The clinical presentation of traumatic injury to the radial nerve will vary with the level at which the injury occurs. Several common injury mechanisms have been identified that are associated with lesions at various levels. Injury to the nerve in the axilla, resulting from the use of crutches that are too long, causes extensor weakness and numbness in the radial distribution described earlier. Midshaft humeral fracture or external compression, referred to commonly as *Saturday night palsy* when it occurs after a particularly heavy night's sleep on an extended arm, causes weakness of forearm and wrist extensors with wrist drop and weakness of finger extensors. Elbow extension is preserved.

Iatrogenic trauma to the radial nerve has also been reported in the literature to have occurred with peripheral venous cannulation and arterial monitoring at the wrist, blood pressure cuffs at the midhumeral shaft, and rarely, with vaccine administration in the upper arm. Prognosis is generally good due to the predominant motor component of the radial nerve limiting motor/sensory crossreinnervation and synergy between radial nerve innervated muscles.

Ulnar Nerve

The ulnar nerve is a terminal branch of the medial cord of the plexus and contains fibers from C8 to T1 nerve roots. It descends between the biceps and triceps before moving posteriorly to pass behind the medial epicondyle and through the cubital tunnel to the forearm. It provides motor fibers to the flexor carpi ulnaris and flexor digitorum profundus II before passing through Guyon canal into the hand. The ulnar nerve terminates as a superficial sensory branch, which supplies the palmar and dorsal sides of the ulnar part of the hand and the palmar and dorsal surfaces of the little finger and the medial half of the ring finger. A deep motor branch supplies the abductor, opponens, and flexor digiti minimi medially and the adductor pollicis and the medial half of the flexor pollicis brevis laterally. It is responsible for many of the fine motor manipulations of the hand, and injury can be quite disabling.

The superficial course of the ulnar nerve behind the medial epicondyle makes this nerve vulnerable to injury by external compression. Ulnar nerve palsy is one of the most commonly reported

P.397

postoperative peripheral nerve complications and may result from poor positioning, insufficient padding around the elbow, or from external pressure by surgical instruments and personnel. Entrapment of the ulnar nerve may also occur at the elbow in the ulnar groove, distal to the elbow as it traverses the cubital tunnel, or within Guyon canal at the wrist. Several cases of ulnar nerve palsy at the wrist have been reported to result from ganglion cysts within Guyon canal, leading to weakness and atrophy of the intrinsic muscles of the hand. Injury to the ulnar nerve may also be seen with articular fractures of the distal humerus. Prolonged denervation may result in clawing of the little and ring finger and atrophy of hypothenar and interosseous muscles.

The likelihood of functional recovery after traumatic injury is lower for the ulnar nerve than for either the median or the radial nerve. This inequity is attributed to the ulnar nerves innervation of muscles responsible for fine movement in the hand, which require greater specificity in reinnervation to regain useful function.

Axillary Nerve

The axillary nerve arises as a terminal branch of the posterior cord with fibers originating from C5 to C6 nerve roots. The axillary nerve crosses anterior to the subscapularis before entering the quadrilateral space and dividing into two main trunks. The posterior branch supplies motor innervation to the teres minor and posterior deltoid before terminating as the superior lateral brachial cutaneous nerve, whereas the anterior branch travels within the deltoid muscle providing motor innervation to the middle and anterior deltoid muscle.

Traumatic injury to the nerve is associated with glenohumeral dislocation, proximal humeral fracture, and direct blow to the deltoid muscle, as can occur during sports events. Compression can also occur within the quadrilateral space, resulting in deltoid muscle weakness and diffuse pain over the posterior shoulder. Compression is thought to be secondary to the development of abnormal fibrous bands and hypertrophy of the muscles forming the boundaries of the anatomic space. The axillary nerve is vulnerable to iatrogenic injury during surgery involving the shoulder and glenohumeral joint, including shoulder arthroscopy during portal placement. Clinically, injury to the axillary nerve may present with weakness of shoulder abduction and paresthesia over the lateral arm. Prognosis for axillary nerve injury is generally good, although it varies with injury mechanism and severity.

LOWER EXTREMITY NERVE LESIONS

Lumbosacral Plexus

The nerve supply to the pelvis and lower limbs originates from the lumbosacral plexus. Functionally and anatomically, the lumbosacral plexus can be divided into two major divisions, the lumbar and sacral plexuses.

The lumbar plexus is formed within the psoas major muscle and is derived from the nerve roots of L2-L4. The lumbar plexus gives rise to the *femoral nerve*, which passes along the lateral border of the psoas major, under

the inguinal ligament, to the anterior leg where it supplies motor innervation to the pectineus, sartorius, rectus femoris, vastus lateralis, vastus intermedius, and vastus medialis muscles. The femoral nerve then terminates as the saphenous nerve, providing sensation to the medial lower leg.

The *obturator nerve* also arises from the anterior branches of L2, L3, and L4. It passes through the obturator canal in the pelvis and gives off anterior branches that supply the adductors. It also may provide sensation to the inner thigh and knee, although cutaneous innervation in this area is highly variable.

A number of smaller sensory nerves also arise from the lumbar plexus. These nerves include the *iliohypogastric*, the *ilioinguinal*, the *genitofemoral*, and the *lateral femoral cutaneous nerve*. Lesions of these nerves is discussed individually in the following text, but traumatic injury is most often iatrogenic or anatomic and rarely the result of acute trauma.

The sacral plexus is formed from the nerve roots of L5, S1, and S2 with variable contribution from L4. The sacral plexus supplies motor innervation to the gluteus minimus, gluteus medius, and tensor fascia lata via the *superior gluteal nerve*, which contains fibers from L4 to S1, whereas the *inferior gluteal nerve*, derived from L5 to S1, supplies the gluteus maximus.

The *sciatic nerve* forms from the posterior divisions of L4-S1. It exits the pelvis through the greater sciatic foramen and through the piriformis muscle, which can act as a site of compression when hypertrophied. The sciatic nerve travels down the posterior leg as two anatomically approximated but functionally distinct components: the lateral peroneal portion and the medial tibial portion. In the posterior thigh, the lateral peroneal portion of the sciatic nerve provides motor innervation to the short head of the biceps femoris, whereas the medial tibial division supplies the long head of the biceps femoris, the semitendinosus, and the semimembranosus. The lateral position of the peroneal portion increases its vulnerability to injury, particularly from penetrating and concussive forces. At the level of the posterior knee, the sciatic nerve divides into the common peroneal and tibial nerves.

Traumatic injury to the lumbosacral plexus is uncommon, although injury has been observed to occur secondary to gynecologic surgery and normal labor due to compression by fetal presenting part or instrumentation used in vaginal delivery. Hematoma, abscess, and tumor may all present with lumbosacral plexopathy. Clinical presentation varies with the site and severity of injury, although damage to the plexus may be distinguished from more peripheral injury if dysfunction of the anal sphincter is present.

The Obturator Nerve

Traumatic injury of the obturator nerve is uncommon; compression may result from expanding pelvic masses such as hematomas, tumors, or abscesses or from compression by the presenting part of the fetus during labor. Clinically, injury to the obturator nerve manifests as abnormal gait due to adductor weakness. Internal and external rotation of the thigh may also be affected.

The Iliohypogastric Nerve

The iliohypogastric nerve is derived from the upper portion of the lumbar plexus. It provides sensation to the upper buttocks and the lower abdomen as well as supplying some motor innervation to the internal oblique and transversus abdominis muscle. Traumatic injury to this nerve is most commonly reported as an iatrogenic complication of surgery. Aberrant suture or staple placement, development of painful neuroma, or entrapment of the nerve in fibrous adhesions can cause anesthesia, pain, and paresthesia that is refractory to most conventional pain management strategies. Entrapment in mesh used for hernia repair has also been reported. In cases of nerve injury uncomplicated by pain, lesion to this nerve may produce minimal deficits with anesthesia over a small strip of skin as the primary manifestation.

The Ilioinguinal Nerve

The ilioinguinal nerve provides sensation to the pubic region, the upper inner thigh, and the external genitalia. Injury to the ilioinguinal nerve often accompanies injury to the iliohypogastric nerves and is associated with similar traumatic mechanisms.

P.398

The Genitofemoral Nerve

The genitofemoral nerve is a sensory nerve that derives from the L2 nerve root. It provides sensation to the scrotum and a portion of the inner thigh. Traumatic injury of this nerve is rare.

The Lateral Femoral Cutaneous Nerve

The lateral femoral cutaneous nerve is derived from nerve fibers between L2 and L3. This sensory nerve travels beneath the fascia of the iliacus and emerges at the anterior superior iliac spine. It divides into two branches: a posterior branch, which provides sensation to the external buttock, and an anterior branch, which provides sensation to the outer lateral thigh. A syndrome called *meralgia paresthetica*, which consists of dysesthesia and sensory loss along the lateral thigh, occurs with compression of the anterior branch. Compression may result as a consequence of tight-fitting belts and pants, lumbar hyperlordosis resulting from pregnancy, prolonged maintenance of the lithotomy position during surgery, or extreme hip flexion during vaginal delivery. Hypertrophy of the iliopsoas, as can occur with dancers who repeatedly maintain the leg in greater than 90 degrees of flexion, has also been reported as a cause of lateral cutaneous femoral neuropathy. Complete examination should be undertaken to rule out more potentially dangerous causes of lateral thigh pain, such as malignancy.

The Femoral Nerve

Traumatic injury to the femoral nerve is less common than injury to the sciatic, common peroneal, or tibial nerves, although injury may result from femur and pubic ramus fractures. More commonly, injury to the femoral nerve is derived from compression within the pelvis by tumor, abscesses, and other space-occupying lesions such as enlarged lymph nodes. Spontaneous hematoma within the iliacus or retroperitoneal space, associated classically with hemophilia and more recently with the use of anticoagulation medication, has also been described in the literature as a cause of femoral neuropathy. In hemophiliacs, it has been shown that bleeding into the iliacus muscle, which occupies a nondistensible space between the pelvic bone and the iliac fascia, raises the pressure within the compartment, compressing the femoral nerve as it travels between the iliacus and psoas muscles. A second mechanism has also been proposed based on more recent anatomic studies, which suggests that blood within the iliac fascia traps the femoral nerve at the point at which it passes beneath the inguinal ligament. In this model, hemorrhagic dissection down to the level of the inguinal ligament is necessary for compression to occur and may explain why femoral neuropathy generally presents in isolation.

Injury to the femoral nerve results in weakness of the iliopsoas, paralysis of the quadriceps femoris, and hypesthesia over the anteromedial leg in the distribution of the saphenous nerve. Patellar reflex is lost and the leg is often held in flexed, abducted, and externally rotated position. Severe abnormalities in gait may be observed, particularly when attempting to walk on an incline or upstairs, as both hip flexion and knee extension are affected.

The Sciatic Nerve

Lesions of the sciatic nerve comprise the largest subset of lower extremity traumatic injuries. At the level of the buttocks, injection injury is the most common cause of traumatic nerve lesion with hip fracture/dislocation; hip arthroplasty; fall-related contusion; gunshot wounds; laceration, such as from a boat propeller; and compression from prolonged immobilization following in descending order. In the thigh, gunshot wounds, followed by stretch

injury associated with femoral shaft fracture, and laceration in the posterior thigh were the most common mechanisms of traumatic injury. In all locations, injury to the common peroneal division of the sciatic nerve occurs more frequently than injury of the tibial division. This is hypothesized to be the result of the lateral position of the peroneal division.

Complete lesion of the sciatic nerve is rare. Clinically, it presents as weakness of knee flexion as well as complete paralysis of all movements of the ankles and toes. Ankle reflex is lost and foot drop is observed on the affected side. Gait is characterized by a circular swinging motion of the hip during leg advancement as patients attempt to compensate for the loss of ankle dorsiflexion. Sensation is altered on the outer surface of the lower leg, over the toes, and on the instep and sole of the foot. *Sciatica*, or pain extending from the low back to the toes following the course of the nerves that is associated with foot drop and weakness in ankle eversion, suggests compression at the level of the L5-S1 nerve roots and should warrant imaging evaluation of the lumbar spine.

The Common Peroneal Nerve

The common peroneal nerve is particularly vulnerable to traumatic injury. Its anatomic course around the fibular head makes it susceptible to stretch, contusion, and compression forces around the knee, as well as to laceration resulting from fibular fracture. Compressive trauma may occur with leg crossing, squatting, or prolonged lateral decubitus position with insufficient padding while sleeping, unconscious, or anesthetized. Injury to the common peroneal nerve results in footdrop and weakness in ankle eversion. Patients may be unable to extend the toes. Depending on the level of injury, sensory loss may occur over the outer leg, shin, instep, and dorsal surface of the four small toes.

Injuries to the common peroneal nerve carry a worse prognosis than do injuries to other nerves of the lower leg. This is thought to be due to a number of factors including the distance from target end organs, the mixed nature of the nerve, the risk for more severe injury associated with the nerve's lateral location, and the characteristics of the target muscles which require coordinated input for effective contraction. Distal injuries tend to have a better chance of recovery than do their proximal counterparts.

The Tibial Nerve

Injury to the tibial nerve occurs significantly less frequently than injury to the common peroneal, and it carries a much better prognosis. Contusion with fracture, laceration, and gunshot wounds are the most common mechanisms of traumatic injury. As the tibial nerve provides motor innervation to the gastrocnemius and soleus, complete lesion of the nerve leads to paralysis of plantar flexion and inversion of the foot as well as flexion and abduction of the toes. Sensory loss occurs over the plantar aspect of the foot and plantar reflex is lost.

A syndrome of chronic trauma by entrapment, called *tarsal tunnel syndrome*, has also been described as occurring within the flexor retinaculum in proximity to the medial malleolus. This syndrome produces a variable pain over the tarsal tunnel behind the medial malleolus with radiation to the plantar aspect of the foot, heel, and arch, which may be described as burning, tingling, or numbness. Discomfort is often exacerbated by prolonged weight-bearing activity and may be present at night. Bifurcation of the tibial nerve into the medial and lateral plantar nerves proximal to the tunnel is thought to be an anatomically predisposing factor for the development of the syndrome.

Prognosis after tibial nerve injury is favorable as compared to that of the common peroneal nerve. This is attributed to several factors intrinsic to the nerve including a greater connective tissue to fascicle ratio, with increased shock-absorbing capabilities; a singular fixation point, which provides more elasticity and protection from stretch; a better blood supply to minimize secondary ischemic damage; and closer proximity to end-organ

targets. Additionally, functional recovery is aided by the size and biomechanical characteristics of the gastrocnemius and soleus muscles, which require relatively little innervation for contraction to be effective.

DIAGNOSIS

The initial diagnosis of traumatic nerve injury is clinical; it relies primarily on a thorough physical examination and the identification of a history that is suggestive of acute or chronic trauma. The mechanism of trauma, along with the presence of injuries to other structures, such as skeletal fractures or lacerations that are commonly associated with injury to peripheral nerves, may help focus the clinician's initial examination on those areas most likely to be effected, although a full cranial and peripheral nerve examination should be undertaken whenever possible. Evaluation may be complicated by injuries that require immediate lifesaving therapeutic intervention, as well as by alterations in level of consciousness in a multi-injury trauma patient.

Once a peripheral nerve injury has been identified by clinical evaluation, additional information should be sought regarding pathophysiology and extent of the injury, as these factors will influence the timing and type of treatment provided. Several laboratory and imaging tools are available to aid in classification, including electrodiagnostic studies, ultrasound, MRI, magnetic resonance neurography, and somatosensory-evoked potentials.

ELECTRODIAGNOSTIC FINDINGS IN PERIPHERAL NERVE INJURY

Electrodiagnostic evaluation, consisting primarily of electromyography (EMG) and nerve conduction studies, is critical for establishing the severity, location, and prognosis of peripheral nerve lesions. Properly timed examination seeks to answer four important questions: (1) localization of the injury, (2) pathophysiology, (3) severity of resultant dysfunction, and (4) progress of reinnervation and likelihood of spontaneous recovery. More detailed information regarding the administration and general characteristics of these tests is provided in Chapter 26. In this section, we focus on the electrophysiologic characteristics associated with each of Seddon's nerve injury types and their impact on surgical planning.

Neurapraxia

Neurapraxic lesions are characterized by focal conduction block at the site of the lesion with no loss of conduction in the distal segment. The injury, which is usually the result of direct compression or ischemia, results in focal demyelination with no associated axonal loss. On nerve conduction studies, this is reflected by maintenance of the compound muscle action potential (CMAP) and sensory nerve action potential (SNAP) on stimulation distal to the lesion site when recording from distal nerve targets. When stimulation is applied proximal to the lesion, CMAP recordings might show loss of amplitude, slowing of conduction velocity, and change in morphology. SNAP will demonstrate a similar pattern, although interpretation of SNAPs is somewhat more complicated, as amplitude is also affected by distance between the stimulating and recording electrodes. Abnormalities are expected to resolve with remyelination, although some conduction slowing may persist permanently, as remyelination results in shorter and thinner internodes than previously present, with slightly decreased conduction capability.

Needle EMG of neurapraxic lesions is characterized by loss of motor unit action potentials that are under voluntary control and abnormal patterns of motor unit recruitment. In incomplete lesions in which some proportion of axons are blocked, rendering some motor units ineffective, remaining unaffected motor units must increase the rate of firing to generate the same amount of force. On EMG, this abnormal recruitment results in a decreased number of motor unit action potentials (MUAPs) of normal morphology, amplitude, and duration, firing rapidly. No MUAPs will be observed with complete neurapraxic lesions. Resolution of these findings will occur with remyelination.

Axonotmesis

In axonotmesis, unlike neurapraxia, injury to the nerve produces complete or partial axonal disruption, resulting in progressive degeneration of the distal stump. The time to completion of the degenerative process depends on the length of the distal stump, as well as on fiber composition, but is generally completed within 10 to 14 days. The time required to complete this process is reflected in the evolution of the electrodiagnostic picture, and studies carried out in the acute traumatic period will not adequately distinguish neurapraxic from axonotmetic and neurotmetic lesions.

Generally, on nerve conduction studies, upon completion of the degenerative process, CMAP and SNAP, distal to the injury, will show a decrease in amplitude that is proportional to the degree of axonal loss. Motor fibers degenerate quicker with completion experimentally determined to occur around 5 to 8 days and complete loss of amplitude observed around 9 days. Sensory fibers require more time and complete loss is generally observed at day 11. Comparison of CMAP amplitude in the injured limb may be made to that of the unaffected side to approximate the degree of axonal loss. Comparison of distal to proximal CMAP amplitude within the affected limb may estimate the amount of demyelination present.

Needle EMG provides a measure of end-organ denervation. Fibrillation potentials and sharp waves are markers of denervation resulting from axonal degeneration in complete lesions. Their appearance distinguishes neurapraxic lesions from axonotmesis and neurotmesis, although the timing of their appearance is dependent on the distance from the injury site. Proximal muscles may begin to show fibrillation potentials at 10 to 14 days, whereas distal muscles may require 3 to 4 weeks. Incomplete lesions will show firing patterns similar to that of neurapraxia.

As regeneration progresses, motor units will remodel. Surviving MUAPs will become increasingly complex and “nascent units” will develop. Nascent units are characteristically of small amplitude, polyphasic, and with a rapid firing rate. These early MUAPs will develop into fully reinnervated units, which exhibit large amplitude, increased duration, and polyphasia, indicating increased motor unit territory. Evidence of such reinnervation, from local sources, may appear as early as 3 weeks, indicating the possibility of spontaneous recovery, although generally axonal reinnervation requires 3 to 4 months before adequate assessment can be made. Serial examinations may be used to follow the progress of reinnervation. If no evidence of regeneration is found within 3 to 6 months, surgical exploration may be appropriate.

P.400

Neurotmesis

Neurotmetic lesions are by definition complete lesions, resulting from transection of all structural nerve elements. Initial electrodiagnostic studies will follow the same pattern of progressive degeneration as occurs in axonotmesis. Unlike axonotmesis, no evidence of reinnervation will be apparent on follow-up examinations, as fully transected nerves are not capable of undergoing functional spontaneous regeneration. Surgical intervention with grafting or tension-free reapproximation is required.

TIMING OF STUDIES

Some debate exists regarding the optimal timing of electrodiagnostic evaluations. Conventional teaching is that initial evaluation should be performed no earlier than 3 weeks to allow for degeneration to be completed. Immediate evaluation, within 7 days of the injury, on the other hand, has been proposed as a potentially valuable tool both in lesion localization and to determine whether a lesion is complete or incomplete. Detection of conduction block precisely identifies the location of the injury, which may be particularly helpful in the setting of extensive or anatomically distorting trauma. Incomplete lesions carry a better prognosis and are less likely to need early surgical intervention.

In general, the timing of studies should reflect the clinical setting and questions to be answered, with the following guidelines applicable: (1) Studies performed within 1 week provide information regarding

completeness of lesion and location; (2) at 1 to 2 weeks, neurapraxia can be separated from axonotmesis and neurotmesis; (3) evaluation at 3 weeks provides the most information regarding lesion type and prognosis; and (4) by 3 to 4 months evidence of reinnervation should be present.

ROLE IN SURGICAL PLANNING

EMG is also an important tool for surgical planning. In thinking about nerve repair and functional recovery, consideration must be given to the time required for regenerating axons to reach the target tissues and establish mature connections. This thought is particularly important for motor recovery, as irreversible changes are observed to occur in muscle within 12 to 18 months, rendering innervation after that point ineffectual. Regeneration, after either grafting or direct anastomosis, occurs at a rate of approximately 1 inch per month. Surgery must be timed to allow for the appropriate period of regeneration to occur. EMG assists in this planning by monitoring the progression of reinnervation. By measuring the distance from the injury site to the most proximal muscle and calculating the time needed for reinnervation to occur based on regeneration rate, EMG evaluation can be planned to assess for spontaneous recovery within a timeframe that would still facilitate successful surgical intervention. Surgery may provide some benefit when performed outside the ideal window, as sensory targets remain viable for up to 2 to 3 years and reestablishment of protective sensation may be achieved.

FIGURE 48.1 Initial evaluation of open nerve injury.

TREATMENT

The timing and technique of surgical intervention is dependent on the mechanism and characteristics of the nerve injury. Injuries may be classified as either open or closed, depending on the status of the associated cutaneous tissue (Figs. 48.1 and 48.2).

Closed peripheral nerve injuries occur most commonly as a result of stretching, contusion, or compression and are more likely to be in continuity. Transection is rare, and neurapraxic and axonotmetic injuries predominate. Lesions of this sort rarely require immediate surgical intervention and should be managed conservatively for a period of at least 3 months to allow for spontaneous recovery.

Open injuries, which result from lacerations, are more frequently associated with neurotmetic lesions and may require early surgery. In general, prognosis for functional recovery is better if

P.401

spontaneous regeneration is able to occur. Therefore, open injuries with a nerve in continuity may be treated conservatively, with medical management, early mobilization and physical therapy, and serial electrodiagnostic studies to monitor progress. If no evidence of reinnervation is found within 3 months, surgical exploration may be appropriate. On the other hand, for open injuries with evidence of nerve transection, early surgical exploration is preferred. The timing and extent of the surgery will differ according to the mechanism of injury.

FIGURE 48.2 Closed nerve injury management.

Sharp injury to a nerve, as is seen most commonly with knife or scalpel wounds, results in clean transection with minimal trauma to adjacent nerve tissue and no inflammation. Sharp injuries should be repaired promptly, ideally within the first 3 days after injury, and are usually able to be directly reapproximated with tensionfree suture. Prognosis is generally good in these cases.

Blunt transections that are often associated with boat propeller accidents have significant inflammation and damage to surrounding tissues. Inflammatory changes in the blunt ends continue to evolve over a period of 3 weeks, and surgical repair should be delayed. Ongoing inflammation can disrupt the repair. Direct reapproximation is less likely to be successfully performed, as the contused areas must be trimmed back to the point of healthy tissue, lengthening the gap. Nerve grafting may be necessary. Prognosis is poorer after grafting than direct termino-terminal *neurorrhaphy* but good functional recovery may still be achieved.

Nerve injuries sustained as a result of gunshot wounds require special consideration. Most lesions caused by gunshot wounds are the result of indirect heat and shock waves generated by the bullet, rather than transection. As continuity is usually preserved, spontaneous recovery may be achieved. Further, damage to

tissues may limit the success of early repairs. Therefore, surgical exploration and repair should be delayed for 3 to 4 months postinjury.

INDICATIONS FOR EARLY OPERATIVE MANAGEMENT

Early operative management may be indicated in certain settings. As discussed earlier, sharp transections, in which transected ends are not significantly contused, benefit from surgery performed within 3 days. Progressive nerve deficit suggests the presence of associated vascular injury or abnormality. Evidence of an expanding hematoma, pseudoaneurysm, or other compressive lesion should prompt early surgical intervention to alleviate compression.

SURGICAL TECHNIQUES

The goal of surgical repair is to restore functional connectivity across the site of lesion and to alleviate neural pain. This may be accomplished by the removal of scar tissue, reapproximation and direct suturing of transected nerve ends, or through the interposition of graft material. The type and extent of surgical intervention is dependent on lesion characteristics.

Neurolysis

The term *neurolysis* refers to the exposure of a peripheral nerve and dissection free of surrounding tissues. External or internal neurolysis may be performed.

External neurolysis is the first step of all surgical peripheral nerve interventions. During this step, the nerve is freed from surrounding tissue and mobilized (Fig. 48.3). Thickened and scarred areas of the endoneurium are removed as the surgeon progresses from normal to abnormal tissue, distal and proximal to the lesion. Careful dissection seeks to minimize disruption to vasculature that could slow healing or cause secondary injury.

For lesions in continuity, upon completion of external neurolysis, intraoperative stimulation and electrophysiologic recording is employed to assess functional connectivity. An electric stimulus is applied proximal to the lesion and response is recorded distally (Fig. 48.4). If a measurable response is present in the distal segment, external neurolysis may be sufficient to relieve pain and support healing. If no response is noted, resection and repair may be warranted. Performing external neurolysis prior to intraoperative electrophysiologic evaluation allows more accurate placement of electrodes.

FIGURE 48.3 Intraoperative photo demonstrating a sural nerve injury that occurred during an Achilles tendon repair. External neurolysis across the injured segment reveals a traumatic neuroma marked by the *black bracket*. The nerve is in continuity.

FIGURE 48.4 Intraoperative photo demonstrating a sural nerve neuroma-in-continuity marked with the *black bracket*. Intraoperative nerve action potential (NAP) recording using the hook electrodes reveal no conduction across the injured segment. Therefore, the neuroma is excised, and a conduit repair is performed.

Internal neurolysis refers to the dissection and mobilization of individual nerve fascicles for evaluation and scar tissue removal. It is indicated for use with incomplete lesions that are associated with pain refractory to conventional medical therapy. Removal of scar tissue from around individual fascicles may help alleviate neuropathic pain, but dissection within the nerve sheath has the potential to damage regenerating axons. Internal neurolysis is also performed as part of a split repair, described in the following text.

Split Repair

Split repair is an operative technique that is used when electrophysiologic examination reveals conductive heterogeneity around the circumference of a nerve. After internal neurolysis is complete, individual fascicles can be tested and preserved if conductance across the lesion is achieved. Those fascicles that do not conduct will undergo resection and repair with either direct end-to-end neurorrhaphy or with grafts. The benefit of the split repair technique is that it allows uninjured fascicles to undergo spontaneous regeneration, which generally is more successful than either direct suturing or graft interposition.

End-to-End Neurorrhaphy

End-to-end neurorrhaphy refers to the reapproximation and suturing together of transected nerve ends. It is commonly used to repair sharp transections and generally carries a better prognosis than grafting. The use of this technique is limited by the size of the gap created after resection of injured tissue. Excessive tension at the suture line can increase scar formation and impede functional recovery. External neurolysis and mobilization of the nerve stumps may help to decrease the gap length. Transposition of some nerves, such as the ulnar nerve at the elbow, may also provide more length. Groups of fascicles may be individually reapproximated and sutured to help minimize formation of neuroma and maximize chance of regeneration. As the composition of fascicles changes

P.403

every 1 to 2 mm, various techniques have been developed to try to match fascicles by predominant component, motor or sensory, to improve the chance of proper end-organ target reinnervation.

Graft Repair

For nerve gaps that are too long to be directly sutured without excessive tension, nerve graft repair is indicated. Longer gap lengths are commonly seen as a result of blunt transections, which damage tissue surrounding the lesion, and moderate to long complete lesions in continuity, which require resection. Although autografts are used most commonly today, cadaveric nerve grafts and specialized hollow tubes have also been used to restore continuity of the nerve.

For this procedure, the sural, antebrachial cutaneous, or superficial sensory radial nerve is harvested from the patient. Damaged nerve tissue is removed from the lesion site proximally and distally until normal fascicular structure is identified. Groups of fascicles are carefully separated and small-caliber donor nerve grafts are sutured to the healthy nerve tissue. The ends of the grafts are “fish-mouthed” or spread to increase the surface area. Good results can be achieved with this technique, although controversy exists regarding the maximum length for which grafts are successful. An inverse relationship has been observed between graft length and prognosis.

Nerve Transfer

Nerve transfer is an additional option for restoring function to an injured limb, particularly when the nerve lesion cannot be repaired by the techniques described earlier. This technique, which is variably referred to as *neurotization*, *nerve crossing*, and *heterotopic nerve suture*, is used most commonly to treat avulsive injuries of the brachial plexus. In this surgical technique, an uninjured nerve is used as a substitute for one that is no longer working. Transfers may be single or dual, in which either one or two nerve transfers are used to restore function. Nerves may be coapted end-to-end or end-to-side in which the proximal end of the recipient nerve is sutured to an epineural window in the intact, donor nerve. Generally, end-to-end direct

neurorrhaphy is preferred. The term *neurotization*, commonly seen in the literature, is reserved for cases of nerve transfer in which a donor nerve is directly implanted into a muscle. The benefit of nerve transfer is that the time for regeneration and reinnervation is shortened by shortening the distance over which a nerve must regenerate. The primary goals of these surgeries include restoration of elbow flexion, shoulder abduction, and protective hand sensation.

The most commonly used procedure for restoration of elbow flexion was described by Oberlin and colleagues in 1994. During the Oberlin procedure, one or two fascicles from the ulnar nerve branch are transferred directly to the motor branch of the biceps. Intraoperative stimulation may be employed to identify fascicles of the ulnar nerve that innervate the flexor carpi ulnaris to minimize resulting deficit. Direct transfer of the ulnar fascicles to the biceps motor branch reduces sensory/motor cross-reinnervation by limiting aberrant motor reinnervation of the sensory territory of the lateral antebrachial cutaneous nerve. A second common procedure used to reestablish elbow flexion is transfer of a group of intercostal nerves to the musculocutaneous nerve. This transfer may be used when the Oberlin procedure is not available. Because the intercostal nerve is not a native elbow flexor, a period of retraining, which can extend from 12 to 24 months, may be necessary to restore function.

Similar procedures are used to restore shoulder abduction and external rotation, which are important for shoulder stability. The most commonly used procedure to restore shoulder abduction is the transfer of the spinal accessory nerve to the suprascapular nerve. In this procedure, distal fascicles of the spinal accessory nerve are directly sutured to the suprascapular nerve, which provides motor innervation to the supraspinatus. Superior branches of the spinal accessory nerve, which innervate the trapezius, are left intact to preserve function. An additional strategy to restore shoulder abduction is transfer of the triceps branch of the radial nerve to the axillary nerve, which innervates the deltoids. Nerve branches of the long, medial or lateral head of the triceps may be used. This procedure may be combined with spinal accessory transfer to maximize chance of functional recovery. In all cases, the choice of intervention derives from the needs and functional status of the individual patient.

Tendon Transfer

A final option for restoring some function and stability for patients who present for late treatment, when successful reinnervation is less likely, is tendon transfer. Tendon transfer consists of the transfer of an entire functioning muscle, with its innervation, to replace the actions of one that is paralyzed and thereby restore some motion across a joint. Tendon transfers are generally the last resort before fusion options are considered.

OUTCOMES

Functional restoration is dependent on both injury and patientspecific factors. Age, mechanism and type of injury, location, and timing of intervention all influence the final outcome. The interaction of these complex clinical characteristics makes prognostication difficult.

In general, neurapraxic lesions have the best prognosis with functional recovery apparent within weeks to a few months. Axonotmetic injuries recover more slowly, requiring several months for regeneration to occur. Neurotmetic lesions carry the worse prognosis with chance of recovery closely related to timing and type of surgical intervention. These lesions will not recover spontaneously. Sensory restoration can continue for a period of up to 3 years, whereas muscle targets are no longer viable after 12 to 18 months. Spontaneous recovery always carries a better prognosis than surgical reapproximation, and clinical recovery may be followed for up to 3 years.

Mild Cognitive Impairment

Lawrence S. Honig

INTRODUCTION

Cognitive complaints are common in the population. In many such cases, history and examination reveal significant impairment in more than one cognitive domain and concomitant functional decline—and in these cases the findings provide for a diagnosis of dementia (see [Chapter 11](#)). However, in many other cases, there may be involvement of just one cognitive domain and/or lack of any clear functional decline, and diagnosis of dementia may not be warranted. An “intermediate state,” neither representing dementia proper nor normality, must exist in the gradually progressive transition from normal brain health to dementia. There needs to be some means to categorize such a state as a diagnostic entity, even though it may simply be early stage of a degenerative brain disease. In the 20th century, a variety of nonspecific terms were invoked to describe this intermediate state, including “pure amnesic disorder,” “age-related memory impairment (ARMI),” “age-associated memory impairment (AAMI),” “questionable dementia (QD),” “cognitive impairment no dementia (CIND),” and “prodromal dementia.” Originally, such terms were predicated on the idea that perhaps this change was to be expected during normal aging. With the increased understanding of the biologic underpinnings of cognitive disorders, this view became less tenable. Thus for individuals with impairment not meeting dementia criteria, the term *mild cognitive impairment* or MCI was coined. The original clinical definition of MCI was memory-based and required a subjective memory complaint, a documented objective deficit in memory, overall normal general cognitive function, and a lack of “significant” functional impairment precluding a diagnosis of dementia. This was codified by the American Academy of Neurology in 2001. A large proportion of these cases ultimately develop dementia, mostly due to Alzheimer disease, at a rate of between 7% and 20% per year, although over a few years, some persons remain relatively stable, nonprogressive, or even improve. The definition of MCI has been broadened to domains other than memory to reflect non-Alzheimer dementias, ([Table 49.1](#)). These other types of MCI include single domain amnesic, amnesic multidomain, nonamnesic single domain, and nonamnesic multidomain impairments ([Table 49.2](#)).

TABLE 49.1 Broad Definition of Mild Cognitive Impairment

Core Criteria	Examples
Subjective (self-reported or informant-reported) cognitive complaint	<ul style="list-style-type: none"> • Forgetfulness about events, appointments, or items of information • Forgetfulness regarding date or time • Misplacing or “losing” objects • Word-finding problems, such as “forgetting words” • Spatial disorientation, such as becoming lost
Objective evidence of cognitive dysfunction on testing	<ul style="list-style-type: none"> • Decreased performance on standardized testing of cognitive domains, including memory, language, visuospatial, attentional, or executive functions or skills^a
Preservation of functional	

activities

- Essentially normal function in living activities^b

Absence of diagnosis of dementia

- Diagnosis of dementia is exclusionary.^c

^aVarious cutoffs have been used for the objective tests, including 1.5 standard deviations below age- and sex-adjusted norms on one or more tests within a particular cognitive domain.

^bFunctional preservation is the most problematic of the three core inclusionary features because function may depend on living situation and demands.

^cDiagnosis of MCI and dementia are mutually exclusionary, but diagnosis of dementia is not independent from the criteria in the table.

MCI has also been codified by the committees of the American Psychiatric Association in 2013. The formulation of the diagnostic criteria of *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*), recognizes that for each dementing disorder, there must be a state in which the impairment does not reach the level of dementia. Thus, each dementing disorder is categorized as a “major neurocognitive disorder” or “minor neurocognitive disorder.” For example, Alzheimer dementia is “major,” whereas amnesic MCI is “minor.” For Alzheimer disease, which is the likely outcome for most amnesic MCI patients, biomarkers have allowed segmentation of the relatively slow neurodegenerative process into different diagnostic phases. The National Institute on Aging and Alzheimer’s Association workgroup in 2011 divided the Alzheimer neurodegenerative spectrum into three phases: “preclinical” disease in which persons are

P.406

asymptomatic but have biomarker evidence of an early Alzheimer process, a “symptomatic predementia phase” synonymous with MCI, and then the actual symptomatic dementia phase of Alzheimer disease ([Table 49.3](#) and [Fig. 49.1](#)). In summary, *mild cognitive impairment* is a diagnostic term referring to a cognitively impaired state of less extent or severity than a dementia. MCI is generally, but not always, an early symptomatic state of a neurodegenerative process.

TABLE 49.2 Classification of Types of Mild Cognitive Impairment

MCI Type	Domains Affected	Possible Prodromal Disease
Amnesic single domain	Memory alone	Alzheimer disease
Amnesic multidomain	Memory PLUS one or more other domain: language, attention, executive, or visuospatial dysfunction	Alzheimer disease
Nonamnesic single	Language, attention, executive, or visuospatial dysfunction	Frontotemporal dementia, Lewy body dementia, vascular dementia, posterior

domain		cortical atrophy, hydrocephalus
Nonamnestic multidomain	Memory not affected but more than one domain affected: language, attention, executive, or visuospatial dysfunction	Frontotemporal dementia, Lewy body dementia, vascular dementia, posterior cortical atrophy, hydrocephalus

Different types of MCI, left-most column, may ultimately more likely represent, as shown in right-most column, prodromal states of different dementia disorders. MCI, mild cognitive impairment.

EPIDEMIOLOGY

Both incidence and prevalence of MCI increase with age. Prevalence estimates vary widely depending on the exact definition of MCI. Subjective memory or other cognitive complaints (e.g., word finding) that are elicited upon interview are extremely common in the elderly, although they depend on the population examined; in the United States, there is a prevalence of about 80% in persons older than age 70 years. However, most such persons will not have MCI when using objective neuropsychological testing measures to confirm memory or other cognitive dysfunction. Only a proportion of persons with subjective memory or cognitive complaints present for neurologic or medical attention. Of those who do present for medical evaluation, yet do not have diagnosable dementia, a high proportion (as many as 85%) will indeed meet MCI criteria.

TABLE 49.3 Stages of Alzheimer Disease

Stage of Alzheimer Disease	Cognitive Signs and Symptoms	Functional Impairment	Biomarker Status
No disease	None	None	Negative
Presymptomatic disease (preclinical Alzheimer)	None	None	Positive
Symptomatic predementia (mild cognitive impairment)	Single or multidomain	Not significant	Positive
Symptomatic dementia (Alzheimer disease)	Multiple domains	Definite Impairment	Positive

This formulation is the result of the National Institute on Aging and Alzheimer's Association workgroups, as published in 2011. Biomarkers include structural MRI (regional hippocampal atrophy), PET metabolic imaging (bitemporoparietal hypometabolism), PET amyloid imaging (evidence of amyloid), and cerebrospinal fluid (low β -amyloid-42, high tau, and high phospho-tau).

MCI, defined as involving reasonably preserved function but combined subjective memory or cognitive change and objective memory or cognitive impairment (see [Table 49.1](#)), is not as common as subjective memory complaints. The prevalence and incidence rates depend on the population assessed, including age, education, and cultural milieu, and the exact diagnostic criteria. Thus in persons older than age 60 years, prevalence

estimates for overall MCI have varied from as low as 1% to 5% to as high as 30% to 40%. Studies of populations older than age 75 years in North America and Europe suggest a convergent estimate of prevalence of about 20%, most of which MCI is amnesic or amnesic multidomain. Incidence rates of overall MCI vary in different reports from as low as 10 to as high as 200 cases per 1,000 person-years, depending on exact age range of elderly, the population studied, the numbers of years followed, and the exact criteria applied.

Risk factors for MCI appear to be the same as the risk factors for dementia conditions, notably Alzheimer disease (see Chapter 50). Age is the dominant risk factor. Gender has not proven to be a risk factor when controlling for age. Lower education has generally been found to be a risk factor, as sometimes has ethnicity, medical illnesses including cardiovascular disease, and genetic factors, including apolipoprotein E (APOE) $\epsilon 4$ allele. If a case of MCI ultimately progresses to a particular dementia, then retrospectively, it is found that the risk factors for that form of MCI were those for the dementia disorder. However, for the MCI patients who improve

P.407

over 1 to 3 years, or stay stable, and do not progress to dementia, the major risk factors, in retrospect, are psychiatric illnesses, including depression and anxiety, and reversible medical conditions.

FIGURE 49.1 MCI on the spectrum of neurodegeneration. The figure shows schematic increases over time in brain biomarkers (*red line*), symptoms (*blue line*), and functional deficits (*green line*). For Alzheimer disease, biomarkers include (1) evidence for fibrillar β -amyloid accumulation in the brain through florbetapir, florbetaben, or flutemetamol imaging or because of low cerebrospinal fluid β -amyloid-42 and (2) evidence of neurodegeneration indicated by decreased hippocampal volume, decreased gray matter gyral thickness, or increased tau and/or phosphotau in the cerebrospinal fluid. Symptoms would include memory, language, visuospatial, or executive dysfunction confirmed on neuropsychological testing. A disease-free (*at risk*) period is followed by an asymptomatic but biomarkerpositive period (*presymptomatic*), followed by a *symptomatic* period. This latter period consists of an intermediate, earlier time period marked by cognitive symptoms without significant effect on function (*MCI*) and a later time period in which cognitive symptoms are more evident and there is concomitant functional impairment (*dementia*).

Overall, younger persons, younger than age 50 to 60 years, presenting with subjective memory complaints, with or without objective confirmation, are more likely to have an underlying psychiatric basis to their dysfunction than

are elderly persons. This is likely due to both the fact that early dementia is less common in the younger population and because anxiety and depression more often present in the younger population than present de novo in the elderly.

Most studies with strict criteria for objective dysfunction show that MCI subtypes of amnesic or amnesic multidomain are more common. Nonamnesic single or multidomain subtypes are less common. This might be expected from the relative prevalences of the underlying dementia disorders (see [Table 49.2](#)).

MCI is not a pathologically specific diagnosis, so the epidemiology of progression to dementia is important. It is clear that the majority of persons meeting criteria for MCI do progress to dementia over a period of 5 to 10 years. Both the rate of such progression and the particular dementia to which there is progression vary, in part depending on severity and in part depending on the type of MCI. Overall, amnesic MCI and amnesic multidomain MCI both most frequently progress to Alzheimer disease at generally reported rates of 10% to 20% per year. Some other less common forms of MCI, such as single-domain visuospatial, may upon progression best fit the clinical syndromic diagnosis of posterior cortical atrophy, which, however, usually still reflects underlying Alzheimer disease pathology. Even persons who “revert” from MCI to normal cognition are at higher future risk of dementia. However, some persons remain stable with a diagnosis of MCI for many years, and the underlying basis of their dysfunction is unclear, as is their ultimate prognosis.

PATHOBIOLOGY

The pathobiology of MCI is that of the disorders for which it is a precursor state. Thus, if MCI is an early form of Alzheimer disease, then Alzheimer pathology is the substrate. Correspondingly, if the MCI is a precursor to frontotemporal dementia (FTD), then the pathology is that of FTD. Thus the condition, as presently defined, is not a homogeneous clinicopathologic entity. The reader is referred to Chapter 11 on the dementias and the individual chapters on Alzheimer disease (see [Chapter 50](#)) and other dementias.

CLINICAL FEATURES, DIAGNOSIS, AND PROGNOSIS

MCI manifestations are subjective and objective cognitive impairment (see [Table 49.1](#)), but each of the cardinal aspects of MCI has interpretative leeway. Generally, a diagnosis of MCI requires a “consistent” symptomatology, not single disturbing events. Corroboration of a patient’s symptoms by a knowledgeable informant also increases likelihood that the symptoms represent abnormal cognition. Assessment of objective memory and cognitive impairment depends on the exact domains (memory, language, attention, executive and visuospatial function), the tests used for each domain, and the criteria for abnormality. Different standards have been used, including 1, 1.5, or 2 standard deviations below the normative mean, without formal consensus or agreement on which of these is most appropriate.

Assuming the unequivocal presence of subjective and objective cognitive changes, often the most diagnostically difficult criteria to assess is that of relative preservation of function. Particularly in the elderly, depending on their spousal or family support and on their residential environment, the patient may not be expected or in the habit of performing routine functions commonly performed earlier in life. Bills may be prearranged; meals may be preprepared; and travel may be circumscribed or always accompanied. In these settings, it is often difficult to assess what is evidence of significant functional decline. Even persons engaged in their occupation may have a narrow range of responsibilities and well-learned skills in their occupational field that makes decline in function invident.

The first criteria for MCI were developed during the 1990s. In 2001, the American Academy of Neurology encoded the criteria (see [Table 49.1](#)) without specifying exact measures for impairments. More recently in 2011, consensus panels sponsored by the National Institute on Aging and the Alzheimer’s Association have provided criteria for MCI with accompanying criteria for preceding (presymptomatic) and frequent subsequent (Alzheimer

dementia) conditions. These National Institute on Aging and Alzheimer's Association criteria are consistent with current biomarker evidence that MCI is the middle part of a spectrum (see [Table 49.3](#) and [Fig. 49.1](#)). This spectrum comprises persons without disease but with a risk factor for dementia such as family history or APOE ε4 genotype, persons who are presymptomatic (showing evidence of early disease biomarkers accumulation such as cerebral amyloidosis), early symptomatic individuals with MCI, and later symptomatic individuals with Alzheimer disease or another dementia.

DIAGNOSTIC TESTING

Diagnostic testing of persons with MCI should consist of testing to exclude reversible causes of cognitive impairment. Thus, in most cases, the evaluation should proceed similarly to the evaluation of the patient with dementia. Neuropsychological testing may have even greater use in the case of suspected MCI than in dementia. Psychometric test results can be helpful in establishing the extent of cognitive impairment, the domains affected, and the degree to which there is impairment, in comparison to a normative sample of others with comparable age, sex, and education. Such testing provides strong assistance in the diagnosis of MCI and also provides a baseline for subsequent evaluations.

Laboratory and imaging studies have two potential roles. The first role is to exclude nonneurodegenerative medical conditions not evident on the clinical examination that might be responsible for the cognitive impairment and might be reversible with known therapies. The second reason is to discern biomarkers whether in cerebrospinal fluid or on brain imaging that might be of value in assessing the prognosis of the MCI state and whether it is more or less likely to progress to a dementing disorder.

Exclusionary tests are those used in Alzheimer disease and include blood laboratory testing to assess the presence of renal or hepatic dysfunction, B₁₂ deficiency, thyroid deficiency, and in some cases, infectious diseases such as Lyme disease, syphilis, or HIV infection. Routine neuroimaging using magnetic resonance imaging (MRI) is often reasonable to exclude structural disorders representing infections, tumors, traumatic, hydrocephalic, or vascular injuries and may also provide information on pattern of brain atrophy indicative of an underlying process (see the following text). Electroencephalography (EEG) or other neurophysiologic measures are rarely needed, unless there is the suggestion of some episodic nature to the symptoms suggesting the possibility of complex partial seizures. EEG would typically be normal or show nonspecific mild temporal slowing or diffuse background rhythm slowing. Cerebrospinal fluid testing is optional. Like MRI, it may rarely reveal the unlikely presence of an unsuspected contributory condition that might have its own specific therapeutic approach. Such disorders include central nervous system (CNS) inflammatory, infectious, or neoplastic disorders, including neurosyphilis, neurosarcoidosis, or meningeal carcinomatosis.

TABLE 49.4 Biomarkers Useful in Prognostication for Mild Cognitive Impairment

Biomarker	Result	Prognostic Implications
Brain MRI	Focal decreased hippocampal volume, parietal gyral atrophy, or cortical thinning	Likely AD
Fluorodeoxyglucose PET imaging	Bitemporoparietal hypometabolism Frontal or anterior temporal hypometabolism	Likely AD Suggestive of FTD Suggestive of PCA or

	Occipital hypometabolism	DLB
Florbetapir, florbetaben, or flutemetamol PET imaging	Positive signal for fibrillar amyloid	Suggestive of AD with or without involvement of DLB
Ioflupane SPECT imaging	Decreased unilateral or bilateral striatal uptake	Suggestive of DLB
Cerebrospinal fluid biomarker analysis	Low β -amyloid-42 High phospho-tau	Suggestive of AD
Apolipoprotein E genotyping	ϵ 4 Allele present	Suggestive of underlying AD
Glucocerebrosidase (GBA) genotyping	Presence of a GBA mutation	Suggestive of possible DLB

MRI, magnetic resonance imaging; AD, Alzheimer disease; PET, positron emission tomography; FTD, frontotemporal dementia; PCA, posterior cortical atrophy; DLB, dementia with Lewy bodies; SPECT, single-photon emission computed tomography.

To determine the etiology of MCI and assist prognostically, a number of tests have been shown to be of value in assessing the likelihood of progression of cognitive symptoms of MCI to dementia (Table 49.4). These tests include structural neuroimaging, molecular neuroimaging, and examination of cerebrospinal fluid biomarkers and genetic biomarkers. Structural MRI may show patterns of cerebral atrophy, which can be suggestive of the presence of a particular neurodegenerative disorder. Early Alzheimer disease is marked by temporal lobe and parietal lobe gyral atrophy and cortical thinning. Studies show that temporal lobe atrophy is associated with a greater risk of progression of memory symptoms and development of Alzheimer dementia. FTD is more often marked by asymmetric or symmetric frontal and anterior temporal atrophy (see Chapter 51). Molecular neuroimaging using positron emission tomography (PET) imaging tracers for amyloid such as florbetapir, florbetaben, or flutemetamol may show the early deposition of fibrillar β -amyloid indicative of the presence of neuritic plaques. Positive amyloid imaging is a strong risk for progression of MCI to Alzheimer disease dementia, and negative amyloid imaging makes it less likely to predict AD, although various cutoffs for imaging have been used. Likewise, cerebrospinal fluid biomarkers, particularly, the presence of low β -amyloid-42 but also likely the presence of high tau and phospho-tau, are associated with MCI progression to Alzheimer disease. Genetic testing for *APOE* genotype is not recommended, but there is evidence that particularly in those older than age 65 years, the presence of one or two *APOE* ϵ 4 alleles is associated with a higher risk of progression to Alzheimer disease. The combinations of these factors in which multiple markers indicate the same incipient disease process are likely of even greater prognostic value, although correspondingly, the presence of discordant biomarkers makes prognostication of progression less clear.

TREATMENT

Because many cases of MCI, particularly amnesic MCI, develop into Alzheimer disease over time, a number of investigations have examined whether any of the four commonly used disease-specific treatments

conversion to dementia¹. The three cholinesterase inhibitors donepezil, galantamine, and rivastigmine have all been the subjects of trials in MCI. Only donepezil (10 mg/day) showed some mild evidence [**Level 1**]¹ of efficacy in delaying progression to a diagnosis of Alzheimer disease (sometimes termed *conversion*). Galantamine trials showed a small degree of increased mortality in drug treatment compared to placebo, but it is suspected that this was a statistical finding, not necessarily indicative of an injurious effect of this drug in MCI. The sole approved noncholinesterase inhibitor Alzheimer medication memantine has been tried in MCI and mild AD and has been found to be inefficacious.

Disease-modifying treatments are not yet available for MCI or Alzheimer disease. The wide presumption is that if a medication is shown to slow the progression of Alzheimer disease, that treatment at the MCI stage would be even more useful than treatment of mild AD. Even if a drug worked equally effectively at different stages of the disease, slowing progressive disease earlier would be more beneficial than slowing it later. Thus, increasingly prospective investigational therapies for Alzheimer disease are also being tested in subject populations with MCI. Such approaches include immune therapies designed to clear β -amyloid monomers or polymers, including active immunogens or passive monoclonal antibodies, β - or γ -secretase inhibitors designed to decrease intracerebral generation of β -amyloid, and other potential treatments that have been proposed to lessen tau aggregation or decrease synaptic or neuronal injury. However, when treating persons with MCI as if they have early Alzheimer disease, it is important to be certain that indeed this disease is the underlying pathologic process. For this reason including imaging biomarkers for β -amyloid and tau, cerebrospinal fluid biomarkers for β -amyloid, tau, phospho-tau, synuclein, and others and genetic markers including APOE genotype may be useful in predicting which persons with MCI are most likely to be in the early phases of Alzheimer disease and thus warrant therapies designed to deter progression of the Alzheimer disease process.

MCI also frequently involves concurrent anxiety or depression. In some cases, as mentioned earlier, the primary etiology of the MCI state may be depression. Thus, for any individual with anxiety or depression, consideration should be given to treatment of the psychiatric symptoms with antidepressants, most commonly selective serotonin reuptake inhibitors such as fluoxetine, sertraline, paroxetine, citalopram, or escitalopram.

Alzheimer Disease

Lawrence S. Honig

Scott A. Small

Richard Mayeux

INTRODUCTION

The most common dementia is Alzheimer disease. The disease was first named by Emil Kraepelin in 1910, after Alois Alzheimer, who in 1906 had described the clinical features and pathologic manifestations of dementia in a 51-year-old woman. For some decades, Alzheimer disease was considered a presenile form of dementia, affecting individuals with symptoms beginning before age 65 years. But the mid-20th century brought the understanding that the same clinical, pathologic, ultrastructural, and biochemical features of presenile Alzheimer disease are shared by those with the more common “senile” (older than age 65 years) dementia. The disease is commonly sporadic, although susceptibility relates to a variety of genetic risk factors. Uncommonly, the disease has an autosomal dominant inheritance pattern, particularly in younger persons. In a look back to the past, an analysis of the DNA of Alois Alzheimer’s first described case, nearly 100 years after her evaluation, revealed that her condition resulted from a mutation (F176L) in exon 6 of one of these autosomal dominant genes, presenilin 1.

EPIDEMIOLOGY

Alzheimer disease is a chronic disease of aging, and both the incidence and prevalence of disease increase with age. Prevalence estimates reveal that fewer than 1% of persons younger than age 65 years are clinically affected, but about 5% are affected at age 65 to 75 years, about 20% at age 75 to 85 years, and likely over 50% at age 85 years and older. The increasing prevalence with age is because the age-specific incidence, or the number of new cases arising over a specific period of time, rises steeply from less than 1% per year before age 65 years to about 6% per year for individuals aged 85 years and older. The average duration of symptoms from first noticeable symptoms until death is typically from 10 to 20 or more years.

It is presumed that both environmental and genetic factors are involved in the risk of the disease. But extensive investigations, as to environmental risk factors other than age, have not resulted in clear risk factors for Alzheimer disease itself. Late-life depression is associated with Alzheimer disease, although the direction of causality is unclear—it is likely that depressive symptoms are often early manifestations of this dementing disorder. Traumatic head injury has been associated with increased risk of dementia, but it is not clear that trauma is a risk for Alzheimer disease itself versus other dementias. Likewise, diabetes and cardiovascular and cerebrovascular disorders have been associated with increased risk of dementia, but these may be due to additive ischemic injury to the brain, rather than a true increase in Alzheimer disease. Studies of identical twins show that they are not necessarily concordantly affected, so almost certainly there are some factors other than classic genetic ones. However, the main risk factors for development of Alzheimer disease, each small in and of itself, appear to be the members of a growing long list of genetic variations ([Table 50.1](#)).

GENETIC BASIS OF ALZHEIMER DISEASE

Most Alzheimer disease is “sporadic” rather than a mendelian dominant or recessive condition. However, a small proportion of the total number of persons with Alzheimer disease (<0.5%) have disease that is transmitted as an autosomal dominant identified monogenic familial disorder, commonly, but not always, with onset before age 65 years. Mutations in three genes, the amyloid precursor protein (APP) gene on chromosome 21, the presenilin 1 (*PSEN1*) gene on chromosome 14, and the presenilin 2 (*PSEN2*) gene on chromosome 1, result in such

autosomal dominant forms of the disease beginning as early as the third decade of life, with essentially complete penetrance (see [Table 50.1](#)). In addition, trisomy 21, or Down syndrome, results in near certainty of Alzheimer disease pathology by age 50 years and in symptoms of the disease in those who survive long enough. Finally, there is a mutation in APP (the “Icelandic” allele, A673T) which is highly correlated with protection from Alzheimer disease. There are at least 204 described different pathogenic mutations in *PSEN1*, and it is the most common form of familial early-onset Alzheimer disease. Mutations in these three genes account for as many as half of the familial forms of early-onset Alzheimer disease and may be considered deterministic because of nearly complete correspondence between the genotype and phenotype. Mutations in these three genes seem to lead to increased production of amyloid- β ($A\beta$) or specifically the $A\beta_{42}$ peptide.

There is a higher risk of Alzheimer disease in first-degree relatives of persons with Alzheimer disease. Siblings of patients have about twice the expected lifetime risk of developing the disease. Monozygotic twins have significantly higher concordance of Alzheimer disease than do dizygotic twins. Some of the genetic risk relates to the $\epsilon 4$ polymorphism of the *APOE* gene on chromosome 19, which shows a strong association with onset of Alzheimer disease in the age range of 60 to 80 years. The $\epsilon 4$ polymorphism of *APOE* is a normally occurring variant of the gene present in about one-third of the unaffected American population but present in about two-thirds of those with late-onset Alzheimer disease. *APOE* has been called a *susceptibility* gene because possession of the $\epsilon 4$ allele, a polymorphism, does not always lead to Alzheimer disease. One *APOE*- $\epsilon 4$ allele is associated with about a 2- to 3-fold increased risk, whereas having two copies is associated with a 5- to 10-fold increased risk. The population attributable risk associated with *APOE*- $\epsilon 4$ is approximately 20%, making it one of the most important risk factors for the disease.

A large number of gene variants have now been identified, that each conveys a smaller risk of Alzheimer disease than that of *APOE*- $\epsilon 4$ (see [Table 50.1](#)). About 20 such genes are currently identified including some involved in lipid biology, intracellular processing, or endosomal pathways (e.g., *SORL1*) and others involved in inflammation or the immune response, cell migration, cytoskeleton, axonal transport, and microglial cell function. Other genes will likely be identified adding to the already complex genetic architecture of this disease.

TABLE 50.1 Chromosomal Loci and Genes Related to Alzheimer Disease

Chromosome Locus	Gene/Candidate	Genetic Inheritance	Possible Mechanism
14q24.13	<i>PSEN1</i>	Autosomal dominant	Increased generation of $A\beta_{42}$
1q31.42	<i>PSEN2</i>	Autosomal dominant	Increased generation of $A\beta_{42}$
21q21.3	<i>APP</i>	Autosomal dominant	Increased $A\beta_{42}$ or $A\beta_{42}$ aggregation
21q21.3	<i>APP(A673T)</i>	Protective factor	Decreased generation of $A\beta_{42}$
19q13.2	<i>APOE</i>	Risk factor	Decreased clearance of $A\beta_{42}$

11q23.3	<i>SORL1</i>	Risk factor	Lipid/protein endocytosis/trafficking
2q14.3	<i>BIN1</i>	Risk factor	Lipid/protein endocytosis/trafficking
6p12.3	<i>CD2AP</i>	Risk factor	Lipid/protein endocytosis/trafficking
11q14.2	<i>PICALM</i>	Risk factor	Lipid/protein endocytosis/trafficking
19p13.3	<i>ABCA7</i>	Risk factor	Lipid/protein endocytosis/trafficking
8p21.1	<i>CLU</i>	Risk factor	Lipid/protein endocytosis/chaperone
1q32.2	<i>CR1</i>	Risk factor	Cell adhesion to particles/complexes
19q13.3	<i>CD33</i>	Risk factor	Cell adhesion/immune response
18q12.1	<i>DSG2</i>	Risk factor	Cell adhesion
14q22.1	<i>FERMT2</i>	Risk factor	Cell adhesion/cytoskeletal function
20q13.31	<i>CASS4</i>	Risk factor	Cell adhesion/cytoskeletal function
7p14.1	<i>NME8</i>	Risk factor	Cytoskeletal function
6p21.3	<i>HLA-DRB5/1</i>	Risk factor	Immune response/trafficking
5q14.3	<i>MEF2C</i>	Risk factor	Immune response/synaptic function
2q37.1	<i>INPP5D</i>	Risk factor	Immune response/signaling
11q12.1	<i>MS4A6A</i>	Risk factor	Signal transduction
7q34	<i>EPHA1</i>	Risk factor	Receptor tyrosine kinase/signaling
8p21.2	<i>PTK2B</i>	Risk factor	Receptor tyrosine kinase/signaling

14q32.12	<i>SLC24A4-RIN3</i>	Risk factor	Cation exchange transporter
7q22.1	<i>ZCWPW1</i>	Risk factor	Regulation gene expression
11p11.2	<i>CELF1</i>	Risk factor	Regulation gene expression (splicing)
6p21.1	<i>TREM2(R47H)</i>	Risk factor	Immune response/A β 42 clearance
6p21.1	<i>TREML2(S144G)</i>	Protective factor	Immune response/A β 42 clearance

List of genetic markers related to risk of Alzheimer disease. PSEN1, PSEN2, and APP are genes for which mutations can lead to autosomal dominant inherited Alzheimer disease, although a particular mutation in APP can also be protective against Alzheimer disease. APOE, SORL1, and the other genes listed all have been shown to have allelic variation that affects risk of Alzheimer disease.

PATHOBIOLOGY

Alzheimer disease pathology is marked by two specific neuropathologic features (Table 50.2; Fig. 50.1): extracellular amyloid plaques molecularly consisting in large part of a fibrillar aggregation of the 40 and 42 amino acid peptides A β 40 and A β 42 and intracellular neurofibrillary tangles, which consist of paired helical filamentous polymers of hyperphosphorylated tau protein. Although these specific features permit pathologic diagnosis of Alzheimer disease, it is likely that the symptoms of the disease relate primarily to extensive synaptic losses and later to frank neuronal losses. Much of the earliest brunt of this injury is borne by the entorhinal region of the medial temporal lobe.

The senile neuritic plaques are spherical microscopic lesions with a core of extracellular A β infiltrated and surrounded by abnormal nerve fibers (neurites). The A β 40 and A β 42 peptides are derived from the APP, a transmembrane protein present in most tissues. A region of the APP resides within an intramembranous domain of intracellular organelles in neurons, and several proteolytic enzyme activities, known as *secretases*, are responsible for cleavage of the protein. When cleaved by α -secretase, a soluble peptide derivative of amyloid is formed. However, when the APP is cleaved by β -secretase, and subsequently by γ -secretase, the peptides A β 40 and A β 42 are generated. These A β peptide monomers aggregate, forming oligomers, and ultimately large polymers, a process that can be demonstrated in vitro and presumably results in the amyloid plaques observed histologically. It is thus not surprising that the three autosomal dominant genes for Alzheimer disease are the APP gene itself and the PSEN1 and PSEN2 genes, which contribute to γ -secretase activity. Although there is little doubt as to a pathologic role of APP products, it is not clear which products might be most responsible for presumed neurotoxicity and synaptic losses: monomers, oligomers, polymers, or even other more soluble fragments. In addition to the parenchymal deposition of amyloid in

P.412

Alzheimer disease, there is in nearly all cases amyloid angiopathy, which is amyloid deposition around meningeal and cerebral vessels. This condition is of varying severity and import in different patients but is accompanied by a propensity for hemorrhages, which may be microscopic, although visible on T2*-weighted gradient echo magnetic resonance imaging (MRI), or macroscopic, with medium or large lobar hemorrhages. In a small proportion of patients, acute localized or diffuse brain edema may occur, now known as *amyloid-related imaging abnormality edema* or ARIA-E, either spontaneously or after delivery of investigational anti-amyloid therapies.

TABLE 50.2 Pathologic Hallmarks of Alzheimer Disease

Macroscopic/Regional	Clinical Implications
Hippocampal atrophy	Memory impairment
Parietotemporal atrophy	Dysnomia/visuospatial impairment
Nucleus basalis cell loss	Attentional impairment
Microscopic	Molecular Concomitant
Neuritic plaques	A β 42 and A β 40 fibrillar aggregates with associated neuritic changes
Diffuse plaques	A β 42 and A β 40 fibrillar aggregates
Neurofibrillary tangles	Paired helical filamentous aggregates of phosphorylated tau protein
Synaptic loss	Not known—but accompanied by decreases in various neurotransmitters
Neuronal loss	Not known
Granulovacuolar degeneration	Intraneuronal vesicular changes

List of pathologic hallmarks of Alzheimer disease, including macroscopic/regional changes and microscopic changes and their clinical and molecular correlates.

FIGURE 50.1 **Top panel** shows a cortical brain section immunohistochemically stained with antibody to β -amyloid. There are extensive stained extracellular deposits, which include plaques and also blood vessel staining in the white matter (amyloid angiopathy). **Bottom left panel** shows section stained with antibody specific for phosphorylated tau protein, and the intracellular stained deposits are neurofibrillary tangles. **Bottom right panel** shows a histochemical stained section (silver stained with the Bielschowsky method), visualizing both plaques and tangles.

Neurofibrillary tangles are fibrillary intracytoplasmic structures within the neurons. Electron microscopy shows paired helical filaments of the microtubule-associated protein, known as *tau protein*. Normally, tau is a protein responsible in part for the axonal cytoskeleton, participating in microtubule assembly. In Alzheimer disease, hyperphosphorylated tau aggregates form, which are recognized in the electron microscope as twisted paired helical filaments and recognized in the light microscope as neurofibrillary tangles. Neurofibrillary tangles are not specific to Alzheimer disease, but in this disease, they occur first in the hippocampal formation and later are seen throughout the cerebral cortex. This apparent topographic spread of tangles has been codified as a staging system by Braak and Braak, including involvement of entorhinal (stages 1 and 2), hippocampal (stages 3 and 4),

disease progression. This is more evident than is the case for amyloid plaques, which latter are often present even before symptoms and do not appear to correlate so highly with disease severity in autopsy tissues. Recent human in vivo imaging evidence suggests that amyloid deposition does indeed increase with disease, but it may “saturate” earlier than the formation of tangles. The relative injurious basis of these two hallmark pathologies is still not clear.

