankets or other residential exposure).

Studies have shown an association between farm and animal exposures and childhood brain tumors and a weak association with toxic exposures occurring in the household. Although not implicated in retrospective studies,

maternal smoking during pregnancy was associated with slightly increased risk of brain tumors in offspring in a prospective study linking birth and cancer registries. The incidence of medulloblastoma in England declined after 1984 when multivitamin supplementation in pregnancy became widespread following reports that folate reduced the risk of neural tube defects. Maternal intake of folic acid in pregnancy was reported to be protective against PNETs, but this association could not be confirmed in a subsequent study. A seasonal variation has been noted in the incidence of medulloblastoma (but not other brain tumors) in the United States between 1995 and 2001, peaking in October. Possibly related is an observation of increased risk of medulloblastoma/PNET associated with paternal exposure to any heat source, such as electric blanket, in the 3 months prior to the index pregnancy.

PATHOBIOLOGY

Current research on CNS tumorigenesis is based on the molecular genetics of tumor-associated syndromes, rodent models of pediatric brain tumors, and technologic advances in efforts to identify genes that regulate normal and neoplastic cells in the developing CNS. Although the names of brain tumors imply that they originate from normal brain cells (e.g., astrocytoma from astrocytes), the primitive embryonal tumors of childhood that arise during brain development more likely result from aberrant regulation of neurodevelopmental genes. Recently, it has been postulated that brain tumors, like hematologic malignancies, contain small numbers of stem cells (identified as CD133-positive), which have marked capacity for proliferation and self-renewal. These stem cells can differentiate to phenotypically recognizable brain tumor cells but also maintain clonal proliferation and may be highly resistant to conventional anticancer treatment such as radiation and cytotoxic chemotherapy. Candidate stem cells have been proposed for medulloblastoma, ependymoma, and malignant gliomas. Further characterization of brain tumor stem cells may offer new insights into mechanisms of tumorigenesis and lead to novel treatment strategies based on preferential targeting of tumor stem cells.

SONIC HEDGEHOG, WNT SIGNALING, CEREBELLAR DEVELOPMENT, AND MEDULLOBLASTOMA

In the 19th century, Obersteiner described the cells of the external granular layer (EGL) in the developing cerebellum. Based on morphologic similarity, granule cell precursors (GCPs) were considered the cells of origin in medulloblastoma. Now, gene chip analysis and mouse models have linked medulloblastoma to molecular markers of GCPs. Only medulloblastomas carry these molecular markers of developing cells, whereas supratentorial PNETs do not.

The cerebellum matures through a complex interplay of genes of general CNS development and specifically cerebellar genes. For instance, *Shh* is a glycoprotein involved in the development of the CNS. In cerebellar development, Purkinje cells secrete Shh to activate genes in GCPs and stimulate proliferation of these cells. Activating mutations of the Shh pathway account for desmoplastic medulloblastoma in the nevoid basal cell carcinoma syndrome (Gorlin syndrome), 10% to 20% of sporadic medulloblastomas, and histologically similar tumors in mice that are heterozygous for the equivalent genes. Genome sequencing of Shh-driven medulloblastomas reveals pathway mutations involving PTCH1 (across all age groups), SUFU (infants, including cases of germ line mutation), and SMO (in adults). Functional assays in different Shh-driven medulloblastoma xenografts demonstrated that tumors harboring PTCH mutation were responsive to SMO inhibition, whereas tumors with SUFU mutation or MYCN amplification were resistant.

Wnt proteins also play a role in CNS development and have been linked to medulloblastoma. Patients with Turcot syndrome, which involves defects in the *APC* (adenomatous polyposis complex) gene, are susceptible to colorectal and brain tumors, notably medulloblastoma. *APC* is an element of the *Wnt* signaling pathway, and up to 30% of spontaneous medulloblastomas show mutations in *APC* and other components of this neurodevelopmental signaling cascade. Cell nuclear accumulation of β -catenin protein is also associated with activation of *Wnt/Wg* signaling, and positive immunostain for β -catenin in medulloblastoma has been associated

with favorable treatment outcome even with metastatic disease at presentation.

Wnt proteins bind to receptors and modulate *C-myc*, a transcription factor that promotes cell cycle progression. Activation of *C-myc* and *N-myc* leads to proliferation, cell growth, and maintenance of an undifferentiated cellular phenotype; these genes are amplified in some medulloblastomas and are associated with a poor clinical outcome. The same genes are amplified by the *Shh* pathway. *Wnt1* is required for mesencephalon/metencephalon patterning early in development. Cerebellar primordia fail to develop in mice lacking *Wnt1*, and mutations in other *Wnt* pathway components have been implicated not only in medulloblastoma but also in colon cancer, hepatocellular carcinoma, and prostate and ovarian cancers.

Deletion of chromosome 17p, the most frequently detected genetic lesion in medulloblastoma, has been identified as a cause of unrestrained hedgehog signaling. This deletion results in loss

P.1267

of REN(KCTD11), a novel hedgehog antagonist, thus removing a checkpoint of hedgehog-dependent events during cerebellar development and tumorigenesis. Inactivation of the tumor suppressor *p53*, also a resident of chromosome 17, may contribute to the growth of tumors resembling medulloblastoma in mice, but there is neither an increased incidence of medulloblastoma in humans lacking *p53* nor a change in *p53* within the medulloblastoma cells.

The gene *Bmi1*, which induces leukemia through repression of tumor suppressors, is overexpressed in many medulloblastomas and promotes cerebellar GCP proliferation. Linked overexpression of *Bmi1* and patched (*PTCH*) in primary human medulloblastomas, together with rapid induction of *Bmi1* expression on addition of *Shh* or overexpression of the *Shh* target *Gli1* in cerebellar granule cell culture, implicates *Bmi1* overexpression as an alternative or additive mechanism in medulloblastoma pathogenesis.

ASTROCYTES, GROWTH FACTORS, TUMOR SUPPRESSORS, AND ASTROCYTOMA

Astrocytes develop later than neurons and continue to do so long after neurogenesis stops. Astrocytes retain the capacity for division throughout life and are more susceptible to transformation. Control over astrocyte proliferation and differentiation may be divided into two main categories: cell signaling and cell cycle arrest pathways. During glial development, precursor cells respond to growth factors such as epidermal growth factor (EGF) or platelet-derived growth factor (PDGF). Their receptors (epidermal growth factor receptor [EGFR] and platelet-derived growth factor receptor [PDGFR]) are activated to stimulate tyrosine kinase activity and intracellular pathways that control proliferation and differentiation, programmed cell death, migration, cellular shape, and metabolism.

Amplification and mutation of EGFR are among the most common genetic abnormalities found in adult glioblastomas, particularly those arising de novo (as opposed to lesions progressing from fibrillary astrocytomas). These tumors contain ligands that may activate the receptor, stimulating a pathway that results in tumor progression. In addition, the receptor may be mutated to a constitutively activated form, unable to bind ligand but generating unregulated tyrosine kinase activity. Mice lacking *EGFR* have fewer glial fibrillary acidic protein (GFAP)-positive cells, and massive neuronal degeneration is attributed to a lack of trophic support from the missing glial cells. Amplification of EGFR is uncommon in pediatric high-grade astrocytomas, but significant differential expression of the *EGFR/FKBP12/HIF-2 α* growth- and angiogenesis-promoting pathway has been demonstrated. High PDGFR protein expression is associated with malignant histology in pediatric glioma but is not an independent prognostic factor. Attempts to block glioma progression through disruption of the EGFR pathway have led to development of drugs targeting EGFR or PDGFR.

Ras is a downstream effector of several growth factor receptors, signaling through both mitogenic and antiapoptotic pathways. It is under control of the NF-1 gene neurofibromin, and loss of function mutations in neurofibromin underlie the NF-1 syndrome, with predisposition to optic nerve glioma, astrocytoma, and

glioblastoma. Neurofibromin functions as a Ras-guanosine triphosphatase-activating protein, but it had been unclear how Ras deregulation was involved in NF-1 pathogenesis. It has now been demonstrated that neurofibromin tightly regulates the mTOR (mammalian target of rapamycin) pathway. mTOR is a highly conserved serine/threonine protein kinase that regulates many steps in cell growth and proliferation, including ribosome biogenesis and protein translation. mTOR is constitutively activated in NF-1-deficient cells and tumors; aberrant mTOR activation depends on Ras and is mediated by the phosphorylation and inactivation of the tuberous sclerosis complex-2 (TSC2)-encoded protein tuberin. Tumor cell lines from NF-1 patients are highly sensitive to the mTOR inhibitor rapamycin, which has therapeutic implications.

Molecular profiling of pediatric glioblastomas identifies at least two subsets. One group is associated with *Ras* and *Akt* pathway activation and exhibits increased expression of genes related to proliferation and a neural stem cell phenotype; this subset has very poor prognosis. A second group with better prognosis is not associated with activation of *Ras* and *Akt* pathways and may originate from astroglial progenitors. Both subsets show overexpression of Y-box protein-1, which may promote oncogenesis.

The tumor suppressor phosphatase with homology to tensin (*PTEN*) is mutated or lost in some pediatric high-grade astrocytomas, as in primary adult glioblastoma. *PTEN* is expressed throughout the embryo and is critical in CNS development. *PTEN* mutations are thought to cause Lhermitte-Duclos disease (dysplastic gangliocytoma of the cerebellum) characterized by enlarged cerebellar foliae, distorted cerebellar cortex, abnormally myelinated axon bundles, and dysplastic neurons. Conditional inactivation of the gene in the cerebellum of developing mice has generated a mammalian model of that disease. Loss of *PTEN* promotes astrocytic growth and survival because it would otherwise act as a repressor of antiapoptotic signaling pathways. *PTEN* is also thought to regulate astrocyte migration and invasion by effects on cell shape and movement. When *PTEN* is overexpressed, it inhibits tumor cell movement; conversely, reduction of *PTEN* activity promotes cell movement, invasiveness, and perhaps metastasis. Loss of *PTEN* has been associated with inferior survival in childhood gliomas. *PTEN* is a component gene in the mTOR pathway; immunohistochemical analysis of Lhermitte-Duclos disease lesions showed high levels of phospho-AKT and phospho-S6 in the large ganglionic cells, indicating activation of the PTEN/AKT/mTOR pathway and suggesting a central role for mTOR in LDD pathogenesis, as well as potential therapeutic intervention through pharmacologic inhibition of mTOR.

The tumor suppressors *retinoblastoma (Rb) protein* and *p53* are also regulators of cell survival and programmed cell death and are intimately involved with astrocytoma. *Rb* mutations in children lead to tumors in the retina, whereas mice null for *Rb* do not survive because of lethally abnormal patterns of neuronal development with pronounced CNS programmed cell death. *Rb* encodes a phosphoprotein important in cell cycle regulation, blocking transcription factors that promote proliferation. In the developing CNS, *Rb* is found in the ventricular zone where neuroblasts proliferate.

Rb is also involved in the regulation of apoptosis through interactions with the tumor suppressor *p53*, a transcription factor upregulated in response to cellular stress to facilitate arrest of the cell cycle for either DNA repair or cell death. Humans with the Li-Fraumeni syndrome lack *p53* and show marked susceptibility to gliomas. *p53* mutant mice develop tumors early in life.

Under conditions of *Rb* inactivation, many cells enter the cell cycle inappropriately and subsequently undergo apoptosis. However, *Rb* loss may synergize with the loss of apoptotic regulators, such as *p53* to promote tumor formation. With the loss of *Rb*, transcription factors go unchecked, which then promotes cell proliferation. Loss of *Rb* might normally lead to apoptosis, but if *p53* is also missing, apoptosis is impaired and tumorigenesis is enhanced. In fact, approximately 75% of adult glioblastomas show impaired apoptotic mechanisms and *p53* pathway defects. Mutations in *p53*

were detected in one-third of childhood high-grade astrocytomas, and nearly half over-expressed the *p53*

protein. This finding was strongly associated with adverse outcome.

Mutations in histone and chromatin remodeling genes appear to be uniquely important in pediatric glioblastoma multiforme. Exome sequencing revealed somatic mutations in the H3.3-ATRX-DAXX chromatin remodeling pathway in nearly half of cases and recurrent mutations in H3F3A (which encodes H3.3) in one-third. H3F3A mutations were specific to GBM, highly prevalent in children and young adults, and tended to be associated with somatic TP53 mutations and alternative telomere lengthening. Increased TERC (telomerase RNA template) and hTERT mRNA (encoding telomerase catalytic component) have been associated with worse overall survival in children with non-brain stem high-grade glioma after controlling for tumor grade and extent of resection.

BRAF alterations (in particular tandem duplication and fusion *BRAF-KIAA1549* on chromosome 7q34) are now widely accepted as molecular markers for pilocytic astrocytoma, in particular for the differential diagnosis of supratentorial pediatric gliomas. Besides their diagnostic use, the evidence of MAPK pathway-activating *BRAF* fusions and mutations in brain tumors has moreover drawn the attention of neurooncologists to the potential use of MEK1/2 and RAF inhibitors in the therapy of high- and low-grade gliomas.

Investigation of molecular aberrations in the most devastating tumor, diffuse intrinsic pontine glioma (DIPG), has lagged because most cases are diagnosed clinically without pathologic confirmation. However, high-resolution single-nucleotide polymorphism-based DNA analysis of a series of DIPGs using postmortem samples revealed recurrent changes distinct from supratentorial high-grade astrocytomas, specifically expression (and gains) of platelet-derived growth factor receptor alpha (PDGFRA) and occasional low-level gains in poly (ADP-ribose) polymerase (PARP)-1. Mutations in H3F3A (encoding histone H3.3) or HIST1H3B (encoding histone H3.1) appear to be common in DIPG. Whole-genome sequencing has identified three molecular subgroups of DIPG (H3-K27M, silent, and MYCN) and recurrent activating mutations involving the activin receptor gene ACVR1 in some cases.

TABLE 145.1 Location of Central Nervous System Tumors in Infants, Children, and Adolescents

Location	Infant	Child	Adolescent
Cerebral	PNET	Low-grade astrocytoma High-grade astrocytoma PNET Ganglioglioma PXA	High-grade astrocytoma Oligodendroglioma Meningioma Lymphoma
Suprasellar and optic pathway	Low-grade astrocytoma Craniopharyngioma	Low-grade astrocytoma Craniopharyngioma Germ cell tumor	Craniopharyngioma Epidermoid
Ventricular	Choroid plexus tumor Ependymoma Colloid cyst	Ependymoma Low-grade astrocytoma	Colloid cyst Central neurocytoma

Midbrain	Low-grade astrocytoma Dermoid	Low-grade astrocytoma High-grade astrocytoma	High-grade astrocytoma
Pineal	Teratoma Pineocytoma	PNET Germ cell tumor	Germ cell tumor
Posterior fossa	Medulloblastoma Ependymoma Low-grade astrocytoma Gangliocytoma	Medulloblastoma Brain stem glioma Ependymoma Low-grade astrocytoma	Low-grade astrocytoma Medulloblastoma Ependymoma Epidermoid
Spinal cord	Low-grade astrocytoma	Low-grade astrocytoma	Low-grade astrocytoma High-grade astrocytoma

PNET, primitive neuroectodermal tumor; PXA, pleomorphic xanthoastrocytoma.

CLINICAL FEATURES

Children with brain tumors often present with symptoms and signs of increased intracranial pressure (ICP). The ventricular or periventricular location of many tumors, and associated mass effect, results in obstruction of normal cerebrospinal fluid (CSF) pathways and ventriculomegaly. Characteristic signs are headache, vomiting, and diplopia, but the onset may be gradual and nonfocal. Fatigue, personality change, or worsening school performance may be described. Symptoms in infants are nonspecific and include irritability, anorexia, persistent vomiting, and developmental delay or regression, with macrocephaly and seemingly forced-downward deviation of the eyes (“sunset sign”). The median duration of symptoms before diagnosis was 2 months in two series; only onethird of the patients were diagnosed in the first month after onset of symptoms, but diagnostic delay is less important than tumor aggressiveness in determining survival outcome. Persistent vomiting, recurrent headache (awakening the child from sleep), neurologic findings (ataxia, head tilt, weakness, vision loss, papilledema), endocrine disturbance (growth deceleration, diabetes insipidus, precocious puberty), and stigmata of neurofibromatosis should all prompt immediate evaluation for the presence of a CNS tumor.

Symptoms and signs reflect tumor location, and in children (unlike adults), CNS tumors are divided about equally between supratentorial and infratentorial sites ([Table 145.1](#)). In a

P.1269

meta-analysis, the ratio of supra- to infratentorial tumors was 0.92, and infratentorial location was more common between the ages of 3 and 11 years ([Table 145.2](#)).

Supratentorial tumors, which predominate in infants and toddlers and also occur in older children, cause headache; limb weakness; sensory loss; and, occasionally, seizures, deteriorating school performance, or personality change. Seizures are a presenting symptom in 10% to 15% of children with brain tumors and may be generalized, focal motor, or psychomotor; electroencephalogram (EEG) is almost always abnormal. Most seizure-associated tumors are in the temporal lobe; frontal lobe tumors more often affect personality and movement, although seizures have been reported with frontal-parietal tumors. The incidence of underlying neoplasm in

children with intractable epilepsy approaches 20%, and the increased risk of having a brain tumor is noted even 10 or more years after a diagnosis of epilepsy.

Parietal lobe tumors affect reading ability and awareness of contralateral extremities (hemineglect). Occipital lobe tumors cause visual field disturbance and occasionally, hallucinations. Suprasellar lesions may cause both visual field defects and endocrine dysfunction. The Parinaud syndrome (upgaze paresis and mild pupil dilatation with better reaction to accommodation than light, retraction or convergence nystagmus, and lid retraction) is found in pineal region tumors.

Infratentorial tumors, which predominate from ages 4 to 11 years, typically cause headache, vomiting, diplopia, and imbalance. Bilateral sixth cranial nerve palsy is a frequent sign of increased ICP. Brain stem tumors cause facial and extraocular muscle palsies, ataxia, and hemiparesis. Leptomeningeal spread occurs at diagnosis or recurrence in up to 15% of children with CNS tumors (more often in medulloblastoma/PNET) and may be asymptomatic or may cause pain, irritability, weakness, or bowel and bladder dysfunction.

TABLE 145.2 Childhood Central Nervous System Tumors Diagnosed in the United States in 2005 to 2009 by Histology and Age at Diagnosis

Histology	0-4	5-9	10-14	15-19	Total
Astrocytoma, low grade	1,220	1,084	1,108	890	3,412
Astrocytoma, high grade	207	431	385	407	1,342
Glioma, malignant, NOS	875	789	427	254	2,345
Oligodendroglioma, anaplastic, oligo, oligoastrocytic tumors	58	61	89	187	419
Ependymoma	402	226	211	273	1,112
Choroid plexus tumors	265	40	38	51	394
Neuronal, mixed neuronal-glial, and other neuroepithelial tumors	248	297	429	482	1,486
Pineal region tumors	53	38	32	42	165
Embryonal tumors (medulloblastoma, sPNET, ATRT)	1,232	737	387	261	2,617
Nerve sheath tumors	272	207	252	369	1,100
Meningioma, other meningeal	70	60	176	369	688
Mesenchymal tumors	56	28	31	35	150

Primary melanocytic lesions	—	—	—	—	19
Lymphoma, other hematologic	—	22	20	35	90
Germ cell tumors	129	133	262	299	823
Pituitary tumors	33	107	392	1,362	1,894
Craniopharyngioma	141	251	216	158	766
Hemangioma	49	38	74	132	293
Neoplasm, NOS	173	136	176	242	727
TOTAL	5,517	4,589	4,740	5,863	20,709

NOS, not otherwise specified; sPNET, supratentorial primitive neuroectodermal tumor; ATRT, atypical teratoid/rhabdoid tumor.

Data from Dolecek TA, Propp JM, Stroup NE, et al. CBTRUS statistical report: primary brain and central nervous system tumors diagnosed in the United States in 2005-2009. *Neuro Oncol.* 2012;14(suppl 5):v1-v49.

DIAGNOSIS

MRI is the preferred imaging modality for evaluation of children with symptoms suggestive of brain tumor (e.g., persistent headache of recent onset, morning vomiting) and abnormal signs on neurologic examination (head tilt, ataxia) or other clinical predictors of brain tumor (diabetes insipidus). Computed tomography (CT) may be the initial evaluation (especially if hydrocephalus or intracranial hemorrhage is suspected), but compared with CT, MRI is more sensitive (especially for nonenhancing, infiltrative tumors and leptomeningeal involvement), may generate images in any plane (e.g., axial, coronal, sagittal), and is not compromised in the posterior fossa by bone artifact. Brain tumors are typically hypo- or isointense on T1-weighted imaging and hyperintense on T2-weighted imaging. Contrast enhancement is a feature of malignant tumors, reflecting blood-brain barrier disruption. Perfusion and diffusion sequences may also be useful in assessing tumor aggressiveness. Magnetic resonance spectroscopy (MRS) can provide additional information; for example, compared to benign

P.1270

tumors or normal brain, malignant tumors have increased choline peaks (reflecting increased membrane turnover) and decreased *N*-acetylaspartate (absence of functional neurons). MRI is repeated postoperatively to confirm extent of tumor resection, although it may be difficult to distinguish tumor from surrounding edema or residual tumor from postoperative changes; for these reasons, postoperative studies should be obtained within 48 hours of surgery.

MRI of the spine has replaced myelography as the standard procedure for evaluation of spinal cord tumors, drop metastases, and leptomeningeal disease. Spine MRI is required in cases of medulloblastoma, ependymoma, choroid plexus carcinoma, ATRT, and pineal region tumors and should be obtained preoperatively if one of these diagnoses is suspected. Lumbar puncture for CSF cytology and tumor

markers should also be done in children with these diagnoses. Recommended baseline and surveillance studies, based on tumor aggressiveness and patterns of recurrence, are shown in [Table 145.3](#).

Treatment responses are determined by change in tumor size on MRI based on the most reproducible measurements from T2/fluid-attenuated inversion recovery (FLAIR)-weighted or postcontrast T1-weighted images, whichever gives the best estimate of tumor size. Measurements of the longest tumor dimension and its perpendicular should be recorded for all target lesions (up to 5) and any new lesions. In assessing response, lesions less than twice the combined thickness of the image slice and interslice gap are discounted, and cystic/necrotic elements and/or leptomeningeal disease are generally not measured. Enlargement or reduction of existing lesions should correlate with increase or decrease in two-dimensional measurement, but increased enhancement on T1 without increase in disease bulk on T2/FLAIR is not considered tumor progression, and decreased enhancement without decreased bulk on T2/FLAIR may represent altered contrast permeability rather than regression. Thus, complete or partial response (CR, PR) requires disappearance or greater than 50% reduction of all target lesions, respectively, whereas 25% increase or the appearance of new lesions or newly positive CSF cytology indicates progressive disease (PD). Imaging may be supplemented by positron emission tomography (PET), which characterizes metabolic abnormalities that distinguish high grade from low grade and residual or recurrent tumor from cerebral necrosis. *Thallium-201* single-photon emission computed tomography (SPECT) is sensitive for recurrent tumors, although MRS offers similar capability and is more widely available.

TREATMENT

SURGERY

The mainstay of therapy is *surgery*, which may be curative by itself in resectable congenital and benign tumors. Gross total resection is generally attempted in malignant tumors and contributes to the cure rates of high-grade astrocytoma, medulloblastoma, or ependymoma. Adoption of intraoperative MRI can improve the rate of tumor resection and may alter surgical strategy. Gross total resection (no visible tumor at completion of surgery) or radical subtotal resection (95% to 99% removal of tumor) should be confirmed by postoperative MRI. Radical resection is generally not attempted for lesions deep in the thalamus or for diffuse, intrinsic brain stem tumors; surgery is typically limited to open or closed biopsy (< 1% resection) or partial or subtotal resection (10% to 49% and 50% to 95% tumor removal, respectively). Multiple biopsies may be useful in lesions appearing heterogeneous on MRI when major resection is not attempted. The introduction of the operating microscope and ultrasonic aspirator has improved both the safety and effectiveness of surgery. Stereotactic (e.g., CT or MRI guided) techniques are used for biopsy or subtotal resection in difficult-to-reach areas such as the basal ganglia. However, even a 99% resection of a lesion that is 10 cm³ in size will leave 10⁸ tumor cells behind, and

P.1271

additional postoperative treatment will be necessary to prevent the lesion from regrowing. Surgery is important for establishing a tissue diagnosis and relieving obstructive hydrocephalus. With temporary placement of an external drain or endoscopic third ventriculostomy, followed by tumor resection, it may be possible to avoid the need for a permanent ventriculoperitoneal shunt, in most patients.

Operative mortality is generally not more than 1%, but morbidity varies according to the site and extent of surgery and the condition of the child. A unique and increasingly recognized complication of midline posterior fossa tumor resection is the *cerebellar mutism syndrome*, consisting of diminished speech progressing to mutism, emotional lability, hypotonia, and ataxia. In two prospective trials for standard and high-risk medulloblastoma, cerebellar mutism was reported in 24% of children. In both cohorts, brain stem invasion by tumor was the only predictive feature. At 1 year from diagnosis, nonmotor speech/language deficits, neurocognitive deficits, and/or ataxia persisted in a substantial proportion of patients.

Surgery may be facilitated by intraoperative monitoring of sensory and other evoked potentials. Adjunctive measures include the use of corticosteroids, which counteract tumor edema and are often used in the perioperative period but should be tapered within 1 to 2 weeks, if possible. Patients undergoing surgery for

supratentorial tumors are placed on anticonvulsants if they have had seizures or if the surgical approach is likely to cause seizures. Prophylactic anticonvulsants are generally continued for 1 week to 12 months.

RADIATION THERAPY

Radiation therapy is used for nearly all malignant CNS tumors and for some benign lesions. Based on standard x-ray (photon) therapy, doses typically administered to achieve local control range from 45 to 55 Gy, in divided fractions of 150 to 200 cGy, to the tumor as localized on MRI plus 1- to 2-cm margin. Higher doses may be given, often in smaller twice-daily doses (e.g., hyperfractionated technique), but with high total doses, there is increased risk of injuring normal brain tissue. The volume irradiated depends on tumor histology and may include an involved field or whole brain and spine. Presymptomatic craniospinal irradiation is almost always given for medulloblastoma because of its propensity to disseminate throughout the neuraxis. Doses of 36 Gy have been used conventionally, but lower doses (23.4 Gy and possibly 18 Gy) are adequate in standard-risk patients if supplemented with adjuvant chemotherapy.

Newer radiotherapy techniques may increase the effective tumor dose and limit toxicity to the surrounding brain. *Three-dimensional conformal radiation therapy* allows tailoring of treatment to the actual tumor volume rather than arbitrary compartments such as the whole posterior fossa. *Stereotactic irradiation* techniques with arc photons, in conjunction with rigid head fixation systems, permit single high-dose delivery (e.g., radiosurgery), which may be useful for management of recurrent lesions in previously irradiated patients. *Intensity-modulated radiation therapy (IMRT)* uses combinations of variable intensity fields from different beam directions to maximize tumor dose while minimizing dose to adjacent normal tissues. *Proton therapy* takes advantage of the superior physical properties of protons compared to photons, with limited penetration of particles beyond the tumor target, less tissue scatter, and little lateral dispersion. Early applications of proton therapy included ocular melanoma and skull base tumors, but the possibility of comparable tumor control with substantially decreased dose to adjacent normal tissues makes the technique potentially advantageous for many pediatric indications. *Interstitial radioactive implants* (brachytherapy) may be appropriate in some cases. Use of *radiation sensitizers*, including chemotherapy agents (carboplatin, capecitabine, tipifarnib) and gadolinium derivatives, is currently under study.

Acute side effects of radiation therapy include headache, nausea, alopecia, skin hyperpigmentation and desquamation, and a transient "somnolence syndrome," occurring 4 to 8 weeks after treatment. Radiation therapy to large volumes is problematic in infants and toddlers because of increased neurocognitive sequelae. Dose-intensive chemotherapy may be used to defer irradiation, or involved field treatment with supplemental chemotherapy may be substituted for whole-brain irradiation (as in medulloblastoma).

CHEMOTHERAPY

Chemotherapy is used as an adjunct to radiotherapy, as primary postsurgical treatment in infants, as neoadjuvant therapy in chemotherapy-sensitive tumors (e.g., germ cell tumors), and in recurrent tumors. Effective agents include the nitrosoureas (e.g., carmustine, lomustine), vincristine, cisplatin, carboplatin, etoposide, and cyclophosphamide. Temozolomide appears promising, although response rates in phase II trials have been relatively low. Chemotherapy is generally given systemically and in combination because of complementary mechanisms of action of different agents and to subvert potential tumor resistance. The effectiveness of systemically administered chemotherapy is limited by the blood-brain barrier. Regional delivery of drugs (e.g., intra-arterial, intrathecal, intratumor) potentially circumvents this problem, and responses to intra-arterial carboplatin- or methotrexate-based chemotherapy with osmotic blood-brain barrier disruption are reported for germ cell tumors and primary CNS lymphoma. The dose intensity of conventional, systemic chemotherapy may be increased with the use of hematopoietic growth factors, which shorten the period of myelosuppression and permit the use of higher doses or shorter intervals between treatments. A related approach is the use of extremely high doses of chemotherapy, supported by

autologous hematopoietic stem cell rescue, and this approach has been used for chemotherapy-sensitive recurrent tumors or as an intensive consolidation therapy for infants.

The role of adjuvant cisplatin-based chemotherapy following radiation is well established for childhood medulloblastoma, pineoblastoma, and supratentorial PNET. For standard-risk medulloblastoma, use of chemotherapy permits reduction in the dose of radiotherapy. Dose-intensive cyclophosphamide-based chemotherapy has been used following radiation therapy for standard- and high-risk medulloblastoma with the goal of reducing exposure to cisplatin. For high-grade astrocytomas, temozolomide is used routinely with and following radiation therapy, as in adults. Preirradiation chemotherapy is being tested in CNS germ cell tumors and ependymoma but has been generally ineffective in medulloblastoma/PNET and malignant gliomas, including brain stem tumors, presumably because of delaying definitive radiation therapy.

In very young patients (infants and toddlers younger than age 3 to 4 years) with malignant brain tumors, dose-intensive chemotherapy is commonly used postoperatively with the goal of deferring or avoiding radiation therapy. This approach appears effective in medulloblastoma and possibly ependymoma.

Intrathecal therapy (intraventricular and intralumbar methotrexate) has also been advocated for medulloblastoma in a protocol designed to avoid radiation therapy.

P.1272

Chemotherapy is commonly used for recurrent CNS tumors, and patients may receive additional irradiation as well. High-dose chemotherapy with stem cell rescue may offer effective salvage therapy for recurrent medulloblastoma at least when combined with radiation therapy in younger previously unirradiated patients. Established and newer chemotherapy agents can be tested against panels of childhood brain tumor xenografts. Doses of certain chemotherapy agents such as irinotecan may require adjustment if patients are also receiving hepatic enzyme-inducing anticonvulsant drugs such as phenytoin, phenobarbital, carbamazepine, and Mysoline.

Biologic agents in clinical trials for recurrent CNS tumors include differentiation agents (retinoic acid), agents targeting tumor growth factor receptors (erlotinib, gefitinib, imatinib, lapatinib), farnesyltransferase inhibitors (tipifarnib), agents interfering with angiogenesis (bevacizumab, cilengitide, lenalidomide), histone deacetylase inhibitors (suberoylanilide hydroxamic acid, valproic acid), heat shock protein inhibitors (17-allylaminogeldanamycin), and DNA repair enzyme inhibitors (O6-benzylguanine).

Immunotherapy would be an attractive option for treatment of pediatric CNS tumors but remains an elusive goal. Convection-enhanced delivery of immunotoxin conjugates is being evaluated in adult patients. Certain glioma-associated antigens are overexpressed on pediatric brain stem and non-brain stem gliomas and could be suitable candidates for vaccine strategies.

SPECIFIC TYPES OF PEDIATRIC BRAIN TUMORS

Pathologic diagnosis is based on the revised WHO classification published in 2007. This classification distinguishes astrocytic tumors, oligodendroglial tumors and mixed gliomas, ependymal tumors, choroid plexus tumors, and neuronal and mixed neuronal-glial tumors. Among entities newly incorporated in the revised classification are angiocentric glioma, papillary glioneuronal tumor, rosette-forming glioneuronal tumor of the fourth ventricle, papillary tumor of the pineal region, pituicytoma, and spindle cell oncocytoma of the adenohypophysis. Newly described histologic variants of pediatric tumors are pilomyxoid astrocytoma, anaplastic medulloblastoma, and medulloblastoma with extensive nodularity. In addition, the rhabdoid tumor predisposition syndrome was added to the list of familial cancer syndromes.

Some childhood brain tumors, such as supratentorial astrocytomas, are difficult to characterize in the WHO classification. A proposed pediatric classification divides tumors into glial, mixed glial-neuronal, neural,

embryonal, and pineal categories. Glial tumors include astrocytoma, ependymoma, oligodendroglioma, and choroid plexus tumor. Mixed glial-neuronal tumors include ganglioglioma and subependymal giant cell tumor. Neural tumors include gangliocytoma. Embryonal tumors are PNET, ATRT, and medulloepithelioma. Pineal tumors are represented by pineocytoma.

Pathologic diagnosis is greatly facilitated by immunostaining for specific markers such as GFAP in glial tumors and neurofilament or synaptophysin in PNETs and gangliogliomas. Other markers have been useful for different tumors: epithelial membrane antigen for ependymoma, α -fetoprotein (AFP) and human chorionic gonadotropin (HCG) for germ cell tumors, S100 for neural tumors, smooth muscle actin (SMA) for ATRT, and cytokeratin for choroid plexus carcinoma (Table 145.4). An important trend in tumor pathology is the application of cytogenetic and DNA approaches. Examples are isochromosome 17q in medulloblastoma, chromosome 1p and 19q deletions in oligodendroglioma, and monosomy or deletion of chromosome 22 (hSNF/INI-1 locus) in ATRT.

CONGENITAL TUMORS

Craniopharyngiomas

Craniopharyngiomas originate from rests of embryonic tissue located in the Rathke pouch, which later form the anterior pituitary gland. They may appear clinically at any age, even later adulthood, and constitute 6% to 10% of intracranial tumors in children. They vary from small, well-circumscribed, solid nodules to huge, multilocular cysts invading the sella turcica. The cysts are filled with turbid fluid that may contain cholesterol crystals.

Craniopharyngiomas are histologically benign and may be categorized as mucoid epithelial cysts, squamous epitheliomas, or adamantinomas. Total surgical removal may be difficult because the tumor may invade the hypothalamus or third ventricle and adhere to optic nerves or blood vessels. Manifestations include short stature, hypothyroidism, and diabetes insipidus, with vision loss and signs of increased ICP. Although CT is useful for demonstrating calcification and bony expansion of the sella, MRI is preferred for better definition of the relationship of the tumor to neighboring vessels, optic chiasm and nerves, and the hypothalamus (Fig. 145.1).

A conservative approach is to drain the cyst and resect nonadherent tumor and then administer radiation therapy to the involved area. Alternatively, gross total resection may be attempted, avoiding irradiation. In addition to the standard transsphenoidal approach, there is renewed interest in the endonasal approach. Recurrence rates are similar (20% to 40%), and radical surgery is likely to be accompanied by panhypopituitarism necessitating lifelong hormonal replacement therapy, whereas irradiation has lesser hormonal sequelae but causes cognitive deficits, especially in younger children. Focused treatment by stereotactic radiosurgery (e.g., Gamma Knife) may be advantageous in this regard. Interferon α -2a and pegylated interferon α -2b have been used in recurrent craniopharyngiomas.

Epidermoid Cysts

Epidermoid cysts (cholesteatomas) account for about 2% of all intracranial tumors. They arise within skull tables or adjacent to the dura usually in the suprasellar region, skull base, brain stem or cerebellopontine angle, or within a ventricle. They arise from epithelial cells retained during neural tube closure, have a pearly appearance, and may contain cyst fluid with cholesterol crystals. Clinical onset is usually in young adulthood, with hearing loss, hemifacial spasm, or trigeminal neuralgia. MRI demonstrates a lesion with low T1- and high T2-weighted signal intensity (Fig. 145.2); involvement of multiple cranial nerves and the internal carotid artery is common. Treatment is surgical resection with radical removal of the tumor capsule. *Dermoid tumors* are also cystic, and sebaceous gland secretions impart a dark yellow color to the cyst fluid. Intracranial dermoids are associated with Goldenhar syndrome (i.e., oculo-auriculo-vertebral dysplasia). Treatment is surgical resection. Epidermoid and dermoid cysts occasionally undergo malignant transformation into squamous cell carcinoma. *Arachnoid cysts* are CSF collections within arachnoid membranes, often in the sylvian fissure, presenting with headache and

occasionally seizures. Diffusion-weighted imaging can be helpful in distinguishing arachnoid cysts from epidermoid cysts. Surgery is indicated for arachnoid cysts, which are symptomatic (obstructive hydrocephalus, seizures); options include cystectomy, fenestration, or cyst-peritoneal shunting.

P.1274

FIGURE 145.2 Sagittal (A) and axial (B) MRIs of a pontomedullary epidermoid cyst.

Teratomas

Teratomas occur in infants and young children. Prenatal diagnosis of an intracranial teratoma has been reported.