An important but nonspecific pathologic feature of Alzheimer disease is widespread, regionally specific losses of synapses and ultimately losses of neurons. Synaptic losses are accompanied by a wide variety of neurotransmitter deficits. These include particular decline in cholinergic terminals in the hippocampus and cortex, which apparently owes to early and prominent degenerative involvement of the nucleus basalis of Meynert, whose large cholinergic neurons project widely. It is this cholinergic deficit that informs the basis for treatment of Alzheimer disease with drugs that increase cholinergic tone. Alzheimer disease is also variably marked by granulovacuolar degeneration of hippocampal pyramidal cells, which is a poorly understood pathologic feature, amyloid deposition in blood vessels, and glial changes. Finally, it is common in Alzheimer to have coexistent pathologies such as intracytoplasmic inclusions of α -synuclein known as *Lewy bodies* or *Lewy neurites*. Lewy bodies are discussed in Chapters 52 and 83, as they represent pathologic hallmarks of Parkinson spectrum disease. They are present in as many as 35% of Alzheimer disease brains and even present in brains of persons with early-onset autosomal dominant Alzheimer disease, for example due to PSEN1 mutations. The reason for the common co-occurrence of these two degenerative pathologies is uncertain. Vascular lesions, in addition to amyloid angiopathy (discussed earlier), are another common coexistent pathology, occurring in 30% to 50% brains of persons with Alzheimer disease. These include microinfarcts, microhemorrhages, and lacunar or large-artery infarcts. It is likely that, when present, Lewy body pathology and vascular pathologies contribute to the phenotype in Alzheimer disease, leading to the term *mixed dementia*. However, most studies show that the burden of plaques and tangles is best correlated with the progressive dementia in Alzheimer disease.

CLINICAL FEATURES

The signs and symptoms of Alzheimer disease present and evolve variably, with the most common early signs being subjectively and objectively impaired memory (see [Chapter 11](#)). Overall, there is slow progressive cognitive impairment, eventually affecting many cognitive domains. When persons live long enough, this disease process results in complete incapacity, and ultimately death, from conditions associated with severe cognitive dysfunction. Course from first symptoms to death is often as long as 20 years, although typically, diagnosis is not made until the disease is well established on a molecular basis (evident through molecular changes in cerebrospinal fluid [CSF] or neuroimaging). Although it is likely that the disease progresses at different rates in different persons, it is unlikely that there is truly any “plateau” or temporary cessation of progression.

Cognitive impairment is the hallmark of Alzheimer disease. Memory impairment is the most common presenting symptom, present in over 90% of affected patients. The difficulty with memory is most prominent for newly acquired information, so-called short-term memory, whereas immediate, or “working” memory, is typically unaffected. “Long-term memory” for remote events is relatively unimpaired in the early phases of the illness but ultimately is also severely affected. As the disease progresses, impairments in language and visuospatial function typically become more prominent ([Fig. 50.2](#)), as well as impairments in abstract reasoning and executive function or decision making. The increasing impairment in language and visuospatial function may be particularly evident on serial office testing (see [Fig. 50.2](#)). In some, language dysfunction may be the earliest subjective symptom or objective sign, and this syndrome of primary progressive aphasia (PPA), often of a “logopenic” variety (lvPPA), is often due to Alzheimer disease and is discussed in [Chapter 51](#). In other persons, visuospatial impairment, which may progress to the extent of complete cortical blindness, may be the presenting symptom of

Alzheimer disease, and this syndrome is termed *posterior cortical atrophy* (PCA).

Behavioral dysfunction is present at some point in the course of most patients with Alzheimer disease. The most common symptoms are depressive, with apathy and anhedonia, but irritability, agitation, insomnia, hypersomnia, decreased or increased food intake, dependency, disinhibition, repetitive or compulsive activities, all may occur. These symptoms in some cases likely relate to neuroanatomic changes but in other cases may represent reactive changes to cognitive incapacities. Psychotic symptoms including delusions and auditory or visual hallucinations may occur. Delusions frequently have paranoid ideation regarding theft or infidelity and also may involve misidentification of place or person; they are much more common than hallucinations. Indeed, the presence of detailed visual hallucinations, in the absence of concomitant primary visual system disease, should be a clue as to involvement of Lewy body dementia (see [Chapter 52](#)) as primary (diffuse Lewy body disease) or contributing (Lewy body variant of Alzheimer disease) dementia disorders.

Functional decline results from both cognitive and behavioral features. Loss of employment, financial difficulties, marital or other family dysfunction, driving difficulties, and difficulties learning new technologies such as automobile controls, home entertainment device remote controls, computers, or home security systems are frequent.

Examination of the patient with Alzheimer disease typically reveals only impairments in mental state. The remainder of the neurologic examination is usually normal, especially in the mild to moderate stages. In the later stages of the disease, extrapyramidal signs, including rigidity, bradykinesia, shuffling gait, and postural change, are not uncommon. These features may in some cases be solely a consequence of Alzheimer disease but in other cases may relate to concomitant involvement of Lewy body dementia (see [Chapter 52](#)). Primary motor and sensory functions are typically spared. Early symptoms of seizures or falling or early signs of cortical motor or sensory dysfunction, cranial or motor neuropathies, or cerebellar dysfunction, should all strongly raise the possibility of some other form of dementia (see [Chapter 11](#)).

DIAGNOSIS

The first organized criteria for clinical diagnosis of Alzheimer disease were established in 1984 by a joint effort of the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Association (previously known as *the Alzheimer's Disease and Related Disorders Association*). These criteria, the NINCDS-ADRDA criteria, consisted of three levels of clinical certainty: definite, reserved only for autopsy-confirmed cases, probable, and possible. The criteria included a history of progressive deterioration in cognitive ability, not explicable by other known disorders, involving memory and at least one other cognitive domain, and causing some significant disturbance of functioning in the patient. These criteria were endorsed by the American Academy

P.414

of Neurology in 2001, with the additional provision of preferred laboratory tests, such as computed tomography (CT) or MRI, and optional laboratory tests, such as serologic testing for syphilis. However, over time, it became clear that these criteria were inadequate due to the requirements for memory involvement, functional disturbance, and the lack of reference to more modern and specific biologic imaging and fluid marker tests, referred to in the following text. New sets of criteria have been developed by consensus sponsored by the National Institute on Aging and the Alzheimer's Association, and these NIA-AA criteria provide for preclinical diagnosis, early symptomatic diagnosis without functional impairment (see [Chapter 49](#)), and presymptomatic diagnosis.

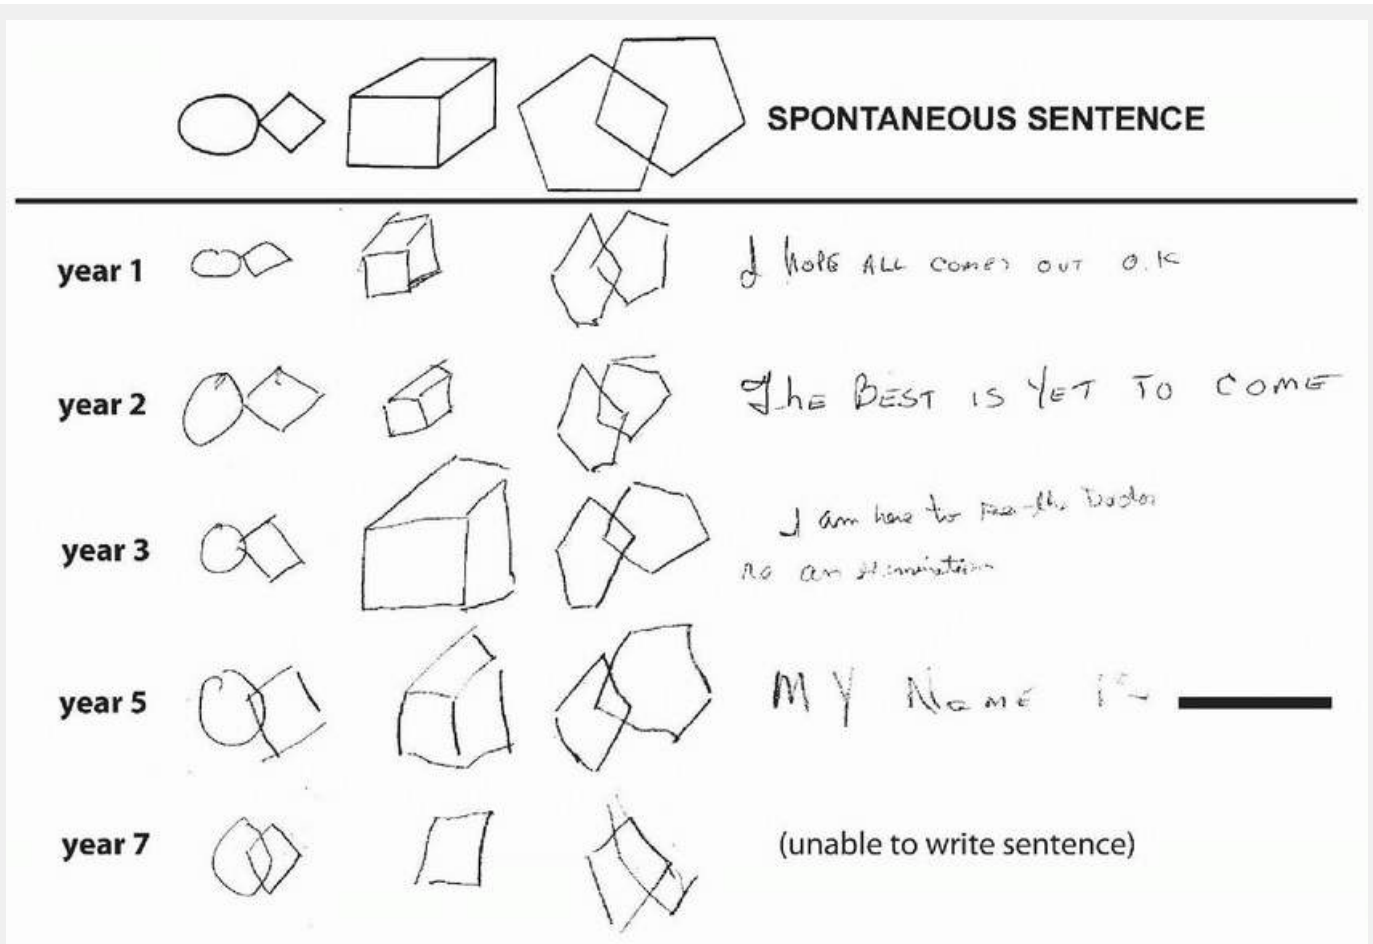

FIGURE 50.2 Mental status testing in a patient with memory problems, for whom a diagnosis of Alzheimer disease was made in year 1. Over a 7-year period, the drawings show increasing impairment in constructional praxis—the ability to copy figures. *Top row* shows example provided to the patient, and subsequent rows are the patient's performance initially and in succeeding years. The patient was also asked each visit to write a full sentence of his or her choice. There is increasing difficulty with both penmanship and content.

DIAGNOSTIC TESTING

Neuropsychological testing is useful in establishing the extent of cognitive impairment in terms of domains affected and in terms of degree of affectation compared to persons of comparable age, sex, and education (normative results). Examination of test results in comparison to persons of a similar group allows for better assessment than results on an absolute basis because of the general wide variation in performance on these tests, which relate in large part to education (see [Chapter 30](#)). Such testing can also be very useful in following progression of disease. Routine laboratory examinations of blood, urine, and CSF are unremarkable in Alzheimer disease. Electroencephalography and other neurophysiologic measures are nonspecific, revealing background rhythm slowing or other changes not diagnostic of any particular brain condition. Likewise, routine imaging by CT or MRI does not reveal gross structural abnormalities other than atrophy, particularly early in the course of the disease. Later in the disease, significant cortical and subcortical atrophy, although not entirely specific, is typically observed ([Fig. 50.3](#)). Most importantly, it has become clear that both CSF and functional brain imaging can show relatively sensitive and specific markers of Alzheimer disease (see [Chapter 11](#), see the following text, and [Fig. 50.4](#)) and can be of use in the differential diagnosis of this disorder. Genetic tests are generally not recommended for diagnosis of Alzheimer disease. However, selected testing may be useful in the diagnosis in families with the rare early-onset autosomal dominant forms of Alzheimer disease. For sporadic or familial late-onset Alzheimer disease (LOAD), the $\epsilon 4$ polymorphism of the apolipoprotein E (APOE) gene is associated with a higher risk of the

disease, but because at least one-third of persons with Alzheimer have no $\epsilon 4$ alleles, and because some persons with even two $\epsilon 4$ alleles are symptom free even in their 10th decade of life, the test does not provide sufficient sensitivity or specificity to be used for diagnosis and is not recommended.

Measurements of CSF proteins (see [Chapter 31](#)) are established to be of use in the diagnosis of Alzheimer disease. Typically in Alzheimer disease, $A\beta_{42}$ is decreased in concentration, perhaps related in part to deposition of amyloid in the brain. Total tau

P.415

protein is typically elevated, relating presumably to neurodegeneration and loss of axonal integrity. Phosphorylated tau (phospho-tau) is also elevated and more specific for Alzheimer disease because in this disorder, the tau protein is abnormally phosphorylated. Combined measures of the concentrations of these three biomarkers results in sensitivity and specificity each in the range of 90%. Of note, it is clear that changes in $A\beta_{42}$, tau, and phosphorylated tau can precede clinical symptoms and diagnosis of disease by up to 15 years. Blood analytes in serum or plasma including $A\beta_{40}$, $A\beta_{42}$, and proteomic and lipidomic panels have not yet proven to be of use in the diagnosis of Alzheimer disease.

FIGURE 50.3 MRI T1-weighted structural images from two patients (**A** and **B**) with Alzheimer disease, including in each patient selected sagittal (*top rows*) and axial (*bottom rows*) images. **A** shows a pattern of atrophy most prominent in parietal regions. **B** shows a pattern of atrophy more prominent in temporal regions.

FIGURE 50.4 **A** shows images from a single patient who underwent an ^{18}F -fluorodeoxyglucose PET scan. *Top row* shows sagittal sections, *middle row* axial sections, and *bottom row* coronal sections. The images demonstrate decreased brain metabolic activity in bilateral parietal, temporal, and to a lesser extent frontal regions. Note that in this color coding scheme, “cooler” colors such as green and blue are lower activity, and “hotter” colors such as yellow, red, and white are higher activity. **B** shows ^{18}F -florbetapir PET scan in two individuals, with a black and white image display scheme, in which blacker represents higher uptake of florbetapir. Each row shows an example of an axial, sagittal, and coronal brain imaging slice. The *top row* is of a normal control individual who shows cerebral uptake of the radioligand only in the white matter. The *bottom row* shows the images of patient with Alzheimer disease, who shows extensive gray matter uptake of the radioligand throughout cerebral cortex including frontal, temporal, and parietal regions, and basal ganglia.

P.416

Brain imaging has become important in diagnosis of Alzheimer disease, can aid in early detection of disease, and may be helpful in research studies following treatment of the disease. Brain imaging includes “structural” imaging, “functional” imaging, and “molecular” imaging. Structural imaging techniques including CT and MRI are used to exclude other causes of dementia, such as tumors or strokes. However, in Alzheimer disease, structural imaging typically reveals dilatation of the lateral ventricles and widening of the cortical sulci, particularly in temporal and parietal regions (see Fig. 50.3). Such cortical atrophy is not specific for Alzheimer disease, as it can be seen in some older individuals who function normally by clinical and neuropsychological testing. During the last decade, MRI approaches have been developed to measure precise volumetric changes in the brain, and these can be useful in differentiating Alzheimer disease from frontotemporal dementia and have been used in monitoring therapies with investigational drugs (see Chapter 21). Functional brain imaging techniques include single-photon emission computed tomography (SPECT), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI) (see Chapters 21 and 22). Although using different technologies, functional imaging techniques hold in common a sensitivity to brain metabolism—either glucose uptake in the case of ^{18}F -fluorodeoxyglucose-PET or the closely correlated blood flow measures examined by $^{99\text{m}}\text{Tc}$ hexamethyl-propylene-aminoxime (HMPAO)-SPECT or fMRI. Studies using PET or SPECT reveal a characteristic pattern of hypometabolism and hypoperfusion in the mesial temporal and posterior parietal lobes, with preservation of function of the deep gray nuclei and the primary sensory and motor cortices (see Fig. 50.4A). With the superior spatial resolution afforded by fMRI, studies have begun to map patterns of dysfunction in smaller brain subregions of the medial temporal lobe, the general area where the disease is thought to begin. Within the hippocampal

formation, high-resolution fMRI has shown that, in contrast to the early stages of Alzheimer disease that target the entorhinal cortex, normal aging involves the dentate gyrus, a neighboring hippocampal subregion. Finally, the most recent development in brain imaging is being able to detect the molecular features of Alzheimer disease: amyloid-containing plaques and neurofibrillary tangles. The first such molecular imaging reagent for detecting neuritic plaques in vivo was “Pittsburgh compound B” (PIB, whose chemical formulation is ^{11}C -6-OH-benzothiazole-1), but there are currently three approved ^{18}F -labeled reagents: florbetapir, florbetaben, and flutemetamol, all of which have been shown through clinical and autopsy studies to show cortical binding of radioligand in Alzheimer disease (see Fig. 50.4B). The absence of cortical binding is inconsistent with Alzheimer disease. However, as might be expected for a disease that starts with small amounts of asymptomatic A β 42 deposition, a substantial fraction of clinically normal elders (e.g., about 25% of those older than age 65 years, with increasing proportions in older age groups) do have some binding, consistent with the possibility that they may later develop Alzheimer disease. New investigational radioligands for aggregated tau, as well as SPECT and PET radiopharmaceutical reagents to examine dopaminergic systems, promise a greater armamentarium of advanced molecular imaging biomarkers that may assist in early diagnosis and assessment of disease.

TABLE 50.3 Treatments of Alzheimer Disease

Medication	Dosages	Presumed Mechanism
Tacrine hydrochloride	40-160 mg/day oral	Cholinesterase inhibition
Donepezil hydrochloride	5-10 mg/day PR or 23 mg/day ER oral	Cholinesterase inhibition
Galantamine hydrobromide	8-24 mg/day PR or ER oral	Cholinesterase inhibition
Rivastigmine tartrate	3-12 mg/day oral or 4.5-13.3 mg/day transdermal	Cholinesterase inhibition
Memantine hydrochloride	5-20 mg/day PR or 7-28 mg/day ER oral	NMDA receptor inhibition

List of the five medications approved by the U.S. Food and Drug Administration (FDA) specifically for Alzheimer disease. Tacrine is rarely used due to dosing schedule and required laboratory monitoring. Donepezil and rivastigmine are labeled for use in mild, moderate, and severe disease; galantamine is labeled for use in mild and moderate disease; memantine is labeled for use only in moderate and severe disease.

ER, extended release; PR, prompt release; NMDA, *N*-methyl-D-aspartate.

Therapies for Alzheimer disease are currently symptomatic, as there are no proven disease-modifying treatments. Nonspecific treatments for secondary symptoms of Alzheimer disease can be useful. These include treatment of depressive symptomatology with antidepressants including selective serotonin reuptake inhibitors. Likewise, treatment of psychotic symptoms such as delusions and hallucinations, as well as agitation and irritability can be managed with judicious use of antipsychotic medications. Side effects of these medications can be impairing, including drug-induced parkinsonism. Neuroleptics have, in some studies but not others, been associated with small increases in mortality from various causes. Anxiolytics such as benzodiazepines may also be used but are generally avoided due to adverse effects on cognition. Despite potential risks, pharmacologic treatment of behavioral symptoms with neuroleptics can be of major help to patients and their caregivers.

There are five disease-specific treatments available for Alzheimer at this time. These five medications are symptomatic and do not appear to modify disease course but have received U.S. Food and Drug Administration (FDA) approval for specific treatment of the disease ([Table 50.3](#)) on the basis of level 1 randomized

P.417

placebo-controlled trials. Four of these are cholinesterase inhibitors, which effectively increase synaptic levels of brain acetylcholine through inhibition of synaptic acetylcholinesterase, which normally hydrolyzes acetylcholine released from the presynaptic neuron into the synaptic cleft. Tacrine was the first such drug [**Level 1**],¹ but it is no longer in common use due to four times daily dosing and hepatotoxicity. The three cholinesterase inhibitors currently in common use are donepezil [**Level 1**],^{2,3,4} rivastigmine [**Level 1**],⁵ and galantamine [**Level 1**].⁶ The evidence is that these three have similar mild efficacy in improving cognition and may also cause small improvements in behavior and function in patients with mild, moderate, or severe Alzheimer disease (see Level 1 Evidence in the following section). One other drug, memantine, has been approved for treatment only of moderate to severe Alzheimer disease, for which there is level 1 evidence [**Level 1**],^{7,8} whereas such evidence is lacking for mild disease. Memantine is an activity-dependent *N*-methyl-D-aspartate receptor antagonist and provides an independent modest benefit in cognition, behavior, and function in persons with moderate to severe disease. This benefit occurs in both settings of monotherapy [**Level 1**]⁷ and concomitant therapy with cholinesterase inhibitors [**Level 1**]⁸ in such patients.

Disease-modifying treatments are not yet available. However, the increasing understanding of Alzheimer disease as a disorder characterized by accumulation of β -amyloid, and tau aggregates has given rise to a significant number of experimental drugs that have been studied or are currently under investigation. Current approaches to potentially ameliorating the course of Alzheimer disease include monoclonal antibodies or active immunizations designed to clear amyloid protein from the brain, β -secretase inhibitors designed to decrease intracerebral generation of β -amyloid, and other therapies proposed to deter tau aggregation or neuronal dysfunction.

Frontotemporal Dementia

Edward D. Huey

Stephanie Cosentino

INTRODUCTION

Frontotemporal dementia (FTD) is the most common clinical presentation of frontotemporal lobar degeneration (FTLD). Two main FTD phenotypes are seen. One form is primarily a disorder of behavior and executive function (bvFTD), and the second, less frequent form is primarily a disorder of language, termed *primary progressive aphasia* (PPA) and defined by predominant language impairment for at least 2 years. Classifications of PPA include nonfluent/agrammatic (naPPA), semantic variant (svPPA), and logopenic variant (lvPPA). Combinations of behavioral and language symptoms that do not fit clearly into defined clinical subtypes reflect overlapping distributions of neuropathology in prefrontal and anterior temporal regions and can be present at disease onset but typically become more frequent with advancing disease severity.

EPIDEMIOLOGY

Overall, FTD is the fourth most common dementia (behind Alzheimer disease [AD], vascular dementia, and dementia with Lewy bodies), affecting 1% to 16% of all people with dementia; FTD is the most common cause of dementia prior to age 60 years and approaches the prevalence of AD prior to age 65 years. Approximately 60% of cases occur in individuals aged 45 to 64 years. Although we do not yet have definitive epidemiologic studies, the estimated point prevalence of FTD within this age range, based on studies primarily including Caucasians in North America and Europe, is 15 to 22/100,000. Most studies implicate an equal distribution by gender.

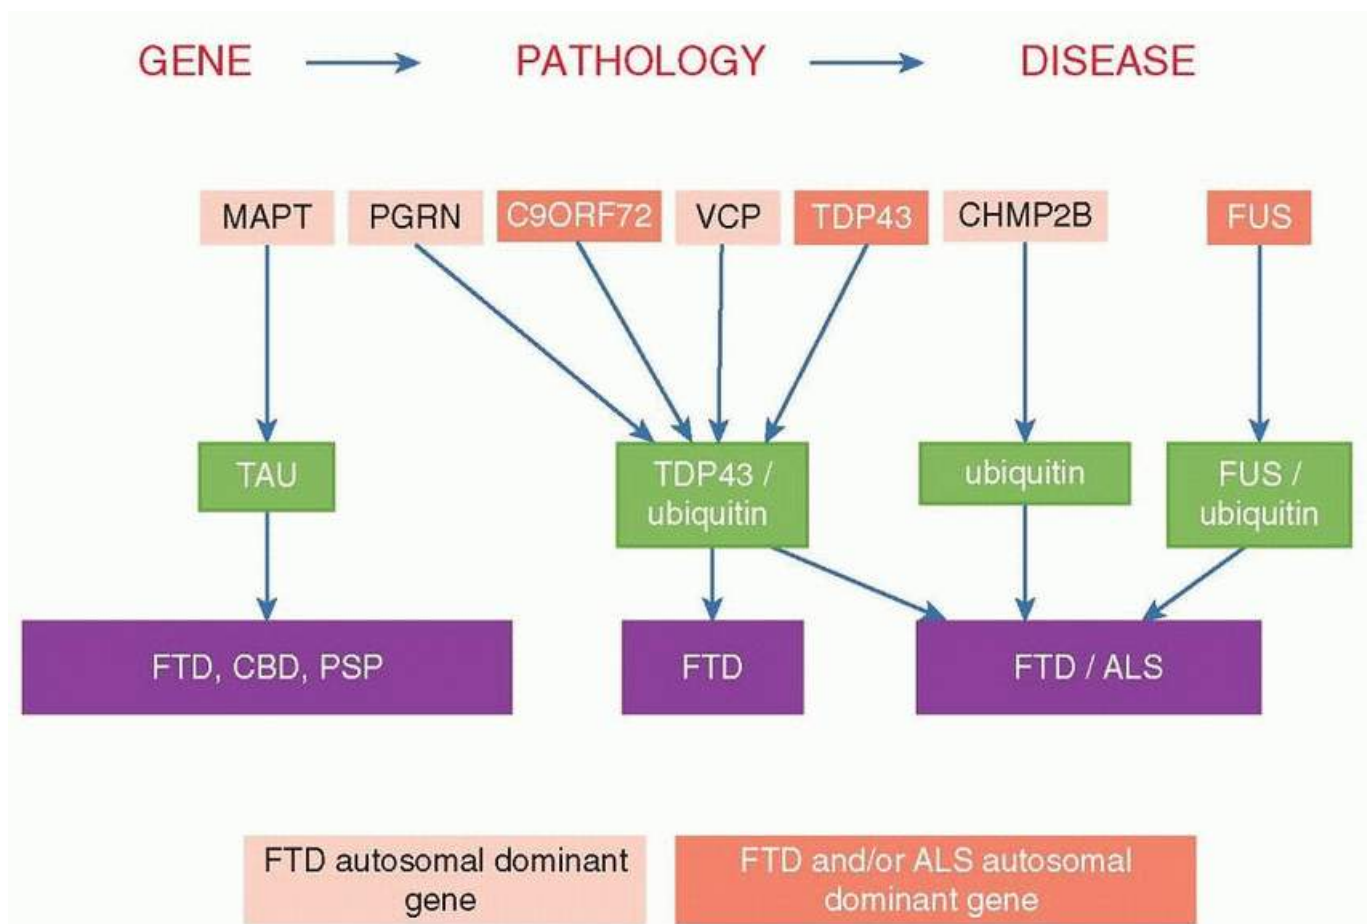

FIGURE 51.1 Association between pathologic, genetic, and clinical variants of FTD. CBD, corticobasal degeneration; PSP, progressive supranuclear palsy.

PATHOBIOLOGY

At autopsy, gross frontal and temporal lobe atrophy is usually evident, with histopathology revealing neuronal loss and gliosis affecting superficial cortical lamina of these same cortical regions, along with absence of the typical pathologic findings of AD. FTLN encompasses several different pathologies, including neuronal inclusions containing TAR DNA binding protein (TDP-43), tau isoforms, and fused in sarcoma (FUS) protein. Some patients have evidence of amyotrophic lateral sclerosis (ALS). As demonstrated in [Figure 51.1](#), several gene mutations associated with FTD result in specific neuropathologies and sometimes specific clinical presentations. Therefore, for some patients, the clinician can infer the neuropathology based on some (e.g., FTD-ALS), but not other (e.g., behavioral variant FTD), clinical presentations.

Only fewer than half of all FTD patients will demonstrate prominent tau aggregates, whereas approximately half will stain for ubiquitin, a nonspecific marker of cell death, although the breakdown of pathologies across subtypes differs ([Fig. 51.2](#)). A major FTLN subtype associated with tau aggregates is Pick disease. First described by Alois Alzheimer, Pick disease is characterized by argyrophilic cytoplasmic tau inclusions (Pick bodies) and swollen neurons (Pick cells). Ubiquitin-positive cases of FTLN were recently discovered to be characterized by inclusions composed

P.420

of aggregates of TDP-43 and more rarely FUS. The clinical presentation of FTD-ALS is associated with TDP-43 positive FTLN (see [Fig. 51.1](#)).

FIGURE 51.2 Distribution of neuropathology across clinical subtypes of FTD. (Permission to reproduce this figure granted by Dr. Glenda Halliday, University of New South Wales, Sydney, Australia. Chare L, Hodges JR, Leyton CE, et al. New criteria for frontotemporal dementia syndromes: clinical and pathological diagnostic implications. *J Neurol Neurosurg Psychiatry*. 2014;85[5]:865-870.)

GENETICS

An estimated 40% of cases of FTLD are familial, but only 10% follow a clear autosomal dominant pattern. Mutations in three genes account for the great majority of cases of FTD with an identified genetic cause (see Fig. 51.1). The most common genetic cause of both FTD and ALS appears to be the recently identified hexanucleotide repeat expansion in *C9ORF72* on chromosome 9. This expansion accounts for approximately 34% of familial ALS, 6% of sporadic ALS, 26% of familial FTD (with or without ALS), and 5% of sporadic FTD. The discovery of *C9ORF72* links FTD and ALS with several other neurologic disorders involving repeat expansions including Huntington disease, fragile X syndrome, myotonic dystrophy, and some of the spinocerebellar ataxias. The phenotype associated with *C9ORF72* expansions can be FTD, ALS, or combined FTD-ALS.

The two other known major genetic causes of FTD are mutations in the *MAPT* (tau) and *GRN* genes. Tau binds to microtubules, and it exists in isoforms of three and four microtubule-binding domains generated by alternate splicing of exon 10. Deposition of three-repeat tau is associated with Pick disease, whereas four-repeat tau is associated with CBD and PSP. *GRN* is an oncogene that codes for the protein granulin, which is a growth factor involved in wound healing. Reduced levels of granulin are associated with FTD, but elevated levels of granulin are associated with certain tumors including teratomas and breast, esophageal, and liver cancers. This is similar to another FTD/oncogene, *FUS*. Rare other genetic causes of FTD include mutations in valosin-containing protein, *TDP-43*, and *CHMP2B*. Clinical genetic testing can be considered with the guidance of a genetic counselor. Until recently, it was generally thought that an FTD patient should have a first-degree relative with FTD or a related illness to be offered clinical genetic testing. However, genetic testing of cases of FTD-ALS without a family history for *C9ORF72* should be considered. Clinical presentation and pathology in family members can guide genetic testing and whether to test only for known mutations or to sequence the gene.

CLINICAL MANIFESTATIONS

BEHAVIORAL VARIANT

The ventral prefrontal cortex is usually involved in bvFTD and appears to play an important role in social cognition and behavior. Alteration in personality and behavior, reflecting impaired judgment of social norms, is a hallmark feature of bvFTD. Patients display a loss of social graces, generally characterized by decreased empathy, diminished reactions to emotional events, excessive familiarity with strangers or acquaintances, inappropriate jocularity, and a general lack of self-consciousness. Distractibility, impulsivity, and apathy are also components of bvFTD. Such symptoms may be subtle at onset. The apathetic and amotivational aspect of bvFTD may initially be mistaken for depressed mood; however, it is relatively rare for patients with bvFTD to endorse feelings of sadness or hopelessness. Patients may also present with stereotyped behaviors, involving movement, language, or more complex behaviors. Increased appetite and hyperphagia, particularly for

P.421

sweets, and hyperorality can also occur. Patients with bvFTD frequently demonstrate reduced awareness of or lack of concern for their symptoms.

PRIMARY PROGRESSIVE APHASIA

The three PPA phenotypes reflect disruption to different components of the language network, with naPPA reflecting left frontal perisylvian involvement, svPPA reflecting anterior temporal involvement, and lvPPA associated with left posterior temporoparietal compromise. naPPA patients generally demonstrate reduced speech output that is both effortful and dysgrammatic. Such symptoms may be preceded by anomia, subtle deficits in sentence construction, as well as apraxia of speech (i.e., impaired motor planning and sequencing of the movements required for correct speech production). Comprehension is generally preserved, although

patients may have difficulty decoding syntactically complex phrases. In contrast, svPPA is a fluent aphasia, with normal prosody and tempo, but patients have progressive loss of semantic knowledge (i.e., understanding and recognizing the meaning of words and/or objects). Anomia and single-word comprehension deficits are the core diagnostic criteria. Surface dyslexia, the phonologic decoding or “regularization” of irregularly spelled words (e.g., *sue* for *sew*), is also a feature of svPPA, reflecting loss of item-specific knowledge. Patients with svPPA are also described to present with fixations on and/or frequent questions about the meaning of a word (e.g., “What is a comb?”). Behavioral changes are also typical of svPPA, including obsessive-compulsiveness and socioemotional changes characterized by indifference and lack of warmth particularly with differential right hemisphere involvement. There is evidence that the behavioral syndrome associated with svPPA overlaps with, but differs in some ways from, the behavioral symptoms in bvFTD. Additional signs of compromise to right anterior temporal regions include prosopagnosia (inability to recognize faces) and loss of semantic knowledge for other visual stimuli. Finally, lvPPA is characterized by slow spontaneous speech, with frequent word finding pauses and difficulty naming, phonologic paraphasias (i.e., use of an incorrect word that is phonologically related to the intended word), as well as sentence repetition errors. Repetition errors are generally seen for sentences of increasing length and complexity rather than for single words or simple phrases and appear to reflect limited auditory short-term memory capacity. lvPPA is most often associated with AD pathology but reflects FTD pathology in approximately one-third of cases.

In addition to the primary behavioral and language phenotypes described earlier, patients with FTD may present with or develop various movement abnormalities. Approximately 15% of patients with bvFTD exhibit signs of motor neuron disease consistent with ALS, whereas 20% to 30% of all patients with FTD display parkinsonism at some point. There are also an increasing number of reports of patients who present with psychosis, most frequently in the case of *C9ORF72* or *GRN* mutations.

DIAGNOSIS

Rapidly developing knowledge regarding the phenotypes associated with FTLD has resulted in recent revisions to the diagnostic criteria in 2011. The new bvFTD criteria allow for heterogeneous presentation of disease as well as levels of diagnostic certainty (i.e., possible, probable, definite), whereas the new PPA criteria include lvPPA as a third variant. In one neuropathologic case series, addition of the lvPPA diagnostic category resulted in reclassification of approximately half of cases that had been previously diagnosed as naPPA and improved separation of FTD versus AD pathology.

The diagnostic probability of FTD is heightened in those younger than 65 years and in those with an autosomal dominant pattern of inheritance. The diagnostic workup for FTD begins with cognitive and behavioral assessment. Formal neuropsychological testing can identify subtle language or executive dysfunction that aid in the differential diagnosis of FTD from other dementias as well as in the characterization of the FTD phenotype. Regarding the cognitive profile of FTD versus AD, a common differential diagnosis, visuospatial functions are generally well preserved in FTD. Moreover, although the retrieval of information from memory may be equally impaired in both groups, it is generally the case that the ability to store new information in long-term memory is preserved in FTD as compared to AD. Indeed, the integrity of memory storage, measured through recognition testing and proportion of information retained after a delay, has traditionally served as a critical variable for differentiating AD from FTD. However, it is increasingly recognized that poor performance on these metrics may be more common in FTD than initially appreciated. New diagnostic criteria for bvFTD (2011) allow for inclusion of individuals with atypical cognitive presentations such as those with severe amnesia or spatial disorientation. Finally, it is possible that objectively measured cognition can be within normal limits in patients with bvFTD despite marked behavioral changes in everyday life, or alternatively, performance may be globally impaired secondary to

apathy, inattention, or automatic responding.

Magnetic resonance imaging (MRI) in FTD often reveals cortical volume loss in the frontal and anterior temporal lobes with relative sparing of posterior parietal and occipital cortices (Figs. 51.3 and 51.4). Functional neuroimaging (18-fluoro-deoxy-glucose positron emission tomography [FDG-PET] or technetium-99m hexamethylpropyleneamine oxime single-photon emission computed tomography [HMPAO-SPECT]) often reveals frontotemporal hypometabolism. nPPA is associated with left-sided frontal perisylvian involvement and svPPA with anterior temporal involvement. Cerebrospinal fluid (CSF) findings include normal cell counts and protein. CSF tau and A β 42 levels have not demonstrated sufficiently

P.422

reliable differences from controls to use as a diagnostic test for FTD, but these protein levels can be useful to distinguish FTD and AD, as patients with AD will usually show elevated levels of tau and phosphorylated tau and reduced levels of A β 42 compared to controls and patients with FTLD. These tests can be helpful when AD and FTLD are in the differential diagnosis and to determine the neuropathologic process associated with certain clinical presentations such as logopenic PPA. The differential diagnosis for FTD can contain both neurodegenerative and psychiatric illnesses. The development of motor symptoms can elucidate the underlying pathology with symptoms of corticobasal syndrome or progressive supranuclear palsy associated with underlying tau pathology and symptoms of ALS associated with underlying TDP-43 pathology.

FIGURE 51.3 MRI demonstrating frontal atrophy in a patient with behavioral variant FTD.

FIGURE 51.4 Sagittal brain magnetic resonance image of the patient shown in [Figure 51.3](#).

TREATMENT

Currently, we do not have medications that have been shown to be disease-modifying therapies for FTD. Cholinesterase inhibitors do not appear to help (level 2 studies). Serotonergic antidepressants show some efficacy reducing certain behavioral symptoms including agitation and repetitive behaviors in level 1 and 2 studies [**Level 1**].¹ Atypical antipsychotic medications are also often used to attempt to reduce behavioral symptoms in FTD. Cognitive deficits and apathy generally do not improve with medication treatment. Memantine has not demonstrated efficacy for the treatment of FTD [**Level 1**].²

Management of FTD relies in large part on nonpharmacologic interventions. Foremost of these is patient and family education. At diagnosis, patients and families will want to know what to expect in the years to come. Genetic counselors can be useful for education about genetic testing. Referral to local support groups and to nationwide organizations such as the Association for Frontotemporal Degeneration can be helpful. A symptom diary can be a useful tool to track symptoms, especially behavioral symptoms, as the disease progresses, and to see the effects of therapeutic interventions as they are introduced. Environmental modifications, including locking doors and removing visible food, can be helpful for wandering behavior and hyperphagia. Providing only small portions on plates can also be useful. Wander bracelets can improve safety and now can be equipped with GPS to help in finding the patient. Physicians should continually assess if the level of assistance provided to the caregiver is sufficient. The behavioral

symptoms of bvFTD can put family members of patients at risk for physical injury or sexually inappropriate behavior toward minors. Children are often at greater risk for exposure to behavioral symptoms in FTD than in other types of dementia because the patients are often younger, more likely to have young children at home, and more mobile. These behaviors will likely necessitate placement out of the home. In the later stages of the illness, palliative care and hospice referrals can be helpful in managing symptoms.

OUTCOME

Knowledge on the natural history of FTD is limited to epidemiologic studies drawn from dementia specialty centers. The median time from first symptom onset to death ranges from 9 years for bvFTD (range 3 to 16 years), to 9.5 years for PPA (range 3 to 12 years), to 12 years for semantic dementia (range 6 to 18 years). Comorbid motor neuron disease shortens life span, with median survival of 5 years from symptom onset (range 3 to 12 years). The ways in which people die from FTD are similar to other types of dementia and include infection, often related to decreased mobility, aspiration, or incontinence, and decreased oral intake of food and water leading to dehydration and malnutrition.

Lewy Body Dementias

Sarah C. Janicki

Karen S. Marder

INTRODUCTION

Dementia with Lewy bodies (DLB) and Parkinson disease dementia (PDD) share many clinical and pathologic features. They are therefore discussed together and referred to as Lewy body dementias (LBD). Whether DLB and PDD are distinct disorders, or whether they represent different presentations of the same disease, is an area of ongoing investigation. Symptoms of each disorder may arise from variations in regional and temporal onset of neural dysfunction and degeneration. By consensus, when cognitive impairments are coincident with or appear within 1 year of the motor signs, DLB is diagnosed; the term *Parkinson disease dementia* is used when decline occurs in the course of well-established Parkinson disease (PD). Pathologically, both conditions are characterized by the presence of Lewy bodies, intraneuronal inclusions containing α -synuclein and ubiquitin in the brain stem, limbic area, forebrain, and neocortex.

EPIDEMIOLOGY

DLB and PDD are relatively common conditions, together affecting an estimated 1.3 million individuals in the United States.

DEMENTIA WITH LEWY BODIES

DLB is considered to be a common cause of dementia, with an estimated worldwide population prevalence of 4.2% to 7.5% and incidence of 3.8% in those newly diagnosed with dementia; however, the actual prevalence and incidence rates may be much higher due to the clinical difficulty of diagnosing DLB. Men may be more susceptible to DLB and have a worse prognosis than women.

PARKINSON DISEASE DEMENTIA

The estimated prevalence of PDD among the general population is 2% to 3%. Among patients diagnosed with PD, the prevalence of dementia is more than 30%, with a lifetime incidence of up to 80% of individuals with PD who reach the age of 90 years. Although the majority of PD patients will eventually develop dementia, the time from the onset of motor symptoms to dementia varies markedly. Few prospective biomarker studies exist to assist in prediction of patients' clinical course. Risk factors for dementia in PD include older age, age at onset of PD 60 years or older, duration of PD, and severity of parkinsonism, particularly the postural instability gait difficulty (PIGD) subtype. However, even patients with mild PD may have symptoms of cognitive impairment that does not meet criteria for dementia (mild cognitive impairment in Parkinson disease [PD-MCI]). PD-MCI may occur in up to one-quarter of patients at the time of initial PD diagnosis.

PATHOBIOLOGY

NEUROPATHOLOGY

Common pathologic findings of LBD are illustrated in [Figure 52.1](#). Lewy body (LB) pathology, particularly in the cortex, is the most important factor in the development of both DLB and PDD. There have been few comparative neuropathologic studies to determine whether the neuropathology of PDD differs from DLB or whether both conditions exist on a continuum. Neuronal loss in the substantia nigra may be more extensive in PDD than in DLB; other features including cortical LB and Alzheimer pathology have not been found to differ in PDD and

DLB.

Dementia with Lewy Bodies

Pathologic features associated with DLB are summarized in [Table 52.1](#). LBs are the only essential feature in the pathologic diagnosis of DLB; other features are apparent in most but not all cases.

LEWY BODIES

LBs are eosinophilic intracytoplasmic neuronal inclusion bodies and are found in both the subcortical regions and brain stem as well as in the cortex in DLB (see [Fig. 52.1A](#)). Brain stem LB occurs in the substantia nigra and locus coeruleus. The term *cortical Lewy body* refers to less well-defined spherical inclusions seen in cortical neurons (see [Fig. 52.1B](#)). In some individuals, proper identification of cortical LB may be overshadowed by the coincidence of severe Alzheimer changes; in other individuals, limitations in sampling may lead to an underidentification of cortical LB.

LEWY NEURITES

Lewy neurites (LN) are neurofilament abnormalities and a distinctive part of LB pathology in which proteins cluster into diffuse aggregates (see [Fig. 52.1C and D](#)). They occur in the hippocampus (cornu ammonis two-third region), amygdala, nucleus basalis of Meynert, dorsal vagal nucleus, and other brain stem nuclei.

ALZHEIMER PATHOLOGY

Most cases of DLB demonstrate comorbid Alzheimer disease (AD) pathology including amyloid plaques and neurofibrillary tangles. Plaque types in DLB are classified as either diffuse/immature plaques with tau-positive neurites or diffuse/immature plaques with tau-negative, ubiquitin-positive neurites.

SPONGIFORM CHANGE/MICROVACUOLATION

This is a feature of some DLB cases and occurs mainly in temporal cortex. It may relate to the severity of the disease. Although similar to spongiform change in Creutzfeldt-Jakob and prion-related diseases, there is no evidence that DLB is a transmissible disorder or linked to abnormal prion protein.

Parkinson Disease Dementia

Although PD often coexists with other common causes of dementia, such as AD, neuropathologic studies have found that the degree of LB pathology (including LB and LN) may have a closer correlation with cognitive decline and dementia in PD than does the degree of AD pathology.

FIGURE 52.1 Pathology of Lewy body dementias. **A:** Pars compacta of the substantia nigra: two pigmented neurons each one including two Lewy bodies. Subcortical Lewy bodies have a basophilic central core or are eosinophilic depending on the plane of section and are surrounded by a pale, narrow halo. **B:** Occipitotemporalis gyrus, fifth layer including a cortical Lewy body-containing neuron. Cortical Lewy bodies are ill defined and diffusely eosinophilic. The nuclear chromatin of cortical Lewy body-containing neurons is often vesiculated. **C:** Nucleus coeruleus. **D:** Substantia innominata or nucleus of Meynert. Both **C** and **D** exhibit α -synuclein-labeled Lewy bodies and Lewy neurites. (**A** and **B**, Luxol fast blue counterstained with hematoxylin and eosin; **C** and **D**, α -synuclein. Original magnification: **A**, 400 \times ; **B**, 630 \times ; **C** and **D**, 200 \times . Courtesy of JP Vonsattel, MD.)

A possible synergistic role between AD and PD pathology needs further research. A few studies have found that reduced amyloid β_{1-42} in the cerebrospinal fluid is associated with cognitive decline in patients with PD, as it is in patients with AD alone. Other data suggest that that α -synuclein deposition promotes the intracellular aggregation of tau and β -amyloid in cell models and that there is a more rapid disease progression in PDD cases with coexistent AD. It is likely that given the substantial prevalence of both AD and PD, at least some patients with PD may have cognitive decline that is attributed to or exacerbated by AD.

NEUROTRANSMITTER SYSTEMS

The exact mechanisms leading to dementia in DLB and PDD are unknown. However, there is an association between structural neuropathologic findings in LBD; dopamine depletion; and noradrenergic, serotonergic, and cholinergic dysfunction. LBs have a predilection for the substantia nigra, and both PDD and DLB are characterized by dopaminergic changes in the striatum and frontal cortex, leading to parkinsonism. In addition to motor control, dopamine is involved in a range of nonmotor behaviors such as cognition, motivation, sleep, and mood. The cholinergic nucleus basalis is another LB predilection site, leading to widespread and severe cortical cholinergic deficits. LBD pathology may also affect brain stem nuclei such as the locus coeruleus, which receives noradrenergic activation, and the serotonergic raphe nuclei. All of these areas are known to be involved in modulation of cognitive and psychiatric symptoms.

GENETIC RISK FACTORS

Although large genome-wide association studies (GWAS) have identified a variety of genes contributing to sporadic PD, similar large studies have not been published yet for PDD, and only one

P.426

GWAS study has been done in DLB. However, the importance of genetic factors for these diseases has begun to be established.

TABLE 52.1 Pathologic Features Associated with Dementia with Lewy Bodies

Essential for diagnosis of DLB:

- Lewy bodies

Associated but not essential for diagnosis of DLB:

- Lewy-related neurites
- Plaques (all morphologic types)
- Neurofibrillary tangles
- Regional neuronal loss, especially in the brain stem (including the substantia nigra and the locus coeruleus) and the nucleus basalis of Meynert
- Microvacuolation (spongiform changes) and synapse loss
- Reduced concentrations of choline acetyltransferase (ChAT) in neocortex

DLB, dementia with Lewy bodies.

Glucocerebrosidase

Several individual studies and an international multicenter collaborative study have demonstrated that patients with PD who carried mutations for the lysosomal enzyme glucocerebrosidase (*GBA1*) have a higher incidence of PD-MCI and PDD. Other multicenter autopsy studies have demonstrated that subjects with DLB were more than eight times more likely to carry a *GBA1* mutation than were controls. Further analyses indicate that *GBA1* mutations are also significantly associated with earlier age at onset and death in DLB. Although mechanisms underlying *GBA1*-associated parkinsonism and dementia are still not completely understood, accumulating evidence suggests that impairment of the aging lysosome, enhanced by deficient or mutant glucocerebrosidase,

can affect α -synuclein degradation.

Leucine-Rich Repeat Kinase 2

To date, cross-sectional studies have not identified specific cognitive dysfunction associated with mutations in leucine-rich repeat kinase 2 (*LRRK2*), a common cause of genetic PD. Of note, *LRRK2* G2019S carriers are more likely to have the PIGD phenotype, which is more likely to be associated with cognitive impairment. The PIGD phenotype, however, has not been associated with cognitive impairment in cross-sectional studies of *LRRK2* G2019S carriers.

Apolipoprotein E

Although cross-sectional studies have yielded disparate results, two prospective cohort studies found no association between *APOE* ϵ 4 genotype and the development of PDD or rate of change on the MMSE in patients with PD. One study examined rate of change on the Mattis Dementia Rating Scale (MDRS) over time and showed that the ϵ 4 allele was associated with a more rapid decline in MDRS scores (3 points per year; hazard ratio 2.8). In contrast, a recent large multinational case-control genetic association study using pathologically diagnosed samples demonstrated that the *APOE* ϵ 4 allele was a strong genetic risk factor for DLB.

CLINICAL MANIFESTATIONS

DEMENTIA WITH LEWY BODIES

The core diagnostic criteria for probable and possible DLB as proposed by the third report of the DLB consortium, and as commonly used in clinical practice, are included in [Table 52.2 \[Level 1\]](#).¹ These core criteria have a sensitivity of 83% and a specificity of 95% for the presence of neocortical LBs at autopsy. However, these core criteria are more predictive of the relatively rare “pure” form of DLB rather than the more common findings of mixed DLB and AD pathology.

Supportive clinical features include repeated falls, syncope, transient loss of consciousness, severe autonomic dysfunction, depression, systematized delusions, or hallucinations in other sensory and perceptual modalities. The presence of low uptake in a myocardial scintigraphy study has been included as a supportive feature in recently revised criteria for diagnosis of DLB. Although these features may support the clinical diagnosis, they lack diagnostic specificity of the core features and can be seen in other neurodegenerative disorders.

PARKINSON DISEASE DEMENTIA

The diagnosis of PDD requires a clinical diagnosis of PD accompanied by cognitive impairment of sufficient magnitude to interfere with social or occupational function and the criteria for diagnosis as outlined by the International Parkinson and Movement Disorder Society are presented in [Table 52.3](#). Criteria for diagnosis of PD-MCI have also been established ([Table 52.4](#)). It is estimated that PD-MCI occurs in up to 25% of nondemented individuals with PD and predicts a more rapid cognitive decline and shorter time to dementia.

TABLE 52.2 Diagnostic Criteria for Dementia with Lewy Bodies

Core features of DLB

- Fluctuating attention and concentration
- Recurrent well-formed visual hallucinations

- Spontaneous parkinsonism

Suggestive features of DLB

- Rapid eye movement (REM) behavior disorder
-

- Severe neuroleptic sensitivity
-

- Low dopamine transporter uptake in the basal ganglia demonstrated by ioflupane I-123 dopamine transporter SPECT imaging (DaTscan)
-

Probable DLB: dementia *plus*

- Two core features OR
- One core feature AND one suggestive feature

Possible DLB: dementia *plus*

- One core feature OR

TABLE 52.3 Criteria for Parkinson Disease Dementia

	Core Features	Associated Features	Exclusions
Probable PDD	<ul style="list-style-type: none"> • PD diagnosis • Slowly progressive dementia 	<ul style="list-style-type: none"> • Cognitive deficits in two of four domains (attention, executive function, visuospatial function, and free recall) • At least one behavioral symptom (apathy, depression/anxiety, hallucinations, delusions, or excessive daytime sleepiness) 	<ul style="list-style-type: none"> • Vascular disease on imaging or other abnormality that may cause cognitive impairment but not dementia • Unknown time interval between motor and cognitive symptoms • Acute confusion resulting from systemic diseases or abnormalities or drug

intoxication

- Features compatible with probable vascular dementia

Possible PDD

- PD diagnosis
- Slowly progressive dementia
- Atypical cognitive deficits in one or more domain (fluent aphasia or storage-failure amnesia) with preserved attention OR
- Vascular disease on imaging or other abnormality that may cause cognitive impairment, but not dementia, and/or unknown time interval between motor and cognitive symptoms
- Acute confusion resulting from systemic diseases or abnormalities or drug intoxication
- Features compatible with probable vascular dementia

PDD, Parkinson disease dementia; PD, Parkinson disease.

Data from Emre M, Aarsland D, Brown R, et al. Clinical diagnostic criteria for dementia associated with Parkinson's disease. *Movement Disorders*. 2007;22: 1689-1707.

Important clinical features of DLB and PDD are discussed in more detail in the following text.

COGNITIVE IMPAIRMENT

Early signs of cognitive impairment in patients with LBD include executive dysfunction, visuospatial impairment, and deficits in verbal memory. Executive dysfunction is a hallmark feature of LBD and includes impairment in set shifting, attention, and planning. Memory deficits in LBD are to be related to retrieval of learned information, which is improved by cuing.

TABLE 52.4 Criteria for Mild Cognitive Impairment in Parkinson Disease

	Inclusion	Exclusion

PSYCHIATRIC SYMPTOMS

Depression, anxiety, apathy, and fatigue commonly occur in LBD and are closely associated with cognitive decline. Detailed visual

P.428

hallucinations frequently occur in both conditions as well. There is often overlap between visual hallucinations and other disorders of visual perception, including misidentification syndromes and visual agnosias. Auditory, tactile, or gustatory hallucinations may also occur but are less common. Visual hallucinations and delusions occur in up to 50% of patients with PDD, and their presence is strongly associated with cognitive dysfunction. Several drugs used in the treatment of PD, including anticholinergic agents, dopaminergic agents, and amantadine can exacerbate psychotic symptoms. In nondemented PD patients, those with hallucinations are more likely to develop dementia than are patients without this symptom.

PARKINSONISM

The most common extrapyramidal findings on examination in LBD are rigidity and bradykinesia, whereas other common signs are hypophonic speech, masked facies, stooped posture, and shuffling gait. Resting tremor is less common in DLB than in PDD, especially in older individuals. In PDD, motor signs predate dementia by 10 years on average. Patients with tremor-dominant PD are less likely to develop cognitive impairment than are those with more prominent PIGD.

SLEEP DISORDERS

Sleep disorders in patients with LBD include sleep fragmentation, nightmares, and rapid eye movement behavior disorder (RBD). Recent research has shown that RBD may occur decades prior to the onset of cognitive and motor symptoms in patients with LBD. RBD is somewhat more common in DLB but occurs in 15% to 30% of patients with PD and is associated with an increased risk of future cognitive impairment or dementia.

AUTONOMIC DYSFUNCTION

Dysautonomias including orthostatic hypotension, erectile dysfunction, and constipation occur an average of 5 years prior to the onset of cognitive or motor symptoms in patients with LBD. Several studies have also shown that LBD patients have an increased prevalence of cardiac abnormalities, particularly prolonged QT syndrome, even in patients who have never complained of chest pain or other cardiovascular problems.

FLUCTUATING ATTENTION AND CONCENTRATION

Significant fluctuations in cognition are one of three core features in DLB but rarely occur in PDD. Patients may show episodic deficits in cognition that alternate with periods of normal or nearnormal performance. Excessive daytime sleepiness with confusion on awakening occurs frequently and may be accentuated by an unstimulating environment. Fluctuations may include both rapid (lasting minutes or hours) as well slower (weekly or monthly) variations in alertness. As a result, changes in mental status and behavior may be seen within a single clinical interview as well as between consecutive examinations. Caregivers are the most reliable source of information regarding the presence of fluctuations.

DIAGNOSIS

A diagnosis of DLB or PDD is based on thorough history and neurologic examination, with documentation of findings as previously described. A careful search for extrapyramidal features should be part of a general neurologic examination. The use of a standardized assessment for parkinsonian features may be particularly useful for research purposes. The Mini-Mental State Examination (MMSE) is less sensitive to the earliest cognitive changes in LBD due to its reliance on memory and language performance and its weakness in assessment of executive dysfunction. Alternative generic tests such as Dementia Rating Scale and Montreal Cognitive Assessment (MoCA) and PD-specific scales such as Parkinson Disease-Cognitive Rating Scale have shown higher sensitivity in PD and have been recommended for use in LBD. Because of the frequent comorbidity of depression in PD, screening for depression as an alternative cause or a contributor to cognitive impairment is recommended.

Medications should be carefully reviewed, and those with potential cognitive side effects, particularly anticholinergic agents, should be eliminated if possible. Laboratory workup is also advised to exclude other potentially reversible causes of symptoms including infection, metabolic derangement, vitamin B₁₂ deficiency, or thyroid disease. Ancillary evaluations may include neuropsychologic testing and neuroimaging.

NEUROPSYCHOLOGIC TESTING

To most thoroughly assess for associated cognitive changes in PDD, formal neuropsychologic testing is recommended. Comparison of neuropsychologic test profiles among patients with AD, DLB, and PDD revealed no differences between DLB and PDD. Although patients with PDD and DLB were more likely to have visuospatial and attentional deficits, AD patients were more likely to have significant impairment on memory testing, particularly memory encoding; however, there is a subset of PDD patients who have prominent verbal memory impairment as a presenting sign. The presence of prominent deficits on tests of executive function and problem solving, such as the Wisconsin Card Sorting Test (WCST), the Trail Making Test (TMT), and verbal fluency for categories and letters, may be useful clinical diagnostic indicators of LBD, as may pronounced impairment on tests of visuospatial performance such as block design, clock drawing, or figure copy tests. With the progression of dementia, the selectivity of this pattern for LBD versus AD may be lost. As a result, making an accurate differential diagnosis during the later stages of dementia using clinical presentation and neuropsychologic testing alone becomes increasingly difficult, as the cognitive deficits demonstrated in advanced LBD frequently overlap with those seen in AD. For such patients, functional neuroimaging may assist in diagnosis.

NEUROIMAGING

Magnetic Resonance Imaging

A structural imaging study, including computed tomography (CT) of the head without contrast or magnetic resonance imaging (MRI), should be obtained on patients without recent brain imaging to assess for alternative structural abnormalities that may be contributing to or causing patients' complaints, including

localized neoplasms, infections, strokes, or diffuse subcortical cerebrovascular disease. However, CT or MRI as isolated studies have limited diagnostic use. Generalized atrophy and white matter hyperintensities are nonspecific findings in dementia, and MRI may play a limited role in differentiating between types of dementia. Several studies indicate that MRI coronal sections through the hippocampi usually show a greater degree of hippocampal atrophy in AD compared with DLB. Volumetric analyses of MRI scans have also suggested atrophy of the putamen and dorsal mesopontine gray matter in

P.429

DLB compared with AD. There is insufficient evidence for use of MRI to differentiate DLB from PDD. Despite the changes in the occipital lobe on functional imaging as described in the following text, regional occipital atrophy is generally not observed on MRI in DLB or PDD.

Functional Brain Imaging

On single-photon emission computed tomography (SPECT) and positron emission tomography (PET) scans, DLB, and PDD patients show decreased perfusion and metabolism in the lateral frontal, temporoparietal, and occipital lobes, respectively. These occipital lobe findings have potential diagnostic use in distinguishing DLB from AD, with a sensitivity and specificity for SPECT of 65% and 87% and for PET of 90% and 80%. Some imaging studies find that mediotemporal glucose metabolism is decreased in DLB and AD but preserved in PDD.

Using specific ligands for the dopamine transporter, ioflupane I-123 dopamine transporter SPECT imaging (DaTscan) demonstrates reduced striatal dopaminergic activity in DLB and PDD. These findings are also seen in PD, multiple systems atrophy, and progressive supranuclear palsy but not in AD. A study in 326 patients with dementia reported a sensitivity of 78% and a specificity of 90% for DLB versus AD using DaTscan. A positive DaTscan result is considered a suggestive feature in the diagnosis of probable or possible DLB.

Amyloid Imaging

The high frequency of concomitant AD pathology in LBD has prompted investigations in amyloid imaging, although it is not commonly used in the clinical setting at the current time. Most studies demonstrate higher amyloid binding in DLB compared with PDD and in PDD compared with PD and controls. According to a recent meta-analysis, about 57%, 35%, 13%, and 21% of amyloid scans in DLB, PDD, PD, and controls, respectively, have positive amyloid imaging findings. The pattern of amyloid tracer binding in positive scans in DLB and PDD is very similar to that seen in AD, with preferential binding in the frontal lobes, posterior cingulate and precuneus, temporoparietal region, and striatum.

AUTONOMIC TESTING

Autonomic studies may be useful in distinguishing between DLB and AD. Patients with DLB may have abnormal cardiac ¹²³I-meta-iodobenzylguanidine (MIBG) uptake, vagal dysfunction, and abnormal skin reflexes on sudomotor testing.

DIFFERENTIAL DIAGNOSIS

In practice, alternative diagnostic considerations are AD (with coexisting parkinsonism or prominent psychiatric features) and vascular dementia.

Although subtle extrapyramidal signs may be present in early stages of AD, notable parkinsonism does not develop until latestage AD. Alternatively, AD may develop in a patient with PD, as the two disorders are common. This might be difficult to distinguish from PDD early on, but the early appearance of cortical dysfunction, such as aphasia or apraxia, or profound early memory loss usually suggests the presence of concomitant AD. Given that the pathologic changes of AD and DLB often occur together, it can be particularly difficult to clinically differentiate these diagnoses particularly in later stages. In these

cases, functional neuroimaging may provide some indication of underlying pathologic etiology.

Infarctions in multiple vascular territories affecting periventricular and subcortical white matter, basal ganglia, and brain stem can produce dementia and vascular parkinsonism. A history of vascular risk factors, abrupt onset of symptoms with stepwise progression over time, focal neurologic signs, and evidence of diffuse vascular disease on neuroimaging suggest this alternate diagnosis.

A broader differential diagnosis includes Parkinson-plus syndromes including corticobasal syndrome (CBS) and progressive supranuclear palsy (PSP). Alternately, cognitive and behavioral decline may be related to depression or medication effects, and delirium may be caused by metabolic or systemic disorders.

TREATMENT

The treatment of patients with LBD is clinically challenging and limited to symptomatic management. Because medications may be poorly tolerated, patient and caregiver education regarding risks, benefits, and limitations of treatment is important. Although common treatment regimens can be followed for several LBD symptoms, management of parkinsonism and psychosis varies subtly between DLB and PDD.

COGNITIVE SYMPTOMS

The first step in the treatment of cognitive decline in patients with LBD should be elimination of medications with detrimental cognitive effects, including anticholinergic medications.

The cholinesterase inhibitor rivastigmine (9.5 mg/day by transdermal patch or 6 to 12 mg/day orally) is U.S. Food and Drug Administration (FDA) approved for the symptomatic treatment of cognitive impairment in PDD [**Level 1**].² Although there are no FDA-approved treatments for DLB, the use of rivastigmine is supported by meta-analysis as well as by report of benefit in openlabel studies and two randomized, controlled trials. Rivastigmine treatment has been shown to improve neuropsychologic test performance as well as function in activities of daily living (ADLs) in LBD patients. It may also reduce psychiatric and motor symptoms, although benefits for visual hallucinations and delusions have not been demonstrated. There have been case reports of worsening cognitive function, rapid eye movement sleep disorder, or parkinsonism with cholinesterase inhibitors, so patients should be followed carefully while using these drugs. These medications also carry risk of gastrointestinal side effects including nausea, vomiting, or diarrhea, although risk appears to be minimized through transdermal delivery. If cholinesterase inhibitors are discontinued, they should be tapered as opposed to abruptly stopped in order to minimize risk of sudden cognitive and behavioral worsening.

Studies of the effects of memantine (10 mg orally twice per day) in LBD are inconsistent, but some limited trials demonstrate benefit on cognition, sleep, motor symptoms, and quality of life. However, other studies have noted that memantine may worsen delusions and hallucinations in patients with LBD.

MOTOR SYMPTOMS

Given patients' risk of falls and fluctuations in alertness, clinicians should encourage caregivers to take preventative steps to improve safety in the home environment. Physical therapy and mobility aids may help in the management of motor symptoms.

Parkinson Disease Dementia

Treatment of motor symptoms is similar in PD with and without dementia. However, patients with PDD may be particularly susceptible to the neuropsychiatric side effects of dopaminergic medications,

P.430

which may limit dosage level or require concomitant use of antipsychotic agents. Anticholinergic agents frequently worsen cognitive impairment and should be avoided in patients with PDD. Patients with PDD are generally excluded from consideration for deep brain stimulation (DBS) therapy due to poor outcome.

Dementia with Lewy Bodies

Dopaminergic therapy is less effective in treating motor symptoms in DLB than in PDD. There is open-label evidence supporting the use of carbidopa/levodopa in DLB but with a risk for worsening of psychotic symptoms. Carbidopa/levodopa may be more effective than dopamine agonists in DLB and causes fewer side effects. A suggested initial dose is one tablet of carbidopa/levodopa 25/100 mg daily, titrated upward over several weeks to one tablet three times per day as tolerated and according to clinical response.

PSYCHOSIS

Parkinson Disease Dementia

Visual hallucinations and delusions can be treated with atypical antipsychotic agents. Caution should be used with these agents because of the risk of motor side effects. Severe side effects, although not as common as in DLB, do occur in a substantial portion of patients with PDD. Doses should be started at the lowest possible and titrated upward gradually.

Among the atypical antipsychotic agents, clozapine has the best established use [**Level 1**],³ with an extremely low risk of exacerbating parkinsonism; however, it has a risk of fatal agranulocytosis and requires close monitoring of white blood cell count. Quetiapine is also effective and has a more favorable side effect profile; however, patients and caregivers must be educated about its association with increased risk of cardiac morbidity and mortality and stroke in elderly patients with dementia. Conventional antipsychotic agents are much more likely to exacerbate motor parkinsonism and should be avoided in PDD.

Dementia with Lewy Bodies

Because patients with DLB can be very sensitive to neuroleptic agents, older conventional antipsychotics should be avoided. It is estimated that almost 60% of patients with DLB may exhibit exaggerated extrapyramidal signs, sedation, immobility, or neuroleptic malignant syndrome (NMS) with fever, generalized rigidity and muscle breakdown following exposure to neuroleptics. Passive observation of visual hallucinations and delusions can be considered if these symptoms are not causing significant disruption. If a patient experiences severe, disabling psychosis, a trial of a cholinesterase inhibitor or lowering the dose of dopaminergic medications should be considered first. Randomized, placebo-controlled studies suggest that antipsychotic agents have limited efficacy in patients with DLB. If antipsychotic therapy is required, only atypical neuroleptics, in particular quetiapine or clozapine, should be used in the smallest doses possible and patients and caregivers should be warned about the possibility of severe side effects. If clinical response is not seen from one medication, it should be discontinued and another agent tried, rather than escalating the dose of the first agent.

MOOD DISORDERS

Selective serotonin reuptake inhibitors (SSRIs) may be effective in treating anxiety and depression in patients with LBD; however, more research needs to be performed on the safety of these medications in

these patient populations. Electroconvulsive therapy (ECT) has been successfully used to treat depression. Benzodiazepines should be avoided (except in RBD), especially for long-term use, because of the potential for worsening confusion, gait disorder, and paradoxical agitation. Tricyclic antidepressants should be avoided due to their anticholinergic effects.

SLEEP

Proper sleep hygiene is important in optimizing the sleep-wake cycle. Maintaining a daily routine, exposure to natural light during the daytime hours, eliminating daytime naps, and elimination of late-day caffeine consumption are important recommendations.

If RBD is present, clonazepam (0.25 to 1.5 mg orally before bed) or melatonin (3 mg orally before bed) can be used to effectively treat symptoms. Nonpharmacologic treatments may include the placement of the mattress on the floor, padding the corners of furniture, and removing potentially dangerous objects from the bedroom.

AUTONOMIC SYMPTOMS

Use of fludrocortisone (initial dosage 0.1 mg orally daily), midodrine (10 mg orally three times per day), or a combination of the two can improve symptoms of orthostatic hypotension. Nonpharmacologic treatment may include use of compression stockings and salt tablets. Stool softeners can be considered for constipation, and adult diapers can be used for urinary incontinence.

OTHER CONSIDERATIONS

In addition to symptomatic treatment, it is important to discuss management of finances and medications with patients and caregivers. Cognitive impairment and parkinsonism associated with LBD place patients at higher risk for driving impairment. A formal driving evaluation should be considered in patients with DLB who wish to continue driving.

FUTURE DIRECTIONS

No clinical trials published to date have investigated disease-modifying agents in PDD or DLB. Future clinical trial investigations in LBD may include stimulation of endogenous neurotrophic factors, reduction of α -synuclein aggregation, immune-modulating therapies, and inflammatory inhibitors.

OUTCOME

DEMENTIA WITH LEWY BODIES

There is no cure or disease-modifying therapy for DLB. Psychotic symptoms, particularly visual hallucinations, persist over time. Parkinsonism also worsens over time, especially in patients for whom this is an early symptom. Although some studies have reported that the rates of cognitive decline are similar for AD and DLB, others report a disparity. In one study, survival time in DLB was 7.7 years from onset of cognitive symptoms versus 9.3 years for patients with AD, a finding supported in another cohort. Other studies have found that patients with DLB progress to institutionalization earlier than patients with other types of dementia, perhaps due to earlier development of parkinsonism and daytime somnolence. Survival after nursing home placement is significantly impacted by the presence of depression and parkinsonism, including rigidity and gait abnormalities.

Dementia in PD is associated with reduced patient and caregiver quality of life, reduced survival, and increased risks of nursing home admission. Incident dementia in PD has been associated with a twofold increase in mortality over a 4-year time period, even after controlling for severity of motor symptoms.

Nikolaos Scarmeas

INTRODUCTION

During much of the 20th century, it was assumed that most dementia of the elderly was vascular in origin, an assumption challenged during the last few decades after the recognition and importance of Alzheimer-type pathologic changes. Nevertheless, with wider use of modern sophisticated neuroimaging techniques and accumulation of more knowledge on cerebral microinfarcts, interest in the role of vascular disease on cognitive decline reemerged and the clinical importance of vascular lesions in cognitive performance has been a new focus of attention lately.

Brain injury caused by stroke can undoubtedly contribute to dementia and intellectual impairment. Vascular dementia is a progressive cognitive dysfunction caused by stroke, often ischemic, but also hemorrhagic cerebrovascular disease as well as ischemic white matter disease or sequelae of hypotension or hypoxia.

Diagnosis of vascular dementia has been controversial, and its definition has been unsettled despite numerous attempts at clarification. Unlike other neurodegenerative dementias, there are no specific pathologic criteria. Cerebrovascular disease is itself a heterogeneous disorder, with a variety of pathophysiologic mechanisms and clinical manifestations, and correspondingly, vascular dementia manifests also as a heterogeneous syndrome. Vascular dementia can result from a variety of mechanisms ([Table 53.1](#) and [Figs. 53.1, 53.2, 53.3](#)).

TABLE 53.1 Proposed Types of Vascular Dementia Based on Localization and Pathophysiologic Mechanism

Vascular Dementia Subtype	Comments/Additional Information for Each Subtype, Including Localization, and Mechanisms
Critically located (strategic “single”) infarcts	Bilateral frontal infarctions from anterior cerebral artery occlusions Bilateral thalamic infarction from posterior cerebral artery occlusions Middle cerebral artery occlusions leading to frontal/parietal infarcts, etc.
Multiple ischemic infarcts affecting large vessels	Not necessarily in critical locations but leading to significant parenchymal volume loss
Small-vessel disease	Multiple lacunar infarcts in the basal ganglia Multiple lacunar infarcts in subcortical or periventricular white matter leading to a more widespread, patchy pattern often described as leukoariosis in brain imaging studies (<i>Binswanger disease</i>)

Hemorrhagic infarcts	Intraparenchymal hemorrhages due to chronic vascular damage from hypertension Amyloid angiopathy Intracerebral or subdural hematomas or subarachnoid hemorrhage
Hypoperfusion	Due to systemic causes such as heart failure, hypotension, bypass surgery, cardiac arrest, medications, or other systemic conditions
Other mechanisms	Combinations of the above Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), an autosomal dominant form of cerebrovascular dementia (and also migraines and psychiatric symptoms) related to mutations in the <i>notch3</i> gene on chromosome 19 Mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes (MELAS)

There are many criteria for the clinical diagnosis of “vascular dementia,” some not adequately validated, many inconsistently applied and in general lacking satisfactorily high sensitivity and specificity. In terms of terminology, the concept of “vascular cognitive impairment” has been also recently proposed; a more general term referring to “cognitive impairment that is caused by or associated with vascular factors” and includes severity stages corresponding to either dementia or mild cognitive impairment.

Overall, as a practical rule, a diagnosis of vascular dementia requires (1) clinically (symptoms/signs) and radiologically ascertained strokes (see [Figs. 53.1, 53.2, 53.3](#)), (2) dementia, and (3) a clear temporal relationship between stroke(s) and dementia.

EPIDEMIOLOGY

As many as 15% to 20% of patients with acute ischemic stroke older than age 60 years have dementia at the time of the stroke,

P.433

and 5% per year become demented thereafter. On a clinical basis, vascular dementia has been long considered as the second (after Alzheimer disease) or even the third (after Alzheimer and dementia with Lewy bodies) most frequent cause of dementia. Considering pathologic series data and related clinical-pathologic correlations makes the issue quite more complex.

FIGURE 53.1 Binswanger disease in an 85-year-old man with dementia. **A-D:** Axial fluid-attenuated inversion recovery magnetic resonance images show extensive symmetric hyperintensity involving periventricular and lobar white matter. These lesions have a rather sharp outer border and show sparing of the U-fibers. This diffuse involvement was considered more than 25% of the total white matter. There are also a lacunar right thalamic infarct (*arrow*), several bilateral hypointense lesions within the periventricular hyperintensity representing lacunar infarcts and an important global cerebral atrophy. (From Guermazi A, Miaux Y, Rovira-Cañellas A, et al. Neurological findings in vascular dementia. *Neuroradiology*. 2007;49[1]:1-22.)

Although the vast majority of elderly demented patients have Alzheimer-type pathologic changes (70% to 80%), approximately half of them have coexisting cerebrovascular infarctions too, whereas only about 30% have “pure” Alzheimer only pathology. Therefore, the majority of demented subjects have mixed Alzheimer and vascular pathologic changes. Adding to the argument of higher contribution rates of vascular dementia is the fact that most pathologic studies consider only larger infarcts, whereas microinfarcts (if time and resources permit their identification) are extremely common and diffuse in the brain. Finally, many white matter abnormalities visualized on brain magnetic resonance imaging are often undetectable by

standard neuropathologic examinations performed on autopsy, suggesting limited sensitivity of neuropathology for detection of cerebrovascular damage.

FIGURE 53.2 Amyloid angiopathy in a 66-year-old man with dementia. **A:** Axial spin-echo T2-weighted MR image shows bilateral large frontal hemorrhages surrounded by a rim of hypointensity due to hemosiderin deposition. There is also another right frontal punctate hypointense lesion (*arrows*), best seen on **B**, the axial gradient echo T2-weighted MR image. **C:** Axial gradient echo T2-weighted MR image caudal to **B** shows additional hypointensities bilaterally in the basal ganglia and the right parietal lobe (From Guermazi A, Miaux Y, Rovira-Cañellas A, et al. Neuroradiological findings in vascular dementia. *Neuroradiology*. 2007;49[1]:1-22.)

On the counterargument, the clinical salience of such microinfarcts on cognitive function has not been convincingly demonstrated. Additionally, dementia due to infarcts solely without significant pathologic contributions of the Alzheimer or Lewy body type (i.e., pure vascular dementia) is strikingly uncommon with estimated rates between 2% and 10% of dementias (not more than 5% of dementias in the United States).

FIGURE 53.3 CADASIL in a 57-year-old man with cognitive impairment. **A:** Axial spin-echo T2-weighted MR images show an extensive white matter abnormalities with characteristic symmetric involvement of the anterior part of the temporal lobes and **(B)** external and extreme capsules without involvement of the internal capsules. They also show **(C)** extensive white matter changes in the centrum ovale, extending toward the cortex in some places. There are also two small lacunar infarcts in the right basal ganglia (*arrowheads*). (From Guermazi A, Miaux Y, Rovira-Cañellas A, et al. Neuroradiological findings in vascular dementia. *Neuroradiology*.

PATHOBIOLOGY: CAUSES OF VASCULAR DEMENTIA

Overall, strokes themselves and factors that predispose to cerebrovascular disease are considered risk factors for vascular dementia.

P.435

Predisposing conditions for cerebral infarcts are numerous and should be included in patients' workups. Patients with vascular dementia are usually old and may suffer from cardiovascular disease, including heart attacks, cardiac arrhythmias, congestive heart failure, or from diabetes, hypertension, dyslipidemia, with eventual damage in many organs. Beyond genetic susceptibility to strokes, rare genetic causes of vascular dementia include cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy and mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes.

Whether Alzheimer-type pathologic changes induce cerebrovascular damage or whether brain infarcts promote Alzheimer neuropathology is not settled. Overall, there is a complex interaction between stroke, vascular risk factors, and Alzheimer disease, although the exact nature of this interaction remains unknown.

CLINICAL MANIFESTATIONS

The symptoms and signs of vascular dementia may include impairment in acquiring and remembering new information, impaired reasoning, judgment and handling of complex tasks, deficits in visual spatial abilities, problems with language function (comprehension, expression, etc.), and changes in personality or behavior. The exact mix of the aforementioned in each case depends on cerebral localization of infarcts. If for example, the temporal lobe neural circuits responsible for memory functions are less affected, amnesic deficits, a key feature in Alzheimer disease, may be less prominent in vascular dementia. Focal noncognitive deficits related to vascular dementia causing strokes may also coexist.

A more "cortical" version with more clear stepwise deterioration including focal motor or sensory symptoms and signs, aphasia, neglect, abulia, apraxia, agnosia, amnesia, etc. resulting from repeated distinct strokes may be present. However, vascular dementia often presents as a more "subcortical" syndrome that is characterized by apathy, inertia, bradyphrenia, deficits in attention and concentration, executive dysfunction (problems with organization, planning, and strategy), often abnormal gait (which may mimic apraxic or magnetic or that of lower body parkinsonism), urinary urgency or incontinence, depression as well as emotional incontinence ("pseudobulbar affect"), including inappropriate crying or laughing.

In general, in the differential diagnosis from Alzheimer disease, features that would favor the diagnosis of vascular dementia would include (to a certain extent temporally and clinically relating to cerebral infarcts) an abrupt onset of dementia, a stepwise deterioration and a fluctuating course.

DIAGNOSIS

There are no diagnostic tests specific for vascular dementia.

Clinical presence of stroke documented by either history (symptoms) or neurologic examination (residual signs), although not entirely required, enhances specificity of vascular dementia diagnosis.

Presence of infarcts in brain imaging studies is a requirement. Their nature (hemorrhagic, ischemic), size (small, large), number (one strategic, many), or location (cortical, subcortical, different brain structures) can widely vary. Widespread, confluent white matter disease often called *leukoaraiosis* can be noted.

Evaluation to define a specific stroke subtype and etiology should be definitely included.

Deficits may be detected in neuropsychological evaluation, but their nature is also nonspecific because they

depend on stroke localization that may vary from patient to patient. However, deficits in frontal function, including difficulties with attention-concentration, slow speed of processing, difficulties with initiation, and executive dysfunction may be prominent. Particularly in subcortical forms of vascular dementia, amnesic deficits may be characterized by difficulties in free recall with relative improvement in recognition (i.e., when aided with various strategy cues).

TREATMENT

Because stroke is the cause of vascular dementia, primary prevention of stroke may reduce vascular dementia rates and treatment of already existing stroke—secondary preventions of stroke recurrence are central to vascular dementia course and prognosis. For example, smoking cessation, control-treatment of hypertension, diabetes, dyslipidemia, obesity, etc. are indicative preventive strategies. Similarly, antiplatelets, anticoagulants, and carotid endarterectomy (whenever indicated according to specific stroke characteristics) are examples of stroke recurrence prevention approaches. Stroke treatment and stroke preventative strategies are discussed in more detail in Chapters 35 and 44.

The efficacy of cholinesterase inhibitors and memantine, proven therapies for dementia of the Alzheimer type, is not that extensively studied in vascular dementia. In general, efficacy of all these medications — medication classes has been demonstrated in mixed (Alzheimer and vascular) dementia and not in pure vascular dementia [Level 1].^{1,2,3,4,5,6,7} Given that such mixed dementia is quite common and that it is clinically often hard to exclude coexisting Alzheimer pathologic changes in many patients diagnosed with vascular dementia, it stands to reason to offer cholinesterase inhibitors and memantine therapy to such patients. Initiation with one of the three cholinesterase inhibitors subsequently followed by addition of memantine is the common practice. The doses commonly prescribed and corresponding titration schedules toward the maximum dose (occurring during the course of weeks/months depending on the particular medication) are those used for Alzheimer dementia, the main official indication for such treatments (Table 53.2).

OUTCOME

Prognosis in vascular dementia is more variable than that of Alzheimer disease because it is largely dependent on coexisting strokes. If, particularly with modification of cerebrovascular disease

P.436

risk factors, none or only a limited number of future strokes occur, the cognitive deficits can remain relatively static for protracted periods or until death. For other vascular dementia patients who continue to suffer from additional cerebral infarcts, a progressive cognitive decline and dementia deterioration is usually noted.

TABLE 53.2 Medications Commonly Prescribed for Vascular Dementia

Medication - Active Substance	Route	Targeted Maximum Daily Dose	Frequency of Administration
Donepezil	Oral	10 mg	Once a day
Rivastigmine	Oral	12 mg	6 mg twice a day

Rivastigmine	Transdermal	13.3 mg	Once a day
Galantamine	Oral	24 mg	Once a day
Memantine	Oral	20 mg	10 mg twice a day
Memantine	Oral	28 mg	Once a day

Primary and Secondary Headache Syndromes

Peter J. Goadsby

Denise E. Chou

ANATOMY AND PHYSIOLOGY OF HEADACHE

Headache is one of the most common symptoms evaluated by neurologists and bears a vast differential diagnosis. The successful management of both primary and secondary headache disorders requires an understanding of the relevant neuroanatomy and underlying physiology.

Pain typically occurs when peripheral nociceptors are stimulated in response to factors such as tissue injury or visceral distension. In this setting, pain perception is a normal physiologic response mediated by a healthy nervous system. However, pain can also occur from damage or inappropriate activation of pain-producing pathways of the peripheral or central nervous system. Headache may result from either or both of these mechanisms. There are relatively few pain-generating cranial structures, which include the scalp, falx cerebri, dural sinuses, and proximal segments of the large pial arteries. The majority of the brain parenchyma, ventricular ependyma, choroid plexus, and pial veins are not thought to be capable of producing pain.

The key structures involved in primary headache appear to be the following:

- the large intracranial vessels, dura mater, and the peripheral terminals of the trigeminal nerve that innervate these structures
- the caudal portion of the trigeminal nucleus, which extends into the dorsal horns of the upper cervical spinal cord and receives input from the first and second cervical nerve roots (the trigeminocervical complex)
- rostral pain-processing regions, such as the ventroposteromedial thalamus and the cortex
- pain modulatory systems in the brain that modulate input from trigeminal nociceptors at all levels of the pain-processing pathways and influence vegetative functions, such as hypothalamus and brain stem structures

The innervation of the large intracranial vessels and dura mater by the trigeminal nerve is referred to as the *trigeminovascular system*. Cranial autonomic symptoms, such as *lacrimation, conjunctival injection, nasal congestion, rhinorrhea, periorbital swelling, aural fullness, and ptosis*, are prominent in the trigeminal autonomic cephalalgias (TACs) and may also be seen in migraine. Such autonomic symptoms result from activation of cranial parasympathetic pathways; functional imaging studies also suggest that vascular changes in migraine and cluster headache, when present, are similarly driven by these cranial autonomic systems. These symptoms can often be mistaken for signs of sinus inflammation, frequently resulting in inappropriate management.

Migraine and other primary headache syndromes are not primarily “vascular headaches” as was once thought; these disorders do not reliably demonstrate vascular changes, and treatment outcomes cannot be predicted by vascular effects. Migraine is fundamentally a brain disorder and should be understood and treated as such.

CLINICAL EVALUATION OF HEADACHE DISORDERS

The differential diagnosis of a new, severe headache is quite different from a chronic, recurrent headache. There is a greater likelihood of finding a potentially serious cause with new-onset and severe headache than with recurrent headache over years. Lifethreatening headache is relatively uncommon, but vigilance is required in order to recognize and appropriately treat such patients. Serious causes to be considered include meningitis, subarachnoid hemorrhage, epidural or subdural hematoma, glaucoma, tumor, and purulent sinusitis. The

approach to the patient presenting with severe, new-onset headache is also discussed in Chapter 7.

A classification system for headache disorders has been established by the International Headache Society (IHS)—the International Classification of Headache Disorders, now in its third edition. The most recent version divides headache disorders into *primary syndromes* (in which the headache and associated features constitute the disorder itself) and *secondary disorders* (in which the headache results from exogenous causes).

SECONDARY HEADACHE

Concerning underlying conditions that are associated with headache are described in the following text and detailed further in Chapter 7; however, it should be noted that the vast majority of patients presenting with severe headache have a benign cause. The management of secondary headache focuses on diagnosis and treatment of the underlying cause.

- **Meningitis:** Acute, severe headache with fever and stiff neck suggests meningitis (see [Chapter 61](#)). Often, there is significant worsening of pain with eye movement. Lumbar puncture is necessary for diagnosis. Meningitis can be easily mistaken for migraine in that the cardinal symptoms of pounding headache, photophobia, nausea, and vomiting are frequently present, perhaps reflecting the underlying physiology in some of these cases.
 - **Subarachnoid hemorrhage:** Acute, severe headache with stiff neck but without fever suggests subarachnoid hemorrhage (see [Chapter 39](#)). A ruptured aneurysm, arteriovenous malformation, or intraparenchymal hemorrhage may also present with headache alone. In rare cases (particularly if the hemorrhage is small or below the foramen magnum), head computed tomography (CT) can be normal. Thus, lumbar puncture may be required for definitive diagnosis of a subarachnoid hemorrhage.
-
- P.438
- **Brain tumor:** Brain tumor is a rare cause of headache and even less commonly a cause of severe pain. The head pain is generally nondescript—an intermittent deep, dull ache of moderate intensity, which may worsen with exertion or change in position and may be associated with nausea and vomiting. Such symptoms are caused by migraine far more often than from brain tumor. The headache of brain tumor awakens patients from sleep in about 10% of cases. Vomiting that precedes the development of headache by weeks is highly characteristic of posterior fossa brain tumors. Head pain triggered by Valsalva maneuvers such as bending, lifting, or coughing can be due to a posterior fossa mass. De novo headache in a patient with known malignancy may suggest cerebral metastases and/or carcinomatous meningitis.
 - **Temporal arteritis:** Temporal (giant cell) arteritis is an inflammatory disorder of arteries that frequently involves the extracranial carotid circulation. The average age of onset is 70 years, and women account for 65% of cases. About half of patients with untreated temporal arteritis develop blindness due to involvement of the ophthalmic artery and its branches. Because treatment with glucocorticoids is effective in preventing this complication, prompt recognition of the disorder is important. Headache is the dominant symptom and often appears in association with malaise and myalgias. Head pain may be unilateral or bilateral and is located temporally in 50% of patients but may involve any and all aspects of the cranium. The quality is almost always described as dull and boring, with superimposed episodic stabbing pains and exquisite scalp tenderness. Patients often describe a superficial origin of their headache (external to the skull, rather than originating deep within the head as in migraine). Headache is usually worse at night and often aggravated by exposure to cold. Additional findings may include reddened, tender nodules or red streaking of the skin overlying the temporal arteries and tenderness of the temporal or, less commonly, the occipital arteries. The management of temporal arteritis is further discussed in Chapters 7 and 42.
 - **Glaucoma:** Glaucoma may present with a prostrating headache associated with nausea and vomiting. The

headache often starts with severe eye pain. On physical examination, the eye is often red with a fixed, moderately dilated pupil.

PRIMARY HEADACHE SYNDROMES

Primary headache syndromes are disorders in which the headache and associated features occur in the absence of exogenous etiologies. The most common are migraine, tension-type headache, and the TACs, notably cluster headache; the complete list is in [Table 54.1](#).

MIGRAINE

EPIDEMIOLOGY

Migraine is the second most common cause of headache and ranks among the top 20 causes of disability worldwide by the World Health Organization. It afflicts approximately 12% of the population annually (15% of women and 6% of men over a 1-year period). Migraine is a recurring syndrome of head pain along with symptoms of neurologic dysfunction, such as sensitivity to sensory stimuli (light, sound, smell, or movement); nausea and vomiting often accompany the headache.

The migraine brain is particularly sensitive to environmental and sensory stimuli; migraine-prone patients do not habituate easily to sensory input. Headache can be initiated or amplified by various triggers, including bright lights, sounds, smells, or other afferent stimulation; hunger; stress or the let down from stress; physical exertion; stormy weather, altitude, or barometric pressure changes; hormonal fluctuations during menses; lack of or excess sleep; and alcohol or other chemicals, such as nitrates. Identifying a patient's susceptibility to specific triggers can be useful in advising lifestyle adjustments as part of the treatment plan.

PATHOPHYSIOLOGY

The sensory sensitivity that is characteristic of migraine is probably due to dysfunction of monoaminergic sensory control systems located in the brain stem and diencephalon. Activation of cells in the trigeminal nucleus results in the release of vasoactive neuropeptides, particularly calcitonin gene-related peptide (CGRP), at vascular terminations of the trigeminal nerve and within the trigeminal nucleus. Centrally, second-order trigeminal neurons cross the midline and project to ventrobasal and posterior nuclei of the thalamus for further processing. There are additional projections to the periaqueductal gray and hypothalamus, from which reciprocal descending systems have established antinociceptive effects. Other brain stem regions likely to be involved in descending modulation of trigeminal pain include the nucleus locus coeruleus in the pons and the rostroventromedial medulla.

Pharmacologic and other data implicate the involvement of the neurotransmitter 5-hydroxytryptamine (5-HT or serotonin) in migraine. The *triptans* were designed to selectively stimulate subpopulations of 5-HT receptors; at least 14 different 5-HT receptors have been identified in humans. The triptans are potent agonists of 5-HT_{1B} and 5-HT_{1D} receptors, and some are active at the 5-HT_{1F} receptors (agonists of the latter are called *ditans*). Triptans arrest nerve signaling in the nociceptive pathways of the trigeminovascular system, at least in the trigeminal nucleus caudalis and trigeminal sensory thalamus, in addition to cranial vasoconstriction. *Ditans*, recently shown to be effective in acute migraine, act only at neuronal targets. An interesting range of neural targets is now being actively pursued for the acute and preventive management of migraine.

Data also support a role for dopamine in the pathophysiology of migraine. The majority of migraine symptoms can be induced by dopaminergic stimulation. Moreover, there is dopamine receptor hypersensitivity in migraineurs, as demonstrated by the induction of yawning, nausea, vomiting, hypotension, and other symptoms of a migraine attack by dopaminergic agonists at doses that do not affect

nonmigraineurs. Dopamine receptor antagonists are effective therapeutic agents in migraine, especially when given parenterally or concurrently with other antimigraine agents. Moreover, hypothalamic activation, anterior to that seen in cluster headache, has now been shown in the premonitory phase of migraine using functional imaging and this may hold a key to understanding some part of the role of dopamine in the disorder.

Migraine genes have been identified by studying families with familial hemiplegic migraine (FHM) and reveal involvement of ion channels, suggesting that alterations in membrane excitability can predispose to migraine. Mutations involving the $Ca_v2.1$ (P/Q)-type voltage-gated calcium channel *CACNA1A* gene are now known to cause FHM-1; this mutation is responsible for about 50% of cases of FHM. Mutations in the Na^+-K^+ ATPase *ATP1A2* gene, designated FHM-2, are responsible for about 20% of FHM.

P.439

Mutations in the neuronal voltage-gated sodium channel *SCN1A* cause FHM-3.

DIAGNOSIS AND CLINICAL FEATURES

Diagnostic criteria for migraine headache are summarized in [Table 54.2](#). Migraine has several forms that have been defined: migraine with and without aura, episodic migraine, and chronic migraine (see [Table 54.1](#)). The migraine aura, such as the visual disturbances with flashing lights or zigzag lines moving across the visual field or other neurologic symptoms, is reported in only 20% to 25% of patients. Patients with episodes of migraine that occur on 15 or more days per month are considered to have chronic migraine. Most patients with disabling headache likely have migraine, as opposed to tension-type headache, which is the most common primary headache disorder (discussed later in this chapter).

Patients with acephalgic migraine (typical aura without headache, 1.2.1.2) experience recurrent neurologic symptoms, frequently with nausea or vomiting, but with little or no headache. Vertigo can be prominent; it has been estimated that one-third of

P.440

patients referred for vertigo or dizziness have a primary diagnosis of migraine. Migraine aura can have prominent brain stem symptoms (such as diplopia, ataxia, altered consciousness, dysarthria, tinnitus, and vertigo) and the terms *basilar artery* and *basilar-type migraine* have now been replaced by *migraine with brain stem aura* (see [Table 54.1](#)).

TREATMENT OF MIGRAINE

Once a diagnosis of migraine has been established, it is important to assess the extent of a patient's disease and

level of functional impairment. The Migraine Disability Assessment Score (MIDAS) is a well-validated, easy-to-use tool. A headache diary also helps assess disability as well as the frequency of abortive medication use. Patient education is an important aspect of migraine management. It is useful for patients to understand that migraine is an inherited vulnerability for head pain and associated neurologic symptoms and that although the disorder cannot be “cured,” migraine can be modified and managed by lifestyle adjustments and medications. Furthermore, patients should be reassured that migraine is generally not associated with serious or life-threatening illnesses.

Nonpharmacologic Management

Migraine can often be managed at least in part by a variety of nonpharmacologic approaches. Many benefit by identifying and avoiding specific headache triggers. A regulated lifestyle is important, including a healthy diet (with a regular eating schedule), exercise, routinized sleep patterns, avoidance of excess caffeine and alcohol, and minimizing acute changes in stress levels (such as through biofeedback, meditation, or yoga). Lifestyle modifications that are effective in reducing headache frequency should be maintained on a routine basis, as these provide a simple, cost-effective approach to migraine management. If these measures fail to prevent an attack, abortive pharmacologic measures are then needed.

Pharmacologic Treatment

ABORTIVE (ACUTE ATTACK) THERAPIES

Table 54.3 summarizes the commonly used medications for acute migraine, which include the nonsteroidal anti-inflammatory drugs (NSAIDs), 5-HT_{1B/1D} receptor agonists, and dopamine receptor antagonists [**Level 1**]. [1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16](#) Selecting the optimal regimen for an individual patient depends on several factors, the most important of which is the severity of the attack. Mild migraine attacks can usually be managed by oral agents, with an average efficacy rate of 50% to 70%. Severe migraine attacks may require intranasal or parenteral treatments for faster onset. In general, an adequate dose of the selected medication should be used as soon as possible after the onset of an attack. If additional medication is required within 1 hour due to persistence or recurrence of symptoms, the initial dose should be increased or a different class of rescue therapy should be taken. Migraine therapy must be individualized; a standardized approach for all patients is not feasible. Furthermore, a treatment regimen may need to be frequently revised until a successful plan is reached that provides rapid, complete, and consistent relief with minimal side effects (Table 54.4).

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

NSAIDs can significantly reduce the severity and duration of a migraine attack and are most effective when taken early in the attack. However, these agents alone may not completely abort a moderate or severe migraine attack. The combination of aspirin and metoclopramide has been shown to be comparable to a single dose of oral sumatriptan. Important side effects of NSAIDs include dyspepsia and gastrointestinal irritation, as well as potential cardiovascular and renal effects (particularly with frequent or long-term use).

5-HYDROXYTRYPTAMINE_{1B/1D} RECEPTOR AGONISTS (TRIPTANS)

Stimulation of 5-HT_{1B/1D} receptors can abort an acute migraine attack. Ergotamine and dihydroergotamine are nonselective receptor agonists, whereas the triptans are selective 5-HT_{1B/1D} receptor agonists. A variety of triptans, 5-HT_{1B/1D} receptor agonists—sumatriptan, almotriptan, eletriptan, frovatriptan,

naratriptan, rizatriptan, and zolmitriptan—are now available for the acute treatment of migraine. Each drug in the triptan class has similar pharmacologic properties but varies slightly in terms of clinical efficacy. Rizatriptan and eletriptan are the most likely to be efficacious. Sumatriptan and zolmitriptan have similar rates of efficacy as well as time to onset, with an advantage of having different routes of administration. Almotriptan has a similar rate of efficacy to sumatriptan but is better tolerated, whereas frovatriptan and naratriptan are somewhat slower in onset yet have milder side effect profiles. Clinical efficacy appears to be related more to the t_{max} (time to peak plasma level) than to the potency, half-life, or bioavailability. This observation is consistent with various studies indicating that faster acting analgesics are more effective than slower acting agents.

Unfortunately, monotherapy with oral triptan therapy does not yield rapid, consistent, and complete relief of migraine in all patients. Triptans may not be effective in migraine with aura unless taken after completion of the aura and initiation of the headache; recurrence of headache is another limitation of triptan use. Evidence from randomized controlled trials demonstrates that coadministration of a longer acting NSAID (such as naproxen 500 mg) with sumatriptan will augment the initial effect of sumatriptan and, importantly, reduce rates of headache recurrence. Side effects of triptans include nausea, chest tightness, dizziness, asthenia, and flushing. 5-HT_{1B/1D} agonists are contraindicated in individuals with a history of cardiovascular or cerebrovascular disease.

Nasal formulations of dihydroergotamine (Migranal), zolmitriptan (Zomig nasal), or sumatriptan can be useful in patients

P.441

requiring a nonoral route of administration (e.g., due to nausea/vomiting). Intranasal administration can result in substantial blood levels within 30 to 60 minutes. Although nasal sprays in theory might provide faster and more effective relief than oral formulations, their reported efficacy is only 50% to 60%. Studies with a new inhalational formulation of dihydroergotamine indicate that its absorption problems can be overcome to produce rapid onset of action with good tolerability.

TABLE 54.3 Acute Treatment of Migraine Attacks

Drug	Trade Name	Dosage
NSAIDs		
Naproxen ^a	Aleve, Anaprox, generic	220-550 mg PO b.i.d.
Ibuprofen ^a	Advil, Motrin, Nuprin, generic	400-800 mg PO q6-8h
Acetylsalicylic acid ^a	Aspirin, generic	500-1,000 mg PO b.i.d.
Tolfenamic acid	Clotam	200 mg PO; may

	Rapid	repeat × 1 after 1-2 h
Diclofenac potassium ^a	Cambia, generic	50 mg PO with water
Compound Analgesics		
Acetaminophen, aspirin, caffeine ^a	Excedrin Migraine	Two tablets or caplets q6h (max 8 per day)
5-HT ₁ B/1D Agonists		
<i>Oral</i>		
Naratriptan ^a	Amerge, generic	2.5-mg tablet at onset; may repeat once after 4 h
Rizatriptan ^a	Maxalt, generic Maxalt-MLT	5-10-mg tablet at onset; may repeat after 2 h (max 30 mg/day)
Sumatriptan ^a	Imitrex, generic	50-100-mg tablet at onset; may repeat after 2 h (max 200 mg/day)
Frovatriptan ^a	Frova	2.5-mg tablet at onset, may repeat after 2 h (max 5 mg/day)
Almotriptan ^a	Axert	6.25-12.5-mg tablet at onset, may repeat after 2 h (max 25 mg/day)
Eletriptan ^a	Relpax	20-40-mg mg tablet at onset (max 80 mg/day)

Zolmitriptan ^a	Zomig, generic Zomig Rapimelt	2.5-5-mg tablet at onset; may repeat after 2 h (max 10 mg/day)
<i>Nasal</i>		
Dihydroergotamine ^a	Migranal Nasal Spray	Prior to nasal spray, the pump must be primed four times; 1 spray (0.5 mg) is administered, followed in 15 min by a second spray
Sumatriptan ^a	Imitrex Nasal Spray	5-20-mg intranasal spray as four sprays of 5 mg or a single 20-mg spray (may repeat once after 2 h, not to exceed a dose of 40 mg/day)
Zolmitriptan ^a	Zomig	2.5-5 mg intranasal spray as one spray (may repeat once after 2 h, not to exceed a dose of 10 mg/day)
<i>Parenteral</i>		
Dihydroergotamine ^a	DHE-45	1 mg IV, IM, or SC at onset and q1h (max 3 mg/day, 6 mg/week)
Sumatriptan ^a	Imitrex injection, generic	6 mg SC at onset (may repeat once)

Alsuma Sumavel DosePro	after 1 h for max of two doses in 24 h)
------------------------------	---

Dopamine Receptor Antagonists

Oral

Metoclopramide	Reglan, ^b generic ^b	5-10 mg/day
----------------	--	-------------

Prochlorperazine	Compazine, ^b generic ^b	1-25 mg/day
------------------	---	-------------

Promethazine	Phenergan, ^b generic ^b	25-50 mg/day
--------------	---	--------------

Chlorpromazine	Thorazine, ^b generic ^b	25-50 mg/day
----------------	---	--------------

Parenteral

Metoclopramide ^a	Reglan, ^b generic	10 mg IV
-----------------------------	---------------------------------	----------

Prochlorperazine ^a	Compazine, ^b generic ^b	10 mg IV
-------------------------------	---	----------

Chlorpromazine ^a	Thorazine, ^b generic ^b	12.5-25 mg IM or IV (0.1 mg/kg IV at 2 mg/min)
-----------------------------	---	--

Promethazine	Phenergan, ^b generic ^b	12.5-25 mg IM or IV (slow)
--------------	---	-------------------------------

Antiemetics (e.g., domperidone 10 mg or ondansetron 4 or 8 mg) or prokinetics (e.g., metoclopramide 10 mg) are sometimes useful adjuncts.

^aSupported by level 1 evidence. ^bNot all drugs are specifically indicated by the FDA for migraine. Local regulations and guidelines should be consulted. NSAIDs, nonsteroidal anti-inflammatory drugs; PO, by mouth; 5-HT, 5-hydroxytryptamine; IV, intravenous; IM, intramuscular; SC, subcutaneous.

TABLE 54.4 Clinical Stratification of Acute Specific Migraine Treatments

Clinical Situation	Treatment Options
Failed NSAIDs/analgesics	First tier Sumatriptan 50-100 mg PO Almotriptan 12.5 mg PO Rizatriptan 10 mg PO Eletriptan 40 mg PO Zolmitriptan 5 mg PO Slower effect/better tolerability Naratriptan 2.5 mg PO Frovatriptan 2.5 mg PO
Early nausea or difficulty taking tablets	Zolmitriptan 5 mg nasal spray Sumatriptan 20 mg nasal spray Rizatriptan 10 mg MLT wafer Zolmitriptan 5 mg ZMT Rapimelt
Early vomiting	Zolmitriptan 5 mg nasal spray Sumatriptan 6 mg SC
Headache recurrence	Naratriptan 2.5 mg PO Almotriptan 12.5 mg PO Eletriptan 40 mg PO
Tolerating acute treatments poorly due to side effects	Naratriptan 2.5 mg PO Almotriptan 12.5 mg PO
Menstrual-associated headache	Frovatriptan 2.5 mg with Naprosyn 500 mg around menses
Rapidly developing symptoms	Zolmitriptan 5 mg nasal spray Sumatriptan 6 mg SC Dihydroergotamine 1 mg IM

NSAIDs, nonsteroidal anti-inflammatory drugs; PO, by mouth; SC, subcutaneous; IM, intramuscular.

Sumatriptan and dihydroergotamine are also available in injection formulations. Sumatriptan 4 to 6 mg subcutaneously (SC) is effective in approximately 50% to 80% of patients. Peak plasma levels of dihydroergotamine are achieved 3 minutes after intravenous (IV) dosing, 30 minutes after intramuscular (IM) dosing, and 45 minutes after SC dosing. If an attack has not already reached peak, SC or IM administration

of 1-mg dihydroergotamine can be effective in about 80% to 90% of patients.

DOPAMINE RECEPTOR ANTAGONISTS

Oral or parenteral dopamine receptor antagonists can be considered as adjunctive acute migraine treatments. Drug absorption is impaired during migraine due to reduced gastrointestinal motility (even in the absence of nausea) and is related to the severity of the attack, rather than duration. Therefore, when oral NSAIDs and/or triptans fail, the addition of a dopamine receptor antagonist (such as metoclopramide 10 mg) should be considered to enhance gastric absorption, as well as to decrease nausea/vomiting. Certain phenothiazine drugs (such as promethazine, prochlorperazine, or chlorpromazine) can also independently improve headache pain, particularly when given parenterally, although may be sedating due to their antihistamine properties.

OTHER MEDICATIONS FOR ACUTE MIGRAINE

Opioids are modestly effective in the acute treatment of migraine and are commonly administered in the emergency room. Such agents can “help” in the sense that the pain of migraine is eliminated or reduced. However, this regimen is suboptimal for patients with recurrent headache. Opioids do not treat the underlying headache pathophysiology; rather, they act to alter the sensation of pain, and there is evidence that they can render other migraine medications (such as triptans) less effective. Moreover, frequent opioid use can result in medication overuse headache and result in physical dependence or addiction; opioid craving and/or withdrawal can in turn worsen migraine. Therefore, it is recommended that opioid use in migraine be restricted to patients with severe, but infrequent, headaches that are unresponsive to other pharmacologic approaches or who have contraindications to other treatments.

Butalbital-containing compounds (such as Fioricet or Fiorinal) are also frequently given for acute migraine treatment. Although these medications may provide analgesic relief, there is a high potential for dependence and the development of medication overuse headache (also known as *rebound headache*), which is a state of refractory daily or near-daily headache. This condition is likely not a separate headache entity but a reaction of the migraine patient to a particular medicine. Butalbital-containing medications have been banned in some countries and although still available in the United States, should be avoided.

PREVENTIVE TREATMENTS FOR MIGRAINE

Patients who experience an increasing frequency of migraine attacks or attacks that are poorly responsive to abortive medications, warrant preventive therapy. In general, a preventive medication should be considered for patients with four or more attacks a month; however, the decision of when to start a preventive agent may also depend on the severity and duration of attacks. Many of these medications have significant side effects, and the therapeutic dose can vary significantly among individual patients. The mechanism of action of these drugs is not entirely known; it is likely that they modify the brain sensitivity that underlies migraine. Patients are usually started on a low dose of the selected medication; the dose is then gradually titrated up to a reasonable maximum to achieve clinical response. A preventive medication must be taken daily, and there is usually a lag of at least 2 to 12 weeks before benefit may be seen.

Commonly used medications for the prevention of migraine are listed in [Table 54.5](#) [**Level 1**]. [17,18,19,20,21,22,23,24,25,26,27,28,29,30,31,32,33,34,35,36,37,38,39](#) The drugs that have been approved by the U.S. Food and Drug Administration (FDA) for the prophylactic treatment of migraine include propranolol, timolol, sodium valproate, topiramate, and methysergide (not available in the United States). In addition, a number of other drugs appear to display prophylactic efficacy. This includes amitriptyline, nortriptyline, candesartan, flunarizine, phenelzine, gabapentin, and cyproheptadine. Onabotulinum toxin type A has been shown

to be effective in placebo-controlled studies for the prevention of chronic migraine but not of episodic migraine. The probability of success with any one of these medications is approximately 50% to 75%. Once effective stabilization is achieved, the drug is continued for approximately 6 to 12 months and then slowly tapered to assess whether continuation is needed. Many patients are able to wean off prophylactic medications successfully, with fewer and milder attacks for long periods, suggesting that these drugs may alter the natural history of migraine.

TABLE 54.5 Preventive Treatments in Migraine^a

Drug	Dose	Selected Side Effects
β-Blockers		Fatigue, postural symptoms, bradycardia, depression, nightmares
Propranolol ^b	40-120 mg b.i.d.	Caution in patients with asthma
Metoprolol ^b	25-100 mg b.i.d.	—
Timolol ^b	5-10 mg b.i.d.	—
Atenolol	25-100 mg q.d.	—
Nadolol	40-240 mg divided b.i.d. or t.i.d.	—
Anticonvulsants		
Topiramate ^b	25-200 mg/day	Paresthesias, cognitive impairment, weight loss, nausea, fatigue, glaucoma, and metabolic acidosis; caution with nephrolithiasis
Valproate ^b	400-600 mg b.i.d.	Drowsiness, weight gain, hair loss, tremor, hematologic or liver abnormalities, fetal abnormalities
Gabapentin	900-3,600 mg q.d.	Dizziness, sedation, weight gain
Antidepressants		
Amitriptyline	10-100 mg at night	Drowsiness, dry mouth, constipation, blurred vision, postural hypotension, weight gain
Nortriptyline	10-100 mg at night	Note: Some patients may only need a total dose of 10 mg, although generally, 1-1.5 mg/kg body weight is

required.

Doxepin	10-75 mg at night	Sedation, dry mouth, weight gain
Venlafaxine ^b	75-150 mg q.d.	Nausea, insomnia, dizziness, fatigue, nervousness
Serotonergic drugs		
Methysergide ^c	1-4 mg q.d.	Drowsiness, leg cramps, hair loss, retroperitoneal fibrosis (1-month drug holiday is required every 6 mo)
Other Classes		
Flunarizine ^c (calcium channel blocker)	5-15 mg q.d.	Drowsiness, weight gain, depression, parkinsonism
Candesartan (ARB inhibitor)	16 mg q.d.	Dizziness, hypotension
Pizotifen ^c	0.5-2 mg q.d.	Weight gain, drowsiness
Onabotulinum toxin type A ^b (Botox)	155 units divided in 31 sites (PREEMPT protocol)	Loss of brow furrow, ptosis, pain at injection sites, neck stiffness
Complementary Agents		
Petasites (butterbur) ^b	75 mg b.i.d.	Stomach upset
Riboflavin (vitamin B2)	400 mg q.d.	Urine discoloration
Magnesium	500-600 mg q.d.	Increased bowel motility
Feverfew (MIG-99)	6.25 mg t.i.d.	Stomach upset, nausea

^aCommonly used preventives are listed with typical doses and common side effects. Not all listed medicines are approved by the FDA; local regulations and guidelines should be consulted. ^bSupported by level 1 evidence. ^cNot available in the United States.

ARB, angiotensin II receptor blocker; PREEMPT, Phase III Research Evaluating Migraine Prophylaxis Therapy protocol.

TENSION-TYPE HEADACHE

CLINICAL FEATURES

Tension-type headache (TTH) is the most common primary headache disorder, although patients rarely present to the clinic due to the low level of associated disability. TTH is characterized by bilateral tight, bandlike head discomfort of mild to moderate severity. The pain usually progresses slowly, fluctuates in severity, and may

P.444

persist more or less continuously for many days. The headache may be episodic or chronic (present on 15 or more days per month). Unlike migraine, TTH is otherwise featureless and lacks accompanying features such as nausea, vomiting, photophobia, phonophobia, osmophobia, throbbing, and aggravation with movement.

PATHOPHYSIOLOGY

The pathophysiology of TTH is incompletely understood. It seems likely that TTH is due to a primary disorder of central nervous system pain modulation alone, unlike migraine, which involves a more generalized disturbance of sensory modulation. Data suggest a genetic contribution to TTH, although this may not be a valid finding, as these studies likely included many migraine patients. The name *tension-type headache* implies that pain is a product of *nervous tension*; however, there is no clear evidence for tension as an etiology. Muscle contraction has been considered to be a feature that distinguishes TTH from migraine, but there appear to be no differences in contraction between the two headache types.

TREATMENT

The pain of TTH usually responds to simple analgesics such as acetaminophen, aspirin, or other NSAIDs. Behavioral approaches including relaxation can also be effective. Clinical studies have demonstrated that triptans in pure TTH are not helpful, although triptans are effective in TTH when the patient also has migraine. For chronic TTH, amitriptyline (10 to 100 mg/day) is the only proven treatment; other tricyclics, selective serotonin reuptake inhibitors, and the benzodiazepines have not been shown to be effective. There is no evidence for the efficacy of acupuncture. Placebo-controlled trials of onabotulinum toxin type A in chronic TTH have been negative.

TABLE 54.6 Clinical Features of the Trigeminal Autonomic Cephalalgias

	Cluster Headache	Paroxysmal Hemicrania	SUNCT/SUNA
Gender pain	M > F	F = M	F ~ M
Type	Stabbing, boring	Throbbing, boring, stabbing	Burning, stabbing, sharp
Severity	Excruciating	Excruciating	Severe to excruciating

Site	Orbit, temple	Orbit, temple	Periorbital
Attack frequency	1/alternate day-8/day	1-20/day (>5/day for more than half the time)	3-200/day
Duration of attack	15-180 min	2-30 min	5-240 s
Autonomic features	Yes	Yes	Yes (prominent conjunctival injection and lacrimation) ^a
Migrainous features ^b	Yes	Yes	Yes
Alcohol trigger	Yes	No	No
Cutaneous triggers	No	No	Yes
Indomethacin effect	—	Yes ^c	—
Abortive treatment	Sumatriptan injection or nasal spray Oxygen	No effective treatment	Lidocaine (IV)
Prophylactic treatment	Verapamil Methysergide Lithium	Indomethacin	Lamotrigine Topiramate Gabapentin

^aIf conjunctival injection and tearing not present, consider SUNA. ^bNausea, photophobia, or phonophobia; photophobia and phonophobia are typically unilateral on the side of the pain. ^cIndicates complete response to indomethacin.

SUNCT, short-lasting *unilateral neuralgiform* headache attacks with conjunctival injection and tearing; SUNA, short-lasting *unilateral neuralgiform* headache attacks with cranial *autonomic* features; M, male; F, female; IV, intravenous.

TRIGEMINAL AUTONOMIC CEPHALALGIAS

The TACs describe a group of primary headaches including cluster headache, paroxysmal hemicrania, SUNCT (short-lasting *unilateral neuralgiform* headache attacks with conjunctival injection and tearing)/SUNA (short-lasting *unilateral neuralgiform* headache attacks with cranial *autonomic* symptoms), and hemicrania continua

(see [Table 54.1](#)). The TACs are characterized by relatively short-lasting attacks of head pain associated with cranial autonomic symptoms, such as lacrimation, conjunctival injection, or nasal congestion ([Table 54.6](#)). Pain is usually severe and may occur more than once a day. Because of the associated nasal congestion or rhinorrhea, patients are often misdiagnosed with “sinus headache” and treated with decongestants, which are ineffective. The key feature of this class of headaches is the lateralized nature of symptoms (e.g., side-locked head pain and ipsilateral cranial autonomic features).

TACs must be differentiated from short-lasting headaches that do not have prominent cranial autonomic syndromes, notably trigeminal neuralgia, primary stabbing headache, and hypnic headache. The cycling pattern and length, frequency, and timing of attacks are useful in classifying patients. Patients with TACs should undergo pituitary imaging and pituitary function tests, as there is an excess of TAC presentations in patients with pituitary tumor-related headache.

P.445

CLUSTER HEADACHE

CLINICAL FEATURES

Cluster headache is a rare primary headache syndrome with a population frequency of approximately 0.1%, affecting men more than women at a ratio of 3:1. The pain is deep, usually retroorbital, often excruciating in intensity, nonfluctuating, and explosive in quality. A core feature of cluster headache is periodicity. At least one of the daily attacks of pain recurs at about the same hour each day for the duration of a cluster bout. Onset is nocturnal in about 50% of patients. The typical cluster headache patient has daily bouts of one or two attacks of relatively short-duration unilateral pain for 8 to 10 weeks a year; this is usually followed by a pain-free interval that averages a little less than 1 year. Cluster headache is characterized as chronic when there is less than 1 month of sustained remission without treatment. Patients with cluster headache tend to be restless during attacks and may pace, rock, or rub their head for relief; some may even become aggressive during attacks. This is in sharp contrast to patients with migraine who prefer to remain motionless during attacks.

PATHOPHYSIOLOGY

Cluster headache is likely to be a disorder involving central pacemaker neurons in the posterior hypothalamic region, thus accounting for its periodicity. Other hallmark features of cluster headache include the ipsilateral symptoms of cranial parasympathetic autonomic activation: conjunctival injection or lacrimation, rhinorrhea or nasal congestion, or cranial sympathetic dysfunction such as ptosis. The sympathetic deficit is peripheral and likely due to parasympathetic activation with injury to ascending sympathetic fibers surrounding a dilated carotid artery as it passes into the cranial cavity. When present, photophobia and phonophobia are far more likely to be unilateral and on the same side of the pain, rather than bilateral, as is seen in migraine. This phenomenon of unilateral photophobia/phonophobia is characteristic of TACs.

TREATMENT

As with migraine, there are both abortive (acute) medications and preventive therapies that can be used during a cluster bout [**Level 1**].[40,41,42,43,44,45,46,47,48](#)

ABORTIVE TREATMENT

Cluster headache attacks peak rapidly, and thus a treatment with quick onset is required. Many patients with acute cluster headache respond very well to oxygen inhalation. This should be given as

100% oxygen at 10 to 12 L/min for 15 to 20 minutes at the onset of the attack. Sumatriptan 6 mg SC is rapid in onset and will usually shorten an attack to 10 to 15 minutes; there is no evidence of tachyphylaxis. Sumatriptan (20 mg) and zolmitriptan (5 mg) nasal sprays are also both effective in acute cluster headache. Oral sumatriptan is not effective for either prevention or acute treatment of cluster headache.

PREVENTIVE TREATMENTS

Table 54.7 summarizes commonly used treatments for the prevention of cluster headache. The choice of a preventive treatment in cluster headache depends in part on the length of the bout. Patients with long bouts or those with chronic cluster headache require medicines that are safe when taken for long periods. For patients with relatively short bouts, limited courses of oral glucocorticoids can be very useful. A 10-day course of prednisone, beginning at 60 mg daily for 7 days and followed by a rapid taper, can also help to interrupt the cycle. Lithium (400 to 800 mg/day) appears to be particularly useful for the chronic form of the disorder.

TABLE 54.7 Preventive Management of Cluster Headache

Short-Term Prevention	Long-Term Prevention
Episodic Cluster Headache	Episodic Cluster Headache and Prolonged Chronic Cluster Headache
Prednisone 1 mg/kg up to 60 mg q.d, tapering over 21 days	Verapamil 160-960 mg/day (<i>immediate-release formulation, divided b.i.d. or t.i.d.</i>)
Verapamil 160-960 mg/day	Lithium 400-800 mg/day
Greater occipital nerve injection ^a	Topiramate ^b 100-400 mg/day Gabapentin ^b 1,200-3,600 mg/day Melatonin ^b 9-12 mg/day

^aSupported by level 1 evidence. ^bUnproven but of potential benefit.

Many experts favor verapamil as the first-line preventive treatment for patients with chronic cluster headache or prolonged bouts. Although verapamil compares favorably with lithium in practice, some patients require verapamil doses far in excess of those administered for cardiac disorders. The initial dose range is 40 to 80 mg twice daily; effective doses may be as high as 960 mg/day. Side effects include constipation and lower extremity edema. Of greater concern is the cardiovascular safety of verapamil, particularly at high doses. Verapamil can induce heart block by slowing conduction in the atrioventricular node and thus requires close monitoring of the PR interval with serial electrocardiograms (ECGs). Approximately 20% of patients treated with verapamil develop ECG abnormalities, which can occur at doses as low as 240 mg/day; these abnormalities can worsen over time in patients on stable doses. A baseline ECG is recommended for all patients. The ECG is then

repeated 10 days after a dose change in those patients whose dose is being increased above 240 mg daily. Dose increases are usually made in 80-mg increments. Patients on long-term verapamil should have ECG monitoring every 6 months.

NEUROSTIMULATION THERAPY

When medical therapies fail in chronic cluster headache, neurostimulation strategies can be considered. Deep brain stimulation of the region of the posterior hypothalamic gray matter has proven successful in a substantial proportion of patients, although with its morbidity and possible mortality, it is not recommended prior to less invasive approaches. Favorable results have also been reported with the less invasive approach of occipital nerve stimulation and sphenopalatine ganglion stimulation, as well as with a noninvasive vagal nerve stimulator.

PAROXYSMAL HEMICRANIA

Paroxysmal hemicrania (PH) is characterized by unilateral, severe, short-lasting attacks (2 to 45 minutes) of head pain that are frequent (more than five times per day). Like cluster headache, the pain tends to be retroorbital but also may be experienced in

P.446

other regions of the head and is associated with ipsilateral cranial autonomic phenomena such as lacrimation and nasal congestion. However, unlike cluster headache, which predominantly affects males, the male-to-female ratio in PH is close to 1:1. Episodic PH is characterized by periods of remission, whereas the nonremitting form is termed *chronic PH*. The course of PH is typically rapid (<72 hours) and is marked by an excellent response to indomethacin (25 to 75 mg t.i.d.), which can completely suppress attacks. Although therapy may be complicated by indomethacin-induced gastrointestinal side effects, currently, there are no consistently effective alternatives. Topiramate (50 to 300 mg/day) has been reported to be helpful in some cases, as has piroxicam (20 to 40 mg/day), although not to the same extent as indomethacin. Verapamil, an effective treatment for cluster headache, does not appear to be useful for PH. In occasional patients, PH can coexist with trigeminal neuralgia (PH-tic syndrome); similar to cluster-tic syndrome, each component may require separate treatment.

Secondary PH has been reported from lesions in the region of the sella turcica, including arteriovenous malformation, cavernous sinus meningioma, pituitary pathology, and epidermoid tumors. Secondary PH is more likely if the patient requires high doses (>200 mg/day) of indomethacin. In patients with apparent bilateral PH, raised cerebrospinal fluid (CSF) pressure should be suspected. It is important to note that indomethacin reduces CSF pressure. When a diagnosis of PH is considered, as with other TACs, magnetic resonance imaging (MRI) is indicated to exclude a pituitary lesion.

SUNCT/SUNA

CLINICAL FEATURES

SUNCT is a rare primary headache syndrome characterized by severe, unilateral orbital or temporal pain that is stabbing or throbbing in quality. Diagnosis requires at least 20 attacks, lasting for 5 to 240 seconds; ipsilateral conjunctival injection and lacrimation should be present. In some patients, conjunctival injection or lacrimation is missing, and the diagnosis of SUNA can be made.

The pain of SUNCT/SUNA is unilateral and may be located anywhere in the head. Three basic patterns can be seen: *single stabs*, which are usually short-lived; *groups of stabs*; or a longer attack consisting of many stabs between which the pain does not completely resolve, thus yielding a “*sawtooth*” pattern with attacks lasting many minutes. Each pattern may be seen in the context of an underlying continuous head pain. Characteristics that

lead to a suspected diagnosis of SUNCT are the cutaneous (or other) triggerability of attacks, a lack of refractory period to triggering between attacks, and the lack of a response to indomethacin. Apart from trigeminal sensory disturbance, the neurologic examination is normal in primary SUNCT.

The diagnosis of SUNCT is often confused with trigeminal neuralgia (TN) particularly in first-division TN (as discussed in Chapter 55). Minimal or no cranial autonomic symptoms and a clear refractory period to triggering indicate a diagnosis of TN. Secondary SUNCT can be seen with posterior fossa or pituitary lesions. All patients with SUNCT/SUNA should be evaluated with pituitary function tests and a brain MRI with pituitary views.

TREATMENT

Abortive therapy is not practical in SUNCT/SUNA because the attacks are of such short duration. The main goal of treatment is long-term prevention to minimize disability. The most effective prophylactic medication is lamotrigine at doses of 200 to 400 mg/day. Topiramate (50 to 300 mg/day) and gabapentin (800 to 2,700 mg/day) may also be effective. Carbamazepine (400 to 600 mg/day) has been reported by some to be moderately helpful. Surgical approaches such as microvascular decompression or destructive trigeminal procedures are seldom useful and often cause long-term complications such as permanent numbness and anesthesia dolorosa. Greater occipital nerve blocks may yield limited benefit in some patients. Occipital nerve stimulation is probably helpful in a subgroup of patients with SUNCT/SUNA. For intractable cases, short-term prevention with IV lidocaine, which can arrest symptoms rapidly, can be useful.

HEMICRANIA CONTINUA

The essential features of hemicrania continua are moderate and continuous unilateral pain with superimposed exacerbations of severe pain, which may be associated with cranial autonomic features and photophobia/phonophobia on the affected side. The age of onset ranges from 11 to 58 years; women are affected twice as often as men. The cause is unknown, although as with other TAC syndromes, pituitary pathology has been associated with HC.

As with PH, definitive treatment is indomethacin (25 to 75 mg t.i.d.); other NSAIDs appear to be of little or no benefit. Indomethacin should be initiated at 25 mg PO t.i.d., then increased to 50 mg t.i.d. if no effect, and further to 75 mg t.i.d. if needed. Up to 2 weeks at the maximal dose may be necessary to assess whether a dose has a useful effect. Topiramate can be helpful in some patients, as can greater occipital nerve blocks. Occipital nerve stimulation probably has a role in patients with hemicrania continua who are unable to tolerate indomethacin.

OTHER PRIMARY HEADACHES

PRIMARY COUGH HEADACHE

Primary cough headache is a generalized headache that begins suddenly, lasts for several minutes, sometimes up to a few hours, and is precipitated by coughing; it is preventable by avoiding coughing or other precipitating events, which can include sneezing, straining, laughing, or stooping. In all patients with this syndrome, serious etiologies must be excluded before a diagnosis of “benign” primary cough headache can be established (as discussed earlier in this chapter and also in Chapter 7). Benign cough headache can resemble benign exertional headache (in the following text), but patients with the former condition are typically older.

Indomethacin 25 to 50 mg two to three times daily is the treatment of choice. Some patients with cough headache obtain complete cessation of their attacks with lumbar puncture; this is a simple option when compared to prolonged use of indomethacin, and it is effective in about one-third of patients. The mechanism of this response is unclear.

PRIMARY EXERTIONAL HEADACHE

Primary exertional headache (PEH) has features resembling both cough headache and migraine. It may be precipitated by any form of exercise and often has the pulsatile quality of migraine. The pain, which can last from 5 minutes to 24 hours, is bilateral and throbbing at onset; migrainous features may develop in patients susceptible to migraine. When seen, it tends to be shorter in adolescents. PEH can be prevented by avoiding excessive exertion, particularly in hot weather or at high altitude.

P.447

The mechanism of PEH is unclear. Acute venous distension may account for the acute onset of headache with straining and breath holding. As with primary cough headache, serious underlying conditions must be excluded. Pain from angina may be referred to the head, probably by central connections of vagal afferents, and may present as exertional headache (cardiac cephalgia) upon exercising. Other potential causes include pheochromocytoma, intracranial lesions, and carotid artery stenosis.

Treatment for benign PEH includes indomethacin (25 to 150 mg/day) and modification of one's exercise regimen. Propranolol may also provide prophylactic benefit. Indomethacin (50 mg), ergotamine (1 mg orally), or dihydroergotamine (2 mg intranasally) taken 30 to 45 minutes before exercise can be helpful as prophylaxis.

PRIMARY HEADACHE ASSOCIATED WITH SEXUAL ACTIVITY

The pain of primary sex headache usually begins as a dull, bilateral headache that suddenly becomes intense at orgasm. The headache can be prevented or eased by ceasing sexual activity before orgasm. Three types of sex headache are reported: a dull ache in the head and neck that intensifies as sexual excitement increases; a sudden, severe, explosive headache occurring at orgasm; and a postural headache developing after coitus that resembles the headache of low CSF pressure. The latter arises from vigorous sexual activity and is a form of low CSF pressure headache. Headaches developing at the time of orgasm are not always benign; 5% to 12% of cases of subarachnoid hemorrhage are precipitated by sexual intercourse. Sex headache is reported by men more often than women and may occur at any time during the years of sexual activity. It may develop on several occasions in succession and then disappear, even without an obvious change in sexual activity. In patients who stop sexual activity when headache is first noticed, the pain may subside within a period of 5 minutes to 2 hours. In about half of patients, sex headache will self-remit within 6 months. About half of patients with sex headache have a history of exertional headaches, and comorbid migraine is also more likely in this population.

Treatment includes reassurance (once serious causes have been excluded) and advising patients to cease sexual activity if a "warning" headache develops. If the headache occurs regularly, propranolol can be used for prevention (40 to 200 mg/day) or alternatively diltiazem (60 mg t.i.d.). Ergotamine (1 mg) or indomethacin (25 to 50 mg) taken about 30 to 45 minutes prior to sexual activity can also be helpful.

PRIMARY STABBING HEADACHE

Primary stabbing headache (PSH) is characterized by stab-like pains in the head or, rarely, the face, lasting from one to many seconds or minutes and occurring as a single stab or a series of stabs, absence of associated cranial autonomic features, absence of cutaneous triggering of attacks, and a pattern of recurrence at irregular intervals (hours to days). The pains have been variously described as *ice pick pains* or *jabs and jolts* and are more common in patients with other primary headaches, such as migraine and the TACs. If pain is frequent, indomethacin (25 to 50 mg b.i.d. or t.i.d.) can be used for prophylaxis.

NUMMULAR HEADACHE

The pain in nummular headache is localized to a round or elliptical focus that is fixed in place, ranging in size from 1 to 6 cm and may be continuous or intermittent. In rare cases, it may be multifocal. Nummular headache is

usually continuous with exacerbations, although can be episodic. There may be focal sensory disturbances, such as allodynia or hypesthesia. The pathophysiology is unknown, although a focal neuropathic disorder has been suggested. Local dermatologic or bony lesions must be excluded by examination and investigation. Treatment includes tricyclics, such as amitriptyline, or anticonvulsants, such as topiramate, valproate, or gabapentin; however, the condition may be difficult to treat.

HYPNIC HEADACHE

Hypnic headache is marked by occurrence after a few hours following sleep onset. The headache lasts from 15 to 30 minutes and is typically generalized and moderate in severity, although can also be unilateral and throbbing. Photophobia or phonophobia and nausea are usually absent. Attacks can occur up to three times throughout the night, and daytime naps can also precipitate head pain. Most patients are female, and the onset is usually after age of 60 years. The major secondary consideration in this headache type is poorly controlled hypertension; 24-hour blood pressure monitoring is recommended in such cases.

Patients with hypnic headache usually respond to lithium carbonate (200 to 600 mg nightly). For those intolerant of lithium, verapamil (160 mg) or indomethacin (25 to 75 mg) may be tried. One to two cups of coffee or oral caffeine (60 to 100 mg) at bedtime may be effective in approximately one-third of patients. Case reports suggest that melatonin and flunarizine (5 mg nightly) can also be helpful.

NEW DAILY PERSISTENT HEADACHE

New daily persistent headache (NDPH) is a clinically distinct syndrome, characterized by daily headache from onset for at least 3 months. The patient with NDPH can clearly recall the exact date and moment of onset. The headache usually begins abruptly, although onset may be more gradual in some cases; evolution over 3 days has been proposed as the upper limit for this syndrome. Antecedent illness (such as an upper respiratory infection or viral prodrome) has been reported in about one-third of patients with NDPH in one series. However, often there is no remarkable triggering event. The first priority is to distinguish between a primary and a secondary cause of this syndrome. Subarachnoid hemorrhage is the most serious of the secondary causes and must be excluded either by history or appropriate investigation. Other causes include chronic meningitis, as well as abnormalities of CSF pressure (see [Chapter 7](#)).

Primary NDPH can be of the migrainous type or can be appear featureless, appearing as new-onset TTH. Migrainous features are common and include unilateral headache and throbbing pain; nausea, photophobia, and/or phonophobia occur in about half of patients. Some patients have a previous history of episodic migraine. Treatment of migrainous-type primary NDPH consists of using standard migraine preventive therapies (see earlier discussion). Featureless NDPH tends to be most refractory to treatment—although conventional headache preventive therapies (such as tricyclic antidepressants and anticonvulsants) can be offered, most are ineffective.

POSTTRAUMATIC HEADACHE

A traumatic event can trigger a headache process that lasts for many months or years after the event. The term *trauma* is used here very broadly: Headache can develop following an injury to the head (including after neurosurgical; dental; or ear, nose, and throat procedures), but it can also develop after an infectious episode such

P.448

as with viral meningitis or a flulike illness. The underlying theme appears to be that a traumatic event involving the pain-producing meninges can trigger a headache process that lasts for many years. Complaints of dizziness, vertigo, and impaired memory can accompany the headache. Symptoms may remit after several weeks or persist for months and even years after the injury. Typically, the neurologic examination is normal and CT or MRI

studies are unrevealing. However, serious underlying causes must be ruled out, such as chronic subdural hematoma, subarachnoid hemorrhage, and carotid dissection.

Cranial Neuralgias and Facial Pain Disorders

Marianna Shnayderman Yugrakh

Denise E. Chou

INTRODUCTION

Facial pain can originate from various facial structures and includes pain due to disorders of the sinuses, ears, and nose, temporomandibular disorders (TMD), dental and oral pathologies, and various ophthalmologic problems, all of which can activate nociceptive pathways via infection, inflammation, trauma, or malignancy. Primary nervous system disorders causing facial pain span the breadth of the neuraxis and include cranial neuralgias, small fiber neuropathies, primary headache disorders, and central pain disorders involving the spinothalamocortical system. Facial pain may be perceived away from a region of pathology (referred pain) due to the complex sensory innervation of the face (including cranial nerves V, VII, IX, and X, with overlapping innervation of the ear), dural innervation from branches of the trigeminal and vagus nerves, as well as proximity of the spinal trigeminal nucleus to upper cervical afferent pathways. Sensory input convergence in the spinal trigeminal nucleus is one of the mechanisms of referred pain. [Table 55.1](#) highlights etiologies of facial pain including the peripheral nervous system and the tissues innervated. Primary pain syndromes can be recognized and treated only after a workup for secondary etiologies. The general principle for the diagnosis of secondary facial pain disorders, based on the *International Classification of Headache Disorders*, 3rd edition (*ICHD-3*), is establishment of a causal relationship between pain and a disorder of facial or cranial structures with respect to chronology, congruous exacerbation, and improvement in symptoms, and signs of the primary pathology evoking pain on physical examination.