Mature teratomas are generally lobulated and cystic, often containing differentiated tissues such as bone, cartilage, teeth, hair, or intestine. Immature and malignant teratomas are less common; posterior fossa immature teratoma in an infant with trisomy 21 has been reported. Teratomas tend to occur in the pineal region, presenting with Parinaud syndrome and hydrocephalus. They comprise about 4% of childhood intracranial tumors and also occur in the spine. Treatment is surgical resection.

Chordomas

Chordomas develop from remnants of the embryonic notochord. Half are in the sacrococcygeal region, one-third at the sphenoid-occipital junction, and the remainder elsewhere along the spinal column. They are rare, accounting for less than 1% of CNS tumors, and usually remain asymptomatic until adulthood. These tumors are locally invasive and cause vision loss or cranial nerve dysfunction. They may invade the nasopharynx or intracranial sinuses and may extend into the neck causing torticollis.

Chordomas have a smooth, nodular surface that resembles cartilage; the characteristic histologic feature is the presence of large masses of physaliferous cells, round or polygonal cells arranged in cords and having large cytoplasmic vacuoles containing mucin. Chordomas grow slowly but may recur after excision. A malignant variant is distinguished by mitotic spindle cells and may metastasize to the lung. Chordoma should be suspected in a patient presenting with multiple cranial nerve palsies or erosion of the skull base. Treatment is surgical resection, although gross total resection is rarely achieved, occasionally with postoperative irradiation. Radiation therapy may be used postoperatively or at recurrence. Proton radiotherapy is advocated because it may confer effective local control and possibly better cosmetic outcome than with conventional irradiation.

Choroid Plexus Tumors

Choroid plexus tumors are rare congenital tumors arising in the choroid plexus of the lateral or fourth ventricles. They may cause symptoms shortly after birth, and most are diagnosed before age 2 years. The first manifestation is likely to be macrocephaly resulting from hydrocephalus, with bulging fontanelle and split sutures noted in infants. Excess CSF production arising from the tumor may approach 2,000 mL/day. The majority are papillomas (WHO grade I), hamartomatous lesions which grow into the ventricle and tend not to be invasive. Papillomas are often calcified on CT scan and enhance with contrast; they must be distinguished in the infant age group from ependymomas, which lack calcification. *Atypical papillomas* (WHO grade II) have a higher growth fraction (mitotic rate by MIB-1 >2%). Total excision of localized lesions may be curative and stops the excessive CSF production, but malignant transformation of incompletely resected papillomas has been reported.

Choroid plexus carcinomas (WHO grade III) typically invade the brain parenchyma and cause hydrocephalus (Fig. 145.3). Carcinomas are more heterogeneous than papillomas on imaging due to focal necrosis and surrounding vasogenic edema; in nearly half of cases, there is disseminate in the leptomeninges. Choroid plexus carcinomas may be a manifestation of Li-Fraumeni syndrome, and evidence should be sought for germ line mutation in *p53*. Adjuvant chemotherapy or irradiation has been advocated for carcinomas, even following apparent gross total resection, owing to their invasiveness and guarded prognosis (median survival 6 months in one series). For patients undergoing subtotal resection of carcinomas, both chemotherapy and craniospinal irradiation are recommended.

FIGURE 145.3 MRI of a choroid plexus carcinoma of the lateral ventricle with parenchymal invasion.

P.1275

Colloid Cysts

Colloid cysts presumably arise from the anlage of the paraphysis. These lesions grow in the anterior superior portion of the third ventricle as small, white cysts filled with homogeneous, gelatinous material. They do not usually cause symptoms until adulthood when there may be intermittent hydrocephalus. Disturbance of the limbic system may cause emotional and behavioral changes in some instances. Colloid cysts are T2 hyperintense on MRI without enhancement. Treatment is surgical excision. Endoscopic procedures are gaining acceptance as an alternative to microsurgical resection.

Gangliogliomas

Gangliogliomas are rare, glioneural tumors that account for 2.5% of pediatric brain tumors. The peak age incidence is 10 to 20 years. They arise mainly in the temporal lobe but also in other lobes or spinal cord. The usual syndrome is a long history of refractory epilepsy. Imaging reveals a solid to cystic lesion with calcification on CT and hypometabolic activity on PET. Total surgical resection is recommended, and prognosis for long-term seizure control is excellent. Malignant transformation to glioblastoma may follow incomplete resection. Radiation therapy and chemotherapy are of uncertain benefit.

Desmoplastic infantile ganglioglioma (DIG) is a rare cerebral glioneural tumor of early childhood. DIGs are large hemispheric tumors that are generally benign, but deep lesions may be aggressive. Treatment is resection. Related glioneural tumors include *desmoplastic astrocytoma of infancy* (DAI) and *pleomorphic xanthoastrocytoma* (PXA), which usually cause seizures and headache.

Dysplastic gangliocytoma of the cerebellum (*Lhermitte-Duclos disease*) is a rare, benign entity characterized by loss of normal cerebellar cortical architecture and may be associated with macrocephaly and mental retardation. MRI appearance is a well-circumscribed lesion with characteristic laminar pattern of alternating high and low T2

signal. The disorder has been linked with Cowden disease, with increased risk of breast, uterine, and thyroid cancer and harbors abnormalities in the PTEN/AKT pathway, consistent with germ line mutation in the PTEN tumor suppressor gene in Cowden disease.

Dysembryoplastic Neuroepithelial Tumor

Dysembryoplastic neuroepithelial tumor (DNT) is a rare, low-grade (WHO grade I) mixed neuronal and glial tumor often associated with intractable seizures in children and young adults. DNTs comprise up to 17% of underlying diagnoses in epilepsy surgery series. Cortical dysplasia is found in 30% of cases. Enhancement on MRI is patchy and multifocal; perfusion-weighted MRI and MRS may aid in diagnosis. Unlike other epilepsy-associated glioneuronal tumors, where seizures arise within the lesion, seizures associated with DNT are considered to arise from the surrounding dysplastic brain; thus, extended resection is preferred over lesionectomy alone. Risk factors for recurrent seizures include age older than 10 years and epilepsy duration more than 2 years prior to diagnosis.

ASTROCYTOMAS

Low-Grade Astrocytomas

Low-grade astrocytomas (WHO grades I and II) include superficial lesions in the cerebral or cerebellar cortex and deeper infiltrative lesions of the optic pathways and midbrain. *Cerebellar astrocytomas* constitute about one-third of posterior fossa tumors. The peak incidence is early in the second decade. These tumors arise most often in the lateral cerebellar hemispheres rather than in the vermis. Symptoms of clumsiness and unsteadiness may be present for months and eventually are accompanied by intermittent morning headache and vomiting. Midline lesions have a shorter symptom interval. Truncal ataxia, dysmetria, and papilledema are usually present at diagnosis. Head tilt may be present, but other cranial nerve palsies or long-tract signs are infrequent and suggest brain stem invasion. Cerebellar astrocytomas may be primarily cystic or solid, and cystic lesions may have a nodule (Fig. 145.4). The typical juvenile pilocytic astrocytoma (WHO grade I) contains areas of compact fibrillated cells with microcysts and eosinophilic structures called *Rosenthal fibers*. These lesions have greater than 90% survival with surgery alone. The tumor and associated cyst should be removed completely, and if residual tumor is identified postoperatively, resection should be considered, as irradiation will not delay tumor progression. Diffuse astrocytomas (WHO grade II) may infiltrate the brain stem and be more difficult to resect entirely, with more guarded prognosis for survival.

Cerebral hemisphere low-grade gliomas have a peak incidence between ages 2 and 4 years and again in early adolescence. In toddlers, there may be symptoms of increased ICP, developmental delay, and growth retardation and specific signs such as weakness, sensory loss, or vision deficit. These slow-growing pediatric tumors are far less likely than adult gliomas to undergo malignant degeneration. They are infiltrating, however, and may cause seizures, either generalized or focal, the latter particularly suggestive of an occult brain tumor such as a ganglioglioma.

CT often reveals a relatively homogeneous, low-density, variably enhancing lesion with indistinct margins. MRI is more sensitive, showing decreased T1- and increased T2-weighted signal and providing better resolution of tumor and edema. Fibrillary astrocytomas (WHO grade II) are the most frequent histologic variant; protoplasmic and gemistocytic variants are less common. Gross total resection often affords long-term disease control but may not be curative. Five-year survival rates are 75% to 85%. Radiation therapy at doses of 50 to 55 Gy may be given postoperatively following incomplete resection or at progression at least in older children but reoperation should also be considered. For younger children with residual or recurrent tumor, chemotherapy (e.g., vincristine and

carboplatin) has been used in an attempt to defer radiotherapy, and prospective trials evaluating this approach are in progress.

FIGURE 145.4 MRI showing lateral location of a partly cystic, partly solid cerebellar astrocytoma.

Diencephalic and optic pathway gliomas constitute up to 5% of childhood CNS tumors. Unilateral optic nerve tumors are generally diagnosed in the first decade of life, and optic chiasm tumors tend to present either in infancy or the second decade. An association with NF-1 is present in 50% to 70% of patients with isolated optic nerve tumors and 10% to 20% of patients with optic chiasm tumors. Adolescents are more likely to complain of slowly progressive vision loss. Infants are more likely to be evaluated because of strabismus, nystagmus, or developmental delay. Patients with contiguous optic nerve involvement usually present with proptosis and optic pallor or atrophy. Intraorbital lesions usually cause decrease in central vision, whereas chiasmatic tumors produce bitemporal hemianopic field cuts. Nystagmus may be present in the more involved eye, and amblyopia is common. With routine MRI of NF-1 patients, lesions may be detected before onset of symptoms. There may be endocrine disturbances, such as growth deceleration, precocious puberty, and diencephalic emaciation.

Thalamic lesions may cause acute hemiparesis or hemisensory loss, signs of increased ICP, seizures, or involuntary movements. Infants tend to have macrocephaly, psychomotor delay, and vision deficits. Hypothalamic tumors have insidious onset and may be associated with altered mental status, endocrine dysfunction, and focal neurologic deficits.

On CT or MRI, diencephalic gliomas are hypo- or isodense lesions with variable contrast enhancement. Larger lesions may be cystic (Fig. 145.5A and B). Visual pathway tumors may be confined to the optic chiasm (Fig. 145.6A and B) or may show abnormal enhancement along the optic tracts and radiations. This streaking phenomenon is best appreciated on MRI, particularly with FLAIR sequence. Most diencephalic tumors are low-grade pilocytic astrocytomas.

An increasingly recognized variant in infants and young children is pilomyxoid astrocytoma (WHO grade II), which is locally aggressive. Thalamic tumors are often fibrillary astrocytomas, which can also be locally aggressive. The natural history of these lesions is unpredictable. Spontaneous regression has been noted. An increased MIB-1 labeling index identifies the more aggressive pilocytic astrocytomas. Visual pathway tumors have a particular tendency to spread to contiguous structures. The role of surgery is unclear.

FIGURE 145.5 Coronal (A) and sagittal (B) MRIs of a large hypothalamic glioma.

Low-grade astrocytomas of the optic pathway, thalamus, and hypothalamus are generally unresectable. In patients with diffusely infiltrating lesions, especially with NF-1, diagnosis may be confirmed with near certainty on neuroimaging alone, and surgery may be deemed of little benefit. In patients with unilateral blindness, surgery may be recommended for treatment of a severely proptotic eye. However, if some vision persists, local radiotherapy may be recommended. Radiotherapy at doses of 45 to 55 Gy generally reverses tumor progression in nearly all patients and stabilizes or improves vision in most. There may be apparent tumor enlargement at 6 to 12 weeks as a transient effect of the radiation. Patients with very large lesions may benefit from preliminary surgical debulking.

The major disadvantages of radiotherapy are adverse endocrine and neurocognitive effects, especially in younger children. Chemotherapy (based on vincristine and carboplatin) has been beneficial as initial treatment in younger children who have progressive optic pathway and hypothalamic/chiasmatic gliomas, delaying the need for radiotherapy by a median of 4 years; most eventually relapse, however, except for NF-1 patients who tend to have indolent disease. The same chemotherapy regimen has been advocated as initial treatment for infants with tumor-associated diencephalic syndrome of emaciation. Overall survival for optic pathway gliomas exceeds 85% at 10 years but is less than 50% for thalamic lowgrade gliomas and considerably worse for high-grade (especially bithalamic) astrocytomas.

Several chemotherapy regimens are active in pediatric lowgrade astrocytomas. Two regimens were compared in a Children's Oncology Group study for recurrent/progressive or symptomatic tumors: carboplatin + vincristine (CV) and thioguanine + procarbazine + lomustine (CCNU) + vincristine (TPCV). Fiveyear event-free and overall survival rates across all tumor locations were 45% and 86%, respectively, with slightly better event-free survival (EFS) with TPCV and inferior survival with tumor location in the thalamus. A regimen of weekly vinblastine shows comparable activity, even in patient previously treated with CV or TPCV. A regimen of cisplatin and etoposide is

FIGURE 145.6 Sagittal (A) and coronal (B) MRIs of an optic pathway tumor.

Based on frequent occurrence of *BRAF* mutations in pilocytic astrocytomas, *BRAF* inhibitors are being tested in children with tumor progression. Because of histologic evidence of vascular proliferation in recurrent low-grade astrocytomas, treatment with antiangiogenic agents such as bevacizumab and lenalidomide has also been explored. Of interest, treatment of children with optic pathway gliomas with bevacizumab produced marked recovery of vision in addition to response on MRI. Experience with sorafenib, a multikinase inhibitor of *BRAF*, *VEGFR*, *PDGFR*, and *c-kit*, provides a cautionary note, however, as treatment with sorafenib produced unexpected acceleration of tumor growth, perhaps by paradoxical *ERK* activation. The best example of successful targeted therapy is *subependymal giant cell astrocytoma* (SEGA), a low-grade glioma typically arising in individuals with tuberous sclerosis. SEGAs bear mutations in *TSC1* and *TSC2* genes and have dysregulated activation of *mTOR* signaling. An *mTOR* inhibitor, everolimus, showed substantial activity in patients with unresectable SEGAs.

High-grade Astrocytomas

High-grade astrocytomas account for about 10% of brain tumors in children and include anaplastic astrocytoma, oligodendroglioma, and oligoastrocytoma (WHO grade III) and glioblastoma multiforme and gliosarcoma (WHO grade IV). The WHO classification emphasizes degree of cellularity, nuclear and cellular pleomorphism, mitosis, endothelial proliferation, and necrosis. In general, *anaplastic astrocytomas* are composed of astrocytes with increased cellularity, pleomorphism, and numbers of mitoses. There may be focal necrosis, but it may not be so extensive as to form pseudopalisades. In contrast to low-grade pilocytic tumors, anaplastic astrocytomas have an unstable vasculature, with a predominance of immature vessels distinguished by negative immunostaining for α -SMA. Vascular endothelial growth factor and anti-*flt-1/VEGF receptor-1* immunoreactivity was detected in anaplastic astrocytomas but not pilocytic astrocytomas. *Glioblastoma multiforme* has prominent vascular proliferation and a pseudopalisading pattern of necrosis. Cytogenetic analyses developed mainly of tumors from adults has shown consistent chromosomal abnormalities in all tumor grades; however, one aberration—the loss of part or all of chromosome 10—has been specifically associated with glioblastoma multiforme, and amplification and rearrangement of the *EGFR* gene have also been associated with malignant histology. Gene profiling shows overexpression of hypoxia-inducible transcription factor (*HIF*)-2 α and FK506-binding protein (*FKBP*) 12-associated genes, including *EGFR* and insulin-like growth factor-binding protein 2.

Prognosis in high-grade astrocytomas is quite guarded compared to low-grade astrocytomas. Common symptoms of cerebral cortical high-grade astrocytomas include headache, vomiting, seizures, motor weakness,

and behavioral abnormalities. Cerebellar lesions may present with ataxia. Symptom duration is generally less than 3 months. Diagnosis is made by CT or MRI. Surgery is important for diagnosis and for removing tumor; major resection improves survival. However, these infiltrative tumors may disseminate in the CSF and will almost certainly recur without further therapy. Postoperative involved-field irradiation (59 to 60 Gy) and adjuvant chemotherapy both increase survival. Adjuvant vincristine plus lomustine was somewhat effective in CCG-943 and CCG-945, but survival rates remained below 35%. Chemotherapy prior to or with radiation therapy may contribute to survival in patients undergoing complete tumor resection. Temozolomide with and following radiation therapy has become standard treatment for adult GBM, yielding 26% 2-year survival, and this regimen appears to have comparable efficacy in children (ACNS0126). Survival is influenced by extent of tumor resection and by histology (e.g., anaplastic astrocytoma vs. glioblastoma multiforme).

Bevacizumab/irinotecan has been the first-line salvage therapy as in adults. High-dose chemotherapy with autologous stem cell rescue afforded occasional long-term survival in recurrent patients with minimal residual tumor following surgical debulking.

Brain Stem Gliomas

Brain stem gliomas are a heterogeneous group. The diffuse, intrinsic pontine lesions carry the worst prognosis of any childhood brain tumor. In contrast, small, intrinsic, tectal gliomas are indolent and may be managed conservatively. Brain stem tumors constitute 10% to 20% of posterior fossa tumors, with a peak incidence at ages 5 to 8 years. Most arise in the pons, and there may be contiguous spread to the medulla or midbrain. Despite the clinical aggressiveness of these tumors, the histologic appearance at initial diagnosis is quite variable, but at autopsy, most show anaplastic features. This may reflect sampling error at initial biopsy or subsequent malignant transformation. These tumors infiltrate the brain stem and compress normal structures while extending superiorly and inferiorly to produce diffuse enlargement of the brain stem. DIPGs are nearly uniformly fatal within 18 to 24 months. Some tumors extend ventrally, laterally, or posteriorly, and the primarily exophytic

P.1278

tumors tend to be more accessible to surgical resection and carry a better prognosis as do focal midbrain lesions.

FIGURE 145.7 A: Sagittal MRI of a diffuse brain stem glioma. **B:** Axial image showing infiltration of the medulla.

The course is insidious with slowly progressive cranial neuropathy, motor symptoms and disturbance of gait,

swallowing, and speech. Vomiting and headache indicate the presence of hydrocephalus, which is generally a late finding. Children with dorsal exophytic lesions may have more unsteadiness and less evidence of cranial nerve dysfunction. CT shows a low-density lesion in the brain stem, with compression and obliteration of surrounding cisterns but little if any contrast enhancement. Uncommonly, brain stem tumors may be isodense or hyperdense with cystic areas. MRI is preferred because of the detail appreciated on sagittal images typically revealing more extensive disease than appreciated on CT. The magnetic resonance (MR) appearance is of decreased signal intensity on T1-weighted images (Fig. 145.7A) and increased T2-weighted signal. Ring enhancement with contrast administration is prognostically unfavorable. MRI may also demonstrate infiltration of the medulla (Fig. 145.7B) or thalamus.

Given the accuracy of MR diagnosis, the morbidity of surgery, and the variable prognostic impact of biopsy, it has been accepted that surgery is not warranted for most patients with diffuse intrinsic pontine lesions, in whom major resection when attempted has not improved survival. Biopsy may be offered in the context of research protocols accruing tissue samples for molecular studies. Patients with exophytic, cervicomedullary tumors are more likely to benefit from surgery as are patients with atypical clinical courses or MR findings (e.g., symptom duration exceeding 6 months, absence of cranial nerve findings primarily exophytic or focal ring-enhancing lesions). Children younger than age 3 years may fare better. Standard treatment is field-radiation therapy except for completely resected focal lesions. Most children with brain stem gliomas benefit at least transiently from radiation therapy to a dose of 54 to 56 Gy. Although leptomeningeal dissemination may occur, the main risk is for local recurrence. Median survival is only 9 to 12 months with 3-year survival of 13%. Chemotherapy (including temozolomide and topotecan) and immunotherapy (such as β -interferon) have been unsuccessful in this condition, although new agents continue to be studied. Novel approaches include use of the histone deacetylase inhibitor vorinostat or the prodrug capecitabine with and following radiation therapy or regional tumor treatment by convection-enhanced delivery of drugs and immunotoxins. Determination of responses is complicated by interobserver variability in tumor measurement; the most consistent results are derived from FLAIR images. It has been suggested that clinical trials should incorporate other objective end points, such as survival, rather than radiologic response alone. Children with brain stem tumors should be monitored for signs of hydrocephalus because CSF diversion by shunting or third ventriculostomy can improve quality of life.

Spinal Cord Astrocytomas

Spinal cord astrocytomas account for about 4% of childhood CNS neoplasms. Other primary spinal cord tumors in children include gangliogliomas and ependymomas. Spinal high-grade astrocytomas and PNETs are uncommon. Astrocytomas may occur in any part of the cord but are seen most often in the cervical region, with the solid component extending an average of five spinal segments. Most have benign histologic appearance and grow slowly. Symptoms and signs may include pain (i.e., localized or radicular), weakness or spasticity, gait disturbance, and bowel or bladder dysfunction. Gadolinium-enhanced MRI is preferred for demonstrating the location of the solid tumor, associated cysts, and edema. Treatment may be attempted gross-total or near-total resection or partial resection with decompression of cysts with postoperative radiotherapy.

The degree of neurologic recovery depends on the preoperative condition of the patient. A potential complication is spinal deformity, resulting from laminectomy, radiotherapy, or both. About one-third of patients require a spine stabilization procedure. For children with low-grade tumors, survival rates of 55% at 10 years have been reported after partial resection and radiotherapy. Chemotherapy has been substituted for radiotherapy in very young children. The prognosis for children with high-grade tumors is worse, although 5-year progression-free survival (PFS) of 46% was reported in a study using combined radiation therapy and chemotherapy.

EMBRYONAL TUMORS

Medulloblastomas and Primitive Neuroectodermal Tumors

Medulloblastoma and supratentorial (PNETs) collectively are the most common malignant CNS tumors of childhood. Most PNETs arise in the posterior fossa and are specifically called

P.1279

medulloblastomas. Posterior fossa and supratentorial PNETs are histologically identical (WHO grade IV) and have similar epidemiologic profiles but distinct biologic properties. The incidence of medulloblastoma/PNET before age 20 years rose by 23% from 1973 to 1977 to 1993 to 1998.

As described earlier, the presumed cell of origin of *medulloblastoma* is derived from fetal external granular cells of the cerebellum or rests in the posterior medullary velum. These tumors account for about 30% of infratentorial tumors in children but are uncommon in adults. Medulloblastomas typically involve the cerebellar vermis, grow to fill the fourth ventricle, and may infiltrate the floor of the ventricle and adjacent structures. The tumor may arise more laterally, especially in older patients.

Supratentorial PNETs generally arise in the cerebral cortex or pineal region. These lesions appear to originate from the germinal matrix of the primitive neural tube. Most are diagnosed before age 10 years.

“Classic” medulloblastoma has the histologic appearance of a small, round, blue cell tumor with a diffuse pattern of poorly differentiated cells. Neuroblastic (“Homer-Wright”) rosettes may be present but are not required for diagnosis. Immunohistochemical staining is typically positive for synaptophysin and occasionally for neurofilament protein or GFAP, although the latter usually represents reactive intratumoral astrocytes. Desmoplastic/nodular (D/N) medulloblastoma typically arises in cerebellar hemispheres and is characterized by nodular islands of differentiating neuroblasts; an “extensively nodular” variant is recognized in infants. Large cell/anaplastic (LCA) medulloblastoma vaguely resembles large cell lymphoma, with large neoplastic cells having vesicular nuclei and prominent nucleoli. Most medulloblastomas fall between these histologic extremes, but one-quarter exhibit at least moderate anaplasia and an associated, aggressive clinical behavior. In infants, medulloblastoma must be distinguished from ATRT, which has a small cell component resembling medulloblastoma but also cords of cells in a mucinous background that resemble chordoma, with a rhabdoid appearance of the cytoplasm of the larger cells.

A specific chromosome abnormality, isochromosome 17q (i.e., duplication of the long arm or deletion of the short arm of chromosome 17), is seen in one-third of cases of medulloblastoma. This could result in inactivation of a tumor suppressor gene, which is located on chromosome 17 but is distinct from *p53*. It is unclear whether chromosome 17p deletions impart poor prognosis, but diploid tumors have worse outcome than aneuploid or hyperdiploid tumors.

It is now apparent that medulloblastomas comprise at least four distinct subtypes based on aberrant activation of signaling pathways regulating cerebellar development or oncogene amplification: (1) WNT tumors (named for *Drosophila wingless*) with classic histology and very good prognosis; (2) Shh tumors (named for sonic hedgehog), relatively more common in infants and adults, with D/N histology and intermediate prognosis (good in infants); (3) “group 3” tumors with overrepresentation of LC/A histology, MYC amplification, very frequent metastasis, and poor prognosis; and (4) “group 4” tumors with classic histology but tendency for metastasis, occasional MYCN amplification, and intermediate prognosis. Immunohistochemical correlations are nuclear positivity for β -catenin in WNT tumors, GAB1 positivity in Shh tumors, and filamin A and YAP1 positivity in both. Correlation with cytogenetic findings shows isochromosome 17q to be typical of group 3 and 4 tumors, monosomy 6 associated with WNT tumors, and 9q and 10q deletion in Shh tumors. Profiling six FISH biomarkers (GLI2; MYC; and chromosomes 11, 14, 17p, and 17q) reliably identifies very low-risk and very high-risk patients within Shh, group 3, and group 4 medulloblastomas.

Exome sequencing has revealed subtype-specific somatic mutations in known medulloblastoma-related genes (CTNNB1, PTCH1, MLL2, SMARCA4) and genes not previously considered medulloblastoma-related (DDX3X,

CTDNEP1, KDM6A, TBR1). In particular, mutant DDX3X potentiates transactivation of a TCF promoter and enhances cell viability in combination with mutant β -catenin. Growth factor-independent 1 family protooncogenes GFI1 and GFI1B have been identified as oncogenic drivers for group 3 and 4 tumors, an example of “enhancer hijacking” wherein coding sequences are juxtaposed proximal to active enhancer elements. Epigenetic alterations also contribute to medulloblastoma tumorigenesis, including highly prevalent regions of hypomethylation correlating with increased gene expression.

Relatively less is known about the cytogenetic and molecular features of supratentorial PNETs, but gene expression analysis shows distinct patterns of gene activation that differ from those of medulloblastoma. Three molecular subgroups have been proposed based on differential expression of cell lineage markers LIN28 and OLIG2: (1) primitive neural (younger females with poorest survival), (2) oligoneural (older males with best survival), and (3) mesenchymal (older males with highest incidence of metastatic disease and intermediate survival). A high-level amplicon involving the chr19q13.41 microRNA cluster (C19MC) identifies an aggressive subgroup of CNS PNET with distinct gene expression profiles and poor survival. ATRTs have monosomy or deletion of chromosome 22, and inactivating mutations of the hSNF5/INI-1 gene at 22q11.2 are considered fundamental to pathogenesis. Loss of chromosome 19 has been reported in ATRT.

Children with medulloblastoma typically have symptoms of increased ICP (e.g., vomiting, lethargy, morning headache), unsteadiness, and diplopia. The median age is 5 years. Symptom duration is generally of less than 3 months. There may be recent onset of head tilt resulting from ophthalmoparesis or incipient cerebellar herniation. Laterally situated lesions present slightly differently with symptoms of cerebellopontine angle disturbance or limb ataxia. These tumors appear isodense or hyperdense on CT and usually enhance homogeneously. Hydrocephalus is seen in more than 80% of patients. Other CT features include small cysts, calcification, and hemorrhage. Children with supratentorial PNET present with headache and vomiting due to increased ICP; infants may have lethargy, irritability, and an enlarging head circumference.

MRI may give better indication of tumor extent (Fig. 145.8A) and possible leptomeningeal dissemination (Fig. 145.8B and C). MRI is also preferred to facilitate evaluation of disseminated spinal tumor, which is found in up to one-third of patients with medulloblastomas. Aggressive surgical resection is recommended for medulloblastoma/PNET. Surgery achieves complete or near-complete resection of medulloblastomas in most cases, limited mainly by tumor infiltration of the fourth ventricle, the brain stem, or one of the cerebellar peduncles. Morbidity may include the posterior fossa syndrome of aseptic meningitis or, less commonly, of mutism, pharyngeal dysfunction, and ataxia. Preoperative ventriculoperitoneal shunting is not done routinely owing to the risk of upward herniation and because hydrocephalus will be relieved by tumor removal in most patients. About 30% to 40% of patients require permanent shunting.

Postoperative CT or MRI is indicated to confirm the extent of resection, and this study should be done within 48 hours when there is less edema than later. Patients with medulloblastoma may be stratified clinically as *average risk* (i.e., localized posterior fossa

P.1280

medulloblastoma with no more than 1.5 cm² postoperative residual tumor) and *high risk* (i.e., more than 1.5 cm² residual or dissemination outside the posterior fossa, including positive CSF cytology). LC/A medulloblastomas are also categorized as high risk, even if localized and completely resected, because of more aggressive behavior. Average-risk children have 80% 5-year diseasefree survival. High-risk children have approximately 65% 5-year survival. Infants younger than age 3 years have inferior outcome and are considered high-risk patients even with localized tumors; an exception appears to be Shh tumors in infants for whom deescalation of therapy may be considered.

FIGURE 145.8 Sagittal MRI of a medulloblastoma in the posterior fossa (A) with (B) coronal image showing parenchymal nodules and (C) spine images showing seeding of the cord.

Radiation therapy is the standard postoperative treatment for medulloblastoma/PNET, and craniospinal irradiation is given because the entire neuraxis is at risk for tumor recurrence. Conventional doses are 36 Gy to the brain and spine, with an 18- to 20-Gy boost to the local tumor site. Adjuvant (postirradiation) chemotherapy with vincristine and lomustine was shown to improve survival in advanced stages of medulloblastoma; the addition of cisplatin afforded a remarkable 5-year PFS rate of 85% in one series. Preirradiation chemotherapy did not improve survival. Accordingly, adjuvant chemotherapy was introduced for average-risk patients, and the combination of reduced neuraxis irradiation, followed by vincristine, lomustine, and cisplatin chemotherapy (COG A9961), resulted in a 5-year PFS rate of 79%. Even better outcomes have been reported with dose-intensive adjuvant cyclophosphamide-based adjuvant chemotherapy with hematopoietic stem cell support in both average- and high-risk patients. With recognition of the four subtypes of medulloblastoma, it may be possible through preclinical testing to identify chemotherapeutic agents with selective effectiveness against particular subtypes. For example, screening murine group 3 medulloblastomas against a library of 7,000 compounds in a high-throughput cell-based assay revealed synergistic antitumor activity of pemetrexed and gemcitabine as

combination therapy in group 3 tumors overexpressing MYC.

Chemotherapy has also been used preoperatively (following control of hydrocephalus and diagnostic biopsy), and in particular as primary postoperative treatment in infants, to avoid radiotherapy. Current protocols for infants up to age 3 years use this approach, with increasingly intensive regimens (some requiring autologous hematopoietic stem cell support) to enhance the response rate to chemotherapy and to improve the control of leptomeningeal disease. Based on favorable results, the upper age for this approach has been extended to 5 to 6 years. Early tumor progression on chemotherapy has remained a major problem. Addition of high-dose methotrexate to cisplatin-based chemotherapy for young children with newly diagnosed disseminated medulloblastoma (including autotransplant consolidation) resulted in a high response rate and 49% 3-year event-free survival. Some protocols for older infants

P.1281

combine local tumor irradiation (i.e., using confocal techniques) and chemotherapy, either conventional or high dose (with autologous stem cell rescue). Another strategy has been to incorporate intraventricular methotrexate with systemic chemotherapy, avoiding irradiation.

The combination of temozolomide and irinotecan appears active in recurrent medulloblastoma, as does oral etoposide, although overall prognosis after recurrence remains guarded. Recurrence tends to be local in Shh medulloblastoma and metastatic in group 3 and 4 tumors. Targeted therapy with agents such as Shh inhibitors is under investigation. High-dose chemotherapy with hematopoietic stem cell rescue has been used for selected patients with recurrent medulloblastoma who remain chemotherapy sensitive. Increasing pursuit of targeted therapy may be anticipated following successful treatment of a young adult with Shh-driven medulloblastoma with the hedgehog pathway inhibitor GDC-0449 and demonstration of antitumor activity of vismodegib in a child with Shh medulloblastoma.

Supratentorial PNETs are histologically equivalent to medulloblastoma and have been treated with the same approach of resection, craniospinal irradiation, and chemotherapy. Prognosis is worse for these patients, however, with only 40% 5-year survival. A primary postoperative chemotherapy approach in infants and young children resulted in similar outcome without radiotherapy in the majority of patients. As with medulloblastoma, preirradiation chemotherapy seems to compromise survival. Hyperfractionated radiotherapy with cisplatin-based maintenance chemotherapy (HIT 2000) afforded 58% 5-year survival. Pineal region PNETs (i.e., pineoblastomas) have a better outcome than nonpineal supratentorial PNET, approximately 70% 5-year eventfree survival, although very young children may do worse. Pineoblastomas must be distinguished from pineal germ cell tumors (see later discussion) and pineocytomas (benign pineal parenchymal tumors treated by surgery alone or with radiotherapy).

Embryonal tumor with multilayered rosettes (ETMR) include three histologic variants with uniform molecular signatures (LIN28A positive, C19MC mRNA amplification, and trisomy 2). *Ependyoblastoma* is an aggressive (WHO grade IV) PNET variant of infants and young children arising in cerebral cortical and paraventricular sites and associated with hydrocephalus and poor outcome. Radical resection, craniospinal irradiation, and/or high-dose chemotherapy with autologous stem cell rescue may offer prolonged survival. *Embryonal tumor with abundant neuropil and true rosettes* (ETANTR) also occurs in young children presenting as a supratentorial mass with increased ICP; prognosis is poor despite multimodality therapy. *Medulloepithelioma* is an aggressive cerebral hemispheric tumor of infants and young children showing a range of differentiation from embryonal primitive neuroepithelioma to mature cells. Outcome is generally poor, although medulloepithelioma arising in the eye or orbit may be cured by gross total resection.

Central neurocytoma is a WHO grade II neuroepithelial intraventricular tumor typically presenting in older children or young adults with hydrocephalus and occasionally seizures. Variants include cerebral (extraventricular) neurocytoma and ganglioneurocytoma (with ganglion cell differentiation. Histologic appearance

may resemble oligodendroglioma. Surgical resection is curative.

Atypical Teratoid/Rhabdoid Tumors

CNS ATRT is a rare, highly aggressive embryonal tumor of infants and young children accounting for up to 20% of cases in some infant series. ATRT is associated with somatic mutations of the tumor suppressor gene *INI1/hSNF5* on chromosome 22q11, part of the SWI/SNF chromatin remodeling complex. This gene is also mutated in renal rhabdoid tumors, and germ line mutations have been reported in patients with multifocal tumors. Outcome with conventional chemotherapy has been poor (median survival <12 months), but 2-year PFS of 53% was achieved with surgery, radiation therapy, and parenteral and intrathecal chemotherapy based on the Intergroup Rhabdomyosarcoma Study III. Better outcome has been associated with older age, localized presentation, and gross total resection. Addition of myeloablative chemotherapy with autologous stem cell rescue resulted in inferior outcome but demonstrated the possibility of long-term survival without irradiation.

EPENDYMOMAS

Ependymomas are glial neoplasms typically arising within or adjacent to the ependymal lining of the ventricular system, most often in the posterior fossa. Ependymomas constitute 5% to 10% of all primary childhood brain tumors. Most appear to be histologically mature (WHO grade II). Variants include anaplastic ependymoma (WHO grade III), which carries a worse outcome in some series, and the clinically indolent subependymoma and myxopapillary ependymoma (WHO grade I).

Simian virus 40-related DNA sequences have been demonstrated in ependymomas and choroid plexus carcinomas suggesting a viral etiology. Cytogenetic and molecular studies of childhood ependymomas have revealed isochromosome 1q as an early genetic event, as well as rearrangements or deletions of chromosomes 6, 17, and 22. Human telomere reverse transcriptase (hTERT) expression predicts tumor progression. Tumor-derived stem cells show a radial glia phenotype with gene expression patterns corresponding to radial glia cells from anatomically distinct compartments of the CNS. Posterior fossa ependymomas exhibit a CpG island methylator phenotype (CIMP); transcriptional silencing of differentiation genes is driven by CpG methylation. Transcriptional profiling of posterior fossa ependymoma reveals two demographically, genetically, and clinically distinct groups: (1) younger patients (median age 2.5 years) with laterally located tumors with balanced genome, tendency for metastatic recurrence, and poor PFS (18% at 5 years) versus (2) older patients (median age 20 years) with higher degree of tumor genomic instability and cytogenetic aberrations but much better EFS (91% at 5 years).

Clinical symptoms depend on tumor location. Children with ependymomas filling or compressing the fourth ventricle have obstructive hydrocephalus with nausea, vomiting, and morning headaches. Tumors arising low in the fourth ventricle and extending into the lower medulla may cause neck pain, whereas cranial nerve palsies may result from brain stem invasion or compression of cranial nerves. In patients with supratentorial lesions, seizures and focal deficits are seen. Features on CT include calcification and variable enhancement. MRI will better demonstrate invasion by posterior fossa lesions into the brain stem ([Fig. 145.9](#)) or upper cervical spinal cord.