FACIAL PAIN DUE TO DISORDERS OF SINUSES, EARS, AND NOSE

RHINOSINUSITIS

Epidemiology and Pathobiology

Rhinitis and sinusitis are not uncommon causes of facial pain and may exacerbate a primary headache disorder. However, the term *sinus headache* is frequently misused to describe facial and head pain (which in actuality is most often migraine) incorrectly denoting that underlying sinus pathology is the etiology of pain. This attribution of head and facial pain to sinus pathology may have two causes: (1) migraine is a disorder associated with increased parasympathetic outflow with nasal congestion and lacrimation, and (2) the causality between headache and inflammatory changes in the nasal sinuses is difficult to establish, as the latter is highly prevalent and can be asymptomatic. Nasal mucosal changes (particularly in the ethmoid and maxillary sinuses), which may be signs of acute or chronic rhinosinusitis, can be identified in almost 50% of adults who undergo magnetic resonance imaging (MRI) testing for suspected intracranial disease. Although acute rhinosinusitis has long been considered a cause of facial and head pain, only the 3rd edition of the *ICHD* from 2013 has included chronic rhinosinusitis as a potential etiology. This revision was based on findings from recent studies, such as the American Migraine Prevalence and Prevention (AMPP) study, which reported that patients with chronic rhinitis were one-fourth more likely to be of higher headache frequency categories.

Nasal and sinus mucosa are innervated by the first and second divisions of the trigeminal nerve. The first division innervates the frontal and anterior ethmoid sinuses, whereas the second carries nociceptive signals from the maxillary, sphenoid, and posterior ethmoid sinuses. Infectious or allergic triggers result in release of inflammatory mediators that activate nociceptive neurons in the spinal trigeminal nucleus, signaling local facial

pain and additionally may produce referred head pain. More frequent or persistent referred pain may result from peripheral and central sensitization of the trigeminal system.

Clinical Manifestations and Diagnosis

Acute rhinosinusitis symptoms include rhinorrhea and purulence, fever, hyposmia, halitosis, and symptoms akin to an upper respiratory tract infection. Acute sinusitis pain can be localized, described as deep pressure, congestion, or fullness felt in the face and teeth, and is often exacerbated by lying down. Pain may be facial but can also be referred posteriorly. Frontal sinusitis pain is typically behind the eyes and around the center of the forehead, with the frontal region being sensitive to percussion and associated with supraorbital nerve sensitivity. In ethmoid sinusitis, pain is also retroorbital and may radiate to the temples, with eye sensitivity to pressure. Maxillary sinusitis pain is appreciated over the cheeks, but can radiate to the ear or teeth, with sensitivity of teeth to percussion. Isolated sphenoid sinusitis is a relatively rare, serious disorder with the potential complication of cavernous sinus thrombophlebitis. It most commonly presents with refractory nonlocalizing headache, followed by visual complaints and cranial nerve palsies. Because of its deep location, tenderness on exam is not appreciable. Computed tomography (CT), MRI, or endoscopic techniques allow for the diagnosis.

ICHD-3 diagnostic criteria for headache or facial pain attributed to acute rhinosinusitis requires clinical, nasal endoscopic, and/or imaging evidence of acute rhinosinusitis, and two of the following: (1) establishment of a temporal relation of pain to onset of rhinosinusitis, (2) either improvement or worsening of pain symptoms paralleling improvement or worsening of rhinosinusitis symptoms, (3) pain exacerbated by pressure applied over the paranasal sinuses, and (4) pain localized ipsilateral in the case of unilateral rhinosinusitis. Headache or facial pain attributed to chronic rhinosinusitis is diagnosed based on evidence of current or past infection, and evidence of causation as discussed earlier.

Treatment and Outcome

Infectious rhinosinusitis may be treated with antibiotics, depending on patient risk profile for bacterial infection. Facial pressure and pain caused by inferior and middle nasal turbinate congestion can

P.451

be relieved with a nasal corticosteroid spray, such as mometasone furoate, or systemic decongestants. Allergic rhinitis treatment involves identifying the allergens and desensitization, or antihistamine use during seasonal episodes, and topical steroids. If aggressive medical therapy fails, surgical approaches targeting nasal anatomic abnormalities predisposing recurrent infection may be considered.

TABLE 55.1 Etiologies of Facial Pain Including the Peripheral Nervous System and Tissues Innervated

Nerve and Sensory Distribution	Primary PNS Disorders	Disorders Outside of the Nervous System	
Trigeminal nerve, ophthalmic division	Classical TN (idiopathic or with vascular loop) Painful trigeminal neuropathies:	Eyes ^a :	acute angle-closure glaucoma, iritis, uveitis, scleritis, conjunctivitis, trochleitis

- Symptomatic TN (tumor, vascular malformation, multiple sclerosis plaque at dorsal root entry zone)
- Herpes zoster ophthalmicus and postherpetic trigeminal neuropathy
- Posttraumatic (anesthesia dolorosa)

Paratrigeminal oculosympathetic syndrome (Raeder syndrome)

Sinuses (frontal and anterior ethmoid):

acute rhinosinusitis, septal deflections, hypertrophic turbinates, nasal spurs

Arteries:

giant cell arteritis (temporal arteritis)

Trigeminal nerve, maxillary division

Classical TN
Painful trigeminal neuropathies:

- Symptomatic TN
- Acute herpes zoster and postherpetic trigeminal neuropathy
- Posttraumatic (anesthesia dolorosa)

Maxillary teeth:

pulpitis, cracked tooth syndrome, dentine sensitivity, dental abscess

Oral cavity:

mucosal malignancies, infections, inflammation, blockage of a major salivary gland duct

Sinuses (maxillary, sphenoid, posterior ethmoid):

acute rhinosinusitis, chronic rhinosinusitis

Trigeminal nerve, mandibular division

Classical TN
Painful trigeminal neuropathies:

- Symptomatic TN
- Acute herpes zoster and postherpetic trigeminal neuropathy
- Posttraumatic (anesthesia dolorosa)

Auriculotemporal syndrome (Frey syndrome)
Burning mouth syndrome

Mandibular teeth, oral cavity, tongue:

as per maxillary teeth and oral cavity

Temporomandibular joint:

temporomandibular disorders: arthritic and degenerative joint disease, disk displacement, myalgia and myofascial pain

External auditory meatus, anterior pinna:

laceration and tumors of pinna:
external otitis, foreign bodies, squamous cell and basal cell carcinomas, adenocarcinoma

		Arteries:	giant cell arteritis (temporal arteritis)
Facial nerve, nervus intermedius branch 	Nervus intermedius neuralgia Trigeminal neuropathies: <ul style="list-style-type: none"> • Herpes zoster (Ramsey-Hunt syndrome) and postherpetic neuralgia Acoustic neuroma	Mastoid cells and skin overlying the mastoid process: External auditory meatus, lateral pinna: Nasopharynx, palate:	otitis media, mastoiditis external otitis, foreign bodies, local tumors local/infiltrative tumors, inflammation
Glossopharyngeal nerve and vagal nerve 	Glossovagopharyngeal neuralgia Nerve compression by elongated styloid process (Eagle syndrome)	External ear canal and tympanic membrane: Upper pharynx, posterior tonsils, base of tongue, soft palate:	external otitis, foreign bodies, squamous cell and basal cell carcinomas, adenocarcinoma, tympanic membrane perforation local tumors, inflammation, infection

Pain in a specific distribution should warrant consideration of the various etiologies listed in addition to consideration of central nervous system causes.

^aEye pain without ophthalmoplegia.

PNS, peripheral nervous system; TN, trigeminal neuralgia.

FACIAL PAIN ATTRIBUTED TO DISORDERS OF THE NOSE AND MUCOSAL CONTACT POINTS

Other conditions that may cause facial pain and headache include nasal passage abnormalities due to septal deflections, hypertrophic turbinates, and nasal septal spurs. Mucosal contact points are defined as two structures in the nasal cavity that remain in contact after decongestion therapy, and have been cited as an etiology of facial pain; several surgical outcomes series indicate that patients obtain relief from headache and facial pain after endoscopic endonasal surgery. On the other hand, a large cohort study of consecutive patients in a rhinology clinic identified equal prevalence of nasal mucosal contact points in patients with and without facial pain, and yet another study found presence of contact points on CT imaging in 55% of patients without correlation to facial or head pain, both suggesting that their coexistence is coincidental. The causality of mucosal contact points and facial pain requires further investigation.

OTALGIA ATTRIBUTED TO DISORDER OF EARS AND REFERRED PAIN

Otalgia is diagnosed based on the identification of a primary ear disorder and evidence of causation. Ear pain can be dull, aching, or stabbing; may radiate to the temples; and may be associated with ear fullness, tenderness, burning, or itching. Primary disorders of the ear by compartment are listed in [Table 55.1](#). About half of all earaches are due to structural lesions of the external or middle ear; the rest are due to referred pain from remote structures. This is due to overlapping sensory innervation in this small region: branches of the mandibular division of V and branches of C2 and C3 to the pinna; mandibular division branches of V as well as VII, IX, and X branches to the external auditory canal and the tympanic membrane; and branches of VII to the middle ear. Etiologies of referred otalgia are also summarized in [Table 55.1](#).

FACIAL PAIN DUE TO TEMPOROMANDIBULAR DISORDERS AND DISORDERS OF THE TEETH OR MOUTH

Dental pain, frequently poorly localized, has several major causes as summarized in [Table 55.1](#). Nondental intraoral pain can be secondary to oral mucosa malignancies, inflammatory and infectious disorders, or blockage of a major salivary gland duct with pain that is predominantly preprandial. Periodontal disorders involve bone and periodontal ligament; these are associated with clearly localized pain and are typically managed with conventional dental treatments. Atypical odontalgia, or posttraumatic trigeminal neuropathic pain that is localized to an area where a tooth has previously been extracted, is a subtype of persistent idiopathic facial pain discussed later in the chapter.

TEMPOROMANDIBULAR JOINT DISORDERS (TMD)

Epidemiology and Pathobiology

TMDs encompass pathologies related to the joint and/or to the muscles and constitute one of the most common causes of orofacial pain, affecting 10% to 15% of the population. The temporomandibular joint (TMJ) is composed of an upper and lower compartment separated by a fibrocartilaginous disk allowing rotary and translational movement of the mandible. Dysfunction may be secondary to trauma, changes in occlusion, and behavioral influences including clenching and grinding of the teeth. Other risk factors include asymmetry in joints, poor posture causing muscle strain, and female gender. Joint disorders associated with pain include arthritis, degenerative disk disease, and joint dysfunction such as disk-condyle incoordination or articular disk displacement. Pain is mediated via the pain-sensitive joint capsule and posterior disk attachment, with nociceptive signals transmitted via the mandibular branch of the trigeminal nerve. The pathophysiology of primary muscle pain, including myalgia and myofascial pain with referral is poorly understood.

P.453

Pressure on tender trigger points, or nodular bands under the skin in muscles, tendons, or fascia, can cause pain locally or in other parts of the body via referral patterns. Initial muscle aggravation may be associated with oral habits or postural abnormalities.

Clinical Manifestations and Diagnosis

Common symptoms of TMD, in addition to jaw pain, include discomfort with biting or chewing, clicking or popping sounds when opening or closing the mouth, markedly limited mouth opening (<40 mm) if a disk becomes permanently displaced relative to the joint, and crepitus with mandibular movements in degenerative joint disease. MRI is the gold standard for imaging soft tissues and disk position, whereas CT can identify degenerative changes. The evidence-based diagnostic protocol and classification system for TMD, updated in 2014, combines clinical and radiologic findings. Pain originating in the TMJ may be aching, throbbing, sharp, or a tightening sensation, present at rest or provoked with movement in the ramus

of the mandible, temporal area, and preand postauricular areas. Myofascial pain is described as dull or achy, associated with the presence of trigger points which may involve the masseters or temporalis muscles directly or refer pain to the preauricular area, temporal region, ear, or head. Facial pain or headache secondary to TMD is diagnosed based on evidence of causation including temporal relationship of pain to the disorder, exacerbation of pain by movement or pressure on the joint or muscles, and same laterality.

Treatment and Outcome

Temporomandibular disorders are usually self-limiting and few require therapeutic interventions. Management includes patient education about avoiding clenching behaviors and chewy foods, performing jaw stretching exercises, progressive relaxation, and biofeedback. Physical therapy for posture training and joint mobility, as well as stabilization devices and anterior positioning appliances can reduce TMD-related pain. Nonsteroidal anti-inflammatory drugs, particularly naproxen [Level 1],¹ and muscle relaxants are first-line pharmacologic treatments, followed by tricyclic antidepressants, which have been used extensively for chronic musculoskeletal pain and facial pain as well as high-dose gabapentin, around 3,400 mg/day [Level 1].²

TRIGEMINAL AND OTHER CRANIAL NEURALGIAS

Compression or traction on several cranial nerves by a structural lesion may lead to paroxysms of stabbing pain in the innervated region, or *neuralgia*. In trigeminal neuralgia, the most common of the neuralgias, the majority of cases involve lesions affecting the dorsal root entry zone without compromising the function of the nerve. In this region, myelin is generated by astrocytes, rather than Schwann cells, and is more vulnerable to compression than the nerve in its more peripheral course, suggesting susceptibility to ephaptic transmission with crossed modality activation, or allodynia, and hyperexcitability. In some cases, an underlying vascular loop can be identified on imaging or intraoperatively as a cause of compression. In other cases, bilateral vascular loops are incidentally identified in symptomatic patients or in up to 8% of asymptomatic patients who obtain imaging for other reasons, making it difficult to determine if the neuralgia is primary or secondary. For this reason, the *ICHD-3* and current literature use the terms *classical neuralgia* to diagnose the syndrome where a structural lesion such as a vascular loop may exist but has not been identified yet, and *symptomatic neuralgia* or *painful neuropathy* for the syndrome with an identified lesion other than vascular loops.

TRIGEMINAL NEURALGIA

Epidemiology and Pathobiology

Classical trigeminal neuralgia (TN) is characterized by severe, lancinating pain strictly limited to the distribution of one or more divisions of the trigeminal nerve. There is typically a refractory period up to minutes, during which usual triggers cannot provoke another attack. TN is relatively rare, with a prevalence of 0.07% to 0.3%. It is more common among individuals older than 60 years of age, with a female-to-male ratio of approximately 2:1. Classical TN is idiopathic or caused by compression or stretching of the nerve roots by arteries (particularly the superior cerebellar artery) or veins. Tumors, including meningiomas and neuromas, cysts, and vascular malformations can produce identical symptoms if there is only distention of the trigeminal roots without invasion.

Although pain is typically discrete during bouts, a period of days to years of atypical continuous pain termed *pretrigeminal neuralgia* as well as background pain between attacks have been reported. Trigeminal neuralgia with concomitant persistent facial pain is often referred to as *atypical TN* or *TN type 2*, and central sensitization is thought to account for the interictal pain. In this variant, neurovascular compression is less likely to be

identified.

Clinical Manifestations and Diagnosis

The pain of TN is severe in intensity, electrical shock-like or stabbing in quality, and lasts seconds to a few minutes but can become prolonged over time. Although not every attack need be provoked, at least three should be precipitated to meet diagnostic criteria for typical TN. Mechanical stimulation in the trigeminal distributions (or trigger zones) may set off pain, including otherwise innocuous stimuli such as breeze or wind, brushing teeth, chewing, and combing hair. Diagnosis requires that the pain be limited to one or more divisions of the trigeminal nerve, typically unilateral, with no radiation beyond the trigeminal distribution. Mild ipsilateral parasympathetic symptoms including facial flushing, lacrimation, and conjunctival injection may also accompany the pain.

The differential for TN includes short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (SUNCT) or short-lasting unilateral neuralgiform headache attacks with cranial autonomic symptoms (SUNA) syndrome (discussed previously in Chapter 54). Although attacks in TN and SUNCT/SUNA have phenotypic overlap, including trigger areas, length, and quality of pain, the two conditions can be distinguished by a refractory period (present in TN and often absent in SUNCT/SUNA), extent of associated cranial autonomic features (prominent in SUNCT/SUNA and less so in TN), and treatment response (described in the following text). It is crucial to differentiate these syndromes in order to institute appropriate first-line medical therapy early and to avoid unnecessary surgical interventions for vascular abnormalities that may be incidentally identified in patients with a SUNCT or SUNA phenotypes, although a few cases of successful microvascular decompression have been described. Functional MRI may also be of diagnostic use, as ipsilateral hypothalamic activation may be seen in SUNCT and not in TN. The presence of bilateral symptoms and trigeminal sensory deficits may suggest symptomatic TN, although the absence of such features does not necessarily exclude an underlying structural or systemic disorder.

Electromyogram (EMG) trigeminal reflex testing

P.454

is sensitive and specific for identifying symptomatic TN and is a reasonable early diagnostic test. Additionally, all patients with TN symptomatology should undergo brain imaging to evaluate for secondary causes, as well as compressive vascular lesions (as in classical TN). Different MRI sequences have been used to optimize visualization of veins and arteries surrounding the trigeminal nerve. If standard T1-weighted MRI does not provide sufficient visualization of the trigeminal nerve, axial fast imaging employing steady-state acquisition (FIESTA) and three-dimensional (3D)-spoiled gradient echo (SPGR) multiplanar reconstruction sequences with and without contrast may be used. Standard MRI sequences can identify other secondary causes of TN including tumors and multiple sclerosis (MS) plaques, particularly in the cases of bilateral TN. Painful trigeminal neuropathy from demyelinating lesions can present with all the characteristics of classical TN and affects up to 5% of patients with MS. If there is hypoesthesia in the affected trigeminal distribution, a more extensive workup for the etiology of nerve damage is warranted, as detailed in Chapter 86.

Treatment and Outcome

Medical treatment, summarized in [Table 55.2](#), is aimed at reducing attack frequency and severity over time and is effective for approximately 70% to 80% of patients with classical TN. Several randomized controlled trials (RCTs) have demonstrated efficacy of carbamazepine [**Level 1**],³ with 58% to 100% of patients achieving near-complete pain control and treatment response beginning as soon as 2 days after initiation. Other RCTs have shown probable efficacy of oxcarbazepine and possible effectiveness of baclofen and

lamotrigine. Additionally, smaller studies suggest that gabapentin, valproate, and levetiracetam, as well as phenytoin and tizanidine (although both with rapidly diminishing effects over time), may have benefit in TN. Type 2 TN is less likely to respond to any of the aforementioned treatments. OnabotulinumtoxinA [**Level 1**],⁴ injected to the affected skin or mucosal region, has also been recently shown to be effective in reducing pain severity and attack frequency in a double-blind, saline injection placebo-controlled trial, although side effects included facial asymmetry lasting up to 7 weeks.

TABLE 55.2 Medications Commonly Used in Cranial Neuralgias

Medication	Maintenance Dose	Side Effects	Additional Considerations
Carbamazepine	300-1,600 mg/day	Sedation, dizziness, cognitive impairment, hyponatremia, rash, aplastic anemia	<ul style="list-style-type: none"> • Multiple drug interactions (CYP450 inducer) • Response can be seen within 48 h.
Oxcarbazepine	600-1,800 mg/day	Less severe than with carbamazepine but include sedation, dizziness, hyponatremia, rash	<ul style="list-style-type: none"> • Cross-allergy with carbamazepine in 25% of cases • Equally effective to carbamazepine
Gabapentin	600-2,400 mg/day	Sedation, peripheral edema	<ul style="list-style-type: none"> • Extra doses can be used for acute treatment.
Lamotrigine	150-400 mg/day	Stevens-Johnson syndrome, sedation, dizziness	<ul style="list-style-type: none"> • Very slow dose up titration necessary
Baclofen	30-80 mg/day	Sedation, ataxia, fatigue	<ul style="list-style-type: none"> • Risk of seizures if stopped rapidly
Phenytoin	200-400 mg/day	Sedation, ataxia, cognitive impairment, rash	<ul style="list-style-type: none"> • Multiple drug interactions (CYP450 inducer) • Used as an initial intravenous treatment, but therapeutic effect lost quickly
Tizanidine	12 mg/day	Sedation, dizziness, orthostatic hypotension	<ul style="list-style-type: none"> • Therapeutic effects are lost within 1-3 mo.
Levetiracetam	3-4 g/day	Irritability, depression	<ul style="list-style-type: none"> • Used as an add-on therapy

OnabotulinumtoxinA 75 units

Facial weakness,
transient edema

- 5 units (0.1 mL) injected in 15 points in epidermis/dermis or submucosally to region affected

Evidence for use derived from trigeminal neuralgia clinical studies.

If medical therapy fails or is poorly tolerated, interventional treatments can be considered. Microvascular decompression (MVD) involves craniotomy and repositioning of vessels out of contact from the trigeminal nerve. Up to 80% of patients become pain-free following the procedure, with 73% maintaining pain freedom at 5 years; however, there are multiple risks of serious complications, as well as sensory loss in 7% of patients and hearing loss in up to 10% of patients. Gamma knife radiosurgery, in which a beam of radiation is focused at the trigeminal root, has been reported to result in pain freedom in 69% of patients after 1 year, with the number falling to 52% at 3 years. Complications include sensory loss or paresthesias in 6% to 13% of patients. Finally, percutaneous procedures on the Gasserian ganglion, or rhizotomies, involve penetration of the foramen ovale and lesioning of the trigeminal ganglion and/or its roots via glycerol injection, radiofrequency thermocoagulation, or mechanical compression. In a few studies using independent outcome measures, pain freedom was attained in 90% of patients immediately following rhizotomy, but dropped to 54% to 64% after 3 years. Adverse effects are frequent, with sensory loss occurring in almost half of cases, dysesthesias in 6%, masticatory difficulties in up to 50%, and anesthesia

P.455

dolorosa, or painful numbness that can develop 3 to 6 months after the procedure, in about 4%. Peripheral techniques involving interruption of the trigeminal nerve have only been reported in case series, and to date, there are no direct comparative studies of procedural therapies for TN.

GLOSSOPHARYNGEAL NEURALGIA

Glossopharyngeal neuralgia, also known as *vagoglossopharyngeal neuralgia*, is characterized by paroxysms of severe stabbing pain in the ear, base of tongue, and/or tonsils. These regions are innervated by the auricular and pharyngeal branches of the glossopharyngeal nerve and by the vagus nerve. Neurovascular compression of the glossopharyngeal nerve, particularly by the posterior inferior cerebellar artery lying anteriorly to the nerve root entry zone, may be demonstrated on imaging or intraoperatively. Annual incidence rates for the disorder are 0.4 to 0.8 per 100,000 person-years. Diagnostic criteria are similar to TN, with attacks precipitated by talking, coughing, yawning, or swallowing. Weight loss may be seen in such cases due to avoidance of eating. Symptoms can be bilateral in up to 12% of patients, and nearly 75% experience remissions. Interestingly, up to 11% of patients with glossopharyngeal neuralgia may have comorbid TN. Paroxysms can occur in association with vagal symptoms of bradycardia and syncope, as well as hoarseness. There are also reports of symptomatic neuralgia, or glossopharyngeal neuropathy, caused by multiple sclerosis, Arnold-Chiari malformation, cerebellopontine angle tumors, as well as local tumors in the regions of pain. Treatment options are drawn from experience in TN, [Table 55.2](#). Surgical treatments include ablation or decompression of both glossopharyngeal and vagal nerve roots, with microvascular decompression and intracranial sectioning of nerve rootlets or rhizotomy having more favorable outcomes than either radiofrequency neurolysis or gamma knife radiosurgery.

NERVUS INTERMEDIUS NEURALGIA

Facial nerve, or nervus intermedius, neuralgia is characterized by paroxysms of severe lancinating pain deep in the auditory canal. The nervus intermedius is a sensory branch of the facial nerve that innervates the external auditory canal, middle ear, nasopharynx, and palate. Diagnostic criteria are similar to that of TN, except pain can be precipitated by stimulation of the pinna or posterior wall of the external auditory canal. There is often tenderness in this region and there may be associated lacrimation or excessive salivation. Unlike in TN and glossopharyngeal neuralgia, neurovascular compression is rarely visualized on MRI because the nervus intermedius is less than 0.5 mm in diameter and variable in course. Nervus intermedius neuropathy may be due to acute herpes zoster, or Ramsay Hunt Syndrome, which is further described in Chapter 86. Pharmacotherapy is similar to TN, and surgical management, which typically targets branches of the glossopharyngeal and vagal nerves, can also be considered.

IDIOPATHIC FACIAL PAIN

BURNING MOUTH SYNDROME

Burning or dysesthesia of the mouth or tongue without evidence of oral mucosal diseases is referred to as *burning mouth syndrome* (BMS). It is more common among women, particularly after the fourth decade of life. The diagnosis requires having constant daily pain for a minimum of 3 months, lasting at least for several hours per day. Pain is described as burning and is felt superficially in the oral mucosa, often affecting tip and anterior tongue bilaterally. Other symptoms include dysgeusia and sensation of dryness. The underlying pathophysiology has not been fully elucidated, although trigeminal small-fiber sensory neuropathy with loss of epithelial and subpapillary nerve fibers (akin to the burning feet syndrome) has been demonstrated. Increased expression of TRPV1, a heat- and capsaicin-activated cation channel that is upregulated in several chronic hypersensitivity and pain disorders, has also been noted in patients with BMS. Possible central pathways include abnormalities in tonic inhibition of sensory pathways due to dysfunctional gustatory signaling, as well as changes in central pain modulation with reduced endogenous dopamine levels in the putamen and dysfunction of the nigrostriatal dopaminergic pathway.

Workup includes evaluation for secondary causes of oral mucosal pain, including candidiasis and lichen planus, disorders of salivation and xerostomia due to medications or Sjögren syndrome, hormonal disturbances, hematologic disorders, nutritional deficiencies, and diabetes mellitus. No clinical abnormalities in oral mucosa have been identified on morphologic evaluation, except for increased keratin marker expression suggesting epithelial differentiation and proliferation. Treatment options evaluated in randomized clinical trials include topical clonazepam, selective serotonin reuptake inhibitors, topical and systemic capsaicin (although poorly tolerated), and alpha-lipoic acid. Based on expert opinion, current understanding of the pathophysiology, and common clinical practice, a trial of tricyclic antidepressants should also be considered.

PERSISTENT IDIOPATHIC FACIAL PAIN

Previously called *atypical facial pain*, persistent idiopathic facial pain (PIFP) is a diagnosis of exclusion that is denoted by facial pain lacking characteristics of cranial neuralgias and is not associated with any physical signs or evidence of primary pathology. This syndrome is rare, with an estimated prevalence of 0.03% and usually affecting the middle-aged demographic. The pathogenesis of the disorder is not understood; similar mechanisms have been implicated as in burning mouth syndrome. Patients frequently attribute their pain to an antecedent event, such as a dental procedure or minor trauma to the face, although symptoms may persist long after the initial injury has healed without any residual local pathology. Atypical odontalgia may be a subtype of PIFP, referring to pain in one or more teeth following root canal treatment or in tooth sockets after extraction and deafferentation of trigeminal nerve fibers, without evidence of persistent etiology. Psychological distress is an important factor in the evaluation and treatment of patients with persistent facial pain; although causation is not established, anxiety disorders as well as affective and somatoform disorders are highly prevalent in this

population.

Patients with PIFP describe daily unremitting pain that does not localize to a nerve distribution; quality is dull, aching, or nagging but may present with sharp exacerbations. There are no associated symptoms or neurologic deficits and for diagnosis, a dental cause is excluded by appropriate investigations. The diagnosis of PIFP is made after 3 months of persistent daily pain lasting several hours per day. Treatment options are based on expert opinion rather than controlled studies and include amitriptyline, gabapentin, venlafaxine, and topiramate.

PRIMARY HEADACHE DISORDERS PRESENTING AS FACIAL PAIN

A subset of patients with migraine may experience pain in facial areas, referred to as *facial migraine* or *lower half headache* in

P.456

the literature. The prevalence of facial pain in a population of 517 migraineurs was estimated to be nearly 9%, and patients with facial pain experienced more cranial autonomic symptoms than those without facial pain. Carotidynia is also frequently reported and/or noted on physical examination (with tenderness on gentle palpation of the carotid artery). Facial-only migraine otherwise shares similar characteristics to traditional migraine regarding pain quality and associated features as well as treatment response to oral triptans. Similarly, cluster headache and paroxysmal hemicrania can also present as pain in the orofacial area without associated headache. Recognizing that facial pain may be a manifestation of a primary headache syndrome can prevent unnecessary interventions, workup, and delays in appropriate therapy.

Complex Regional Pain Syndrome

Michael L. Weinberger

Thomas H. Brannagan III

INTRODUCTION

The complex regional pain syndrome has a long and changing history in medical practice. Veldman suggested that Ambrose Pare, in 1598, may have been the first to describe the syndrome of widespread limb pain with swelling, discoloration, and temperature change. Silas Weir Mitchell, a civil war era physician, discussed the relationship of the central and peripheral mechanisms and “reflex transfers” in the spinal cord along with his description of *causalgia* in soldiers who had intense nerve pain and autonomic dysregulation after gunshot wounds in battle. The term *causalgia* is attributed to Mitchell and the term *reflex sympathetic dystrophy* to Evans 80 years later. Other terms include the hand-shoulder syndrome, sympathalgia, algodystrophy, and Sudeck dystrophy. A consensus conference in 1993 led to a redefinition as the “complex regional pain syndrome” (CRPS). CRPS type 1 was intended to replace reflex sympathetic dystrophy (RSD) and CRPS type 2 to replace “causalgia.” These changes were an attempt to eliminate the implication that the sympathetic nervous system is involved in generating pain while agreeing that sympathetically maintained pain is a symptom.

EPIDEMIOLOGY

In two population-based studies, the incidence of CRPS was 5.46 to 26.2 per 100,000 person-years. The prevalence was estimated at 20.57 per 100,000 in Olmsted County. Women are three times more likely to be affected and postmenopausal women have the highest risk. The mean age at onset is 46 years, with the highest incidence between ages 61 and 70 years.

CLINICAL MANIFESTATIONS

CRPS 1 is a disorder with pain out of proportion to the severity of the injury, allodynia, vasomotor disturbances, motor disturbances, and trophic changes in the skin. Allodynia is defined as “pain resulting from a stimulus (such as a light touch of the skin) that would not normally provoke pain.” The symptoms typically follow trauma, which may be mild, but can occur after a myocardial infarction or varicella-zoster infection. A bone fracture is a common preceding event in about 45% of all patients. The arm is affected more commonly than the leg.

The pain is described as deep, sharp, sensitive, and hot. Patients are often sensitive to cold sensations and often guard their limbs to avoid physical contact. Swelling, edema, heat, and color changes occur in the affected limb, followed by osteoporosis and changes in hair, skin, and nail growth. The pain does not conform to nerve or root distribution and usually spreads beyond the area of injury. Some patients with CRPS 1 have dystonic postures of a hand or foot. Features similar to psychogenic movement disorders have been noted by some authors, including the difficulty initiating movement, abrupt onset, and dystonia at rest.

PATHOLOGY

CRPS 2 is defined by the presence of a nerve injury. In a single autopsy case of a CRPS 1 patient, pathologic changes included loss of posterior horn cells and activation of microglia and astrocytes. These changes were most prominent at the site of injury but extended throughout the length of the spinal cord. A study of amputated limbs noted microvascular changes with thickened basal membranes in capillaries in muscle and the loss of C fibers in some patients. In skin biopsy, CRPS 1, defined by the absence of an identified nerve injury, may show fewer small sensory epidermal nerve fibers than controls. Functional magnetic resonance imaging (fMRI) has

demonstrated cortical reorganization with shrinkage of the contralateral primary somatosensory cortex, which can be reversed with pain relief.

PATHOBIOLOGY

There is little information about the pathophysiology of CRPS. Both peripheral and central neural mechanisms have been proposed. Human leukocyte antigen (HLA) associations have been described but not confirmed. Theories of the pathogenesis have centered on central sensitization, oxidative damage, and inflammation. After an injury, an initial barrage of C fiber afferent activity may result in central sensitization (see [Chapter 57](#)) of dorsal horn neurons, resulting in allodynia and expansion of the distribution of pain. Patients with CRPS have increased levels of proinflammatory cytokines and markers of glial cell activation in the cerebrospinal fluid (CSF). They also have increased markers for oxidative damage, including malondialdehyde. Loss of inhibitory dorsal horn neurons may be evident. More recently, an autoimmune mechanism has been proposed. Studies have demonstrated autoantibodies to autonomic nervous system autoantigens in 30% to 40% of CRPS patients but not in controls or neuropathy patients. Immunoglobulin G (IgG) antibodies to autonomic receptors (β_2 adrenergic receptor and muscarinic-2 receptor) has been demonstrated. Also, α_1 adrenoreceptors on nociceptive afferents has been shown to be upregulated in dermal nerves and epidermal cells, which may augment pain and neuroinflammation in CRPS.

DIAGNOSTIC CRITERIA

In addition to the changes in terminology, diagnostic criteria have also evolved. Early attempts to define diagnostic criteria were based on anecdotal accumulation of signs and symptoms. Kozin et al. established diagnostic criteria in 1976, including categories for definite, probable, and doubtful RSD. Gibbons proposed a diagnostic

P.459

scale based on clinical signs and symptoms and laboratory tests including response to sympathetic nerve block. Blumberg proposed a numeric grading scale based on autonomic symptoms, motor symptoms, and sensory symptoms.

The International Association for the Study of Pain (IASP) diagnostic criteria for CRPS from Merskey and Bogduk (1994) include the following:

1. The presence of an initiating noxious event or a cause of immobilization
2. Continuing pain, allodynia, or hyperalgesia with which the pain is disproportionate to any inciting event
3. Evidence at some time of edema, changes in skin blood flow, or abnormal sudomotor activity in the region of pain
4. This diagnosis is excluded by the existence of conditions that would otherwise account for the degree of pain and dysfunction: type 1: without evidence of major nerve damage; type 2: with evidence of major nerve damage.

A consensus workshop in 2003 proposed changes because of the concern that the aforementioned criteria lack specificity in the face of high sensitivity. Validation studies of these criteria suggest that overdiagnosis may be a problem and the inclusion of objective data beyond the subjective and historic data currently called for may improve specificity with modest diminishment in sensitivity.

The Budapest criteria have been accepted by the IASP for the third revision of formal taxonomy and diagnostic criteria of pain states. Clinical diagnostic criteria for CRPS include an array of painful conditions characterized by continuing (spontaneous or evoked) regional pain that is seemingly disproportionate in time or degree to the usual course of any known trauma or other lesion. The pain is regional (not in a specific nerve territory or

dermatome) and usually shows distal predominance of abnormal sensory, motor, sudomotor vasomotor, or trophic findings, all with variable progression over time.

CLINICAL DIAGNOSTIC CRITERIA

1. *Continuing pain disproportionate to an inciting event*
2. *Must include at least one symptom in three of the four following categories:*
 - a. Sensory: hyperesthesia, allodynia, or both
 - b. Vasomotor: temperature asymmetry, skin color changes, skin color asymmetry, or all of these
 - c. Sudomotor/edema: edema, sweating, sweating asymmetry, or all three
 - d. Motor/trophic: decreased range of motion, motor dysfunction (weakness tremor, dystonic posture), trophic changes (hair, nail, skin), or all three
3. *Must display at least one sign at the time of evaluation in two or more categories:*
 - a. Sensory: hyperalgesia (to pinprick), allodynia (to light touch, temperature sensation, or deep somatic pressure or joint movement), or combinations of these
 - b. Vasomotor: evidence of temperature asymmetry ($>1^{\circ}\text{C}$), skin color changes or asymmetry, or combinations
 - c. Sudomotor/edema: edema, sweating changes, or sweating asymmetry
 - d. Motor/trophic: decreased range of motion, motor dysfunction (weakness, tremor, dystonia), or trophic changes (hair, skin, nails)
4. *No other diagnosis better explains the sign and symptoms.*

These criteria have no implications of etiology or pathophysiology. Tests of these criteria demonstrated lower rates of overdiagnosis with little loss of sensitivity.

Published data report that the clinical criteria result in a sensitivity of 85% and specificity of 69% and the research criteria, 70% and 96%, respectively.

Other diagnostic tests have included thermography, bone scans, and quantitative sensory testing. Schurmann et al. studied patients with acute radial fracture who met the 1994 IASP criteria and the 1999 Bruehl research criteria. They found a high specificity but low sensitivity for bone scans. Thermography demonstrated poor sensitivity and specificity. Magnetic resonance imaging (MRI) showed high specificity but poor sensitivity. Plain x-rays showed high specificity but low sensitivity with a positive predictive value of 58% and a negative predictive value of 86%. The authors suggest that these tests are not useful for screening but bone scan and MRI have high specificity; however, clinical criteria are still the gold standard.

Historically, three stages of CRPS have been described. Recent analyses have not supported this theory but have suggested three possible subtypes: (1) limited syndrome with predominance of vasomotor signs, (2) limited syndrome with predominance of neuropathic pain/sensory abnormalities, and (3) full blown CRPS with greatest degree of motor/trophic and disuse-related changes.

TREATMENT

Because the etiology of CRPS is uncertain and treatment proposals for CRPS have been untested in placebo-controlled trials but based on historic precedent and anecdotal reports, therapy is debated. Physical therapy and functional restoration have played a major role in the treatment of CRPS. Current guidelines have been developed by consensus. The focus is gradual and progressive movement and use of

the limb with increased load bearing as well as desensitization to sensory stimuli. Nerve block, psychotherapy, cognitive behavioral techniques, and pharmacotherapy are added to allow a patient to participate in occupational and physical therapy. Edema must also be addressed with active motion or special garments. The goal is to progress through desensitization, increasing flexibility, edema control, increased range of motion, stress loading, normal postures and balance, and then to normal usage, with vocational and functional rehabilitation.

Few placebo-controlled randomized trials of drug therapy for CRPS have been carried out, and current therapy is largely based on treatment of neuropathic pain. *Biphosphonates*, including clodronate and alendronate, have been shown to provide effective pain relief in placebo-controlled trials (Table 56.1) [Level 1].^{1,2} IV ketamine in anesthetic doses over 5 to 10 days has also been reported in open-label controlled trials to be effective in producing symptom reduction or remission in a subgroup of patients refractory to other therapies [Level 1].^{3,4} A study of subanesthetic doses of ketamine in refractory CRPS patient was not effective [Level 1].⁵ A recent Cochrane Review concluded that there is moderate to low quality evidence supporting its use in the treatment of CRRPS [Level 1].¹ Oral steroids (*methylprednisolone* 32 mg for 2 weeks, then tapering off for 2 weeks or *prednisone* 30 mg for 12 weeks) have been reported to be more effective than placebo, but the weight of current evidence indicates that overall there is no evidence for their effectiveness [Level 1].^{1,3} Intravenous (IV) phentolamine (0.5 g/kg) has shown no significant pain relief but sympatholytic agents (also including phenoxbenzamine and clonidine) have been used despite lack of supportive data from clinical

P.460

studies. Other treatments that have been used without clear evidence of efficacy include topical agents such as *dimethyl sulfoxide* (DMSO) and *lidocaine*, *thalidomide* (doses ranging from 50 mg twice a week to 400 mg a day), calcitonin, and *gabapentin* (600 mg titrated up to 1,800 mg a day).

TABLE 56.1 Therapies with Evidence of Efficacy for Pain Relief in Complex Regional Pain Syndrome

Strong Level of Evidence	
<i>Biphosphonates</i>	
IV Pamidronate	60 mg IV single dose
IV Alendronate	7.5 mg QD IV × 3 days
PO Alendronate	40 mg QD × 8 weeks
IV Clodronate	300 mg QD IV × 10 days
Moderate Level of Evidence	
IV Ketamine	Up to 0.35 mg/kg/hr ^a
Limited level of Evidence	

PO Tadalafil	20 mg QD × 12 weeks
IV immunoglobulin	0.4 g/kg over 5 days
IV Bretylium	1.5 mg/kg (with lidocaine 0.5 mg/kg)
Epidural clonidine	300 µg via intrathecal injection

^aInfusion can be given continuous for up to 4 days, or over 4 hours per day over 10 days.

Adapted from Complex regional pain syndrome: concise guidance to good practices. *Clin Med.* 2011;11(6):596-600.

Other recommended drugs are those used for neuropathic pain conditions such as peripheral diabetic neuropathy and postherpetic neuralgia. Antidepressants such as *amitriptyline* or *nortriptyline* (10 mg titrating up to 150 mg) with secondary consideration of *venlafaxine* (75 mg titrating up as needed to 225 mg), *duloxetine* (20 mg titrating up to 60 to 120 mg q.d.), and *bupropion* (150 to 300 mg q.d.) should be considered. Anticonvulsants beyond gabapentin may also be helpful, despite evidence supporting their use. *Carbamazepine* (50 mg titrating up to maximum of 1,600 mg q.d.) has been used as an add-on included with spinal cord stimulation in CRPS patients. Opioids may also be considered. The diversity of recommendations is a measure of the lack of efficacy.

Interventional techniques include sympathetic block for differentiating sympathetically maintained versus independent pain. There is limited evidence for the efficacy of stellate and lumbar sympathetic blocks for CRPS. IV regional anesthesia with guanethidine or reserpine has failed but bretylium and clonidine have been reported to show efficacy. Epidural infusions with a local anesthetic alone or with opioid or clonidine have all been reported to provide pain relief. Neurolytic sympathetic techniques have been used since 1889. Open surgical sympathectomy was replaced by endoscopic procedures and radiofrequency has been used. Radiofrequency ablation has been advocated.

Spinal cord stimulation improved pain and quality of life in a randomized controlled trial by Kemler et al. Intrathecal drugs have been given by implantable pump, including morphine, bupivacaine, clonidine, ziconotide, and baclofen. Intrathecal baclofen has also been used for CRPS-related dystonia. The diversity of recommended therapies is an indication that none is generally more effective than any other.

INTRODUCTION

In addition to numbness, neuropathic pain may result from damage to any level of the sensory pathway, from the small nerve fibers to the sensory cortex. This large category includes some of the most agonizing of human afflictions. This chapter reviews the normal neurologic processing of pain, the mechanisms underlying neurogenic pain, its clinical features, and the broad range of its pharmacologic therapies, with a particular emphasis on painful polyneuropathy.

DEFINITIONS

See the glossary in [Table 57.1](#).

Pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage. Pain can be classified broadly as nociceptive or neuropathic. Nociceptive pain clearly serves a protective function, warning of the presence of injury and is frequently the decisive factor prompting a patient to seek medical care. Sensitization of peripheral nociceptors and central nervous system (CNS) changes occur, protecting the damaged area, by avoiding contact. Neuropathic pain is a maladaptive pain, which results from nervous system damage and pain in the absence of nociceptor stimulation or an inappropriate response to nociceptor stimulation. Nociceptive and neuropathic pains are not synonymous with acute and chronic pain. Rheumatoid arthritis, for example, is a chronic pain, which is nociceptive. A herniated disk may acutely cause radicular pain, which is neuropathic.

TABLE 57.1 Glossary of Neuropathic Pain Terms

Allodynia: occurs when a nonnociceptive stimulus is perceived as painful

Central sensitization: an abnormal sensitivity with a spread of hypersensitivity to uninjured sites and pain resulting from stimulation of low-threshold A β mechanoreceptors. Central sensitization follows a brief high-frequency input, and the increased response to subsequent inputs may be prolonged after the high-frequency input ceases.

Neuralgia: pain in the distribution of a single peripheral nerve

Neuropathic pain: pain resulting from noninflammatory dysfunction of the peripheral nervous system or CNS, without peripheral nociceptor stimulation or trauma

Nociceptive pain: pain that is protective and arises when the process injuring tissue stimulates pain receptors.

Pain: an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage

Windup: results from repetitive C-fiber firing at low frequencies that results in a progressive buildup of the amplitude of the response of the dorsal horn neuron, only during the repetitive train

CNS, central nervous system.

Neuropathic pain is defined as pain resulting from noninflammatory dysfunction of the peripheral nervous system or CNS, without peripheral nociceptor stimulation or trauma. It must be distinguished from primary nociceptive pain, which arises when the process injuring the tissue stimulates pain receptors.

Deafferentation pain follows interruption of the primary afferent nociceptive pathways at any point, although this term most often refers to syndromes following CNS injury.

Neuropathic pain often refers to pain associated with injury to the peripheral nervous system. This general term is often used, synonymously, with *painful polyneuropathy*, although it also encompasses pain syndromes that follow focal peripheral nerve injury. *Neuralgia* refers more specifically to pain in the distribution of a single peripheral nerve.

Other clinical syndromes with neurogenic pain include the *complex regional pain syndrome* (CPRS). CPRS I was formerly known as *reflex sympathetic dystrophy*, and CPRS II was formerly *causalgia*.

Some neurogenic pain syndromes are so unique that they have individual designations, including thalamic pain syndrome, trigeminal neuralgia, and postherpetic neuralgia.

NORMAL PROCESSING OF PAIN

PERIPHERAL NOCICEPTION

Following noxious chemical, mechanical, or thermal stimulation, transduction occurs at the peripheral sensory nerve terminal through a poorly understood process, causing depolarization of the distal nerve fibers and transmission of nociceptive impulses up the sensory axons to the dorsal root ganglion (DRG) and dorsal nerve roots. Axons carrying nociceptive information are divided into three primary groups: (1) the heavily myelinated, rapidly conducting, intermediate-diameter beta fibers; (2) the finely myelinated, slower conducting, small-diameter A-delta fibers; and (3) the unmyelinated, very slowly conducting, very-small-diameter C fibers. Local factors at the site of injury may sensitize nociceptors and cause hyperalgesia, including potassium leaked from damaged cells, histamine, and bradykinin, whereas prostaglandin and leukotriene formation concurrently cause vasodilatation, local edema, and erythema.

A normally propagated nociceptive action potential may also rebound antidromically through other axonal branches at a site of injury, resulting in the release of substance P from the distal sensory nerve terminal. Substance P activates other C fibers and contributes to the release of histamine, further promoting nociception, vasodilation, and enlarging the region of hypersensitivity. Substance P also acts as a nociceptive neurotransmitter in the dorsal horn of the spinal cord, exciting the relay neurons that modulate pain transmission.

P.463

CENTRAL NOCICEPTION

Sensory axons carrying nociceptive impulses project to the spinal cord via the DRG and terminate in the dorsal horn. There, Rexed laminae I, II, and V play a role in modulating nociceptive transmission. Layer I, the marginal zone, caps the top of the dorsal horn and the A-delta nociceptors largely terminate here. Most lamina I cells are nociceptive-specific, responding only to noxious stimuli, and ultimately project to the contralateral midbrain and thalamus. The majority of C-fiber nociceptors terminate in lamina II (i.e., substantia gelatinosa). Very few

laminae-II neurons project to sites rostral to the spinal cord, instead forming interneuronal connections that modify input from the primary sensory neurons. Lamina V receives some direct input from the A-delta neurons, but the receptive fields of the neurons in this lamina are larger than those in the lamina I, suggesting more neuronal convergence at this level, and some dendrites from laminae V extend dorsally into laminae I and II. Cells in the deeper layers of the spinal cord gray matter have extremely complex receptive fields and wide areas of cutaneous input, with some input from deeper tissues.

Many nociceptive impulses ultimately pass contralaterally, across the spinal cord through the anterior commissure, to the spinothalamic tract, before ascending to brain stem targets, including the reticular formation in the rostral medulla and the periaqueductal gray matter in the dorsal midbrain. Most of the spinothalamic neurons ultimately ascend to the ventroposterolateral nucleus of the thalamus, although they may branch to provide input to these brain stem targets. However, some axons terminate solely in these bulbar regions, which then send projections to thalamic nuclei.

The periaqueductal gray matter, the reticular formation, and the raphe magnus nucleus also harbor neurons containing endorphins or having endorphin receptors. *Endorphins* are endogenous chemical transmitters whose receptors may also be activated by morphine and other exogenous narcotics; this collection of neurons is known as the *enkephalinergic system*. After synapsing in the thalamus, a final group of neurons convey primary nociceptive information through the posterior limb of the internal capsule to the postcentral gyrus. Many nociceptive axons also project to a much wider area, the full range of which has not been fully defined.

The sensation and the subjective experience of pain are produced by a complex series of interactions. Transmission of nociception in spinal neurons depends not only on input from peripheral nociceptive neurons but also on input from nonnociceptive primary afferents as well as modulation at several levels. Enkephalinergic neurons play a critical role in the modulation of nociceptive input, extending from the cortex and hypothalamus through the periaqueductal gray matter of the midbrain and the rostral medulla to the dorsal horn of the spinal cord. Nociceptive, cortical, and other inputs activate neurons in the reticular formation and the raphe magnus, which then descend to the substantia gelatinosa (Rexed lamina II) in the dorsal horn of the spinal cord, to inhibit nociceptive input from peripheral neurons, thereby diminishing pain.

Unlike the discriminative somatosensory experience, the affective component of pain varies considerably between individuals and may help explain the substantial differences in pain tolerance in the general population. Central pathways proposed as mediators of the affective experience of pain include the reticular formation and its projections to the thalamus as well as the medial thalamic nuclei and their projections to the frontal lobes. The discharge of neurons within the reticular formation correlates with escape behavior in animals, and frontal lobe lesions (e.g., frontal lobotomy) as well as bilateral medial thalamic lesions produce subjective indifference to pain in humans, despite normal somatosensory discrimination. Psychological factors, including the anxiety level, unpleasant memories of physically painful experiences, the anticipation of imminent physical injury or possible death, and others may also bear on our perception of pain. Both psychological factors and the physiologic modulation of the nociceptive impulse are influenced by changes in serotonergic activity.

PATHOBIOLOGY OF NEUROPATHIC PAIN

PERIPHERAL MECHANISMS

Transection of a peripheral nerve induces retrograde shrinkage of both myelinated and unmyelinated axons and reduced conduction velocities. Axonal sprouting from the proximal nerve stump is a normal reaction to such injury, and these sprouts grow toward the distal nerve stump in an attempt to restore axonal continuity. Within 1 to 2 days, multiple unmyelinated sprouts appear and grow from transected axons. If these sprouts fail to enter a Schwann cell tube in the distal nerve segment, they curl to form a mass containing fibrous tissue, blood vessels, clusters of unmyelinated axons, and Schwann cells, known as a *neuroma*. Division of an entire nerve trunk with

prevention of regeneration (e.g., amputation) yields a nerve-end neuroma, whereas total division with partial regeneration (e.g., surgical nerve repair) may create a neuroma-in-continuity at the site of the anastomosis. Trauma over the length of a nerve, even without transection (e.g., stretch injury), may damage small axon fascicles or individual axons at multiple levels, creating disseminated microneuromas. Neuromas may also appear following crush injury. Unfortunately, neuroma formation favors nociceptive afferents.

Neuromas are a source of both spontaneous and evoked electrical discharges, as indicated by recording from dorsal root filaments with the injured nerve at rest. These discharges increase with mechanical stimulation at the site of the neuroma and are more likely to affect sensory rather than motor or autonomic fibers. Chronic discharges, particularly, appear to originate primarily in the C fibers. Ectopic neuropacemakers remain near thresholds for repetitive firing and often generate repetitive afterdischarges following a single depolarization. This activity may be due to the high density of sodium channels, originally destined for the transected distal axon, that accumulate in the stump neuroma, enhancing sodium influx and chronically lowering the membrane potential toward the depolarization threshold. Close contact between the disorganized axonal sprouts within the neuroma may also cause current to be passed laterally from one axon to another, a short circuit called *ephaptic transmission*. Recurrent after discharges and other sustained activity may also result from the cyclic passage of current back and forth in a loop between two ephapses (i.e., *circus propagation*, as seen in some cardiac arrhythmias).

Faulty axonal regeneration and ephapse formation may also appear in nerves chronically injured by demyelination or axonal degeneration, in the absence of external trauma. Spontaneous discharges may be induced not only by mechanical stimulation but also by heat, cold, ischemia, chemical irritation, and metabolic stimuli. Mechanical stimulation may induce a burst of discharges and afterdischarges, and heating and cooling modulate discharge rates and patterns. Peptides and other neuroactive substances, especially α -adrenergic agonists, increase activity in experimental neuromas.

Ectopic pacemaker activity has been recorded in the phantom limb syndrome and may explain the hypersensitivity to heat and

P.464

cold in that syndrome. Many of the core features of painful neuropathy and neuralgia, such as spontaneous electric, burning, and aching dysesthesias and hyperesthesia, could also be related to ectopic discharges. Sensitivity to mechanical stimulation in neuralgia or compressive mononeuropathy, which may provoke pain long outlasting the inciting stimulus, may result from the repetitive discharges and afterdischarges provoked by neuroma compression.

CENTRAL MECHANISMS

Although the aforementioned peripheral mechanisms play a role in neuropathic pain, central mechanisms are also important and may predominate in chronic peripheral nerve injury. The failure of measures designed to interrupt peripheral input from the painful region to fully relieve the pain of phantom limb syndrome, including pharmacologic blockade of the damaged nerve proximal to the site of injury, dorsal rhizotomy, and even spinal and other CNS block illustrates the confounding influence of central mechanisms. After peripheral nerve injury, the aberrant rerouting of impulses within the brain and spinal cord may result in the diversion of impulses from nonnociceptive pathways to nociceptive pathways. This has been demonstrated experimentally in mapping studies of the spinal cord and brain, done before and after transection of a single peripheral nerve in one limb. Initially, the central pain pathways serving the denervated area fall silent, but electrical activity gradually resumes within a few days. Some of this activity may be induced by nonnociceptive stimulation of areas supplied by an uninjured nerve that is remote from the dermatomes supplied by the injured nerve, suggesting spread of nonnociceptive impulses from normal routes into nociceptive pathways that were previously supplied by the

injured nerve.

This phenomenon, known as *somatotopic reorganization*, could result from limited axonal sprouting over short distances within the spinal cord, and the formation of new synapses, prompted when primary sensory input is interrupted. Another explanation is that the loss of primary afferent input to a central spinal pathway following peripheral nerve injury may unmask previously quiescent synapses. These synapses, supplied by nearby spinal axons serving sensation in other regions, enable surreptitious stimulation of the denervated pathway, and produce phantom sensations, including pain.

Afferent fiber discharges may trigger cell death of neurons in the dorsal horn, where inhibitory interneurons are concentrated, possibly through an excitotoxic mechanism. This may result in increased pain transmission.

C-fiber afferents release glutamate and synapse on second-order neurons in the dorsal horn to have excitatory effects on glutamate synapses at AMPA receptors, which results in depolarization of the membrane. This depolarization releases the inhibition of the NMDA receptor by the magnesium ion, and there is an influx of calcium. Second-order neurons are gradually depolarized and responses are amplified, changing the response of neurons to subsequent input.

Two processes that are distinct occur at the dorsal horn, which are designated “windup” and “central sensitization.” Windup results from repetitive C-fiber firing at low frequencies that results in a progressive buildup of the amplitude of the response of the dorsal horn neuron, only during the repetitive train. Central sensitization is an abnormal sensitivity with a spread of hypersensitivity to uninjured sites and pain resulting from stimulation of low-threshold $A\beta$ mechanoreceptors. Central sensitization follows a brief high-frequency input, and the increased response to subsequent inputs may be prolonged, after the high-frequency input ceases. Both can be blocked by NMDA receptor antagonists. Central sensitization can result from windup. This is a result of the calcium influx through the NMDA receptor following depolarization of the dorsal horn membrane. The intracellular calcium activates a number of kinases, among which protein kinase C (PKC) is likely important. PKC enhances the NMDA receptor, which results in subsequent glutamate binding of the NMDA receptor generating an inward current. Although windup can result in central sensitization, it is not necessary for central sensitization to occur.

Similar observations were noted long ago by Denny-Brown, who described an enlarged and hypersensitive dermatomal region in primates after severance of the surrounding nerve roots distal to the DRG, compared to section proximal to the DRG. This suggested plasticity of the dorsal horn neurons secondary to input from the DRG.

Mapping CNS pathways during selective stimulation of cutaneous fields demonstrates wide-ranging synaptic inputs that reach well beyond their normal functional boundaries within the spinal cord. Similar phenomena have also been demonstrated at more rostral levels of the nervous system, including the thalamic nuclei. These phenomena could explain the phantom limb syndrome, in which a patient has the sensation that an amputated limb is still present. They may also play a role in some of the features of neuropathic pain, including the perception of one type of stimulus as another (i.e., *allosthesia*), when touch is perceived as heat, or when a nonnociceptive stimulus is perceived as painful (i.e., *allodynia*).

CLINICAL MANIFESTATIONS

Neuropathic pain is estimated to affect up to 1% of the population and is even more prevalent in the elderly. It affects 10% of people with diabetic neuropathy and is often the complication having the greatest impact on the quality of life for the patient with diabetes. The repertoire of agents effective for the control of this potentially debilitating symptom has expanded considerably in the last decade.

Trauma to the peripheral nervous system can take a variety of forms; it may be predominantly axonal or predominantly demyelinating and may disproportionately affect the sensory or motor nerves, or the small or large

nerve fibers. It may begin acutely or chronically, depending on the cause. Small-fiber dysfunction classically causes loss of temperature and pain sensation, with subjective feelings of numbness, most often starting in a distal, symmetric pattern in the feet, with gradual ascension. However, pure small-fiber injury often presents with paresthesias (e.g., tingling, cold, or burning sensations) and neuropathic pain (e.g., electric, lancinating, stabbing, or aching quality). Patients may also complain of allodynia and are particularly bothered by contact of the feet and bedsheets. Unlike large-fiber, sensory nerve injury, tendon reflexes may be preserved in these patients. The most common cause is diabetes mellitus, but the many other causes include Sjögren syndrome, alcohol or drug toxicity, HIV, hyperlipidemia, amyloidosis, Tangier disease, and Fabry disease (see [Table 87.1](#)).

Large-fiber, sensory nerve injury typically causes loss of vibration and position sense, with subjective numbness. Also, it usually begins in a distal symmetric pattern, affecting the feet and gradually ascending. With sufficient progression, it causes lower limb incoordination and unsteadiness of gait. Tendon reflexes are diminished or absent, and motor nerve involvement may produce weakness. Neuropathic pain may follow injury to the large sensory fibers, although concurrent small-fiber injury is also present in most of these

P.465

cases. Patients with symptoms suggesting painful polyneuropathy must undergo a thorough neurologic evaluation, including detailed history, physical examination, electrophysiologic studies, imaging, and serum studies (see [Chapter 87](#)). Other, nonneurogenic causes of pain must be excluded. Patients with pure small-fiber neuropathy, however, may have normal electrophysiologic studies. A skin biopsy to count epidermal nerve fiber density can be used to confirm the diagnosis (see [Fig. 87.11](#)). Epidermal nerve fiber density less than the 5th percentile of normal is considered abnormal. Treatment of these patients focuses on the cause of nerve injury, if reversible.

TREATMENT

GENERAL PRINCIPLES

Patients with neuropathic pain vary more in response to treatments than patients with other disorders and the course of neuropathic pain may be difficult to predict, with unexpected exacerbations and spontaneous remissions. The therapeutic goal of treatment is to return the patient to normal functioning, with reduction of pain to tolerable levels. The patient should understand and accept this goal at the outset and not expect complete elimination of pain. Furthermore, the patient should also understand that numbness, weakness, and other neuropathic symptoms would not be improved by these medications. Patients often benefit from physical therapy, regular exercise, and constructive activity. Refractory symptoms may lead to treatment by a multidisciplinary team in a reputable pain clinic. This team should include not only a physician specialist but also a psychiatrist or psychologist trained in pain management who may assist with analysis of the affective component of the symptoms and issues such as secondary gain as well as with conditioning and psychotherapy. Some patients may also benefit from adjunctive (i.e., complementary) biofeedback and meditation methods.

PHARMACOLOGIC THERAPY

A summary of the major drugs evaluated for the treatment of neuropathic pain, along with their efficacy, is presented in [Table 57.2](#).

Antinociceptive Agents

Unlike primary nociceptive pain, neuropathic pain is often resistant to traditional analgesic therapy, including that of NSAIDs such as ibuprofen and aspirin. Acetaminophen is generally minimally effective. Opioid analgesics are also less likely to provide chronic relief than in other pain states, although they may be useful as part of a multimodal regimen in refractory patients. They have been shown in short-term,

placebo-controlled, double-blind randomized trials to be beneficial in neuropathic pain. Physicians regularly employing opioids for the treatment of neuropathic pain should be trained in chronic use and must be vigilant in monitoring patients' patterns of drug consumption and response to avoid addictive patterns. Patients taking opioid therapy may benefit from a referral to a pain clinic for appropriate long-term monitoring and evaluation of tolerance, dependence, and drug abuse, when appropriate.

TRAMADOL HYDROCHLORIDE

Tramadol hydrochloride, unlike most other analgesics, has been proved effective for the treatment of painful neuropathy in a placebo-controlled, double-blind, randomized trial [**Level 1**].¹ It is a weak inhibitor of norepinephrine and serotonin reuptake and has low affinity for the μ -opioid receptors (i.e., approximately one-tenth the strength of codeine). The beneficial effects in neuropathic pain are attributed to serotonergic modulation of pain transmission within the brain and spinal cord. It is well-tolerated but may cause mild constipation, headache, or sedation. Therapy is usually initiated at 50 mg/day, gradually increasing on a weekly schedule to 150 to 200 mg/day, or the maximal effective dose, whichever is lower. Some relief may appear almost immediately, but maximal benefit may not be seen for 1 to 2 weeks after initiation or dosage change.

Anticonvulsants

The antiexcitatory properties of the antiepileptic drugs (AEDs) make them attractive agents for the suppression of the spontaneous neuronal discharges underlying neuropathic pain. Early trials of phenytoin gave conflicting results, but carbamazepine was effective in two placebo-controlled and one comparative study (vs. tricyclic antidepressants [TCAs]) at doses of 300 to 1,000 mg/day. Common adverse effects of carbamazepine include somnolence, dizziness, and gait disturbances, and rarely, leucopenia, hepatotoxicity, and inappropriate secretion of antidiuretic hormone. Oxcarbazepine may also be effective, with fewer side effects.

Gabapentin and pregabalin are effective AEDs for suppressing neuropathic pain, proven in placebo-controlled trials for painful diabetic neuropathy, postherpetic neuralgia, and other neuropathic pain syndromes [**Level 1**].^{2,3} They act by modulating the alpha 2 delta subunit of the calcium channel, which has been shown to be upregulated after nerve injury. Side effects are generally mild, although sedation is often a limiting factor in the elderly. Ankle swelling and weight gain occur in some patients. Initial doses of pregabalin are 150 mg/day, in two divided doses, are gradually increased to efficacy over several weeks; the slow increase may prevent excessive sedation.

Lamotrigine, a voltage-dependent sodium channel blocker, proved effective in treating the pain of HIV neuropathy and in trigeminal neuralgia but was negative in a large neuropathic pain trial [**Level 1**].⁴ In those studies demonstrating efficacy, doses of 50 to 400 mg/day were used. The most concerning side effect of lamotrigine is a Stevens-Johnson rash; to avoid the rash, a slow titration is used typically starting at 25 mg/day. Zonisamide, a sodium and T-type calcium channel blocker and enhancer of GABA release, tiagabine, and topiramate may have a role in the treatment of neuropathic pain.

Lacosamide, a medication that enhances slow inactivation of voltage-gated sodium channels, reduced diabetic neuropathy pain in double-blind, randomized, placebo-controlled trials, at a dose of 400 mg a day.

Tricyclic Antidepressants

Amitriptyline was one of the first agents proven effective for the treatment of painful neuropathy. The TCAs block serotonin and noradrenalin reuptake and modulate pain transmission within the CNS. They may also inhibit sodium channel function, and the pain relief they provide is independent of any effect on mood. Amitriptyline has been effective in numerous double-blind, placebo-controlled trials [**Level 1**].⁵ Other TCAs, such as desipramine and nortriptyline may also be effective and may sometimes work when amitriptyline does not [**Level 1**].⁶ Unfortunately, the TCAs have anticholinergic effects including sedation, orthostatic

hypotension, and urinary retention that often limit their use in diabetic and elderly subjects. Sedation during initial therapy may improve over 1 or 2 weeks.

Typical starting doses are 10 to 25 mg at bedtime, gradually increasing every 2 weeks to effect or maximally tolerated dose (i.e., not more than 150 mg/day). If no benefit appears after 4 to 6 weeks at maximally tolerated doses, another agent should be tried.

TABLE 57.2 Medications Used to Treat Neuropathic Pain

Medication	Starting Doses	Maintenance Doses	Data Supporting the Use	Selected Side Effects
Antidepressants				
Duloxetine	20-30 mg q.d.	60-120 mg/day	PCT—diabetic neuropathy	Diarrhea, nausea, dizziness
Amitriptyline	10-25 mg q.h.s.	50-150 mg/day	PCT—diabetic neuropathy	Arrhythmia, urinary retention, sexual dysfunction
Nortriptyline	10-25 mg q.h.s.	50-150 mg/day	Anecdotal reports	Less somnolence and orthostatic hypotension than amitriptyline
Venlafaxine	37.5 mg q.d.	150-375 mg/day	Anecdotal reports—neuropathy, postherpetic neuralgia	Hypertension, sexual dysfunction, nausea
Bupropion SR	150 mg q.d.	150 mg b.i.d.	PCT—neuropathic pain	Dry mouth, headache, insomnia, dizziness
Anticonvulsants				
Pregabalin	75 mg b.i.d.	150-300 mg b.i.d.	PCT—diabetic neuropathy, postherpetic neuralgia	Somnolence, fatigue, pedal edema, weight gain
Gabapentin	100 mg t.i.d.	300 mg t.i.d.-1,200 mg q.i.d.	PCT—diabetic neuropathy, postherpetic neuralgia	Somnolence, fatigue, pedal edema
Lamotrigine	25 mg q.d.	100-250 mg b.i.d.	PCT—HIV neuropathy, diabetic neuropathy	Stevens-Johnson rash

Oxcarbazepine	75 mg q.h.s.	300-1,200 mg b.i.d.	Anecdotal reports— trigeminal neuralgia	Gastrointestinal ataxia, hyponatremia, rash
Topiramate	15-25 mg q.h.s.	100-400 mg b.i.d.	Anecdotal reports— diabetic neuropathy, neuropathic pain	Somnolence, word- finding difficulties, kidney stones
Lacosamide	100 mg q.d.	400 mg q.d.	PCT—diabetic neuropathy	Dizziness, nausea
Other Medications				
Mexiletine	150 mg daily	600-1,200 mg daily	Anecdotal, subgroup analysis of PCT	Nausea/vomiting, palpitations, chest pain
Tramadol	25 mg daily	200-400 mg daily	PCT—diabetic neuropathy	Seizures, nausea, headache, constipation, somnolence
CR-oxycodone	10 mg q.d.	40 mg q.d.	PCT—diabetic neuropathy	Constipation, somnolence, nausea, dizziness, vomiting
Tapentadol ER	50 mg b.i.d.	100-250 mg b.i.d.	PCT—diabetic neuropathy [Level 1] ⁹	Constipation, somnolence, dizziness, nausea, vomiting, fatigue
Tizanidine	1 mg daily	4-36 mg daily	Open label studies in neuropathic pain	Dizziness, drowsiness, fatigue, liver damage
Methadone	5 mg daily	10-20 mg daily	PCT—neuropathic pain	Nausea, dizziness, constipation
Capsaicin 8% patch	1 patch	1 patch q12wk	PCT—postherpetic neuralgia, HIV neuropathy	Application site reactions, including increase in pain, nausea
Lidocaine patch 5%	1 patch for 12 h	1-3 patches for 12 h	PCT—postherpetic neuralgia	Application site reactions

PCT, placebo-controlled trials; SR, sustained release; CR, controlled release; ER, extended release.

Selective Serotonin Reuptake Inhibitors

Selective serotonin reuptake inhibitors (SSRIs) have not been studied as extensively as the TCAs in the

treatment of neuropathic pain. However, paroxetine and citalopram were more effective than placebo but less effective than the TCAs in treating neuropathic pain, whereas fluoxetine has not been effective in the limited studies performed thus far.

Serotonin-Norepinephrine Reuptake Inhibitors

Duloxetine is beneficial for diabetic neuropathy pain, with efficacy demonstrated in double-blind, placebo-controlled trials [**Level 1**].⁷

P.467

The typical starting dose is 20 to 30 mg/day, which is titrated up to 60 mg/day. Some patients have an improved response to 120-mg dose. Nausea and dizziness are the most common side effects. Venlafaxine is a serotonin and weak noradrenalin reuptake inhibitor that demonstrated efficacy equivalent to imipramine in a randomized trial.

Other Drugs

Both intravenous lidocaine and its oral conjoiner, mexiletine, (150 to 1,200 mg) have great potential, theoretically, for the suppression of aberrant neuronal excitation, but results have been inconsistent. The lidocaine patch delivers topical agent to an affected area, decreasing spontaneous discharge in cutaneous nerves. It may reduce regional pain in severely affected areas, such as the soles of the feet. Capsaicin (0.075%) cream, which depletes substance P from the cutaneous sensory nerves with chronic topical use, is effective. However, patients find this drug inconvenient because topical application is required three times per day. It is caustic and irritates any mucous membranes it may contact (e.g., eye and mouth, after accidental transfer from the hand during application). It also actually increases neuropathic pain during the initial 1 to 2 weeks of therapy (i.e., the early depletion phase), before producing relief. A high-concentration capsaicin (8%) patch results in prolonged pain relief with a single application for up to 12 weeks [**Level 1**].⁸

Timothy A. Pedley

INTRODUCTION

An epileptic seizure is the result of a temporary physiologic dysfunction of the brain caused by an abnormal, self-limited, and hypersynchronous electrical discharge of cortical neurons. There are many different kinds of seizures, each with characteristic behavioral changes and electrophysiologic disturbances that can usually be detected in scalp electroencephalography (EEG) recordings. The particular manifestations of any single seizure depend on several factors: whether most or only a part of the cerebral cortex is involved at the beginning, the functions of the cortical areas where the seizure originates, the subsequent pattern of spread of the electrical ictal discharge within the brain, and the extent to which subcortical and brain stem structures are engaged.

A seizure is a transient epileptic event, a symptom of disturbed brain function. Although seizures are the cardinal manifestation of epilepsy, not all seizures imply epilepsy. For example, seizures may be self-limited in that they occur only during the course of an acute medical or neurologic illness such as metabolic disarray or drug intoxication; they do not persist after the underlying disorder has resolved. Some people, for no discoverable reason, have a single unprovoked seizure. These kinds of seizures are not epilepsy.

Epilepsy is a chronic disorder, or group of chronic disorders, in which the indispensable feature is recurrence of seizures that are typically unprovoked and usually unpredictable. About 50 million people are affected worldwide. Each distinct form of epilepsy has its own natural history and response to treatment. This diversity presumably reflects the fact that epilepsy can arise from a variety of underlying conditions and pathophysiologic mechanisms, although most cases are classified as idiopathic (of presumed genetic origin) or cryptogenic (arising from a past injury that is not defined).

CLASSIFICATION OF SEIZURES AND EPILEPSY

Accurate classification of seizures and epilepsy is essential for understanding epileptic phenomena, developing a rational plan of investigation, making decisions about when and for how long to treat, choosing the appropriate antiepileptic drug (AED), and conducting scientific investigations that require delineation of clinical and EEG phenotypes.

CLASSIFICATION OF SEIZURES

The classification that is still followed today is the 1981 classification of epileptic seizures developed by the International League Against Epilepsy (ILAE; [Table 58.1](#)). This system classifies seizures by clinical symptoms supplemented by EEG data.

TABLE 58.1 International League Against Epilepsy Classification of Epileptic Seizures

I. Partial (focal) seizures

A. Simple partial seizures (consciousness not impaired)

1. With motor signs (including jacksonian, versive, and postural)

2. With sensory symptoms (including visual, somatosensory, auditory, olfactory, gustatory, and vertiginous)

3. With psychic symptoms (including dysphasia, dysmnesic, hallucinatory, and affective changes)

4. With autonomic symptoms (including epigastric sensation, pallor, flushing, pupillary changes)

B. Complex partial seizures (consciousness is impaired)

1. Simple partial onset followed by impaired consciousness

2. With impairment of consciousness at onset

3. With automatisms

C. Partial seizures evolving to secondarily generalized seizures

II. Generalized seizures of nonfocal origin (convulsive or nonconvulsive)

A. Absence seizures

1. With impaired consciousness only

2. With one or more of the following: atonic components, tonic components, automatisms, autonomic components

B. Myoclonic seizures

Myoclonic jerks (single or multiple)

C. Tonic-clonic seizures (may include clonic-tonic-clonic seizures)

D. Tonic seizures

E. Atonic seizures

III. Unclassified epileptic seizures

From the Commission on Classification and Terminology of the International League Against Epilepsy. Proposal for revised clinical and electroencephalographic classification of epileptic seizures. *Epilepsia*. 1981;22:489-501.

Inherent in the ILAE classification are two important physiologic principles. First, seizures are fundamentally of two types: those with onset limited to a part of one cerebral hemisphere (*partial* or *focal* seizures) and those that seem to involve the brain diffusely from the beginning (*generalized* seizures). Second, seizures are dynamic

P.469

and evolving; clinical expression is determined as much by the sequence of spread of electrical discharge within the brain as by the area where the ictal discharge originates. Variations in the seizure pattern exhibited by an individual imply variability in the extent and pattern of spread of the electrical discharge. Both generalized and partial seizures are further divided into subtypes. For partial seizures, the most important subdivision is based on consciousness, which is preserved in *simple* partial seizures or lost in *complex* partial seizures. Simple partial seizures may evolve into complex partial seizures, and either simple or complex partial seizures may evolve into secondarily generalized seizures. In adults, most generalized seizures have a focal onset whether or not this is apparent clinically. For generalized seizures, subdivisions are based mainly on the presence or absence and character of ictal motor manifestations.

The initial events of a seizure, described by either the patient or an observer, are usually the most reliable clinical indication to determine whether a seizure begins focally or is generalized from the moment of onset. Sometimes, however, a focal signature is lacking for several possible reasons:

1. The patient may be amnesic after the seizure, with no memory of early events.
2. Consciousness may be impaired so quickly or the seizure may generalize so rapidly that early distinguishing features are blurred or lost.
3. The seizure may originate in a brain region that is not associated with an obvious behavioral function. Thus, the seizure becomes clinically evident only when the discharge spreads beyond the ictal-onset zone or becomes generalized.

In 2010, the ILAE published a proposal for a revised classification of the epilepsies based on “terminology and concepts for organization.” As many epilepsy syndromes include both focal and generalized seizures, the classification distinguishing focal from generalized epilepsies was abandoned. In addition, a focal seizure was conceptualized as originating at some point within networks limited to one hemisphere. In contrast, a generalized seizure was conceptualized as originating at some point within, and then rapidly involving, networks distributed bilaterally. The three broad etiologic categories became genetic, structural/metabolic, and unknown, instead of cryptogenic, symptomatic, and idiopathic.

Partial Seizures

Simple partial seizures result when the ictal discharge occurs in a limited and often circumscribed area of cortex, the *epileptogenic focus*. Almost any symptom or phenomenon can be the subjective (aura) or observable manifestation of a simple partial seizure, varying from elementary motor (jacksonian seizures, adverse seizures) and unilateral sensory disturbance to complex emotional, psychoillusive, hallucinatory, or dysmnestic phenomena. Especially common auras include an epigastric rising sensation, fear, a feeling of unreality or detachment, déjà vu and jamais vu experiences, and olfactory hallucinations. Patients can interact normally with the environment during simple partial seizures except for limitations imposed by the seizure on specific localized brain functions.

Complex partial seizures, on the other hand, are defined by impaired consciousness and imply bilateral spread of the seizure discharge at least to basal forebrain and limbic areas. In addition to loss of consciousness, patients with complex partial seizures usually exhibit automatisms, such as lip smacking, repeated swallowing, clumsy perseveration of an ongoing motor task, or some other complex motor activity that is undirected and inappropriate. Postictally, patients are confused and disoriented for several minutes, and determining the

transition from ictal to postictal state may be difficult without simultaneous EEG recording. Of complex partial seizures, 70% to 80% arise from the temporal lobe; foci in the frontal and occipital lobes account for most of the remainder.

Generalized Seizures

Generalized tonic-clonic (grand mal) seizures (Video 58.1) are characterized by abrupt loss of consciousness with bilateral tonic extension of the trunk and limbs (*tonic phase*), often accompanied by a loud vocalization as air is forcibly expelled across contracted vocal cords (*epileptic cry*), followed by synchronous muscle jerking (*clonic phase*).

In some patients, a few clonic jerks precede the tonic-clonic sequence; in others, only a tonic or clonic phase is apparent. Postictally, patients are briefly unarousable and then lethargic and confused, often preferring to sleep. Many patients report inconsistent nonspecific premonitory symptoms (*epileptic prodrome*) for minutes to a few hours before a generalized tonic-clonic seizure. Common symptoms include illdefined anxiety, irritability, decreased concentration, and headache or other uncomfortable feelings; these are not auras.

Absence (petit mal) seizures are momentary lapses in awareness that are accompanied by motionless staring and arrest of any ongoing activity. Absence seizures begin and end abruptly; they occur without warning or postictal period. Mild myoclonic jerks of the eyelid or facial muscles, variable loss of muscle tone, and automatisms may accompany longer attacks. When the beginning and end of the seizure are less distinct, or if tonic and autonomic components are included, the term *atypical absence* seizure is used. Atypical absences are seen most often in children with epilepsy who are developmentally delayed or in epileptic encephalopathies, such as the Lennox-Gastaut syndrome (defined later in the chapter). *Myoclonic* seizures are characterized by rapid brief muscle jerks that can occur bilaterally, synchronously or asynchronously, or unilaterally. Myoclonic jerks range from isolated small movements of face, arm, or leg muscles to massive bilateral spasms simultaneously affecting the head, limbs, and trunk.

Atonic (astatic) seizures, (Video 58.2) also called *drop attacks*, are characterized by sudden loss of muscle tone, which may be fragmentary (e.g., head drop) or generalized, resulting in a fall. When atonic seizures are preceded by a brief myoclonic seizure or tonic spasm, an acceleratory force is added to the fall, thereby contributing to the high rate of self-injury with this type of seizure.

CLASSIFICATION OF EPILEPSY (EPILEPTIC SYNDROMES)

Attempting to classify the kind of epilepsy a patient has is often more important than describing seizures because the formulation includes other relevant clinical information of which the seizures are only a part. The other data include historical information (e.g., a personal history of brain injury or family history of first-degree relatives with seizures); findings on neurologic examination; and results of EEG, brain imaging, and biochemical studies.

The ILAE classification separates major groups of epilepsy first on the basis of whether seizures are partial (*localization-related epilepsies*) or generalized (*generalized epilepsies*) and second by cause (*idiopathic, symptomatic, or cryptogenic epilepsy*). Subtypes of epilepsy are grouped according to the patient's age and, in the case of localization-related epilepsies, by the anatomic location of the presumed ictal-onset zone.

Classification of the epilepsies has been less successful and more controversial than the classification of seizure types. A basic problem is that the classification scheme is empiric, with clinical and EEG data traditionally emphasized over anatomic, pathologic,

P.470

or specific etiologic information. This classification is useful for some reasonably well-defined syndromes, such as *infantile spasms* or *benign partial childhood epilepsy with central-midtemporal spikes*, especially because of the prognostic and treatment implications of these disorders. On the other hand, few epilepsies imply a specific

disease or defect. A further drawback to the ILAE classification is that the same epileptic syndrome (e.g., infantile spasms or Lennox-Gastaut syndrome) may be “symptomatic” of a specific disease (e.g., tuberous sclerosis), considered “cryptogenic” on the basis of nonspecific imaging abnormalities, or categorized as “idiopathic.” Another biologic incongruity is the excessive detail in which some syndromes are identified, with specific entities culled from what are more likely simply different biologic expressions of the same abnormality (e.g., childhood and juvenile forms of absence epilepsy). As a result, a new classification of epilepsy syndromes has been proposed and is presently under discussion (Engel, 2006).

With the foregoing reservations, there is little question that defining common epilepsy syndromes has practical value. [Table 58.2](#) gives a modified version of the current ILAE classification.

TABLE 58.2 Modified Classification of Epileptic Syndromes

I. Idiopathic epilepsy syndromes (focal or generalized)

A. Benign neonatal convulsions

1. Familial

2. Nonfamilial

B. Benign childhood epilepsy

1. With central-midtemporal spikes

2. With occipital spikes

C. Childhood/juvenile absence epilepsy

D. Juvenile myoclonic epilepsy (including generalized tonic-clonic seizures on awakening)

E. Idiopathic epilepsy, otherwise unspecified

II. Symptomatic epilepsy syndromes (focal or generalized)

A. West syndrome (infantile spasms)

B. Lennox-Gastaut syndrome

C. Early myoclonic encephalopathy

D. Epilepsia partialis continua

1. Rasmussen syndrome (encephalitic form)

2. Restricted form

E. Acquired epileptic aphasia (Landau-Kleffner syndrome)

F. Temporal lobe epilepsy

G. Frontal lobe epilepsy

H. Posttraumatic epilepsy

I. Other symptomatic epilepsy, focal or generalized, not specified

III. Other epilepsy syndromes of uncertain or mixed classification

A. Neonatal seizures

B. Febrile seizures

C. Reflex epilepsy

D. Other unspecified

SELECTED GENERALIZED EPILEPSY SYNDROMES

INFANTILE SPASMS (WEST SYNDROME)

The term *infantile spasms* denotes a unique age-specific form of generalized epilepsy that may be either idiopathic or symptomatic. When all clinical data are considered, including results of imaging studies, only about 15% of patients are now classified as idiopathic. Symptomatic cases result from diverse conditions, including cerebral dysgenesis, tuberous sclerosis, phenylketonuria, intrauterine infections, or hypoxic-ischemic injury.

Seizures are characterized by sudden flexor or extensor spasms that simultaneously involve the head, trunk, and limbs. The attacks usually begin before 6 months of age. The EEG is grossly abnormal, showing chaotic high-voltage slow activity with multifocal spikes, a pattern termed *hypsarrhythmia*. The treatment of choice is corticotropin or prednisone; spasms are notoriously refractory to conventional AEDs. Exceptions are topiramate and zonisamide, which have been shown to be an effective alternative to corticotropin in selected cases. Vigabatrin is also effective, especially in children with tuberous sclerosis. Patients on this drug must be monitored for visual field deficits. Although treatment with corticotropin, vigabatrin, zonisamide, or topiramate usually controls spasms and reverses the EEG abnormalities, it has little effect on long-term prognosis. Only about 5% to 10% of children with infantile spasms have normal or near-normal intelligence, and more than 66% have severe disabilities.

CHILDHOOD ABSENCE (PETIT MAL) EPILEPSY

This disorder begins most often between the ages of 4 and 12 years and is characterized predominantly by recurrent absence seizures, which, if untreated, can occur literally hundreds of times each day. EEG activity during an absence attack is characterized by stereotyped, bilateral, 3-Hz spike-wave discharges. Generalized tonic-clonic seizures also occur in 30% to 50% of cases. Most children are normal, both neurologically and

intellectually. Ethosuximide and valproate are equally effective in treating absence seizures, but valproate or lamotrigine are preferable if generalized tonic-clonic seizures coexist. Topiramate, levetiracetam, and zonisamide may also be effective in generalized-onset seizures.

LENNOX-GASTAUT SYNDROME

This term is applied to a heterogeneous group of childhood epileptic encephalopathies that are characterized by mental retardation, uncontrolled seizures, and a distinctive EEG pattern. The syndrome is not a pathologic entity because clinical and EEG manifestations result from brain malformations, perinatal asphyxia, severe head injury, central nervous system (CNS) infection, or, rarely, a progressive degenerative or metabolic syndrome. A presumptive cause can be identified in 65% to 70% of affected children. Seizures usually begin before age 4 years, and about 25% of children have a history of infantile spasms. No treatment is consistently effective, and 80% of children continue to have seizures as adults. Best results are generally obtained with broad-spectrum AEDs, such as valproate, clobazam, lamotrigine, topiramate, or zonisamide. Rufinamide may be particularly effective for atonic seizures associated with this syndrome. Despite the higher incidence of severe side effects, felbamate is often effective when these other agents do not result in optimal seizure control. Refractory cases may be considered for vagus nerve stimulation or anterior corpus callosotomy. Both of these are palliative procedures, and complete seizure control is rare.

P.471

JUVENILE MYOCLONIC EPILEPSY

The juvenile myoclonic epilepsy (JME) subtype of idiopathic generalized epilepsy most often begins in otherwise healthy individuals between the ages of 8 and 20 years. The fully developed syndrome comprises morning myoclonic jerks, generalized tonic-clonic seizures that occur just after waking, normal intelligence, a family history of similar seizures, and an EEG that shows generalized spikes, 4- to 6-Hz spike waves, and multiple spike (polyspike) discharges. The myoclonic jerks vary in intensity from bilateral massive spasms and falls to minor isolated muscle jerks that many patients consider nothing more than “morning clumsiness.” Linkage studies have produced conflicting results with different groups reporting susceptibility loci on chromosomes 6p, 5q, and 15q. A mutation in the α -1 subunit of the γ -aminobutyric acid (GABA)_A receptor has been found in a large French Canadian family with JME but not in individuals with the common sporadic form of JME. Valproate is the treatment of choice and controls seizures and myoclonus in more than 80% of cases. Lamotrigine, zonisamide, levetiracetam, and topiramate can be equally effective in many patients, although lamotrigine sometimes exacerbates myoclonus.

SELECTED LOCALIZATION-RELATED EPILEPSY SYNDROMES

BENIGN FOCAL EPILEPSY OF CHILDHOOD

Several “benign” focal epilepsies occur in children, of which the most common is the syndrome associated with central-midtemporal spikes on EEG. This form of idiopathic focal epilepsy, also known as *benign rolandic epilepsy*, accounts for about 15% of all pediatric seizure disorders.

Onset is between 4 and 13 years of age; children are otherwise normal. Most children have attacks mainly or exclusively at night. Sleep promotes secondary generalization, so that parents report only generalized tonic-clonic seizures; any focal manifestations go unobserved. In contrast, seizures that occur during the day are clearly focal, with twitching of one side of the face; speech arrest; drooling from a corner of the mouth; and paresthesias of the tongue, lips, inner cheeks, and face. Seizures may progress to include clonic jerking or tonic posturing of the arm and leg on one side. Consciousness is usually preserved.

The interictal EEG abnormality is distinctive and shows stereotyped diphasic or triphasic sharp waves over the

central-midtemporal (rolandic) regions. Discharges may be unilateral or bilateral. They increase in abundance during sleep and, when unilateral, switch from side to side on successive EEGs. In about 30% of cases, generalized spike-wave activity also occurs. The EEG pattern is inherited as an autosomal dominant trait with age-dependent penetrance. The inheritance pattern of the seizures, although clearly familial, is probably multifactorial and less well understood. More than half the children who show the characteristic EEG abnormality never have clinical attacks. Linkage has been reported in some families to chromosome 15q14.

The prognosis is uniformly good. Seizures disappear by mid to late adolescence in all cases. Seizures in many children appear to be self-limited, and not all children need AED treatment. Treatment can usually be deferred until after the second or third attack. Because seizures are easily controlled and self-limited, drugs with the fewest adverse effects, such as carbamazepine, oxcarbazepine, or gabapentin, should be used. Low doses, often producing subtherapeutic blood concentrations, are generally effective. Polytherapy should be avoided.

TEMPORAL LOBE EPILEPSY

This is the most common epilepsy syndrome of adults. In most cases, the epileptogenic region involves mesial temporal lobe structures, especially the hippocampus, amygdala, and parahippocampal gyrus. Seizures usually begin in late childhood or adolescence, and a history of febrile seizures is common. Virtually all patients have complex partial seizures, some of which secondarily generalize. Auras are frequent; visceral sensations are particularly common. Other typical behavioral features include a motionless stare, loss of awareness that may be gradual, and oral-alimentary automatisms, such as lip smacking (Video 58.3). A variable but often prolonged period of postictal confusion is the rule. Interictal EEGs show focal temporal slowing and epileptiform sharp waves or spikes over the anterior temporal region. AEDs are usually successful in suppressing secondarily generalized seizures, but most patients continue to have partial attacks. When seizures persist, anterior temporal lobe resection or selective amygdalohippocampectomy is the treatment of choice. For appropriate patients with mesial temporal sclerosis, ablation with laser or Gamma Knife has also been used, although it is not known whether these are as effective as more traditional resection in the long term. The results of a randomized controlled trial comparing seizure outcomes in patients treated either medically or surgically were striking: 58% of surgically treated patients were seizure free at 1 year compared with 8% of medically treated patients. Other series have shown that temporal lobe resection for refractory medial temporal lobe epilepsy associated with hippocampal sclerosis results in complete seizure control for at least 1 year in over 80% of patients. More controversial is the need for long-term anticonvulsant drug treatment after successful operation; a minority of patients may relapse several years later.

FRONTAL LOBE EPILEPSY

The particular pattern of the many types of frontal lobe seizures depends on the specific location where the seizure discharge originates and on the pathways subsequently involved in propagation. Despite this variability, the following features, when taken together, suggest frontal lobe epilepsy:

1. Brief seizures that begin and end abruptly with little, if any, postictal period
2. A tendency for seizures to cluster and to occur at night
3. Prominent, but often bizarre, motor manifestations, such as asynchronous thrashing or flailing of arms and legs; pedaling leg movements; pelvic thrusting; and loud, sometimes obscene, vocalizations, all of which may suggest psychogenic seizures (Video 58.4)
4. Minimal abnormality on scalp EEG recordings
5. A history of status epilepticus

Frontal lobe epilepsy occurs in some families as an autosomal dominant syndrome. In these patients, seizures

almost always occur during sleep. Most patients respond well to medication.

POSTTRAUMATIC SEIZURES

Seizures occur within 1 year in about 7% of civilian and in about 34% of military head injuries. The differences relate mainly to the much higher proportion of penetrating wounds in military cases. The risk of developing posttraumatic epilepsy is directly related to the severity of the injury and also correlates with the total volume of brain lost as measured by computed tomography (CT). Depressed skull fractures may or may not be a risk; the rate of posttraumatic epilepsy was 17% in one series but not increased above control

P.472

levels in another. Head injuries are classified as *severe* if they result in brain contusion, intracerebral or intracranial hematoma, unconsciousness, or amnesia for more than 24 hours or in persistent neurologic abnormalities, such as aphasia, hemiparesis, or dementia. *Mild* head injury (brief loss of consciousness, no skull fracture, no focal neurologic signs, no contusion or hematoma) does not increase the risk of seizures significantly above general population rates.

Nearly 60% of those who have seizures have the first attack in the first year after the injury. In the Vietnam Head Injury Study, however, more than 15% of patients did not have epilepsy until 5 or more years later. Posttraumatic seizures are classified as *early* (within the first 1 to 2 weeks after injury) or *late*. Only recurrent late seizures (those that occur after the patient has recovered from the acute effects of the injury) should be considered *posttraumatic epilepsy*. Early seizures, however, even if isolated, increase the chance of developing posttraumatic epilepsy. About 70% of patients have partial or secondarily generalized seizures. *Impact seizures* occur at the time of or immediately after the injury. These attacks are attributed to an acute reaction of the brain to trauma and do not increase the risk of later epilepsy.

Overt seizures should be treated according to principles reviewed later in this chapter. The most controversial issue concerns the prophylactic use of AEDs to retard or abort the development of subsequent seizures. Based on the data of Temkin et al. (1990), we recommend treating patients with severe head trauma, as just defined, with an antiepileptic medication for the first week after injury to minimize complications from seizures occurring during acute management. If seizures have not occurred, we do not continue medication beyond the initial 1 to 2 weeks because evidence does not show that longer treatment prevents the development of later seizures or of posttraumatic epilepsy. Data suggest that valproate is less effective than phenytoin in suppressing acute seizures and is also ineffective in preventing the development of posttraumatic epilepsy.

EPILEPSIA PARTIALIS CONTINUA

Epilepsia partialis continua (EPC) refers to unremitting motor seizures involving part or all of one side of the body. They typically consist of repeated clonic or myoclonic jerks that may remain focal or regional or may march from one muscle group to another, with the extent of motor involvement waxing and waning in endless variation (Video 58.5). In adults, EPC occurs in diverse settings, such as with subacute or chronic inflammatory diseases of the brain (Kozhevnikov Russian spring-summer encephalitis, Behçet disease) or with acute strokes, metastases, and metabolic encephalopathies, especially hyperosmolar nonketotic hyperglycemia.

The most distinctive form of EPC, known as the *Rasmussen syndrome*, occurs in children; it usually begins before the age of 10 years. The underlying disorder is chronic focal encephalitis, although an infectious agent has not been identified consistently. About two-thirds of patients report an infectious or inflammatory illness 1 to 6 months before onset of EPC. Generalized tonic-clonic seizures are often the first sign and appear before the EPC establishes itself. About 20% of cases begin with an episode of convulsive status epilepticus. Slow neurologic deterioration inevitably follows, with development of hemiparesis, mental impairment, and, usually, hemianopia. If the dominant hemisphere is affected, aphasia occurs. EEGs are always abnormal, but findings are not specific, and they frequently do not correlate with clinical manifestations. Magnetic resonance imaging (MRI)

may be normal early but later shows unilateral cortical atrophy and signal changes consistent with gliosis. Autoantibodies to the GluR3 protein of the glutamate receptor have been found in some patients, suggesting that autoimmunity may play a role in the pathogenesis of the disorder in some patients, and immunotherapy is sometimes beneficial. AEDs are usually ineffective in controlling seizures and preventing progression of the disease, as are corticosteroids and antiviral agents. When seizures have not spontaneously remitted by the time there is a severe degree of hemiparesis, functional hemispherectomy can control seizures and leads to substantial intellectual improvement in many patients. Controversy arises in the decision about the best time for hemispherectomy, for example, whether it should be performed earlier before there is serious motor or language impairment.

EPIDEMIOLOGY

In the United States, about 6.5 persons per 1,000 population are affected with recurrent unprovoked seizures, so-called active epilepsy. Based on 1990 census figures, age-adjusted annual incidence rates for epilepsy range from 31 to 57 per 100,000 in the United States (Fig. 58.1). Incidence rates are highest among young children and the elderly; epilepsy affects males 1.1 to 1.5 times more often than females.

Complex partial seizures are the most common seizure type among newly diagnosed cases, but age-related variability occurs in the proportions of different seizure types (Fig. 58.2). The cause of epilepsy also varies somewhat with age. Despite advances in diagnostic capabilities, however, the “unknown” etiologic category remains larger than any other for all age groups (Fig. 58.3). Cerebrovascular disease, associated developmental neurologic disorders (e.g., cerebral palsy and mental retardation), and head trauma are the other most commonly identified causes.

Although defined genetic disorders account for only about 1% of epilepsy cases, heritable factors are important. Monozygotic twins have a much higher concordance rate for epilepsy than do dizygotic twins. By age 25 years, nearly 9% of children of mothers with epilepsy and 2.4% of children of affected fathers develop epilepsy. The reason for an increased risk of seizures in children of women with epilepsy is not known.

Some forms of epilepsy are more heritable than others. For example, children of parents with absence seizures have a higher risk of developing epilepsy (9%) than do offspring of parents with other types of generalized seizures or partial seizures (5%). As a general rule, though, even offspring born to a high-risk parent have a 90% or greater chance of being unaffected by epilepsy.

FIGURE 58.1 Age-specific incidence of epilepsy in Rochester, Minnesota, 1935-1984. (From Hauser WA, Annegers JF, Kurland LT. Incidence of epilepsy and unprovoked seizures in Rochester, Minnesota: 1935-1984. *Epilepsia*. 1993;34(3): 453-468.)

FIGURE 58.2 Proportion of seizure types in newly diagnosed cases of epilepsy in Rochester, Minnesota, 1935-1984. (From Hauser WA, Annegers JF, Kurland LT. Incidence of epilepsy and unprovoked seizures in Rochester, Minnesota: 1935-1984. *Epilepsia*. 1993;34(3):453-468.)

Many persons who experience a first unprovoked seizure never have a second. By definition, these people do not have epilepsy and generally do not require long-term drug treatment. Unfortunately, our ability to identify such individuals with accuracy is imperfect. Treatment decisions must be based on epidemiologic and individual considerations. Some seizure types, such as absence and myoclonic, are virtually always recurrent by the time

the patient is seen by a physician. On the other hand, patients with convulsive seizures may seek medical attention after a first occurrence because of the dramatic nature of the attack. Prospective studies of recurrence after a first seizure indicate a 2-year recurrence risk of about 40%, which is similar in children and adults. The risk is lowest in people with an idiopathic generalized first seizure and normal EEG (about 24%), higher with idiopathic generalized seizures and an abnormal EEG (about 48%), and highest with symptomatic (i.e., known preceding brain injury or neurologic syndrome) seizures and an abnormal EEG (about 65%). Epileptiform, but not nonepileptiform, EEG abnormalities impart a greater risk for recurrence. If the first seizure is a partial seizure, the relative risk of recurrence is also increased. The risk for further recurrence after a second unprovoked seizure is greater than 80%; a second unprovoked seizure is, therefore, a reliable marker of epilepsy.

FIGURE 58.3 Etiology of epilepsy in all cases of newly diagnosed seizures in Rochester, Minnesota, 1935-1984. (From Hauser WA, Annegers JF, Kurland LT. Incidence of epilepsy and unprovoked seizures in Rochester, Minnesota: 1935-1984. *Epilepsia*. 1993;34(3):453-468.)

About 4% of persons living to age 74 years have at least one unprovoked seizure. When provoked seizures (i.e., febrile seizures or those related to an acute illness) are included, the likelihood of experiencing a seizure by age 74 years increases to at least 9%. The risk of developing epilepsy is about 3% by age 74 years.

Of persons with epilepsy, 60% to 70% achieve remission of seizures with AED therapy. Factors that favor remission include an idiopathic (or cryptogenic) form of epilepsy, normal findings on neurologic examination, and onset in early to middle childhood (except neonatal seizures). Unfavorable prognostic factors include partial seizures, an abnormal EEG, and associated mental retardation or cerebral palsy (Table 58.3). Those who fail to achieve remission have drug-resistant epilepsy and may be candidates for alternative therapies, including surgery or devices as well as additional drug treatment. Drug-resistant epilepsy is defined by the ILAE as “failure of adequate trials of two tolerated and appropriately used antiepileptic drugs to achieve sustained seizure freedom.”

Frequent generalized seizures

Failure to achieve control readily

Evidence of brain damage

A specific cause of the seizures

Severe EEG abnormality

Low IQ

Atonic atypical absence seizures

EEG, electroencephalogram.

Mortality is increased in persons with epilepsy, but the risk is incurred mainly by symptomatic cases in which higher death rates are related primarily to the underlying disease rather than to epilepsy. Accidental deaths, especially drowning, are more common, however, in all patients with epilepsy. Sudden unexplained death is nearly 25 times more common in patients with epilepsy than in the general population; estimates of incidence rates range from 1 in 500 to 1 in 2,000 per year. Severe epilepsy, uncontrolled generalized convulsions, especially nocturnal, and need for multiple AEDs are risk factors.

INITIAL DIAGNOSTIC EVALUATION

The diagnostic evaluation has three objectives: to determine if the patient has epilepsy; to classify the type of epilepsy and identify an epilepsy syndrome, if possible; and to define the specific underlying cause. Accurate diagnosis leads directly to proper treatment and formulation of a rational plan of management. The differential diagnosis is considered in Section II, Chapter 5.

Because epilepsy comprises a group of conditions and is not a single homogeneous disorder and because seizures may be symptoms of both diverse brain disorders and an otherwise normal brain, it is neither possible nor desirable to develop inflexible guidelines for what constitutes a standard or minimal diagnostic evaluation. The clinical data from the history and physical examination should allow a reasonable determination of probable diagnosis, seizure and epilepsy classification, and likelihood of underlying brain disorder. Based on these considerations, diagnostic testing should be undertaken selectively.

FIGURE 58.4 Risk factors for epilepsy. ^aRelative to people without these adverse exposures. ^bNot statistically significant. ^cOne pint of 80 proof, 2.5 bottles of wine. (From Hauser WA, Hesdorffer DC. *Epilepsy: Frequency, Causes and Consequences*. New York: Demos; 1990.)

HISTORY AND EXAMINATION

A complete history is the cornerstone for establishing a diagnosis of epilepsy. Because patients frequently have no or only limited recall of their attacks, it is important to obtain additional information from family members or friends who have witnessed seizures. An adequate history should provide a clear picture of the clinical features of the seizures and the sequence in which manifestations evolve; the course of the epileptic disorder; seizure precipitants, such as alcohol or sleep deprivation; risk factors for seizures, such as abnormal gestation, febrile seizures, family history of epilepsy, head injury, encephalitis or meningitis, and stroke; and response to previous treatment. In children, developmental history is important.

In describing the epileptic seizure, care should be taken to elicit a detailed description of any aura. The aura was once considered to be the warning of an impending attack, but it is actually a simple partial seizure made apparent by subjective feelings or experiential phenomena observable only by the patient. Auras precede many complex partial or generalized seizures and are experienced by 50% to 60% of adults with epilepsy. Auras confirm the suspicion that the seizure begins locally within the brain; they may also provide direct clues about the location or laterality of the focus. Information about later events in the seizure usually are obtained from an observer because of the patient's impaired awareness or frank loss of consciousness or because of postictal amnesia, even though responses to questions during the seizure indicate preserved responsiveness.

The nature of repetitive automatic or purposeless movements (automatisms), sustained postures, presence of myoclonus, and the duration of the seizure help to delineate specific seizure types or epileptic

syndromes. Nonspecific postictal findings of lethargy and confusion must be distinguished from focal neurologic abnormalities, such as hemiparesis or aphasia, which could point to the hemisphere of seizure onset.

Information about risk factors (Fig. 58.4) may suggest a particular cause and assist in prognosis. In addition to these risk factors, migraines with auras and depression have been reported to be independent risk factors for unprovoked seizures. Discussion of risk factors with parents may be necessary because children or adults

P.475

may be uninformed about, or may not recall, early childhood events, such as perinatal encephalopathy, febrile seizures, brain infections, head injuries, or intermittent absence seizures. Age at seizure onset and course of the seizure disorder should be clarified because these features differ in the various epilepsy syndromes.

Findings on neurologic examination are usually normal in patients with epilepsy but occasionally may provide etiologic clues. Focal signs indicate an underlying cerebral lesion. Asymmetry of the hand or face may indicate localized or hemispheric cerebral atrophy contralateral to the smaller side. Phakomatoses are commonly associated with seizures and are suggested by café au lait spots, facial angioma, conjunctival telangiectasia, hypopigmented macules, fibroangiomatous nevi, or lumbosacral shagreen patches.

ELECTROENCEPHALOGRAPHY

Because epilepsy is fundamentally a physiologic disturbance of brain function, the EEG is the most important laboratory test in evaluating patients with seizures. The EEG helps both to establish the diagnosis of epilepsy and to characterize specific epileptic syndromes. EEG findings may also help in management and in prognosis.

Epileptiform discharges (spikes and sharp waves) are highly correlated with seizure susceptibility and can be recorded on the first EEG in about 50% of patients. Similar findings are recorded in only 1% to 2% of normal adults and in a somewhat higher percentage of normal children. When multiple EEGs are obtained, epileptiform abnormalities eventually appear in 60% to 90% of adults with epilepsy, but the yield of positive studies does not increase substantially after three or four tests. Prolonged ambulatory or inpatient recordings increase the yield of interictal epileptiform abnormalities both because of the longer sampling times but also because complete sleep-wake cycles are included. It is important to remember, therefore, that 10% to 40% of patients with epilepsy do not show epileptiform abnormalities on routine EEG. Thus, a normal or nonspecifically abnormal EEG never excludes the diagnosis. Sleep, hyperventilation, photic stimulation, and special electrode placements are routinely used to increase the probability of recording epileptiform abnormalities. Different and distinctive patterns of epileptiform discharge occur in specific epilepsy syndromes as summarized in Chapter 25.

FIGURE 58.5 Mesial temporal sclerosis. **A,B:** Short-tau inversion recovery (STIR) coronal magnetic resonance images through the temporal lobes show increased signal and decreased size of right hippocampus as compared with left. These findings are characteristic of mesial temporal sclerosis. Note incidental focal dilatation of left choroid fissure, which represents a choroid fissure cyst and is a normal variant. (Courtesy of Dr. S. Chan, Columbia University College of Physicians and Surgeons, New York, NY.)

BRAIN IMAGING

MRI should be performed in all patients older than age 18 years and in children with abnormal development, abnormal findings on physical examination, or seizure types that are likely to be manifestations of symptomatic epilepsy. CT will often miss common epileptogenic lesions such as hippocampal sclerosis, cortical dysplasia, and cavernous malformations. Because CT is very sensitive for detecting brain calcifications, a noncontrast CT (in addition to MRI) may be helpful in patients at risk for neurocysticercosis.

Routine imaging is not necessary for children with idiopathic epilepsy, including the benign focal epilepsy syndromes (see [section “Benign Epilepsy Syndromes”](#)). Brain MRI, although more costly, is more sensitive than CT in detecting potentially epileptogenic lesions, such as cortical dysplasia, hamartomas, differentiated glial tumors, and cavernous malformations. Both axial and coronal planes should be imaged using both T1 and T2 sequences. Gadolinium injection does not increase the sensitivity for detecting cerebral lesions but may assist in differentiating possible causes.

Imaging in the coronal plane perpendicular to the long axis of the hippocampus and other variations in technique have improved the detection of hippocampal atrophy and gliosis, findings that are highly correlated with mesial temporal sclerosis ([Fig. 58.5](#)) and an epileptogenic temporal lobe. An even more sensitive measure of hippocampal atrophy is MRI measurement of the volume of the hippocampus. Hippocampal volume measurements in an individual patient then can be compared with those of normal control subjects. In patients being considered for surgery, interictal

P.476

positron emission tomography (PET) scans can add valuable localizing information, especially when the MRI scan is negative. Singlephoton emission computed tomography (SPECT) scans are also used, although resolution is less than either MRI or PET. Subtraction ictal SPECT co-registered with MRI (SISCOM) is also

helpful in localizing the epileptogenic brain region in some cases.

OTHER LABORATORY TESTS

Routine blood tests are necessary in newborns and in older patients with acute or chronic systemic disease to detect abnormal electrolyte, glucose, calcium, or magnesium values or impaired liver or kidney function that may contribute to seizure occurrence. They are rarely diagnostically useful in healthy children or adults. Serum electrolytes, liver function tests, and a complete blood count (CBC) should be obtained when infectious or metabolic abnormalities are suspected, but they are useful mainly as baseline studies before initiating AED treatment.

Any suspicion of meningitis or encephalitis mandates lumbar puncture. Urine or blood toxicologic screens should be considered when otherwise unexplained new-onset generalized seizures occur.

LONG-TERM MONITORING

The most direct and convincing evidence of an epileptic basis for a patient's episodic symptoms is the electrographic recording of a seizure discharge during a typical behavioral attack. Such recordings are especially necessary if the history is ambiguous, EEGs are repeatedly normal or nonspecifically abnormal, and reasonable treatment has failed. Because most patients have seizures infrequently, routine EEG rarely records an attack. Long-term monitoring permits continuous EEG recording for extended periods, thus increasing the likelihood of recording seizures or interictal epileptiform discharges. Two methods of long-term monitoring are now widely available: simultaneous closed-circuit television (CCTV) and EEG (CCTV/EEG) monitoring and ambulatory EEG. Both have greatly improved diagnostic accuracy and the reliability of seizure classification, and both provide continuous recordings through one or more complete sleep-wake cycles, which increases the likelihood of capturing actual ictal events. Each has its own specific advantages and disadvantages. The method chosen depends on the question posed by a particular patient. Long-term monitoring using CCTV/EEG, usually in a specially designed hospital unit, is the procedure of choice to document psychogenic seizures and other nonepileptic paroxysmal events. It can also establish electrical-clinical correlations, confirm seizure type, and direct further treatment including the localization of epileptogenic foci for possible resective surgery. The emphasis in monitoring units is usually on behavioral events, not interictal EEG activity. The availability of full-time technical or nursing staff ensures high-quality recordings and permits examination of patients during clinical events. AEDs can be discontinued safely to facilitate seizure occurrence. Computerized detection programs are used to screen EEG continuously for epileptiform abnormalities and subclinical seizures.

Ambulatory EEG is another method for long-term monitoring that is designed for outpatient use in the patient's home, school, or work environment. This is often especially helpful in evaluating children who are usually more comfortable in their familiar and unrestricted home environments. The major limitations of ambulatory monitoring are the variable technical quality resulting from lack of expert supervision and maintenance of electrode integrity, frequent distortion of EEG data by environmental contaminants, and the absence of video documentation of behavioral changes. Ambulatory monitoring is most useful in documenting interictal epileptiform activity when routine EEGs have been repeatedly negative or in recording ictal discharges during typical behavioral events. It may also reveal the presence of unrecognized electrographic seizures (particularly absences) if frequent. At the present time, however, ambulatory EEG is not a substitute for CCTV/EEG monitoring, especially when psychogenic seizures are an issue or when patients are being evaluated for epilepsy surgery.

MEDICAL TREATMENT

Therapy of epilepsy has three goals: (1) to eliminate seizures or reduce their frequency to the maximum extent possible, (2) to avoid side effects associated with long-term treatment, and (3) to assist the patient in maintaining or restoring normal psychosocial and vocational adjustment. No medical treatment now available can induce a permanent remission (“cure”) or prevent development of epilepsy by altering the process of epileptogenesis.

The decision to institute AED therapy should be based on a thoughtful and informed analysis of the issues involved. Isolated infrequent seizures, whether convulsive or not, probably pose little medical risk to otherwise healthy persons. However, even relatively minor seizures, especially those associated with loss or alteration of alertness, can be associated with many psychosocial, vocational, and safety ramifications. Finally, the probability of seizure recurrence varies substantially among patients, depending on the type of epilepsy and any associated neurologic or medical problems. Drug treatment, on the other hand, carries a risk of adverse effects, which approaches 30% after initial treatment. Treatment of children raises additional issues, especially the unknown effects of long-term AED use on brain development, learning, and behavior. These considerations mean that although drug treatment is indicated and is beneficial for most patients with epilepsy, certain circumstances call for AEDs to be deferred or used only for a limited time. As a rule of thumb, AEDs should be prescribed when the potential benefits of treatment clearly outweigh possible adverse effects of therapy.

ACUTE SYMPTOMATIC SEIZURES

These seizures are caused by, or associated with, an acute medical or neurologic illness (see [Chapter 6](#)). A childhood febrile seizure is the most common example of an acute symptomatic seizure, but other frequently encountered causes include metabolic or toxic encephalopathies, head trauma, and acute brain infections. Prophylactic phenytoin has been shown to reduce the frequency of seizures in patients with severe traumatic brain injury from 14% to 4% during the first week after injury [**Level 1**].² To the extent that these conditions resolve without permanent brain damage, seizures are usually self-limited. The primary therapeutic concern in such patients should be identification and treatment of the underlying disorder. If AEDs are needed to suppress seizures acutely, they generally do not need to be continued after the patient recovers.

THE SINGLE SEIZURE

About 25% of patients with unprovoked seizures come to a physician after a single attack, nearly always a generalized tonic-clonic seizure. Most of these people have no risk factors for epilepsy, have normal findings on neurologic examination, and have a normal first EEG. Only about 25% of such patients later develop epilepsy. For this group, the need for treatment is questionable. For many years,

P.477

no convincing data indicated any beneficial effect of treatment on preventing recurrence. In 1993, a large multicenter randomized study from Italy convincingly demonstrated that AEDs reduce the risk of relapse after the first unprovoked convulsive seizure. Among nearly 400 children and adults, treatment within 7 days of a first seizure was followed by a recurrence rate of 25% at 2 years. In contrast, untreated patients had a recurrence rate of 51%. When patients with previous “uncertain spells” were excluded from the analysis, treatment benefit was still evident, but the magnitude of the effect was reduced to a recurrence rate of 30% in the treated group and 42% in untreated patients.

Although treatment of first seizures reduces the relapse rate even in low-risk patients, there is no evidence that such treatment alters long-term prognosis. In 2015, a new evidence-based guideline for management of adults with a first unprovoked seizure identified the following risk factors for progression to epilepsy: a prior brain insult, an EEG with epileptiform abnormalities, a significant brain-imaging abnormality, and a nocturnal

seizure [Level 1].² Clinicians' recommendations whether to initiate immediate AED treatment after a first seizure should be based on individualized assessments that weigh the risk of recurrence against the potential side effects of AED therapy and consider patient preferences. Immediate treatment will not improve the long-term prognosis for seizure remission but will reduce seizure risk over the subsequent 2 years. In most patients with idiopathic epilepsy, deferring treatment until a second seizure occurs is a reasonable and often preferable decision.

BENIGN EPILEPSY SYNDROMES

Several electroclinical syndromes begin in childhood and are associated with normal development, normal findings on neurologic examination, and normal brain imaging studies. They have a uniformly good prognosis for complete remission in mid to late adolescence without long-term behavioral or cognitive problems. The most common and best characterized of these syndromes is benign partial epilepsy of childhood with central-midtemporal sharp waves (rolandic epilepsy). Most seizures occur at night as secondarily generalized convulsions. Focal seizures occur during the day and are characterized by twitching of one side of the face, anarthria, salivation, and paresthesias of the face and inner mouth followed variably by hemiclonic movements or hemitonic posturing. Other generally benign syndromes include childhood epilepsy with occipital paroxysms and benign epilepsy with affective symptoms.

Because of the good prognosis, the sole goal of treatment in such cases is to prevent recurrence. Because many children, especially those who are older, tend to have only a few seizures, treatment is not always necessary. AEDs are usually reserved for children whose seizures are frequent or relatively severe or whose parents, or the children themselves, are frightened at the prospect of future attacks. With these considerations in mind, only about half the children with benign partial epilepsy require treatment.

ANTIEPILEPTIC DRUGS

Selection of Antiepileptic Drugs

Two nationwide collaborative Veterans Administration Cooperative Studies (1985 and 1992) compared the effectiveness of the then available major AEDs. In the 1985 study, carbamazepine, phenytoin, primidone, and phenobarbital were equally effective in controlling complex partial and secondarily generalized seizures [Level 1].³ In the 1992 study, carbamazepine was slightly more effective than valproate in treating complex partial seizures, but both drugs were of equal efficacy in controlling secondarily generalized seizures [Level 3].⁴ These studies also demonstrated that despite their relatively uniform ability to suppress seizures, the drugs had different risks of adverse effects. More recently, there have been randomized trials in patients with partial seizures comparing the effectiveness of gabapentin, lamotrigine, topiramate, or oxcarbazepine to that of carbamazepine and phenytoin. None has shown definite superiority, although many have demonstrated that the newer agents have improved tolerability. *A survey of epilepsy experts in North America found that carbamazepine remains the drug of first choice for partial seizures when both efficacy and tolerability are considered.* Gabapentin, pregabalin, lamotrigine, topiramate, oxcarbazepine, levetiracetam, and phenytoin remain reasonable alternatives for many patients. The SANAD trial, a large open-label study, randomized patients with focal epilepsy to carbamazepine, lamotrigine, oxcarbazepine, or topiramate. Lamotrigine had a slight advantage in time to treatment failure, but as in previous comparative studies, the differences among agents in terms of effectiveness were minimal [Level 1].⁵ Many smaller trials have directly compared various drugs against each other with similar findings; although there may be differences in tolerability, there are no clear advantages in efficacy when an appropriate agent is used at a therapeutic dose [Level 1].⁶

In general, valproate is the drug of choice for generalized-onset seizures and can be used advantageously as monotherapy when several generalized seizure types coexist (Table 58.4). Lamotrigine, levetiracetam, topiramate, and zonisamide are suitable alternatives if valproate is ineffective or not tolerated. A second arm of the SANAD trial compared the effectiveness of valproate, lamotrigine, and topiramate in patients with all types of generalized or unclassified seizures. Valproate was found to be slightly more effective overall, especially for idiopathic epilepsy, although the differences were minimal [**Level 1**].⁷ Phenytoin, carbamazepine, and oxcarbazepine are useful in suppressing generalized tonic-clonic seizures, but the response is less predictable than that with valproate. Carbamazepine, phenytoin, gabapentin, and lamotrigine can aggravate myoclonic seizures; all of these except lamotrigine also sometimes exacerbate absence seizures. Tiagabine can aggravate or induce absence

P.478

seizures. Ethosuximide is as effective as valproate in controlling absence seizures and has fewer side effects. Ethosuximide is ineffective against tonic-clonic seizures, however, so its main use is as an alternative to valproate in patients who have only absence seizures.

TABLE 58.4 Drugs Used in Treating Different Types of Seizures

Type of Seizure	Drugs ^a
Localization related epilepsy	
Simple and complex partial; secondarily generalized	Carbamazepine, lamotrigine, topiramate, levetiracetam, lacosamide, oxcarbazepine, pregabalin, valproate, gabapentin, zonisamide, phenytoin, primidone, phenobarbital, perampanel, ezogabine, clobazam
Primary generalized seizures	
Tonic-clonic	Valproate, lamotrigine, topiramate, levetiracetam, zonisamide, carbamazepine, oxcarbazepine, phenytoin
Absence	Valproate, lamotrigine, ethosuximide, zonisamide
Myoclonic	Valproate, clonazepam, levetiracetam
Tonic	Valproate, felbamate, clonazepam, zonisamide, rufinamide

^aNot all drugs have FDA approval for listed uses.

Many of the newer AEDs have been shown to be effective as adjunctive or add-on therapy for patients with seizures that are refractory to a single medication. Gabapentin can be effective for the treatment of mixed seizure disorders, and gabapentin, lamotrigine, oxcarbazepine, and topiramate for the treatment of refractory partial seizures in children. Evidence also suggests that

lamotrigine and topiramate are also effective for adjunctive treatment of idiopathic generalized epilepsy in adults and children, as well as treatment of the Lennox Gastaut syndrome [**Level 1**].⁸ Clobazam was recently U.S. Food and Drug Administration (FDA) approved for add-on therapy in severe epilepsies such as Lennox-Gastaut syndrome. It is also effective in focal epilepsies that are refractory to other medications and has been widely prescribed worldwide for this indication. Vigabatrin was approved by the FDA for treating infantile spasms in children 1 month to 2 years of age.

Of the more recently introduced antiepileptic medications, lacosamide, ezogabine, and perampanel have been approved for use in focal epilepsies refractory to other medications, and rufinamide was additionally approved to treat seizures associated with Lennox-Gastaut syndrome. Elderly patients with epilepsy require special consideration because of age-related changes in both pharmacokinetic profiles and pharmacodynamic characteristics. Relevant physiologic changes include decreased hepatic metabolism and plasma protein binding, decreased renal clearance, and slower gastrointestinal motility and absorption. There is greater sensitivity to both desirable and undesirable effects on brain function. Additionally, concurrent medical illnesses are common, and as a result, most elderly patients take multiple drugs, which increase the likelihood of clinically significant drug interactions. Several clinical trials involving elderly patients, including a large Veterans Administration cooperative study, have found that lamotrigine and gabapentin are better tolerated than carbamazepine, although, as in younger patients, differences in effectiveness, if any, are small.

Adverse Effects of Antiepileptic Drugs

All AEDs have undesirable effects in some patients. Although interindividual variation occurs, most adverse drug effects are mild and dose related. Many are common to virtually all AEDs, especially when treatment is started. These include sedation, mental dulling, impaired memory and concentration, mood changes, gastrointestinal upset, and dizziness. The incidence of particular adverse effects varies with the individual agent. In general, sedation and cognitive effects are less likely with lamotrigine or gabapentin than with older agents, especially in elderly persons. Some adverse effects are relatively specific for particular drugs.

DOSE-RELATED SIDE EFFECTS

These typically appear when a drug is first given or when the dosage is increased. They usually, but not always, correlate with blood concentrations of the parent drug or major metabolites ([Table 58.5](#)). Dose-related side effects are always reversible on lowering the dosage or discontinuing the drug. An exception to this is the peripheral vision loss with vigabatrin, which may progress despite stopping the drug. Adverse effects frequently determine the limits of treatment with a particular drug and have a major influence on compliance with the prescribed regimen. Because dose-related side effects are broadly predictable, they are often the major differentiating feature in choosing among otherwise equally effective therapies.

IDIOSYNCRATIC SIDE EFFECTS

Idiosyncratic responses account for most serious and virtually all life-threatening adverse reactions to AEDs. Many AEDs can cause similar serious side effects (see [Table 58.5](#)), but with the exception of rash, these are fortunately rare. For example, the risk of carbamazepine-induced agranulocytosis or aplastic

anemia is about 2 per 575,000; with felbamate, the risk of aplastic anemia may be as high as 1 per 5,000. Idiosyncratic reactions are not dose related; rather they arise either from an immune-mediated reaction to the drug or from poorly defined individual factors, largely genetic, that convey an unusual sensitivity to the drug. An example of the genetic mechanism is valproate-induced fatal hepatotoxicity. Valproate, like most AEDs, is metabolized in the liver, but several biochemical pathways are available to the drug. Clinical and experimental data indicate that one of these pathways results in a hepatotoxic compound that may accumulate and lead to microvesicular steatosis with necrosis. The extent to which this pathway is involved in biotransformation is age dependent and promoted by concurrent use of other drugs that are eliminated in the liver. Thus, most patients who have had fatal hepatotoxicity were younger than 2 years of age and treated with polytherapy (Table 58.6). In addition, most had severe epilepsy associated with mental retardation, developmental delay, or congenital brain anomalies. No hepatic deaths have occurred in persons older than 10 years treated with valproate alone.

No laboratory test, certainly not untargeted routine blood monitoring, identifies individuals specifically at risk for valproate hepatotoxicity or any other drug-related idiosyncratic reaction. Clinical data, however, permit identification of groups of patients at increased risk for serious adverse drug reactions, including patients with known or suspected metabolic or biochemical disorders, a history of previous drug reactions, and medical illnesses affecting hematopoiesis or liver and kidney function.

Rash can occur with virtually any drug, and rarely, this results in Stevens-Johnson syndrome. The frequency of severe rash is about the same with carbamazepine, phenytoin, phenobarbital, and (if started slowly over several weeks) lamotrigine. There is some cross-reactivity among these drugs, so that a patient who develops a rash with one has a slightly increased risk of developing a rash with another. Rash is unusual with valproate, gabapentin, pregabalin, or levetiracetam. To date, life-threatening idiosyncratic effects have not been reported with gabapentin, pregabalin, topiramate, oxcarbazepine, tiagabine, or levetiracetam.

Antiepileptic Drug Pharmacology

Table 58.7 provides summary information about dose requirements, pharmacokinetic properties, and therapeutic concentration ranges for the major AEDs available in the United States. Of patients with epilepsy, 60% to 70% achieve satisfactory control of seizures with currently available AEDs, but fewer than 50% of adults achieve complete control without drug side effects. Many patients continue to have frequent seizures despite optimal medical therapy.

Treatment should start with a single AED chosen according to the type of seizure or epilepsy syndrome and then be adjusted as necessary, by considerations of side effects, required dosing schedule, and cost. Phenytoin, phenobarbital, gabapentin, and levetiracetam can be loaded acutely. There is evidence either from comparative or dose-controlled trials that gabapentin, lamotrigine, topiramate,

P.479

and oxcarbazepine have efficacy as monotherapy in newly diagnosed adolescents and adults with either partial or mixed seizure disorders. There is also evidence that lamotrigine is effective for newly diagnosed absence seizures in children. In the absence of status epilepticus (Chapter 6), AEDs should be started at low dosages to minimize acute toxicity. They can then be increased according to the patient's tolerance and the drug's pharmacokinetics. The initial target dose should produce a serum concentration in the low to mid therapeutic range. Further increases can then be titrated according to the patient's clinical progress, which is measured mainly by seizure frequency and the occurrence of drug side effects. A drug should not be judged a failure unless seizures remain uncontrolled at the maximal tolerated dosage, regardless of the blood level.

TABLE 58.5 Toxicity of Antiepileptic Drugs

Dose-Related Adverse Effects

Systemic Toxicity

Gastrointestinal (dyspepsia, nausea, diarrhea; esp. valproate, zonisamide)

Benign elevation in liver enzymes (esp. valproate, phenobarbital, phenytoin, carbamazepine, oxcarbazepine)

Benign leukopenia (esp. carbamazepine)

Gingival hypertrophy (esp. phenytoin)

Weight gain (esp. valproate, gabapentin, pregabalin)

Anorexia and weight loss (esp. felbamate, topiramate, zonisamide)

Hair loss, change in hair texture (esp. valproate)

Hirsutism (esp. phenytoin, valproate)

Hyponatremia (esp. carbamazepine, oxcarbazepine)

Coarsening of facial features (esp. phenytoin)

Dupuytren contracture, frozen shoulder

Osteoporosis (esp. phenytoin, carbamazepine, valproate)

Impotence (esp. phenobarbital, carbamazepine)

Neurologic Toxicity

Drowsiness, sedation

Impaired cognition (memory, concentration; esp. topiramate)

Depression and mood changes (esp. phenobarbital, levetiracetam, topiramate)

Irritability, hyperactivity

Insomnia (esp. felbamate)

Peripheral visual field restriction (vigabatrin)

Dizziness/vertigo

Nystagmus, diplopia

Ataxia

Tremor, asterixis

Dyskinesias, dystonia, myoclonus

Dysarthria

Headache

Sensory neuropathy

Systemic Toxicity

Rash (rare with valproate, gabapentin, levetiracetam, pregabalin)

Exfoliative dermatitis

Erythema multiforme

Stevens-Johnson syndrome (esp. lamotrigine)

Agranulocytosis

Aplastic anemia (esp. felbamate)

Hepatic failure (esp. felbamate, valproate)

Pancreatitis

Connective tissue disorders

Thrombocytopenia (esp. valproate)

Pseudolymphoma syndrome

TABLE 58.6 Effect of Age and Treatment on Risk of Developing Fatal Valproate Hepatotoxicity

Age	Monotherapy	Polytherapy
<2 yr	1/7,000	1/500
>2 yr	1/80,000	1/25,000

Modified from Dreifuss FE, Santilli N, Langer DH, et al. *Neurology*. 1987;37:379-385.

Dosage changes generally should not be made until the effects of the drug have been observed at steady-state concentrations (a time about equal to five drug half-lives). If the first drug is ineffective, an appropriate alternative should be gradually substituted (see Table 58.4). Combination treatment using two drugs should be attempted only when monotherapy with primary AEDs fails. Combination therapy is sometimes effective, but the price of improved seizure control is often additional drug toxicity. Sometimes, combination therapy with relatively nonsedating drugs (e.g., carbamazepine, lamotrigine, gabapentin, or valproate) is preferable to high-dose monotherapy with a sedating drug (e.g., phenobarbital or primidone). When used together, carbamazepine and lamotrigine result in a pharmacodynamic interaction that often produces neurotoxicity at dosages that are usually well tolerated when either drug is used alone.

Dosing intervals should usually be less than one-third to one-half the drug's half-life to minimize fluctuations between peak and trough blood concentrations. Large fluctuations can result in drug-induced side effects at peak levels and in breakthrough seizures at trough concentrations. Sometimes, however, a drug has a relatively long pharmacodynamic half-life, so that twice a day dosing is reasonable even if the pharmacokinetic half-life is short. This is typically the case with valproate, tiagabine, pregabalin, gabapentin, and levetiracetam. Extended-release formulations of most commonly used AEDs are available, which allow less frequent dosing and decreased peak and trough levels, thereby potentially

P.480

improving tolerability and compliance. Bioavailability is not necessarily equivalent to immediate-release formulations, and different extended-release delivery systems with alternate manufacturers of the same drug can also create variation in peak and trough levels, as well as total absorption.

TABLE 58.7 Antiepileptic Drugs: Dosage and Pharmacokinetic Data

Drug	Usual Adult Dose 24 h (mg)	Half-life (h)	Usually Effective Plasma Concentration (µg/mL)	Time-to-Peak Concentration (h)	Bound Fraction (%)
Phenytoin	300-400	22	10-20	3-8	90-95
Carbamazepine	800-1,600	8-22	8-12	4-8	75
Phenobarbital	90-180	100	15-40	2-8	45

Valproate	1,000-3,000	15-20	50-120	3-8	80-90
Ethosuximide	750-1,500	60	40-100	3-7	<5
Felbamate	2,400-3,600	14-23	20-140	2-6	25
Gabapentin	1,800-3,600	5-7	4-16 ^a	2-3	<5
Lamotrigine	100-500	12-60 ^b	2-16 ^a	2-5	55
Topiramate	200-400	19-25 ^b	4-10 ^a	2-4	9-17
Vigabatrin	1,000-3,000	5-7	NE	1-4	5
Tiagabine	32-56	5-13	NE	1	95
Levetiracetam	1,000-3,000	6-8	5-45 ^a	1	<10
Oxcarbazepine	900-2,400	8-10 ^c	10-35 ^a	3-13	40 ^c
Zonisamide	100-600	24-60 ^b	10-40 ^a	2-6	40
Pregabalin	150-600	5-7	NE	1	<5
Lacosamide	200-400	12-16	NE	1-4	<15
Rufinamide	2,400-3,200	6-10	NE	4-6	34
Clobazam	10-40	36-42	NE	0.5-4	80-90
Ezogabine	600-1,200	7-11	NE	0.5-2	80
Perampanel	8-12	105	NE	0.5-2.5	95

^aNot established; corresponds to usual range in patients treated with recommended dose. ^bHighly dependent on concurrently administered drugs. ^cOf methoxy derivative, the active metabolite.

NE, not established.

Therapeutic drug monitoring has greatly improved the care of patients with epilepsy, but published therapeutic ranges are only guidelines. Most patients whose drug concentrations are within a standard therapeutic range usually achieve adequate seizure control with minimal side effects, but notable exceptions occur. Some patients develop unacceptable side effects at “subtherapeutic” concentrations; others benefit from “toxic” concentrations without adverse effects.

Determining serum drug concentrations when seizure control has been achieved or when side effects appear can assist future management decisions. Drug levels are also useful in documenting compliance and in assessing the magnitude and significance of known or suspected drug interactions. Therapeutic drug monitoring is an essential guide to treating neonates, infants, young children, elderly persons, and patients with diseases (e.g., liver or kidney failure) or physiologic conditions (e.g., pregnancy) that alter drug pharmacokinetics. Although the total blood concentrations that are routinely reported are satisfactory for most indications, unbound (free) concentrations are useful when protein binding is altered, as in renal failure, pregnancy, extensive third-degree burns, and combination therapy using two or more drugs that are highly bound to serum proteins (e.g., phenytoin, valproate, tiagabine).

Specific Drugs

Phenytoin is unique among AEDs because it exhibits nonlinear elimination at therapeutically useful serum concentrations. That is, hepatic enzyme systems metabolizing phenytoin become increasingly saturated at plasma concentrations greater than 10 to 12 $\mu\text{g/mL}$, and metabolic rate approaches a constant value at high concentrations. With increasing doses, phenytoin plasma concentrations rise exponentially (Fig. 58.6), so that steady-state concentration at one dose cannot be used to predict directly the steady-state concentration at a higher dose. Clinically, this requires cautious titration within the therapeutic range, using dose increments of 30 mg to avoid toxic effects.

Carbamazepine induces activation of the enzymes that metabolize it. The process, termed *autoinduction*, is time dependent. When carbamazepine is first introduced, the half-life approximates 30 hours. With increasing hepatic clearance in the first 3 to 4 weeks of therapy, however, the half-life shortens to 11 to 20 hours. As a result, the starting dose should be low and then increased gradually, and dosing should be frequent (three or four times daily). Extended-release formulations permit twice a day administration. The principal metabolite is carbamazepine-10,11-epoxide, which is pharmacologically active. Under certain circumstances (e.g., when

P.481

coadministered with valproate or felbamate), the epoxide metabolite accumulates selectively, thereby producing neurotoxic effects even though the plasma concentration of the parent drug is in the therapeutic range or even low.

FIGURE 58.6 Phenytoin dose concentration curves from three representative adult patients. Note the markedly nonlinear relationship in the 200- to 400-mg dose range. Careful dose titration is necessary in this portion of the curve to avoid neurotoxicity. K_m , Michaelis-Menten constant; V_{max} , maximum elimination rate.

Valproate is highly bound to plasma proteins, but the binding is concentration dependent and nonlinear. The unbound fraction increases at plasma concentrations greater than 75 $\mu\text{g/mL}$ because protein-binding sites become saturated. For example, doubling the plasma concentration from 75 to 150 $\mu\text{g/mL}$ can result in a more than sixfold rise in concentration of free drug (from 6.5 to 45 $\mu\text{g/mL}$). Therefore, as the dose of valproate is increased, side effects may worsen rapidly because of the increasing proportion of unbound drug. Furthermore, adverse effects may vary in the course of a single day or from day to day because concentrations of unbound drug fluctuate despite seemingly small changes in total blood levels. Additionally, circulating fatty acids displace valproate from protein-binding sites. If fatty acid levels are high, the amount of unbound valproate increases. Lamotrigine and felbamate prolong the half-life of valproate and therefore a reduced dosage is typically necessary when these drugs are added.