The most important predictor of outcome in these cases is the extent of surgical resection as confirmed by postoperative imaging. Successive clinical trials for ependymoma show that the rate of complete resection has increased from 50% to 75%. Resectability of posterior fossa lesions may be limited by brain stem infiltration, extension into the cerebellar pontine angle, or involvement of cranial nerve nuclei. Supratentorial lesions may also be infiltrative and difficult to remove. Gross total resection of ependymomas followed by involved-field irradiation (tumor bed with 1-cm margin)

affords up to 75% survival, whereas local recurrence is the rule following subtotal resection, and survival rates drop below 30%. Patients with tumor dissemination at diagnosis (fewer than 10% of cases) also do poorly.

FIGURE 145.9 MR appearance of an ependymoma showing tumor extension through the foramen of Luschka (*arrow*) and invasion of the brain stem.

Postoperative radiation therapy increases survival rates for patients with localized ependymoma, and treatment to an involved field (at a dose of 55 Gy) is generally considered sufficient because relapses are overwhelmingly local. Completely resected supratentorial nonanaplastic ependymomas may be observed without radiation therapy.

Adjuvant chemotherapy may improve outcome based on the responses of recurrent ependymomas to cisplatin and other agents and responses in infants. Preirradiation cisplatin-based chemotherapy for patients with postoperative residual tumor (CCG-9942) produced objective responses in 57% of patients, and 5-year eventfree survival of patients receiving chemotherapy for incompletely resected tumors equaled that of patients with complete resection and no chemotherapy (55% vs. 58%). A successor study (ACNS-0831) randomizes all patients to postradiation chemotherapy versus radiation alone.

Primary postoperative chemotherapy with irradiation at progression has been reported in children younger than age 5 years with 59% 4-year survival (23% without irradiation). A similar study in children younger than age 3 years found 61% survival at 3 years leading to a larger study (POG-9233/34) demonstrating that with prolonged dose-intensive chemotherapy, 40% of infants with ependymoma could be cured without radiotherapy. Recurrent ependymomas are managed by resection and chemotherapy or by stereotactic radiosurgery.

Prospects for targeted therapy focus on histone deacetylase inhibitors, gamma secretase inhibitors (blocking notch signaling pathway activation), telomerase inhibitors (in hTERT-positive ependymoma), and lapatinib (a dual EGFR antagonist). Potential predictive biomarkers were analyzed prospectively in an Italian cooperative group trial; better outcome was associated with lower hTERT mRNA expression and nucleolin protein

expression; mRNA expression levels of EGFR and prominin 1 (PROM1)/CD133 were not significant on multivariate analysis, although the PROM/CD133 cancer stem cell marker was strongly expressed in a substantial fraction of cases and appeared to be associated with more indolent disease.

GERM CELL TUMORS

Germ cell tumors tend to arise in the pineal and suprasellar regions. They account for about half of all pineal tumors and 5% to 10% of parasellar lesions. Pineal germ cell tumors have a male preponderance and usually present in adolescence, whereas suprasellar germ cell tumors predominate in younger females. About 50% to 65% of germ cell tumors are germinomas, histologically primitive lesions resembling gonadal germ cell tumors and presumably derived from embryonic migration of totipotent germ cells. Teratomas and mixed germ cell tumors are variously composed of mature, immature, and malignant elements. Choriocarcinomas are rare but highly malignant. Chromosomal comparative genomic hybridization analysis of CNS germ cell tumors suggests that genomic alterations are essentially indistinguishable from those found in extracranial germ cell tumors.

Symptoms and signs of pineal region germ cell tumors most often include headaches and Parinaud syndrome of upgaze paresis. With extension to the overlying thalamus, there may be hemiparesis, incoordination, vision disturbances, or movement disorders. Suprasellar germ cell tumors produce pituitary and hypothalamic dysfunctions but usually not vision loss. CT appearance is of an irregular lesion of mixed density, occasionally with calcification and with variable enhancement.

MRI is more sensitive for purposes of follow-up evaluation. MRI may reveal a pineal cyst in otherwise healthy children being evaluated for headache; lack of hydrocephalus and Parinaud syndrome should lead one away from the diagnosis of a pineal tumor. Diagnosis may be aided by measurement of AFP and β -subunit of HCG, which are secreted by germ cell tumors but not pineal parenchymal cell tumors or cysts and are detectable in serum and CSF. AFP is elevated in endodermal sinus tumors and some immature teratomas; HCG is elevated in choriocarcinoma and embryonal carcinomas. Elevations associated with both indicate the presence of mixed malignant elements. Even with tumor marker elevation, however, histologic confirmation is recommended.

Surgery for pineal region tumors is technically difficult, but major resections may be achieved with acceptable morbidity rates by the use of supratentorial suboccipital or infratentorial supracerebellar approaches. Most patients require CSF shunting. There may be transient visual migraines caused by occipital lobe contusions. Teratomas may be encapsulated and are therefore easier to remove. Germ cell tumors may disseminate throughout the neuraxis in up to 10% of cases. Radiotherapy is the standard treatment for pure germinomas given typically as 35 to 45 Gy to the brain and spine with a 10- to 15-Gy boost to the area of the tumor affording 90% survival at 5 years. Chemotherapy may allow reductions in the extent of irradiation potentially lessening the considerable endocrine, neuroophthalmologic, and neuropsychological sequelae of treatment.

Survival rates for mixed malignant germ cell tumors are considerably lower, especially with radiotherapy alone, but have improved with the addition of chemotherapy. Current protocols are based on cisplatin- or carboplatin-containing regimens active in gonadal germ cell tumors; patients achieving a complete response to intensive chemotherapy may receive no further treatment, whereas those with incomplete response undergo second-look surgery or irradiation. Five-year overall survival rates are about 75% and the event-free survival rate is 36%. High-dose chemotherapy with autologous stem cell rescue, an effective strategy in recurrent

P.1283

germinomas, is being tested in refractory mixed malignant germ cell tumors.

LYMPHOMAS

Primary CNS lymphomas are rare, constituting fewer than 1% of intracranial tumors. They may occur at any age and are generally of B-lymphocyte origin, including Burkitt type, often seen with congenital or acquired

immunodeficiency. The tumor location most commonly seen is the cerebral cortex. CNS lymphomas appear isodense or hyperdense on CT with enhancement. MRI shows an iso- to hypointense lesion on T1-weighted images and iso-, hypo-, or slightly hyperintense lesion on T2-weighted images with variable enhancement.

Whole-body ^{18}F -fluorodeoxyglucose positron emission tomography (FDG PET) may reveal extracranial sites of disease not seen on other imaging such as CT scan. Whole-brain irradiation has produced survival rates of 20% to 30%. A prospective trial in immunocompetent adults with primary CNS lymphoma showed that preirradiation, high-dose methotrexate chemotherapy improved survival rates over whole-brain irradiation alone. In addition, there was a 94% objective-response rate to preirradiation chemotherapy, but there was also a 15% incidence of life-threatening, delayed neurologic toxicity. For these reasons, methotrexate- and cytarabine-based chemotherapy without irradiation is now the preferred treatment.

MENINGIOMAS AND MESENCHYMAL TUMORS

Meningiomas are rare in childhood, accounting for 2.5% of pediatric brain tumors. There is an association with NF-2, and this diagnosis should be sought in any child with meningioma. These tumors usually arise on the meningeal surface but (in contrast to adults) may grow as parenchymal lesions presumably from meningeal cell rests. CT and MRI show an isointense or hyperintense lesion enhancing with contrast (Fig. 145.10).

Most lesions are clinically benign, although 10% of pediatric or NF-2-associated tumors show anaplasia and 50% have atypical features. Overall prognosis is worse than in adults. High mitotic index, MIB-1 labeling index, and variant histology (e.g., papillary, clear cell) are associated with invasiveness and adverse outcome. Deletions of NF2, DAL-1, and chromosome 1p and 14q are common. Surgery is the primary treatment. Radiotherapy is of uncertain value but has been used for recurrent tumors, especially after unsuccessful resection. Meningiomas may occasionally involve the leptomeninges, primarily, and these tumors (i.e., meningeal sarcomas) tend to behave aggressively. Treatment has been combined radiation and chemotherapy.

FIGURE 145.10 Axial MRI of a meningioma.

Meningeal sarcomas may extend intracranially from the skull or arise directly from the dura or develop within meningiomas. Treatment includes surgery, radiotherapy, and chemotherapy guided by the particular histologic subtype. *Fibrous histiocytomas* arise from the dura or grow in brain parenchyma. Benign variants are curable by surgical resection, but malignant fibrous histiocytoma has guarded prognosis despite multimodality therapy. *Solitary fibrous tumors* arise from the dura and grow slowly; they are distinguished from fibrous meningioma by immunohistochemical positivity for CD34, vimentin, and Bcl-2. Surgical resection is curative. *Hemangiopericytomas* occur mainly in adults, grow rapidly, and may present with seizures. Local recurrence is a problem, as well as neuraxis spread and extracranial metastasis; radiotherapy and chemotherapy (including antiangiogenic agents) may be useful.

Primary malignant melanomas arise in children as well as adults, usually associated with the meninges (whereas metastatic lesions more commonly involve the brain parenchyma), with gadolinium enhancement on MRI and possible leptomeningeal spread. Most lesions contain melanosomes, and electron microscopy can confirm the diagnosis. Prognosis is poor, and tumors are radioresistant, although newer targeted therapies may supplement surgery. *Meningeal melanocytomas* occur mainly in adults and arise in the posterior fossa or spinal cord. Without complete resection, these lesions may transform to malignant melanoma.

LATE EFFECTS OF TREATMENT AND QUALITY OF LIFE

The health of children surviving brain tumors is generally worse than that of survivors of other childhood cancers. Children with supratentorial astrocytomas or craniopharyngioma have a lower health status index than children with other types of brain tumors. A survey of health-related quality of life in childhood brain tumor survivors found cognitive impairment in two-thirds of the children and pain in almost one-third. Global health status was lowest in children given radiation therapy before age 5 years and in those with residual disease. Even among survivors of pediatric low-grade glioma who continue to have excellent long-term survival into adulthood, the greatest risk of death in multivariate analysis was administration of radiation.

Another survey of residual physical handicap in survivors found motor impairment in 56% of patients, cognitive impairment (i.e., IQ score <80) in 30%, visual impairment in 24%, and epilepsy in 21%.

A study of psychological outcomes in long-term survivors found that the prevalence of psychological distress (11%) exceeded that in siblings (5%) and was not a direct result of cancer treatment but rather was associated with diminished social functioning and vocational skills. Another report found increased risk of hospital admission was the focus for psychiatric disorders among patients with brain tumors who had survived at least 3 years from diagnosis compared to other childhood cancer survivors, in whom there was no increased risk.

RADIATION EFFECTS

Radiation effects include a transient somnolence syndrome of sleepiness, irritability, anorexia, and headaches lasting about a week. Radiation necrosis develops in 0.1% to 5.0% of patients after

P.1284

conventional treatment at 50 to 60 Gy in daily fractions of 180 to 200 cGy. The onset may be within 3 months and is usually seen by 3 years, although occasionally not until much later; the symptoms and signs are those of a recurrent intracranial mass with possible seizures and progressive neuropsychological impairment. Surgical resection should be attempted; unresectable lesions may be treated with corticosteroids, but it may be difficult to reduce the dose later. Cavernous hemangiomas (cavernomas) developed in 3.4% of children at a median of 37 months following radiotherapy for brain tumors. Median age at treatment was 7 years. These benign vascular malformations may cause seizures or hemorrhage. Large-vessel thrombosis is a rare complication of radiation therapy occurring between 2 and 30 years after cranial irradiation. The relative risk of stroke for 5-year survivors of brain tumors was 29.0 compared to sibling controls with dose-dependent increased risk following cranial

irradiation exceeding 30 Gy. Treatment is symptomatic.

ENDOCRINE DYSFUNCTION

Endocrine dysfunction may follow irradiation to the hypothalamus and pituitary. Doses as low as 18 Gy may produce growth hormone deficiency, and doses above 36 Gy may cause hypothyroidism and gonadal dysfunction in more than half of patients. Nearly 40% of brain cancer survivors in the Childhood Cancer Survivor Study were below the 10th percentile for height. Risk factors included age younger than 5 years at diagnosis and radiation therapy to the hypothalamic-pituitary axis. Growth hormone deficiency in the absence of other anterior pituitary hormone deficiencies in children receiving cranial irradiation for posterior fossa tumors suggests growth hormone is the hormone most sensitive to radiation injury. Hypothalamic obesity, a syndrome of intractable weight gain, is an uncommon but serious complication of hypothalamic irradiation at doses exceeding 50 Gy.

Brain tumor survivors are at risk for hypothyroidism as a collateral effect of cranial or craniospinal irradiation. The incidence of hypothyroidism appears to be considerably lower in children receiving hyperfractionated irradiation compared to those receiving conventional once-daily dosing. Precocious puberty has been noted in nearly one-quarter of girls treated with irradiation. Frank adrenal insufficiency is uncommon, but subtle abnormalities in adrenal function may be present particularly in survivors of craniopharyngioma, other sellar tumors, and medulloblastoma. There is also an increased incidence of osteoporosis.

Children should be followed for measurement of linear growth, periodic thyroid function studies, and additional endocrine evaluation if there is precocious or delayed-onset puberty. Growth hormone treatment improves final height in children with growth hormone deficiency after brain tumor therapy. Growth hormone response depends on adequate thyroid function, and thyroid supplementation may be required. In the subset of patients in whom growth was further limited by early puberty, the combination of gonadotrophin-releasing hormone analogs and growth hormone is reported to improve prospects for attainment of target height. A survey of growth hormone replacement therapy in patients with medulloblastoma suggests a trend toward underutilization, despite ample evidence that there is no increased risk of brain tumor recurrence associated with growth hormone therapy. There is, however, evidence of an increase in the already existing risk for second malignant neoplasms in patients previously treated with radiation therapy. This increased risk of second neoplasms in growth hormone (GH)-treated childhood cancer survivors is now listed in the United States labeling for recombinant human growth hormone (rhGH) products.

CARDIOVASCULAR EFFECTS

Cardiovascular late effects in children treated for brain tumors include increased risk of stroke, blood clots, and angina-like symptoms. Late effects are common in those treated with surgery and radiation and higher still in those treated with surgery, radiation, and chemotherapy. Cardiovascular problems may be compounded by restrictive lung disease and cardiotoxicity in recipients of craniospinal irradiation or intensive chemotherapy. Among survivors of childhood brain cancer whose mean age was 26 years and mean posttreatment interval was 16 years, systolic blood pressures and waist-to-hip ratios were higher than controls, as were blood lipid abnormalities. These findings identify dyslipidemia, central obesity, and hypertension as controllable risk factors for cardiovascular disease.

NEUROLOGIC AND OTHER SEQUELAE

Neurologic and neurosensory sequelae in adult survivors of childhood brain tumors include hearing loss, blindness, cataracts, and diplopia. Nearly half of the survivors have coordination problems, and one-quarter have motor control problems after radiation doses of 50 Gy to frontal brain regions. Seizures are reported in one-quarter of patients, especially after radiation doses of 30 Gy or more. Atonic seizures in particular are difficult to control and are associated with pervasive cognitive impairments. Patients treated with surgery alone generally

have no more than minor neurologic impairment that does not interfere with activities of daily living, but one-third have severe ataxia, spastic paresis, visual impairment, or epilepsy.

Radiation therapy is a principal cause of *neurocognitive disorders* in children with CNS tumors. Other factors include acute or chronic increased ICP, tumor mass effect, poorly controlled seizure disorders, hormonal deficits, and complications of surgery and chemotherapy. A neurologic predictor scale has been developed to quantify the influence of the various tumor- and treatment-related risks for neurocognitive problems. Radiologic evaluation of patients treated for medulloblastoma with craniospinal irradiation, with or without chemotherapy, showed reduced volumes of normal white matter, which correlated with full-scale IQ. Neurocognitive problems are more likely in children treated at a young age or with high doses of radiation, especially when applied to cerebral-cortical areas associated with higher functions. The effects may be progressive for years and may include attention deficit, impaired memory, and lowering IQ. In one series, mean observed full-scale IQ was 97.1 for nonirradiated patients and 78.8 for irradiated patients. For children with standard-risk medulloblastoma, hyperfractionated radiotherapy was associated with better executive function than standard radiotherapy without any difference in behavior or quality of life. These children generally require psychological intervention and special education programs.

Chronic neurotoxicity of chemotherapy used in treating CNS tumors includes hearing loss (e.g., especially after cisplatin therapy) and peripheral neuropathy (e.g., with vincristine or occasionally cisplatin and etoposide). Renal impairment and hypertension are associated with cisplatin therapy. Osteopenia is found in half of the children surviving brain tumors, and bone pain may limit physical activity. Chemotherapy may potentiate the deleterious effect of craniospinal irradiation on growth. There is an increased risk (3% to 5%) of second tumors, including meningiomas and sarcomas arising 10 to 20 years after cranial irradiation treatment. Secondary leukemia has been reported after chemotherapy with alkylating agents and etoposide. In a cohort of patients surviving

P.1285

5 years from diagnosis of a CNS tumor, survival estimates were 91% at 10 years and 86% at 15 years; causes of late mortality were PD (58%), second malignant tumor (21%), and medical complications (18%). Among 5-year survivors treated between 1973 and 1998, the risk of second malignant neoplasms is higher for patients treated after 1985, even controlling for radiotherapy, consistent with increased use of intensive chemotherapy in recent years.

Pediatric Brain Injury and Shaken Baby Syndrome

Joshua Cappell

Steven G. Kernie

INTRODUCTION

The still-developing nervous system holds the potential for greater recovery from traumatic brain injury while also carrying the risk of disordered development, dysplasia, and other adverse sequelae. At the same time, mechanical factors may differentiate pediatric from adult injury such as the unfused or less mineralized calvarium and the narrower subarachnoid and sulcal spaces. Pediatric head trauma also differs not only from adult but also within the childhood age spectrum. The mechanisms, including not only the velocity but also the *intentionality*—whether the injury was accidental—strongly affect the severity distribution. Greater impact force, as seen in vehicular (especially unrestrained)-induced injury or nonaccidental injury, skews the distribution toward more severe presentation and worse outcomes.

EPIDEMIOLOGY

Trauma is the major cause of morbidity and mortality in childhood and nervous system involvement is the biggest determinant of severity. Children account for about one-half million incidents of traumatic brain injury (TBI) per year in the United States, a rate disproportionately high for their part of the overall population. Although the mechanisms and circumstances vary across the pediatric age range—with child abuse dominant in infancy and self or mutual violence, vehicular, firearm use, and other high-risk behaviors prevalent in adolescence—it remains true across the pediatric age range that the causes are to a great extent socially influenced rather than purely sporadic and therefore often at least potentially preventable. As such, the reduction of the immense toll of brain injury relies on two distinct approaches: prevention of primary injury and of secondary injury.

The former is an educational and legal as much as medical task. Initiatives such as infant car seats, bike helmets, and statewide abuse recognition and reporting systems are critical components. Although recent public attention to cumulative and late effects of concussion was largely generated by cases of prominent adult athletes, much of the response has been to change practice from middle school through college, the duration of the athletic careers of most of the public.

PATHOGENESIS

The pathophysiology of primary and secondary brain injury is distinct. The primary injury depends on linear and angular velocity, mechanism (penetrating or closed), biomechanical factors (contrecoup injury), trajectory, and compartment. The consequences can be considered based on the tissue impacted. Epidural and subdural bleeds contribute to injury largely due to the pressure they cause by stealing intracranial space. Gray matter architecture can be disrupted in concussion, contusion, or abrasion. Cortical projections and corticocortical connections can be interrupted by penetrating foreign bodies or bone fragments. Less obvious on initial computed tomography imaging but highly influential on outcome is the diffuse axonal injury, the shearing of fiber tracts from torsional forces. Cerebral ischemia due to vascular dissection, occlusion, and thrombosis can be as injurious as force to the parenchyma directly. In intentionally inflicted trauma, multiple mechanisms may have contributed. The injuries of the “shaken baby” can be compounded by impact, partial strangulation, or carotid compression.

Secondary injury encompasses all subsequent deleterious processes at various levels of organization ([Table](#)

146.1). On a macroscopic scale, the pediatric brain is at high risk from loss of volume. As brain growth drives skull growth in childhood and the atrophy of adulthood is not yet present, accommodation of hematoma and cerebral edema (which evolves largely over the first 3 days post injury) is poor. Although the dura and unfused calvarium of the neonate and infant flexibly allows reshaping (as required during parturition), it maintains intracranial volume nearly constant as it is inelastic to outward stretch. Consequently, babies too are subject to severe restriction of the intracranial vault. Pressure can cause herniation, compromise cerebral perfusion pressure globally, or compress adjacent cerebral vessels exacerbating tissue compromise.

TABLE 146.1 Example Mechanisms of Secondary Brain Injury after Trauma

Systemic

Hypoperfusion due to the following:

- Respiratory cause: hypoventilation, airway obstruction, lung injury

- Cardiac causes: commotio cordis, stunned myocardium, arrhythmia

- Vascular cause: hypotension due to hemorrhagic hypovolemia, spinal shock, adrenal injury or insufficiency, dysautonomia, especially associated with delirium

- Electrolyte abnormalities of central cause but with systemic effect (salt wasting, diabetes insipidus [DI], syndrome of inappropriate antidiuretic hormone secretion [SIADH])

Intracranial

- Hypoperfusion due to expanding mass

- Subdural, epidural, parenchymal hematoma (which can be due to loss of clotting factors to systemic injury), hydrocephalus, or swelling of diffuse axonal injury

- Excitotoxicity and energy exhaustion due to seizures

Injury to Intervening and Adjacent Structures

- Carotid occlusion or dissection, poor jugular drainage

- Infection due to penetrating injury, of particular concern with injury to the sinuses

Multiple factors threaten the already wounded cortical tissue. Cerebral autoregulation is less robust after injury, increasing the risk that cerebral perfusion pressure will fall beneath the compensated range. Injury to the

normally well-sealed and precisely regulated blood-brain barrier implies loss of control of the neuronal microenvironment.

At the cellular level, excitotoxicity due to excessive glutamate release, calcium entry, and hyperactivated intrinsic membrane conductances place increased metabolic demands and interfere with cell volume regulation. At the same time, mitochondrial dysfunction and impaired perfusion make the cells less able to meet these increased demands, leading to cell death.

Although overlapping with mechanisms of secondary injury in the adult, the distribution of injury may differ in the child because of incomplete myelination and selective expression of transmitter and voltage-dependent conductances in specific developmental windows.

CLINICAL ASSESSMENT AND TREATMENT

Medical management is directed toward secondary prevention, providing, through optimized care, the best possible outcome obtainable given that an injury has already occurred. This is the medical challenge commonly faced by practitioners in a chain from the first responder to the emergency room and the pediatric intensive care unit (ICU). To date, few modalities are available to promote reversal of injury, and neuroprotection in the strictest sense, of physiologically isolating the brain from systemic changes, remains largely experimental. Consequently, the focus of management in the acute period is on preventing additional injury so that the body may gradually heal itself to the maximum extent to which it is intrinsically capable rather than extrinsically promoting healing.

The mechanisms of potential secondary injury to be intercepted are several: Head trauma is often accompanied by systemic trauma. This in turn can cause brain hypoperfusion at the very moment that the brain is most susceptible to hypoperfusion due to impairment of the usual protective reflexes that ordinarily prioritize the maintenance of cerebral blood flow. Consequently, the highest priority in the acute management of pediatric brain injury is on stabilizing perfusion: providing adequate oxygenation, ventilation, and blood pressure. Hypotension in particular is common due to many mechanisms (see [Table 146.1](#)) and has been shown to be quite deleterious, independent of other factors. It should be combatted aggressively by fluid resuscitation and, as needed, by pressor support and transfusion.

Differences between pediatric and adult TBI are emphasized by improved outcomes when children are treated at pediatric-experienced centers. Direct admission to such a center is superior to secondary transfer.

Although the perception of some practitioners may be that highly specialized elective procedures or workups mandate tertiary care, whereas trauma is the “bread and butter” of community hospitals, studies show to the contrary that not only is trauma experience important but also pediatric-specific experience in particular matters in childhood injury.

As in all cases of pediatric trauma, clinicians must always consider whether the child presenting with TBI has injuries consistent—in both severity and wound age—with the reported mechanism. Infants are most vulnerable both because they are affected at higher rates and because they are unable to recount events. Difficult legal and ethical questions arise often, as many traumas result from poor supervision, raising concern for negligence even when there was no intent to harm. In inadequately explained trauma, a social or home safety screening, involvement of child protection specialist, and discussion with the jurisdictional agency is imperative. Screenings are mandated whenever even a concern has been raised by a presentation not only when there is a high suspicion or certainty. As such, it is most constructive for parents to regard reporting as a chance to assess and mitigate risks rather than an accusation, much less a determination, of criminality. Factors to be considered are shown in [Table 146.2](#).

TABLE 146.2 Considerations In Evaluation of Possible or Suspected Nonaccidental Trauma

- Establish age of injury or injuries and determination of consistency with reported history.

- Social work screen, discuss with child protective services, police, or district attorney's office

- Ophthalmology consult with dilated examination

- Skeletal survey and/or radionuclide study for reactive changes of older, healing bone injury

- Exclude (by clinical findings or lab test) other causes such as coagulopathy, osteogenesis imperfecta, or glutaric aciduria.

SEVERITY GRADATION AND MINOR TRAUMATIC BRAIN INJURY

Patients presenting with a Glasgow Coma Scale (GCS) score of 8 or less (see [Table 46.3](#)) are defined by most studies as having severe head trauma. Patients with a GCS of 14 or 15 are generally regarded as having minor head trauma. This category often overlaps with concussion, defined as a head injury causing transient loss or alteration of consciousness or loss of memory. Increasing evidence that lasting encephalopathy can result from the cumulative effects of even minor head trauma in professional sports has made this a source of greater societal and parental concern. American Academy of Neurology (AAN) guidelines recommend refraining from activities with recurrent injury risk (practice or play) until resolution of concussion and associated symptoms such as headache. American Academy of Pediatrics (AAP) guidelines also recommend “cognitive rest” including reducing academic activities to prevent exacerbation of symptoms. However, there is no evidence supporting this as either necessary or beneficial for recovery.

INDICATIONS FOR HEAD COMPUTED TOMOGRAPHY IMAGING

Several studies have established criteria mandating a head computed tomograph (CT) in infants and children presenting with injury, aiming to eliminate unnecessary scans while assuring that no potentially actionable findings are missed by not scanning. The Canadian Assessment of Tomography in Childhood Head Injury or “CATCH” rule is to scan any child with any of the following: GCS less than 14, suspected open or depressed skull fracture, worsening headaches, or irritability on exam. Application of this rule identified 98% of patients with CT findings of injury and all patients requiring surgical intervention among the 2,043 CTs performed.

The Pediatric Emergency Care Applied Research Network (PECARN) conducted a large study across 25 centers to identify

P.1295

and validate a decision rule to determine necessity of head CT for children (younger than 18 years) presenting with a GCS of 14 or 15 [**Level 1**].¹ Among children younger than 2 years of age, criteria with predictive value were alteration of mental status per examiner *or* not at baseline per parent, presence of nonfrontal scalp hematoma, loss of consciousness longer than 5 seconds, severe mechanism (vehicular, hit by high-velocity object or >3 feet fall), or palpable fracture. Absence of these elements had a predictive value approaching 100% for excluding clinically important injury warranting CT scanning. In the children 2 years or older, validated criteria were any alteration of mental status, *any* loss of consciousness (even <5

seconds), emesis, severe injury (in these meaning vehicular, high-velocity object or > 5 feet fall), signs of basilar skull fracture (Battle's or "raccoon" sign, hematotympanum, or cerebrospinal fluid oto- or rhinorrhea), and severe headache. Absence of these factors was greater than 99% predictive for the absence of a clinically significant injury to be found on imaging, providing a level I evidence basis for decision making.

SEVERE TRAUMATIC BRAIN INJURY

In an effort to improve and standardize the management of severe pediatric TBI, a collaborative literature review was undertaken to assemble evidence-based guidelines. These have recently been updated and are the basis of [Table 146.3](#). Regarding some interventions, large, well-designed trials have been performed, for example, showing that cooling did not show a demonstrable neuroprotective benefit in children, nor did steroids in a large adult trial. In [Table 146.4](#), the order in which interventions are implemented is presented with higher "tiers" offering more aggressive measures for the circumstance that the prior, less invasive tier has failed to adequately control intracranial pressure (ICP). Particular management considerations and evidence are described in the following text.

INTRACRANIAL PRESSURE IN CHILDREN

Normal ICP in children ranges up to 28 cm H₂O corresponding to 20 mm Hg. Elevations of ICP after trauma have been associated with higher mortality in observational studies, especially if elevated ICP has been unresponsive to interventions. Although ICP monitors have not been directly demonstrated to improve outcomes, they do allow the titration of therapies that reduce ICP. Lower ICP, even when achieved by intervention, correlates with better outcome. Consequently, the latest pediatric TBI guidelines include a level III recommendation for the consideration of ICP monitoring in severe TBI. A recent trial in Bolivia and Ecuador directly comparing management with and without the use of ICP monitoring included some adolescents (age older than 13 years). However, the study was not powered to analyze teenagers separately. No corresponding study yet exists for younger children.

Hypothermia as a treatment modality after TBI was carefully evaluated by the Canadian Critical Care Trials Group in the Hypothermia Pediatric Head Injury Trial [**Level 1**].² Two hundred twenty-five children were randomly assigned to either hypothermic therapy 90.5°F, initiated within 8 hours of the injury and maintained for 24 hours or normothermia. No advantage was found for hypothermia, a level I evidence finding (this and other level I designations in the present chapter are based on criteria comparable to the original version of the pediatric severe TBI guidelines, generally corresponding to level II in the second edition). In fact, more hypotension was seen in the hypothermia group with a possible trend toward greater mortality. Whether there exist individual subgroups, such as refractory elevated ICP awaiting decompression,

P.1296

who may benefit, remains uncertain. Meanwhile, routine use of hypothermia cannot be recommended for pediatric TBI.

TABLE 146.3 Best Evidence Management for Severe Traumatic Brain Injury

Invasive pressure monitoring

Use of ICP monitoring may be considered in infants with severe TBI (level III).

Intracranial pressure

Treatment of ICP may be considered at a threshold of 20 mm Hg (level III).

Cerebral perfusion pressure

A CPP threshold of 40-50 mm Hg may be considered. There may be age-specific thresholds with infants at the lower end and adolescents at the higher end of this range (level III).

Advanced neuromonitoring

IF brain oxygenation monitoring is used, maintenance of a partial pressure of brain tissue oxygen >10 mm Hg may be considered (level III).

Hypothermia

Moderate hypothermia (89.6°F to 91.4°F) beginning early after severe TBI and continuing for only 24 h should be avoided (level II). Moderate hypothermia (89.6°F to 91.4°F) beginning early after severe TBI and continuing for 48 h may be considered (level III).

Hyperventilation

Avoidance of severe hypoventilation (<30 mm Hg) may be considered in the 48 h after severe TBI (level II).

Anticonvulsant therapy

Prophylactic treatment with phenytoin may be considered to reduce the risk of early posttraumatic seizures in pediatric patients with severe TBI (level III).

Use of steroids

The use of steroids is NOT recommended to improve outcome or reduce ICP for children with severe TBI (level II).

Sedatives

Etomidate and thiopental may be considered to reduce refractory ICP. For etomidate, risks of adrenal suppression must be considered (level II).

Reimaging

In the absence of neurologic deterioration or increase in ICP, obtaining a routine repeat CT scan >24 h after admission and initial follow-up study may not be indicated for the decisions about neurosurgical intervention (level III).

Hyperosmolar therapy

Hypertonic saline (3%) should be considered for the acute management of severe pediatric TBI associated with intracranial hypertension. The effective dose for acute therapy ranges 6.5-10 mL/kg (level II).

As a continuous infusion the effective dose range is 0.1-1 mL/kg per hour. The minimum dose needed to maintain ICP <20 mm Hg should be used; serum osmolarity should be maintained <360 mOsm/L.

ICP, intracranial pressure; TBI, traumatic brain injury; CPP, cerebral perfusion pressure; CT, computed tomography.

Based on Kochanek P, Carney N, Adelson PD, Wong H, et al. Guidelines for the acute medical management of severe traumatic brain injury in infants, children, and adolescents. 2nd ed. *Pediatr Crit Care Med*. 2012;13:S1-S82.

Levels shown here are their designations.

TABLE 146.4 Stepwise Approach to Management of Elevated Intracranial Pressure

Tier 1

-
- Head of bed elevation
-
- Sedation and neuromuscular blockade
-
- Mechanical ventilation to normal arterial carbon dioxide pressure
-
- Active normothermia
-
- Hyperosmolar therapy
-
- External ventricular drainage

Tier 2

-
- Moderate hyperventilation
-
- Mild hypothermia (to 35°C)
-
- Thiopental infusion

Tier 3

-
- Decompressive craniectomy

SEIZURE PROPHYLAXIS

The original Temkin study in 1990 established a benefit to the short-term use of phenytoin in patients older than 16 years of age to reduce seizures in the week after injury. Indications for prophylaxis were the presence of intracranial blood and/or a depressed skull fracture [Level 1].³ In a retrospective analysis of pediatric cases, low GCS scores were most predictive of early seizures, and treatment with phenytoin was associated with a lower seizure rate. In one prospective trial, no benefit for rate of seizures within 48 hours was seen in children receiving phenytoin within 1-hour of arrival [Level 1].⁴ However, benzodiazepines given for elevated ICP or intubation may have masked the effect. The current pediatric TBI guidelines include a level II recommendation for consideration of phenytoin prophylaxis. Since the introduction of intravenous levetiracetam, this is an increasingly chosen option because of a perceived high degree of efficacy and a favorable side effect profile. The feasibility of this was demonstrated by a phase II trial in 2013 in which levetiracetam 55 mg/kg/day, divided twice a day (b.i.d.), was administered to children ages 6 to 17 years for 30 days. A prospective trial will be needed to confirm benefit.

REPEAT IMAGING

Criteria for repetition of imaging in pediatric TBI are not well established. In one analysis, worsening was found in 13% of follow-up scans. However, among these, all requiring surgical intervention had clinical indications of worsening neurologic status. Consequently, the pediatric TBI guidelines include a level II recommendation suggesting that repeat imaging may not be warranted in the absence of clinical change or increasing ICP. On the other hand, in a separate large retrospective case series, 27% of patients showed worsening, of whom less than a fifth had accompanying clinical signs. Furthermore, among those whose CTs led to surgical intervention, two-thirds did not have clinical signs. This would suggest that high clinical concern based on initial findings or clinical picture in addition to worsening or rising ICP is sufficient justification for repeat CT.

The recent DEcompressive CRAniectomy (DECRA) trial which did not show a survival benefit to decompressive craniectomy as a rescue therapy did not include children. A prospective but small early pediatric trial found a trend toward benefit of decompressive bitemporal craniectomy in patients with medically refractory ICP. However, the decompression in this study was performed without duraplasty, different from the techniques more commonly employed. A larger study in children including duraplasty has yet to be done, and the use of decompressive craniectomy including duraplasty is regarded as a level III option in the pediatric TBI guidelines.

OUTCOME

Except in the most severe of cases, the degree of injury, whether by clinical criteria or imaging, incompletely predicts ultimate outcome. Consequently, prognostic prediction during the acute treatment should be cautious. In children, recovery may continue long after the injury. Diffusion tensor imaging (DTI) is emerging as the best predictor, especially for the extent of white matter damage in diffuse axonal injury. There is less clinical experience with the use of serum markers for gradation in trauma.

Patients with moderate and severe injuries typically will require inpatient rehabilitation after their stabilization. Impairments of gross and fine motor skills are easily identified and readily justify the need for physical and occupational therapy. However, parents should be forewarned of the possibility of more subtle deficits that may even be unapparent on screening neurologic exam but can impose large burdens as the patient attempts to resume activities of daily living and education. Posttraumatic changes in memory, attention, motivation, as well as migraine or tension-like headaches can all interfere with return to school.

Neuropsychological testing can be helpful in identifying cognitive disabilities. Schools can be asked to structure an individualized education plan or supplemental services and accommodation (commonly known as a *504 plan*, referring to Section 504 of Federal Disability Law) to smooth the transition.

Neurologic follow-up may be warranted to treat sequela such as headaches or chronic posttraumatic seizures. Also, in infants, screening may be needed to identify failure of proper skull healing. The incompletely fused or partially mineralized pediatric skull can undergo aberrant healing. Pressure on a fracture or diastasis of an existing suture can lead to a “growing fracture.” Over a period of weeks to months, this can allow formation of so-called leptomenigeal cysts, a misnomer used to describe what is actually a dural herniation through the skull defect. This entity, extremely rare in adults, can be ruled out in young children with severe TBI by a follow-up skull film 6 weeks to 3 months after injury.