Gabapentin requires an intestinal amino acid transport system for absorption. Because the transporter is saturable, the percentage of drug that is absorbed after an oral dose decreases with increasing dosage. More frequent dosing schedules using smaller amounts may therefore be necessary to increase blood levels. When dosages above 3,600 mg/day are used, blood levels can be helpful in demonstrating that an increase in dosage is reflected in an increased serum concentration. Gabapentin does not interact to any clinically significant degree with any other drugs, which makes it especially useful when AED polytherapy is necessary and in patients with medical illnesses that also require drug treatment. It is not metabolized in the liver, but as it is excreted unchanged by the kidneys, dose adjustment is required in patients with renal failure. *Pregabalin* is structurally and mechanistically similar to gabapentin but does not show dose-dependent absorption. It has increased potency compared with gabapentin and can be effective with twice-daily dosing.

Lamotrigine is highly sensitive to coadministration of many other AEDs. Enzyme-inducing agents, such as phenytoin and carbamazepine, decrease the half-life of lamotrigine from 24 to 16 hours (or less) as

do oral contraceptive agents. In contrast, enzyme inhibition by valproate increases the half-life of lamotrigine to 60 hours. Therefore, lamotrigine dosing depends very much on whether it is used as monotherapy or in combination with other AEDs. Lamotrigine concentrations are also lowered by administration of oral contraceptives, and levels can decrease dramatically during the latter months of pregnancy requiring frequent monitoring and dose adjustment. Lamotrigine has little or no effect on other classes of drugs. Rash occurs in about 10% of patients; it is more common in children and rarely leads to Stevens-Johnson syndrome. The incidence of rash can be minimized by slow titration schedules.

Levetiracetam, like gabapentin, has no appreciable interactions with other drugs and therefore has advantages in medically complicated patients. The plasma half-life is 6 to 8 hours, but clinical trials support twice-daily dosing, possibly owing to a longer pharmacodynamic half-life. Metabolism occurs in the liver, and there is also renal clearance. Adverse effects are generally mild and self-limited, although mood changes and even psychosis occur in a small subset of patients. No life-threatening idiosyncratic reactions have yet been described.

Oxcarbazepine is structurally similar to carbamazepine, but it is metabolized by a different pathway. As a result, there is no epoxide metabolite that is responsible for some of the adverse effects of carbamazepine. Although individual patients may tolerate oxcarbazepine better than carbamazepine, the overall profiles of the two drugs are similar, including development of leukopenia (usually transient, asymptomatic, and benign), mild increase in hepatic enzymes, and hyponatremia. Pharmacologic half-life of the active metabolite, a methoxy derivative (MHD), is 8 to 10 hours. Clinical studies support twice-daily dosing, although peak toxicity can occur when this is done at higher dosages.

Topiramate is affected by other AEDs taken concurrently. Carbamazepine, phenytoin, and phenobarbital shorten its half-life;

P.482

valproate has little effect. Topiramate does not affect most other drugs, although phenytoin blood levels may increase by 25%. Adverse cognitive effects, especially word-finding difficulty and impaired memory, frequently limit the dosage patients can tolerate. These are usually dose dependent and can be minimized with slow titration schedules. Cognitive effects are also less common in monotherapy. Glaucoma, anhydrosis, and renal stones occur rarely. Doses above 400 mg/day do not usually lead to better seizure control but are associated with an increasing incidence of side effects.

Tiagabine is highly bound to serum proteins and will therefore displace other drugs (e.g., phenytoin, valproate) that are also protein bound. Other drugs do not affect tiagabine's metabolism significantly. Gastrointestinal side effects usually limit the rate at which the dosage may be increased.

Zonisamide is affected by other drugs that induce hepatic enzymes. As monotherapy, zonisamide's half-life is about 60 hours. When coadministered with enzyme-inducing drugs, its half-life can be reduced to 24 hours. In either case, once-daily dosing is appropriate. Although its metabolism occurs primarily in the liver, zonisamide itself does not appear to affect other drugs. Rash, renal stones, and anhydrosis are rare side effects.

Felbamate has a much higher risk of serious adverse reactions, including aplastic anemia and hepatic failure, than other AEDs. The actual risk has been difficult to estimate but is probably between 1 per 5,000 and 1 per 20,000 exposures. For this reason, its use is currently restricted to patients who are refractory to other agents and in whom the risk of continued seizures outweighs the risk of side effects. Use of felbamate is also limited by other common but less serious adverse effects, including anorexia, weight loss, insomnia, and nausea, and by numerous complex drug interactions. Nonetheless, felbamate remains useful in cases of severe epilepsy such as Lennox-Gastaut syndrome.

Lacosamide enhances the slow inactivation of sodium channels without affecting fast inactivation. It may prolong the PR interval, which can result in cardiac conduction problems. A baseline electrocardiogram (ECG) is suggested prior to initiating this drug.

Rufinamide is a triazole derivative whose exact mechanism is unknown. *In vitro* prolongs the inactive state of the sodium channels, thereby limiting repetitive firing of Na⁺-dependent action potentials mediating anticonvulsant effects. Its use is limited largely to refractory generalized epilepsies, especially in controlling tonic seizures.

Clobazam has been used in many countries around the world, but it was only recently FDA approved in the United States for adjunctive treatment of Lennox-Gastaut syndrome. It is widely used off-label as adjunctive treatment for partial seizures. In catamenial epilepsy, it can be prescribed in doses of 20 to 30 mg daily for 10 days during the perimenstrual period. Serious reactions including Stevens-Johnson syndrome and toxic epidermal necrolysis (TEN) have been reported.

Ezogabine is FDA approved as an adjunctive medicine in patients with partial seizures. All patients starting on this medication should undergo a baseline and periodic eye exams every 6 months including dilated funduscopy and visual acuity testing. Blue discoloration of the skin, especially of the lips and nail bed, has been reported. QT prolongation has also been observed, warranting monitoring with ECG especially in patients with electrolyte and cardiac abnormalities. This medicine can cause urinary retention and therefore is better avoided in elderly male patients with prostate enlargement.

Perampanel, which is FDA approved as an adjunctive medication in partial seizures, has a unique mechanism of action in that it is the first noncompetitive antagonist of the AMPA glutamate receptor. It comes with a boxed warning of dose-related serious neuropsychiatric events including homicidal thoughts and aggression. Being both an inducer and a substrate of the CYP3A4 enzymes, drug interactions with other antiseizure medications exist.

Discontinuing Antiepileptic Drugs

Epidemiologic studies indicate that 60% to 70% of patients with epilepsy become free of seizures for at least 5 years within 10 years of diagnosis. Similarly, prospective clinical trials of treated patients whose seizures were in remission for 2 years or more showed that a nearly identical percentage of patients remained seizure free after drug withdrawal [Level 1].⁹ Chance of recurrence continues to decline with seizure freedom for 2 to 5 years. These studies also identified predictors that permit patients to be classified as being at low or high risk for seizure relapse after drug therapy ends. The risk of relapse was high if patients required more than one AED to control seizures, if seizure control was difficult to establish, if the patient had a history of generalized tonic-clonic seizures, and if the EEG was significantly abnormal when drug withdrawal was considered. Continued freedom from seizures is favored by longer seizure-free intervals (>4 years) before drug withdrawal is attempted, few seizures before remission, monotherapy, normal EEG, and no difficulty establishing seizure control.

All benign epilepsy syndromes of childhood carry an excellent prognosis for permanent drug-free remission. In contrast, JME has a high rate of relapse when drugs are discontinued, even in patients who have been seizure free for years. The prognosis for most other epilepsy syndromes is largely unknown.

Discontinuing AED therapy in appropriate patients can be considered when they have been seizure free for at least 2 years. The most powerful argument for stopping AEDs is concern about longterm systemic and neurologic toxicity, which can be insidious and not apparent for many years after a drug has been introduced. On the other hand, however, is the concern of the patient or family about seizure

recurrence. Even a single seizure can have disastrous psychosocial and vocational consequences, particularly in adults. Therefore, the decision to withdraw drugs must be weighed carefully in the light of individual circumstances. If a decision is made to discontinue AEDs, we favor slow withdrawal, over 3 to 6 months, but this recommendation is controversial because few studies of different withdrawal rates have been conducted.

REPRODUCTIVE HEALTH ISSUES

Gender-based differences in AED pharmacokinetics, sex steroid hormones, and reproductive life events raise special issues for women with epilepsy. The management of pregnancy in a woman with epilepsy is discussed in detail in Chapter 124. This section focuses on the effects of reproductive hormones on seizures and on the effects of seizures and AEDs on reproductive health.

Although the prevalence of epilepsy is not higher in women, epilepsy in women can be specially affected by changes in reproductive steroids. Estrogen is a proconvulsant drug in animal models of epilepsy, whereas progesterone and its metabolites have anticonvulsant effects. Ovarian steroid hormones act at the neuronal membrane and on the genome to produce immediate and longlasting effects on excitability. Estrogen reduces GABA-mediated inhibition, whereas progesterone enhances GABA effects. Estrogen also potentiates the action of excitatory neurotransmitters in some brain regions and increases the number of excitatory synapses. These dynamic and significant changes in neuronal excitability are

P.483

observed with changes in estrogen and progesterone concentrations similar to those observed in the human menstrual cycle.

Approximately one-third of women with epilepsy report patterns of seizure occurrence that relate to phases of the menstrual cycle (*catamenial seizures*). Women with catamenial seizures indicate that seizures are more frequent, or more severe, just before menstruation and during the time of menstrual flow. In some women, seizures also increase at ovulation. These are times in the menstrual cycle when estrogen levels are relatively high and progesterone concentration is relatively low. Several small clinical trials have described benefit from chronic progesterone therapy in women with catamenial seizure patterns. Changes in seizures related to puberty and menopause are not well understood.

The pharmacokinetics of some AEDs can complicate epilepsy management in women. AEDs that induce activity of the cytochrome P-450 enzyme system (carbamazepine, phenytoin, phenobarbital, primidone, and, to a lesser extent, topiramate and oxcarbazepine) interfere with the effectiveness of estrogen-based hormonal contraception. In women taking these drugs, the metabolism and binding of contraceptive steroids is enhanced, thus reducing the biologically active fraction of steroid hormone. The failure rate of oral contraceptive pills exceeds 6% per year in women taking enzyme-inducing AEDs, in contrast to a failure rate of less than 1% per year in medication-compliant women without epilepsy. A woman motivated to avoid pregnancy should consider using a contraceptive preparation containing 50 µg or more of an estrogenic compound or using an additional barrier method of contraception. Alternatively, she should discuss with her physician the possibility of selecting an AED that does not alter steroid metabolism or binding.

Reproductive health may be compromised in both women and men with epilepsy. Fertility rates for men and women with epilepsy are one-third to two-thirds those of men and women without epilepsy. Lower birth rates cannot be explained on the basis of lower marriage rates because marriage rates for women with epilepsy are now similar to those of nonepileptic women. Reduced fertility appears to be the direct result of a disturbance in reproductive physiology.

Men and women with epilepsy show a higher than expected frequency of reproductive endocrine disturbances. These include abnormalities both in the cyclic release and concentration of pituitary luteinizing hormone and prolactin and in the concentration of gonadal steroid hormones. Some of these abnormalities are likely to be a consequence of seizure activity. AEDs can also alter concentrations of gonadal steroids by affecting steroid hormone metabolism and binding. AEDs that increase steroid metabolism and binding reduce steroid hormone feedback at the hypothalamus and pituitary. AEDs that inhibit steroid metabolism (e.g., valproate) increase concentrations of steroid hormones, particularly androgens.

The polycystic ovary syndrome (PCOS) is a gynecologic disorder affecting approximately 7% of reproductive-age women. Women with epilepsy are at risk for developing features of this syndrome. Diagnostic requirements for PCOS are phenotypic or serologic evidence for hyperandrogenism and anovulatory cycles (Morrell, 2003). Phenotypic signs of hyperandrogenism include hirsutism, truncal obesity, and acne. Hirsutism presents as increased facial and body hair, coarsening of pubic hair with extension down the inner thigh, and male pattern scalp hair loss—temporal recession and thinning over the crown. Health consequences of PCOS include infertility, accelerated atherosclerosis, diabetes, and endometrial carcinoma, underscoring the importance of detection and treatment. As many as 30% of cycles in women with epilepsy are anovulatory, and anovulatory cycles appear to be most frequent in women receiving valproic acid (VPA). Women with epilepsy are more likely to have polycystic-appearing ovaries, which along with hyperandrogenism occur in as many as 40% of women with epilepsy receiving VPA. The long-term consequences of PCOS in women with epilepsy are unknown. Data such as these suggest that epilepsy and some AEDs individually affect fertility and that these effects may be additive. This implies that optimal therapy for epilepsy will consider disease-treatment effects on reproductive health.

Sexual dysfunction affects about one-third of men and women with epilepsy. Men report low sexual desire, difficulty achieving or maintaining an erection, or delayed ejaculation. Women with epilepsy can experience painful intercourse because of vaginismus and lack of lubrication. Although there are certainly psychosocial reasons for sexual dysfunction in some people with epilepsy, physiologic causes are demonstrable in others. Physiologic causes of sexual dysfunction include disruption of brain regions controlling sexual behavior by epileptogenic discharges, abnormalities of pituitary and gonadal hormones, and side effects of AEDs.

Although no anticonvulsant drug is free of teratogenic effects, the risk is low and generally less than that of uncontrolled seizures during pregnancy. The exceptions to this are valproate and topiramate, both of which are associated with increased risk of congenital malformations in prospective monotherapy studies.

Valproate has also been shown to carry a dose-dependent risk of decreased IQ compared with phenytoin, carbamazepine, and lamotrigine. In all cases, the lowest effective dose should be used, and polypharmacy should be avoided [Level 1].¹⁰ Women with epilepsy who have difficulty conceiving, irregular or abnormal menstrual cycles, midcycle menstrual bleeding, sexual dysfunction, obesity, or hirsutism should be referred for a reproductive endocrine evaluation. Men with sexual dysfunction or difficulty conceiving should also have an endocrine evaluation and semen analysis. All the reproductive disorders seen in people with epilepsy are potentially treatable.

BONE HEALTH

Persons with epilepsy are at greater risk for bone disease, which typically presents as pathologic fractures. Bone biochemical abnormalities described in people with epilepsy include hypocalcemia, hypophosphatemia, elevated serum alkaline phosphatase, elevated parathyroid hormone (PTH), and reduced levels of vitamin D and its active metabolites (Pack & Morrell, 2004). The most severe bone and biochemical abnormalities are found in patients

receiving AED polytherapy and in those who have taken AEDs for a longer time. Effects are more pronounced with enzyme-inducing AEDs, especially phenytoin.

SURGICAL TREATMENT

Surgery should be considered when seizures are uncontrolled by optimal medical management and when they disrupt the quality of life. Quantifying these issues, however, has defied strict definition, perhaps deservedly, because intractability is clearly more than continued seizures. Only patients know how their lives differ from what they would like them to be; the concept of *disability* includes both physical and psychological components. Some patients with refractory seizures suffer little disability; others, for whatever reason, find their lives severely compromised by infrequent attacks. Still, others have had their seizures completely cured by surgery but are still disabled and incapable of functioning productively. Determining which patients are “medically refractory” and which are “satisfactorily controlled” can always be argued in the abstract.

P.484

Fortunately in practice, there is usually general agreement about which patients should be referred for surgical evaluation.

Patients are less likely to benefit from further attempts at medical treatment if seizures have not been controlled after two trials of high-dose monotherapy using two appropriate drugs and one trial of combination therapy. These therapeutic efforts can be accomplished within 1 to 2 years; the detrimental effects of continued seizures or drug toxicity warrant referral to a specialized center after that time.

There are few blanket contraindications to epilepsy surgery today, although patients with severe concurrent medical illness and progressive neurologic syndromes are usually excluded. Some centers prefer not to operate on patients with psychosis or other serious psychiatric disorder, those older than 60 years, and those with an IQ of less than 70. Patients in these categories, however, must be considered individually. Many patients who undergo corpus callosum section for atonic seizures associated with Lennox-Gastaut syndrome have IQs less than 70. Although surgery for epilepsy is increasingly performed in children, functional resections in infancy remain controversial for several reasons: the uncertain natural history of seizures in many of these patients; the unknown effects of surgery on the immature brain; and the lack of data about longterm neurologic, behavioral, and psychological outcomes.

Because of technical advances in imaging and electrophysiologic monitoring, epilepsy surgery is no longer automatically contraindicated in patients with multifocal interictal epileptiform abnormalities or even foci near language or other eloquent cortical areas.

RESECTIVE PROCEDURES

Focal brain resection is the most common type of epilepsy surgery. Resection is appropriate if seizures begin in an identifiable and restricted cortical area, if the surgical excision will encompass all or most of the epileptogenic tissue, and if the resection will not impair neurologic function. These criteria are met most often by patients with temporal lobe epilepsy, but extratemporal resections are increasingly common.

ANTERIOR TEMPORAL LOBE RESECTION

This resective procedure is the most common, but the operation varies in what is considered “standard,” especially with regard to how much lateral neocortical and mesial limbic structures are removed. The traditional operation is Spencer’s 1991 anteromedial temporal lobe resection, which includes removal of the

anterior middle and inferior temporal gyri, parahippocampal gyrus, 3.5 to 4 cm of hippocampus, and a variable amount of amygdala. For nondominant foci, this approach may be slightly modified to include the anterior superior temporal gyrus as well. Increasingly, some centers (including ours) are using selective amygdalohippocampectomy, a smaller resection with similar efficacy. Patients with medial temporal lobe epilepsy associated with hippocampal sclerosis are ideal candidates for either operation because over 80% will become seizure free, with the remainder having substantial improvement. Results of a large multicenter study in the United States were reported by Spencer et al. in 2003, confirming the high rates of complete seizure control following temporal lobe resection [Level 1].¹¹ A randomized controlled Canadian trial has demonstrated clear superiority of surgery over medical management in patients with medial temporal lobe epilepsy [Level 1].¹² Other methods of mesial temporal ablation have been reported, including Gamma Knife radiation and localized laser ablation. Although preliminary results are encouraging, it is not known whether these methods are as effective at seizure control as traditional resection or if there are differences in adverse effect outcomes.

Lesionectomy

Well-circumscribed epileptogenic structural lesions (cavernous angiomas, hamartomas, gangliogliomas, and other encapsulated tumors) can be removed by stereotactic microsurgery. The extent to which tissue margins surrounding the lesion are included in the resection depends on how the margins are defined (radiologic, visual, electrophysiologic, or histologic inspection) and the surgeon's preference. Seizures are controlled by this method in 50% to 60% of patients. A lesion involving the cerebral cortex should always be considered the source of a patient's seizures, unless compelling EEG evidence suggests otherwise.

Nonlesional Cortical Resections

When a lesion cannot be visualized by MRI, it is difficult to demonstrate a restricted ictal-onset zone outside the anterior temporal lobe. Although alternative imaging (PET or SPECT scan) may help identify the seizure-onset zone, this situation almost always requires placement of intracranial electrodes to map the extent of epileptogenic tissue and to determine its relation to functional brain areas. Outcome after nonlesional cortical resections is not as good as with anterior temporal lobectomy or lesionectomy, mainly because the boundaries of epileptogenic cortical areas often cannot be delineated precisely, and removal of all the epileptogenic tissue often is not possible.

CORPUS CALLOSOTOMY

Section of the corpus callosum disconnects the two hemispheres and is indicated for treatment of patients with uncontrolled atonic or tonic seizures in the absence of an identifiable focus suitable for resection. Leaving the posterior 20% to 30% of the corpus callosum intact seems to reduce complications. Most patients referred for corpus callosotomy have severe and frequent seizures of multiple types, usually with mental retardation and a severely abnormal EEG (the Lennox-Gastaut syndrome).

Unlike resective surgery, corpus callosotomy is palliative, not curative. Nonetheless, it can be strikingly effective for generalized seizures, with 80% of patients experiencing complete or nearly complete cessation of atonic, tonic, and tonic-clonic attacks. This outcome is often remarkably beneficial because it eliminates falls and the associated self-injury. The effect on partial seizures, however, is inconsistent and unpredictable. Complex partial seizures are reduced or eliminated in about half the patients, but simple or complex partial seizures are exacerbated in about 25%. Therefore, refractory partial seizures alone are not an indication for corpus callosotomy. Similarly, absence, atypical absence, and myoclonic seizures either do not benefit or show an inconsistent response.

HEMISPHERECTOMY

Removal (hemispherectomy) or disconnection (functional hemispherectomy) of large cortical areas from one side of the brain is indicated when the epileptogenic lesion involves most or all of one hemisphere. Because

hemispherectomy guarantees permanent hemiplegia, hemisensory loss, and usually hemianopia, it can be considered only in children with a unilateral structural lesion that has already resulted in those abnormalities and who have refractory unilateral seizures. Examples of conditions suitable for hemispherectomy include infantile hemiplegia syndromes, Sturge-Weber disease, Rasmussen syndrome, and severe unilateral developmental anomalies, such as hemimegalencephaly. In appropriate patients, the results are dramatic. Seizures cease, behavior improves, and development accelerates (Table 58.8).

TABLE 58.8 Outcome after Epilepsy Surgical Procedures

Procedure	Seizure Free (%)	Improved (%)	Not Improved (%)	<i>n</i>
Anterior temporal lobectomy	69	22	9	3,579
Lesionectomy	67	22	12	293
Nonlesional extratemporal neocortical resection	45	35	20	805
Hemispherectomy	67	21	12	190
Corpus callosum section	8	61	31	563

Modified from Engel J Jr. *Surgical Treatment of the Epilepsies*. 2nd ed. New York: Raven; 1993.

PREOPERATIVE EVALUATION

The objective in evaluating patients for focal resection is to demonstrate that all seizures originate in a limited cortical area that can be removed safely. This determination requires more extensive evaluation than is necessary in the routine management of patients with epilepsy. The different tests used provide complementary information about normal and epileptic brain functions.

CCTV/EEG monitoring is necessary to record a representative sample of the patient's typical seizures to confirm the diagnosis and classification and also to localize the cortical area involved in ictal onset. Volumetric or other special MRI techniques may demonstrate unilateral hippocampal atrophy or other anatomic abnormalities that may be epileptogenic. PET and ictal SPECT are useful in demonstrating focal abnormalities in glucose metabolism or cerebral blood flow that correspond to the epileptogenic brain region. Neuropsychological testing is useful in demonstrating focal cognitive dysfunction, especially language and memory. Intracarotid injection of amobarbital (the *Wada test*) to determine hemispheric dominance for language and memory competence is generally considered necessary before temporal lobectomy, but the implications of a failed test are uncertain. Although functional MRI (fMRI) reliably lateralizes language, determining memory competence of one temporal lobe has not yet been reliably established.

Intracranial electrodes are necessary if noninvasive methods do not unequivocally localize the epileptogenic area or if different noninvasive tests give conflicting results. Intracranial electrode placement is also

necessary when vital brain functions (language, motor cortex) must be mapped in relation to the planned resection.

NEUROSTIMULATION IN DRUG-RESISTANT EPILEPSY

When epilepsy surgery is not possible due to multiple foci of seizure onset or seizure onset in eloquent cortex that is not resectable, neurostimulation has emerged as an alternative to failed drug therapy.

Vagus Nerve Stimulation

This is the first FDA-approved device for the treatment of medically refractory partial seizures. Like corpus callosotomy, vagus nerve stimulation (VNS) is a palliative procedure because very few patients become seizure free. VNS is delivered via a stimulating lead attached to the left vagus nerve. The stimulus generator is implanted in the upper left chest. The device is usually programmed to give a 30-second electrical pulse every 5 minutes, although stimulus parameters can be adjusted to the requirements of an individual patient. In patients with aura, a magnetic wand can be used to deliver VNS on demand, which may abort seizure progression. About 55% of children have at least a 50% reduction in seizure frequency, which compares favorably with the efficacy of new AEDs [Level 1].¹³ VNS may be considered for seizures in children, for Lennox Gastaut associated seizures, and for improving mood in adults with epilepsy (Level C). VNS may be considered to have improved efficacy over time. Children should be carefully monitored for site infection after VNS implantation. Chronic adverse effects include hoarseness and difficulty swallowing, both of which increase at the time of stimulation.

Because VNS became FDA approved, several other therapies using neurostimulation have been developed, including responsive neurostimulation, deep brain stimulation of the anterior nucleus of the thalamus, trigeminal nerve stimulation, and transcutaneous VNS.

Deep Brain Stimulation

The anterior nucleus of the thalamus, a core component of the Papez circuit, serves as a relay station that can amplify and synchronize seizure discharges from the hippocampus and the thalamus. Therefore, its inhibition by electrical stimulation is thought to abort or prevent seizures. Multicontact depth electrodes are implanted bilaterally into the anterior nuclei using a stereotactic approach. In the pivotal DBS study, depression (14.8% in active treatment vs. 1.8% in controls) and memory impairment (13% in active treatment vs. 1.8% in controls) were the most common adverse events. Asymptomatic hemorrhages occurred in 4.5% of subjects, but no disability or death was attributed to the hemorrhages.

Responsive Neurostimulation

The responsive neurostimulation (RNS) is now FDA approved as of November 2013 and commercially available as the NeuroPace device for individuals 18 years of age or older with drug-resistant epilepsy and partial-onset seizures that localize to no more than two epileptogenic foci. The NeuroPace responsive neurostimulation system consists of a pulse generator, seizure detection software, and recording and stimulating intracranial electrodes. Unlike the other systems described earlier which deliver a preprogrammed stimulation to prevent seizures, the RNS system works by detecting a seizure and then delivering a stimulus to terminate the electrical component of the seizure at its point of origin. In the pivotal trial which was randomized, prospective, double-blind, sham stimulation controlled, there was no difference in the rate of adverse events between the active and sham stimulation groups. However, the study demonstrated that patients with the device turned on had a 38% reduction in the average number of seizures per month,

P.486

compared to a 17% reduction in the sham group. The depth or subdural strip electrodes are placed in close proximity to the seizure focus that is predetermined by surface/depth electrode video EEG evaluation. Hence, patients who are a high surgical risk cannot receive this device.

Once the device is implanted, patients cannot have an MRI, electroconvulsive therapy, transcranial magnetic stimulation, and diathermy procedures. Status epilepticus is covered in Section II, Chapter 6.

GENE MUTATIONS IN EPILEPSY

Genetic factors are implicated strongly in several epilepsy syndromes, and twin studies have confirmed important genetic determinants in both localization-related and generalized types of seizure disorders. The concordance rate for monozygotic twins with idiopathic generalized epilepsy is well over 75%. Hereditary aspects are easiest to discern in childhood absence epilepsy, JME, benign rolandic epilepsy, and idiopathic grand mal seizures. Some inherited disorders, such as tuberous sclerosis and neurofibromatosis, are associated with brain lesions that in turn give rise to symptomatic epilepsies. In most cases of epilepsy, however, the role of genetic factors is complex because there are multiple interacting genes that convey varying degrees of seizure susceptibility and also affect the brain's response to environmental influences. In any given patient, the relative contribution from genetic or acquired factors determines whether the epilepsy presents as an idiopathic syndrome or as a symptomatic disorder. In addition, however, there also seems to be some degree of sharing of genetic susceptibilities in both the idiopathic and symptomatic epilepsies because children of parents with either localization-related or generalized epilepsy develop seizures at increased rates, although the difference is greatest in families with idiopathic generalized epilepsy. Thus, a major challenge facing investigators today is to clarify how different genes alter an individual's susceptibility to seizures and epilepsy in the presence of acquired brain pathology or as a reaction to acute or subacute cerebral dysfunction. This is no easy task, however, because the number of genes that encode molecules that regulate cortical excitability directly through membrane and synaptic functions and the second messenger cascades that indirectly regulate membrane proteins involved in signal transduction is very large.

A number of causative genes have been identified in idiopathic epilepsies with a monogenic mode of inheritance (Table 58.9). Mutations in two voltage-gated potassium channel genes, *KCNQ2* (chr 20q13) and *KCNQ3*, (chr 8q24), cause benign familial neonatal convulsions. Autosomal dominant frontal lobe epilepsy is caused by mutations in two cholinergic receptor genes, the *CHRNA4* (chr 20q13) and *CHRNA2* (chr 1q). A syndrome of generalized epilepsy with febrile seizures (GEFS⁺) has been related to mutations in three Na⁺ channel subunits: *SCN1B* (chr 19q13), *SCN1A* (2q24), and *SCN2A* (2q24). A similar syndrome has also been seen in families with mutations in the $\gamma 2$ subunit gene (*GABRG2* on chr 5q34) of the GABA_A receptor. De novo mutations in the $\alpha 1$ subunit of the Na⁺ channel also cause severe myoclonic epilepsy of infancy (Dravet syndrome). Mutations in the *CLCN2* gene encoding a Cl⁻ channel have recently been described in three families with idiopathic generalized epilepsies of heterogeneous phenotype. An autosomal dominant form of JME occurring in a French Canadian family is associated with a mutation in the $\alpha 1$ subunit of the GABA receptor (*GABRA1*). A mutation in the leucine-rich glioma inactivated (*LCI1*) gene on chromosome 10q22-24 causes an autosomal dominant form of partial epilepsy with auditory features.

TABLE 58.9 Genes Identified in Idiopathic Human Epilepsies

Gene	Syndrome	Chromosome
Na⁺ Channels		
SCN1A	Generalized epilepsy with febrile seizures plus (GEFS ⁺)	2q24

SCN1A	Severe myoclonic epilepsy of infancy	2q
SCN2A	Benign familial neonatal seizures and GEFS ⁺	2q24
SCN1B	GEFS ⁺	19q13
K⁺ Channels		
KCNQ2	Benign familial neonatal seizures	20q13
KCNQ3	Benign familial neonatal seizures	8q24
Cl⁻ Channels		
CLN2	Idiopathic generalized epilepsy (heterogeneous)	3q26
Ca²⁺ Channels		
CACNA1A (P/Q)	Absence epilepsy and cerebellar ataxia	19q
CACNB4	Idiopathic generalized epilepsy (heterogeneous)	2q22-23
Nicotinic AChR		
CHRNA4	Autosomal dominant nocturnal frontal lobe epilepsy	20q13
CHRNA2	Autosomal dominant nocturnal frontal lobe epilepsy	1q
GABA_A Receptor		
GABRG2	GEFS ⁺	5q34
GABRA1	Juvenile myoclonic epilepsy (French Canadian family)	
Other		
LGI1	Autosomal dominant partial epilepsy with auditory features	10q22-24

AChR, acetylcholine receptor; GABA, γ -aminobutyric acid.

The impact of epilepsy on the quality of life is usually greater than the limitations imposed by the seizures alone. The diagnosis of epilepsy frequently carries other consequences that can greatly alter the lives of many patients. For adults, the most important problems are discrimination at work and driving restrictions, which lead to loss of mobility and independence. Children and adults alike may be shunned by uninformed friends. Patients must learn to avoid situations that precipitate seizures, and a change in lifestyle may be necessary. Common factors that increase the likelihood of seizure occurrence include sleep deprivation (whether due to lifestyle

P.487

or to coexisting sleep disorders), alcohol (and other drugs), and emotional stress (Table 58.10). Compliance with AED treatment is often an issue, especially with adolescents. Psychiatric symptoms, especially depression, may complicate management.

TABLE 58.10 Factors that Lower the Seizure Threshold

Common	Occasional
Sleep deprivation	Barbiturate withdrawal
Alcohol withdrawal	Hyperventilation
Stress	Flashing lights
Dehydration	Diet and missed meals
Drugs and drug interactions	Specific “reflex” triggers
Systemic infection	
Trauma	
Malnutrition	
Noncompliance	

Some restrictions are medically appropriate, at least for limited times. For example, when seizures impair consciousness or judgment, driving and certain kinds of employment (working at exposed heights or with power equipment) and a few other activities (swimming alone) should be interdicted. On the other hand, legal prohibitions on driving vary in different states in the United States and in different countries and are often not medically justified. Employers frequently have unrealistic fears about the physical effects of a seizure, the potential for liability, and the impact on insurance costs. In fact, the Americans with Disabilities Act prohibits denying employment to persons with disability if the disability does not prevent them from meeting job requirements.

Children have special problems because their seizures affect the entire family. Parents may, with the best of intentions, handicap the child by being overly restrictive. The necessary and special attention received by

the “sick” child may encourage passive manipulative behavior and overdependence while unintentionally exacerbating normal sibling rivalries.

The physician must be sensitive to these important quality of life concerns, even when they are not raised spontaneously by the patient or family. In fact, psychosocial issues often become the major focus of follow-up visits after the diagnosis has been made, the initial evaluation completed, and treatment started. We cannot emphasize too much the physician’s responsibility to educate society to counter misperceptions and prejudices and to separate myth from medical fact. The Epilepsy Foundation (Landover, MD; 1-800-332-1000; www.epilepsyfoundation.com) and its nationwide system of affiliates have a wealth of materials about epilepsy suitable for patient, family, and public education.

Depression is common in people with epilepsy: Over half of patients with uncontrolled seizures are depressed. Even patients with well-controlled seizures have higher rates of depression than the general population. Suicide rates are tripled, with the highest rates seen in the 6 months after diagnosis. Patients should be observed for signs of depression and queried specifically about their mood, with attention to the potential need for psychiatric referral and initiation of antidepressant drugs. A simple screening tool developed specifically for use in people with epilepsy appears to allow rapid and accurate recognition of major depression. The FDA recently released an advisory indicating an increased risk of suicidal thoughts in patients enrolled in clinical trials (0.43% in patients adding any additional agent vs. 0.22% for those adding placebo). The significance for newly diagnosed patients is unclear, but it seems prudent to observe patients starting new AEDs closely for mood changes.

Treatment of depression begins with optimal treatment of the seizure disorder. Barbiturate and succinimide drugs may adversely affect mood, inducing symptoms that mimic endogenous depression. Topiramate and levetiracetam seem to cause depression in a small minority of patients, whereas lamotrigine can occasionally improve depression. Levetiracetam has also been associated with rare psychosis. Although tricyclic antidepressants reduce the seizure threshold in experimental models of epilepsy, this is not a practical concern because they only rarely trigger seizures or increase seizure frequency in humans. Monoamine oxidase (MAO) inhibitors neither induce seizures nor increase seizure frequency. Modern electroconvulsive therapy does not worsen epilepsy. We have used all available selective serotonin reuptake inhibitors (SSRIs) without exacerbating seizures.

Anxiety disorders are also common in epilepsy patients. When present, some AEDs can exacerbate the condition, mainly levetiracetam, topiramate, and zonisamide. Other agents (including gabapentin, pregabalin, and benzodiazepines) can improve anxiety. Of the benzodiazepines, only clonazepam and clobazam are used for chronic treatment of epilepsy.

The relation between psychosis and epilepsy is controversial. No convincing evidence shows that interictal psychosis is a manifestation of epilepsy, but some demographic features are overrepresented in patients with epilepsy. Postictal psychosis is, however, a well-recognized and self-limited complication of epilepsy. Its cause is unknown, but it may represent a behavioral analog of Todd paresis. Symptoms typically appear 24 to 72 hours after a lucid interval following a prolonged seizure or cluster of seizures and are more common in patients with a history of encephalitis or a family history of neuropsychiatric problems. Postictal psychosis is more common with ambiguous localization on monitoring suggesting that broad, bilaterally distributed epileptogenic networks may be a risk factor. Delusions and paranoia are common. The psychosis is self-limited, usually to a few days, although symptoms occasionally last as long as 1 to 2 weeks. Treatment with haloperidol or risperidone is usually effective. In cases where postictal psychosis regularly follows clusters of seizures, chronic treatment with lowdose risperidone can be helpful. Long-term emphasis should be on improving seizure control. Phenothiazines, butyrophenones, and clozapine lower seizure threshold in experimental animals and occasionally seem to induce seizures in nonepileptic patients. Most occurrences have been associated with high drug doses or a rapid increase in dose. With the possible

exception of clozapine, however, little evidence supports the notion that reasonable and conservative use of antipsychotic medications increases seizure frequency in patients with epilepsy.

Interictal aggressive behavior is not more common in people with epilepsy. Directed aggression during seizures occurs in less than 0.02% of patients with severe epilepsy; it is almost certainly less common in the general epilepsy population. Undirected pushing or resistance occasionally occur postictally when attempts are made to restrain confused patients.

COMPLIANCE

The most common cause of breakthrough seizures is noncompliance with the prescribed therapeutic regimen. Only about 70% of patients take antiepileptic medications as prescribed. For

P.488

phenytoin or carbamazepine, noncompliance can be inferred when sequential blood levels vary by more than 20%, assuming similarly timed samples and unchanged dosage. Persistently low AED levels in the face of increasing dosage also generally imply poor compliance. Caution is warranted with phenytoin, however, because as many as 20% of patients have low levels as a result of poor absorption or rapid metabolism.

Noncompliance is especially common in adolescents and elderly persons, when seizures are infrequent or not perceived as disabling, when AEDs must be taken several times each day, and when toxic effects persist. Compliance can be improved by patient education, by simplifying drug regimens (using less frequent dosing with extended-release preparations when appropriate), and by tailoring dosing schedules to the patient's daily routines. Pillbox devices that alert the patient to scheduled doses can be useful.

PSYCHOGENIC SEIZURES

Psychogenic nonepileptic seizures (PNES) are diagnosed in 20% to 30% of patients who present to epilepsy centers for difficult to control seizures. They are often misdiagnosed as epileptic seizures and are treated with antiseizure medications without adequate investigation, quite often resulting in significant morbidity. The estimates of prevalence of concurrent epilepsy among patients with PNES vary from 5% to 56%. They are believed to be a manifestation of an underlying psychological stress and are classified under conversion disorders, which are a type of somatoform disorder. A specific traumatic event at any point of time in the patient's life, including physical or sexual abuse, death of a loved one, divorce, or other similar loss may be identified in patients with PNES. The diagnosis of PNES can be challenging, as the presentation of these seizures is very diverse; they can range from mimicking a generalized convulsion to less often, an atonic event. Although no single semiologic feature is specific for diagnosing PNES, the motor manifestations usually are more asynchronous, variable, and fluctuating in intensity, and specific movements such as writing, thrashing, pelvic thrusting, opisthotonus, and jactitation are more suggestive of PNES (Video 58.6). Ictal stuttering, weeping, and eye closure are relatively uncommon in epileptic seizures and are suggestive of, but not diagnostic of, PNES. In one study, the occurrence of an episode in the doctor's examination room was estimated to have a 75% predictive value for PNES. Video-EEG evaluation is almost always required to verify the diagnosis, as descriptions of patients and onlookers are invariably incomplete, and even trained medical personnel cannot reliably distinguish epileptic from nonepileptic seizures by visualization alone. PNES also can occur in patients with concurrent epilepsy, further confounding accurate diagnosis of each event. Even with video-EEG recording, some frontal lobe seizures with bizarre semiologies can be misdiagnosed as PNES and often do not have an ictal EEG correlate. The key challenge is in presenting the diagnosis to patients, as acceptance of the diagnosis is a very important factor in response to treatment and counseling. Psychiatric intervention is the mainstay of treating PNES and is individualized according to the underlying psychiatric comorbidity. Ideally after diagnosis, the patients should be followed by a neurologist and a psychiatrist with close dialogue between the two, and cautious

discontinuation of the antiseizure medication should be coordinated, where applicable. Neurologic follow-up should be maintained after the diagnosis, until the patient has been fully transitioned to psychiatric care.

Videos can be found in the companion e-book edition. For a full list of video legends, please see the front matter.

Ménière Syndrome, Benign Paroxysmal Positional Vertigo, and Vestibular Neuritis

Ian S. Storper

INTRODUCTION

Three of the most common causes of peripheral vertigo are Ménière syndrome, benign paroxysmal positional vertigo, and vestibular neuritis. Each syndrome has its own distinct type of vertigo. The purpose of this chapter is to explain the clinical presentation and current treatment principles of each syndrome to aid the clinician in diagnosis and management.

MÉNIÈRE DISEASE

Although Ménière disease was described over 140 years ago, little about it is understood. The condition is often progressive; with medical and surgical treatment options, however, disability may be averted or ameliorated. A recent study using health claims data from 60 million patients in the United States reports prevalence as 190 per 100,000 with a female-to-male ratio of 1.89:1 [Level 1].¹ The prevalence increases with age.

This disease was first reported by Prosper Ménière in Paris in 1861 [Level 1].¹³ As described, patients typically suffered recurrent attacks of vertigo lasting from hours to days. Coincident with the attacks were episodes of unilateral hearing loss and roaring tinnitus. At first, the hearing loss and tinnitus occurred only with the attacks, but as the disease progressed, they became permanent. In 1943, Cawthorne added a fourth symptom: fullness in the affected ear. Table 59.1 lists the clinical features of Ménière disease. Although the cause of Ménière disease still remains unknown, it was postulated by Knapp in 1871 that symptoms were caused by dilatation of the endolymphatic compartment of the inner ear during attacks and renormalization afterward [Level 1].¹¹ This idea is still widely accepted, as the vast majority of patients respond to sodium management.

DEFINITIONS

Ménière disease is defined as the *idiopathic* occurrence of attacks of vertigo, hearing loss, tinnitus, or fullness in the affected ear. If a cause is assumed, the term is *Ménière syndrome*. The causes of Ménière syndrome are listed in Table 59.2.

Episodes typically last from hours to days. After an attack, the patient often feels “foggy” or tired. Initially, only one or two symptoms may be present; for example, a patient may experience only episodic vertigo; the hallmark is fluctuation. In the early stages, patients are often asymptomatic between attacks. With progression, low-frequency hearing loss can become permanent and may progress to all frequencies. Tinnitus is usually loud and roaring. Vertigo can be severe, a true spinning sensation of the patient or surroundings. Nausea, vomiting, sweating, and pallor are typical, as the vertigo arises in the inner ear rather than in the brain. Some describe a linear motion or feel as if they are on a boat. Rarely, vertigo is noted only with change of position, mimicking benign paroxysmal positional vertigo. It is distinguishable because positional vertigo of Ménière disease occurs in attacks. If left untreated, disequilibrium may persist between attacks of vertigo. Most Ménière sufferers are women, attributable to hormonal causes of increased water retention. Symptoms may be worse prior to the menstrual cycle.

TABLE 59.1 Ménière Disease Clinical Features

Episodes of the following:

- Unilateral hearing loss
- Tinnitus in affected ear
- Vertigo
- Fullness in affected ear

TABLE 59.2 Some Causes of Ménière Syndrome

- Trauma or trauma or rupture of the inner ear membranes (perilymphatic fistula)

- Postinfectious: labyrinthitis, meningitis, Lyme disease, or otosyphilis

- Congenital anatomic abnormality

- Tumor, e.g., vestibular Schwannoma pressing on the eighth nerves

- Vertebrobasilar insufficiency—central signs and symptoms are also seen

Typically, attacks become less frequent and less severe over time, with or without medical management. Within about 2 years of diagnosis, more than half of all patients are better, even without treatment. Treatment decreases the frequency and severity of attacks and minimizes permanent hearing or balance loss. Only 5% of medically treated patients progress to surgery.

About 10% of patients never experience vertigo; their disorder is termed *cochlear Ménière disease*. Ten percent of patients never experience auditory symptoms. The term *burned out Ménière disease* applies to the patient who has totally lost auditory and vestibular function. There is no loss of consciousness during Ménière attacks; if it occurs, neurologic disease is likely. A rare entity associated with Ménière disease is referred to as *drop attack* or *crisis of Tumarkin*; the patient suddenly drops to the ground. Head injury may ensue.

DIAGNOSIS

Ménière disease is diagnosed clinically; no test has sufficient sensitivity and specificity to be pathognomonic. Tests are used to rule out other disorders and to help confirm the diagnosis. Careful history and physical examination are essential. Ménière disease should be considered in any patient without other obvious cause who suffers episodic vertigo, hearing loss, tinnitus, or fullness in the ear. Ménière disease is not diagnosed unless symptoms have occurred at least twice. Between attacks, the examination is often normal, especially early in the disease. During an attack, a patient typically

vertical, central nervous system (CNS) disease is considered.

Tests that aid in the diagnosis of Ménière disease include audiometry (complete audiologic evaluation [CAE]), videonystagmography (VNG), and magnetic resonance imaging (MRI). If the symptoms are bilateral, blood tests for autoimmune inner ear disease and infections are ordered. Early in the disease, the CAE is often normal. Later, low-frequency sensorineural hearing loss can develop. Ultimately, hearing loss may also involve high frequencies. Rarely, the hearing asymmetries may be in the high frequencies rather than the low frequencies. During an attack, there may be hearing loss in the affected ear, which may resolve afterward. If conductive hearing loss is found, other diagnoses, such as superior semicircular canal dehiscence or cholesteatoma, should be considered.

Early in Ménière disease, the VNG is usually normal because vestibular function recovers between attacks. As the disease progresses, caloric testing often yields a unilateral vestibular weakness. If testing is inadvertently performed during an attack, hyperfunction of the affected ear is usually seen. In end-stage disease, there is complete weakness (100%) in the affected ear. If central pathology is the cause of vertigo, caloric test results are usually normal. Gaze and positional testing, as well as optokinetic nystagmus testing, are often abnormal.

MRI is recommended for every patient with recurrent vertigo, asymmetric sensorineural hearing loss, or unilateral constant tinnitus. The study should include the brain and internal auditory canals, with and without gadolinium. This test evaluates intracranial pathology such as vestibular Schwannoma, stroke, or demyelination, which can cause these symptoms. If symptoms begin after age 60 years, Doppler examinations are performed to evaluate possible cerebrovascular disease. Electrocochleography is helpful in diagnosing Ménière disease. The test demonstrates high ratios of the summing potential/action potential in Ménière patients; sensitivity and specificity are not high enough for routine use. Once other causes are excluded, the most accurate way to establish the diagnosis is to determine whether it responds to treatment.

MEDICAL TREATMENT

Therapy begins with diet and medication. Approximately 85% of patients respond very well, with significant decrease in frequency and severity of attacks. About 5% of patients find that therapy with diet and medication is inadequate and requires middle ear injections or surgery.

The standard for medical management is a low-sodium diet and thiazide diuretic. First, it should be ascertained that this is safe for the patient by consultation with their internist. A new patient should be started on a diuretic between attacks of vertigo. Diet should be a strict 1,500 mg/day sodium regimen; the patient should be informed that this requires checking labels carefully. If patients eat outside the home, it should be in places where they can limit the amount of sodium. Sodium intake should be even with each meal to avoid surges in pressure. Patients are advised to drink copious amounts of water to help flush out the sodium and maintain blood pressure. They are urged to avoid caffeine and alcohol, which are thought to aggravate symptoms. Emotional stress can also aggravate Ménière disease, and psychiatric consultation may be necessary.

Because sodium levels are hormonally regulated, adding a diuretic is useful. Typically, the patient is started on hydrochlorothiazide 37.5 mg/triamterene 25 mg once daily. This diuretic sheds sodium well and is required only once daily. Triamterene typically protects the potassium level. Electrolyte levels and renal function should be monitored periodically while this diuretic is being taken. Discontinuation or dose adjustment may be required. Patients should be advised that it can take a few weeks to know if this regimen is beneficial.

TABLE 59.3 Medical Treatment of Ménière Disease

- 1,500 mg/day sodium diet and increased water intake

- Thiazide diuretic

- Vestibular suppressants

- Anticholinergics

- Antihistamines

- Benzodiazepines

- Corticosteroids

Vestibular suppressants can help control vertigo during attacks. Anticholinergic drugs are useful because they are not severely sedating. The author prefers glycopyrrolate 2 mg by mouth (PO) twice daily as needed during attacks. An alternative is meclizine 12.5, 25, or 50 mg PO up to three times daily. Although meclizine is effective, it is sedating. Benzodiazepines are also vestibular suppressants. Diazepam 5 mg PO three times daily during attacks can be useful but is also sedating and habit forming. It should be used with caution if vertigo does not respond to the other drugs mentioned. Corticosteroids may also be beneficial.

[Table 59.3](#) summarizes medical treatment of Ménière disease.

In the event of intractable vertigo with nausea and vomiting, an emergency room visit may be necessary. Intravenous hydration should be administered, being careful not to overload the patient with sodium. Promethazine 75 mg intramuscularly or droperidol 0.625 mg intravenously are useful for emergencies, but both are heavily sedating.

SURGICAL MANAGEMENT

Surgical treatments for Ménière disease may be destructive or conservative. In all cases, these operations are performed only if symptoms persist despite medical optimization.

Conservative Procedures

ENDOLYMPHATIC SHUNT

These procedures are designed to decrease the pressure in the endolymphatic compartment by shunting the fluid out of it. Current shunting procedures are performed under general anesthesia by drilling medially through the mastoid cortex down to the endolymphatic sac, opening it, and allowing the fluid to drain into the mastoid cavity.

In the past, shunts were controversial. The controversy arose in the 1980s when a Danish group found similar vertigo control in patients who had undergone endolymphatic shunts to those who had undergone only mastoidectomy (“sham procedures”) [Level 1].¹⁷ However, the same data were reevaluated in 2000

by Welling and Nagaraja [**Level 1**].¹⁸ In comparing the shunt group to the sham group, vertigo control was significantly better in the shunt group, nausea and vomiting were significantly less in the shunt group, and tinnitus was significantly less in the shunt group. Sood et al. in 2014 published a meta-analysis of all articles citing results from this operation according to current guidelines from 1970 to 2013. They report that endolymphatic shunt controls vertigo effectively in 75% of patients who failed medical treatment [**Level 1**].¹⁶ Complications of shunt procedures are rare and do not differ significantly from those of mastoidectomy. It is a reasonable first procedure for patients with good hearing and mild to moderate vertigo.

P.492

VESTIBULAR NEURECTOMY

The vestibular nerve can be separated from the cochlear nerve and sectioned. Although the vestibular nerve is cut, this procedure is generally considered a conservative procedure because hearing is preserved. The risks of craniotomy must be considered, and the indications are more stringent. Patient selection criteria for vestibular neurectomy include episodic disabling vertigo owing to Ménière disease, serviceable hearing in the affected ear, and failure of medical management. Moreover, there must be unilateral vestibular weakness in the affected ear on caloric testing but not 100%. This procedure should not be performed on the side of an only hearing or significantly better hearing ear. The results of vestibular neurectomy are excellent [**Level 1**].^{3,12} Vertigo is controlled in 94% of patients. Hearing loss, tinnitus, and fullness are unaffected; the patient must continue on low-sodium diet and diuretic. Complications include sensorineural hearing loss in 2% to 3% of patients, cerebrospinal fluid (CSF) leak in 5% to 12%, temporary unsteadiness in up to 25%, headache in 10%, and tinnitus in 7%. It should be performed in patients with disabling episodic vertigo or in those who have failed shunt surgery.

DESTRUCTIVE PROCEDURES: LABYRINTHECTOMY

In this operation, the vestibular portion of the inner ear is destroyed and all five end organs are removed. Because the hearing in the operated ear is destroyed, this procedure is limited to patients with no serviceable hearing in the affected ear; who suffer from episodic, disabling vertigo; and in whom medical management has failed. This is the standard for vertigo control in patients with no hearing. Vestibular weakness must be shown in the affected ear on caloric testing but not 100%. Labyrinthectomy typically eradicates attacks of vertigo about 95% of the time. Aside from temporary postoperative unsteadiness in 10% of patients, the risks of this procedure do not differ significantly from those of mastoidectomy. [Table 59.4](#) lists surgical options for Ménière disease.

OTHER TREATMENT METHODS

Intratympanic Corticosteroids

Intratympanic dexamethasone given at regular intervals has been described as a method of controlling episodes of Ménière disease which continue despite adherence to low sodium diet and diuretic therapy [**Level 1**].²⁰ Typically three perfusions of dexamethasone 24 mg/ml separated by 10 minutes are performed for a total of 1 ml. Repeat injections may be necessary for recurrent symptoms.

Intratympanic Gentamicin

Gentamicin is instilled into the middle ear, which provides a pathway into the inner ear via the round window. This aminoglycoside preferentially destroys vestibular hair cells over cochlear hair cells. Results vary. Vertigo control is about 80%, but there is significant incidence of sensorineural hearing loss. In one study, it was found that patients given intratympanic gentamicin had a statistically significant decrease in pure tone average and

speech discrimination scores but that patients undergoing vestibular neurectomy did not. Vertigo control was achieved in 80% of patients given gentamicin and in 95% of patients with neurectomy. In another study, 90% of patients had complete initial control of vertigo after gentamicin, but 29% had recurrence after 4 months. In a third more recent study, 85% of patients had complete control of vertigo from gentamicin perfusion, but hearing was decreased in 25.6% [Level 1].^{8,9,19} Gentamicin is less effective for vertigo control than surgery. There is risk of postprocedure long-term unsteadiness. In 2014, Casani et al. demonstrated less long-term unsteadiness and hearing loss using a lower dose regimen [Level 1].⁴

TABLE 59.4 Surgical Options for Ménière Disease

- Endolymphatic shunt

-
- Vestibular neurectomy

-
- Labyrinthectomy

Meniett Device

This device delivers pressure pulses to the inner ear via a tympanostomy tube to generate gradients in the endolymphatic compartment via the round window. The device is worn for 5 minutes three times per day. Significant benefit from the use of this device has not been clearly demonstrated.

Streptomycin

This drug has been banned by the U.S. Food and Drug Administration (FDA) because of its inner ear toxicity. However, it is useful for end-stage patients with bilateral Ménière disease who still have attacks of vertigo and no hearing. The drug is administered intramuscularly, in regular doses, until caloric responses disappear. The drug eradicates the remaining vestibular function.

BENIGN PAROXYSMAL POSITIONAL VERTIGO

Benign paroxysmal positional vertigo (BPPV) has been described as the most common cause of peripheral vertigo with prevalence from 10.7 to 64 cases per 100,000 and prevalence over a lifetime of 2.4% [Level 1].¹⁰ The average age of onset is from 50 to 60 years, with a 2 to 3:1 female-to-male ratio. It was first described by Barany in 1921 [Level 1].² Patients report episodic vertigo sensations, which are caused by head motion; often, patients describe it as being aggravated by arising from or getting into bed or tossing during sleep. These episodes can be intense and can cause a fall. Characteristically, there is no vertigo if there is no head motion. Each episode typically lasts for less than a minute. There is no hearing loss, tinnitus, or fullness in the ear associated with this condition. The incidence increases with age and there is a slight female-to-male predominance. Approximately half of cases occur after head trauma.

This disorder is thought to be caused by dislodgement of otoconia—calcium carbonate crystals normally present in the utricle or saccule—into the semicircular canals. These crystals add inertia to the torsion-pendulum model of semicircular canal activation. When there is a mismatch of inertia between the two ears, there is disagreeing signal sent along the right and left vestibular nerves, resulting in nystagmus and a sensation of vertigo until the

inner ear motion has stopped. This condition is self-limited; it, however, can be present for an extended period of time prior to dissipating. This condition most commonly occurs in the posterior semicircular canal and occasionally the horizontal semicircular canal; it rarely occurs in the superior semicircular canal.

Diagnosis is established by provocative positional maneuvers. For posterior canal BPPV, the Dix-Hallpike maneuver is performed, where the patient's head is turned toward the affected side and they lie back quickly, extending the neck [Level 1].¹⁵ If the maneuver is positive, vertical-torsional nystagmus is seen for a number of seconds, with latency and fatigability. For horizontal canal BPPV, diagnosis is established by seeing horizontal nystagmus with latency and fatigability when rolling the head to the affected side in the supine position. Diagnosing superior canal BPPV involves eliciting vertical nystagmus and central lesions need to be excluded. These maneuvers should not be performed unless neurovascular problems have been excluded first.

P.493

Treatment involves canalith repositioning maneuvers, thought to dislodge the crystals and allow them to drop out into a safe compartment of the inner ear. Although there are a numerous maneuvers, the most common ones are those described by Epley in 1992 [Level 1].⁶ For posterior semicircular canal BPPV, the maneuver consists of five steps: (1) Dix-Hallpike maneuver; (2) turning the head to the opposite side; (3) rolling over onto the opposite side, head downward; (4) sitting up and then turning the head forward; and (5) tucking the chin. The maneuver is repeated until nystagmus dissipates. The patient is instructed to keep their head level for the next 48 hours. This maneuver is highly successful but sometimes has to be repeated over multiple sessions. Physical therapists can be consulted. For severe, recalcitrant cases, singular neurectomy can be offered.

VESTIBULAR NEURITIS

Vestibular neuritis (or vestibular neuronitis) was described by Dix and Hallpike in 1952. It is a clinical syndrome where a patient develops severe vertigo, often associated with nausea, vomiting, and/or prostration, which resolves over a period of days to weeks. There are no other neurologic deficits and there is no loss of consciousness. In general, older age portends a prolonged and possibly incomplete recovery. Vestibular neuritis has an incidence of about 3.5 cases per 100,000 persons [Level 1].¹⁵ Typical age of onset is between 30 and 60 years and there is no gender difference. Approximately 30% of affected individuals suffered an upper respiratory infection preceding their symptoms.

The cause of this condition has been postulated to be reactivation of herpes simplex or other neurotropic virus, but this has not been proven. Histologic findings performed postmortem on individuals who have suffered this condition have shown an atrophic superior vestibular nerve and ganglion [Level 1].¹⁴

Treatment is supportive. Hydration may be required and during the intense period, vestibular suppressants are helpful. They should be discontinued as soon as reasonable as they can prolong recovery time. Imaging studies such as MRI and computed tomography angiography (CTA) are typically ordered to rule out neurovascular or other central causes. Patients usually exhibit nonfatigable horizontal nystagmus at presentation. After the initial severe vertigo has dissipated, recovery time can be prolonged in some individuals whence vestibular rehabilitation can be beneficial. A recent study showed that corticosteroids administered over the first 3 weeks after onset improved symptoms more quickly than vestibular rehabilitation but that long-term results were similar [Level 1].⁷

CONCLUSION

The clinical syndromes of three of the most common types of peripheral vertigo have been discussed. It should be remembered that there are numerous other causes of peripheral and central vertigo to be considered when evaluating patients.

Transient Global Amnesia

John C. M. Brust

INTRODUCTION

Transient global amnesia (TGA) is characterized by sudden inability to form new memory traces (*anterograde amnesia*) in addition to retrograde memory loss for events of the preceding days, weeks, or even years.

EPIDEMIOLOGY

Patients are usually middle aged or elderly and otherwise healthy. Recurrent attacks occur in 15% to 30% of cases, and fewer than 3% have more than three attacks. Intervals between attacks range from 1 month to 19 years.

PATHOBIOLOGY

The cause of TGA is uncertain. Case-control series and anecdotal reports variably implicate seizures, stroke, or migraine. Against an epileptic basis for TGA are the infrequency of recurrence, absence of other seizure phenomena, and normal electroencephalogram (EEG) even during attacks. In transient epileptic amnesia (TEA), attacks are usually less than an hour in duration, tend to occur on awakening, are often accompanied by other ictal symptoms, and are likely to recur; ictal and interictal EEG abnormalities are often present, and symptoms respond to anticonvulsant therapy.

TGA has been anecdotally described in association with carotid artery occlusion and amaurosis fugax, with infarction of the inferomedial temporal lobe, the cingulate gyrus, or the retrosplenial corpus callosum and with cerebral angiography (especially vertebral). In large series, however, major risk factors for stroke (hypertension, diabetes mellitus, tobacco, ischemic heart disease, atrial fibrillation, and past stroke or transient ischemic attack [TIA]) are no more common among patients with TGA than in age-matched controls, and TGA is not a risk factor for stroke. Studies addressing a possible association of TGA with cardiac valvular disease or patent foramen ovale have been inconsistent. Patients with amnesic stroke owing to documented posterior cerebral artery occlusion do not report previous TGA; their neurologic signs usually include more than simple amnesia (e.g., visual impairment), and they do not exhibit repetitive queries. Reduced blood flow to the thalamus or temporal lobes has been documented during attacks of TGA but could be secondary to neuronal dysfunction rather than its cause.

Valve incompetence of the internal jugular vein is present in many patients with TGA, raising the possibility of cerebral venous congestion during Valsalva-like activities. Intracranial venous reflux during Valsalva maneuver could not be demonstrated in the same patients, however, and such a mechanism is unlikely to explain symptoms that last hours and seldom recur.

Epidemiologic studies confirm an association of TGA with migraine, even though in most migraine patients, headache attacks are recurrent, whereas attacks of TGA are not. Sometimes, both amnesic and migrainous attacks (including visual symptoms and vomiting) occur simultaneously or follow one another. A case report described a man with repeated episodes of TGA associated with sexual activity whose spells cleared as long as he took the β -blocker metoprolol. Cortical spreading depression (possibly the pathophysiologic basis of cerebral symptoms of migraine) could, by affecting the hippocampus, explain some cases of TGA.

CLINICAL MANIFESTATIONS

During attacks, which affect both verbal and nonverbal memory, there is often bewilderment or anxiety and a tendency to repeat one or several questions (e.g., “Where am I?”). Physical and neurologic examinations, including mental status, are otherwise normal. Immediate registration of events (e.g., serial digits) is intact, and self-identification is preserved. Attacks last minutes or hours, rarely longer than a day, with gradual recovery. Retrograde amnesia clears in a forward fashion, often with permanent loss for events occurring within minutes or a few hours of the attack; there is also permanent amnesia for events during the attack itself. Headache frequently accompanies attacks; less often, there is nausea, dizziness, chills, flushing, or limb paresthesias. TGA is frequently precipitated by physical or emotional stress, such as sexual intercourse, driving an automobile, pain, photogenic events, or swimming in cold water. Because amnesia can accompany a variety of neurologic disturbances, such as head trauma, intoxication, partial complex seizures, or dissociative states, criteria for diagnosing TGA should include observation of the attack by others.

Permanently impaired memory following an acute attack is rare, although subtle defects have been reported.

DIAGNOSIS

Diffusion-weighted magnetic resonance imaging (MRI) detected highly focal lesions in the CA1 field of the hippocampus in 70% of TGA patients, bilaterally in only 12%, appearing 24 to 48 hours after TGA onset (i.e., not during the acute memory impairment) and disappearing over several weeks. Magnetic resonance (MR) spectroscopy identified reversible lactate peaks within the same lesions, consistent with ischemia. Functional MRI during the acute phase of amnesia identified reversible reduced functional connectivity bilaterally in hippocampi and other temporo limbic regions considered part of an “episodic memory network.”

TREATMENT

A study of 142 cases plus literature review suggested three subgroups of TGA (excluding patients with epilepsy or TIA). In women, TGA was mainly associated with an emotional precipitating event and a history of anxiety or depression. In men, attacks are more often followed a physical precipitating event perhaps associated with a Valsalva maneuver. In younger patients, an association with

P.495

migraine was most prominent. Thus, even when strict diagnostic criteria are applied, TGA probably has diverse origins. In patients in whom epilepsy and migraine can be excluded and who have risk factors for cerebrovascular disease, antiplatelet drugs should be considered, but the benign natural history makes it difficult to evaluate any preventive treatment.

Acute Bacterial Meningitis and Infective Endocarditis

Burk Jubelt

Barnett R. Nathan

INTRODUCTION

The parenchyma, coverings, and blood vessels of the nervous system may be invaded by virtually any pathogenic microorganism. It is customary, for convenience of description, to divide the syndromes produced according to the initial site of involvement. This division is arbitrary because the inflammatory process frequently involves more than one of these structures.

Involvement of the meninges by pathogenic microorganisms is known as *leptomeningitis* when the infection and inflammatory response are confined to the subarachnoid space and the arachnoid and pia. Cases are divided into acute, subacute, and chronic meningitis according to the rapidity with which the inflammatory process develops. This rate of development, in part, is related to the nature of the infecting organism. Chronic meningitis is discussed in Chapter 64. In some cases, acute bacterial meningitis can be complicated by focal purulent abscesses of the central nervous system (CNS) (Fig. 61.1) or its surrounding structures (empyema). These focal bacterial infections are discussed in Chapter 62.

FIGURE 61.1 Epidural abscess. **A:** Axial, noncontrast CT demonstrates a right posterior temporal lucent epidural collection with prominent white matter edema in the underlying cerebral parenchyma. Calcified choroid in the effaced atrium of the right lateral ventricle is shifted anteromedially. **B:** Postcontrast scan at this same level demonstrates abnormal dural enhancement and shift of the internal cerebral veins owing to the mass effect. (Courtesy of Drs. J. A. Bello and S. K. Hilal.)

Acute bacterial meningitis presents as a neurologic emergency and often overlaps with sepsis, and the principles of therapy are the same: early initiation of broad-spectrum antibiotics, volume resuscitation and vasopressors in

the face of hypotension, and careful attention to airway control and oxygenation.

ACUTE BACTERIAL MENINGITIS

Bacteria may gain access to the ventriculosubarachnoid space by way of the blood, in the course of septicemia, or as a metastasis from infection of the heart, lung, or other viscera. The meninges may also be invaded by direct extension from a septic focus in the skull, spine, or parenchyma of the nervous system (e.g., sinusitis, otitis, osteomyelitis, brain abscess). Organisms may also gain entrance to the subarachnoid space through compound fractures of the skull and fractures through the nasal sinuses or mastoid or after neurosurgical procedures. Pathogen introduction by lumbar puncture is rare. The pathologic background, symptoms, and clinical course of most patients with acute purulent meningitis are similar

P.497

regardless of the causative organism. The classic triad of fever, neck stiffness, and altered mental status occurs in less than half of all patients, but 95% have at least two of four symptoms of fever, neck stiffness, altered mental status, and headache. Empiric therapy depends on age, whether the infection is community or nosocomially acquired, and other risk factors (head trauma or surgery, crowded living conditions, and underlying illnesses [e.g., diabetes, alcoholism, hematologic and immunologic disorders]). Diagnosis and therapy depend on the isolation and identification of the organism and determination of the source of the infection (Fig. 61.2).

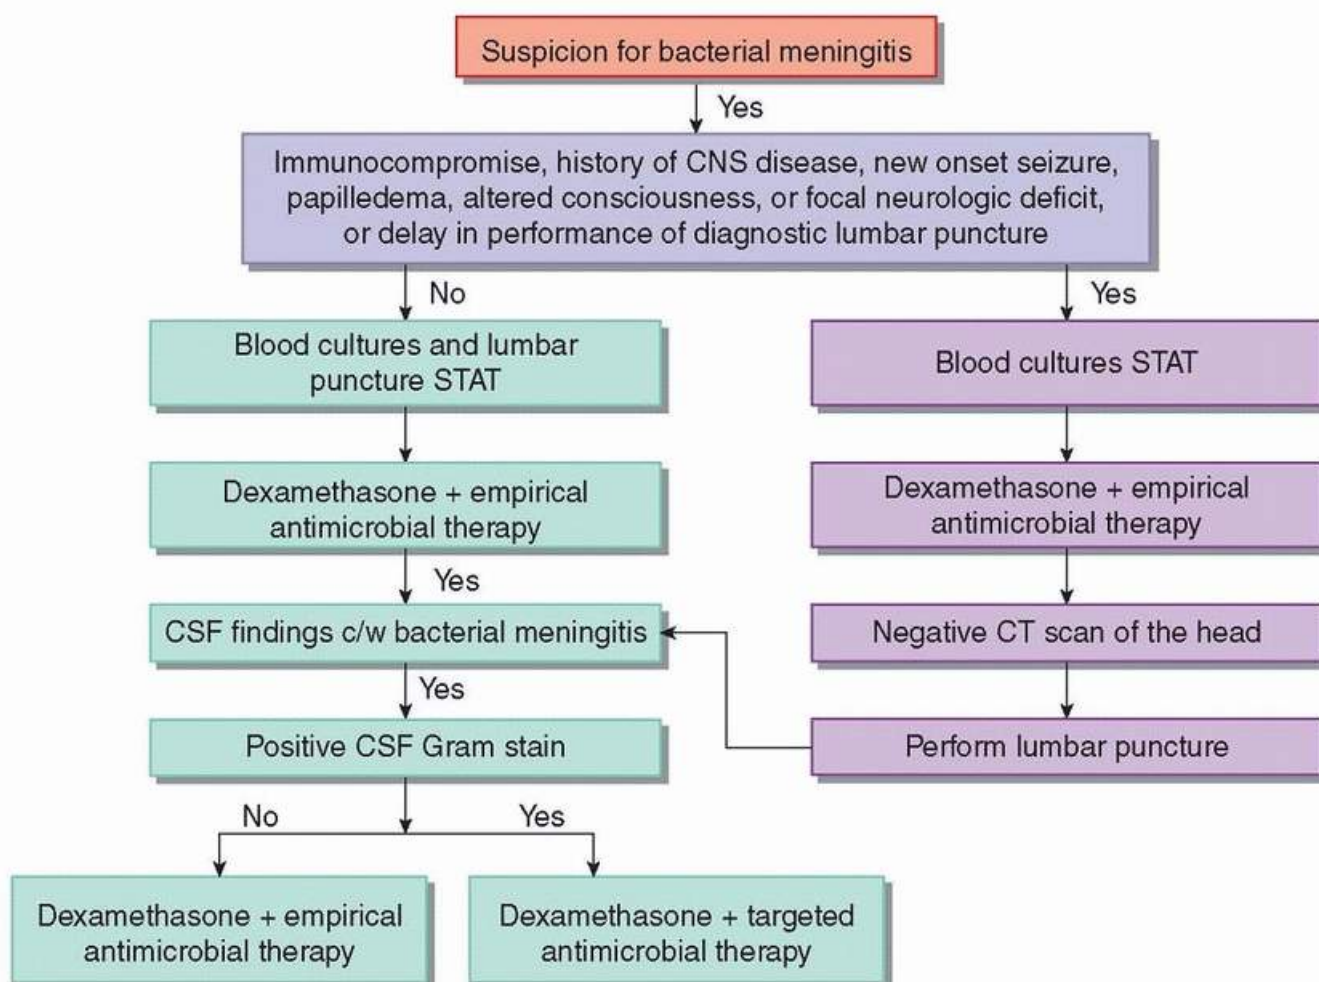

FIGURE 61.2 Management algorithm for adults with suspected acute bacterial meningitis. CNS, central nervous system; STAT, immediately; CSF, cerebrospinal fluid; CT, computed tomography. (From Tunkel AR, Hartman BJ, Kaplan SJ, et al. Practice guidelines for the management of bacterial meningitis. *Clin Infect Dis*. 2004;39:1267-1284.)

Acute purulent meningitis may be the result of infection with almost any pathogenic bacteria. Isolated examples of

infection by uncommon forms are recorded in the literature. In the United States, *Streptococcus pneumoniae* now accounts for about one-half of cases when the infecting organism is identified, and *Neisseria meningitidis* accounts for about one-fourth of the total cases (Table 61.1).

In the neonatal period, group B streptococci and *Escherichia coli* are the most common causative agents. Approximately 60% of the postneonatal bacterial meningitis of children used to be caused by *Haemophilus influenzae*. Introduction of the *H. influenzae* type B vaccine was followed by a 100-fold decrease in incidence. However, the peak incidence still occurs in children younger than 2 months of age. Overall fatality rate from bacterial meningitis is now about 15%. Many deaths occur during the first 48 hours of hospitalization.

TABLE 61.1 Causes of Bacterial Meningitis in the United States

Organism	Adults (18 Yr and Older)		Children (17 Yr and Younger)	
	No. of Cases Reported	Percentage of Total	No. of Cases Reported	Percentage of Total
<i>Haemophilus influenzae</i>	65	6%	47	8%
<i>Streptococcus pneumoniae</i>	769	71%	200	34%
<i>Neisseria meningitidis</i>	130	12%	106	18%
Group B <i>Streptococcus</i>	76	7%	223	38%
<i>Listeria monocytogenes</i>	46	4%	12	2%
Total	1,086	100%	588	100%

Data from Thigpen MC, Whitney CG, Messonnier NE, et al. Bacterial meningitis in the United States, 1998-2007. *N Engl J Med.* 2011;364(21):2016-2025.

MENINGOCOCCAL MENINGITIS

Meningococcal meningitis occurs in sporadic form and at irregular intervals in epidemics. Epidemics are especially likely to occur during large shifts in population, and crowding as in a time of war, and in college dormitories.

Epidemiology

Meningococcus is the causative organism in about 25% of all cases of bacterial meningitis in the United States. Serogroup B is now the most commonly reported serotype (50%). Children and

young adults are predominantly affected. The normal habitat of the meningococcus is the nasopharynx, and the disease is spread by colonized individuals. A polysaccharide vaccine for groups A, C, Y, and W-135 meningococci has reduced the incidence of meningococcal infection among military recruits. The vaccine also has been used for control of serogroup C outbreaks in schools and on college campuses and for children with increased risk of infection (asplenia, HIV infection, complement deficiencies).

Pathobiology

Meningococci (*N. meningitidis*) may gain access to the meninges directly from the nasopharynx through the cribriform plate. The bacteria, however, are usually recovered from blood before meningitis commences, indicating that colonization of the nasopharynx with subsequent bacteremia and spread to the CNS is more common.

The bacterial polysaccharide capsule seems to be most important in attachment and penetration to gain access to the body. Elements in the bacterial cell wall (pili, fimbria) are critical for penetration into the cerebrospinal fluid (CSF) through the vascular endothelium and in induction of the inflammatory response.

In acute fulminating cases, death may occur before there are any significant pathologic changes in the nervous system. In the usual case, when death does not occur for several days after onset of the disease, an intense inflammatory reaction occurs in the meninges. The inflammatory reaction is especially severe in the subarachnoid space over the convexity of the brain and around the cisterns at the base of the brain. It may extend along the Virchow-Robin perivascular spaces into the brain and spinal cord. Meningococci, both intra- and extracellular, are found in the meninges and CSF. With progression of the infection, the pia-arachnoid becomes thickened and adhesions may form. Inflammatory reaction and fibrosis of the meninges along the roots of the cranial nerves are thought to cause the cranial nerve palsies that are seen occasionally.

Damage to the auditory nerve often occurs suddenly, and the resulting hearing loss is usually permanent. The damage may result from extension of the infection to the inner ear or from thrombosis of the nutrient artery. Signs and symptoms of parenchymal damage (e.g., hemiplegia, aphasia, and cerebellar signs) are caused by infarcts resulting from thrombosis of inflamed arteries or veins.

In the past, the inflammation in meningitis had been attributed mainly to the toxic effects of bacteria. In all types of meningitis, the contribution to the inflammatory process of cytokines released by phagocytic and immunoreactive cells, particularly interleukin 1 and tumor necrosis factor, has been recognized. These studies have formed the basis for the use of anti-inflammatory corticosteroids in the treatment of meningitis.

Clinical Manifestations

The onset of meningococcal meningitis is similar to that of other forms of meningitis and is accompanied by chills and fever, headache, nausea and vomiting, pain in the back, stiffness of the neck, and prostration. The occurrence of a petechial or hemorrhagic skin rash is a manifestation of meningococcemia. At the onset of meningitis, the patient is irritable. In children, there is frequently a characteristic sharp, shrill cry (meningeal cry). With progress of the disease, the sensorium becomes clouded and stupor or coma may develop. Occasionally, the onset may be fulminant and accompanied by deep coma. Convulsive seizures are often an early symptom, especially in children, but focal neurologic signs are uncommon in the initial presentation.

The patient appears acutely ill and may be confused, stuporous, or obtunded. The temperature is elevated at 101°F to 103°F, but it may occasionally be normal at the onset. The pulse is usually rapid and the respiratory rate is increased. Blood pressure is normal except in acute fulminating cases when there may be profound hypotension. A petechial rash may be found in the skin, mucous membranes, or conjunctiva in meningococcemia but never in the nail beds. It usually fades in 3 or 4 days. There is rigidity of the neck with Kernig and Brudzinski

signs. These signs may be absent in newborn, elderly, or comatose patients. Increased intracranial pressure causes bulging of an unclosed anterior fontanelle and periodic respiration. Cranial nerve palsies and focal neurologic signs are uncommon and usually do not develop until several days after the onset of infection. The optic discs are normal, but papilledema is a sign of increased intracranial pressure.

Complications and sequelae include those commonly associated with any inflammatory process in the meninges and cerebral blood vessels (i.e., convulsions, cranial nerve palsies, focal cerebral lesions, damage to the spinal cord or nerve roots, hydrocephalus) and those that are due to involvement of other portions of the body by meningococci (e.g., panophthalmitis and other types of ocular infection, arthritis, purpura, pericarditis, endocarditis, myocarditis, pleurisy, orchitis, epididymitis, albuminuria or hematuria, adrenal hemorrhage). Disseminated intravascular coagulation may complicate the meningitis. Complications may also arise from intercurrent infection of the upper respiratory tract, middle ear, and lungs. Any of these complications may leave permanent residua, but the most common sequelae are due to injury of the nervous system. These include deafness, ocular palsies, blindness, changes in cognitive functioning, convulsions, and hydrocephalus. With the available methods of treatment, complications and sequelae of meningeal infection are rare, and the complications due to the involvement of other parts of the body by the meningococci or other intercurrent infections are more readily controlled.

Diagnosis

The white blood cell count is increased, usually in the range of 10,000/mm³ to 30,000/mm³, but occasionally may be normal or higher than 40,000/mm³. The urine may contain albumin, casts, and red blood cell (RBC). Meningococci may be cultured from the nasopharynx in most cases, from the blood in more than 50% of the cases in the early stages, and from skin lesions when these are present.

The CSF is under increased pressure, usually between 200 and 500 mm H₂O. The fluid is cloudy (purulent) because it contains a large number of cells, predominantly polymorphonuclear leukocytes. The cell count in the fluid is usually between 2,000/mm³ and 10,000/mm³. Occasionally, it may be less than 100/mm³ and infrequently, more than 20,000/mm³. The protein concentration is increased. The glucose concentration is decreased usually to levels below 20 mg/dL. Gram-negative diplococci may be seen intra- and extracellularly in stained smears of the fluid, and meningococci may be cultured in more than 90% of untreated patients. Meningococcal meningitis may be diagnosed with certainty only by the isolation of the organism from the CSF. The diagnosis may be made, however, with relative certainty before the organisms are isolated in a patient with headache, vomiting, chills and fever, neck stiffness, and a petechial cutaneous rash, especially if there is an epidemic of meningococcal meningitis or if there has been exposure to a known case of meningococcal meningitis.

To establish the diagnosis of meningococcal meningitis, cultures should be made of skin lesions, nasopharyngeal secretions, blood, and CSF. The diagnosis may be established in many cases by examination of smears of the sediment of the CSF after application of the Gram stain.

Treatment

Antibiotic therapy for bacterial meningitis usually commences before the causative organism is confirmed (empiric therapy). Therefore, the initial regimen should be appropriate for most likely organisms, the determination of which depends to some extent on the patient's age and the predisposing and associated conditions. Third- or fourth-generation cephalosporins, usually ceftriaxone or cefotaxime, in combination

with vancomycin have become the first choice of treatment for bacterial meningitis (Table 61.2). Their spectrum is broad, and they have become particularly useful since the occurrence of *S. pneumoniae* strains that are resistant to penicillin or ampicillin and amoxicillin. Once the result of culture and sensitivities is known, antibiotic therapy is modified accordingly (Table 61.3). Unless a dramatic response to therapy occurs, the CSF should be examined 24 to 48 hours after the initiation of treatment to assess the effectiveness of the antibiotic. Posttreatment examination of the CSF is not a meaningful criterion of recovery, and the CSF does not need to be reexamined if the patient is clinically well. The recommended duration of treatment is 7 days.

Several studies have suggested an improved outcome with the use of corticosteroids particularly if dexamethasone 6 mg every 6 hours is given shortly before the initiation of antibiotic treatment and continued for 4 days [Level 1].¹ Corticosteroids are beneficial in treating children with acute bacterial meningitis, especially in preventing hearing loss. Data in adults confirmed meningococcal meningitis favor steroid therapy to prevent hearing loss and decrease morbidity for those living in high-income countries. The lack of benefit in low-income countries may be due to the length of time between symptom onset and medical care, as well as poor nutrition and other comorbidities.

TABLE 61.2 Recommended Empiric Antibiotics for Suspected Bacterial Meningitis according to Age or Predisposing Factors

Age or Predisposing Feature	Antibiotics
Age 0-4 wk	Ampicillin plus either cefotaxime or an aminoglycoside ^a
Age 1 mo-50 yr	Vancomycin plus cefotaxime or ceftriaxone ^b
Age older than 50 yr	Vancomycin plus ampicillin plus ceftriaxone or cefotaxime plus vancomycin ^b
Impaired cellular immunity	Vancomycin plus ampicillin plus either cefepime or meropenem
Recurrent meningitis	Vancomycin plus cefotaxime or ceftriaxone
Basilar skull fracture	Vancomycin plus cefotaxime or ceftriaxone
Head trauma, neurosurgery, or CSF shunt	Vancomycin plus ceftazidime, cefepime, or meropenem

^aUsually gentamycin 50 to 100 mg/kg.

^bAdd ampicillin if *Listeria monocytogenes* is a suspected pathogen. CSF, cerebrospinal fluid.

From van de Beek D, Brouwer MC, Thwaites GE, et al. Advances in treatment of bacterial meningitis. *Lancet*. 2012;380(9854):1693-1702.

TABLE 61.3 Dosing of Empiric Antibiotics for Acute Bacterial Meningitis

Medication	Dosing
Pediatric Dosing ^a	
Cefotaxime	50 mg/kg IV every 6 h up to 12 g/day
Ceftriaxone	75 mg/kg initially, then 50 mg/kg every 12 h, up to 4 g/day
Vancomycin	15 mg/kg IV every 8 h
Ampicillin	50 mg/kg IV every 6 h
Penicillin G	250,000 to 400,000 U/kg/day in four to six divided doses
Gentamycin	2.5 mg/kg IV every 8 h
Adult Dosing	
Cefotaxime	2 g IV every 4 h
Ceftriaxone	2 g IV every 12 h
Cefepime	2 g every 8 h
Vancomycin	750-1,000 mg IV every 12 h or 10-15 mg/kg IV every 12 h
Ampicillin	2 g IV every 4-6 h
Penicillin G	4 million units IV every 4 h
Meropenem	2 g IV every 8 h

^aOlder than 1 month of age.

IV, intravenous.

Dehydration is common in this condition, and fluid balance should be monitored carefully to avoid hypovolemic shock. Hyponatremia frequently occurs and may be caused either by overzealous free-water replacement, cerebral salt wasting, or inappropriate antidiuretic hormone (ADH) secretion. Heparinization should be considered if disseminated intravascular coagulation occurs. Anticonvulsants should be used to

control recurrent seizures. Cerebral edema may require the use of osmotic diuretics, corticosteroids, and hyperventilation.

Meningococcus can be highly contagious and is spread by droplets. Persons who have had intimate contact with patients with acute meningococcal meningitis should be given oral (PO) rifampin (children: 20 mg/kg/day; adults: 600 mg/day) as a prophylactic measure.

Outcome

The mortality rate of meningococcal meningitis has historically ranged 50% to 90%. With present-day therapy, however, the overall mortality rate is about 10%, and the incidence of complications and sequelae is low. Features of the disease that influence the mortality rate are the age of the patient, bacteremia, rapidity of treatment, complications, and general condition of the individual. The lowest fatality rates are seen in patients aged between 5 and 10 years. The highest mortality rates occur in infants, in elderly, in debilitated individuals, and in those with extensive hemorrhages into the adrenal gland.

PNEUMOCOCCAL MENINGITIS

Pneumococcus (*S. pneumoniae*) is about twice as frequent as the meningococcus as a cause of meningitis.

P.500

Epidemiology

S. pneumoniae accounts for about 50% of all bacterial meningitis. The infection may occur at any age, but more than 50% of the patients are younger than 1 year or older than 50 years. The frequency should begin to decline with vaccination of children between 2 and 23 months of age and the elderly. Clinical symptoms, physical signs, and laboratory findings in pneumococcal meningitis are similar to those in other forms of acute purulent meningitis.

Pathobiology

Meningeal infection is usually a complication of infections of the lungs, otitis media, mastoiditis, sinusitis, fractures of the skull, CSF fistulas, and upper respiratory infections. Alcoholism, surgical or functional asplenicism, sickle cell disease, and cochlear implants predispose patients to developing pneumococcal meningitis.

Diagnosis

Diagnosis is usually made without difficulty because the CSF contains many organisms. Gram-positive diplococci are seen in smears of the CSF or its sediment and identified in CSF and blood cultures.

Treatment

The prevalence of penicillin- and cephalosporin-resistant *S. pneumoniae* has made a third- or fourth-generation cephalosporin plus vancomycin the initial treatment for *S. pneumoniae* meningitis until sensitivities are known (see [Table 61.2](#)). Treatment should be continued for 2 weeks. The use of corticosteroids, especially dexamethasone 6 mg every 6 hours, for the first 4 days of illness, started before antibiotics, significantly decreases mortality, hearing loss, and morbidity in adults from high-income countries [**Level 1**].¹ Any primary focus of infection should be eradicated by surgery if necessary. Persistent CSF fistulas after fractures of the skull must be closed by craniotomy and suturing of the dura. Otherwise, the meningitis will almost certainly recur.

Outcome

Before the introduction of sulfonamide antibiotics, the mortality rate in pneumococcal meningitis was almost 100%. It is now approximately 20% to 25%. The prognosis for recovery is best in cases that follow fractures of the skull and those with no known source of infection. About 30% of survivors have permanent sequelae. The mortality rate is especially high when the meningitis follows pneumonia, empyema, or lung abscess or when a persisting bacteremia indicates the presence of an endocarditis. The triad syndrome of pneumococcal meningitis, pneumonia, and endocarditis (Austrian syndrome) has a particularly high fatality rate.

HAEMOPHILUS INFLUENZAE MENINGITIS

Infections of the meninges by *H. influenzae* were historically a disease of infants and children until the introduction of the *H. influenzae* vaccine. Now, meningitis due to *H. influenzae* is more common in adults.

Epidemiology

In the United States and other countries where *H. influenzae* type B vaccination is widespread, the incidence of meningitis due to this organism in children is now negligible. It remains an important disease elsewhere, however. Where the vaccine is not available, *H. influenzae* meningitis is predominantly a disease of infancy and early childhood; more than 50% of the cases occur within the first 2 years of life and 90% before the age of 5 years. In the United States, *H. influenzae* meningitis is now more common in adults.

Pathobiology

In adults, *H. influenzae* meningitis is more commonly secondary to acute sinusitis, otitis media, or fracture of the skull. It is associated with CSF rhinorrhea, immunologic deficiency, diabetes mellitus, and alcoholism. Currently, cases tend to occur in the autumn and spring, with fewest occurring in the summer months. The pathology of *H. influenzae* meningitis does not differ from that of other forms of acute purulent meningitis. In patients with a protracted course, localized pockets of infection in the meninges or cortex, hydrocephalus, cranial nerve palsies, and cerebrovascular complications may occur.

Clinical Features

The symptoms and signs of *H. influenzae* meningitis are similar to those of other forms of acute bacterial meningitis.

Diagnosis

The CSF abnormalities are similar to those described for the other acute meningitides. The organisms may be identified by Gram stain and cultured from the CSF. Blood cultures are often positive early in the illness.

Treatment

Because of resistance to ampicillin, third- or fourth-generation cephalosporins are used in initial therapy of *H. influenzae* meningitis and are effective. Further treatment can be directed by culture and sensitivities. A total duration of 7 days of treatment is usually sufficient. Recent studies have indicated that treatment with dexamethasone (6 mg every 6 hours, for the first 4 days of illness, started before antibiotics) may reduce the frequency of sequelae, including hearing loss and morbidity [Level 1].¹

Outcome

Antibiotic treatment has reduced the mortality rate to less than 10%, but sequelae are not uncommon. These include paralysis of extraocular muscles, deafness, blindness, hemiplegia, recurrent convulsions, and cognitive impairment. Subdural effusion, which may occur in infants with any form of meningitis, is most commonly seen with *H. influenzae* meningitis. These typically resolve without therapy.

STAPHYLOCOCCAL MENINGITIS

Staphylococci (*Staphylococcus aureus* and coagulase-negative staphylococci) are a relatively infrequent cause of meningitis. Meningitis may develop as a result of spread from furuncles on the face or from staphylococcal infections elsewhere in the body. Staphylococcal meningitis can be a complication of endocarditis, epidural or subdural abscess, and neurosurgical procedures involving shunting to relieve hydrocephalus. Intravenous treatment with either penicillinase-resistant penicillin (nafcillin) or vancomycin is the preferred treatment. Complications, such as ventriculitis, arachnoiditis, and hydrocephalus, may occur. The original focus of infection should be eradicated. Laminectomy should be performed immediately when a spinal epidural abscess is present, and a cranial subdural abscess should be drained through craniotomy openings.

P.501

STREPTOCOCCAL MENINGITIS

Infection with streptococcal strains other than *S. pneumoniae* account for less than 5% of all cases of meningitis. The symptoms are the same as for other forms of meningitis. Treatment is the same as outlined for the treatment of pneumococcal meningitis together with surgical eradication of the primary focus.

LISTERIA MONOCYTOGENES

Meningitis caused by *Listeria monocytogenes* occurs in the elderly, infants, or adults with chronic diseases (e.g., renal disease with dialysis or transplantation, cancer, connective tissue disorders, chronic alcoholism). It may occur, however, without any predisposing factor, and the incidence of such cases appears to be increasing. *L. monocytogenes* is a gram-positive, facultative anaerobic bacterium. The primary disease processes to which it is associated are sepsis and meningitis.

Epidemiology

The estimated incidence is 0.2 cases per 100,000 adults per year in developed countries. The highest incidence occurs in neonates and adults older than 60 years of age. *Listeria* is the third most frequent cause of community-acquired bacterial meningitis after *S. pneumoniae* and *N. meningitidis*.

Pathobiology

Listeriosis, both sporadic and epidemic, is primarily food-borne disease. Milk products have historically been associated with *Listeria*; however, the contamination is not just associated with dairy. There have been reports of vegetable, meat, and cold cuts. Additionally, it is reported in as many as 3% of hospital-acquired meningitis.

Clinical Manifestations

Symptoms and signs of patients presenting with *L. monocytogenes* meningitis are not significantly different from those found in the general population of patients with community-acquired bacterial meningitis. In a prospective study of patients with *L. monocytogenes* meningitis, the prevalence of the classic triad of fever, neck stiffness, and altered mental status was 43%, and almost all patients presented with at least two of the four classic

symptoms of headache, fever, neck stiffness, and altered mental status. Similar presentations have been reported in other types of community-acquired bacterial meningitis. The disease, however, can be more subacute than other causes of bacterial meningitis, with a large proportion of patients having days of symptoms prior to presentation. Occasionally, *L. monocytogenes* meningitis occurs with prominent brain stem findings (rhombencephalitis).

Diagnosis

Diagnostic workup of listeria meningitis should include a CSF examination. A higher number of patients will have atypical CSF findings (normal in up to 25%) than other types of bacterial meningitis, although the majority will still have an elevated CSF white blood cell count, elevated protein, and low glucose. Gram stain of the CSF is typically negative, although a laboratory report of “diphtheroids” seen on Gram stain can occur. Blood cultures for *L. monocytogenes* are positive in up to half of the cases of meningitis. A high number of patients develop hyponatremia.

Treatment

Ampicillin is the drug of choice for *L. monocytogenes* because the bacterium is resistant to cephalosporins. If *Listeria* is considered a reasonable possibility, ampicillin 2 g IV q4 to 6 hours should be added to the initial therapy (see [Table 61.3](#) for empiric antibiotic regimens and dosing). Trimethoprim/sulfisoxazole 10 to 20 mg/kg daily divided q6 to 12 hours is an acceptable alternative. Because most cases occur in patients with an already abnormal immune system, corticosteroids should probably not be used as adjunctive therapy.

Outcome

Even with appropriate antibiotic therapy, listeria meningitis has one of the highest mortalities of all causes of community-acquired bacterial meningitis ranging from 30% to 40%. Neurologic sequelae occur in approximately 15% of survivors.

ACUTE MENINGITIS CAUSED BY OTHER BACTERIA

Meningitis in the newborn infant is most often caused by group B β -hemolytic streptococci. Coliform gram-negative bacilli especially *E. coli* are also common. Meningitis due to these organisms often accompanies septicemia. The infant shows irritability, lethargy, anorexia, and bulging fontanelles. Meningitis caused by gram-negative enteric bacteria also occurs in immunosuppressed or chronically ill, hospitalized adult patients, and in persons with penetrating head injuries, neurosurgical procedures, congenital defects, or diabetes mellitus. In these circumstances, meningitis may be difficult to recognize because of altered consciousness related to the underlying illness.

A third- or fourth-generation cephalosporin is typically used for treatment of gram-negative meningitis. If *Pseudomonas aeruginosa* is present or suspected, ceftazidime or meropenem is preferred. Care also must be taken to ensure that the organism is sensitive to the agents chosen.

ACUTE PURULENT MENINGITIS OF UNKNOWN CAUSE

Patients may have clinical symptoms indicative of an acute purulent meningitis but with atypical CSF findings. These patients have usually manifested nonspecific symptoms and have often been treated for several days with some form of antimicrobial therapy in dosages sufficient to modify the CSF abnormalities but not sufficient to

eradicate the infection. In these cases, the CSF pleocytosis is usually only moderate (500 to 1,000 cells/mm³ with predominance of polymorphonuclear leukocytes), and the glucose concentration is normal or only slightly decreased. Organisms are not seen on stained smears and are cultured with difficulty. Repeated lumbar puncture may be helpful in arriving at the correct diagnosis. CSF polymerase chain reaction (PCR) tests may identify the organism when cultures are negative.

Antibiotics should be selected on the basis of epidemiologic or clinical factors. The age of the patient and the setting in which the infection occurred are the primary considerations. In patients with partially treated meningitis and in those with meningitis of unknown etiology, third- or fourth-generation cephalosporins and vancomycin are the antibiotics of choice for initial therapy. Ampicillin should be added in neonates or if *L. monocytogenes* is a possibility. Therapy should be modified based on antimicrobial sensitivity testing. The mortality and

P.502

frequency of neurologic complications of these patients are similar to those of patients in whom the responsible bacteria have been identified.

RECURRENT BACTERIAL MENINGITIS

Repeated episodes of bacterial meningitis signal a host defect, either in local anatomy or in antibacterial and immunologic defenses. Recurrent bacterial meningitis usually follows trauma; several years may pass between the trauma and the first bout of meningitis. *S. pneumoniae* is the most common pathogen accounting for about a third of cases. Bacteria may enter the subarachnoid space through the cribriform plate, a basilar skull fracture, erosive bony changes in the mastoid, congenital dermal defects along the craniospinal axis, penetrating head injuries, or neurosurgical procedures. CSF rhinorrhea or otorrhea is often present but may be transient. It may be detected by testing for a significant concentration of glucose in nasal or aural secretions. Cryptic CSF leaks may be demonstrated by monitoring the course of radioiodine-labeled albumin instilled intrathecally or by CT after intrathecal injection of water-soluble contrast material.

Treatment of culture-documented recurrent meningitis is similar to that for first bouts. Patients with recurrent pneumococcal meningitis should be vaccinated with pneumococcal vaccine. Surgical closure of CSF fistulas is indicated to prevent further episodes of meningitis.

ENDOCARDITIS AND SEPTIC EMBOLISM

Infective endocarditis (IE) is a systemic disease with a multitude of manifestations. Of these, perhaps none is more devastating than the effects on the brain. Cerebrovascular complications have been reported to occur in 25% to 80% in the case of IE, although most studies hover around 30%.

EPIDEMIOLOGY

The etiology of IE has changed remarkably in the antibiotic era. Rheumatic heart disease now accounts for fewer than 25% of cases, whereas it once accounted for nearly 75%. At the present time, endocarditis is secondary to prosthetic valves, intravenous drug use, and degenerative cardiac disease related to aging. Congenital heart abnormalities remain an important cause, especially in children. Unfortunately, morbidity and mortality rates have not been affected much by these etiologic changes and the use of antibiotics, thus probably reflecting more severe infections at the present time. In the past, the terms *acute* or *subacute* were used to describe IE. These subdivisions, however, are artificial; the underlying cause of the endocarditis and the specific organism involved are more useful considerations when determining prognosis and treatment.

PATHOBIOLOGY

S. aureus and viridans streptococci are the most common causative organisms of endocarditis and its associated cerebrovascular complications.

CLINICAL MANIFESTATIONS

Neurologic complications of IE are important because of their frequency and severity. They may be the first manifestation of the underlying intracardiac infection. *Cerebral infarcts*, either bland, or less often hemorrhagic are most common. Infarcts of cranial or peripheral nerves and of the spinal cord rarely occur. *Intracranial hemorrhages* caused by focal segmental infectious vasculitis, mycotic aneurysms, or, rarely, brain abscess also are frequent. These complications presumably result from emboli of infective material from the heart. Inflammatory arteritis also has been implicated as a cause particularly of intracranial hemorrhage when no mycotic aneurysm is apparent. An encephalopathy, sometimes with prominent psychiatric features, may occur and may be related to microemboli with or without microabscess formation, vasculitis, toxic effects of medications, or metabolic abnormalities associated with the illness occurring either individually or concurrently. Seizures may occur in association with any of the cerebral complications.

IE always should be considered in sudden neurologic vascular events, particularly when known predisposing factors exist, such as cardiac disease, intravenous drug use, fever, or infection elsewhere in the body. The frequency of neurologic events is between 20% and 40% in most reported series of endocarditis. As might be anticipated, neurologic complications are more frequent in endocarditis that affects the left side of the heart. The type of organism is also important in determining the frequency of neurologic events. *S. aureus* in particular is associated with a high risk of nervous system complications.

DIAGNOSIS

The identification of the infecting organism of endocarditis is made by blood cultures. Always draw at least two sets of blood cultures. Two sets of blood cultures have greater than 90% sensitivity when bacteremia is present. Three sets of cultures improve sensitivity and may be useful when antibiotics have been administered previously. For diagnosing subacute IE, draw at least three sets of blood cultures over 24 hours. This can detect up to 98% of cases in patients who have not recently received antibiotics. In the case of acute IE, three sets may be drawn over 30 minutes (with separate blood draws). Transthoracic echo is a good screening tool for identifying a cardiac vegetation. Sensitivity is even greater with transesophageal echocardiography. Evidence suggests that the diagnosis and treatment regimen are changed in about 15% of cases when a transesophageal echo is used.

Diagnostic evaluation of neurologic events depends in part on whether the presence of IE already has been established. Imaging studies are important to define the nature of lesions that have focal neurologic findings. Differentiation of infarcts from hemorrhages or abscesses may be accomplished by either computed tomography (CT) or magnetic resonance imaging (MRI). On occasion, both techniques may be necessary to clearly define the nature of the lesion. Analysis of the CSF is mandatory in cases of meningitis regardless of whether the diagnosis of IE has already been made. Such analysis also is useful in encephalopathic conditions to evaluate for low-grade meningitic infection. Lumbar puncture should be considered strongly when stroke is associated with fever, even if endocarditis is not yet documented. Lumbar puncture is probably not useful in known cases of IE with focal CNS presentations where a clearly defined lesion has been identified with imaging studies. Demonstration of suspected mycotic aneurysms may be made by arteriography, magnetic resonance angiography (MRA) or CT angiography. However, some practitioners have advocated arteriography in all cases of IE. No controlled studies have been done. In a retrospective analysis, hemorrhage was less likely to occur if surgery was postponed until MRI contrast enhancement around small hemorrhage, microbleeds, or small infarcts had resolved.

TREATMENT

Management of the neurologic complications of IE includes early antibiotic therapy directed empirically at the appropriate organism and then focused once the organism has been identified and sensitivities documented. Early diagnosis and antibiotic treatment does help reduce neurologic sequela. Although there are no randomized trials investigating the role of thrombolysis, heparin anticoagulation, or antiplatelet agents in acute ischemic stroke secondary to IE, case series suggest that there is a high risk of hemorrhagic conversion when using these agents. Prolonged antibiotic treatment is required, and surgical replacement of infected valves may be necessary. Brain abscesses that do not resolve rapidly with systemic antibiotics should be aspirated. Mycotic aneurysms are typically managed by endovascular therapy, such as coiling and embolization.

SEPSIS-ASSOCIATED ENCEPHALOPATHY

Sepsis-associated encephalopathy (SAE) or septic encephalopathy is broadly described as the alteration in level of consciousness that is frequently seen in association with sepsis and systemic inflammatory response syndrome (SIRS). Sepsis is broadly defined as an infection with the addition of SIRS. The criteria for SIRS include increased or decreased body temperature ($>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$), tachycardia (>90 beats per minute), tachypnea (respiratory rate >20 breaths per min or an arterial partial pressure of carbon dioxide <32 mm Hg), and abnormally low or high white blood cell count ($>12,000$ or $<4,000$ cells/ μL). The diagnosis of SAE is essentially a diagnosis of exclusion. It is not attributed to medications, direct CNS injury or infection, hepatic or renal encephalopathy, seizures, and not directly attributed to infection (i.e., not from septic emboli). SAE presents with altered mental status and without focal neurologic deficits. There can be mild delirium to coma and it frequently precedes diagnosis of sepsis by 24 to 48 hours.

The incidence of SAE is difficult to ascertain, as it is a diagnosis of exclusion. There are no diagnostic tests and most studies are retrospective. Sepsis and SIRS are common; it is estimated that there are over 1 million cases per year in the United States or 50 to 100 cases per 100,000. It is estimated that over 50% of septic patients are delirious, with SAE as the single most likely cause of delirium in the intensive care unit (ICU). Additionally, delirious patients in the ICU have a higher mortality than those without mental status changes. Of those septic patients developing SAE, their mortality is also significantly higher than those who do not develop SAE (56% vs. 35%).

There are numerous proposed mechanisms for the development of SAE. These include the release of inflammatory cytokines, damage to the blood-brain barrier, development of microscopic brain injury and altered cerebral metabolism, microcirculation, and neurotransmitters. Treatment of SAE mostly involves stopping or eliminating confounders that may be contributing to the encephalopathy and treating the sepsis and organ failure. Withdrawal of sedative medications (particularly benzodiazepines) is crucial. Dexmedetomidine may be useful adjunct to decrease encephalopathy, ventilator days, and duration of ICU stay in patients with septic encephalopathy [Level 1].²

ASEPTIC MENINGEAL REACTION

Aseptic meningeal reaction refers to those cases with evidence of a meningeal reaction in the CSF in the absence of any infecting organism. These conditions are discussed in this chapter because the main differential diagnosis is bacterial meningitis.

Aseptic or noninfectious meningeal inflammation results from four general causes: (1) in reaction to a parameningeal focus of infection or necrosis focus within the skull or spinal canal, (2) introduction of foreign substances (e.g., air, dyes, drugs, blood) into the subarachnoid space, (3) connective tissue disorders, and (4)

systemically administered medications (e.g., trimethoprim/sulfoxazole, nonsteroidal anti-inflammatory agents, intravenous immunoglobulin (IVIG), isoniazid, carbamazepine, OKT3 monoclonal antibodies).

The symptoms present in the patients in the first group are associated with the infection or morbid process in the skull or spinal cavity. Only occasionally are there any symptoms and signs of meningeal irritation.

In the second group of patients, where the meningeal reaction is the result of the introduction of foreign substances into the subarachnoid space, fever, headache, and stiffness of the neck may occur. The appearance of these symptoms leads to the suspicion that an actual infection of the meninges has been produced by the inadvertent introduction of pathogenic organisms. The normal glucose concentration of the CSF and the absence of organisms in culture establish the nature of the meningeal reaction.

An aseptic meningeal reaction may complicate the course of systemic lupus erythematosus (SLE) and other collagen-vascular diseases. In certain instances, the meningeal reaction in patients with SLE may be induced by nonsteroidal anti-inflammatory drugs or azathioprine.

The findings in the CSF characteristic of an aseptic meningeal reaction are an increase in pressure, a varying degree of pleocytosis (10 to 4,000 cells/mm³), a slight or moderate increase in the protein concentration, normal glucose concentration, and the absence of organisms in culture. Exceptionally, and without explanation, the aseptic meningeal reaction of SLE may be accompanied by low CSF glucose concentrations. With a severe degree of meningeal reaction, the CSF may be purulent in appearance and may contain several thousand cells per cubic millimeter with a predominance of polymorphonuclear leukocytes. With a lesser degree of meningeal reaction, the CSF may be normal in appearance or only slightly cloudy and may contain a moderate number of cells (10 to several hundred cells per cubic millimeter), with lymphocytes being the predominating cell type in the CSF.

The pathogenesis of the changes in the CSF is not clearly understood. The septic foci in the head, more commonly associated with an aseptic meningeal reaction, are septic thrombosis of the intracranial venous sinuses; osteomyelitis of the spine or skull; extradural, subdural, or intracerebral abscesses; or septic cerebral emboli. Nonseptic foci of necrosis are accompanied only rarely by an aseptic meningeal reaction. Occasionally, patients with an intracerebral tumor or cerebral hemorrhage located near the ventricular walls may show similar changes in the CSF.

The diagnosis of an aseptic meningeal reaction in patients with a septic or necrotic focus in the skull or spinal cord is important in that it directs attention to the presence of this focus and the necessity for appropriate surgical and medical therapy before the meninges are actually invaded by the infectious process or before other cerebral or spinal complications develop.

Brain Abscess and Parameningeal Infections

Gary L. Bernardini

BRAIN ABSCESS

A brain abscess is a focal purulent infection within the brain parenchyma. A brain abscess starts as a localized area of cerebritis; abscesses vary in size from a microscopic collection of inflammatory cells to an area of purulent necrosis presenting as a mass lesion.

Advances in the diagnosis and treatment of brain abscesses have been achieved with the use of computed tomography (CT), magnetic resonance imaging (MRI), magnetic resonance spectroscopy (MRS), stereotactic brain biopsy and aspiration, and newer broad-spectrum antibiotics.

EPIDEMIOLOGY

A brain abscess is two to three times more common in males than in females, with the highest morbidity in fourth decade of life. Over the past 30 years, advances in management of brain abscesses have resulted in a significant decline in mortality from 30% to 50% before 1980, to 4% to 20% today. Up to 25% of all cases occur in children younger than 15 years old, with a cluster in the 4- to 7-year-old age group, usually the result of cyanotic congenital heart disease or an otic infection.

ETIOLOGY

A brain abscess is classified based on the likely source of infection. A brain abscess may develop from any of the following predisposing or associated conditions: (1) direct extension of cranial infection, ethmoid or frontal sinusitis, subacute or chronic otitis media, or mastoiditis; (2) hematogenous dissemination of infection from elsewhere in the body (e.g., lung abscess, bacterial endocarditis, intra-abdominal infections, dental infections, congenital heart disease); and (3) direct inoculation via wounds, fracture of the skull, or neurosurgical procedures.

Infection in the middle ear or mastoid may spread to the cerebellum or temporal lobe through involvement of bone and meninges or by seeding of bacteria through valveless emissary and sinus veins that drain these regions. Infection may originate from tonsils or abscessed teeth, or frontal, ethmoid, or rarely the maxillary sinuses, with sinus infections often spreading to frontal lobes through erosion of the skull.

For hematogenous spread, cerebral lesions are found in distal territories of the middle cerebral artery and frequently are multiple, often seen at the junction of gray-white matter. Potential sources for hematogenous spread of infection include upper respiratory tract (lung abscess or empyema), bacterial endocarditis, skin infections, intra-abdominal, or pelvic infections. Twenty percent to 30% of brain abscesses have no obvious source, and are so-called cryptogenic brain abscesses. In some cases, cryptogenic brain abscess may have a cardiac or lung source. For example, congenital cardiac defects and pulmonary arteriovenous malformations (e.g., hereditary hemorrhagic telangiectasia) predispose to brain abscess. In these two disorders, infected emboli bypass pulmonary filtration system and gain access to the cerebral arterial system. Similarly, cases of cryptogenic brain abscess caused by vegetations on patent foramen ovale (PFO) or right-to-left shunting via PFO have been reported. In infants and children, congenital heart disease is a common predisposing factor for brain abscess. The predisposing conditions of hereditary hemorrhagic telangiectasia or Rendu-Osler-Weber disease can be the source of a brain abscess via paradoxical septic emboli from lung.

A brain abscess can occur following penetrating head injury or neurosurgical procedures, although occurrence of

abscesses after penetrating brain injury is low. In children, penetration of a lead pencil tip through the thin squamous portion of the temporal bone has resulted in abscess formation. Finally, brain abscess is almost never a consequence of bacterial meningitis, except in infants.

CAUSATIVE ORGANISMS OF BRAIN ABSCESS

The infecting organism may be any of the common pyogenic bacteria depending on the site of entry; the most common are *Staphylococcus aureus*, streptococci (anaerobic, aerobic, or microaerophilic species), *Enterobacteriaceae*, *Pseudomonas* spp., and anaerobes such as *Bacteroides* spp. (Table 62.1). In infants, gram-negative organisms are the most frequent isolates. In adult patients with direct spread of infection from an otogenic source, the most common organisms are streptococci, *Bacteroides* spp., *Pseudomonas* spp., *Enterobacteriaceae*, and *Haemophilus*. Other causative organisms from oral or hematogenous spread include streptococci, *S. aureus*, *Bacteroides* spp., and *Fusobacterium* spp. After penetrating head injury or neurosurgical procedure, abscess formation is usually due to *S. aureus* (methicillin-resistant *Staphylococcus aureus* or MRSA), *Staphylococcus epidermidis*, streptococci, *Enterobacteriaceae*, *Pseudomonas*, or *Clostridium* spp. Brain abscesses as a complication of bacterial endocarditis are due to streptococci, MRSA, and *Serratia marcescens*. In the immunocompromised host, *Toxoplasma*, *Listeria*, *Nocardia*, *Aspergillus*, *Cryptococcus*, *Coccidioidomycosis*, *Mycobacterium tuberculosis*, *Enterobacteriaceae*, and other fungal pathogens are causative organisms of brain abscess. Brain abscess may be due to a parasitic infection such as *Entamoeba histolytica*, cysticercosis, *Schistosoma*, or toxocariasis. Following liver transplantation, invasive pulmonary aspergillosis can be a source of brain abscesses. Cultures may be sterile in patients who have received antimicrobial therapy before biopsy but any material obtained should be sent to the laboratory. A positive Gram stain guides therapy even when the culture is negative. In a study of 90 patients with diagnosis of brain abscess, microbiologic diagnosis was obtained in 83% of cases. More than one pathogen was found in 23% of cases.

PATHOBIOLOGY

The pathologic changes in brain abscesses are similar regardless of the origin: direct extension to the brain from a contiguous site of infection, retrograde thrombosis of veins, or hematogenous dissemination (Fig. 62.1).

P.506

TABLE 62.1 Brain Abscess

Source	Pathogen
Oral cavity, hematogenous spread (intra-abdominal/pelvic infections), otitis, mastoiditis, paranasal sinusitis	Streptococci spp. (aerobic and anaerobic), <i>Staphylococcus aureus</i> , <i>Bacteroides</i> spp., <i>Pseudomonas</i> spp., <i>Haemophilus</i> spp., <i>Enterobacteriaceae</i> , <i>Prevotella melaninogenica</i> , <i>Fusobacterium</i>
Trauma/neurosurgical procedure	<i>Staphylococcus aureus</i> or <i>Staphylococcus epidermidis</i> , <i>Streptococcus</i> spp., <i>Enterobacteriaceae</i> , <i>Pseudomonas</i> spp., <i>Clostridium</i> spp.
Pyogenic lung infections	Streptococci, staphylococci, <i>Bacteroides</i> spp., <i>Fusobacterium</i> spp., <i>Enterobacteriaceae</i>
Cardiac origin (e.g., cyanotic heart)	<i>Streptococcus</i> spp., <i>Serratia marcescens</i> , methicillin-resistant

disease, right-to-left shunts, bacterial endocarditis)	<i>Staphylococcus aureus</i> (MRSA)
Immunocompromised	<i>Pseudomonas, Toxoplasma, Listeria, Nocardia, Aspergillus, Cryptococcus, Coccidioides, Mycobacterium tuberculosis, Enterobacteriaceae</i> , other fungal pathogens
Parasitic infections	<i>Cysticercosis, Entamoeba histolytica, Schistosoma, Paragonimus</i>

Four stages of maturation of brain abscess are recognized: (1) within the first 3 days, suppurative inflammation of brain tissue is characterized by *early cerebritis*, appearing as either a patchy or nonenhancing hypodensity on CT or MRI; (2) *late cerebritis* (days 4 to 9) with an area of central necrosis, edema, and ring enhancement on CT and MRI; (3) *early capsule formation* (days 10 to 14); and (4) *final maturation* of the capsule, which takes about 2 weeks. When host defenses control the spread of the infection, macroglia and fibroblasts proliferate in an attempt to surround the infected and necrotic tissue, and granulation tissue and fibrous encapsulation develop. The developing capsule around the abscess formed by the inflammatory response is thicker on the cortical surface than on the ventricular side. If the capsule ruptures, purulent material is released into the ventricular system, a process associated with a high mortality rate. Edema surrounding a brain abscess is common.

Two signal-mediated CNS immune responses to invading pathogens that may be important in the developing abscess include the Toll-like and Nod-like receptors (TLR and NLR, respectively) systems. Activation of TLR by invading pathogens leads to a complex array of immune-mediated response including control of infection burden, immune infiltrates, and inflammatory mediators. Likewise, NLR activates a number of immune-specific interleukins responsible for bacterial recognition and subsequent cytokine release that acts to restrict bacterial spread during abscess formation.

FIGURE 62.1 Brain abscess. Abscess in frontal lobe secondary to pulmonary infection. (Courtesy of Dr. Abner Wolf.)

CLINICAL MANIFESTATIONS

The symptoms of a brain abscess are typical of an expanding mass lesion in the brain with elevated intracranial pressure (ICP) and include headache with or without fever as the initial symptoms, followed by nausea, vomiting, lethargy, and focal neurologic deficits. Fever is present in approximately 50% of patients; however, the combination of fever and leukocytosis is present in over 50% cases of brain abscess. Sudden worsening of preexisting headache, new-onset nuchal rigidity, and seizures may herald rupture of brain

P.507

abscess into the ventricular space. The abrupt onset of a severe headache is less common with abscess and is more often associated with acute bacterial meningitis or subarachnoid hemorrhage. Seizures, focal or generalized, are common with abscess.

Focal neurologic deficits develop in approximately 50% of patients, depending on abscess location. Hemiparesis, apathy, and confusion may be seen with lesions of the frontal lobe, hemianopia, and aphasia, particularly anomia, with abscesses in the temporal or parietooccipital lobes and ataxia, intention tremor, nystagmus, with cerebellar abscess (Fig. 62.2). The presence of papilledema and/or third or sixth cranial nerve palsies may be

due to increased ICP.

Abscesses in the brain stem are rare. The classic findings of brain stem syndromes are often lacking because abscess tends to expand longitudinally along fiber tracts rather than transversely. Subdural or, rarely, epidural infections in the frontal regions may present with the same signs and symptoms as those of an abscess in the frontal lobe. Fever and focal seizures favor the diagnosis of subdural rather than intraparenchymal abscess, although these findings are not specific.

FIGURE 62.2 Cerebellar abscess with mastoiditis. **A:** Sagittal MRI T1-weighted image after gadolinium administration demonstrates ring enhancement (*white arrow*) of cerebellar abscess. **B:** MRI spectroscopy demonstrating characteristic lactate “peak” associated with necrotic tissue of abscess. **C:** Complication of mastoiditis with bilateral transverse sinus thrombosis (*arrows*). **D:** CT bone windows demonstrating sclerotic change of the right mastoid sinus (*left arrow*), consistent with chronic mastoiditis. (Courtesy of Dr. William Wagle.)

Transverse sinus thrombosis often follows middle ear or mastoid infection (see Fig. 62.2) and may be accompanied by seizures and signs of increased ICP, making the clinical differentiation between this condition and abscess of the temporal lobe or hemispheres difficult. With transverse sinus thrombosis, papilledema may result from blockage of venous drainage from the brain. Focal neurologic signs favor the diagnosis of abscess.

DIAGNOSTIC TESTING

Brain abscess should be suspected when seizures, focal neurologic signs, or increased ICP develop in a patient with known acute or chronic infection in the middle ear, mastoid, nasal sinuses, heart, or lungs and in those with congenital heart disease. Neuroimaging by CT or MRI is essential to making the diagnosis.

Although CT scan can be useful, MRI neuroimaging is the neuroimaging study of choice, both for diagnosis and treatment of brain abscess. MRI with gadolinium is more sensitive and specific than contrast CT in diagnosing early cerebritis. On neuroimaging, abscesses are frequently found in the gray-white junction in watershed regions between vascular territories. Serial MRI permits accurate localization of cerebritis or abscess and serial assessment of the size of the lesion, its demarcation, the extent of surrounding edema, and total mass effect and allows for staging of the abscess. MRS may help differentiate brain abscesses based on metabolic patterns of lactate, amino acids, or acetate from other similar appearing lesions (e.g., tumor). The presence of lactate, amino acids, acetate, and succinate on MRS is considered specific for brain abscess (see [Fig. 62.2](#)). With a mature encapsulated abscess, both contrast CT and MRI with gadolinium reveal the ring-enhancing mass with surrounding vasogenic edema. Additional MRI sequences with fluid-attenuated inversion recovery (FLAIR), T2- and diffusion-weighted images show characteristic changes ([Fig. 62.3](#)).

FIGURE 62.3 Brain abscesses. **A-I:** MRI T1-weighted images (**A and B**) show right frontal lobe abscess with adjacent, smaller anterior-located abscess with typical ring enhancement after gadolinium administration (**C and D**). (*continued*)

The differential diagnosis, based on the appearance of lesions seen on CT or MRI, includes glioblastoma, metastatic tumor, infarct, arteriovenous malformation, resolving hematoma, and granuloma. Features supporting the diagnosis of brain abscess include gas within the center of a ring-enhancing lesion, a thinner enhancing rim (<5 mm) than with brain tumors, more regular borders with ringlike enhancement, and ependymal enhancement associated with ventriculitis or ventricular rupture (see Fig. 62.3). MRI with diffusion-weighted image (DWI) and calculation of the apparent diffusion coefficient (ADC) may aid in differentiating tumor from abscess. With brain abscess, MRI DWI signal is hyperintense with associated low ADC values, compared to brain tumor with similar DWI appearance but high ADC. Thallium-201 brain single-photon emission computerized tomography (SPECT) may differentiate intracerebral lymphoma from *Toxoplasma* encephalitis in patients with AIDS. Unlike pyogenic brain abscesses, the signal of *Toxoplasma* abscesses may not be hyperintense on DWI MRI. Often, empiric treatment for *Toxoplasma* can be initiated with evaluation for responsiveness to treatment using follow-up MRI

imaging several weeks later.

Either CT or MRI may distinguish abscess from mycotic aneurysms or herpes encephalitis, each of which may cause similar symptoms and signs. Mycotic aneurysm, usually in the distribution of the middle cerebral arteries, may be accompanied by meningitis

P.509

P.510

in bacterial endocarditis. CT or MRI may exclude abscess, but CT angiography is often necessary to identify the aneurysm before rupture. Herpes simplex encephalitis presents with headache, fever, and an acute temporal lobe or frontal lobe syndrome. On CT or MRI, the temporal lobe is swollen, with irregular lucency and patchy contrast enhancement.

FIGURE 62.3 (continued) Note enhancement of right frontal sinuses (*arrows*) as source of infection. MRI diffusion-weighted images (DWI) show typical bright-appearing lesions of abscess (**E and F**). The brain abscesses with evidence of edema and mass effect are seen on MRI FLAIR and T2-weighted images (**G and H**). MRI sagittal T1-weighted images post gadolinium show enhancing frontal sinus infection with direct extension to

brain parenchyma and ventricles (**I**). Bright signal seen in ventricles on T1-weighted image after gadolinium is indicative of ventriculitis. (Courtesy of Dr. James Thomas.)

Lumbar puncture is contraindicated in patients suspected of having a brain abscess because of the clear risk of transtentorial herniation.

Both erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) may be elevated in patients with brain abscess. Blood cultures are positive in patients with hematogenous dissemination as the source of infection.

Extension of the abscess to the meninges or ventricles is accompanied by findings associated with acute meningitis or ventriculitis. Rupture of an abscess into the ventricles is signaled by a sudden rise in ICP and the presence of free pus, with marked increases in CSF cell count to levels of 20,000/mm³ to 50,000/mm³. A decrease in glucose content below 40 mg/dL indicates that the meninges have been invaded by bacteria. Only rarely are CSF cultures positive.

TREATMENT

The introduction of CT revolutionized the management of brain abscess. Now with MRI, it is possible to diagnose and localize cerebritis or abscess, dictate choice of treatment, and monitor patient response. Current recommended treatment for most brain abscesses is stereotactic aspiration to obtain specimens for culture and special studies, and guide treatment with appropriate antimicrobial therapy.

Surgical treatment in the past included open evacuation and excision or freehand needle aspiration through burr hole. Currently, most surgeons prefer CT-guided stereotactic aspiration and drainage. This method is the treatment of choice for most abscesses, particularly those that are deep-seated, multiple, or located in eloquent areas of the brain. Empiric antimicrobial therapy is based on Gram stain results from the specimen obtained by stereotactic aspiration and on the presumptive source of the abscess. Open craniotomy with excision is now performed infrequently and is reserved for patients with multiloculated abscesses, those with antimicrobial-resistant pathogens, abscesses due to *Nocardia*, abscesses containing gas resistant to antibiotics, and posttraumatic abscesses containing foreign bodies or contaminated bone fragments.

Choosing the appropriate antimicrobial therapy depends on the ability of the drug to penetrate the abscess cavity and its activity against the suspected pathogen. Penicillin and chloramphenicol was the standard therapy for brain abscesses at one time but is rarely used today. These have been replaced by vancomycin, third- and fourth-generation cephalosporins (e.g., cefotaxime, ceftriaxone, ceftazidime, and cefepime), metronidazole, and meropenem (Table 62.2). Combination therapy with third- or fourth-generation cephalosporins and vancomycin appears to be highly effective for empiric treatment of a brain abscess. Metronidazole is added when otitis, mastoiditis, or paranasal sinusitis is the suspected source of infection. Additional antibiotic coverage may be needed for some organisms (e.g., *Actinomyces* species) when the abscess is secondary to dental procedures or dental abscess. Special consideration of antimicrobial coverage must be given for *Enterobacteriaceae* or *Pseudomonas aeruginosa* particularly when an otogenic source of brain abscess is suspected. Vancomycin plus a third-generation cephalosporin may be given initially in cases of brain abscess from neurosurgical procedures, while awaiting final culture results. Vancomycin is also used in cases of MRSA abscesses. The rare tuberculosis abscesses can be treated with combination of isoniazid, rifampin, ethambutol, and pyrazinamide for 2 to 4 months, and thereafter isoniazid and rifampin are given for at least 1 year. Aspergillosis abscesses are most effectively treated with voriconazole. Amphotericin B may be considered if voriconazole cannot be given. It is generally recommended that parenteral antibiotics for most abscesses be given for a total of 6 to 8 weeks, followed by an additional 2- to 3-month course of oral antibiotic therapy.

TABLE 62.2 Specific Intravenous Antimicrobials for Treatment of Brain Abscess

Vancomycin ^a	45-60 mg/kg/day, q6-12h
Meropenem	2 g q8h (used as first-line or second-line therapy)
Cefotaxime	2 g q4-8h (maximum 12 g/day)
Ceftriaxone	2 g q12h (maximum 4 g/day)
Ceftazidime	1-2 g q4-8h (maximum 6 g/day)
Cefepime	2 g q8h (maximum 6 g/day)
Metronidazole	500 mg q6h (1,500-2,000 mg/day)
Voriconazole	Loading dose of 6 mg/kg q12h × 2, followed by 4 mg/kg q12h

^aDoses adjusted based on serum peak and trough levels; adjusted based on creatinine clearance.

Clinical improvement and CT or MRI s are used to monitor the effectiveness of antibiotic treatment. Follow-up CT may show a small area of residual enhancement even after adequate antimicrobial therapy. Occasionally, previous ring-enhancing lesion on CT disappears with medical management, suggesting that these reversible lesions are forms of suppurative cerebritis.

Seizures may occur in up to 50% of patients with brain abscess, early in the course. However, one large retrospective study found seizures in only 16% of patients with brain abscess. Anticonvulsants may be administered for prophylaxis or to prevent the recurrence of seizures. Newer agents such as levetiracetam are as effective as other anticonvulsants (e.g., phenytoin or carbamazepine) that have been used in the past. Generally, these agents are given for at least 3 months after surgery for abscess and electroencephalogram (EEG) may be useful to help guide duration of therapy.

The use of corticosteroids for these patients is controversial. In patients with life-threatening cerebral edema, midline shift, or impending herniation, a short course of high-dose corticosteroids may be appropriate. Further deterioration with severe brain edema may require intubation with intensive care management to control elevated ICP. Hemispherectomy may be considered in cases of increased ICP refractory to medical therapy. Prolonged use of corticosteroids is not recommended because the steroids may interfere with granulation tissue formation and reduce the concentration of antibiotics within the infected tissue.

OUTCOME

The outcome of untreated brain abscess is, with rare exceptions, death. Mortality in pre-CT series varied from 35% to 55%. In the era of advanced neuroimaging with CT and MRI, the mortality rate of brain abscesses is 0% to 30%. Overall morbidity and mortality of brain abscess is related to delayed diagnosis, presence of single or multiple abscesses, intraventricular rupture, presence of coma or rapidly declining

consciousness on admission tend to do poorly. Intraventricular rupture of a brain abscess and posterior fossa location are associated with mortality rates exceeding 80%. In a univariate analysis of mortality, Glasgow Coma Scale score on admission of less than or equal to 9 was an independent predictor of in-hospital mortality in one study. Immunocompromised individuals have worse outcomes and higher mortality rates. The highest death rate is found when the primary infection is in the lungs.

Sequelae of brain abscess include recurrence of the abscess or the development of new abscesses if the primary focus persists. Residual neurologic sequelae with hemiparesis, seizures, or intellectual or behavioral impairment are seen in 30% to 56% of patients.

SUBDURAL EMPYEMA

A subdural empyema is a collection of loculated pus in the subdural space. The symptoms are similar to those of a brain abscess. A subdural infection in adults usually arises from a contiguous spread of infection; paranasal sinusitis is the most common source. Otitis, head trauma, and neurosurgical procedures are other sources of infection. The most common pathogen in subdural empyema are anaerobic and microaerophilic streptococci. In a minority of cases, *S. aureus* and multiple organisms, including gram-negative organisms such as *Escherichia coli* and anaerobic organisms, such as *Bacteroides*, may be present. *P. aeruginosa* or *S. epidermidis* may be found in cases following neurosurgical procedures. In addition, *Clostridium perfringens* subdural empyemas can occur from the site of recent surgical wound or trauma.

The infection spreads to the subdural space through retrograde thrombophlebitis via venous sinuses or direct extension through bone and dura. Once the infection develops, it may spread over the convexities and along the falx, although characteristic loculation is common. Associated complications include septic cortical vein thrombosis, brain or epidural abscess, and meningitis. Subdural empyema typically presents with focal headache, fever, and in 80% to 90% of patients, focal neurologic signs. The combination of fever, rapidly progressive neurologic deterioration, and focal seizures is particularly suggestive of this disorder. Symptoms of subdural empyema may begin 1 to 2 weeks after a sinus infection. Infratentorial empyema is a rare complication of bacterial meningitis and can present with nonlocalizing symptoms of neck stiffness and decreased level of consciousness.

DIAGNOSIS

Neuroimaging with either CT or MRI reveals a typical crescent-shaped area of hypodensity over a hemisphere, along the dura, or adjoining the falx, with enhancement of the margins around the empyema after administration of contrast. However, the diagnostic test of choice is MRI with gadolinium enhancement for the delineation of the presence and extent of the subdural empyema and to identify concurrent intracranial infections. CT may miss some lesions that can be detected by MRI. Lumbar puncture is contraindicated for the same reason it is with brain abscess, i.e., because of mass effect and potential for herniation.

TREATMENT

Treatment of nearly all cases of subdural empyema is immediate surgical drainage and antibiotic therapy. Intravenous antibiotics are given depending on the organism identified, or if unknown, empiric treatment with antibiotics similar to those used in brain abscess based on predisposing or associated conditions.

Anticonvulsants are frequently required. There is controversy about which type of neurosurgical technique is useful for drainage of subdural empyema. CT accurately localizes the pus collection, and some advocate drainage through selective burr holes. Others prefer open craniotomy for more complete removal of the infection, especially when the empyema is loculated. Limited craniotomy is also used for placement of a drain into the subdural space and for local infusion of antibiotics. Use of either burr hole or craniotomy for drainage of subdural empyema is individualized. Neuroendoscopic technique for drainage of both brain abscess and subdural empyema is an alternative to surgical treatment. In cases of fulminant subdural empyema, decompressive craniectomy, irrigation of the empyema, and subdural drainage may be required. The recommended duration of antibiotic therapy is 3 to 4 weeks after surgical drainage.

SPINAL EPIDURAL ABSCESS

Spinal epidural abscess is infection in the epidural space around the spinal cord and may arise from hematogenous spread from a distant site, direct inoculation, or contiguous spread from skin, soft tissue, or bone infection. Typically, spinal epidural abscess is associated with diabetes, trauma, intravenous drug use, alcohol, age, or immunosuppression with the single most important risk factor being diabetes. The most important pathogen for spinal epidural abscess is *S. aureus* found in over 60% of cases. Most common sources of infection are skin abscesses and bony infections involving the spine. The most common location of spinal epidural abscesses is in dorsal epidural space, although one 10-year study found up to 30% may be located in the ventral epidural space.

The clinical presentation of spinal epidural abscess is back pain and fever; these symptoms commonly are followed by focal neurologic deficits of radiculitis, then paraparesis, sensory level, bladder or bowel dysfunction, and eventual para- or quadriplegia.

DIAGNOSIS

As with brain abscess, both ESR and CRP are invariably elevated. Complete blood count and blood cultures should be obtained. Lumbar puncture is contraindicated, as it can lead to introduction of infection into subarachnoid space. Magnetic resonance imaging is more sensitive than CT with contrast in identifying spinal epidural abscess, with MRI approaching 90% sensitivity in some studies. Additional benefits of MRI include the ability to detect cord involvement (swelling or necrosis), diskitis, and osteomyelitis (Fig. 62.4).

TREATMENT

Treatment for spinal epidural abscess includes surgery (e.g., decompression with laminectomy) and antibiotics. Initial antimicrobial therapy should include antibiotics for MRSA and gram-negative bacilli. A combination of a third- or fourth-generation cephalosporin and vancomycin are recommended. Once the specific organism is identified from surgical specimen and antimicrobial sensitivity, then antibiotic therapy is modified accordingly. Some reports suggest spinal epidural abscess can be successfully treated with antibiotics alone (before neurologic symptoms appear); however, surgical decompression and drainage remains the mainstay of treatment in most cases.

OUTCOME

The prognosis in spinal epidural abscess is dependent on the mechanism causing the neurologic deficits. Compression of the cord can be helped by surgery, but deficits due to vascular ischemia,

with thrombosis or thrombophlebitis involving surrounding leptomeningeal vessels, or inflammatory response of glial cells, are not improved by surgery. Rehabilitation can significantly affect outcome in spinal epidural abscess.

FIGURE 62.4 Spinal epidural abscess. MRI T2-weighted image showing increased signal in anterior epidural space at C3 spinal level (*large arrow*) consistent with abscess. Prevertebral soft-tissue infection (*three solid arrowheads*) is the source of infection. Evidence of osteomyelitis and involvement of intervertebral disk with diskitis at C3 vertebral body (*two small arrows*). (Courtesy of Dr. Karen Roos.)

MALIGNANT OTITIS EXTERNA

Malignant (necrotizing) otitis externa is an invasive infection of the external auditory canal and skull base; it penetrates epithelium and spreads to surrounding soft tissue to cause cellulitis and abscess. If untreated, the infection may extend to the temporomandibular joint, mastoid, or more commonly to soft tissues below the temporal bone. The syndrome occurs more frequently in elderly diabetic patients and immunocompromised persons (e.g., patients with HIV, chemotherapy, or organ transplantation) than in immunocompetent individuals.

Common symptoms of malignant otitis externa are severe otalgia that worsens at night, purulent otorrhea, and painful swelling of surrounding tissues. Conductive hearing loss may result from obstruction of the external auditory canal. Trismus may indicate irritation of the masseter muscles or involvement of the temporomandibular joint. Owing to its anatomic location in the temporal bone and petrous apex, the facial nerve may be affected as the first symptom in up to 30% of patients. Facial nerve involvement is most common, followed (in order) by glossopharyngeal, vagal, and spinal accessory nerves at the jugular foramen; hypoglossal nerve as it exits the hypoglossal canal; and trigeminal and abducens nerves at the petrous apex. Olfactory, oculomotor, and trochlear

nerves are spared. Rarely, dysphagia results from lesions of cranial nerves IX through XII, and the findings may be mistaken for laryngeal carcinoma. Fever and weight loss are uncommon. Mastoid tenderness is evident on examination. The diagnostic finding of granulation tissue, stemming from extension of infection to the cartilaginous portion of the ear canal, may be seen on otoscopic examination. In rare cases, meningitis, brain abscess, and dural sinus thrombophlebitis can occur and are often fatal.