HIV, Fetal Alcohol Syndrome, and Drug Effects

Claudia A. Chiriboga

PEDIATRIC AIDS AND HIV INFECTION

Most children with AIDS in the United States are infected perinatally. Intravenous (IV) drug abuse and sexual contact with HIV-infected partners are the maternal risk factors in nearly all perinatal cases. Mother-to-child HIV transmission rates have dropped below 2% with the use of highly active antiretroviral drugs treatment (HAART) during pregnancy from a rate of 25% without prophylaxis. In the United States, 166 children younger than the age of 13 years were diagnosed with HIV in 2009, 13 of whom were diagnosed with AIDS. In contrast, among older children (older than age 13 years), the incidence of HIV infection continues to rise mostly in boys as a result of male-to-male sexual transmission. Racial and ethnic minority children are disproportionately affected by perinatal HIV infection accounting in 2009 for 90% of HIV infections. Most infections occur in the last trimester of pregnancy and at the time of delivery. Risk factors for vertical transmission are recent maternal HIV seroconversion, high viral burden, and maternal AIDS. Premature infants are also at increased risk of infection. Infection may result from exposure to blood and other body fluids at delivery. Breastfeeding is, thus, not recommended in the United States; cesarean section is not routinely recommended unless maternal viral burden is high.

Determining transmission of HIV infection to offspring based on detection of HIV antibody has been replaced by infant HIV polymerase chain reaction (PCR). Further, maternal HIV infection status is no longer required to determine infant HIV infection status. The Centers for Disease Control and Prevention (CDC) surveillance definition states a child is considered definitively infected if he or she has positive virologic results on two separate specimens or is aged older than 18 months and has either a positive virologic test or a positive confirmed HIV antibody test. HIV-seropositive children who do not meet these criteria are considered perinatally exposed and later seroreverters when antibodies turn negative. The 1994 clinical classification system for confirmed cases of HIV infection in children has been replaced by a five staging system that applies to both adults and children: 0, 1, 2, 3, or unknown. Stage 0 corresponds to early infection as noted by a negative HIV test within 6 months of HIV diagnosis. Stages 1 to 3 are classified immunologically (absolute CD4 count or percent CD4 count) depending on the child's age (younger than 12 months, 1 to 5 years, and older than 6 years): stage 1, no evidence of immune suppression; stage 2, moderate immune suppression; and stage 3, severe immune suppression (either a low CD4 count or whether an opportunistic illness was diagnosed) (Table 147.1). T-cell counts in infants and toddlers are higher for a specific immune category and reach adult levels after age 6 years.

TABLE 147.1 Infection Stage Based on Age-Specific CD4+ T-lymphocytes Count or Age-Specific CD4+ T-lymphocyte Percentage of Total Lymphocytes

Stage	Immunologic Category	<12 mo		1-5 yr		>6 yr	
		Cells/ μ L	(%)	Cells/ μ L	(%)	Cells/ μ L	(%)
1	No evidence of suppression	$\geq 1,500$	(≥ 34)	$\geq 1,000$	(≥ 30)	≥ 500	(>26)

2	Moderate suppression	750-1,499	(26-33)	500-999	(22-29)	200-499	(14-25)
3	Severe suppression	<750	(<26)	<500	(<22)	<200	(<14)

Adapted from Selik RM, Mokotoff, ED, Branson B, et al. Revised surveillance case definition for HIV infection—United States, 2014. *MMWR Morb Mortal Wkly Rep.* 2014;63:1-10.

DIAGNOSTIC TESTS

Because of early testing, most HIV-positive children are identified soon after birth, especially in States with universal perinatal screening. HIV DNA PCR is the preferred diagnostic method, whereas quantitative HIV RNA PCR is more sensitive in determining plasma concentration (copies/mL) of HIV RNA, commonly referred to as *plasma viral load*. By age 6 months, 100% of HIV-infected children are identified by a positive PCR. In newborns, a negative PCR test for HIV does not exclude infection but decreases the risk of HIV infection to 3%. Viral load runs higher in asymptomatic children than in asymptomatic adults. Sustained high viral load and low CD4 count predict progression to AIDS. High viral loads in early infancy predict early onset of symptomatic HIV disease. In the post-HAART era, most progression to AIDS is related to nonadherence to HAART of any cause (i.e., medical or social), which in turn facilitates development of drug resistance. HIV-1 syncytial-inducing phenotypes are linked to aggressive early symptomatic disease.

CLINICAL MANIFESTATIONS

Mild HIV infection includes diarrhea, unexplained persistent fever, lymphadenopathy, and parotitis. Lymphoid interstitial pneumonitis and recurrent bacterial infections are seen in HIV-infected children but not in infected adults. Prior to the advent of antiretroviral therapy, severe manifestations in early infancy, such as progressive encephalopathy or opportunistic infections (e.g., *Pneumocystis carinii*), carried a poor prognosis for survival but with effective antiretroviral therapy, these disorders are compatible with survival to adulthood.

P.1299

MECHANISM OF ACTION

HIV infection is maintained by viral persistence in helper T lymphocytes and macrophages. HIV strains with tropism for monocytederived macrophages have a predilection to infect cerebral vascular endothelium and the central nervous system (CNS). Infected macrophages traverse the blood-brain barrier and infect microglial cells; astrocytes are infected nonproductively, whereas neurons are spared from direct infestation. Neuronal dropout is seen as the disease advances, but it is not known how HIV induces neural damage. Postulated mechanisms include release of soluble neurotoxins by HIV-infected macrophages and lymphocytes (e.g., cytokines, quinolinic acid, viral antigens, or undefined viral products), neurotoxin amplification by astrocyte-macrophage interaction, and impaired blood-brain barrier function secondary to HIV-related endothelial damage. Nonproductive infection of a portion of astrocytes is reported to amplify bystander neurotoxicity. These neurotoxins are thought to produce a reversible metabolic encephalopathy that may disappear with effective antiretroviral treatment.

PATHOLOGY

Glial nodules and endothelial hyperplasia with calcification, dystrophic calcification, and perivascular mononuclear inflammation are common pathologic findings of subacute encephalitis in HIV-infected brains. The glial nodule comprises a cluster of chronic inflammatory cells in the neuropil and is often associated with multinucleated giant cells that are presumed to arise from coalescent microglia.

HIV ENCEPHALOPATHY

Two types of encephalopathy are seen in children: progressive and static. The evolution of the progressive encephalopathy may be fulminant, inexorably progressive, or stepwise. Progressive encephalopathy is characterized by loss of developmental milestones, progressive pyramidal tract dysfunction, and acquired microcephaly or impaired brain growth. The static encephalopathy is less well defined and may not be related to direct HIV CNS disease.

The neurologic abnormalities commonly include abnormalities of muscle tone, hyperreflexia, clonus, and impaired head growth. Hypotonia with corticospinal tract dysfunction may be seen in infants early in the course of the encephalopathy and evolves into a spastic diparesis; with newer antiretroviral treatments, progression to a spastic tetraparesis, with or without pseudobulbar palsy, is seldom seen. Ataxia and rigidity are uncommon. Prior to HAART, progressive neurologic dysfunction was the first evidence of progression to AIDS in 10% of infected children. In young children, early presentation may mimic a leukodystrophy. At the time of onset of neurologic symptoms, there is always evidence of underlying HIV infection, such as immunologic compromise (low CD4 counts) or high viral load. Many infected children exhibit global developmental delay, regardless of neurologic findings.

The rate of neurologic abnormalities reported in HIV-infected cohorts before the advent of antiretroviral treatments was 15% to 30%. The incidence of progressive HIV encephalopathy in 2000 was less than 2% in the cohort followed. Children most at risk are those who have recovered from HIV encephalopathy. Older HIV-infected children may show problems in visual-spatial processing functions and expressive language and may develop AIDS dementia complex indistinguishable from that described in adults. Children with HIV encephalopathy who respond to antiretroviral therapy may show reversal of microcephaly and cognitive impairments. The most frequent sequelae of “arrested” HIV encephalopathy are learning difficulty and nonprogressive mild spastic diparesis.

HIV-associated myelopathy, polyneuropathy, and myopathy are rare in children. Spinal cord pathology may show demyelinating changes of the corticospinal tracts, vacuolar changes, or myelitis attributable to HIV or other virus. Acute inflammatory demyelinating polyneuropathy is a rare complication in pediatric HIV.

FOCAL MANIFESTATIONS

HIV brain infection is nonfocal and subcortical. Seizures are not common. Focal signs or seizures raise the possibility of neoplasm, strokes, or, less likely, opportunistic infections.

Primary Central Nervous System Lymphoma

Rates of CNS lymphoma have decreased since the advent of HAART from an incidence ratio (IR; HIV-infected children/uninfected children) of 1,994 down to an IR of 1,088. CNS lymphoma is still the most common cause of focal cerebral signs in HIV-infected children (see also [Chapter 99](#)). It is often multifocal, and seizures are reported in about 33% of patients. It may be difficult to differentiate this tumor from a toxoplasmic brain abscess by neuroimaging, but a positive PCR for Epstein-Barr virus (EBV) in cerebrospinal fluid (CSF) is highly suggestive of CNS lymphoma. Thallium single-photon emission computed tomography (SPECT) and magnetic resonance (MR) spectroscopy may prove helpful in distinguishing CNS toxoplasmosis from lymphoma ([Table 147.2](#)). Diagnostic confirmation may require brain biopsy.

Stroke

Untreated HIV infection produces inflammation of cerebral vessels, increasing the risk of stroke, which occurred at a rate of 1.3% a year in symptomatic HIV-infected children. More than 50% of strokes were hemorrhagic and occurred with thrombocytopenia (especially immune thrombocytopenic purpura) or CNS neoplasia.

Nonhemorrhagic stroke and subarachnoid hemorrhage are attributed to an arteriopathy of large vessels in the circle of Willis (fusiform aneurysms) or meninges (Fig. 147.1). HIV-related strokes may be clinically silent, so the true incidence is probably higher. In cases of stroke, varicella-zoster virus (VZV) should be excluded as the etiologic agent by CSF PCR, especially when small intracranial vessels are involved. Ocular involvement should be excluded by pupillary dilatation for ophthalmologic assessment. Any vasculopathy in an HIV-infected patient is presumed to be infectious (from either HIV

P.1300

or VZV) and should be treated with appropriate antiretroviral and antiviral medication.

TABLE 147.2 Distinguishing Features between Central Nervous System Lymphoma and Toxoplasmosis Abscess

	Lymphoma	Toxoplasmosis
Distribution of lesion	Often solitary, subependymal spread	Typically multifocal, basal ganglia or corticomedullary junction
Enhancement	Typically homogenous	Often ring or nodular
MR perfusion	Increased rCBV	Decreased rCBV
SPECT	Increased uptake	Decreased uptake
MRS	Increased choline peak	Decreased choline peak

MR, magnetic resonance; rCBV, relative cerebral blood volume; SPECT, single-photon emission computed tomography (thallium); MRS, magnetic resonance spectroscopy.

FIGURE 147.1 Fusiform aneurysm in a child with advanced HIV encephalopathy presenting with intraventricular hemorrhage and stroke.

Opportunistic Central Nervous System Infection

As opposed to adults, opportunistic infections (OIs) in children involve primary infections rather than reactivation. Exposure rates to OI pathogens are cumulative and approximate adult rates by adolescence. Hence, rates of CNS OI occur less frequently in HIV-infected young children. Presentation and treatment of OIs are akin to what is described among HIV-infected adults (see [Chapter 67](#)). Survival of children with progressive multifocal leukoencephalopathy (PML) has increased with antiretroviral treatment (e.g., *cidofovir*) and effective antiretroviral combination therapy.

IMAGING

In children with HIV encephalopathy, brain atrophy (cortical and subcortical) is the most common imaging abnormality ([Fig. 147.2](#)). Periventricular or parietooccipital demyelination can be observed on magnetic resonance imaging (MRI) ([Fig. 147.3](#)). Frontal lobe or basal ganglia enhancement and calcifications are late manifestations of HIV encephalopathy, best seen on computed tomography (CT), and occur primarily in symptomatic infants (see [Fig. 147.2](#)). Imaging findings may be indistinguishable from Aicardi-Goutières syndrome. HIV myelopathy may show a high signal on spinal MRI but is usually normal. Bilateral cerebral lesions may mimic myelopathy and must be excluded with MRI or CT. Lesions of PML are commonly located in the parietooccipital or frontal regions, affecting both periventricular and subcortical white matter. These lesions may be difficult to distinguish from HIV demyelination.

CEREBROSPINAL FLUID

CSF findings are commonly normal in children with HIV infection. In the absence of OI, CSF analysis in children with progressive encephalopathy may show nonspecific changes of lymphocytic pleocytosis and elevated protein content. Intra-blood-brain barrier synthesis of HIV-specific antibody or antigen detection in CSF has not been useful in predicting encephalopathy. CSF viral load, although not routinely available, may prove useful in determining HIV encephalopathy in children, especially in cases of compartmentalization (i.e., a sequestered HIV reservoir in the CNS), in which systemic measures of viral load do not parallel the CNS level of viral replication.

FIGURE 147.2 CT scan of an infant with HIV encephalopathy showing cortical and subcortical atrophy, basal ganglia, and frontal lobe calcifications. (Courtesy of Dr. Ram Kairam.)

ANTIRETROVIRAL THERAPY

HAART, consisting of a protease inhibitor (PI) or a nonnucleoside reverse transcriptase inhibitor (NNRTI) administered in combination with nucleoside reverse transcriptase inhibitors (NRTIs), have been reported to suppress viral replication, improve immune function, and decrease AIDS-related death as well as diminish rates of HIV encephalopathy. High systemic viral load tends to predict the development of HIV encephalopathy, whereas CD4 counts tend to predict HIV disease progression primarily from OIs. Children younger than 1 year tend to be at greatest risk for progression and should be treated regardless of symptomatology. After 12 months,

treatment is not indicated if child is asymptomatic or minimally symptomatic.

ANTIRETROVIRAL THERAPY SIDE EFFECTS

Treatment with nucleoside inhibitors of viral reverse transcriptase can alter mitochondrial (mt) function by inhibiting mtDNA poly-merase- γ , which is responsible for the replication of mtDNA. Inhibition of mtDNA results in diminished synthesis of respiratory chain enzymes, causing the syndrome of mt depletion. Antiretroviral-induced mt dysfunction in turn is responsible for diverse adverse effects frequently observed in HIV-infected patients. Nonneurologic side effects include hepatic steatosis, lactic acidemia (>2 mmol/L), and lipodystrophy, a disorder characterized by the accumulation of visceral fat, breast adiposity, cervical fat pads, hyperlipidemia,

P.1301

insulin resistance, and fat wasting in face and limbs. Neurologic side effects include myopathy, peripheral neuropathy, and parkinsonism. Mt depletion myopathy can be seen in children treated with combination therapy, especially with NRTI that have a high affinity to mt polymerase- γ . Low-dose treatment with didanosine (ddl) causes a painful sensory neuropathy in less than 10% of patients treated. The neuropathy is dose related and usually clears with cessation of treatment. ddl, stavudine, and zalcitabine have a high affinity for binding polymerase- γ , whereas zidovudine, abacavir, tenofovir, and lamivudine have a lower affinity for that enzyme. Changing antiretroviral agents usually relieves the symptoms.

FIGURE 147.3 Parietal occipital demyelination on (A) axial fluid-attenuated inversion recovery (FLAIR) and (B) coronal T2 images in a child with advanced HIV encephalopathy and high viral load (RNA HIV = 1.5 million copies per milliliter).

In the immune reconstitution syndrome (IRS), worsening or de novo manifestations of OI (clinically or radiographically) are seen after introduction of HAART. The syndrome coincides with improving CD4 count and is not caused by treatment failure or a new infection. In a Johns Hopkins cohort, the independent predictors of IRS in adults were boosted (with ritonavir) PI and rapid decline of viral load (>2.5 log). The infection most commonly reported in adult IRS is cryptococcal meningitis, but PML and HIV dementia have also been reported. Among immune-suppressed (i.e., CD4 $<15\%$) Thai children, the incidence of IRS following HAART was 19%, the median time of onset was 4 weeks, and the primary pathogens involved were VZV and tuberculosis. Most cases of IRS occur within the first 3 months of treatment, although delayed cases are reported.

FETAL ALCOHOL SYNDROME

Fetal alcohol syndrome (FAS) affects children of chronic alcoholic women but also occurs with binge drinking, as defined by five drinks or more on one occasion. Fetal susceptibility to the effects of alcohol is greatest during the first trimester of pregnancy. FAS is characterized by abnormalities of growth, CNS, and facial features; birth defects are common (Table 147.3). The severity of the facial dysmorphism correlates with neurodevelopmental impairment. FAS rates in the United States range from 0.3 to 1.5 cases per 1,000 live births. Rates of FAS are highest among Alaska Native and Native American populations. FAS is confined to infants of alcohol-abusing women and occurs in about 2% to 4% of their offspring. Risk factors for FAS include poverty, poor maternal nutrition, and advanced maternal age. Risk of FAS is modulated by genetic factors: Certain enzyme polymorphisms confer protection (e.g., alcohol dehydrogenase [ADH] enzyme and cytochrome P4502E1), whereas others increase risk (absence of ADH2).

 - Thin upper lip
 - Flattening of the maxillary area
-

P.1302

Most children with FAS are mildly or moderately retarded, with mean IQ scores of 65 to 70, but intellectual ability varies widely. In families with several affected siblings, the youngest child is usually the most cognitively impaired. Learning disabilities—in particular, difficulty with arithmetic, speech delay, and hyperactivity—are commonly observed.

Less severe alcohol-related effects, termed *fetal alcohol effects*, are associated with different patterns of drinking and lack the typical facial dysmorphism seen with FAS. Fetal alcohol effects are probably a low point on the continuum of alcohol effects on the fetus. Maternal alcohol abuse increases the risk of spontaneous

abortions, infant mortality, intrauterine growth retardation, and prematurity. Birth defects are common; congenital anomalies occur in about a third of infants born to heavy drinkers, compared with 9% of minor anomalies in infants of women who abstain from alcohol. Decreasing alcohol intake during pregnancy is beneficial to offspring, reducing the frequency of growth retardation and dysmorphic features. Heavy alcohol exposure prenatally, but not mild or moderate exposure, has been linked to lower IQ scores, hyperactive behavior, attention problems, learning difficulty, and speech disorders. Neuroimaging abnormalities are common among alcohol-exposed infants and commonly include volume loss/microcephaly and developmental anomalies of cerebellum or corpus callosum (agenesis, hypoplasia). Neuroimaging abnormalities correlate with neurocognitive impairments.

POSTNATAL ALCOHOL EXPOSURE

Alcohol transferred through breast milk impairs motor development but not mental development at age 1 year. Ingestion of alcohol by children may lead to hypoglycemic seizures.

WITHDRAWAL SYNDROME

Infants born to women who drink large amounts of alcohol during pregnancy may rarely exhibit signs of withdrawal. Restlessness, agitation, tremulousness, opisthotonus, and seizures are seen shortly after birth and disappear within a few days.

PRENATAL COCAINE EXPOSURE

Although the cocaine epidemic has abated, cocaine is still one of the most frequent hard drugs of abuse in urban centers, whereas methamphetamine is the preferred substance of abuse in rural settings (with effects similar to those of cocaine).

Cocaine use during pregnancy has been linked to spontaneous abortion, abruptio placentae, stillbirth, and premature delivery. These events may immediately follow a large intake of cocaine and are attributed to drug-induced vasoconstriction of intrauterine vessels. Women who use cocaine tend to resort to prostitution, increasing risks for syphilis and HIV. They also tend to lack prenatal care, adding to the risks of infant death, low birth weight, and prematurity.

Low birth weight and intrauterine growth retardation are common among cocaine-exposed infants. Fetal brain growth is impaired independently of birth weight or gestational age. Sudden infant death syndrome (SIDS) has also been linked to cocaine exposure in utero. In addition to any specific cocaine-related effects, offspring are at increased risk because of polydrug exposure, as cocaine is rarely the only drug used.

NEUROBEHAVIOR

State regulation difficulties are well described among cocaine-exposed newborns. Findings vary from irritability and excitability to decreased organizational response and interactive behavior, even if the exposure to cocaine was limited to the first trimester of pregnancy. Modulation of attention is impaired among cocaine-exposed infants who, unlike unexposed infants, prefer higher rates of stimuli when in a high level of arousal. Infant processing abilities, as reflected by looking time at novel stimuli, are also affected by prenatal cocaine exposure. Exposed infants show motor and movement abnormalities, including excessive tremor and hypertonia. Dose-response effects of cocaine on state regulation and neurologic findings that tend to be transient are reported in newborns and infants. Some studies show no neurobehavioral effects, however.

STROKES

Experimentally, cocaine and its main metabolite, benzoylecgonine, cause vasoconstriction of fetal cerebral vessels. Neonatal stroke and porencephaly have been associated with prenatal cocaine exposure. Some cases may be related to other neonatal stroke risk factors that accompany fetal cocaine exposure, such as abruptio

placentae or birth asphyxia. Intraventricular hemorrhage is observed among infants more heavily exposed to cocaine.

SEIZURES

Focal seizures may occur in cocaine-exposed newborns with strokes. EEGs in cocaine-exposed infants show bursts of sharp waves and spikes that are often multifocal. These findings do not correlate with clinical seizures or neurologic abnormalities and may disappear in 3 to 12 months. Cocaine-exposed premature infants are at increased risk of neonatal seizures. Seizures are rare if there is no stroke.

MALFORMATIONS

Prenatal cocaine exposure has been linked with urogenital malformations, limb reduction deformities, and intestinal atresia and infarction. Agenesis of the corpus callosum and septo-optic dysplasia has also been noted. These teratogenic effects may result from cocaine-induced vasoconstriction and fetal vascular disruption in early organogenesis.

NEURODEVELOPMENTAL IMPACT

In experiment models, prenatal cocaine has been reported to affect serotonin, norepinephrine, dopaminergic, and GABA systems. Lower CSF levels of homovanillic acid found in human newborns exposed to cocaine suggest dopaminergic involvement. In infancy, there may be a high incidence of global hypertonia that resolves prior to age 24 months (Table 147.4). Many studies in toddlers and school-aged children have failed to show that prenatal cocaine exposure adversely affects cognition, except as mediated through cocaine effects on brain growth. Cocaine-exposed children seem to suffer from language delays and an excess of neurobehavioral abnormalities, including irritability, impaired attention, inhibitory control, impulsivity, and aggressive behavior. Early neurobehavior involving orientation and irritability tend to improve over the first 2 years of life. Heavy prenatal cocaine exposure has been associated with delinquent behavior in both genders at older ages.

COCAINE EXPOSURE IN CHILDHOOD

Passive intoxication with cocaine may be caused by breastfeeding or passive inhalation of free-base cocaine (crack). Seizures are the chief manifestation of symptomatic intoxication, but intoxication may be unsuspected. Urine toxicology screening is used to detect

P.1303

illicit substances in evaluating seizures in infants and children, regardless of socioeconomic status.

WITHDRAWAL SYMPTOMS

There is no evidence of a cocaine-induced withdrawal syndrome. Even with remote prenatal cocaine exposure, cocaine-exposed infants may show hypertonicity and tremor, which are probably manifestations of a transient embryopathy resulting from cocaine-related perturbations.

PRENATAL OPIATE EXPOSURE

Cheap and abundant supplies of heroin are fueling a nationwide epidemic of late, especially in urban centers. Prospective studies, however, on the developmental impact of prenatal heroin exposure are sparse. Methadone, on account of its controlled administration, has been more extensively studied. The main risk factor linked to developmental effects and lower IQ scores is the presence of neonatal withdrawal syndrome.

WITHDRAWAL SYMPTOMS

A neonatal withdrawal syndrome is well described in infants born to opiate-dependent mothers ([Table 147.5](#)). It is characterized by signs and symptoms of central nervous system hyperirritability, gastrointestinal dysfunction, respiratory distress, and autonomic disturbances. CNS signs and symptoms consist of hypertonicity, tremor, hyperreflexia, irritability, sleep disturbances, feeding difficulties, and occasionally seizures. Onset of neonatal withdrawal from heroin usually begins within 24 hours of birth, withdrawal from methadone usually starts around 24 to 72 hours of age, and withdrawal to buprenorphine starts at around 40 hours and peaks in severity at 70 hours of age. The neonatal withdrawal syndrome associated with methadone is more severe and occurs more often (84%) than that described with buprenorphine (60%). For both opioids, signs of withdrawal may be delayed in onset until 5 to 7 days of age or later. Among neonates acutely withdrawing from opioids, seizures are observed in 2% to 11% and EEG abnormalities without evidence of seizures in over 30%. Mild withdrawal does not require treatment, other than swaddling and a quiet room, but symptomatic infants are likely to require pharmacologic intervention. The two most popular agents used to treat withdrawal are paregoric (camphorated tincture of opium) and phenobarbital. Of the two, paregoric is more physiologic because it substitutes for the substance causing withdrawal but is only effective for opiate withdrawal. Other opiates studied include morphine and buprenorphine. For suspected polydrug exposure, phenobarbital may be preferable.

The most widespread scale in use to assess the severity of withdrawal syndrome is that developed by Finnegan: It assesses 21 signs in three domains: CNS, gastrointestinal, and autonomic/sleep/respiratory. Assessments are recommended every 2 to 4 hours after birth, and treatment is suggested for withdrawal scores 8 or higher.

P.1304

Paregoric or phenobarbital is then titrated according to the severity of withdrawal score. There is no agreed upon standard treatment protocol to manage neonatal abstinence. When using phenobarbital, one can choose to load (15 mg/kg) prior to titrating maintenance (5 to 8 mg/kg) dose. Paregoric doses may start at 0.2 mL q3h and titrate by 0.05 mL according to withdrawal score. Tapering of the dose may commence by

the end of the second week as tolerated.

148 Psychosis

Jacob S. Ballon
T. Scott Stroup

INTRODUCTION

Psychosis is characterized as a detachment from reality, often including hallucinations or delusions. Psychotic symptoms are a core feature of schizophrenia but may also be seen in other serious psychiatric disorders including bipolar disorder, major depressive disorder, and posttraumatic stress disorder (PTSD). Importantly, psychosis may also be a prominent symptom in many neurologic disorders, other medical conditions, substance intoxications, and withdrawal syndromes. New-onset psychosis should prompt a thorough workup to determine the etiology of such symptoms.

Psychotic experiences can be characterized as phenomena in which sensory experiences are generated by aberrant brain stimuli rather than external inputs. Hallucinations can be auditory (e.g., hearing voices), visual (seeing objects that are not there), or can occur in other sensory domains, although olfactory, tactile, and gustatory hallucinations are less typical of psychiatric illness. Hallucinations can be differentiated from illusions by having no basis in reality, whereas illusions are misperceptions of natural sensations. Delusions are fixed, false beliefs that persist in spite of contradictory evidence. Often, delusions are paranoid (e.g., a feeling of being watched or followed) or grandiose (e.g., possessing special powers or relationships with powerful people). Hallucinations and delusions must be considered within the relevant cultural context.

The lifetime prevalence of psychosis is between 3% and 5% in the general population. Most cases of psychosis are due to causes other than schizophrenia. The majority of nonschizophrenia psychosis is seen in drug-induced psychosis, mood disorders, and general medical causes.

SCHIZOPHRENIA AND OTHER PSYCHOTIC DISORDERS

EPIDEMIOLOGY

Globally, estimates suggest that almost 1% of the population will develop schizophrenia in their lifetime. The typical age of onset of schizophrenia is the late teens or early 20s, with men diagnosed on average a few years younger than women. Most people who develop schizophrenia have a prodromal period of illness before they meet the threshold for diagnosis characterized by subthreshold psychotic symptoms in conjunction with declines in social and occupational functioning. Schizophrenia typically follows a relapsing and remitting course characterized by periods of stability with episodic exacerbations of symptoms. Although antipsychotic medications are efficacious in reducing psychotic symptoms, many individuals may still have symptoms despite usual treatment.

NEUROBIOLOGY

Scientists debate whether schizophrenia is a degenerative brain disease, neurodevelopmental disease, or a combination of both. Several studies have shown that there are neuroanatomic differences in ventricle size, cortical thickness, gray and white matter, and overall brain volume in people with schizophrenia. Supporting neurodevelopmental hypotheses, neuroanatomic differences are seen before the onset of psychosis. However, favoring degenerative hypotheses, these differences increase over the course of illness. Further, although many studies have shown that cognitive decline predates the onset of psychosis, there is some evidence that cognitive deficits worsen over time. It is difficult to isolate a specific degenerative impact of schizophrenia itself apart from other environmental factors such as chronic exposure to antipsychotic drugs.

Much work has been done to isolate the specific neurotransmitter systems responsible for psychosis and schizophrenia. Although no single system is responsible for the overall psychotic phenotype, several have been shown to contribute to the development of symptoms. Dopamine is often most closely associated with psychosis and all currently marketed antipsychotic drugs are dopamine D2 antagonists but those drugs do not address all facets of the illness. Other neurotransmitters implicated include serotonin, glutamate, and acetylcholine.

CLINICAL FEATURES AND DIFFERENTIAL DIAGNOSIS

Schizophrenia is a serious mental illness responsible for significant morbidity, diminished quality of life, loss of productivity, and premature mortality. There is a 5% to 10% risk of suicide, and schizophrenia is a leading cause of disability throughout the world. Symptoms of schizophrenia can be categorized into positive, negative, and cognitive domains. Positive symptoms refer to delusions, hallucinations, and disorganized speech or behavior. Negative symptoms include apathy and avolition and generally refer to deficits in functioning. Cognitive symptoms affect multiple domains including primarily executive functioning, verbal learning, and working memory.

Although schizophrenia cannot be diagnosed until psychosis has been present for at least 1 month, nonspecific symptoms have been seen from early childhood in people who later develop schizophrenia. For example, young children who go on to develop schizophrenia have increased incidence of deficits in motor skills compared to children who do not develop schizophrenia or other psychiatric disorders.

The *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*), which was released in 2013, modified the criteria for psychotic disorders (Fig. 148.1). A schizophrenia diagnosis requires at least two out of five symptoms including hallucinations,

P.1306

delusions, disorganized speech, disorganized behavior, or negative symptoms for at least 1 month and with an overall duration of illness of at least 6 months. New in *DSM-5* is a requirement for hallucinations, delusions, or disorganized speech; only having disorganized behavior and negative symptoms does not meet the new criteria. If mood symptoms are present, a timeline is essential to determining the correct diagnosis. If there are concurrent mood symptoms along with the hallucinations or delusions, the criteria for schizoaffective disorder are met if the psychotic symptoms persist for at least 2 weeks in the absence of mood symptoms and if the mood symptoms are present for the majority of the entire illness. If the psychotic symptoms occur only in the context of a mood disorder (bipolar disorder or major depressive disorder), then the diagnosis is bipolar disorder or major depressive disorder with psychotic features. If the only psychotic symptom is a delusion, then the diagnosis may be delusional disorder, particularly if there is limited functional impairment. Catatonia is a constellation of psychomotor features that may include stupor, posturing, mutism, stereotypy, and other odd mannerisms. Catatonia is often associated with schizophrenia but can be present in most other serious mental illnesses. Catatonia is included in the *DSM-5* as a specifier for several mental disorders and is seen in approximately 10% of patients hospitalized with schizophrenia.

FIGURE 148.1 Diagnostic algorithm for a patient with psychotic symptoms. (Based on American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Washington, DC: American Psychiatric Association; 2013.)

Psychotic symptoms frequently occur in other psychiatric disorders. Up to 60% of people with bipolar disorder have a history of at least one psychotic symptom, and psychosis is seen in up to 50% of manic episodes. Psychosis may also be present in depression, especially when it is severe. Overall, people with depression are three times more likely to have hallucinations and nine times more likely to have delusions compared to those without depression. Up to 15% of people with schizophrenia have comorbid obsessive-compulsive symptoms. People with social phobia and general anxiety also have an increased incidence of psychosis. Data from the National Comorbidity Survey suggests that psychosis should

P.1307

lead to a separate subtype categorization of PTSD and a subtype of “with dissociative symptoms” was added to *DSM-5*. Substance abuse and schizophrenia frequently co-occur, with rates of substance use disorders as high as 70% in people with schizophrenia. In a large European study of first-episode schizophrenia, already 31.1% of patients reported a comorbid substance use disorder, including 22.2% who used marijuana. Comorbid substance use is associated with poorer medication adherence, more hospitalizations, and overall worse functional outcomes, with the worst effects seen in heavy substance users.

SCHIZOPHRENIA-SPECTRUM CASE

A 21-year-old male collegian is brought to the student health service by his resident advisor (RA). The RA notes that over the past several months, the student has withdrawn from fellow students and stopped participating in dormitory activities. His grades have suffered, and he was caught smoking marijuana in his room. He recently began putting tape over the cameras in the computer lab and foil over the windows of his room. When asked about these behaviors, the student said that the Central Intelligence Agency (CIA) was tracking his movements through a vast network of computers. He spent several nights sleeping in the library or in a local 24-hour coffee shop to avoid detection. He believed that the CIA considered him to have special knowledge of operations within the government. The student believed that everyone knew about him because the CIA had put up a website about him. He said that he could hear agents and other people talking to him through the walls of his room, commenting on his behaviors, and telling him that he was stupid. His sleep was poor and he was using marijuana to help sleep and to manage his anxiety.

TREATMENT/OUTCOME

Antipsychotic Medication

The mainstay of treatment for schizophrenia and other psychotic disorders is antipsychotic medication. Antipsychotics reduce psychotic symptoms and reduce relapse rates [Level 1].¹ All currently available antipsychotic medications antagonize dopamine D2 receptors in the brain, which is thought to be their primary mechanism of action. Historically, antipsychotic medications have been categorized based on their potency at the D2 receptor into high-potency and low-potency categories. Antipsychotics also affect other neurotransmitters including serotonergic, histaminergic, and adrenergic receptors. Effects on the various neurotransmitters determine therapeutic and adverse effects.

All antipsychotic drugs are capable of inducing neurologic side effects including abnormal involuntary movements known as *tardive dyskinesia* (TD), *akathisia* (restlessness), *dystonia*, and *pseudoparkinsonism* (tremor, rigidity, and bradykinesia) (Table 148.1). By definition, TD is associated with prolonged (at least 3 months) exposure to an antipsychotic agent. Increased age, female gender, and duration of exposure are the greatest risk factors for TD. Newer (or second-generation) antipsychotics tend to have lower risk of TD but risk varies according to individual drug characteristics, as well as dose and duration of exposure. Drugs with lower potency at the D2 receptor tend to be associated with more adverse metabolic side effects (weight gain, diabetes, dyslipidemia), whereas those with higher potency are more likely to cause neurologic side effects. Severe dystonias, especially those involving laryngeal or extraocular muscles, require emergency treatment with intramuscular diphenhydramine (50 mg) or benztropine (2 mg). Oral benztropine (1 to 4 mg daily) is effective for treatment of antipsychotic-induced tremors, and propranolol (30 to 90 mg daily) is often used for treatment of akathisia.

Metabolic side effects are closely associated with many antipsychotic treatments, in particular clozapine, olanzapine, quetiapine, and risperidone. The mechanism by which antipsychotics cause these effects is not conclusively known. Schizophrenia has long been associated, even before the introduction of antipsychotic medications, with

increased rates of diabetes and obesity compared the general population. Clozapine, olanzapine, and quetiapine are potent antihistaminergic agents and thus are associated with drowsiness and central histamine H1 receptor activity, which may contribute to their risk of weight gain. Other theories regarding the metabolic effects focus on shared signaling pathways between insulin regulation and psychosis involving the kinase *AKT1* in the brain, pancreas, and liver. Peripheral response to antipsychotic drugs may feedback to the brain in a way that alters insulin secretion, which may have effects on weight. Although diabetes may often result from the central adiposity associated with antipsychotics, there are likely multiple pathways responsible for these metabolic effects, as people may develop insulin resistance and diabetes in the absence of weight gain and vice versa.

A dangerous but rare side effect of antipsychotic drugs is neuroleptic malignant syndrome (NMS). NMS is characterized by tremors, muscle rigidity and myalgias, extreme fever, other autonomic instability, and altered mental status. The muscle rigidity ultimately leads to rhabdomyolysis, with increased creatine kinase (CK) and white blood cell counts. The resultant muscle breakdown products can lead to acute renal failure. Without rapid and intensive intervention, NMS can be fatal and is in nearly 10% of cases. Treatment of NMS focuses on stopping the antipsychotic immediately, cooling the hyperthermia rapidly, and protecting the kidneys from myoglobinemia through aggressive hydration.

Antipsychotics differ mainly in side effects, but some small to moderate differences in efficacy have also been detected. All three of the medicines with better efficacy that are available in the United States (clozapine, olanzapine, and risperidone) are associated with adverse metabolic effects. This finding leads to a clinical dilemma in which clinicians and patients must balance the opportunity for maximum symptom improvement with significant metabolic risk.

Clozapine has a special role because it is more efficacious than other antipsychotics in patients with treatment-resistant schizophrenia and has been shown to decrease suicidality and to cause the fewest abnormal involuntary movements. However, in addition to weight gain and significant metabolic side effects, clozapine is also associated with agranulocytosis and subsequent risk of death due to infection. Therefore, patients taking clozapine must be enrolled in a clozapine registry and monitored carefully for decreases in granulocyte counts. Other risks of clozapine include myocarditis and seizures. However, with close clinical monitoring, clozapine can be highly effective for many patients.

Nonpharmacologic Treatment

Nonpharmacologic treatments for schizophrenia that are supported by some evidence include repetitive transcranial magnetic stimulation (rTMS) for auditory hallucinations that do not respond to antipsychotic medications [Level 1].¹ Several psychosocial treatments are effective for specific problems associated with persistent psychotic illnesses. For example, multidisciplinary teams known as *Assertive Community Treatment (ACT)* teams provide outreach and comprehensive care, which reduces rates of hospitalization [Level 1].² Supported employment programs are effective in helping people with schizophrenia obtain jobs [Level 1].²

P.1308

TABLE 148.1 Selected Information on Commonly Used Antipsychotics

Antipsychotic Medication	Haloperidol	Aripiprazole	Clozapine	Olanzapine	Paliperidone	Quetiapine	Risperidone	Ziprasidone	Lurasidone
Typical dose range for maintenance treatment of schizophrenia	Oral: 2-12 mg	Oral: 10-30 mg	Oral: 150-600 mg	Oral: 10-30 mg	Oral: 6-12 mg	Oral: 300-800 mg	Oral: 2-8 mg	Oral: 80-160 mg	Oral: 40-80 mg
Side Effect Risk									
Akathisia/parkinsonism	+++	+	0/+	+	++	0/+	++	+	++
QT prolongation on ECG	+	+	+	+	+	+	+	++	0

P.1309

OTHER CAUSES OF PSYCHOSIS

When a patient presents with psychosis for the first time, it is important to remember that psychotic symptoms are associated with numerous brain conditions and the cause may not always be identifiable. A thorough workup should be conducted to make sure that potentially reversible causes of psychosis are ruled out (Table 148.2).

The workup for reversible causes of psychosis should start broadly and then focus more narrowly according to the specific presentation. Laboratory tests are used to investigate possible metabolic or nutritional abnormalities, signs of infection/inflammation, and autoimmune processes. Neuroimaging may be indicated, particularly if there are focal neurologic deficits or an acute personality change. Lumbar puncture (LP) and electroencephalogram may also be part of a workup when associated symptoms suggest the possibility of infection.

Delirium is a common cause of psychosis and should be suspected in any patient with acute psychosis, particularly those who are older than typical first-episode psychosis patients (Table 148.3). Although the definitive intervention for delirium is treatment of the underlying medical condition, there are important steps to take while the underlying cause is sought and treated. The first step is to ensure the patient's physical safety. Efforts to normalize the sleep-wake cycle should be a priority. Frequent reminders of location, time, and situation are helpful to reorient patients to their surroundings. Medications that cause or exacerbate delirium, including anticholinergic agents, should be avoided as much as possible. Benzodiazepines should also be avoided in nonalcoholic delirium. Antipsychotic medications can be useful in symptomatic treatment of delirium and associated psychosis. Antipsychotics have been shown to shorten the duration of delirium episodes with similar efficacy seen across multiple agents.

TABLE 148.2 Suggested Medical Workup for Psychosis

In all patients:

- Complete blood count (CBC)
- Glucose, chemistries, liver function tests
- Thyroid-stimulating hormone (TSH)
- Vitamin B₁₂ and folate
- Urinalysis
- Urine drug screen
- HIV test

Secondary testing to be done as clinically indicated:

- Brain imaging with CT or MRI
- Electroencephalogram
- Lumbar puncture
- Chest radiography
- Blood and urine cultures
- Arterial blood gases
- Serum cortisol levels
- Antinuclear antibodies (to test for autoimmune disorders such as systemic lupus erythematosus)
- Ceruloplasmin (to test for Wilson disease)
- Rapid plasma reagin (to test for syphilis)
- Toxin search/drug levels

CT, computed tomography; MRI, magnetic resonance imaging.

Based on Freudenreich O, Schulz SC, Goff DC. Initial medical work-up of first-episode psychosis: a conceptual review. *Early Interv Psychiatry*. 2009;3(1):10-18.

TABLE 148.3 Medical Conditions that Can Present with Psychosis

- Delirium
- Dementia/neurodegenerative disorders
- Neoplasms

Seizures
Intoxications/medications
HIV/AIDS/other infections
Autoimmune/limbic encephalitis
Systemic lupus erythematosus
Neurovascular events
Leukodystrophies
Endocrine disorders
Mitochondrial disorders

Psychosis is associated with drug intoxication and withdrawal states. In severe alcohol and benzodiazepine withdrawal, patients may experience delirium tremens (DTs), which is fatal in approximately 1% of cases. This is characterized by autonomic instability, hallucinations, and agitation. Benzodiazepines (e.g., lorazepam 2 mg every 2 hours as needed) are the mainstay of treatment for significant alcohol withdrawal and DTs [Level 1].³ Many drug intoxications can yield psychotic symptoms. Cannabis, particularly as it has become more potent in recent years, often causes a transient psychotic state characterized mostly by paranoia. Sympathomimetic drugs, such as amphetamine or methamphetamine, can cause paranoia and hallucinations with acute and chronic use. *N*-methyl-D-aspartate (NMDA) antagonists such as PCP and ketamine are also associated with auditory hallucinations, paranoia, and negative symptoms. These drugs, as well as amphetamines, are often used in animal models of schizophrenia because of the similarity in presentation to schizophrenia. Tactile hallucinations are often seen with amphetamines and cocaine.

Psychosis is also common in major neurocognitive disorders such as dementias. Patients with dementia often report paranoid delusions or feelings that people are stealing from them. In dementia with Lewy bodies (DLB), many patients report delusions and visual hallucinations (including “lilliputian hallucinations” of little people/animals) and develop pseudoparkinsonism even with low doses of antipsychotics. Antipsychotics can be helpful in treating these psychotic symptoms and can help reduce dementia-related agitation but should be used with caution and in low dosages. In many circumstances, cholinesterase inhibitors are effective and should be considered first in DLB. If using antipsychotics in treating patients with DLB, quetiapine, at low doses (e.g., 25 to 50 mg daily), is a good first choice. Clozapine (e.g., 25 to 50 mg daily) is a second choice if quetiapine is not effective. Dementia is not an U.S. Food and Drug Administration (FDA)-approved indication for antipsychotics, and all antipsychotics carry a black box warning for this use because of an increased risk of mortality for elderly dementia patients. The possible benefits of antipsychotics

P.1310

in reducing psychosis or agitation must be weighed against the small but significant risk of increased mortality as well as the other adverse effects of antipsychotics. Importantly, if an antipsychotic is used for a patient with dementia, it should be discontinued unless there are clear benefits.

Because brain tumors can have many psychiatric manifestations, including psychosis, the workup for new-onset psychotic symptoms should include neuroimaging. Although rare, the presence of other focal neurologic findings should raise the index of suspicion for psychosis secondary to a brain lesion. Peripheral tumors including small cell lung cancer (and resultant paraneoplastic syndrome), steroid-producing hormones such as adrenal tumors (Cushing disease), and pheochromocytoma may also cause psychosis. Another rare cause of psychosis is autoantibodies to the NMDA receptor. These antibodies, most often seen in young women, often derive from ovarian teratomas or other tumors; surgical removal of the tumors may resolve the symptoms. Immunotherapy (e.g., steroids, intravenous immunoglobulins, and plasmapheresis) can also be used to treat the psychosis and associated symptoms with good effect.

Seizures may also cause psychotic symptoms, and the presence of other seizure sequelae, such as auras or postictal periods, should prompt testing in that domain including electroencephalogram. Psychosis may occur intractally or postictally. Temporal lobe epilepsy is classically associated with psychotic symptoms including *déjà vu* (a sense of reexperiencing something that is novel), fear without identifiable cause, or olfactory hallucinations. Treatment of epileptic-related psychosis can be complicated because antipsychotic medications can lower the seizure threshold. However, this effect is generally not clinically significant except in the case of clozapine (e.g., at doses ≥ 600 mg daily or when blood levels rise rapidly). Some antiepileptic drugs (AEDs) including levetiracetam, vigabatrin, and topiramate can worsen psychosis. In addition, carbamazepine induces antipsychotic drug metabolism and may lead to decreased blood levels, resulting in the emergence of psychotic symptoms. On the other hand, valproic acid (e.g., 500 to 1,500 mg daily) is commonly used off-label as adjunctive agent to potentiate the initial efficacy of antipsychotic drugs in the treatment of schizophrenia, although the efficacy of this strategy is uncertain. Ultimately, if antipsychotics are indicated in someone with a seizure disorder, then the choice of drug depends largely on tolerance for side effects and drug-drug interactions.

Several infections can cause psychotic symptoms. Infections that yield brain lesions, such as neurocysticercosis or other fungal infections, seen as ring-enhancing lesions on magnetic resonance imaging (MRI), can cause both seizure activity and associated psychosis. Up to 15% of HIV patients may experience psychotic symptoms generally through opportunistic infections, HIV-associated neoplasms, or HIV-associated delirium/dementia. More commonly, HIV is associated with psychotic symptoms, both through progression of the illness or through drug interactions with antiretroviral therapy or from highly active antiretroviral therapy (HAART) medications themselves. Other infections sometimes associated with psychosis include Lyme disease, herpes, and neurosyphilis. Herpes encephalitis, the most common sporadic viral encephalitis in the United States, requires immediate attention because there is a high risk of mortality if not treated promptly. Acyclovir (30 mg/kg/day) should be started while waiting for the results of LP and imaging studies.

Many medications are associated with psychosis. Steroids are most commonly implicated in causing psychotic symptoms and can also cause other significant emotional side effects including depression and anxiety. Treatment of Parkinson disease is often complicated by psychosis when using prodopaminergic agents. Low doses of quetiapine (25 to 50 mg daily) or clozapine (25 to 50 mg daily), which have a relatively low risk of pseudoparkinsonism, are recommended for treating psychotic symptoms in patients with Parkinson disease. Psychoactive medications including sympathomimetic agents, opioids, and benzodiazepines can cause psychosis, particularly in high dosages. Psychosis has also been reported to be associated with antibiotics, antimalarials (particularly mefloquine), antituberculous drugs, and muscle relaxants.

DELIRIUM WITH PSYCHOSIS CASE

A 73-year-old man is admitted to orthopedic surgery for surgical repair of his left hip. On postoperative day 2, nurses report that he is agitated and complaining that he sees a “crippled equestrian” near the air conditioning vent. Nurses also report that he was awake much of the night and sleeping during the day. He was given lorazepam last night to help him sleep, but the report from nursing staff is that it made him agitated, and he needed to be placed on 1:1 observation because he did not sleep and tried to get out of bed unsafely. He’s been picking at his bed sheets and nearly pulled out his intravenous (IV) line. When you see him at the bedside, he says that the year is 1968 and he is at a racetrack. His vital signs show a low-grade fever and tachycardia, and his complete blood count (CBC) shows a mildly elevated white count.

CONCLUSION

Psychosis presents in many psychiatric and other medical conditions and is generally a sign of a severe underlying problem. Not all cases of psychosis are due to a primary psychotic disorder such as schizophrenia, and many represent urgent medical problems. This is particularly important in older patients and in cases that do not otherwise fit the typical pattern of schizophrenia onset. A broad differential should be considered to identify reversible and potentially progressive causes of psychosis. Prompt, appropriate treatment will lead to improved outcomes.

Mood Disorders

Licinia Ganança

Alejandro S. Cazzulino

Maria A. Oquendo

INTRODUCTION

Mood disorders are defined by the presence of a distinct period of persistently altered disposition, specifically, depressed, manic, or hypomanic states. These states are categorized as depressive or bipolar disorders depending on the presenting symptoms and the longitudinal course of the illness. Comorbidity between mood and neurologic disorders occurs frequently. Furthermore, not only may mood, especially depressive, symptoms be part or precede the clinical presentation of some neurologic disorders (e.g., Huntington disease [HD]) but they may also increase the risk for cerebrovascular disorders, and possibly some dementias, and therefore have a considerable impact in the prognosis and quality of life of primary neurologic disorders.

EPIDEMIOLOGY

Major depression is one of the leading causes of disability in the United States and worldwide. It ranked 11th in terms of disability-adjusted life years (DALYs) in a study of 291 diseases and injuries conducted in 21 regions. Moreover, according to the National Mental Health Association, depression affects 1 in every 33 children and 1 in every 8 adolescents. In any given year, about 21 million people in the United States will suffer from major depression (<http://www.nimh.nih.gov/health/publications/the-numbers-count-mental-disorders-in-america/index.shtml#MajorDepressive>).

The incidence of depression is nearly twice as high in women as it is in men, and suicide attempts are more numerous in women. However, death from suicide is far more common in men. Additionally, postpartum depression occurs after as many as 10% of all deliveries. The 12-month prevalence of depression in the U.S. population is estimated to be around 8.1% for women and 4.6% for men.

Bipolar disorder has a lifetime risk of 0.3% to 1.5%, with equal prevalence among men and women. It is estimated that around 10% of depressed patients may in fact be bipolar but have yet to be diagnosed.

PATHOPHYSIOLOGY

Although the underlying biology of depression has not been fully elucidated, it is clear that several key systems are involved. These include the serotonergic, glutamatergic, noradrenergic, and dopaminergic systems. Other putative pathophysiologic processes include neuroinflammation, hypothalamic-pituitary-adrenal axis dysfunction, and neuroplasticity.

Genetic factors are thought to be relevant due to the high heritability of mood disorders, estimated at about 30% to 40%. The data from twin studies indicates that environmental factors also play an important role in the expression of mood disorders. Nonetheless, the risk of becoming ill increases two- to threefold for first-degree family members of patients with mood disorders. Of note, despite early suggestions that bipolar disorder is more heritable than depressive disorders, the evidence that genetic vulnerability or heritability of mood disorders differs between bipolar and unipolar conditions is mixed and far from definitive.

The serotonergic system plays a key role in depression, with studies demonstrating an overall decrease in serotonin (5-HT) function. Brain imaging studies demonstrate increased 5-HT_{1A}-receptor binding and fewer

brain 5-HT reuptake sites. Tryptophan (serotonin's precursor) depletion has been shown to produce rapid depressive relapses in patients with a history of depression but no change in subjects with no personal or familial history of mood disorders. This suggests that low levels of 5-HT in the brain are not sufficient to cause depression but may act in concert with other factors in vulnerable individuals to cause symptoms. Indeed, many antidepressants exert their action through modulation of serotonin transmission.

Other neurotransmitter systems have been implicated in depression as well. For example, norepinephrine is linked to the pathophysiology of severe depression, as is dopamine, a neurotransmitter involved in incentive behavior and reward. Low cerebrospinal fluid levels of the dopamine metabolite, homovanillic acid, have been documented in depressed patients and exposure to dopamine-depleting drugs such as reserpine is known to precipitate depression. Changes in other neurotransmitters such as glutamate have also been identified. Glutamate, the main excitatory neurotransmitter appears to be increased in major limbic and cortical systems, possibly in response to stress, and may exert pathogenic effects either by limiting neurogenesis or dendritic remodeling directly or in concert with other factors that have similar effects on neuroplasticity.

Stress is implicated in the pathophysiology of depression, not only as mediated through glutamatergic changes in response but also as exemplified by prominent changes to the neuroendocrine system, especially in the hypothalamic-pituitary axis (HPA). Under normal conditions, stress prompts the HPA axis to secrete serum cortisol. In mood disorders, the HPA axis may become unresponsive to normal negative feedback loop, leading to a failure to restore cortisol to normal levels once the stressor is removed. These changes may be accompanied by the loss of normal diurnal variation in cortisol levels. Whether these changes are linked to early life experiences, leading to enduring changes in the HPA axis thereby increasing the probability of developing a mood disorder later in life, is not known.

Another hypothesis about the pathophysiology of depression posits that depression is a neuroinflammatory process, a concept bolstered by the observation that depressive symptoms (fatigue, anhedonia, anorexia, etc.) could be viewed as "sickness behaviors." Indeed, changes in inflammatory markers, such as increased interleukin (IL)-6 and tumor necrosis factor (TNF)- α levels have been consistently found in patients with depression. Furthermore, administration of therapeutic cytokines has been shown to cause significant depressive symptoms in 50% of exposed individuals, providing further evidence for the role of neuroinflammation.

P.1313

As noted earlier, neuroplastic changes in the hippocampus have been linked to depression. Chronic stress is associated with decreased hippocampal neurogenesis, a phenomenon often observed in animal models of depression and postmortem tissue. Treatments with antidepressants seem to reverse these hippocampal deficits in neurogenesis. Both stress and antidepressants have been shown to affect levels of brain-derived neurotrophic factor (BDNF), which is normally highly expressed in hippocampus and prefrontal cortex and plays a major role in neuronal growth, survival, and maturation. BDNF also seems to have antidepressant-like actions and can induce molecular transcription in several key pathways.

Most psychosocial models focus on loss as the cause of depression in vulnerable, or less resilient, individuals. Exogenous factors may include social rejection or loss (interpersonal, financial, or health-related). Certainly, loss of income, job, social status, or the failure to achieve a life goal may produce profound mourning. Regardless, clinical manifestations in response to these stressors are ultimately mediated through brain circuitry and neurochemistry.

The pathophysiology of bipolar disorder is still being clarified, but studies have shown both structural and functional changes in those with the condition. Structural evidence from brain imaging studies shows a reduction of neurons and glial cells in areas such as the prefrontal cortex, amygdala and striatal regions, as

well as white matter hyperintensities. Positron emission tomography (PET) studies suggest serotonergic abnormalities reflected in fewer serotonin transporters and more serotonin 1a receptors. Other relevant neurotransmitters include dopamine and glutamate. For instance, drugs that increase dopamine release, such as amphetamines, can induce manic-like symptoms. Similarly, decreased dopamine reuptake and reductions in dopamine transporter availability are linked to bipolar disorder. In addition, increased cortical glutamate levels and vesicular glutamate transporter gene expression are also implicated in the neurobiology of bipolar disorder.

As with depression, bipolar disorder can be viewed as a disorder related to synaptic plasticity involving dysfunction of neuroprotective pathways and impaired neuronal resilience. Multiple pathways related to plasticity are implicated including impaired regulation of calcium signaling cascades, associated with oxidative stress, and mitochondrial and endoplasmic reticulum stress response dysfunction.

Several intracellular molecular pathways affected by lithium and pertinent to neuroplasticity have been investigated as potential pathophysiologic contributors. The phosphoinositol pathway, involved in protein kinase C activation, regulates expression of several genes including BDNF. In fact, altered levels of BDNF are posited to contribute to the polarity switch process. Another lithium target, glycogen synthase kinase-3 (GSK3) is a key component of Wnt signaling and has effects on neurotransmission, neuroplasticity, neuronal growth, and metabolism.

CLINICAL FEATURES

DEPRESSIVE DISORDERS

A depressive episode is distinct from the normal emotional feelings of sadness or loss or a passing state of these emotions. Functional impairment and significant distress are key criteria and indeed, depression encompasses dysfunction in affective, cognitive, behavioral, and psychomotor domains.

In order to make the diagnosis, at least one of two gateway symptoms must be present for a minimum of 2 weeks: depressed mood and/or substantial decrease in interest or pleasure. Interestingly, depressed mood can manifest in a variety of ways and patients may report feeling down, sad, depressed, anxious, angry, or irritable. Of note, males may be more likely to present with irritability or anger, sometimes making the diagnosis more challenging to identify. Women more often present with “classic” sadness or depression. Anhedonia, or inability to feel pleasure, manifests as a reduction or loss of interest in things, people, or activities. As “gateway symptoms,” the diagnosis of depression cannot be made in the absence of at least one of them.

Cognitively, patients may experience difficulty concentrating or making decisions, a decrease in productivity, forgetfulness, and slowed thoughts. In addition, patients often report distorted thoughts that are negative and pessimistic, including feelings of worthlessness, loss of self-esteem, and unreasonable self-blame or guilt. The future is regarded with a sense of doom or dread and hopelessness. Moreover, negative memories from the past may be preferentially recalled. At times, such cognitive distortions may be of delusional intensity. For example, patients may become convinced they are gravely ill or impoverished and unable to process or “believe” results from medical tests or bank reports. Other delusions typical of depression with psychotic features focus on pessimism or deserved punishment. Auditory hallucinations that are usually simple and mood congruent may be present as well.

The behavioral symptoms of depression include changes in appetite and weight and disruptions of sleep patterns. Sleep disturbances include difficulty falling asleep (early insomnia), waking up in the middle of the night (middle insomnia), and waking up earlier than usual (terminal insomnia). Middle and terminal insomnias are more specific to depression than early insomnia, which is more common in the absence of a mood disorder. However, some patients experience hypersomnia rather than insomnia. Similarly, patients often report poor appetite and

weight loss, although increased appetite and weight are sometimes observed, too. Other behavioral symptoms include loss of libido.

Psychomotor activity is usually diminished in depression and low energy and physical fatigue are often present. Patients may experience difficulty completing day-to-day activities and self-care or find that these activities require greater effort. In extreme cases, patients may become virtually immobile and mute, and this condition combined with loss of appetite and overall self-neglect can result in a medical emergency due to dehydration or poor nutrition. In contrast, some patients exhibit psychomotor agitation, which is often accompanied by intense anxiety. Agitation can often be seen in depressed patients but may also result from the side effects of antidepressant medications.

Perhaps, the most worrisome symptom of depression is suicidal thinking or behavior. Suicidal ideation may range from passing thoughts that life is not worth living to well-defined plans with intent to kill oneself. About 15% of patients with depression acknowledge a suicide attempt at some point in their lives and between 2% and 12% of patients with depression commit suicide. This is another way in which depression can lead to morbidity and mortality.

On examination, depressed patients characteristically exhibit a dejected posture, with bent shoulders, frowning, and a downcast gaze. Gestural movements and facial expressions are reduced, and grooming may be neglected. Patients usually take more time to start answering questions and speak slowly and softly.

BIPOLAR DISORDERS

The distinguishing feature of bipolar disorder is the presence of a manic or hypomanic state that lasts a week or longer (can be less for

P.1314

hypomania). As with depressive disorders, there are impairments in affective, cognitive, psychomotor, and behavioral domains.

Mania, lasting a minimum of 1 week, is characterized by abnormally elevated or euphoric feelings. As with depression, there can be significant irritability and anger, especially when the patient is frustrated. Patients often appear exaggeratedly cheerful and happy.

Cognitive abnormalities include rapid or even racing thoughts, which may translate into rapid, pressured speech that can, as the severity of mania progresses, become increasingly disorganized. As thoughts become disorganized, speech can exhibit flight of ideas or loosening of associations. In addition, patients are easily distracted and have difficulty focusing on tasks that require concentration. Patients also frequently exhibit impaired judgment and engage in activities they would normally eschew if well. Patients may go on spending sprees, engage in promiscuous sexual behaviors, or make risky business decisions. Cognitive distortions in mania often include inflated self-esteem and grandiose ideas such as a sense of being special, capable of anything, or possessing special powers. As in depression, the cognitive distortions can cross the line into delusional or psychotic thinking. Grandiose delusions are a common psychotic feature in mania.

Behaviorally, manic patients are usually overactive with increased energy levels and engage in multiple activities. Typically, the number of hours of sleep is reduced, without the sensation of fatigue or sleepiness. In fact, insomnia is often the first recognizable symptom of a manic episode. Appetite is usually reduced and combined with increased activity can lead to significant weight loss. Manic patients classically dress with bright colors, use excess make up, or wear extravagant clothing. Movements are exaggerated or theatrical, and patients may express excessive familiarity toward strangers.

From a psychomotor vantage, manic patients frequently have increased psychomotor activity. They may engage in both goal-oriented activities at an accelerated pace or be overactive in a general way, with pacing or fidgeting.

Interviewing can be very difficult, as manic psychopathology tends to block communication. It is usually counterproductive for the physician to spend time arguing with or countering the illogical thinking of the patient. Insight is absent in virtually all cases and, therefore, patients typically object to treatment.

Hypomania has a similar clinical presentation but may be briefer, cause less functional impairment, and has no psychotic symptoms.

Although the presence of manic or hypomanic episodes differentiates bipolar from depressive disorders, depression is prominent in bipolar disorder. In fact, over the course of the disorder, most bipolar patients spend significantly more time depressed than manic or hypomanic. Bipolar depression usually has an earlier onset, greater risk of suicidal behavior, likely linked to the greater time spent depressed, and more episodes of illness.

DIAGNOSIS

There is no pathognomonic sign or symptom and, as of yet, no biologic or neuroimaging markers that can establish the diagnosis of a mood disorder. Therefore, mood disorder diagnoses are established according to their clinical features. Each category has specific criteria, which are defined by consensus and described in manuals such as the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*). It is likely that these diagnoses will ultimately be understood as a grouping of multiple distinct disorders and more specific entities within the current disorders will be defined using genetics, epigenetics, brain imaging, and other methods.

Major depressive disorder (MDD) is diagnosed by the presence of at least one major depressive episode. Episodes can occur a single time but, more often, they are recurrent.

Persistent depressive disorder is a form of depression that has less than 5 symptoms, as required in MDD, but lasting for at least 2 years, with little or no remission during that time. Typical symptoms include low mood, lack of energy and interest, low self-esteem, and irritability. Chronic forms of depressive disorders are associated with poorer response to treatment, slower rate of improvement over time, younger age of onset, longer episodes, greater disease burden, higher rates of medical and psychiatric comorbidity, and higher rates of suicidal ideation.

Mood and associated physical symptoms may occur in relation to the menstrual cycle. **Premenstrual dysphoric disorder** is diagnosed if symptoms are present during the last week of the luteal phase, remit within a few days of the follicular phase, and are absent in the week following menses. A prospectively documented cyclical pattern over at least 2 consecutive months must be present to confirm the diagnosis.

Mood disorders in children and adolescents bring specific diagnostic challenges. Behavioral problems are common and include withdrawal, sullenness, truancy, poor grades, and tantrums. Children and adolescents showing persistent irritability, which manifests as frequent temper outbursts and angry, irritable mood in between outbursts, may be eligible for the diagnosis of **disruptive mood dysregulation disorder** (DMDD).

The presence of at least one manic episode is required to diagnose a **bipolar I disorder**. In contrast, a **bipolar II disorder** diagnosis requires a history of both depressive and hypomanic episodes. Recurrence of episodes, interspersed with periods of normal mood (euthymia), is the norm, although single episodes are possible. In some cases, patients never fully recover and continue on a chronic course.

Patients with **cyclothymia** alternate between mild, short-lived depressions and hypomania. The cycles may be continuous and last for several weeks to several months. Rarely do these patients complain specifically about the highs and lows they experience. More commonly, patients will complain only of being depressed at times, not realizing that they have been hypomanic at other times. Cyclothymia is sometimes a precursor to the more classic form of bipolar disorder.

Substance/medication-induced bipolar or depressive disorders can occur when mood episodes develop during or soon after substance intoxication or withdrawal or alternatively after exposure to a medication. Note that in cases where mania or hypomania ensues after treatment with an antidepressant, the diagnosis of bipolar disorder is warranted if the manic/hypomanic symptoms do not remit upon withdrawal of the antidepressant (considering the time needed for metabolic elimination of the compound). Similarly, **bipolar or depressive disorders due to another medical condition** occur when there is evidence from the history, medical examination, or laboratory findings that the mood episode is a direct pathophysiologic consequence of another medical condition. See [Table 149.1](#) for a list of common neurologic disorders associated with mood symptoms.

When patients present with the characteristic symptoms of a depressive or bipolar disorders but do not meet all the full criteria, a diagnosis of **other specified bipolar or depressive disorders** can be established if the condition causes clinically significant distress or impairment.

DIFFERENTIAL DIAGNOSIS

Sadness is a normal reaction to life adversity and is characterized by an adequate response in proportion to the provoking stimulus,

P.1315

relatively brief duration, and lack of a major impact on psychosocial functioning. In normal bereavement and adjustment disorders, there is typically a reduction in depressive symptoms after the removal of provoking stressors.

TABLE 149.1 Neurologic Disorders Commonly Associated with Mood Symptoms

Depressive Symptoms	Manic Symptoms
<ul style="list-style-type: none"> Stroke (depression as both risk factor and sequelae) 	<ul style="list-style-type: none"> Focal strokes in right basotemporal and inferofrontal region
<ul style="list-style-type: none"> Parkinson disease 	<ul style="list-style-type: none"> Stroke/tumor in perihypothalamic region
<ul style="list-style-type: none"> Huntington disease 	<ul style="list-style-type: none"> Huntington disease
<ul style="list-style-type: none"> Essential tremor 	<ul style="list-style-type: none"> Multiple sclerosis
<ul style="list-style-type: none"> Multiple sclerosis 	<ul style="list-style-type: none"> Head trauma
<ul style="list-style-type: none"> Epilepsy 	<ul style="list-style-type: none"> Neurosyphilis
<ul style="list-style-type: none"> Dementia 	<ul style="list-style-type: none"> Creutzfeldt-Jakob disease
	<ul style="list-style-type: none"> Frontotemporal dementia

Some medical conditions cause prominent mood symptoms. In addition to the history and physical examination, laboratory testing should include hepatic and thyroid function, studies of electrolytes, calcium, blood urea nitrogen, creatinine, a complete blood count, and a urinalysis (for drug abuse screening).

DIFFERENTIAL DIAGNOSIS WITH NEUROLOGIC DISORDERS

Twenty-five percent to 40% of patients with neurologic conditions, including Parkinson disease (PD) and HD, as well as Alzheimer dementia, develop a marked depressive syndrome at some point over the course of the illness. Evidence shows that mood symptoms may even precede neurologic manifestations in the cases of PD, HD, and essential tremor (ET). Critically, PD shares some symptoms with major depression, such as bradykinesia, decreased or even expressionless faces, bradyphrenia, stooped posture, loss of interest and concentration, and reduced libido. Comorbidity between the two disorders is highly prevalent, around 40%. Bromocriptine treatment is also associated with depressive symptoms. Features that facilitate the diagnosis of depression in these patients include the presence of a pervasive low mood (sometimes with diurnal variation), early morning awakening, pessimism (not proportional to the level of neurologic disability), and suicidal ideation. Of note, some psychiatric drugs directly affect dopaminergic transmission, such as first and second-generation antipsychotics or some specific selective serotonin reuptake inhibitors (SSRIs) in high doses, and can cause or worsen parkinsonian symptoms or cause tardive dyskinesias.

Depressive symptoms can occur in patients with ET with prevalences as high as 49%. Not only do these symptoms result from the functional impairment associated with a disabling tremor but also may be a part of the pathophysiologic process and in some cases even precede the onset of motor symptoms. A recent study revealed lower scores on items such as “reported sadness,” “inability to feel,” and “pessimistic thoughts” in depressed patients with ET.

Euphoria can also be seen in organic states. Frontal lobe lesions can manifest with euphoria, often in the form of silliness and lack of foresight. Extreme social disinhibition, in the absence of other features of mania, strongly suggests frontal lobe pathology.

Patients suffering from dementia may present with manic-like agitation or depression. Cognitive and behavioral changes mimicking depression, such as apathy and loss of concentration, are more common than those that mimic mania, such as restlessness and combativeness. The medical evaluation is most important in elderly patients because they are at the greatest risk of having another illness comorbid with depression. They may also have a different medical condition presenting as depression. Although “pseudodementia” may be a sign of depression in the elderly, this assumption should be regarded as a diagnosis of exclusion. The appearance of a late-life affective disorder, especially in patients with no family history of such a condition, suggests a medical etiology.

Psychiatric symptoms, such as irritability, impulsivity, anxiety, and depressed mood, are almost ubiquitous in HD, which may initially present as a depressive illness. Depression may predate the neurologic diagnosis by 4 to 10 years. Apathy is a symptom that typically worsens as the disease progresses and may be related to the disorder itself. Suicide and suicide attempts are common. Manic symptoms can occur but are not as common. Family history is indicative of HD, and the definitive diagnosis is made through genetic testing.

Mood disorders are very common in epilepsy, 55% of epileptics report depression, and they tend to have a pleomorphic presentation, sometimes not meeting full *DSM-5* criteria. Depressed mood, irritability, and anxiety are common. Mood disorders are classified according to their temporal relation to the occurrence of seizures as ictal, interictal, or postictal.

In some situations, as in the so-called masked depression, patients fail to report feeling sad or depressed and can present with pain, fatigue, and other vague medical complaints. The presence of at least five of the

necessary symptoms establishes the correct diagnosis. The differential diagnosis is especially important in neurology, as these patients often complain of headaches or backaches that are not amenable to conventional treatments with pain medication.

Sleep apnea can cause fatigue, diminished concentration, and other symptoms similar to those of depression. A polysomnographic study may be warranted, especially in obese patients presenting with depressive symptoms.

DIFFERENTIAL DIAGNOSIS WITH OTHER PSYCHIATRIC DISORDERS

The distinction between mood disorders and other psychiatric disorders can be difficult and further complicated by the fact that comorbidity is very common. The negative symptoms of schizophrenia, such as apathy, anhedonia, decreased motor activity, social withdrawal, and cognitive decline can resemble depression. On the other hand, patients with schizophrenia can present with grandiose delusions and florid agitation similar to mania. In mood disorders, delusional themes tend to be congruent with the main presenting mood. A history of periodic psychotic illnesses with a return to proper functioning between episodes is more suggestive of an affective disorder, whereas a history of chronic or deteriorating functioning is more suggestive of schizophrenia. A diagnosis based on a longitudinal evaluation is the most reliable. In the case of schizoaffective disorder, in which psychotic and mood symptoms coexist, the persistence of psychotic symptoms after resolution of mood symptoms validates the diagnosis.

Comorbidity with substance abuse disorders is prominent. In community samples, over 50% of individuals with mood disorders meet criteria for alcohol and/or substance abuse disorders. Patients may view substance abuse as a form of “self-medication” but often,

P.1316

symptoms are in fact caused or exacerbated by the substance. Such changes may be limited to the period of intoxication or occur after intoxication. If intoxication occurs frequently, it may produce diagnostic uncertainty, and prolonged abstinence may be necessary to make an accurate diagnosis. Patients with mood disorders who abuse both alcohol and drugs are more difficult to treat and have a higher rate of suicide attempts and suicide. Alcohol is often used in suicide attempts and may be the factor that triggers impulsive, selfdestructive behavior or that intensifies the effects of an overdose.

Depressed patients often have severe anxiety and sometimes experience panic attacks as part of their illness. Predominance of either anxiety or depressive symptoms usually helps to establish the correct diagnosis. Nevertheless, there is a high rate of comorbidity with depression and all forms of anxiety disorders.

In the case of personality disorders, especially borderline personality disorder, the differential diagnosis is made if characteristic personality features, such as feelings of emptiness, extreme rejection sensitivity, and frantic efforts to avoid perceived abandonment, exist outside mood episodes.

TREATMENT

TREATMENT OF DEPRESSIVE DISORDERS

Depression can be treated with either pharmacotherapy or manualized therapies such as cognitive behavioral therapy or interpersonal therapy. More severe depression may require both medication and psychotherapy as opposed to one treatment approach alone. Hospitalization may be necessary, especially for actively suicidal patients or for those whose personal care is so impaired that around the clock nursing is essential.

A family history of effective drug response or previous response to a medication may be used to inform

treatment selection. It is best with most medications to start with a low dose and increase slowly. Full benefit may take up to 4 to 6 weeks. After an initial episode, treatment should continue for 6 to 9 months at full dosage after the acute phase in order to prevent relapse.

Symptomatic relief with treatment may not result in immediate improvement of psychosocial function, which may be delayed. Relapses occur in up to 20% of patients in 6 months and over 30% in 1 year according to Keller. The risk of recurrence increases by 16% with each recurrent episode. The high rates of relapse have led to recommendations of maintenance treatment with drug therapy and prophylactic psychotherapy for patients with at least two episodes of depression.

Fifty percent to 60% of patients respond (50% improvement or better) to an initial course of antidepressant, whereas only 10% to 20% of severely depressed patients improve when given placebo. However, remission (return to baseline or near baseline) is harder to attain and only about a third of patients remit after a first antidepressant treatment, requiring use of a different medication or augmentation strategies (see in the following text).

Antidepressant medications are classified by molecular structure or by effects on neurotransmitters.

SSRIs and other new-generation antidepressants (mirtazapine, bupropion) are the drugs of choice for the treatment of depression. Common side effects include gastrointestinal disturbance, agitation (especially early in treatment), and sexual dysfunction. Note that patients with psychotic depression rarely respond to antidepressants alone and require either the addition of an antipsychotic drug or a course of electroconvulsive therapy (ECT) (see the following text).

Although in general, SSRIs are as effective as tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs) in mild to moderate depression, TCAs and MAOIs introduced in the 1960s are often still used for patients who do not respond to one or more of the newer medications. The relative reluctance to use TCAs and MAOIs is due to issues of tolerability and/or serious side effects, as well as the fact that they may be lethal if used in a suicide attempt. The most common adverse reactions when using TCAs are mainly due to their cardiovascular and anticholinergic effects.

As with any medication, drug interactions may occur and cross checking for these is key. MAOIs have important, life-threatening interactions with several drugs as well as interactions with food and, therefore, dietary precautions are essential.

Depression is often resistant to treatment. Several strategies have been developed to overcome this issue, such as combining antidepressants or augmenting antidepressant efficacy by adding other drugs such as lithium, stimulants (e.g., dextroamphetamine or methylphenidate), antipsychotics, buspirone, or thyroid hormone. Empirical data driving decision making around intervention selection for treatment-resistant depression is still lacking. Studies comparing outcomes have not shown an advantage for any of the augmentation or second-tier strategies described thus far.

Electroconvulsive treatment is indicated for patients with the following characteristics:

1. Failure to respond to adequate antidepressant pharmacotherapy trials
2. Depression with psychotic or catatonic features
3. Actively suicidal patients or manic patients so severely agitated that they must be rapidly controlled
4. Intolerance of side effects, as can happen in patients with PD, or allergies to multiple antidepressants
5. Inability to participate in pharmacotherapy or psychotherapy due to refusal to eat or drink or markedly slowed speech and cognition

ECT is a safe treatment and generally well tolerated. The most common side effect is mild, temporary memory loss. Because it is administered under general anesthesia, risks associated with anesthesia are also present. With proper medical preparation and screening, treatments may be administered even in the

presence of neurologic or cardiovascular conditions. At the end of the course of treatment, a maintenance regimen must be instituted to prevent relapse. This can take the form of antidepressant medications, usually in combination, or “maintenance” ECT, generally administered monthly.

TREATMENT OF BIPOLAR DISORDERS

Mood stabilization treatment is the gold standard for bipolar disorders. It serves to both control acute phases of the disease and prevent future episodes. Lithium is a potent antimanic. Remission is achieved in about 60% to 70% of cases, especially for patients with euphoric mania and infrequent episodes, although it takes several weeks for it to fully exert its therapeutic benefits. Lithium therapy requires regular blood level monitoring to prevent toxicity, which manifests at higher levels and can be life threatening. Agitated and medically ill patients are at increased risk for toxicity. Lithium can cause hypothyroidism in 10% to 20% of patients and is relatively contraindicated in renal disease. Tremor is a common side effect.

Anticonvulsants such as valproate or carbamazepine can be used with good results in dysphoric mania or rapid cycling. They are often combined with lithium. Mood stabilization with

P.1317

second-generation antipsychotics (olanzapine, quetiapine, risperidone, or lurasidone) is usually quicker and may also be more effective when psychotic symptoms are present. Sedating agents can also be used as adjunctive therapy for rapid control of agitated patients. The anticonvulsant lamotrigine has been shown to prevent recurrence of depression, but the data on its ability to control manic or hypomanic phases is weak. In the case of bipolar depression, treating a depressive episode with antidepressants alone carries the risk of switching to mania or hypomania. Nonetheless, aggressive treatment of depression is essential in bipolar disorder because it is in this phase that suicidal behavior occurs. Thus, although less dramatic than mania, it is certainly just as dangerous, if not more. Using mood stabilizers alone is only effective in a few cases. Most commonly, bipolar depression is treated with a combination of antidepressants and mood stabilizers. Quetiapine and lurasidone both have antidepressant effects and are U.S. Food and Drug Administration (FDA) approved for monotherapy in bipolar depression.

Manic relapse may be spontaneous, induced by therapeutic drugs, or induced by substances. With continued use of a mood stabilizer, the risk of antidepressant-induced mania is about 10%. Data suggest that newer antidepressants are less likely than tricyclics to precipitate manic “switches.”

After the second bipolar episode, regardless of polarity, patients should be treated indefinitely because relapse is almost certain. The treatment goal is to maintain euthymia and prevent either depression or manic episodes. Lithium has been the prophylactic drug of choice for decades, but the antipsychotic mood stabilizers are also approved for long-term prophylaxis. Consideration of side effect profiles as well as therapeutic benefits is essential when considering treatment selection.

TREATMENT OF MOOD DISORDERS COMORBID WITH NEUROLOGIC DISORDERS

Patients with dementia frequently develop psychiatric symptoms, including depression; elation; delusions; hallucinations; and periods of extreme irritability, agitation, or disinhibition, and dementia may be accompanied by full-blown psychiatric syndromes. These episodes are often brief. Nevertheless, modest doses of antidepressants may be of use. Side effects may be minimal with low doses. Antipsychotic medications must be used with extreme care but may be useful to treat agitation. They may induce extrapyramidal symptoms, especially the conventional ones. Depression and depression with dementia occur in almost 25% of patients with PD. The depressive symptoms respond well to low doses of antidepressants including the SSRIs. Occasionally, SSRI therapy increases the parkinsonism, especially sertraline at higher doses, wherein the drug's selective affinity for serotonin transporters is obviated. ECT is safe and effective and may improve both the depression and the motor symptoms of PD. In the case of HD, manic symptoms should be treated with the usual medications but often require smaller (one-third to one-

half) doses. At times, ECT may be lifesaving. Treatment of mood disorders associated with epilepsy depends on whether the episode in question is ictal or peri-ictal. The latter is treated as usual with pharmacotherapy and/or psychotherapy, whereas in the case of ictal episodes, complete resolution of the seizure episode is needed to achieve mood remission. Drugs used to treat mood disorders, including for example, lithium or valproic acid may cause or exacerbate tremor. See [Table 149.2](#) for a list of neurologic adverse effects of common drugs used to treat mood disorders.

TABLE 149.2 Neurologic Side Effects Associated with Drugs Used for Mood Disorders Treatment

Side Effect	Drug
Seizures	(All antidepressants and antipsychotics can potentially induce seizures.) Bupropion Maprotiline Amoxapine Imipramine Escitalopram Clozapine Selegiline
Tremor	Bupropion Lamotrigine SSRIs Antipsychotics (especially conventional) Phenelzine Trazodone Lithium Valproic acid
Akathisia	Aripiprazole and other antipsychotics SSRIs
Dyskinesia	Selegiline
Tardive dyskinesia	Conventional antipsychotics (theoretical risk for new-generation antipsychotics)
Cerebrovascular events	Increased risk with atypical antipsychotics in elderly
Headaches	Trazodone Venlafaxine
Ataxia	Lamotrigine Nefazodone

Aseptic meningitis

Lamotrigine (rare)

SSRIs, selective serotonin reuptake inhibitors.

OUTCOME

Mood disorders are a major cause of disability and are highly associated with poor psychosocial functioning, mainly due to depressive episodes, which are much more common and longer lasting.

First-onset MDD typically peaks from ages 14 to 19 years, although first depressive episodes can appear at any age. If untreated, an episode lasts on average 6 to 9 months. Fifty percent to 70% of patients with major depression have recurrent episodes in their lifetimes. Young age, presence of a severe preceding episode, persistence of even mild depressive symptoms, and a history of multiple episodes increase the likelihood of recurrence. Symptom profiles can often change from one episode to another. Around 12% to 20% of patients will present a chronic course. Risk factors for chronicity include a strong family history of depression, older age, longer duration of illness before treatment is sought, alcoholism, medical illness, disability of spouse, or multiple recent deaths of family members.

Bipolar disorder usually has an earlier age of onset than major depression. The first episode is more frequently depressive, with a

P.1318

peak incidence at age 17 years. Late-onset bipolar disorder is rare and is usually associated with organic disease. Mania typically ensues within 5 years of the first depressive episode.

In terms of the polarity of episodes, very few patients present only recurrent manic episodes with little or no depression. Rather, depressive episodes and symptoms tend to dominate the longitudinal course of bipolar disorder. Bipolar disorder can also vary in terms of the frequency of episodes. Almost all patients with bipolar disorder have recurrent episodes and episodes are more frequent and numerous than in depressive disorders. In some cases, patients may experience four or more mood episodes in a year, termed *rapid cycling*. Once thought to be a characteristic of the patient, rapid cycling can occur and later resolve itself with a return to less frequent episodes.

Bipolar patients usually function well when medicated. Nevertheless, although many patients are able to resume normal activities within several weeks to months after recovery, approximately 40% of patients have significant social dysfunction for up to 2 years after an episode. Persistent cognitive deficits are documented as well. Neurobiologic deterioration from repeated episodes may play a role in this phenomenon.

Suicide is the most dreaded outcome of mood disorders. The suicide rate in bipolar illness is higher than in any other psychiatric illness, responsible for the death of 8% to 15% of patients, and patients with bipolar disorder carry a 15-fold greater risk of suicide than in the general population. Risk is even greater in the case of comorbidity with substance abuse disorders.

Anxiety Disorders, Posttraumatic Stress Disorder, and Obsessive-Compulsive Disorder

Franklin R. Schneier

INTRODUCTION

Anxiety is an adaptive emotional state related to anticipation of threat; it can encompass fearful thoughts, symptoms of physiologic arousal, and preparation for fight or flight. *Anxiety disorders* are characteristic syndromes of maladaptation to various types of anticipated threat. Examples include dangers from predators, interpersonal conflicts, germs, and other hazards. Anxiety disorders are distinguished from mild episodes of anxiety by their persistence and intensity and also by the diagnostic requirement that they cause marked distress or impairment in functioning.

Anxiety disorders have historically included panic disorder, agoraphobia, specific phobias, social anxiety disorder, generalized anxiety disorder, obsessive-compulsive disorder (OCD), acute stress disorder, and posttraumatic stress disorder (PTSD). The recent revision of the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*), places OCD in a separate category of obsessive-compulsive and related disorders and PTSD in a separate category of trauma- and stressor-related disorders, in recognition of their unique features. Two disorders previously categorized as childhood disorders, separation anxiety disorder and selective mutism, are now also recognized as anxiety disorders that can persist into adulthood.

Anxiety and anxiety disorders may co-occur with neurologic disease through a variety of mechanisms. Neurologic disease processes may cause anxiety symptoms directly by dysregulating function of brain circuits that subserve anxiety. Alternatively, primary neurologic illnesses may lead to anxiety via psychological mechanisms as when visible signs of a movement disorder lead to embarrassment and social anxiety or when an uncertain or poor prognosis leads to anticipatory anxiety. A primary anxiety disorder or its treatment may generate neurologic manifestations, such as syncope secondary to hyperventilation in panic disorder, or a seizure due to abrupt discontinuation of a benzodiazepine. Neurologic and psychiatric conditions may also co-occur secondary to another causal agent as when combat trauma leads to both traumatic brain injury (TBI) and PTSD.

EPIDEMIOLOGY

The historical category of anxiety disorders constitutes the most common type of psychiatric disorder with a lifetime prevalence of over 25%. Anxiety disorders are more common in women by a 2:1 ratio, have an age of onset before 30 years in most cases, and tend to be chronic. Community prevalence rates for individual anxiety disorders range from 5% to 12% for social anxiety disorder and specific phobias to 1% to 2% for panic disorder and OCD with intermediate rates for PTSD and generalized anxiety disorder.

PATHOBIOLOGY

The neural circuits, neurochemistry, and behaviors mediating human anxiety share features with neural systems that mediate withdrawal responses to aversive stimuli across species. In humans, these responses incorporate higher cortical functions such as anxious anticipation and adaptations based on life experiences and culture. Twin studies show heritability of specific anxiety disorders in the range of 10% to 60%, but findings for individual genes explain only very small proportions of the overall risk. Environmental risk factors for anxiety disorders include early childhood trauma and acute stressors, such as interpersonal loss.

Studies in rodents and humans have implicated central nervous system (CNS) fear circuitry, including the

amygdala, hippocampus, and prefrontal cortex, in the development and maintenance of conditioned fear; this circuitry is activated when persons with social anxiety disorder, specific phobias, or PTSD are exposed to fear-inducing stimuli (Fig. 150.1). Anxiety disorders also have been shown to be associated with dysfunction of several neurotransmitter systems, including serotonin, norepinephrine, γ -aminobutyric acid (GABA), and glutamate. Dopamine dysfunction has also been reported, and elevated rates of panic disorder, generalized anxiety disorder, and social anxiety disorder have been reported in Parkinson disease. Sympathetic nervous system and hypothalamic-pituitary axis abnormalities have been found across anxiety disorders. Panic disorder has been associated with hyperventilation, hypocapnia, and disordered CO₂ regulation.

The pathobiology of OCD shows some differences from other anxiety disorders. Anatomic and brain imaging evidence suggest hyperactivity in a circuit involving the orbitofrontal cortex, basal ganglia, and thalamus. Acquired lesions in the corticostriato-thalamic circuit, parietal and temporal cortex, cerebellum, and brain stem have been reported to induce compulsivity. OCD has been associated with other neurologic conditions involving the basal ganglia, such as Tourette syndrome, Huntington disease, and Sydenham chorea.

CLINICAL FEATURES

Anxiety disorder patients may present with anxiety, avoidance, physical symptoms, secondary depression, or substance abuse. Complaints of anxiety should be assessed with respect to symptoms and cognitions, frequency and intensity, environmental precipitants, avoidance, and interference with functioning. Some anxiety disorder features can occur across these disorders. *Anticipatory anxiety* refers to apprehension in anticipation of a feared situation and may include worry, difficulty concentrating, or physical symptoms. Anxiety disorders are often marked by a failure of the habituation that normally occurs during continuing exposure to a feared situation. A *panic attack* is defined by intense fear that reaches a peak in minutes and includes a group of physical anxiety symptoms, often with feelings of unreality, dizziness, paresthesias, dyspnea, and fear of dying. *Phobic avoidance* involves excessive avoidance of circumscribed feared situations, and it is often the most directly disabling of anxiety disorder features.

FIGURE 150.1 Brain regions associated with PTSD. PTSD, posttraumatic stress disorder. (From Mahan AL, Ressler KJ. Fear conditioning, synaptic plasticity and the amygdala: implications for posttraumatic stress disorder. *Trends Neurosci.* 2012;35[1]:24-35.)

Anxiety often leads to symptoms of depression, so anxious patients should be evaluated for depressed mood, loss of pleasure, change in weight, sleep disturbance, fatigue, poor concentration, and suicidal ideation. Substance abuse is also common in anxiety disorder patients and may be either a precipitant of anxiety or a response to it. People with anxiety disorders are usually aware that the symptoms are related to an excessive or unrealistic reaction on their part, and in this way, they differ from patients with psychotic disorders with delusional fears.

Anxiety disorders may interact with other medical conditions so that patients with asthma may also experience dyspnea related to panic attacks, and individuals with disorders that attract unwanted attention (e.g., essential tremor) may be impaired by excessive fear of embarrassment as in social anxiety disorder. Medical conditions that can directly mimic anxiety symptoms include hyperthyroidism; hyperparathyroidism; cardiac arrhythmias; reactions to caffeine, cocaine, or marijuana; pheochromocytoma; and vestibular dysfunction.

DIAGNOSIS

See [Table 150.1](#) for key diagnostic features.

PANIC DISORDER AND AGORAPHOBIA

The essential feature of panic disorder, as described in *DSM-5*, is recurrent unexpected panic attacks followed by persistent concerns or significant changes in behavior related to fear of another attack. Patients with panic disorder are often first seen medically because of fears that they are having a heart attack or

stroke. Panic attacks may become cued by specific situations most commonly involving situations in which the person anticipates difficulty escaping or getting help in the event of an attack, such as traveling away from home, being in a crowd, or being alone. When people fear and avoid such situations, the diagnosis of agoraphobia is made.

Case Example of Panic Disorder

A 23-year-old woman presented to the emergency department complaining of 1-hour duration of light-headedness, weak legs, difficulty breathing, tingling sensations in her hands, and fear that she was having a stroke. Symptoms came on suddenly with no specific trigger, although she was feeling stressed after having had an argument with her boyfriend yesterday. Medical and neurologic evaluation was unremarkable. The patient was told that her symptoms were due to anxiety, and they subsequently resolved over a couple of hours. However, the patient developed daily recurrences of attacks over the next week, with fear that the symptoms would be persistent and disabling, even if they were not life-threatening. She called in sick to work and asked a family member to stay with her. Following 8 weeks of treatment with a selective serotonin reuptake inhibitor (SSRI) medication and cognitive behavioral therapy (CBT), her panic attacks remitted, although she continued to experience occasional brief surges of mild anxiety.

P.1321

TABLE 150.1 Key Diagnostic Features of Anxiety Disorders

Diagnosis	Key Diagnostic Features
Panic disorder	Recurrent unexpected panic attacks
Agoraphobia	Avoidance of situations where escape might be difficult in the event of experiencing panic-like symptoms
Social anxiety disorder	Persistent and excessive fears of negative evaluation in social or performance situations
PTSD and acute stress disorder	After a traumatic event, persistent intrusive thoughts, avoidance of reminders, dysphoria, and hyperarousal
Obsessive-compulsive disorder	Obsessive thoughts and repetitive compulsive behaviors
Generalized anxiety disorder	Excessive anxiety and worry about multiple issues
Specific phobia	Persistent and excessive fear of a specific object or situation
Separation anxiety disorder	Persistent and excessive fear of separation from an attachment figure

Selective mutism Persistent failure to speak in specific social situations (e.g., school); usually seen in young children

PTSD, posttraumatic stress disorder.

SOCIAL ANXIETY DISORDER (SOCIAL PHOBIA)

Social anxiety disorder, also known as *social phobia*, is characterized by an excessive fear of social situations due to fears of negative evaluation. The person may avoid social or performance situations or endure them with great distress. Physical symptoms, such as sweating, tremor, and blushing, may be present, but they are not necessary for the diagnosis as per *DSM-5*. The scope of feared situations may encompass most situations and appear similar to extreme shyness or may be limited to performance situations, such as public speaking. Social anxiety disorder is distinguished from normal shyness by its greater persistence and severity and its associated distress or impairment. Persons with social anxiety disorder often have difficulty participating in classroom settings or work meetings, dating, or engaging in social gatherings.

POSTTRAUMATIC STRESS DISORDER AND ACUTE STRESS DISORDER

Stress disorders occur in persons exposed to a traumatic event in which the person experienced, witnessed, or was confronted with actual or threatened death, serious injury, or sexual violence to self or others. PTSD features according to *DSM-5* include more than 1 month of (1) intrusive memories, dreams, or flashbacks or intense psychological and physiologic distress at exposure to reminders of the trauma; (2) avoidance of stimuli associated with the trauma; (3) alterations in cognition or mood, such as self-blame or inability to experience positive emotions; and (4) symptoms of increased arousal, such as hypervigilance, insomnia, poor concentration, irritability, or reckless behavior. Acute stress disorder is diagnosed when a similar syndrome is present in the month after trauma exposure, and it may progress to PTSD. When a TBI cooccurs, PTSD symptoms may overlap TBI-related neurocognitive symptoms.

OBSESSIVE-COMPULSIVE DISORDER

OCD is defined in *DSM-5* by recurrent obsessions or compulsions that are time-consuming (more than 1 h/day) or cause significant distress and impairment. Obsessions are recurrent and persistent thoughts, urges, or images that are experienced as intrusive and unwanted and cause marked anxiety or distress. The individual attempts to ignore or suppress the obsessions or to neutralize them with some other thought or action. Insight into the truth of obsessive beliefs may vary. Compulsions are repetitive behaviors, such as washing or checking, or mental acts, such as counting, that an individual feels driven to perform in response to an obsession or according to rigid rules. The individual may have ideas that the behaviors prevent distress or that they somehow prevent a dreaded event (e.g., death of a loved one). However, these behaviors are not realistically connected with what they are intended to prevent, or they are clearly excessive. Up to 30% of individuals with OCD have a lifetime tic disorder, and in such cases, the diagnosis should be specified as *tic-related*.

GENERALIZED ANXIETY DISORDER

Generalized anxiety disorder is characterized, according to *DSM-5*, by excessive anxiety and worry about a number of events or activities occurring more days than not for at least 6 months. The individual finds it difficult to control the worry, which is associated with three or more of (1) restlessness or feeling keyed up, (2) fatigue, (3) difficulty concentrating, (4) irritability, (5) muscle tension, and (6) sleep disturbance. Generalized anxiety disorder is highly comorbid with depression.

SPECIFIC PHOBIAS

Persons with a specific phobia exhibit persistent fear of a specific object or situation, exposure to which evokes a fear response out of proportion to the actual danger. As specified in *DSM-5*, common types are the following: animal (e.g., spiders or dogs), natural environment (e.g., storms, heights), situational (e.g., airplanes, enclosed places), and blood-injection-injury (e.g., needles, dentist). A vasovagal response has been specifically associated with blood-injection-injury phobia.

SEPARATION ANXIETY DISORDER

Separation anxiety disorder is characterized in *DSM-5* by an excessive fear of separation from an attachment figure as evidenced by at least three of the following: excessive distress related to separation, excessive worry about harm to an attachment figure, excessive worry about an untoward event that results in separation, reluctance to go out (e.g., to work), reluctance to be alone, reluctance to sleep away from an attachment figure, nightmares about separation, and physical symptoms when separated. Adults often worry about a significant other or a child.

SELECTIVE MUTISM

Selective mutism is generally diagnosed in young children but may persist into adulthood. As described in *DSM-5*, the diagnosis is based on observation that an individual manifests a persistent failure to speak in specific social situations (e.g., school) despite speaking in other situations. The behavior interferes with functioning and is not due to a lack of knowledge of the spoken language

P.1322

or a communication disorder (e.g., childhood-onset fluency disorder). A child with selective mutism may be unable to offer an explanation for his or her silence, although high levels of social anxiety often appear to be associated with this reticent behavior.

ANXIETY AND NEUROLOGIC DISEASE: COMORBIDITY AND DIFFERENTIAL DIAGNOSIS

Anxiety disorder symptoms can overlap greatly with symptoms of a variety of neurologic disorders, including movement disorders, epilepsy, or cerebrovascular disease. For example, tremor is a common manifestation of anxiety, and it is particularly common in performance situations for individuals with social anxiety disorder. Light-headedness, occasionally even leading to syncope, is common during panic attacks. Panic-related light-headedness is usually of short duration and accompanied by dyspnea, hyperventilation, and intense fear. Paresthesias, tinnitus, vertigo, impaired concentration, derealization, and depersonalization may also occur during panic attacks or other periods of high anxiety. Importantly, the presence of psychopathology does not rule out the presence of concurrent neurologic disorder, and symptoms of a primary neurologic disorder, such as tremor or vertigo, may be exacerbated by situational anxiety. When a comorbid anxiety disorder complicates a neurologic disorder, treatments targeted at each condition may be necessary.

Obsessive-compulsive symptoms have been specifically associated with several neurologic disorders sharing dysfunction of frontostriatal circuitry, including Huntington disease and Gilles de la Tourette syndrome. In patients with Huntington disease, obsessive-compulsive symptoms, particularly obsessive checking, pathologic impulses, and compulsive rituals, have been reported in 15% to 50% of cases. OCD symptoms are also elevated in persons with the genetic mutation for Huntington but who have not yet met criteria for the diagnosis.

Tics have a compulsive quality, and like compulsions, if resisted, they result in internal tension that is relieved by performance of the behavior. The compulsions of OCD, however, are often accompanied by a complex thought process (e.g., need to relieve a sense of contamination) that seems to motivate

the compulsive behavior. Compulsions that are present in patients with Tourette syndrome tend to be related to symmetry, counting, or “just right” thoughts and less likely to relate to fears of contamination or harm to others. Pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS) is a controversial variant of Gilles de la Tourette syndrome and childhood-onset OCD in which both conditions may be associated with the development of an immune response against group A β -hemolytic *Streptococcus*.

In epilepsy, there is an increased rate of anxiety disorders, and panic disorder symptoms are the anxiety symptoms most likely to be generated directly by a seizure. Patients with primary panic attacks are less likely than seizure patients to experience automatisms, impaired consciousness, or déjà vu experiences and more likely to have accompanying phobias, depression, and anticipatory anxiety.

Dementia is accompanied by elevated rates of anxiety, often in the form of generalized anxiety disorder symptoms. Rates of anxiety symptoms may be particularly greater in vascular dementia and frontotemporal dementia. The presence of anxiety in dementia is associated with a variety of worse outcomes, including more impairment in quality of life, activities of daily living, nighttime awakenings, and neuropsychological performance.

Males with the genetic syndrome fragile X commonly experience symptoms of multiple anxiety disorders, particularly social anxiety symptoms of poor eye contact and excessive shyness. They also have elevated rates of separation anxiety, panic attacks, and agoraphobia. Compulsive behaviors are present in most patients, but these often involve pleasurable activities rather than the unwanted compulsions characteristic of OCD.

In patients with multiple sclerosis, anxiety disorders occur at three times the rate of the general population. Generalized anxiety disorder, OCD, panic disorder, and social anxiety disorder have been found to be elevated in some studies. Anxiety is associated with confirmed exacerbations and pseudoexacerbations of multiple sclerosis and with greater impairment, although it has not been specifically linked to progression of brain lesions.

TREATMENT

GENERAL APPROACHES TO ANXIETY DISORDERS

Psychological and pharmacologic treatments ([Table 150.2](#)) have well-established efficacy for anxiety disorders. The two best established first-line treatments for most of the anxiety disorders are CBT and SSRI medications, based on dozens of controlled trials in specific anxiety disorders. Other psychotherapies, such as short-term psychodynamic therapies, and other medications, such as benzodiazepines, have been demonstrated efficacious in certain anxiety disorders. This section will describe the general features of CBT and classes of medication used for anxiety disorders, as well as their unique adaptations for specific anxiety disorders.

CBTs for anxiety disorders are short-term psychotherapies based on the observation that patients manifest cognitive distortions (irrational negative thoughts) that maintain anxiety and avoidance behaviors, and that deny them opportunities to disprove those fears or to experience habituation of anxiety symptoms.

Components of this therapy may include cognitive restructuring, exposure, and relaxation techniques.

Typically, an active therapist helps the patient identify his or her cognitive distortions and avoidance behaviors and introduces alternative approaches for coping with feared situations. Therapist and patient collaborate to conduct exposures to the feared situations in the presence of the therapist and through

homework assignments. As the patient uses new coping skills to manage the anxiety induced by the exposure without resorting to avoidance or rituals, new learning takes place and the habitual cycle of fear and avoidance recedes. A far smaller body of evidence exists for efficacy of other psychotherapy approaches to anxiety, including psychodynamic therapy. Disorder-specific features of CBT and other psychotherapies are discussed below under specific disorder sections.

SSRIs and serotonin-norepinephrine inhibitors (SNRIs) have emerged as first-line treatments for each of the anxiety disorders (with the exception of specific phobias) based on efficacy and acceptability. No single SSRI has been shown to be superior to others, although individuals often have different responses to different agents. Dosages are similar to those recommended for treatment of depression. Responses typically become apparent after 2 to 4 weeks of treatment, but an adequate acute trial may require 8 to 12 weeks of treatment, and nonresponders should have the dosage gradually increased to the maximum as tolerated. Common side effects include nausea, insomnia, fatigue, weight gain, and sexual dysfunction. Treatment guidelines tend to recommend that responders to an acute trial of medication be maintained on the effective dose for

P.1323

6 to 12 months, and when medication is discontinued, it should be tapered to minimize risk of withdrawal symptoms and relapse.

TABLE 150.2 Medications Used in the Treatment of Anxiety Disorders

Medication	Initial Dose (mg/day)	Target Dose (mg/day)	Indication (Level 1 Evidence)
Selective Serotonin Reuptake Inhibitors			
Sertraline	50 ^a	50-200	OCD, ⁹ PD, ² SAD, ⁶ PTSD, ⁷ GAD ¹²
Paroxetine	10 ^a	10-60	OCD, ⁹ PD, ² SAD, ⁶ PTSD, ⁷ GAD ¹²

50

50-300

GAD¹⁶

^aFor PD, antidepressants are commonly initiated at half the usual initial dose.

PTSD, posttraumatic stress disorder; PD, panic disorder; SAD, social anxiety disorder; OCD, obsessive-compulsive disorder; GAD, generalized anxiety disorder.

Medication is commonly combined with CBT, although evidence for additive efficacy is limited. Other medications, including some classified as benzodiazepines, tricyclic antidepressants, monoamine oxidase inhibitors, anticonvulsants, and antipsychotics, have also been shown to be effective for some of the anxiety disorders. These are discussed where relevant in the following text under specific anxiety disorders.

PANIC DISORDER AND AGORAPHOBIA

CBT for panic and agoraphobia has been shown efficacious in multiple randomized controlled trials (RCTs) [Level 1].¹ It helps patients decatastrophize their beliefs about physical symptoms through cognitive restructuring and interoceptive exposure, which involves purposefully inducing feared physical symptoms (e.g., by exercise or hyperventilation). Patients with agoraphobia purposefully approach their feared situations. Among pharmacologic treatments for panic disorder, SSRIs [Level 1]² and SNRIs [Level 1]² are first-line treatments. Benzodiazepines [Level 1],³ the antidepressant mirtazapine [Level 1],² and the older class of tricyclics (e.g., imipramine) [Level 1]⁴ and clomipramine [Level 1]⁵ have also been shown to be efficacious. Antidepressants are typically started at half of the usual starting dose, as some panic disorder patients will report excessive stimulation with initial dosing. Benzodiazepines are often prescribed on an as-needed basis for intermittent anxiety, but for panic disorder and social anxiety disorder (see the following section), they are most effectively used with standing doses. Alprazolam and clonazepam are the benzodiazepines that have been best studied in panic disorder. Benzodiazepines have rapid onset of effect and a relatively low rate of side effects other than sedation. They are sometimes used in combination with SSRIs. Disadvantages include potential for abuse, cognitive and motor impairment, risk of severe withdrawal symptoms if discontinued abruptly, and lack of efficacy for comorbid depressive symptoms.

SOCIAL ANXIETY DISORDER

CBT [Level 1]¹ is effective in either individual or group formats, incorporating role-playing techniques to practice exposure to feared social scenarios. SSRIs and the SNRI venlafaxine are first-line treatments based on numerous RCTs [Level 1].⁶ A smaller number of RCTs support use of the benzodiazepine clonazepam; the antidepressant mirtazapine, gabapentin, and pregabalin, which act at calcium channels; and the older antidepressant class of monoamine oxidase inhibitors (e.g., phenelzine) [Level 1].⁶ β -Adrenergic blockers (e.g., propranolol), taken on an as-needed basis, are commonly used for anxiety that is limited to predictable performance situations.

POSTTRAUMATIC STRESS DISORDER AND ACUTE STRESS DISORDER

Efficacy of CBT for acute stress disorder and PTSD has been established by more than two-dozen controlled trials [Level 1].¹ Goals of psychotherapy for acute stress disorder are to reestablish a sense of safety, build a therapeutic alliance, provide information, and allow ventilation of emotion only after the perceived threat ends. Treatment of PTSD involves education about the normal course of stress response, relaxation techniques, cognitive therapy to address pathogenic beliefs, and exposure to trauma-related stimuli through imaginal techniques, such as reviewing a script of the trauma, and through in vivo exposure. Pharmacologic treatments for PTSD are used primarily as an adjunct to psychotherapy. The SSRIs

paroxetine, fluoxetine, and sertraline and the SNRI venlafaxine each have a few RCTs supporting efficacy [Level 1].⁷ Benzodiazepines, however, have not been shown to be effective. Single controlled trials have supported efficacy for the serotonergic antidepressant nefazodone [Level 1].⁷ and

P.1324

the α_1 antagonist prazosin [Level 1].⁸ and two very small RCTs have suggested efficacy for the atypical antipsychotic risperidone [Level 1].⁷

OBSESSIVE-COMPULSIVE DISORDER

Exposure and response prevention is the most effective treatment of OCD based on many controlled trials including comparisons to medication treatment [Level 1].¹ This CBT involves systematically exposing a patient to feared situations and preventing ritualizing (e.g., touching dirt without washing, leaving home without checking the lock). Clinical trials report high response rates in patients who participate in this therapy.

SSRIs [Level 1].⁹ and the serotonergic tricyclic antidepressant clomipramine [Level 1].¹⁰ are the only established pharmacologic monotherapies for OCD. Patients may require maximal dosage and a 12-week trial to assess efficacy, and most patients achieve only partial benefit from these medications. The only pharmacologic augmentation strategy shown to be effective for partial responders to SSRIs, on the basis of several small RCTs, is the use of antipsychotic agents, such as haloperidol or risperidone [Level 1].¹¹ Refractory OCD has occasionally been treated neurosurgically by anterior cingulotomy, subcaudate tractotomy, or anterior capsulotomy. Deep brain stimulation has been studied in over 100 patients to date with some reports of at least short-term benefit.

SPECIFIC PHOBIAS

Desensitization by exposure is the preferred treatment for specific phobias, and it is highly effective. Medications have received little study, but benzodiazepines, taken as needed, are useful for feared situations that are encountered only occasionally.

GENERALIZED ANXIETY DISORDER

CBT for generalized anxiety disorder has established efficacy [Level 1].¹ and often incorporates self-monitoring of symptoms and their triggers, and relaxation techniques. In addition to SSRIs and SNRIs, which have established efficacy in multiple RCTs [Level 1].¹² other drugs with evidence for efficacy from RCTs include pregabalin [Level 1].¹² the serotonin 1a receptor agonist-antagonist buspirone [Level 1].¹³ and antihistamines (e.g., hydroxyzine) [Level 1].¹⁴ Although benzodiazepines were once a mainstay for generalized anxiety, recent studies have questioned the quality of the early trials in generalized anxiety disorder that established efficacy of these medications [Level 1].¹⁵ The antipsychotic quetiapine has appeared efficacious in several controlled trials but carries a risk of serious adverse effects, such as tardive dyskinesia [Level 1].¹⁶

SEPARATION ANXIETY DISORDER AND SELECTIVE MUTISM

There have been no studies of treatment of either of these disorders in adults. Controlled trials in children suggest that both SSRIs and CBT are beneficial for separation anxiety disorder. Studies of selective mutism similarly suggest a role for SSRIs and CBT.

TREATMENT OF ANXIETY DISORDERS COMORBID WITH NEUROLOGIC DISORDERS

Although there is little data to guide approaches to these patients, existing studies suggest that standard treatments for the comorbid anxiety disorder can be effective in reducing anxiety symptoms and impairment. For example, CBT has been shown to reduce anxiety symptoms and social adjustment in epilepsy patients with mixed psychiatric problems even in the absence of reduction in seizure frequency. GABAergic anticonvulsants such as benzodiazepines and pregabalin often benefit comorbid anxiety, and SSRIs can be

used with only small effects on seizure threshold. In dementia, psychosocial interventions are preferred for anxiety, as benzodiazepines and antipsychotics carry increased risks for the elderly and cognitively impaired. In Tourette syndrome, CBT and SSRIs should be considered for patients with comorbid OCD. Open trials for poststroke anxiety have suggested possible benefit for buspirone and for SSRIs plus psychotherapy.

OUTCOME

Efficacious psychological and pharmacologic treatments have been well established for most of the anxiety disorders. CBTs have yielded response rates upwards of 80% in some studies for those patients able to complete a course of treatment. Response rates to an initial trial of SSRI medication typically range from 50% to 70%, but less than half of these responders attain remission. These same approaches appear to be useful for anxiety disorders that are comorbid with neurologic disorders. Research is ongoing into exploring anxiety disorder treatments with novel mechanisms, improving treatment selection through personalized medicine, and developing alternative strategies for patients who do not respond fully to first-line treatments.

Somatic Symptom Disorders

Anna Lopatin Dickerman

Philip R. Muskin

INTRODUCTION

Somatic symptom disorders are a group of psychiatric illnesses in which patients experience bodily symptoms along with associated abnormal thoughts, feelings, and behaviors that cause clinically significant distress and functional impairment. Patients with somatic symptom disorders tend to initially present in medical or neurologic settings. The disorders account for medical and psychiatric morbidity among patients, as well as increased costs due to greater chronicity of symptoms, health care use, and higher rates of disability. Patients with somatic symptom disorders can be among the most challenging for both psychiatric and nonpsychiatric clinicians alike, as their presentation initially appears “real.” Evidence-based treatments exist for these illnesses, and timely recognition and appropriate referral may significantly improve outcomes. Therefore, it behooves all clinicians—and in particular neurologists, who often encounter these patients before psychiatrists—to be familiar with these complex conditions. Patients with somatic symptom disorders can present with almost any neurologic complaint, including (but not limited to) headache, sensorimotor loss, problems with gait, tremor and other movement disturbances, cognitive complaints, ocular symptoms, and urogenital symptoms. This chapter provides an overview of the different types of somatic symptom disorders, their epidemiology and pathophysiology, and treatment strategies.

SOMATIC SYMPTOM DISORDERS IN *DIAGNOSTIC AND STATISTICAL MANUAL OF MENTAL DISORDERS*, 5TH EDITION

The somatic symptom disorders have undergone significant diagnostic criteria revision in *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*) ([Table 151.1](#)).

There were several problematic issues with the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (*DSM-IV*), criteria for somatic symptom disorders (formerly referred to as *somatoform disorders*). Clinicians underdiagnosed these illnesses because of confusion about terminology. The *DSM-IV* diagnostic criteria were particularly challenging for nonpsychiatric clinicians, who are often the first to encounter these patients. Furthermore, the hallmark of somatoform disorders in *DSM-IV* was the absence of a medical explanation for the somatic symptoms. This resulted in a problematic mind-body dualism that does not conform well to actual clinical experience. Conditions that are medically “unexplained” are not necessarily psychogenic in origin, that is, fibromyalgia and chronic fatigue syndrome are not considered psychiatric illnesses. Having a medically unexplained symptom is insufficient to make a psychiatric diagnosis; conversely, it is possible to have a documented medical condition and still have an abnormal psychological response to the physical symptoms. Patients with somatic symptom disorders *may or may not have a comorbid diagnosed medical condition*. The distinctive characteristic of these disorders has been shifted away from the somatic symptoms or their underlying etiology per se and focused on the maladaptive way in which the patient presents and interprets symptoms.

The terminology of somatic symptom disorders in *DSM-5* reduces the number of disorders and subcategories to minimize problematic overlap and diagnostic confusion. Somatic symptom disorders are defined on the basis of *positive* psychiatric symptoms rather than the *absence* of medical explanation for symptoms. Diagnosis no longer requires an exhaustive workup necessitating that the clinician rule out any physiologically based medical condition. The notable exceptions to this new rule are conversion disorder (functional neurologic symptom

disorder) and pseudocyesis. *DSM-5* also eliminates the use of arbitrarily high symptom requirements that existed in *DSM-IV* diagnostic criteria for somatoform disorders. A large body of research has shown that the relationship between somatic symptoms and psychopathology exists along a spectrum that was not adequately reflected by these symptom count prerequisites.

The *DSM-IV* diagnosis of body dysmorphic disorder has been moved to the chapter on obsessive-compulsive disorder and related illnesses in *DSM-5*, as there is a large body of research establishing pathophysiologic connections between obsessive-compulsive illness and body dysmorphia. Body dysmorphic disorder is thus no longer considered a somatic symptom disorder. This research has considerable treatment implications. Somatization disorder, hypochondriasis, pain disorder, and undifferentiated somatoform disorder (all diagnoses in *DSM-IV*) have been removed and incorporated into two central diagnoses in *DSM-5*: somatic symptom disorder

P.1327

and illness anxiety disorder. Factitious disorder is now considered a somatic symptom disorder in *DSM-5*, as these patients often present with somatic symptoms in general medical settings. Psychological factors affecting other medical conditions is now a psychiatric diagnosis in *DSM-5*. The diagnosis is quite prevalent in medical and surgical patients. The revised *DSM-5* criteria should result in a reduction of the stigmatization of patients and to an improvement of diagnostic accuracy across various medical disciplines.

TABLE 151.1 *DSM-IV* Somatoform Disorders and New *DSM-5* Somatic Symptom Disorders

<i>DSM-IV</i> Somatoform Disorders	<i>DSM-5</i> Somatic Symptom Disorders
Somatization disorder	Somatic symptom disorder
Hypochondriasis	Illness anxiety disorder
Conversion disorder	Conversion disorder (functional neurologic symptom disorder)
Pain disorder	Factitious disorder
Body dysmorphic disorder	Psychological factors affecting other medical conditions
Undifferentiated somatoform disorder	Other specified somatic symptom and related disorder
Somatoform disorder NOS	Unspecified somatic symptom and related disorder

DSM-IV, *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition; *DSM-5*, *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition; NOS, not otherwise specified.

TABLE 151.2 Clinical Characteristics of *DSM-5* Somatic Symptom Disorders

Somatic symptom disorder

- One or more distressing somatic symptoms (including pain)

	<ul style="list-style-type: none"> • Maladaptive thoughts/feelings/behaviors related to the symptom(s) • Lasts at least 6 mo
Illness anxiety disorder	<ul style="list-style-type: none"> • Preoccupation with having or acquiring a serious illness • Somatic symptoms <i>mild or absent</i> • High level of health anxiety disproportionate to actual physical illness or risk of illness • Lasts at least 6 mo
Psychological factors affecting other medical conditions	<ul style="list-style-type: none"> • Psychological or behavioral symptoms that adversely impact an underlying medical or neurologic condition (either by interference with treatment, by constituting additional health risks, or by adversely impacting underlying pathophysiology)
Conversion disorder (functional neurologic symptom disorder)	<ul style="list-style-type: none"> • One or more symptoms of altered voluntary motor or sensory functions that cause significant distress or impairment • Symptom(s) incompatible with recognized neurologic or medical condition
Factitious disorder	<ul style="list-style-type: none"> • Falsified physical or psychological signs/symptoms via <i>identified deception</i> • Patient presents himself or herself (or his or her relative) as ill, impaired, or injured. • Deceptive behavior in the <i>absence of obvious external reward</i>

Table 151.2 summarizes the hallmark features of the *DSM-5* somatic symptom disorders.

SOMATIC SYMPTOM DISORDER

Somatic symptom disorder (somatization disorder in *DSM-IV*) is defined as an illness in which patients experience at least 6 months of one or more distressing somatic symptoms in addition to maladaptive thoughts, feelings, and behaviors related to these symptoms. This may include disproportionate or persistent thoughts about symptoms, an abnormally high level of anxiety about symptoms, and/or excessive time and energy devoted to the symptoms.

SAMPLE CASE

A 50-year-old woman complains of constant back pain. She is reluctant to take any narcotic analgesics for fear of addiction. Magnetic resonance imaging (MRI) of her back is not diagnostic. She continues to go to work daily but finds herself so exhausted at the end of the day from her pain that she goes to bed immediately when she returns home, unable to participate in any of the family's activities. Each time she improves and the neurologist recommends she return in 6 months, her pain increases and she seeks out a new physician.

EPIDEMIOLOGY

The prevalence of somatic symptom disorder is approximately 5% to 7% in the general adult population. Females report distressing somatic symptoms more frequently than males. Initial symptoms can begin at any age and usually appear by early adulthood.

Certain demographic factors are associated with a more severe clinical course, including female gender and older age. In elderly individuals, somatic symptom disorder is more likely to go unrecognized because of comorbid medical illness. The physical complaints of older patients may also be misattributed to “normal aging” or “understandable” concern.

Somatic symptom disorder occurs more frequently in individuals with lower educational/socioeconomic status. They have more severe illness and worse outcomes. Demographic factors that adversely affect clinical course include unemployment, history of childhood physical or sexual abuse or other adversity, medical and psychiatric comorbidity, and external factors that reinforce the illness (e.g., disability payments).

PATHOPHYSIOLOGY AND ETIOLOGY

As is the case for most psychiatric illnesses, there are biologic, psychological, and social factors that contribute to the development of somatic symptom disorder. Biologic risk factors include genetic vulnerability to increased sensitivity to pain and other physical sensations. There is also an emerging literature to suggest a potential role for psychoneuroimmune mechanisms of somatic symptom amplification. Proinflammatory cytokines are known to be involved in the production of illness behavior; chronic activation or sensitization of this system may result in nonspecific somatic symptoms and chronic pain. Some have hypothesized that immunologic mechanisms in the setting of infectious triggers may contribute to the development of somatic symptom disorders. Functional neuroimaging studies have demonstrated aberrant cortical and limbic activity that may impact conscious processing of mild or chronically painful stimuli.

Psychosocial risk factors for somatic symptom disorder include early childhood trauma such as physical, sexual, or emotional abuse and/or neglect. Social learning mechanisms such as the attention gained from physical illness or lack of reinforcement of nonsomatic (emotional) expressions of distress may also contribute to the occurrence of somatic symptom disorder. Intrinsic temperamental factors may correlate with a higher risk of developing somatic symptom disorder, including alexithymia (difficulty identifying inner emotional states) and neuroticism (high levels of negative affect). Difficulties in communication—from intellectual, emotional, or social limitations—can predispose to bodily expression of distress.

P.1328

DIFFERENTIAL DIAGNOSIS AND COMORBIDITY

Patients with psychiatric illness often present with somatic symptoms. Patients with major depressive disorder may experience prominent fatigue, whereas patients with anxiety disorders may experience tachycardia or abdominal pain. Usually the cardinal feature of these other illnesses is a pronounced mood disturbance accompanied by numerous other physical and mental symptoms, whereas the distress in somatic symptom disorders emanates predominantly from the physical symptoms themselves. Mood and anxiety disorders frequently co-occur with somatic symptom disorders. Depressive disorders are common in patients with somatic symptom disorder, particularly in the elderly. Patients with somatic symptom disorder are at risk to develop secondary substance use disorders.

Medical comorbidity is common among patients with somatic symptom disorder, which may further complicate the diagnosis. Iatrogenic creation of symptoms may be subsequently mislabeled as psychogenic. Common complications of somatic symptom disorder include iatrogenic harm from invasive procedures or dependence on habit-forming substances such as opiates. Greater medical and psychiatric comorbidity is typically associated with greater severity of illness, degree of distress, and functional impairment.

Cultural factors are crucial when considering the diagnosis of somatic symptom disorder; many culture-bound syndromes present with prominent physical symptoms. Differences in medical care across cultures can also affect the presentation and course of somatic symptom disorders. The ways in which individuals recognize and

respond to bodily sensations is influenced by numerous interacting factors that occur within a given social and cultural context, which affects the way in which the patient perceives illness and seeks medical attention.

TREATMENT

Somatic symptom disorder is difficult to treat, and the literature does not suggest a single superior treatment approach. It is recommended that the patient form a stable relationship with a primary care physician who regularly and reliably follows up on a predetermined scheduled basis. When talking to the patient with suspected somatic symptom disorder, a thorough/empathic approach will put the patient at ease and facilitate successful psychiatric referral and follow-up. Objectively corroborated problems should be judiciously investigated; however, unnecessary exhaustive diagnostic testing should be avoided, as this may inadvertently reinforce the development of new somatic symptoms or even cause iatrogenic harm. The therapeutic focus shifts from “cure” toward symptom management. In the case of somatic symptom disorder with predominant pain, use of addictive substances should be avoided.

Early psychiatric intervention is likely to improve outcomes for patients with somatic symptom disorder; greater chronicity of undiagnosed somatization is correlated with worse outcomes and makes subsequent mental health treatment more challenging. An interdisciplinary “team” approach to the patient is crucial; close collaboration between the mental health practitioner and the medical care provider can help minimize errors of diagnostic omission in either domain. Frequent communication between treatment disciplines helps maximize consistency and reduce the likelihood of the patient feeling dismissed or abandoned.

When discussing a suspected diagnosis of somatic symptom disorder with a patient, the clinician may emphasize that stress can generate physical symptoms without the patient's awareness. Providing education about the illness and giving patients a list of psychiatric diagnostic criteria is helpful in legitimizing and validating their complaints by giving them a “genuine” diagnosis. Developing a relationship with the patient's family may also be helpful for understanding and managing the greater social context in which somatic symptoms tend to occur.

Various treatments are successful for somatic symptom disorders. Psychotherapy is the mainstay of treatment for somatizing patients; such approaches include cognitive behavioral therapy [**Level 1**]^{1,2} and psychodynamic psychotherapy [**Level 1**].³

Data suggests that pharmacotherapy can be helpful in the management of somatic symptom disorder. Serotonergic antidepressants are moderately effective in reducing intensity of functional somatic symptoms. Medications are helpful in treating the comorbid depressive and anxiety disorders. Agents commonly used for neuropathic pain such as mixed noradrenergic/serotonergic antidepressants, tricyclic antidepressants, and certain anticonvulsants may be helpful. The mechanism of action for these agents remains to be fully elucidated, but recent research findings suggest potential modulation of the psychoneuroimmune pathophysiology described earlier.

When treating patients with somatic symptom disorder, consider the reinforcing role of secondary gain in maintaining symptoms. Although patients with somatic symptom clearly suffer, they may also obtain relief from certain societal, personal, and professional responsibilities as a result of their illness. Any successful treatment of somatic symptom disorder will seek as much as possible to eradicate these reinforcing agents and help reduce the possibility of further iatrogenic harm.

ILLNESS ANXIETY DISORDER

Illness anxiety disorder, formerly termed *hypochondriasis*, is characterized by a preoccupation with having or acquiring a serious medical illness that leads to clinically significant distress and dysfunction in social and/or

occupational function. In this condition, bodily complaints and symptoms are often absent or mild. The hallmark of illness anxiety disorder is distress and preoccupation related to the individual's *anxiety about the meaning or significance* of the somatic complaint rather than the actual symptoms. Patients with illness anxiety disorder have a high level of health anxiety, disproportionate to their actual physical illness or risk of illness. They may engage in excessive health-related behaviors, including frequently checking their body or researching diseases on the Internet. Medical reassurance or negative diagnostic tests are unlikely to alleviate these patients' excessive concerns.

SAMPLE CASE

A 35-year-old woman finds what she thinks is a lump in her breast. She has a strong family history of breast cancer. She requests an "emergency appointment" with a surgeon who tells her that she does not feel a mass. Imaging of the woman's breast shows no pathology. The woman continues to fear she has breast cancer, examining her breast repeatedly and calling her gynecologist's office weekly regarding her concerns that she might have breast cancer.

EPIDEMIOLOGY

Estimates of the prevalence of illness anxiety disorder are based on epidemiologic studies on the *DSM-IV* diagnosis of hypochondriasis. These community surveys and population-based samples demonstrate a 1- to 2-year prevalence of health anxiety and/or disease

P.1329

conviction ranging from 1.3% to 10%. In ambulatory medical populations, the 6-month/1-year prevalence rates are between 3% and 8%. Illness anxiety is equally prevalent in males and females.

Illness anxiety disorder is a chronic/relapsing condition that begins in early to middle adulthood. In the general population, health-related anxiety increases with age, often focusing on cognitive deficits. In medical settings, no significant age differences have been found between those with low and those with high levels of illness anxiety.

PATHOPHYSIOLOGY AND ETIOLOGY

There are biologic and psychosocial components to the development of illness anxiety disorder. A history of childhood abuse/neglect or serious childhood illness is a risk factor for the development of illness anxiety disorder in adulthood. Major life stressors or illnesses are factors that may trigger the development of illness anxiety disorder.

DIFFERENTIAL DIAGNOSIS AND COMORBIDITY

It is important to consider the presence of underlying medical or neurologic disease. Anxiety related to health and feeling well is a normal response to being diagnosed with a major medical illness. In order to make a diagnosis of illness anxiety disorder, symptoms must be *disproportionate* to the underlying physical disease; the patient must have severe and continuous anxiety that causes significant distress for a minimum 6 months.

Major mood and anxiety disorders are other differential diagnostic considerations. Depressed patients can become preoccupied with concerns about their body and health. What distinguishes illness anxiety disorder from depressive and anxiety disorders is the patient's narrowed and persistent focus on health-related anxiety. Patients who are psychotic and have somatic delusions typically have other symptoms of psychosis. Patients with illness anxiety disorder may develop depression; this may make it difficult to tease apart which of the two is the primary psychiatric diagnosis. Patients with mood disorders and psychotic disorders may develop somatic delusions. Delusions are fixed, false beliefs that are held with a degree of conviction and intensity that is not typically seen in illness anxiety disorder. Patients with delusions are not able to reality-test, whereas patients with illness anxiety disorder are usually able to accept the possibility that they may not be as sick as they fear.

Somatic delusions are often more bizarre or striking than the fears associated with illness anxiety disorder (e.g., delusions of complete bodily decay).

Illness anxiety disorder is a new diagnosis, therefore exact rates of comorbidities are not yet known. Prior research on hypochondriasis suggests that comorbidity is high in these patients. As many as two-thirds of illness anxiety disorder patients are likely to have at least one other major mental illness. Patients with significant illness anxiety are particularly likely to have comorbid depressive and anxiety disorders. Other common comorbid syndromes include somatic symptom disorder and personality disorders.

TREATMENT

The treatment of illness anxiety disorder has not been thoroughly researched. Patients referred early for psychiatric evaluation tend to have a better prognosis compared to those who receive only medical assessment and treatment. Psychiatric referral should be presented as a supplement, rather than an alternative or replacement for ongoing medical care and evaluation. Regularly scheduled, supportive treatment visits with a consistent primary care physician are helpful.

Evidence suggests that serotonergic antidepressants may be effective for somatic symptom disorders characterized by predominant illness anxiety [Level 1].^{4,5} Therapeutic dosages may be higher than those for depressive and anxiety disorders. Cognitive behavioral therapy may be a particularly effective form of psychotherapy [Level 1],^{5,6} with response rates at 12 months as high as 57%.

CONVERSION DISORDER (FUNCTIONAL NEUROLOGIC SYMPTOM DISORDER)

Patients with conversion disorder exhibit one or more symptoms of altered voluntary motor or sensory functions that cause significant distress or functional impairment. *DSM-5* specifies that *conversion disorder symptoms must be incompatible with recognized medical or neurologic conditions*. The diagnosis should not be made simply because diagnostic tests are normal or because the symptom is “bizarre.” Functional neurologic symptoms may be acute or chronic and may affect various sensory or motor modalities. The diagnosis of conversion disorder in *DSM-5* does *not* require that a psychological stressor precede the development of symptoms. This decision was made by experts in the field in recognition of the fact that it is not always possible to immediately identify an antecedent stressor in conversion disorder. Nevertheless, it is important to make the diagnosis as quickly as possible in order to minimize morbidity or iatrogenic complications. The change in the diagnostic criteria is not meant to imply that psychological factors are not present or important for the patient and the symptoms.

The conventional psychodynamic model of conversion is that patients with conversion disorder unconsciously transmute their psychic distress into physical symptoms. It can be difficult to definitively eliminate the possibility of conscious feigning when initially encountering a patient with conversion disorder. Therefore, the assessment of conscious versus unconscious production of symptoms is unreliable. Thus, the new diagnostic criteria for conversion disorder no longer require a definitive judgment that the symptoms are unconsciously produced.

SAMPLE CASE

A 33-year-old woman is admitted to after sudden loss of function of her right arm. She smokes one pack per day, is overweight, and is on oral contraceptives. The loss of function in her arm occurred during an argument with her ex-husband when she admits she felt like “bopping him.” When hypnotized by the psychiatric consultant, she is able to lift her right arm while in the trance; however, the arm becomes limp when she is out of the trance state.

PRESENTATION AND EPIDEMIOLOGY

Methodologic differences in epidemiologic studies of conversion disorder have led to great variability in the reported rates of prevalence. Lifetime prevalence rates in the general population range from 11 in 100,000 to 500 in 100,000. In the general hospital setting and the outpatient neurologic setting, lifetime prevalence rates are 4% to 15%. Conversion disorder usually presents in early adult life, and is approximately two to three times more likely to occur in females.

Conversion disorder is also more frequently seen in those belonging to groups of lower socioeconomic status and those with relatively less education. As with the other somatic symptom disorders, psychiatric comorbidity is high, for example, depressive

P.1330

and anxiety disorders and posttraumatic stress disorder as well as personality disorders and impairment of psychosocial functioning. Although conversion symptoms can be short-lived, it is not unusual for symptoms to recur in the same individual; 1-year relapse rates can be as high as 20% to 25%.

There is great variation in the degree of symptom severity among patients with conversion disorder. Good prognostic factors include acute onset and short duration of symptoms, presence of an identifiable stressor at the onset of illness, short interval between onset and referral to treatment, higher intelligence, and willingness to accept a psychological component to the illness. Underlying personality disorder is a poor prognostic indicator, as is comorbid somatic symptom disorder. The more long-standing the conversion symptoms, the more difficult it becomes to treat the disorder. This may be because of the accumulation of associated benefits over time (e.g., secondary gain). Comorbid psychiatric and medical illness is also associated with worse outcome.

PATHOPHYSIOLOGY AND ETIOLOGY

An underlying personal or family history of organic neurologic disease is a risk factor for the development of conversion symptoms. For example, patients with epilepsy are more likely to develop psychogenic nonepileptic seizures (PNES) than the general population; the estimated comorbidity of PNES in epilepsy patients is approximately 10%. Maladaptive coping style and personality traits as well as difficulty identifying and expressing emotion (alexithymia) may predispose an individual to development of conversion symptoms.

Patients with PNES have been found to have higher basal cortisol levels compared with healthy volunteers, a marker of overall greater stress level that is unrelated to seizure frequency, physical activity, or acute psychological stress. Statistically significant preictal heart rate increases and postictal heart rate reductions normalized to baseline have also been identified in those with PNES compared to patients with complex partial seizures.

Environmental factors such as childhood abuse/neglect and other stressful or traumatic life events are also associated with the development of conversion disorder. Dissociation, a commonly seen psychological response to trauma, has also been described in patients with conversion disorder, particularly those with PNES. Researchers have hypothesized similar psychological processes underlying conversion and dissociative disorders despite the descriptive differences between the two conditions. Any clinician treating patients with conversion disorder should be aware of the potential role of past trauma in this illness and should be sensitive to therapeutic implications in the management of a traumatized patient (particularly as it relates to forming a stable treatment alliance).

Neuroimaging studies in patients with conversion disorder show different patterns of brain activation and deactivation compared to patients who consciously feign symptoms. Although there is no commonly accepted theory about the functional neuroanatomy of conversion disorder, available evidence suggests that the illness may represent a “functional unawareness syndrome” involving networks involved in the processing of emotion

and affect. Several authors have established the presence of abnormal limbic-motor connectivity in conversion disorder.

DIFFERENTIAL DIAGNOSIS AND COMORBIDITY

A diagnosis of conversion disorder should only be made following a thorough neurologic assessment, including detailed history and examination and relevant imaging or other studies. Conversion disorder can be differentiated from organic illness by its incompatibility with known features of neurologic disease; however, as with the other somatic symptom disorders, actual physical illness and conversion disorder (or other apparent functional overlay) are not mutually exclusive. Overt evidence of deliberate feigning or exaggeration of symptoms should guide one away from a diagnosis of conversion disorder and more toward factitious disorder or malingering.

TREATMENT

Effective treatment of conversion disorder begins with empathic and positive communication of the diagnosis. It is generally best to avoid any comments that suggest to the patient that there is nothing “biologically” wrong with him or her in order to prevent embarrassment. It is helpful to inform the patient that he or she is clearly suffering from real symptoms that are concerning and disruptive but the expectation is that he or she will ultimately recover. The patient should be told that there is no need to be exposed to unnecessary medication or studies but that treatment focusing on managing the emotional issues and distress associated with the symptoms is very important for ultimate improvement. This type of phrasing can help engage the patient in a dialogue about any stress associated with the symptoms. Although the psychological conflict producing the symptoms may seem obvious to the physician, delicacy is required in presenting an interpretation of the proposed etiology to the patient. The most common “precipitants” are aggressive and sexual thoughts that are unacceptable to the patient; however, if the patient could easily cope with such thoughts, then the symptoms would not be manifested.

Despite the illness burden of conversion disorder and the therapeutic challenges inherent in its management, there is a lack of empirical data on effective treatment strategies. The majority of evidence for the treatment of conversion disorder is in the form of uncontrolled case series and reports. In general, the cornerstone of management for conversion disorder has been psychotherapy of various sorts. There is little clinical evidence to support the use of pharmacotherapy in the absence of other comorbid psychiatric conditions such as depressive or anxiety disorders. Some success has been reported with antidepressants and antipsychotics. Treatment with the antipsychotics is problematic given the potential for neuroleptic-induced movement disorder in patients who may already have psychogenic movement disorders.

Psychotherapy of patients with conversion disorder should be geared to helping the individual develop more adaptive coping strategies to deal with emotional conflicts and more effective ways of communicating distress. Cognitive behavioral therapy is one such therapeutic modality [Level 1].⁷ Psychoanalytic and psychodynamic approaches to conversion can also be quite effective [Level 1].⁸

In addition to psychotherapy, there are studies of small sample sizes with preliminary findings suggesting possible efficacy for hypnosis [Level 1],^{9,10} behavioral therapy and rehabilitation, physical therapy, and paradoxical intention. These treatments can be potentially “face-saving” for the patient, as they are based on a physical model of recovery, and may be particularly helpful for patients who have difficulty engaging in psychotherapy.

FACTITIOUS DISORDER

Unlike the other somatic symptom disorders, factitious disorder involves *intentional falsification* of physical and/or psychological symptoms or induction of injury or disease. The individual is aware

of the deception and presents himself or herself as ill, injured, or impaired. A subtype of factitious disorder involves the presentation of someone else close to the patient as ill, injured, or impaired. This was previously called *factitious disorder by proxy* in *DSM-IV* and is now referred to in *DSM-5* as *factitious disorder imposed on another*. Patients with factitious disorder may present with single or recurrent episodes. Munchausen syndrome is a particularly chronic and intractable form of factitious disorder.

Unlike the malingering patient, those with factitious disorder exhibit deceptive behavior *in the absence of any obvious external reward*. The traditional model of this illness rests on the idea that patients seek secondary gain via assumption of the sick role; however, *DSM-5* does not specifically list this as a diagnostic criterion because it is often not possible to reliably infer this early on in the disease course.

Common clinical characteristics often include a history of numerous prior medical evaluations and treatments, particularly hospitalizations, surgeries, and other invasive procedures. Other features that suggest the diagnosis include a dramatic or inconsistent history that is vague or variable in its detail, inexplicable laboratory results, inconsistent physical examination findings, use of highly medicalized jargon, minimization of the presence of scars from prior invasive procedures, or confabulation of details when attempts are made to corroborate history. Patients may also demonstrate remission of neurologic deficits when they believe no one is observing. The classic example of a patient with factitious disorder is someone who migrates to different treatment settings in order to avoid discovery of the psychopathology.

SAMPLE CASE

A 48-year-old woman is admitted for evaluation of an inoperable brain tumor. She has extensive records from prior hospitalizations. Neuroimaging reveals no pathology. When confronted, the patient reveals that she falsified the records for her “brain tumor.” She reports that she planned to commit suicide and wanted her family to think she had an incurable cancer and would not be upset when she took her life.

EPIDEMIOLOGY

Because of the level of deception in patients with factitious disorder, exact estimates of prevalence are unknown. In the general hospital setting, approximately 1% of individuals meet criteria for the disorder, but rates may be higher in specialized treatment settings. The typical course of factitious disorder is recurrent, intermittent episodes that last over the course of the life span. Patients usually present during adulthood. Factitious disorder is more common in women, but its course is often more severe and refractory in men.

PATHOPHYSIOLOGY AND ETIOLOGY

Factitious disorder often presents following a hospitalization for a medical condition or mental disorder. In factitious disorder imposed on another, it is following the child or dependent party's hospitalization. Risk factors include a history of childhood abuse, disturbed parental relationships/emotional deprivation, early life illness or extended hospitalizations, and exposure to or employment in the medical setting.

There are several psychodynamic and cognitive, social learning, and behavioral theories that have been posited for the development of factitious disorder. Neurobiologic findings of functional imaging studies have been inconsistent.

DIFFERENTIAL DIAGNOSIS AND COMORBIDITY

The major differential diagnostic consideration in factitious disorder is malingering. Patients may have features or elements of both conditions, that is, a patient who may be subconsciously motivated complain of pain while enjoying access to opiates.

Many clinicians have difficulty differentiating between the somatic symptoms of factitious disorder and those of conversion disorder. The hallmark of factitious disorder is deliberate deception or fabrication of symptoms. In conversion disorder, patients do not intentionally produce symptoms.

Patients with factitious disorder who injure themselves do so specifically in order to assume the sick role. They are not attempting to kill themselves or to obtain affective or emotional release from the self-injury. This distinguishes their self-harming behavior from those of patients with mood or personality disorders. Patients with factitious disorder may have comorbid personality disorders and have frequent comorbid substance use disorders.

TREATMENT

Factitious disorder is one of the most difficult psychiatric illnesses to treat. Not surprisingly, clinicians often have strong negative emotional reactions to patients who falsify symptoms. Care providers may feel exploited, humiliated, or angered. It is important to remember when treating the patient with factitious disorder that he or she is in fact quite ill but not in the way he or she presents. These patients are at significant risk of self-inflicted injury or death. If a diagnosis of factitious disorder is suspected, it is often helpful to confer with hospital administrative and legal services.

An additional therapeutic challenge is the fact that patients often abruptly flee from care once they are confronted about the false nature of their symptoms; other responses include denial or threats of litigation. There is a dearth of comparative literature examining the efficacy of various treatment approaches. In general, it is recommended that treatment be collaborative, involving interdisciplinary team meetings and communication among providers to coordinate efforts and manage negative emotions. Psychodynamic and behavioral approaches have been used to treat the disorder. Pharmacotherapy has a role in treating specific comorbid symptoms, such as mood or psychotic disorders, if present.

PSYCHOLOGICAL FACTORS AFFECTING OTHER MEDICAL CONDITIONS

Psychological or behavioral factors that adversely affect other medical conditions (PFAOMC) are very common. This diagnosis is included in the group of somatic symptom disorders because of its usual appearance in primary care and other medical settings. Psychological or behavioral symptoms may include psychological distress, patterns of interpersonal interaction, coping styles, and maladaptive coping strategies such as denial or poor adherence. These thoughts, feelings, and behaviors can adversely affect known medical conditions in a variety of ways. A common example of this is denial of the significance of physical symptoms, which may in turn lead to delayed medical intervention.

There may be a temporal relationship between psychological factors and development or exacerbation of a medical condition, as in the example of a depressed patient with diabetes mellitus who begins to neglect glucose control. Psychological factors may also interfere with treatment of a medical condition. Patients with a history

P.1332

of trauma may be particularly sensitive to certain invasive procedures and become resistant to medical workups. Psychological factors can constitute additional health risks or adversely influence underlying pathophysiology. A hypoxic patient with pulmonary disease who subsequently develops anxiety will experience vasoconstriction secondary to release of catecholamines, resulting in further reduction of oxygen delivery to tissues and a positive feedback loop contributing to exacerbation of both hypoxia and anxiety.

SAMPLE CASE

A patient with documented epilepsy is admitted in status epilepticus. When he recovers, he states that he has

taken all of his medications regularly; however, his serum levels of the anticonvulsants are zero. When confronted with this information, he admits that it is not “strong” to take medication and he stopped his medication.

EPIDEMIOLOGY

The exact prevalence of PFAOMC is unknown; however, private insurance billing data from the United States indicates that this diagnosis is made more commonly than somatic symptom disorder. Psychological factors may affect a medical illness at any point during the life cycle. Denial of medical illness is not currently a diagnosable disorder in *DSM-5* but is commonly seen in clinical settings.

DIFFERENTIAL DIAGNOSIS AND COMORBIDITY

By definition, the diagnosis of PFAOMC necessitates the presence of a comorbid medical illness along with a psychological symptom or behavior. The hallmark of PFAOMC is the directionality of psychological factors adversely affecting underlying medical or neurologic disease. Conversely, when psychiatric symptoms develop predominantly in response to the stressor of medical illness, a diagnosis of adjustment disorder is more appropriate. In actual clinical practice, psychological syndromes often co-occur with medical illness in a mutually exacerbating fashion, making it difficult to determine the exact direction of causality. If the symptoms leading to aggravation of medical illness are best explained by another major mental illness such as major depressive disorder, then it is this condition that should be noted rather than PFAOMC.

CONCLUSIONS

Somatic symptom disorders are a costly group of psychiatric illnesses that cause much suffering on the part of the patient and frequent frustration on the part of the clinician. This chapter has reviewed major recent findings on epidemiology and pathophysiology specific to each of the somatic symptom disorders. Fortunately, a variety of evidence-based therapeutic modalities are available for some of these disabling disorders. Treatment should be focused on understanding and treating dysfunctional thoughts, feelings, and behaviors related to the somatic symptoms, as opposed to attempting to completely eliminate the symptoms themselves. Invasive workups should be initiated with caution. Early recognition and appropriate referral by general and medical neurologic practitioners remains the initial crucial step in facilitating treatment and may significantly improve outcomes. Neurologic follow-up is important to prevent feelings of abandonment and ensure that relevant medical or neurologic illness has not been missed.

Neurologic Rehabilitation

Heidi Schambra

Laura Lennihan

INTRODUCTION

Neurologic disorders commonly cause impairments that impede intellectual and physical activities. Neurologists play an important role in prescribing and monitoring rehabilitation therapies to maximize functional recovery and in optimizing patient health for maximal engagement in these therapies. The selection and timing of these therapies substantially contribute to the optimal quality of life for patient and family. There is significant variability in access to rehabilitation services, and many people with acute and chronic neurologic conditions do not receive adequate rehabilitation therapy. When given proper training and equipment, these patients may improve in independence, access to the community, and ease with which caregivers assist them. The medical and neurologic management of patients with neurologic injury begins in the acute setting and continues throughout the course of their care, through varied institutional and home settings. Experience with neurorehabilitation is essential in the management continuum of acute to chronic neurologic disorders.

The World Health Organization's (WHO) *International Classification of Functioning, Disability and Health* (ICF) defines limitations caused by disease in three broad categories: bodily functions, personal activities, and societal participation. These definitions provide a structure for understanding the impact of disease on personal independence and integration into society and can help to identify patients who may benefit from rehabilitation. The planning and prescription of a rehabilitation program for a neurologically impaired individual requires characterization of the neurologic disorder in terms of natural history, localization, and extent of nervous system involvement; determination of functional disabilities caused by cognitive and physical impairments; and definition of these disabilities in the context of the patient's physical and social environment. Combining this information with knowledge of available resources for postacute care, the type and intensity of rehabilitation therapies can be planned.

Impairments caused by neurologic disease or injury frequently affect an individual's ability to perform functions, such as activities of daily living (ADLs) and instrumental activities of daily living (IADLs). ADLs include the basic activities an individual performs daily, including feeding, grooming, dressing, toileting, bathing, and mobility. IADLs are activities beyond basic self-care that allow a patient to participate in the home and community, such as meal preparation, housekeeping, laundry, shopping, using a telephone/technology, driving a car/using transportation, and money management. The most commonly used ADL measurement tool in an acute rehabilitation population is the functional independence measure (FIM). The FIM is a seven-point ordinal scale of function, addressing self-care, bladder and bowel continence, mobility, and social cognition. The minimum score is 18 and the maximum is 126, and scores grossly indicate levels of patient dependency and burden of care. A typical trajectory of improvement in the FIM score following an acute stroke in a patient receiving daily intensive comprehensive rehabilitation is about one point per day. Of note, because the FIM evaluates ADLs at the level of task completion, it does not distinguish between gains made from reduced neurologic impairment and gains made using compensatory strategies.

COMPENSATION AND RECOVERY

Two principal approaches are used in neurorehabilitation programs: compensating for impairment and training to reduce impairment. *Compensation* teaches adaptive techniques using preserved neurologic function to

circumvent neurologic impairment. For example, a person with a paralyzed arm can be trained in onehanded techniques using the normal arm, a patient unable to walk can learn to use a wheelchair, or a patient with expressive aphasia can communicate with a picture board. Although this approach yields faster results and improves functional independence by reducing disability at task level, it does little to diminish the original neurologic impairment. Troublingly, rodent models suggest that training compensation after stroke (e.g., using the nonparetic limb to grasp a food pellet) impedes the beneficial effects of training to reduce impairment in the paretic limb.

Training to reduce impairment augments spontaneous neurologic recovery and facilitates the return of neurologic function. For example, a patient practices reaching and grasping with a paretic arm to improve motor control, a patient with gait dysfunction practices locomotion, or a patient with visual neglect practices shifting visual attention to the neglected space. This approach requires intensive training for weeks to months and is superior for the biologic restoration of function. However, in patients who are unable to engage in training due to the severity of their impairment, it may not be a suitable main approach.

Some combination of both strategies is commonly applied in neurorehabilitation programs. However, given ever diminishing lengths of stay and the cost-benefit considerations of compensatory and impairment training, a personalized selection of rehabilitation approaches is warranted. Tailoring the rehabilitative approach based on recovery potential is an area of current clinical research. Knowing a patient's potential would enable clinicians to set sensible rehabilitation goals and could guide the team toward the most appropriate therapeutic approach. A clinical trial is currently underway validating an algorithm for predicting motor recovery potential, which takes into account a patient's motor function and corticospinal tract integrity.

In addition to task-oriented training to reduce motor impairments in patients with motor dysfunction, exercises to increase the strength of muscle groups are also commonly used. However,

P.1336

cortical map reorganization in animal models does not result from resistance training, and there is insufficient evidence from clinical trials to support the use of resistance training to aid in recovery [**Level 1**].¹

Most patients who have marked neurologic injury, particularly those with stroke, are deconditioned and have limited exercise capacity and aerobic reserve. Rehabilitation therapy with mobilization and exercise helps to increase general conditioning and tolerance for exercise. In animal models, cardiovascular exercise increases production of brain-derived neurotrophic factor (BDNF), which supports synaptogenesis and synapse stabilization. A recent meta-analysis of human stroke rehabilitation trials showed improvement in disability with cardiorespiratory training, largely attributed to improved gait and balance metrics [**Level 1**].¹

NEUROPLASTICITY AND RECOVERY

Following focal injury, the central nervous system (CNS) undergoes long-lasting structural and functional changes. Neuroplasticity is heightened by the injury itself, which can be leveraged for enhancing activity-dependent gains made through rehabilitative training. Injury-induced plasticity after CNS injury and activity-dependent plasticity share many common mechanisms and substrates. Importantly, it is the combination of both that produces maximal recovery gains.

INJURY-INDUCED PLASTICITY

Injury to the CNS activates neurobiologic recovery processes. Elucidating the underlying neurobiology of spontaneous recovery, particularly after focal CNS lesions, is a rapidly evolving field. Animal models of CNS injury have helped build our understanding of the complex molecular and cellular aspects of recovery in the brain and spinal cord. Rapid, significant changes in gene expression and protein production which occur after injury, help or hinder plasticity in perilesional and remote brain and spinal cord areas.

At the cellular level, processes that promote plasticity include neuronogenesis and angiogenesis, axonal sprouting, dendritic arborization, synaptogenesis and silent synapse unmasking, changes in synaptic strength, and changes in glutamatergic and GABAergic tone. Processes that limit plasticity include excitotoxicity, free radical formation, delayed neuronal death, edema, inflammation, expression of growth inhibitors, and glial scar formation. Importantly, these processes peak and wane within the first weeks to early months after injury, underscoring the limited time window for optimized combination with rehabilitation training.

Research in targeting these plasticity modifiers, either by upregulating or downregulating their effects, is actively underway. For example, in animal models, selective serotonin reuptake inhibitors (SSRIs) increase expression of BDNF and synaptogenesis. A recent multicenter, double-blinded, randomized controlled trial compared 3 months of fluoxetine versus placebo in severely impaired stroke patients, started within 5 to 10 days after stroke. Both groups received conventional rehabilitation. At 3 months, patients who received fluoxetine had significantly improved motor impairment and disability scores than those who received placebo [Level 1].² There appears to be a modest class-wide effect on recovery [Level 1].³

ACTIVITY-DEPENDENT PLASTICITY

Using training to capitalize on neuroplasticity after brain injury is the objective of neurorehabilitation. The optimal type, timing, and dose of training required to maximize activity-dependent plasticity after CNS injury is an area of active basic and clinical research. Some direction about best practices can be gained from animal stroke studies in the motor system. One clear principle that has emerged from animal models is that injury-induced plasticity requires adjunctive paretic limb training in order to promote recovery. In animal studies, intracortical microstimulation techniques may be used to track in vivo neuroplastic cortical map changes. In healthy animals, skilled training results in the expansion of cortical representations of the training effectors, whereas rote, unskilled movements lead to no change. These cortical map changes are associated with increased synaptogenesis and dendritic arborization. In a nonhuman primate model of motor stroke recovery, lost cortical motor representations do not spontaneously reappear if the paretic arm is not trained and the nonparetic arm is used to compensate. In animals trained to reach and grasp with their paretic arm, perilesional distal forearm representations expand into areas that previously subserved the proximal arm. These results suggest that training directed at reducing impairment promotes neuroplasticity.

How early to begin therapy is a point of debate, given concerns about glutamate excitotoxicity after CNS injury. In rodent models of stroke, paretic limb training started 5 days after stroke results in greater functional gains than the same amount of training started 30 days after stroke. In a recent phase II randomized controlled trial, a faster return to unassisted ambulation was found in patients who were mobilized earlier (< 24 hour after stroke) and who received more intensive gait training compared to those receiving standard of care; a large phase III clinical trial testing this early intervention is currently underway.

The dose of therapy is also an issue of exploration. From animal and human motor learning studies, it is clear that high doses of repetitive, goal-directed practice are required for long-term skill gains. A recent observational study of inpatient and outpatient rehabilitation sessions found the number of functional repetitions to be an order of magnitude less than would be needed for conventional skill gains. Meta-analyses of dose response to training modestly support improved motor outcomes at higher doses of exercise-based therapy.

However, it is possible that too much therapy, particularly initiated early after injury, may be suboptimal. For example, a recent randomized, single-blind phase II trial investigated the long-term motor benefits of different doses of constraint-induced movement therapy (CIMT) initiated within 2 weeks post stroke. CIMT forces the use of the paretic arm through restraint of the unaffected arm. CIMT performed equally well to dose-matched traditional therapy. However, high-dose CIMT, which restrained the nonparetic arm for 90% of waking hours, resulted in less motor improvement. From these results, it appears that moderately intensive therapy delivered

early after an acute CNS insult may be optimal for impairment reduction.

LEVELS OF CARE

Rehabilitation services are provided in a variety of settings and at varied levels of intensity and duration. Postacute care can occur in inpatient rehabilitation facilities (IRFs), in skilled nursing facilities (SNFs), from home health agencies (HHAs), or at outpatient facilities. At IRFs, patients receive 3 hours of therapy 5 to 7 days per week for usually less than 1 month. There is daily physiatrist or neurologist oversight. At SNFs, patients receive 0.5 to 2 hours of therapy 5 to 6 days per week for usually less than 2 months. There is weekly to monthly physician oversight, usually by a general

P.1337

practitioner, internist, or geriatrician. In outpatient therapy, be it in-home or at a facility, patients receive 0.5 to 1 hour of therapy 2 to 3 times per week, durations average 1 month, and there is no physician oversight.

In an IRF, the most common neurologic diagnoses are stroke, traumatic brain injury, and spinal cord injury; also seen are multiple sclerosis (MS), Parkinson's disease, and peripheral neuropathies (particularly critical illness neuromyopathy and acute inflammatory polyneuropathy). For patients hospitalized with acute neurologic injury, functional outcome is improved by an experienced, coordinated interdisciplinary team providing a comprehensive rehabilitation program. Stroke patients who receive rehabilitation therapies on a stroke rehabilitation unit have better functional outcomes and shorter hospital stays than those treated on a general neurology ward, and benefits persist over time. Similarly, stroke patients admitted to hospital-based intensive rehabilitation programs have better functional recovery and are more likely to return home than those treated in a low-intensity rehabilitation program at an SNF.

Multiple considerations go into determining the best placement for the medically stable neurologic patient. For admission to an IRF, the patient must have impairments that necessitate at least two therapy types (see the following text), must tolerate at least 3 hours of therapy daily, and must have 24-hour medical and nursing needs. Placement at an SNF typically occurs when the patient is unable to tolerate a high intensity of rehabilitation or has low capacity for functional improvement and has reduced medical and nursing needs. Outpatient therapy is appropriate for patients with mild and limited deficits or follows a course of inpatient rehabilitation to extend functional training at home or in the community. Interestingly, availability of postacute care is a more powerful predictor of its use than the clinical characteristics of the patients. Nonclinical factors that strongly influence placement include availability, convenience, distance to provider, demographic factors (age, race, and marital status), insurance status, local practice patterns, and characteristics of the discharging hospital (size, ownership, status as a teaching hospital, etc.).

THE DISCIPLINES

A comprehensive inpatient neurorehabilitation program requires an interdisciplinary team composed of the physician, physical therapist, rehabilitation nurse, occupational therapist, speech language pathologist, neuropsychologist, social worker, and recreational therapist. All team members participate in formulating a treatment and discharge plan, working together to attain collective goals of reducing patient disability, and in educating and training the patient and family in preparation for return home. Importantly, patients must also shift from being passive recipients of medical treatment in the acute setting to being active participants in their own therapy to maximize their neurologic recovery.

PHYSICIAN

The physician, as team leader, defines the type and prognosis of the neurologic disorder, sets realistic treatment goals, and coordinates the rehabilitation services. The major role of the physician is to optimize patient engagement in therapy through management of medical issues (e.g., orthostatic hypotension, depression, pain,

constipation or incontinence, infection, nutrition and hydration, etc.). With the team, the physician reviews progress toward attaining functional goals that allow the patient to return home. Roadblocks, alternative strategies, and discharge dispositions are discussed at weekly team rounds. Postdischarge plans for home care and outpatient therapy are coordinated with the patient and family.

REHABILITATION NURSING

Rehabilitation nurses provide general medical and more targeted nursing for patients with neurologic dysfunction. A major nursing focus for the neurologically impaired patient is prevention of pressure ulcers due to immobility and management of bowel and bladder incontinence (see the following section). In the inpatient setting, the nurse helps incorporate skills learned in therapy into the patient's daily routines. The nurse also educates the patient and family in medication administration, self-catheterization, and skin care.

PHYSICAL THERAPY

Physical therapy (PT) focuses on bed mobility, transferring to chair or toilet, ambulating, and stair climbing. Techniques and orthotics are chosen to maximize safe and independent mobility; to optimize energy efficiency; to prevent decubitus skin ulcers, tendon contractures, and falls; and to enhance motor recovery. Limitations in mobility and sensorimotor function are addressed by strengthening exercises, gait and balance training, and stretching. PTs also concentrate on musculoskeletal and orthopedic injuries. Typical problems associated with neurologic injury include musculoskeletal pain, muscle spasm, joint pain, heterotopic ossification, and contractures.

Leg and trunk weakness, impaired postural reflexes, ataxia, proprioceptive loss, and hemineglect may all interfere with ambulation and are actively managed. Bracing, assistive devices (e.g., cane, walker), or a wheelchair are used as compensatory strategies for safe completion of ADLs. Although a person may not be able to walk immediately after neurologic injury, ambulation usually becomes possible with the use of a walker or cane and a combination of bracing at the ankle and sometimes the knee. When ambulation is not possible, mobility is attained through training in the use of a wheelchair of the correct size and height, occasionally employing a special seat to prevent skin breakdown or cushions for trunk support.

OCCUPATIONAL THERAPY

Occupational therapy (OT) focuses on functional loss in ADLs and limitations in the patient's occupational and social role caused by neurologic injury. OTs treat patients with the goal of enabling patients to return to home, community, and work (which was traditionally its focus, hence its name). Typically, OTs concentrate on impairments affecting the use of the arms and hands, such as weakness, sensory loss, ataxia, and abnormal tone. Improving motor skills is only one of the important components in enhancing performance of ADLs. OTs thus also address impaired attention, judgment, cognition, and memory; visuospatial neglect; and apraxia. Training focuses on restoring upper extremity functional skills that are important for self-care at home and autonomy in the community. If necessary, adaptive aids are used to increase the use of the impaired arm and hand, such as hand and wrist orthoses, reachers, Velcro closures, and built-up utensils. When the impairment is unilateral and severe, an occupational therapist may select adaptive equipment and train the patient and family to compensate. Advanced programs may include learning special one-sided techniques, such as driving with the left hand and foot.

OTs additionally manage paretic shoulder subluxation to forestall shoulder-hand syndrome and select orthotics such as wrist and hand splints to prevent contractures. They also optimize safety and functionality in the home environment by training the patient and the family in use of adaptive equipment (e.g., tub benches, elevated toilet

seats, ramps, grab bars, safety rails).

SPEECH, LANGUAGE, AND COGNITIVE THERAPY

The speech-language pathologist (SLP) focuses on dysphagia (see the following section), dysarthria, aphasia, and cognitive dysfunction in the neurologically impaired patient.

Treatment of dysarthria aims to improve intelligibility and includes methods such as slowing and exaggerating articulation, increasing breath support, and pacing speech rate. For aphasia, the SLP identifies areas of strength and weakness in receptive and expressive language. Areas of strength may then be used for compensatory purposes, such as using better preserved written expression in lieu of verbal expression. Therapeutic approaches vary widely but can employ visual and verbal cueing, melodic intonation, and constraint-induced language therapy. For example, use of visual imagery as an internal cue may help to overcome the word blocking of expressive aphasia.

For cognitive rehabilitation, speech and occupational therapists collaborate on program development and implementation, and all members of the rehabilitation team contribute. Neurobehavioral impairments and how they interfere with function are first identified. Diffuse brain injury may affect several cognitive domains, and the therapeutic approach is tailored to the nature and complexity of the symptoms. For example, inattention and distractibility may preclude participation in group activities such as business meetings, or memory impairment may lead to failure at school. In diffuse or multifocal brain injury that impairs attention, behavior, cognition, and language, it is necessary to provide a structured program that minimizes distractions by controlling the noise and activity in the environment. Strategies are used to help compensate for impairments across multiple cognitive domains. For example, memory cues help to improve retention of techniques learned in PT or OT; breaking a task into individual steps and then teaching one step at a time helps to overcome attentional and constructional problems. Finally, the SLP educates the patient and family about aphasia and other cognitive problems. This is essential to reduce frustration with impaired communication, memory, and abnormal behavior.

NEUROPSYCHOLOGY

Neuropsychologists concentrate on the mood, behavioral, and cognitive problems that occur after injury to the brain. They perform detailed neuropsychological testing of the patient to identify cognitive and affective disorders and make therapeutic recommendations to the team. Neuropsychologists may also counsel the patient and family in the management of their disorders.

SOCIAL WORK

Social workers identify concrete resources that will enable the patient to succeed at home, such as finances, availability of caregivers, and community services. They provide counseling, support, and education to the family, who often take on a caregiving role for the patient. Social workers or case managers may directly interact with the patient's insurance provider, supplying medical updates and obtaining authorizations. They also coordinate home services and delivery of adaptive equipment and facilitate discharge planning.

RECREATIONAL THERAPY

Recreational therapy focuses on the patient's social and emotional health through use of enjoyable recreation, with a goal of reintegration into the community. Group activities such as games, karaoke, gardening, and arts and crafts encourage socialization and engage patients physically and cognitively.

SPECIALIZED NEUROLOGIC AND MEDICAL MANAGEMENT

DYSPHAGIA

Swallowing is a complex act involving voluntary and involuntary pairs of muscles including facial, lingual,

masticatory, pharyngeal, esophageal, and respiratory muscles. Neurologic disorders that disturb coordinated contraction and interaction of these muscles can cause dysphagia and, secondarily, dehydration, malnutrition, aspiration pneumonia, and airway obstruction. Dysphagia evaluation is indicated for patients who have any of these complications; who report coughing, choking, or nasal regurgitation while eating; who are dysarthric; or who have a disease commonly associated with dysphagia, such as motor neuron disease, myasthenia gravis, or brain stem stroke. Dysphagia is identified with bedside testing and with video fluoroscopic or fiberoptic endoscopic evaluations of swallowing. Therapeutic approaches include altering the consistency of foods and thickening liquids, using head repositioning strategies such as a chin-tuck technique, and reducing the rate and amount of intake.

BLADDER AND BOWEL DYSFUNCTION

Loss of control of bladder or bowel emptying is a devastating condition and should be addressed by any comprehensive neurorehabilitation programs. The cause of impaired bladder emptying or sphincter incompetence, and therefore the treatment, depends on the site of the neural injury. Evaluation includes clinical observations about incontinence and retention; search for nonneurologic factors, such as infection or mechanical problems, particularly urethral obstruction by prostatic enlargement; and cystometrographic measurements of bladder and sphincter functions. The neurorehabilitation nurse plays a crucial role in the treatment of bladder and bowel disorders, including implementation of voiding programs and training patient and family to use urethral catheters.

The goal of bladder rehabilitation is to allow the bladder to fill under low pressure to a volume of 250 to 500 mL, then empty, whether voluntarily or mechanically and without incontinence between emptying. Incontinence characterized by bladder hyperreflexia, in which the bladder contracts at low urine volumes and voluntary inhibition of bladder contraction and sphincter relaxation fails, commonly complicates cerebral, particularly frontal lobe, injury. Lack of awareness or indifference may impede achievement of continence, but neurologic recovery usually reduces incontinence. Prompted voiding at 2-hour intervals contributes to regaining continence. Detrusor-sphincter dyssynergia, in which dissociated bladder contraction and sphincter relaxation results in the bladder contracting against a closed sphincter, is usually a consequence of lower brain stem or spinal cord lesions. Bladder emptying, if it occurs at all, is incomplete and occurs at high vesicular pressure. Treatment includes bladder antispasmodic drugs and intermittent catheterization at 4- to 6-hour intervals. Hydronephrosis, renal failure, and bladder wall hypertrophy with consequent volume loss are potential complications of a chronically high-pressure bladder.

P.1339

Conversely, peripheral nerve diseases involving the nerves innervating the bladder may cause bladder flaccidity. Bladder emptying, at low pressures, is incomplete, and incontinence occurs between voluntary voiding. Cholinergic agents may improve emptying, but intermittent catheterization is often necessary.

TABLE 152.1 Morbidity in Rehabilitation

Preventable Morbidities	Common Preexisting Comorbidities Requiring Regulation	Secondary Effects
<ul style="list-style-type: none"> • Deep vein thrombosis • Recurrent or progression of stroke • Aspiration pneumonia 	<ul style="list-style-type: none"> • Hypertension • Diabetes • Osteoarthritis • Coronary artery disease 	<ul style="list-style-type: none"> • Partial or generalized seizures • Depression • Cognitive

- Urinary tract infections
- Fecal impaction
- Pressure ulcers
- Falls
- Dehydration
- Malnutrition
- Influenza or pneumococcus infection
- Accelerated osteoporosis
- COPD
- Peripheral vascular disease
- Substance abuse
- Impairments of hearing and vision
- Poor dentition
- Sleep apnea
- impairment
- Intracerebral bleeding
- Hydrocephalus
- CSF leakage
- Autonomic dysreflexia
- Heterotopic ossification
- Surgical site complications
- Infection
- Fever
- Pain
- Musculoskeletal injury

COPD, chronic obstructive pulmonary disease; CSF, cerebrospinal fluid.

Neurologic disorders leading to immobility, decreased fluid access and intake, and loss of cortical control over rectal sphincters may cause severe constipation or impaction. Prevention combines a high-fiber diet, adequate hydration, stool softeners, and regularly scheduled evacuation using suppositories, enemas, and/or digital rectal stimulation. Bowel incontinence can also be lessened by scheduled toileting, providing regular clearance of the rectal vault.

MEDICAL CARE

An important component of rehabilitation neurology is the prevention of secondary complications, the optimized management of existing comorbidities, and the early recognition and treatment of known complications or effects of injury ([Table 152.1](#)). Comorbidities are extremely common and are often dysregulated or exacerbated by the changes in activity, diet, and medications that occur after sudden neurologic injury. For example, poststroke rehabilitation has goals of gradual reduction in blood pressure (BP) to achieve Joint National Committee (JNC) 7 guidelines, proper control of diabetes, dyslipidemia management, appropriate administration of anticoagulation or antiplatelet agents, and counseling on lifestyle changes (e.g., cessation or reduction of alcohol and tobacco use, increase in exercise) [**Level 1**].⁴ Low molecular weight heparins are used to prevent deep vein thrombosis; appropriate oral consistencies are chosen to minimize the risk of aspiration and to maximize nutrition and hydration; and preventative measures are put in place to minimize the risk of falls. A patient may also be given fluoxetine for the potentiation of motor recovery and for the treatment of poststroke depression.

The goal of the physician is to optimize the medical management and lifestyle changes that will reduce comorbidities and secondary effects of brain injury and to coordinate with the patient's primary physician for continuation of optimum outpatient care.

Ethical and End-of-Life Issues in Neurology

Fred Rincon

Lewis P. Rowland

Stephan A. Mayer

INFORMED CONSENT

The concept of informed consent originates from the notion that individuals are autonomous. Rational individuals with decisional capacity, or competency in legal terms, are uniquely qualified to decide what is best for them. It also means that people should be allowed to do what they want, even if doing so involves considerable risk or would be considered foolish by others. This of course is supported only if the individual's decision does not infringe on the autonomy or welfare of another individual (Table 153.1).

When a patient is found not to have decision-making capacity, the health care provider must seek an alternate way to obtain consent. The options in these cases are as follows: (1) to seek a written advance directive such as a living will or durable power of attorney (for health care) or (2) in the absence of an advance directive, the physician must seek the substituted judgment of a proxy or surrogate authorized by the jurisdictional law.

ADVANCE DIRECTIVES

Advance directives are legal documents that can be used to direct care in the event of incapacity and are most often helpful in situations related to terminal conditions. These documents are able to specify the individual's preferences in regard to end-of-life treatments under specific circumstances and may also appoint surrogate decision makers if the individual is not competent to make decisions at some future time. Shortcomings of these documents are as follows: (1) that the health care provider may not find instructions that clearly guide certain treatment decisions and (2) the ethical argument that a person may not be able to predict his own reaction if faced with a disability. Studies have demonstrated a tendency among the nondisabled to view disability as equivalent to death and historically, investigators frequently equate death with the severe disability. In this sense, advance directives or living wills, even if legally valid, are suboptimal to find treatment directions in certain terminal illness particularly when goals of self-determination and perceptions that guide one's chosen moral course may change.

TABLE 153.1 The Informed Consent Process

Components	Example
Verifying that the patient has decision-making capacity	This component verifies that the patient has insight into the proposed procedure or research. A bedside evaluation assessing if the patient can (1) understand the information; (2) understand the current situation and its consequences; (3) rationally consider information in light of one individual's values; and (4) retain the information given, analyze it, and make an informed decision.
Full disclosure	This component is designed to explain the risks and benefits, ratio, complications, and alternatives of the procedure or research. Without disclosure, voluntary choice and competence cannot be properly exercised.

Understanding	In this component, the agent verifies that the patient understands fully the risks and benefits, specifically if the ratio (risk/benefit) is in favor or not.
Voluntary choice	In this component, the agent verifies that there is deliberate informed consent. The informed consent process should be guided by the freedom to act voluntarily without coercive forces or due influence.
Formal authorization	In some jurisdictions, a written document is necessary to fully execute the procedure or research for which the subject has been asked to consent. This should include a statement of risk/benefit and potential complications and alternatives and the signatures of the health care provider, patient or surrogate, and in some instances, a witness.

SUBSTITUTED JUDGMENT STANDARD

Obtaining informed consent by an authorized surrogate decision maker is an alternative to direct informed consent. Appointees by advance directive, or living will, or durable power of attorney (for health care decisions), or a family member identified by jurisdictional law are expected to make the same decisions as the patient would if the patient's capacity were intact and usually based on knowledge of the patient's general values and preferences. Shortcomings of this mechanism are related to the poor accuracy of the proxy's ability to predict the patient's wishes, which some studies have found to be no better than random chance. The inherent difficulty of making decisions for other persons may also make proxies reluctant to participate in the consent process on any level. This can lead to increased reliance on the physician's expertise without fully considering the risks and benefits associated with an intervention.

BEST INTEREST STANDARD

When other sources for consent are lacking, a legal exception may be invoked in emergency situations, in which case the consent of a reasonable person to appropriate treatment is implied, so the *best interest standard* may be applied in these circumstances.

P.1342

The emergency doctrine of "implied consent" allows providers to deliver certain interventions that if not performed in a timely basis could potentially lead to increase morbidity and mortality. The requirements to meet the best interest standard for emergency situations are as follows: (1) The treatment in question represents the usual and customary standard of care for the condition being treated; (2) it would be clearly harmful to the patient to delay treatment awaiting explicit consent; and (3) patients ordinarily would be expected to consent for the treatment in question if they had the capacity to do so. This principle is also applicable in those cases when the burden of a therapy outweighs the benefits and the pain of interventions which would make them inhumane. Despite widely held beliefs to the contrary, it is not necessary to obtain legal counsel before withdrawing life-sustaining therapy. One of the shortcomings of using the *best interest standard* is the possibility of the health care provider being judge as paternalistic based on their inherent role to prevent evil or harm by promoting good and welfare for others.

In some jurisdictions of the United States and the world, the principle of "clear and convincing evidence" may be used in lieu of the *substituted judgment standard*. This is one of the legal principles used in the United States legal system (the other two being beyond the reasonable doubt and preponderance of

evidence). This principle can be used by physicians in certain jurisdictions of the United States (Missouri, New York, Florida) to withdraw life support or any other intervention when there is *clear and convincing evidence* of previous patient's statements and in the absence of a "declaration" such as a living will, advance directive, or durable power of attorney. This principle is valid in many places of the world. However, the logistics and, whether or not the court system needs to be involved are rather jurisdiction specific.

END-OF-LIFE CARE

Neurologic diseases have been at the center of discussions on issues at the end of life. To this end, end-of-life conversations are routine between health care providers and patients suffering certain neurologic diseases. The American Academy of Neurology (AAN) has set standards for the determination of death based on neurologic criteria, prediction of outcome in comatose survivors of cardiac arrest, and for the persistent vegetative state (PVS). Additional diseases such as amyotrophic lateral sclerosis (ALS) and Alzheimer disease have been the focus of debates about physician-assisted suicide. Health care providers practicing in neuro-intensive care units (ICUs) also face end-of-life discussions when withholding or withdrawing life-sustaining therapies. Finally, presymptomatic diagnosis is available for incurable conditions like Huntington disease, creating additional ethical challenge.

INEFFECTIVE, INAPPROPRIATE, AND FUTILE THERAPIES

Health care providers may often encounter clinical situations in which therapies may be found to be ineffective at achieving certain goals. Health care providers don't know whether a therapy, in a particular neurologic condition, will be effective unless the therapy is trialed. In this case, it is always better to attempt a "trial of intervention" by setting up reasonable goals of care, determining whether those goals can be achieved by ongoing reassessment, and allowing the health care provider to find if the therapy is ineffective while maintaining good communication with patient's families, friends, and surrogates. This approach would allow the health care team to withdraw an ineffective therapy rather than withhold a potentially beneficial treatment, limiting the chance for undertreatment and avoiding ethical dilemmas. Some treatments may be considered inappropriate or inadvisable. Such treatments are characterized by extremely low likelihood of achieving the intended goal, minimally or potentially beneficial but extremely expensive, and of uncertain or controversial benefit. Finally, some other treatments may be labeled as futile. There is still controversy about the medical definition of futility, but in general, futile medical interventions serve no meaningful purpose no matter how often they are repeated. Therefore, a futile medical intervention is that for which there is *de facto* knowledge that it will not accomplish its intended goal. Characteristics of a futile therapy are that the intervention has no pathophysiologic rationale, that the intervention has already failed in the patient, and that the unintended effect occurs despite maximal treatment. Futile, inappropriate, or inadvisable cases are fortunately rare but very complicated from the ethical perspective, as they bring the values of the patient, surrogates, health care providers, and the society at odds. For this reason, resolution of these conflicts requires conscientious ethical analysis and a fair process that usually involves a multidisciplinary team, and a bilateral or shared conflict resolution.

WITHHOLDING AND WITHDRAWING

When facing withholding or withdrawal of medical interventions, ethical questions can not be addressed successfully unless the probability of outcomes is entertained. To attain a balanced view of the impact of therapeutic decisions and the expected disability to the patient, the effort requires understanding of disease in question and a multidisciplinary team approach. Morally, there may be no difference between withholding and withdrawing life-sustaining therapies. However, patients, families, and health care providers have strong and divergent views. Some may feel comfortable with both situations, some may feel comfortable only when deciding

not to start a therapy, but some may feel uncomfortable deciding when to stop that therapy. According to Miller and Truog, “what distinguishes withdrawing from withholding, is that in the former, the agent initiates the fatal consequence, as distinct from merely permitting it to continue without intervention to stop it.” The distinction between withdrawing and withholding may cause feelings of reluctance but is morally irrelevant and can be dangerous. From the legal standpoint, the courts in the United States have upheld the concept that there is no difference between withdrawing and withholding. Both are medical decisions that entail a duty to inform the patient and his or her representative.

DEATH, DYING, AND PALLIATIVE CARE

According to the World Health Organization (WHO), health in its broader sense is defined as “a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity.” Because this “state” is sometimes hard to achieve at the end of life, patients suffering terminal neurologic diseases should also have access to therapies that carry different goal in mind: the relief of pain and suffering.

Palliative care is defined by the WHO as “the active total care of patients whose disease is not responsive to curative treatment, where the control of pain, of other symptoms and of psychological, social, and spiritual problems is paramount, and where the goal is the achievement of the best quality of life for patients and their families.”

P.1343

In the case of Karen A. Quinlan (*in the matter of Quinlan, an alleged incompetent, 70 NJ 10, 1976*), the Supreme Court of New Jersey established the concepts that provided the framework for the development of a more patient-centered than physician-centered medical decision-making paradigm and nurtured the palliative care movement in the United States. Ms. Quinlan was a young patient that lapsed into a PVS after suffering hypoxic brain injury. A legal battle ensued between the county's prosecutor, the hospital, and the health care providers that argued that Ms. Quinlan should be kept on life support and never be allowed to die (as there was no advanced directive to guide care) and the family members (devout Catholics) that argued that Ms. Quinlan should be allowed to die with dignity based on known wishes that established that she would have never wanted to live that way. After many years of litigation, the Court finally granted the family's wishes and determined that (1) a guardian *ad litem* (appointed by court order) was not necessary to represent a patient independently in a particular case and (2) allowed family members to make decisions on the patient's behalf. The ruling was rooted on the United States Constitution's individual right to privacy, preventing the Government to prohibit treatments or the refusal of them (under certain circumstances) under the sole argument of Government's interest on preserving life. The Court granted the ability to family members to make assertions on behalf of patients using their own best judgment (see “[Substituted Judgment Standard](#)”). The Court's decision included legal immunity for the physicians and the suggestion to involve ethics committees.

A *hospice program* is often the venue for palliative care. This is sometimes carried out in a hospital or separate physical facility but is increasingly a home care program. Although most Americans express their desire to die at home, relatively few actually die there and die in hospitals or nursing homes. In a study of terminally ill patients, Pritchard et al. shown that terminally-ill patients died at teaching hospitals (56%) more often than home (25%), nursing home (9%), hospice (9%), and en route to the hospital (1%). Many factors affect how individuals die and where they die.

Nationwide, hospice care is used by only 17% of people who are dying. Reasons for the relatively low rate of hospice care include the following: (1) Physicians are uncomfortable about talking with patients about terminal events long enough in advance; (2) it may be difficult to determine precisely the expected time of death; (3) hospices emphasize home care, and family members may not be able to commit the time required or there may be no family members; and (4) financial issues. Although in the United States, a Medicare disease-related group

(DRG) provides reimbursement for the care of patients who are not expected to survive for more than 6 months, many Americans, based on the lack of coverage, may still have to pay out of pocket for some of the palliative care expenses. Another drawback to the use of home or hospice care is the insensitivity of United States physicians to the advance directives of their patients, as detected by the 1995 to 2000 Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment (SUPPORT), which analyzed end-of-life care in over 3,000 hospitalized patients who died. Fifty percent of the physicians polled did not respect or did not know their patient's advance directives; most do-not-resuscitate (DNR) orders were not written until 24 hours before death; and 40% of the patients had severe pain for several days before death. In a follow-up study, an intervention to improve communication resulted in reduction in total ICU days prior to death and no increase in the proportion of patients with a DNR order, which were not written in 50% of the patients surveyed.

PRINCIPLE OF DOUBLE EFFECT

At least 43% of Americans will be admitted to nursing homes prior to death, and more than 1.5 million are currently being cared for in these establishments. According to Teno et al., nearly 15% of these patients are in pain at the time of the initial assessment and approximately 41% are in severe pain later on. Pain management is therefore an important aspect of palliation. Some actions during palliative care aimed at controlling pain are morally and ethically acceptable and may have foreseeable but unintended and undesirable outcomes; the morality of the action depends on the morality of the intended outcome, not the unintended one. Several conditions must be met: (1) The action to be carried out must be morally or ethically acceptable or at least neutral, (2) the good effect must not depend on the undesired or bad effect, and (3) the good effect must be sufficient to justify the risk of the unintended outcome. In practice, this principle makes it possible to administer sufficient analgesic and sedative medication to keep a patient comfortable even though the treatment will not prolong life. The principle of *double effect* is the basis of the hospice program ([Table 153.2](#)).

PALLIATIVE SEDATION

In certain circumstances, the burden of a neurologic disease at the end of life may be higher than expected. Certain patients may not achieve adequate relief of symptoms even with palliative care measures that usually include the titration of opioids. As defined by Broeckaert and Nunez-Olarte, "palliative sedation is the intentional administration of sedative drugs in dosages and in combinations required to reduce the consciousness of a terminal patient as much as necessary to adequately relieve one or more refractory symptoms." This is usually achieved by the use of benzodiazepines, propofol, and barbiturates. It's intended to achieve the relief of overwhelming symptoms when other conventional palliative care strategies have failed. The AMA Council on Ethical and Judicial Affairs has provided support for the use of palliative sedation at the end of life when (1) patients are in the final stages of their disease and are expected to die shortly, (2) conventional treatments have failed to control the symptoms, (3) consent has been obtained from the patient or surrogates, (4) a multidisciplinary team of experts have already assessed the patients symptoms, (5) palliative sedation will not be used to solely relieve existential experiences (anxiety, depression, feelings of isolation, etc.), and (6) it will not be used to intentionally cause a patient's death.

Palliative sedation is usually reserved for the ICU environment or for units designed to fulfill that purpose. Some ethicists have argued about the difference between palliative sedation and euthanasia. The difference lies in the concept of intent and the timing of the procedure. Palliative sedation is used to achieve a control of symptoms during the process of death (last resort), when other measures have failed, and exclusively in actively dying patients.

REFUSAL OF THERAPY, PHYSICIAN-ASSISTED SUICIDE, AND EUTHANASIA

A competent patient's refusal of therapy should not be interpreted as suicidal. In 1983, the President's

Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research published its report entitled *Deciding to Forego Life-Sustaining Treatment*. The conclusion from the President's Commission was that decisions regarding health care, including the refusal or withdrawal of life-sustaining treatment, rest ultimately with the competent patient and exercised through the country's long tradition of procedures for informed consent. On the other hand, refusal or

P.1344

withdrawal of therapies by surrogates on behalf of incompetent patients that remain conscious are ethically and legally permissible as long as there are written statements or in accordance with the patient's "wishes to the extent known." In the absence of these, the decision-making process is based on the patient's best interest.

TABLE 153.2 Palliative Care Protocol during Withdrawal of Life Support

Steps	Procedures
Prewithdrawal of LST	<ul style="list-style-type: none"> • Meet with surrogates and family to discuss withdrawal of LSTs. • If patient is conscious, involve him or her in the discussion. • Prepare to discuss other issues such as organ donation. • Establish a time frame and additional needs: pastoral care, etc. • Document plan and discussion in the chart. • Discuss with clinical team. • Review LSTs to be withdrawn (ventilator, medications^a, IV or enteral fluids, parenteral or enteral nutrition, pacemakers, IABPs, RRT, blood draws, etc).
Sedation/analgesia	
<ul style="list-style-type: none"> • Lorazepam 	<ul style="list-style-type: none"> • If any, continue current infusion if patient is comfortable, then bolus same as hourly dose. May increase by 25%-50%. <p>OR</p> <ul style="list-style-type: none"> • Begin with a bolus of 2.5-10 mg IV. May repeat boluses every 15 min as needed. <p>OR</p> <ul style="list-style-type: none"> • Begin continuous infusion at 2.5-5.0 mg/h.
<ul style="list-style-type: none"> • Morphine 	<ul style="list-style-type: none"> • If any, continue current infusion if patient is comfortable, then bolus same as hourly dose for signs of distress. May increase by 25%. <p>OR</p> <ul style="list-style-type: none"> • Begin with a bolus of 10 mg IV and begin infusion at 5-7 mg/h. If discomfort, repeat boluses equal to hourly infusion dose and increase rate by 25%-50%.
<ul style="list-style-type: none"> • Fentanyl 	<ul style="list-style-type: none"> • If any, continue current infusion if patient is comfortable, then bolus 25%-50% of the hourly dose and increase by 25%. <p>OR</p> <ul style="list-style-type: none"> • Begin with a bolus of 25-100 µg IV and begin infusion at 25-100 µg/h. If discomfort, repeat boluses 50% of hourly infusion dose and increase rate by 25%-50%.

Withdrawal of LST

- Adjust analgosedation to achieve no distress before withdrawal of LST (see above).
- Reduce or eliminate alarm settings and monitors.
- Disconnect cardiac monitors.
- Disconnect other monitoring devices (arterial lines, ICP lines, etc.).
- Disconnect supplemental oxygen.
- Remove lines and enteric feeding tubes, if any.
- Suction and control secretions if needed.

After death

- Inform family and surrogates about official time of death.
- Allow family and staff to surround the patient.
- Allow family to visit patient postmortem if they choose to.
- Assist with postmortem decisions and fill-in pertinent paperwork.
- Document a death note in the chart.

^aMedications that can be continued to provide comfort are, for example, antiepileptics (seizures), antiemetics (rare), and skin or local oral care (glycerine creams, etc.).

LST, life-sustaining therapy; IV, intravenous; IABP, intra-aortic balloon pump; RRT, renal replacement therapy; ICP, intracranial pressure.

In 1994, Oregon became the only state to legalize physician-assisted suicide (PAS) when voters, through a citizen's initiative election, enacted the Oregon Death with Dignity Act (DWDA) through a 51% approval. In order to qualify for PAS in Oregon, the individual must reside in that state, be at least 18 years of age, have the ability to communicate regarding health care issues, and be diagnosed with a terminal disease with 6 months of less of life expectancy (confirmed by two independent physicians). As specified by law in the state of Oregon, it is permissible for a physician to prescribe medication to be used by a patient for the purpose of suicide. However, the physician may not actually administer the drug. Additional states that legalized PAS are Washington, Vermont (via court ruling), and New Mexico. PAS is currently under debate in New Jersey. Although PAS is legal in these states, the United States Supreme Court has upheld criminal statutes that prohibited PAS in New York and Washington negating the constitutionality of the individual's right to PAS. However, it also negates the constitutionality of prohibiting PAS at the state level.

Neurologic diseases generate problems for PAS. Patients may be incompetent and unable to give consent. Other patients may lose the use of their hands from motor neuron diseases such as ALS. Under these circumstances, the patients themselves cannot fill the prescription and take the drug; someone else must assist them physically, which would be euthanasia and specifically banned by the Oregon and others laws. Many authorities have debated the desirability of PAS. Medical and nursing organizations have uniformly opposed legalization.

If in compliance with a patient's request a physician administers a lethal drug by injection or other means, the act is euthanasia,

P.1345

which is illegal in the United States. In euthanasia, the health care provider intends the death of the patient. In doing so, the health care provider selects the type of drugs and doses that are lethal by all objective measures. In the process, the health care provider administers the drug and causes unconsciousness and cardiac arrest. Only if the outcome is achieved, the health care provider can conclude that the intervention was successful.

These contrast with the objective of palliative sedation and palliative care, where the intent is to relieve otherwise unmanageable symptoms (see “[Principle of Double Effect](#)”).

The public, physicians, and courts have had difficulty separating refusal or discontinuation of therapy, which are legal, from assisted suicide and euthanasia, which are not. The distinction between PAS and euthanasia is the most controversial of all. The Supreme Court concluded that palliative care and palliative sedation are permissible but referred the question of PAS back to legislation by the states.

This issue was highlighted in 2002 when Veldink et al. reported experience in the Netherlands, where euthanasia is legal. Among 279 patients who died of ALS, 17% chose euthanasia and 3% died as a result of PAS. Another 24% received palliative care, “which probably shortened their lives.” In an accompanying editorial and correspondence, Ganzini and Block attributed the high rates of assisted death to inadequate palliative care. However, this has been recently contended by the authors.

CONCLUSION

The issues discussed here are among the most controversial in modern life. Consensus is not easy to achieve, but views are changing and current practices are likely to change as well. Already, pain control and palliative care have come to the fore and provide effective alternatives to assisted suicide.

Documenting the preventive value of palliative care is a challenge for all concerned. Legal changes may be anticipated but do not seem imminent.