DIAGNOSIS

The diagnosis of malignant otitis externa is often initially missed but can be made by combination of clinical, laboratory, and radiologic findings. General laboratory testing is invariably normal with the exception of ESR and CRP, which are elevated. The ESR is almost always elevated in greater than 50 mm/h. Both ESR and CRP can be useful in monitoring disease activity.

Neuroimaging

CT is most useful in showing the location and extent of disease and evaluating evidence of bony erosion but may appear normal early in the illness. Initial CT can help predict severity of disease course based on early findings of extension of infection beyond the external auditory canal. The presence of bone erosion along with soft tissue abnormalities in the subtemporal area is almost pathognomonic for the disease. MRI with and without gadolinium is the study of choice, but it is not useful in detecting bony changes. However, MRI can provide useful information regarding

P.513

the extent of skull-base and intracranial soft-tissue involvement. Bone scanning with technetium-99 (scans) methylene diphosphonate can be very sensitive but not specific. Gallium-67 SPECT may be more sensitive and accurate in early detection of malignant external otitis, sensitive in measuring ongoing infectious process, and beneficial in monitoring response to therapy. However, it remains less frequently used compared to serial CT scanning.

Biopsy

The differential diagnosis of malignant otitis externa includes squamous cell carcinoma of the temporal bone. Radiologic testing cannot differentiate tumor from necrotizing infection of malignant otitis externa and biopsy is often necessary to distinguish between these two processes. Findings of positive culture for *Pseudomonas* spp. along with elevated ESR and CRP confirm the diagnosis of malignant otitis externa.

ETIOLOGY

In most cases, *P. aeruginosa* is the causative organism. Less often, cases of malignant otitis externa have been reported due to *Klebsiella*, *S. aureus*, *Proteus mirabilis*, and other *Pseudomonas* spp. In HIV-positive individuals or in AIDS, either *P. aeruginosa* or the fungus *Aspergillus fumigatus* may be isolated. In some patients with AIDS, *Streptococcus*, *Staphylococcus*, and *Proteus* spp. may be isolated as mixed or sole pathogens. Interestingly, ear irrigation with water contaminated with *Pseudomonas* spp. is often the causative event leading to malignant otitis externa.

TREATMENT

Antipseudomonal agents are the agents of choice for treatment of malignant otitis externa ([Table 62.3](#)). Rare cases of fungal (e.g., *Aspergillus* species) malignant external otitis do exist. In the preantibiotic era, mortality rates were greater than 50%, and surgical debridement was the treatment of choice. Likewise, standard treatment with intravenous antibiotics consisted of an antipseudomonal penicillin for 4 to 8 weeks, combined with an aminoglycoside for at least 2 weeks, or if tolerated, 4 to 6 weeks. Current successful

treatment is based on single-drug therapy. Advantages of quinolones include low toxicity, excellent penetration into bone, and no dosage adjustment required in the elderly patient with renal impairment. Double-antibiotic therapy may be considered with more extensive lesions. Fluoroquinolone-resistant strains exist so alternative therapy must be considered. Such alternative treatment includes antipseudomonal beta-lactams, including piperacillin, combination piperacillin-tazobactam, ceftazidime, and cefepime. In some drug-resistant cases, use of cephalosporins and antipseudomonal penicillins in combination with debridement may be necessary. Rare complications of retropharyngeal abscesses are drained surgically. If *Aspergillus* species is causative agent, voriconazole has been successful as first-line treatment and shown superiority to amphotericin B in a randomized trial. Despite these newer treatments, the mortality rate is still 10% to 20% and may be as high as 50% if treatment is delayed.

TABLE 62.3 Antimicrobial Agents for Treatment of Malignant Otitis Externa

Antipseudomonal agents	Ciprofloxacin 400 mg IV q8h Levofloxacin 750 mg IV daily Ceftazidime 2 g IV q8h Cefepime 2 mg IV q8h
Antimicrobials for <i>Aspergillus</i> species	Voriconazole 4-6 mg/kg IV q12h Liposomal amphotericin B 5-7.5 mg/kg/day IV Amphotericin B + itraconazole 5 mg/kg/day + 600 mg oral daily

Hyperbaric oxygen therapy efficacy remains unproven and is rarely now used for refractory cases of malignant otitis externa. Recent studies suggest that facial cranial nerve involvement may be a marker for extension of disease but by itself not an adverse prognostic factor. If untreated or inadequately treated, malignant external otitis may result in osteomyelitis of the base of the skull, sigmoid sinus thrombosis, abscess formation, meningitis, and death.

OSTEOMYELITIS OF THE SKULL BASE

Osteomyelitis of the base of the skull is a rare complication of malignant external otitis, chronic mastoiditis, or paranasal sinus infection. As with malignant otitis, the patients are usually elderly, diabetic, or immunocompromised. Symptoms include headache, otalgia, hearing loss, and otorrhea, but patients are frequently without fever. Osteomyelitis may occur in conjunction with otitis but usually appears weeks or months after starting antibiotics. As the process spreads, cranial nerves may be affected, especially the VII and VIII nerves. Extension of skull base osteomyelitis to the jugular foramen or hypoglossal canal may affect cranial nerves IX through XII, leading to dysphagia. In advanced cases, spread to the petrous pyramid may affect III, IV, V, and VI cranial nerves to cause ocular palsies or trigeminal neuralgia.

DIAGNOSIS

Laboratory abnormalities include a normal or slightly elevated white blood cell (WBC) count and high ESR. In general, leukocytosis is not common and not useful to diagnosis and management. The use of thin-cut CT sections through the skull base and temporal bones to visualize bony involvement plays an important role in the diagnosis of osteomyelitis and in assessing extent of disease. However, because more than 30%

of affected bone needs to be demineralized to appear eroded on CT, early disease may escape detection by CT.

MRI is useful in delineating soft-tissue involvement but has not proved beneficial for initial diagnosis or determining efficacy of treatment for skull-base osteomyelitis. Technetium bone scanning is a sensitive indicator of osteomyelitis but is not helpful in determining resolution of disease. Technetium uptake is nonspecific and may be seen in a number of conditions such as infection, trauma, neoplasm, and postoperatively. Gallium-67 citrate scans may be useful in tracking resolution of disease over time. Neither bone nor gallium scans are useful in determining the exact extent of the infection. Unlike technetium-99 scans, gallium-67 scans return to normal sooner once the infection is resolved and can be useful to signal clearing of infection. *S. aureus* is now the most common isolated organism in osteomyelitis. Other potential causative agents include *P. aeruginosa*, *S. epidermidis*, *Proteus*, *Salmonella*, *Mycobacterium*, *Aspergillus*, and *Candida*.

TREATMENT

Therapy for osteomyelitis consists of intravenous administration of antibiotics, usually a combination of an antipseudomonal penicillin or cephalosporin. Ciprofloxacin, with its strong bone penetration,

P.514

has been effective when used alone or with other antibiotics. Ceftazidime has bactericidal activity against *Pseudomonas* and has been used successfully as monotherapy. The disease is usually extensive, and conservative management of skull-base osteomyelitis is still an extended course of therapy. In rare cases of *Aspergillus* osteomyelitis, surgical debridement with radical mastoidectomy is usually required, in addition to long-term antifungal therapy. Monthly gallium scans may help to determine the response and duration of antibiotic therapy. In refractory cases, hyperbaric oxygen has been used as adjuvant therapy. Antibiotics should be continued for at least 1 week after the gallium scan becomes normal. Duration of antibiotic therapy varies but is usually for at least 1 month and, in some cases, may extend up to 6 months after diagnosis. Follow-up gallium scans may be performed 1 week after completion of antibiotic therapy to detect early recurrence and at 3 months for late recurrence. Mortality rates of 40% have been reported, but with prolonged antibiotic therapy, complete cure may be achieved. Recurrences may manifest up to 1 year later; true cure is considered when the patient is disease-free for a year after the treatment is begun.

Other Bacterial Central Nervous System Infections and Toxins

Barnett R. Nathan

Burk Jubelt

INTRODUCTION

Acute bacterial meningitis (see [Chapter 61](#)) occurs when bacteria invade and infect the leptomeninges, causing an acute clinical syndrome of fever, headache, meningismus, and neurologic dysfunction with polymorphonuclear pleocytosis in the cerebrospinal fluid (CSF). This chapter discusses a wide variety of less common bacterial infections that can either infect the central nervous system (CNS) directly, cause parainfectious central or peripheral neurologic syndromes, or create toxins that lead to neurologic dysfunction.

RICKETTSIAL INFECTIONS

Rickettsiae are obligate, intracellular pleomorphic coccobacilli. Each *Rickettsia* pathogenic for humans is capable of multiplying in arthropods and in animals and humans. They have a gram-negative cell wall and an internal structure similar to that of bacteria (i.e., with a prokaryotic DNA arrangement and ribosomes). Diseases due to rickettsiae are divided into five groups on the basis of their biologic properties and epidemiologic features: typhus, spotted fever, scrub typhus, Q fever, and trench fever. Invasion of the nervous system is common only in infections with organisms of the first three groups. Infection with Rocky Mountain spotted fever is the most important rickettsial infection currently in the United States. A sixth group of rickettsiae in the genus *Ehrlichia* have come to be recognized as significant pathogens in humans in the past 15 years. Ehrlichial infections have also been associated with CNS symptoms, but the frequency of nervous system infection is still not certain.

ROCKY MOUNTAIN SPOTTED FEVER

Rocky Mountain spotted fever (RMSF) is an acute endemic febrile disease due to infection with *Rickettsia rickettsii*. *R. rickettsii* is a gram-negative, obligate intracellular bacterium. It is transmitted to humans by various ticks, the most common of which are the *Dermacentor andersoni* (wood tick), which is found in western region of the United States, and the *Dermacentor variabilis* (dog tick), which is found in the East and South.

Rhipicephalus sanguineus (brown dog tick) is also a vector for RMSF in the southwestern United States.

Rabbits, squirrels, and other small rodents serve as hosts for the ticks and are responsible for maintaining the infection in nature. Diseases of the RMSF group are present throughout the world. Because this is a tick-borne disease, it has a seasonal variation, with the summer months having the greatest number of reports.

Epidemiology

The disease has been reported from almost all states and from Canada, Mexico, and South America.

Approximately 1,000 to 2,000 cases are reported annually in the United States, mostly from rural areas of southwestern and south-central states. Most cases are seen during the period of maximal tick activity—the late spring and early summer months. Men are more commonly affected than women, and cases are most frequently reported in those older than 40 years.

Preventative measures include personal care and vaccination. Tick-infested areas should be avoided. If exposure is necessary, high boots, leggings, or socks should be worn outside the trouser legs. Body and clothing should be inspected after exposure, and attached ticks should be removed with tweezers. Hands should be carefully washed after handling the ticks. Workers whose occupations require constant exposure to tick-infested regions should be vaccinated yearly just before the advent of the tick season.

Pathobiology

The agent has a tropism for vascular endothelial cells. Thus, any organ can be infected. The pathologic changes are most severe in the skin, but the heart, lungs, and CNS are also involved. The brain is edematous, and minute petechial hemorrhages are present. The characteristic microscopic lesions are small, round nodules composed of elongated microglia, lymphocytes, and endothelial cells. These are scattered diffusely through the nervous system in close relationship to small vessels. Vessels in the center of the lesions show severe degeneration. The endothelial cells are swollen, and the lumen may be occluded. Minute areas of focal necrosis are common as the result of thrombosis of small arterioles. Some degree of perivascular infiltration without the presence of nodules may be seen in both the meninges and the brain parenchyma.

Clinical Manifestations

A history of tick bite is elicited in about 70% of patients. The incubation period varies from 3 to 12 days. The onset is usually abrupt, with severe headache, fever, chills, myalgias, arthralgias, restlessness, prostration, anorexia, nausea, vomiting, and at times, delirium and coma. A rose-red maculopapular rash appears between the second and sixth day (usually on the fourth febrile day) on the wrists, ankles, palms, soles, and forearms. The rash rapidly spreads to the legs, arms, and chest. The rash becomes petechial and fails to fade on pressure by about the fourth day. Although cardiac, pulmonary, hepatic, and renal involvement can occur, they are less frequent than neurologic disease.

Neurologic symptoms occur early and are frequently a prominent feature. CNS signs and symptoms affect 20% to 25% of patients. Headache, restlessness, insomnia, and neck and back stiffness are common. Delirium, lethargy, or coma alternating with restlessness is present during the height of the fever. Tremors, athetoid movements, convulsions, opisthotonos, and muscular rigidity may occur. Retinal venous engorgement, retinal edema, papilledema, retinal exudates, and choroiditis may occur. Deafness, visual disturbances, slurred speech, and confusion may be present and may persist for a few weeks following recovery. Encephalitis is the most common major complication. Other major complications include adult respiratory distress syndrome, cardiac arrhythmias, pulmonary edema, skin necrosis, gastrointestinal bleeding, and coagulopathies.

P.517

Diagnosis

The white cell count (WBC) is either normal or mildly elevated. Thrombocytopenia may develop and is common. Proteinuria, hematuria, and oliguria commonly occur. Hyponatremia is also common. CSF pressure and glucose concentration are usually normal. The CSF is clear, but a slight lymphocytic pleocytosis and a slight increase in the protein concentration may occur. Eosinophilic meningitis has been reported.

The diagnosis is made on the basis of the development of the characteristic rash and other symptoms of the disease after exposure to ticks. Clinical distinction from typhus fever may be impossible. The onset of the rash in distal parts of the limbs favors a diagnosis of RMSF. In rare instances, however, neurologic signs may occur before the rash appears.

Diagnosis of RMSF is best performed by indirect immunofluorescence assay (IFA) with *R. rickettsii* antigen performed on twopaired serum samples to demonstrate a significant (fourfold) rise in antibody titers. The first titer, taken in the first week of the disease, will typically be very low or absent. After 2 to 4 weeks, those with disease should have a fourfold rise in antibody titer. Immunoglobulin (Ig) G titers are more specific than IgM. Unfortunately, because the organism is an obligate intercellular bacterium which resides in the endothelial cells, blood for polymerase chain reaction (PCR) is typically low yield. Nonspecific testing including blood work may demonstrate a leukocytosis (with left shift), thrombocytopenia, hyponatremia, and

elevated liver function tests. In patients with neurologic involvement, CSF may be normal but may also develop a lymphocytic or neutrophilic pleocytosis (1 to 200 WBC) and a mild to moderate protein elevated in 30% to 50%. Neuroimaging is nonspecific with cerebral or spinal cord edema, white matter lesions, and at times microhemorrhages.

Treatment

Doxycycline 100 mg twice a day for 7 to 14 days is the first-line treatment for adults and children of all ages and should be initiated immediately whenever RMSF is suspected.

Tetracycline 500 mg four times a day can also be used. There may be value to ciprofloxacin or chloramphenicol in patients unable to tolerate tetracycline or doxycycline. In children, chloramphenicol is the alternative to doxycycline to avoid tooth discoloration caused by tetracyclines. Any patient seriously considered to have RMSF should be treated promptly while diagnostic tests proceed.

Other spotted fever group rickettsiae in the United States that rarely cause an RMSF picture are *Rickettsia akari* (causes rickettsialpox), *Rickettsia parkeri* (eschars and a maculopapular or vesiculopapular rash), and *Rickettsia felis* (cat fleas). Except for some variation in their incubation times, the pathology and clinical picture are similar to those of RMSF. All such infections respond to tetracyclines (doxycycline) or chloramphenicol.

Outcome

There has been a dramatic fall in the mortality rate, decreasing from 28% in 1944 to less than 1% in 2001. In patients who recover, the fever is over by the end of the third week, although mild cases may become afebrile before the end of the second week. Convalescence may be slow, and neurologic sequelae may persist for several months. Long-term prognosis depends on the severity of the infection, host factors (e.g., age, the presence of other illness), and the promptness with which antimicrobial treatment is started.

EPIDEMIC TYPHUS

Three types of infection with rickettsiae of the typhus group are recognized: primary louse-borne epidemic typhus; its recrudescence form, Brill-Zinsser disease; and flea-borne endemic murine typhus.

Epidemiology

Since its recognition in the 16th century, typhus has been known as one of the great epidemic diseases of the world. It is especially prevalent in times of war or whenever there is a massing of people in camps, prisons, or ships.

Epidemic typhus (caused by *Rickettsia prowazekii*) is spread among humans by the human body louse (*Pediculus humanus corporis*). Outbreaks of epidemic typhus last occurred in the United States in the 19th century. Freedom from lice explains the absence of epidemics in the United States. Sporadic cases in the United States have been associated with flying squirrel contact. The location of epidemic disease is now limited to the Balkans, the Middle East, North Africa, Asia, Russia, and the Andes. All age groups are affected.

Rickettsiae may remain viable for as long as 20 years in the tissues of recovered patients without manifesting symptoms. Brill-Zinsser disease is a recrudescence of epidemic typhus that occurs years after the initial attack and may cause a new epidemic.

Murine typhus (*Rickettsia typhi*) is worldwide in distribution and is spread to humans by fleas. In the United

States, the disease is most prevalent in southeastern and Gulf Coast states and southern California, among individuals whose occupations bring them into rat-infested areas. The disease is most common in the late summer and fall months.

Diagnosis

A presumptive diagnosis of typhus fever may be made on the basis of the characteristic skin rash and signs of involvement of the nervous system. The diagnosis is established by serology. Antibodies to specific rickettsiae may be detected.

Clinical Manifestations

The course of typhus fever usually extends over 2 to 3 weeks. Death from epidemic typhus usually occurs between the 9th and 18th day of illness. In patients who recover, the temperature begins to fall after 14 to 18 days and reaches normal levels in 2 to 4 days. Complications include bronchitis and bronchopneumonia; myocardial disease; gangrene of the skin or limbs; and thrombosis of large abdominal, pulmonary, or cerebral vessels. Common neurologic manifestations include confusion, drowsiness, seizures, focal deficits, and coma.

Treatment

Treatment is with doxycycline, clarithromycin, or chloramphenicol, as with RMSF.

Outcome

The prognosis of epidemic typhus depends on the patient's age and immunization status. The disease is usually mild in children younger than 10 years. After the third decade, mortality increases steadily with each decade. Death is usually due to the development of pneumonia, circulatory collapse, and renal failure. The mortality rate for murine typhus in the United States is low (<1%). There are no neurologic residua in patients who recover.

P.518

SCRUB TYPHUS

Scrub typhus is an infectious disease caused by *Orientia tsutsugamushi* (previously called *Rickettsia tsutsugamushi*), which is transmitted to humans by the bite of larval trombiculid mites (chiggers). It resembles the other rickettsial diseases and is characterized by sudden onset of fever, cutaneous eruption, and the presence of an ulcerative lesion (eschar) at the site of attachment of the chigger.

Epidemiology

The disease is limited to eastern and southeastern Asia, India, and northern Australia and adjacent islands.

Clinical Manifestations

The disease begins abruptly after an incubation period of 10 to 12 days, with fever, chills, and headache. The headache increases in intensity and may become severe. Conjunctival congestion, moderate generalized lymphadenopathy, deafness, apathy, and anorexia are common symptoms. In one series, meningitis and encephalitis occurred in 15%. Delirium, coma, restlessness, and muscular twitchings are also present in severe cases. A primary lesion (the eschar) is seen in nearly all cases and represents the former site of attachment of the infected mite. There may be multiple eschars. The cutaneous rash appears between the fifth and eighth day

of the disease. The eruption is macular or maculopapular and nonhemorrhagic. The trunk is involved first with later extension to the limbs.

Diagnosis

The diagnosis is made on the basis of the development of typical symptoms, the presence of the characteristic eschar, and serology. Sensitive PCR techniques are becoming available. Elevation of hepatic enzymes and creatinine as well as thrombocytopenia is common with severe illness.

Treatment and Outcome

In patients who recover, body temperature begins to fall at the end of the second or third week. Permanent residua are not common, but the period of convalescence may extend over several months. In fatal cases, death usually occurs in the second or third week as a result of pneumonia, cardiac failure, or cerebral involvement. In the preantibiotic era, mortality could reach 60% depending on geographic locale and virulence of the strain. Deaths are rare with appropriate antibiotic treatment, which is similar to the treatment for RMSF (doxycycline).

EHRlichiosis AND ANAPLASMOSIS

Ehrlichiosis or anaplasmosis are tick-borne diseases with the preponderance of disease occurring in the summer months. They are small, gram-negative, obligate intracellular bacteria that infect leukocytes. Three forms of human infection have been identified in the United States. One species, *Ehrlichia chaffeensis*, is associated with human monocytotropic ehrlichiosis (HME), and the organism may be preferentially found in these cells. Human granulocytotropic ehrlichiosis (HGE) is also referred to as *human granulocytotropic anaplasmosis* (HGA). HGE is caused by *Anaplasma phagocytophilum*. Both human infections are detectable in the appropriate cells as coccobacillary forms. It has become possible to cultivate the organisms, and PCR reactions are increasingly available. Most diagnostic studies still rely on antibody detection. HME is transmitted by *Amblyomma americanum* (lone star tick) and possibly other ticks, whereas HGE is transmitted by ixodid ticks and probably *D. andersoni*. A third agent, *Ehrlichia ewingii*, causes canine granulocytic ehrlichiosis. It is transmitted by *A. americanum*.

Epidemiology

The epidemiologic range for both agents appears to be extending. In 2010, United States cases attributed to *E. chaffeensis* declined almost 22% (944 to 740 cases), whereas those cases attributed to *A. phagocytophilum* increased by 52% (1,161 to 1,761 cases). HME is more common in the states in the South and Southeast region, whereas HGE was first found in the Midwest. Now, cases are regularly reported from New England, all Atlantic Coast states, south-central states, and California. Coinfection of HGE with *Borrelia burgdorferi* and HME with RMSF has been reported. *E. ewingii* is found in south-central, southeastern, mid-Atlantic, and coastal states.

Clinical Manifestations

Infection usually presents as a febrile, systemic process often associated with myalgia and headache. CNS complications occur in 20% to 35% of infected patients. Changes in mental status, meningitis, meningoencephalitis, seizures, cranial nerve palsies, and ataxia have also been noted and are correlated with more serious illness. Cardiac and respiratory failure can occur. Rashes have been reported in about 20% of cases. This makes it difficult to distinguish the illness from RMSF, whose distribution overlaps with *E. chaffeensis*. *E. ewingii* is more likely to occur in immunocompromised hosts. Children tend to have more severe

disease.

Diagnosis

Because of the nonspecific nature of the symptoms and signs, a high index of suspicion is required. A history of exposure to ticks may be helpful, but epidemiologic studies have shown that serologic evidence of infection usually is not correlated with known tick bites. Lymphopenia is often a feature of *E. chaffeensis* infection, whereas granulocytopenia is usually noted with the HGE infection. Thrombocytopenia and leukopenia are seen with *E. ewingii* infection. Elevated hepatic enzymes are usually present. Microscopic blood examination with a Wright-Giemsa stain may reveal the classic intraleukocytic morula. CSF pleocytosis and an increased protein concentration have been reported and appear to correlate with altered mental status. The most widely available diagnostic test remains a fourfold rise in antibody titer. Confirmation of the diagnosis can be attained by immunofluorescent detection of the intracellular organisms. PCR is available for both HME and HGA, although this test has yet to be standardized and not always readily available. Culturing of the causative organisms is now also possible but is not as sensitive as PCR.

Treatment and Outcome

Complete understanding of the course of ehrlichiosis has yet to be achieved. Initially, a high proportion of reported cases was fatal in both HME and HGE. However, serologic studies indicate that asymptomatic or minor infections are common. Currently reported case fatality rates are 3% to 10%. Clinically, it has also been found that some cases may be self-limited even without treatment. Treatment with doxycycline 100 mg twice a day for 7 days often results in rapid improvement. Therefore, prognosis seems to be good if accurate diagnosis is made and treatment started promptly.

P.519

BRUCELLOSIS

Brucellosis (undulant fever) is a disease with protean manifestations, resulting from infection with short, slender, rod-shaped, gram-negative microorganisms of the genus *Brucella*. The infection is transmitted to humans from animals (cattle, pigs, sheep, goats, and others). The illness is prone to occur in slaughterhouse workers, livestock producers, veterinarians, and persons who ingest unpasteurized milk or milk products.

PATHOBIOLOGY

The two major species that can infect humans are *Brucella suis* from swine and *Brucella abortus* from cattle. Inoculation is via the skin, inhalation, or ingestion. It is a slow-growing organism having an incubation time of up to 2 to 3 weeks.

CLINICAL MANIFESTATIONS

There is a broad clinical spectrum from asymptomatic to fatal disease.

An acute, febrile illness is characteristic of the early stages of the disease. The common symptoms include chills, night sweats, fever, weakness, and generalized malaise; 70% of patients experience body aches and nearly 50% complain of headache. Other symptoms on presentation can include anorexia, nausea and vomiting, arthritis, endocarditis, malodorous sweat, or orchitis. Early constitutional symptoms are followed by the subacute and chronic stages in about 15% to 20% of patients with localized infection of the bones, joints, lungs, kidneys, liver, lymph nodes, and other organs. Neurologic complications have been reported in up to 25% but are more likely much less common occurring in about 5% of cases. These complications can include meningitis, encephalitis,

myelitis, radiculitis, neuritis, and meningovascularitis. Nonspecific neurologic signs and symptoms may include seizures, cranial neuropathies, gait disturbances, hemiparesis and hemisensory disturbance, and mental status changes.

DIAGNOSIS

Diagnosis is made with culture. This is a slow-growing organism and may take up to 30 days to grow. Blood, CSF, or bone marrow can be cultured. Additionally, PCR may be helpful. Screening blood work may demonstrate a pancytopenia. Lumbar puncture may reveal a mildly increased opening pressure and a lymphocytic pleocytosis (<500 WBC), slightly elevated protein, and a small decrease in the glucose concentration. The CSF has increased gamma globulin levels and often contains *Brucella*-agglutinating antibodies. Neuroimaging may demonstrate white matter changes in the brain, particularly in a periventricular distribution. These white matter lesions are seen best with fluid-attenuated inversion recovery (FLAIR) sequences and can enhance with gadolinium.

TREATMENT AND OUTCOME

Treatment likely requires multiple antibiotics for multiple months, although there has been success with monotherapy with doxycycline 100 mg orally (PO) twice a day (b.i.d.) for 45 days, with fewer recurrences than a 30-day course [Level 1].¹ Treatment of systemic disease is with doxycycline plus an aminoglycoside (intramuscular streptomycin or intravenous [IV] gentamicin), rifampin, or ofloxacin [Level 1].^{2,3} Trimethoprim/sulfisoxazole is an alternative to the tetracyclines. Neurologic disease is treated with triple therapy with the addition of trimethoprim-sulfamethoxazole or ceftriaxone to one of the aforementioned regimens.

ANTHRAX

Bacillus anthracis is a large endospore-forming, aerobic, grampositive nonmotile bacterium that produces a black, eschar-like cutaneous lesion after cutaneous inoculation.

EPIDEMIOLOGY

Anthrax is primarily a disease of herbivores; however, it causes cutaneous lesions as well as respiratory and gastrointestinal infections in humans. Anthrax is one of the oldest documented infectious diseases. It may have caused two Egyptian plagues in 1491 BC. Inhalational anthrax occurred in England in the 19th century as woolsorter's disease, and in Germany, it became known as *ragpicker's disease* as a result of the infection of mill workers with anthrax spores from contaminated fibers from goats. Prior to the 2001 bioterrorism-related outbreak of 11 inhalational cases and 12 suspected or confirmed cases of cutaneous anthrax, there had been only 18 sporadic cases total in the United States during the 20th century, with the last case in 1976. Therefore, other than bioterrorist attacks or laboratory accidents, the populations most at risk for anthrax are individuals who work closely with domesticated animals. Countries such as Turkey have much higher incidences of anthrax than the United States.

CLINICAL MANIFESTATIONS

Anthrax meningitis can be acquired via the cutaneous or the inhalation route. Infection via cutaneous inoculation is most common, comprising upwards of 90% of cases. Inhalation accounts for only 5% of cases. *B. anthracis* CNS complications follow skin or inhalation of the spores by 3 days to a week. Meningitis develops as a result of lymphohematogenous spread from the primary lesions. The disease is primarily a hemorrhagic

meningoencephalitis and is fulminant and rapidly progressive.

DIAGNOSIS

The CSF profile is typical of meningitis, with thousands of WBC (neutrophilic), low-glucose, and high-protein concentration. Red blood cells in large numbers are seen in the CSF as well as gram-positive organisms. Computed tomography (CT) and magnetic resonance imaging (MRI) may demonstrate leptomeningeal enhancement and parenchymal or subarachnoid blood and may show basal ganglia enhancement.

TREATMENT AND OUTCOME

Although the cutaneous forms of anthrax can be self-limiting, the hemorrhagic meningoencephalitis has a near 100% mortality rate. Treatment of the meningitis should include a fluoroquinolone plus one or two additional agents with good CSF penetration such as penicillin or ampicillin, meropenem, rifampicin, or vancomycin. Corticosteroids should be considered in cases with severe cerebral edema.

BARTONELLA

Bartonella henselae, the etiologic agent for cat scratch disease (CSD), is a motile, flagellated, gram-negative, intracellular bacterium that is related to *Brucella* and *Rickettsia*. As the name suggests, this agent is common in cats. There is a bacteremia in close to 70% of infected cats. In up to 90% of human disease, there is a history of exposure to cats.

P.520

EPIDEMIOLOGY

The disease in humans is globally endemic, most common in autumn and winter in the United States. Children and young adults are most likely to contract CSD. The disease is likely spread to humans via scratches of domestic or feral cats, particularly kittens. There is also some evidence that suggests that CSD may be transmitted directly to humans by the bite of infected cat fleas, although this has not been proven. Incidence is in the range of 9 to 10 per 100,000 in the United States with 2% to 4% developing encephalopathy (500 to 1,000 cases per year) in the United States.

CLINICAL MANIFESTATIONS

The clinical syndrome of CSD typically begins with a papule or pustule developing at the scratch site approximately 1 week after contact with a cat (usually a kitten). This progresses over the course of 1 to 7 weeks to a painful regional lymphadenopathy. Fever, sometimes relapsing, malaise, fatigue, and headache are common systemic signs and symptoms. In the rare case where encephalopathy develops, this typically follows the painful adenopathy. Of those that advance to CNS disease, 50% to 80% can present with focal or generalized seizures or status epilepticus. Focal deficits such as aphasia, hemiplegia, cranial nerve palsies, ataxia, delirium, and coma can also occur. Ocular findings such as neuroretinitis, optic neuritis, and papillitis can also be commonly seen.

DIAGNOSIS

IFA testing and enzyme-linked immunosorbent assay (ELISA) are used to detect serum antibody to *B. henselae*. A titer greater than 1:64 suggests recent *Bartonella* infection. A fourfold or greater increase (6 weeks later) is confirmatory. The IFA shows cross-reactivity between *Bartonella* species, Epstein-Barr virus, cytomegalovirus, *Toxoplasma gondii*, and *Streptococcus pyogenes*. About 84% of patients have

positive titers within 1 to 2 weeks of clinical CSD, and 16% develop positive titers 4 to 8 weeks later. Nonspecific findings include a peripheral leukocytosis and CSF with a mild lymphocytic pleocytosis and elevated protein concentration (seen in only about one-third of patients). Less than 20% of patients with CNS CSD have neuroimaging findings. Those that have been reported have included cerebral white matter lesions, basal ganglia and thalamic lesions, and rarely, cortical lesions.

TREATMENT AND OUTCOME

CSD is usually self-limited, resolving in 2 to 4 months. It is unclear as to the best treatment for CSD. Many cases including those with CNS involvement are self-limited and require no antibiotic treatment. Most studies of antibiotic treatment are retrospective and small. A randomized controlled trial using azithromycin demonstrated efficacy in reducing lymph node size [Level 1].⁴ Other antibiotics that have shown efficacy in retrospective studies include doxycycline, rifampin, trimethoprim-sulfamethoxazole, and ciprofloxacin. Prognosis is typically good, although some with CNS involvement may develop epilepsy and cognitive deficits.

WHIPPLE DISEASE

Tropheryma whipplei is a rod-shaped, gram-positive bacterium. It was finally isolated in eukaryotic cells in the year 2000 and propagated in culture at 37°C but was believed to resist culturing for a long time. Now it is known that it can only be cultured if part of its eukaryotic host is present.

EPIDEMIOLOGY

T. whipplei is believed to have an environmental derivation because its closest known relatives, Actinobacteria, originated from the soil. However, *T. whipplei* actually is completely dependent on humans for growth. Whipple disease is caused by *T. whipplei*. This is a rare disease, and although there is no current estimate on its incidence, there are only about 1,000 cases reported in the literature. Classic Whipple disease is most common in middle-aged white men, although it can affect any sex, age, and race.

CLINICAL MANIFESTATIONS

The signs and symptoms of classic disease are primarily gastrointestinal. The disease has a prodromal stage with a wide variety of nonspecific symptoms and also arthralgias and arthritis. After the prodromal stage comes the steady-state stage. The time between the stages can be quite long, averaging 6 years. In the steady-state stage, diarrhea and weight loss are the classic symptoms. Neurologic involvement occurs in 6% to 63% of patients with classic Whipple disease. The most common signs and symptoms of CNS Whipple are alterations in cognition and supranuclear gaze palsy, myoclonus, ataxia, hypothalamic dysfunction, and altered level of consciousness. Abnormal movement of the eye muscles, termed *oculomasticatory* or *oculofacioskeletal myorhythmia*, is considered pathognomonic for Whipple disease. Isolated CNS Whipple disease (without gastrointestinal involvement) has been reported in 32 patients. In these cases, the disease progression is more fulminant, with about a third dying from the disease (vs. about 25% with classic Whipple with CNS involvement).

DIAGNOSIS

Laboratory workup for Whipple disease should include routine blood work. Although nonspecific, many with the disease have acute-phase reactants, anemia, leukocytosis, thrombocytosis, and evidence of malnutrition. Thrombocytopenia and eosinophilia have also been reported. The classic diagnostic test is periodic acid-Schiff (PAS) staining of small-bowel biopsy specimens, which on light microscopy shows

magenta-stained inclusions within macrophages of the lamina propria. There is also a PCR test for *T. whipplei*, which should be used in conjunction with the PAS staining.

TREATMENT AND OUTCOME

Treatment for CNS Whipple disease is long-term antibiotic treatment (up to a year). Antibiotics that have had some success with classic Whipple disease include tetracycline, penicillin, trimethoprim-sulfamethoxazole, and ceftriaxone. There have never been any randomized trials, however. Based on in vitro data, a potential regimen for CNS Whipple disease is doxycycline and hydroxychloroquine plus a high dose of sulfamethoxazole or sulfadiazine. Chronic neurologic sequelae are common with CNS involvement.

MYCOPLASMA PNEUMONIAE

Mycoplasmas, originally called *pleuropneumonia-like organisms*, lack a cell wall. Individual mycoplasmas are bound by a unit membrane that encloses the cytoplasm, DNA, RNA, and other cellular components. They are the smallest free-living organisms and are resistant to penicillin and other cell wall-active antimicrobials. Of mycoplasmas that infect humans, *Mycoplasma pneumoniae* is the

P.521

only species that has been clearly shown to be a significant cause of disease.

PATHOBIOLOGY

M. pneumoniae is spread from person to person by infected respiratory droplets. It is a major cause of acute respiratory disease, including pneumonia. Prior to neurologic involvement, an antecedent respiratory illness often occurs. A variety of neurologic conditions has been described *in association with M. pneumoniae* infection: meningitis, encephalitis, postinfectious leukoencephalitis, acute cerebellar ataxia, transverse myelitis, ascending polyneuritis, radiculopathy, cranial neuropathy, and acute psychosis. The most common neurologic condition appears to be meningoencephalitis with alterations in mental status that is a parainfectious immune-mediated disorder rather than infectious disorder. The neurologic features associated with *M. pneumoniae* infection, however, are so diverse that the correct diagnosis may not be made on clinical grounds alone. MRI is usually normal. Focal or diffuse edema is occasionally seen. If postinfectious demyelinating encephalitis occurs, white matter lesions will be seen on FLAIR and T2 images. The CSF usually contains polymorphonuclear leukocytes and mononuclear cells in varying proportions. The CSF has normal or mildly elevated protein concentration and a normal glucose concentration. Bacterial, viral, and mycoplasma cultures of the CSF are usually sterile.

DIAGNOSIS

Retrospective diagnosis may be made by cold isohemagglutinins for human type O erythrocytes. These may be detected in about 50% of patients during the second week of illness; they are the first antibodies to disappear. Specific antibodies may also be demonstrated by enzyme immunoassay and are more accurate. PCR is now being used to on blood and CSF.

TREATMENT AND OUTCOME

Doxycycline (not in children) and the macrolides azithromycin and clarithromycin are the drugs of choice for *M. pneumoniae* infections. It appears that corticosteroids may be beneficial along with antibiotics in severe cases that may be postinfectious. There are no controlled studies.

LEGIONELLA PNEUMOPHILA

Legionella pneumophila is a poorly staining gram-negative bacterium that either does not grow or grows very slowly on most artificial media. The organism was first isolated from fatal cases of pneumonia among persons attending an American Legion Convention in Philadelphia in 1976. The bacterium is acquired by inhalation of contaminated aerosols or dust from air-conditioning systems, water, or soil.

CLINICAL MANIFESTATIONS

Pneumonia is the most typical systemic manifestation of infection. Upper respiratory infection, a severe influenza-like syndrome (Pontiac fever), and gastrointestinal disease may also occur. Several neurologic conditions have been described in association with *L. pneumophila* infection (Legionnaires disease or legionellosis): acute encephalomyelitis, severe cerebellar ataxia, chorea, and peripheral neuropathy. Confusion, delirium, and hallucinations are common symptoms. The pathophysiology of these syndromes is unclear because bacteria have rarely been demonstrated in the CNS. Myoglobinuria and elevated serum creatine kinase levels also have been reported.

DIAGNOSIS

L. pneumophila is rarely recovered from pleural fluid, sputum, or blood; it frequently may be isolated from respiratory secretions by transtracheal aspiration or bronchoalveolar lavage and lung biopsy tissue. Urinary antigen detection methods appear to be very sensitive. A retrospective diagnosis may be made by a significant rise in specific serum antibodies. The CSF, CT, and MRI are usually normal. The electroencephalograph frequently reveals diffuse slowing.

TREATMENT AND OUTCOME

The treatment of choice is azithromycin or clarithromycin. Quinolones (levofloxacin) are equally effective. Relapses are uncommon if treatment is continued for 14 days. When relapses occur, they usually respond to a second course of the antibiotic. The true incidence of neurologic involvement in Legionnaires disease is still unknown. The neurologic deficit is known to be reversible, but little exact information about recovery is available.

BACTERIAL TOXINS: DIPHTHERIA, TETANUS, AND BOTULISM

Clostridium tetani, *Clostridium botulinum*, and *Corynebacterium diphtheriae* each produce toxins that affect the nervous system. In the case of *Corynebacterium diphtheriae*, the toxin produced causes a peripheral (cranial nerve) neuropathy, the toxin of *Clostridium botulinum* affects the neuromuscular junction, and that of *Clostridium tetani* affects the CNS.

DIPHTHERIA

C. diphtheriae is a nonmotile, noncapsulated, club-shaped, grampositive bacillus. Diphtheria is most commonly an infection of the upper respiratory tract and causes fever, sore throat, and malaise. A thick, gray-green fibrin membrane, the pseudomembrane, often forms over the site(s) of infection as a result of the combined effects of bacterial growth, toxin production, necrosis of underlying tissue, and the host immune response. Recognition that the systemic organ damage was due to the action of diphtheria toxin led to the development of both an effective antitoxin-based therapy for acute infection and a highly successful toxoid vaccine.

The exotoxin of *C. diphtheriae* inhibits protein synthesis in mammalian cells by inactivation of transfer RNA

(tRNA) translocase. It is composed of two segments: one necessary for binding to the cell and a shorter portion that then is cleaved and enters the cell. The specificity of the exotoxin for heart and peripheral nerve is attributed to receptor-binding affinity at the cell surface. The development of neuropathy is proportional to the severity of the primary infection. In the pharyngeal infections, palatal and pharyngo-laryngo-esophageal paralysis are early and prominent features. Other than these manifestations and the common ciliary paralysis, the resistance of other cranial nerves and the brain to these effects is unexplained.

BOTULISM

Botulism is a rare and potentially fatal paralytic illness caused by a toxin produced by the bacteria *C. botulinum*. The most common mode of transmission is ingestion of toxic spores produced by the bacteria in contaminated food.

P.522

Pathobiology

C. botulinum is a large, usually gram-positive strictly anaerobic bacillus, which forms a subterminal spore. The species is divided into four physiologic groups. Each strain produce slightly different toxins. A single strain almost always produces only one toxin type. *C. botulinum* spores are found worldwide and inhabit soil samples and marine sediments. These spores are able to tolerate 100°C at 1 atm for several hours; because boiling renders solutions more anaerobic, it may actually favor the growth of *C. botulinum*. Proper preparation of food in a pressure cooker (>1 atm) will kill spores. Botulinum toxin is synthesized as a single polypeptide chain of low potency. It is then nicked by a bacterial protease to produce two chains, with the light chain constituting approximately one-third of the total mass. The nicked toxin type A is, on a molecular weight basis, the most potent toxin found in nature. In contrast to the spores, high temperatures destroy the toxin. Once present at the synapse, the toxin ultimately prevents the release of acetylcholine. The toxin enters the cell by receptor-mediated endocytosis. The result is that stimulation of the presynaptic cell (e.g., the alpha motor neuron) fails to produce transmitter release, thus producing paralysis in the motor system or autonomic dysfunction when parasympathetic nerve terminals or autonomic ganglia are involved. The toxins only affect the free proteins; once vesicular and synaptic proteins have formed a complex to cause transmitter release, they are not subject to attack. Once damaged, the synapse is permanently affected. The recovery of function requires sprouting of the presynaptic axon and the subsequent formation of a new synapse.

In food-borne botulism, toxin is ingested with the food in which it was produced. It is absorbed primarily in the duodenum and jejunum and passes into the bloodstream by which it reaches peripheral cholinergic synapses (including the neuromuscular junction). In cases of wound botulism, spores are introduced into a wound, where they germinate and produce toxin. Infant botulism, and probably adult botulism of unknown etiology, follows ingestion of spores, with subsequent bacterial colonization of the small intestine. Gastric acid-lowering agents and antibiotic use may predispose to gastrointestinal colonization with *C. botulinum*.

Clinical Manifestations

The clinical manifestations of botulism depend on the type of toxin produced, rather than the site of its production. The classic presentation of botulism is that of a patient who develops acute, bilateral cranial neuropathies associated with symmetric descending weakness. *Food-borne* botulism usually develops between 12 and 36 hours after toxin ingestion. The initial complaints are nausea and a dry mouth and sometimes diarrhea. Cranial nerve dysfunction most commonly starts with the eyes, including blurred vision due to pupillary dilation (reflecting parasympathetic dysfunction) or diplopia (reflecting dysfunction of nerves III, IV, or VI). Pupils are either dilated or unreactive in less than 50% of patients. The absence of these signs in no way diminishes the likelihood of botulism. Lower cranial nerve dysfunction manifests as dysphagia, dysarthria, and hypoglossal

weakness. Weakness then spreads to the upper extremities, the trunk, and the lower extremities. Respiratory dysfunction and failure may result from either upper airway obstruction from a weakened glottis or diaphragmatic weakness. Autonomic problems may include gastrointestinal dysfunction, alterations in resting heart rate, loss of responsiveness to hypotension or postural change, hypothermia, or urinary retention, although these are not usually as common or severe as that seen in tetanus. Recovery may not begin for up to 100 days.

Infantile botulism presents with constipation, which may be followed by feeding difficulties, hypotonia, increased drooling, and a weak cry (see also [Chapter 136](#)). Upper airway obstruction may be the initial sign and is the major indication for intubation. In severe cases, the condition progresses to include cranial neuropathies and respiratory weakness, with ventilatory failure occurring in about 50% of diagnosed patients. The condition progresses for 1 to 2 weeks and then stabilizes for another 2 to 3 weeks before recovery starts.

Wound botulism lacks the prodromal gastrointestinal disorder of the food-borne form but is otherwise similar in presentation. Fever, if present, reflects wound infection rather than botulism. The wound itself may rarely appear to be healing well while neurologic manifestations are occurring. The incubation period varies from 4 to 14 days.

Diagnosis

Laboratory evaluation includes anaerobic cultures and toxin assays of serum, stool, and the implicated food if available. Confirmation and toxin typing is obtained in almost 75% of cases. Early cases are more likely to be diagnosed by the toxin assay, whereas those studied later in the disease are more likely to have a positive culture than a positive toxin assay. Specimens should be obtained and sent in consultation with the appropriate officials (in the United States, the Centers for Disease Control and Prevention [CDC]). Toxin excretion may continue up to 1 month after the onset of illness, and stool cultures may remain positive for a similar period.

Electrophysiologic studies reveals normal nerve conduction velocities; the amplitude of compound muscle action potentials is reduced in 85% of cases, although not all motor units may demonstrate this abnormality. Repetitive nerve stimulation at high rates (≥ 20 Hz, compared with the 4 Hz rate employed in the diagnosis of myasthenia gravis) may reveal a small increment in the motor response.

Management

Patients who receive appropriate airway and ventilator management should recover unless there are other complications (see [Chapter 116](#)). There have been increasing survival rates in patients with botulism that follow the improvement in critical care medicine, particularly in the arena of ventilatory support. The decision to intubate is similar to most cases of neuromuscular respiratory failure (i.e., Guillain-Barré, myasthenia gravis) and should be based on (1) assessment of upper airway competency and (2) changes in vital capacity (in general, <12 mL/kg or a rapidly declining vital capacity suggests the need to intubate). Do not wait for the PCO_2 to rise or the oxygen saturation to fall before intubating the patient. If contaminated food may still reside in the gastrointestinal tract, purgatives may be useful unless ileus has occurred, in which case gastric lavage may prove valuable. Patients should be given botulinum antitoxin. In the United States, equine bivalent (A and B) antitoxin is available from the CDC or some state health departments. Monovalent type E antitoxin should be added when type E exposure is suspected. The role of antibiotic treatment is untested, but penicillin G, 10 to 20 million units daily, is frequently recommended. Metronidazole may be an effective alternative. The use of local antibiotics, such as penicillin G or metronidazole, may be helpful in eradicating *C. botulinum* in wound botulism. Antibiotic use, however, is not recommended for infant botulism because cell death and lysis may result in the release of more toxin. Aminoglycoside antibiotics and tetracyclines, in particular, may increase the degree of neuromuscular blockade by impairing neuronal calcium entry. This effect has

not been reported in adult cases but should be considered when gastrointestinal botulism is encountered.

TETANUS

Tetanus is an infectious toxidrome characterized by a prolonged contraction of skeletal muscles. The syndrome is caused by *tetanospasmin*, a toxin produced by *Clostridium tetani*. *C. tetani* is a slender, obligately anaerobic bacillus and although it is classified as a gram-positive organism, it may stain variably, especially in tissue or older cultures. Most strains are slightly motile and they have abundant flagellae during growth. The mature organism loses its flagellae and forms a spherical terminal spore, producing a profile such as that of a tennis racket.

Pathobiology

Tetanospasmin spores resist extremes of temperature and moisture, are stable at atmospheric oxygen tension, and can survive indefinitely and are viable after exposure to ethanol, phenol, or formalin. Death of the spores can be accomplished by exposure to 100°C for 4 hours, autoclaving at 121°C, and 103 kPa (15 psi) for 15 minutes or with exposure to iodine, glutaraldehyde, or hydrogen peroxide. Spores can be isolated from animal feces and therefore are ubiquitous in the environment. The spores of *C. tetani* will germinate and the bacteria proliferate when the oxygen tension of the tissue is low. Once growing, two exotoxins are produced: tetanospasmin and tetanolysin. Tetanospasmin, or “tetanus toxin,” is felt to cause all the typical clinical manifestations of tetanus. It is synthesized as a single 151-kDa (1315 amino acid) chain. This molecule is then cleaved by a bacterial protease into a heavy chain and a light chain connected by a disulfide bridge. The disulfide bridge is necessary for the activity of the toxin. The DNA for this polypeptide resides on a single plasmid; strains of *C. tetani*, which do not have this plasmid, have no toxogenic properties.

Tetanospasmin inhibits neurotransmitter release at the presynaptic nerve terminal and this is what accounts for the clinical presentation of tetanus. The toxin first binds to the presynaptic membrane and then must pass through the cell membrane and into the cytoplasm. Once in the cytoplasm of the presynaptic terminal, tetanospasmin inactivates synaptobrevin, a neuronal protein that “docks” the neurotransmitter filled vesicle to the membrane. Because synaptobrevin is inactivated, the vesicle is unable to fuse with the membrane and neurotransmitter cannot be released. Tetanospasmin travels via retrograde transport back to the cell body and can then cross several orders of synaptically connected neurons. This process allows the toxin to move from the neuromuscular junction of alpha motor neurons to the spinal cord and ultimately to the brain. This explains the effects of tetanospasmin on the neuromuscular junction, autonomic function, and the CNS. Tetanospasmin also is hematogenously spread but ultimately must still enter the nervous system via neurons and retrograde transport.

Once transported to the spinal cord, tetanospasmin primarily affects the inhibitory neurons. These inhibitory neurons use either glycine or γ -aminobutyric acid (GABA) as neurotransmitters. Without these neurons, the motor neuron increases its firing rate, ultimately causing rigidity of the muscle innervated by this neuron. More clinically relevant is the fact that without this inhibition, the normal inhibition of antagonist muscles is impaired, and in response to movement or stimulation, the characteristic tetanic spasm occurs.

Clinical Manifestations

Tetanus is classified into four clinical types: generalized, localized, cephalic, and neonatal. These four clinical subtypes represent the site of toxin action either predominantly at the neuromuscular junction or inhibition in the CNS. Incubation time (the time from spore inoculation to first symptoms) for all clinical types depends on severity and distance of injury or inoculum site to the CNS, with more severe disease developing more quickly and mild disease taking longer.

Generalized tetanus is the most commonly recognized form of the disease with trismus, or lockjaw, as the most common presenting sign. Trismus is caused by rigidity of the masseter muscles that in turn prevent the opening of the mouth. The more severe it is, the smaller the opening between the upper and lower jaw. Trismus results in a facial expression called *risus sardonicus*, which consists of lateral extension of the corners of the mouth, raised eyelids, and wrinkling of the forehead. These facial features may at times be subtle. Involvement of other muscle groups can then follow the onset of trismus, first the neck, then the thorax and abdomen, and finally the extremities.

Tetanospasms, or generalized spasms that superficially resemble opisthotonos, decerebrate posturing, or seizures are elicited by either external or internal stimuli. Because full consciousness is retained, the spasms are extremely painful. This maintenance of consciousness helps to differentiate them from seizures or decerebrate posturing. Respiratory compromise, due to spasm of the glottis, diaphragm, or abdominal muscles, is the most serious early problem in generalized tetanus.

Later in the illness, defects in autonomic dysfunction, usually as manifested by increased sympathetic tone, are frequently noted in patients with severe tetanus. Autonomic dysfunction is now the leading cause of death in tetanus patients. It is characterized by labile hypertension (and sometimes hypotension) and tachycardia, arrhythmias, peripheral vascular constriction, diaphoresis, pyrexia, increased carbon dioxide output, and increased urinary catecholamine excretion. The progression of the disease may last for 10 to 14 days. This reflects the time it takes for the toxin to be transported to the CNS. Recovery may take 4 weeks or more. Without antitoxin, the disease persists for as long as the toxin is produced, and because toxin is produced in insufficient quantities to stimulate an immune response, recurrent tetanus is documented.

Neonatal tetanus is a generalized form of the disease and is far more common in underdeveloped countries than in the developed world. It is the leading cause of neonatal mortality in many parts of the world, and of the diseases which can be vaccinated against, it is second only to measles as a cause of childhood death. It usually follows an infection of the umbilical stump, often because of improper wound care. A lack of maternal immunity to tetanus is also necessary for the development of this disease. The incubation period is anywhere between 1 to 10 days postpartum. The infants usually present with weakness, irritability, and inability to suck. Tetanic spasms occur later, and the opisthotonic posturing can be confused with neonatal seizures or other metabolic or congenital abnormalities which cause posturing in this age group. The hypersympathetic state described earlier is also common and is frequently the cause of death. The mortality rate is up to 90% and developmental retardation is common in those who survive.

Localized and *cephalic* tetanus is characterized by fixed rigidity of the muscles at or near the site of injury. This may be mild or painful and may persist for months, sometimes resolving spontaneously. Partial immunity to the toxin may be mechanism responsible for preventing further spread and generalized tetanus; however, unless treated, localized tetanus can evolve into the generalized form. The cephalic form is an unusual type of localized tetanus and occurs with injuries to the head or at times is

P.524

associated with *C. tetani* infections of the middle ear. Patients on presentation have weakness of the facial musculature, dysphagia, and extraocular muscle involvement. Both cephalic and localized forms of tetanus can spread to become the generalized form.

Diagnosis

The diagnosis of tetanus is primarily clinical. A clinical picture of trismus, muscle rigidity, stimulus-induced tetany, and a history of a wound or injury within the last 3 weeks is highly suggestive of generalized tetanus. Likewise, a newborn with a poor suck and increased muscle rigidity and spasms, in the setting of poor umbilical hygiene and a mother with no immunization history, likely has neonatal tetanus. *C. tetani* is rarely

cultured from the wound, and in any case, a positive culture does not prove the presence of the disease nor does a negative culture disprove it. Blood and serum studies are usually normal or nonspecific and CSF is usually normal.

Treatment

A patient with generalized tetanus or neonatal tetanus will require the facilities and the expertise of an intensive care unit to survive. A review of 335 consecutive tetanus patients revealed that survival drastically improved after the development of intensive care units (44% mortality vs. 15%) and that the major improvement came from the prevention of death from respiratory failure (Table 63.1).

Treatment of generalized tetanus should begin with administration of human tetanus immunoglobulin (HTIG) to neutralize the tetanospasmin, which has not yet entered neurons. A single dose of 500 IU is as effective as higher doses ranging from 3,000 to 5,000 IU. Equine antitetanus serum may be more readily available, particularly in underdeveloped regions; however, it has a much higher incidence of adverse reactions such as anaphylaxis and serum sickness. It is dosed at 10,000 to 1,000,000 units intramuscularly. Debriding the portal of entry does not change the course of the disease, although it may help prevent secondary infection. Antibiotic treatment should be initiated at the outset, although it likely plays a minor role in the treatment of the disease. In an open study comparing metronidazole and penicillin, *metronidazole* 500 mg IV every 6 hours for 7 to 10 days was superior with significantly less progression of the disease, shorter hospitalization, and improved survival.

Muscle relaxation is best accomplished with benzodiazepines or baclofen. Very large doses are required to control spasms. Continuous magnesium infusion (2 to 4 g/h, targeted to serum magnesium levels of 2 to 4 mg/dL) can also aid in reducing neuronal excitability and spasms. If GABA receptor upregulation with benzodiazepines or baclofen is unsuccessful in controlling the muscle spasms, then neuromuscular blockade with vecuronium or rocuronium may be necessary. Control of autonomic instability, primarily sympathetic storming, can be achieved with a variety of agents. IV labetalol, a combined α - and β -blocker, is the first-line treatment of choice. Clonidine and dexmedetomidine are α -2 receptor agonists that reduce basal sympathetic tone and may be helpful in suppressing sympathetic surges. There is no agreed upon specific regimen for the treatment of neonatal tetanus; however, it is treated much like generalized variety.

TABLE 63.1 Mainstays of Treatment for Severe Tetanus

- Neutralizing existing toxin before it enters the nervous system

- Inhibition of further production of tetanus toxin

- Muscle relaxation and sedation

- Management of autonomic instability

- Ventilator, nutritional, and general ICU support

ICU, intensive care unit.

INTRODUCTION

Chronic meningitis is commonly defined as inflammation of the meninges, most often accompanied by a pleocytosis of greater than 5 white blood cells per microliter in the cerebrospinal fluid (CSF), that has persisted for at least 1 month without spontaneous resolution. Clinical presentation often includes headache, nausea, vomiting, cranial neuropathies, symptoms of elevated intracranial pressure, or focal neurologic deficits (Table 64.1). The most common etiologies of chronic meningitis fall into three broad categories: infectious, autoimmune, and neoplastic. This chapter will focus on the most common infectious etiologies of chronic meningitis. Fungal, bacterial, and parasitic pathogens can invade the central nervous system and present clinically as chronic meningitis. Increasing use of immunosuppressant medications for autoimmune disease and posttransplantation immunosuppression, as well as predisposing conditions, such as impaired cellular and humoral immunity, have led to a larger population at risk for infectious causes of chronic meningitis.

Despite an increasing array of diagnostic assays, there remain a large proportion of patients with chronic meningitis who remain without a definitive pathogen identified. A thorough history and skillful physical examination is the key to guide further diagnostic testing (Table 64.2) and management (Table 64.3). When history, examination, CSF analysis, and imaging fail to yield an etiology, biopsy is required to establish a definitive diagnosis.

FUNGAL MENINGITIS

Fungi exist in two forms, molds and yeasts. Molds are the tubular form, consisting of hyphae that can be branched or contain a single filament. Yeasts are thick-walled, single-celled organisms that live inside cells. Dimorphic yeasts assume tubular forms at lower temperature but become encapsulated at temperatures above 35°C. Either fungal form can infect the nervous system, producing meningitis, vasculitis, abscess, granulomas, or encephalitis.

Fungi are universal saprophytic organisms found as spores in soil, on the skin of mammals and birds, and in bat or bird guano. They commonly enter the body through inhalation; direct invasion through the skin, mucus membranes, or sinuses; or via penetrating wounds. Although invasive fungal disease typically affects immunocompromised individuals, some organisms such as *Coccidioides* spp. and *Cryptococcus* spp. can also affect immunocompetent individuals. Fungal infections of the nervous system mainly occur in the presence of immunosuppression as a consequence of AIDS, cancer, hematologic malignancy, hereditary immune defects, organ or stem cell transplantation, or other conditions requiring therapeutic immunosuppression.

CRYPTOCOCCAL MENINGITIS

Epidemiology and Pathobiology

Cryptococcal meningitis is most often caused by the encapsulated yeast *Cryptococcus neoformans*, but other cryptococcal species, such as *Cryptococcus gattii*, are emerging as pathogens that affect immunocompetent individuals. With a worldwide distribution, *C. neoformans* is ubiquitous, found primarily in bird droppings, soil, and citrus peel. *C. gattii* is more commonly associated with the bark of several tree species. Infection usually occurs through inhalation of the organism, followed by a respiratory infection and dissemination. Cryptococcal meningitis is most common in people with impaired cell-mediated immunity, especially those with HIV infection, hematologic malignancies, solid organ transplant recipients, and patients on chronic corticosteroids or other immunosuppressive therapy. In patients immunocompromised due to HIV infection, cryptococcal meningitis is the most common systemic fungal infection and a frequent etiology of central nervous system (CNS) infection, with a prevalence varying from 10% in the United States to as high as 30% in sub-Saharan Africa.

Clinical Features

CRYPTOCOCCUS GATTII

This is a rare pathogen, with disease confined to tropical and subtropical climates, particularly the highly endemic regions of Australia and Papua New Guinea. In 2004, an outbreak of *C. gattii* infections was documented in the United States Pacific Northwest states of Oregon and Washington. A large retrospective review of the Pacific Northwest *C. gattii* infections revealed important clinical differences between *C. gattii* infections in the United States Pacific Northwest and historically endemic areas. Although *C. gattii* in historically endemic areas has been reported to infect primarily immunocompetent persons, causing meningoencephalitis, *C. gattii* infections in Oregon and Washington State occurred frequently in immunocompromised persons and presented most often as respiratory illness. Time from symptom onset to diagnosis of *C. gattii* infection was significantly longer among patients with pulmonary infections (50 days) than those with either CNS (24 days) or bloodstream infections (27 days). There were no differences in immune status between patients with bloodstream infections and either pulmonary or CNS infections.

CRYPTOCOCCUS NEOFORMANS

The clinical manifestations of *C. neoformans* infection depends largely on the host immune status. Severity of infection varies from asymptomatic incidental pulmonary nodules to widely disseminated disease. HIV-infected patients with CD4+ counts of less than 50 cells/μL are especially vulnerable to disseminated infection and meningitis. Cryptococcal meningitis typically begins insidiously, with 75% of patients developing headache and fever over a 2- to 4-week period. As the infection evolves, 50% of people develop nausea, vomiting, and altered mental status. Visual symptoms and seizures are also common. Over half of immunocompromised patients develop intracranial hypertension; this is even more common in immunocompetent hosts. As increased intracranial pressure develops, patients become obtunded, and without intervention, herniation will follow.

TABLE 64.1 Neurologic and Systemic Symptoms and Imaging Characteristics of Chronic Infectious Meningitis

Condition	Neurologic Presentation	Systemic Symptoms	Neuroimaging
Cryptococcosis	Headache and fever (75%), nausea and vomiting (50%), altered mental status (50%), visual symptoms, seizures	Pulmonary, multiorgan involvement	Hydrocephalus, cerebral edema, leptomeningeal enhancement, and cryptococcomas
Coccidioidomycosis	Headache (75%); nausea and vomiting (40%); altered mental status (39%-73%); focal neurologic deficits, including ataxia, gait disturbance, diplopia, or facial palsies (33%-80%); and nuchal rigidity (20%)	Pulmonary, lymph nodes, skin	Hydrocephalus, meningeal enhancement, nodular enhancement, basilar meningitis, cerebral infarction
Blastomycosis	Focal neurologic deficits, seizures, and altered mental status Less common: fever, headache, and meningismus	Pulmonary, verrucous or fungating skin lesions, bones, joints, genitourinary system	Single or multiple abscesses, granuloma, meningeal enhancement, epidural extensions, and overlying osteomyelitis
Histoplasmosis	Headache and altered mental status	Acute pulmonary infection with fever, chills, and pulmonary opacities Multiorgan including bone marrow	Normal, granuloma, meningeal enhancement
Aspergillosis	Solitary mass lesion, cavernous sinus thrombosis, multiple intracranial abscesses, acute or chronic basilar meningitis, vasculitis, or myelitis	Pulmonary, sinusitis, multiorgan involvement	Multiple abscesses, meningeal enhancement, infarction, hemorrhage, sinusitis with extension
Tuberculosis	Headache, vomiting, meningeal signs, focal deficits, vision loss, cranial nerve palsies	Pulmonary, malaise, anorexia, fatigue, weight loss, fever, myalgia	Enhancement of the basilar meninges, thick exudates, obstructive hydrocephalus, miliary pattern, tuberculoma, and periventricular infarcts
Syphilis	Meningitis (headache, photophobia, nausea and vomiting, cranial nerve deficits), general paresis, psychiatric illness, cognitive decline, tabes dorsalis, or vascular disease	Genital ulcers, fever, lymphadenopathy, headache, malaise, myalgia, and a macular or pustular rash of the palms and soles Multiorgan involvement	Leptomeningeal enhancement, white matter disease in the brain and posterior columns, ischemic stroke
Borreliosis	Early: septic lymphocytic meningitis, cranial neuritis, or painful polyradiculitis Late: myelitis, encephalitis, and neurobehavioral changes	Rash, fever, diffuse aches and pains, headaches, malaise, fatigue, carditis	White matter edema with enhancement

Diagnosis

The diagnosis of cryptococcal meningitis should be considered in patients presenting with a subacute presentation of headache and fever, especially in the setting of HIV infection or immunosuppression. Computerized tomography (CT) and magnetic resonance imaging (MRI) are nonspecific for the diagnosis of cryptococcal meningitis but may reveal hydrocephalus, cerebral edema, leptomeningeal enhancement, or cryptococcomas. Classic MRI findings for fungal meningitis are shown in [Figure 64.1](#). Lumbar puncture, the diagnostic procedure of choice, demonstrates an increased opening pressure, a mild mononuclear pleocytosis, increased protein, and low glucose concentrations. Patients with severe immunosuppression may lack this typical CSF appearance. The cryptococcal capsular polysaccharide antigen (CrAg) assay is both sensitive and specific for detecting *C. neoformans* in CSF samples and can be quantitated for prognostication. The CrAg titer is not reliable for determining response to therapy. Although a positive CrAg assay in serum cannot confirm the diagnosis of cryptococcal meningitis, a negative

CrAg assay virtually excludes the diagnosis. Because the CrAg lateral flow assay (LFA) has nearly 100% sensitivity and specificity on CSF samples, it is considered the optimal point-of-care diagnostic assay for cryptococcal meningitis. In areas where CrAg is not available, direct CSF examination with India ink preparation is often used. Fungal culture for the organism is 90% sensitive and can also be useful for speciation, although it typically requires days for culture to grow. *C. neoformans* cultured from CSF, blood, or other sites produces white mucoid (depending on the capsule thickness) colonies, usually within 48 to 72 hours, on most bacterial and fungal media. Although *C. neoformans* grows at 37°C, a temperature of 30°C to 35°C is optimal.

TABLE 64.2 Cerebrospinal Fluid Characteristics and Serum Diagnostics for Chronic Infectious Meningitis

Condition	Microscopic Appearance	LP Opening Pressure	CSF WBC	CSF Differential	CSF Glucose	CSF Protein	CSF Diagnostics	Serum Diagnostics
Cryptococcosis	Encapsulated fungi; yeastlike cells with budding daughter cells; capsule visualized by India ink (halo effect)	High	High or normal	Mononuclear	Low	High	Fungal smear, fungal culture, India ink stain, CrAg lateral flow assay (LFA)	Blood culture
Coccidioidomycosis	Yeast form endosporeulating spherules; branched septate hyphae with alternating arthroconidia	Normal	High	Early PMN, lymphocytic, eosinophilic (70%)	Low	High	Fungal culture, microscopy, complement fixation antibody assay, PCR	Microscopy from bronchoalveolar lavage (BAL) fluid, or other body fluid, or a positive culture from any location
Blastomycosis	Mycelium at room temperature; yeast phase at 37°C. Conidia, yeast cells with multinucleate broad budding.	High	High	Early PMN, lymphocytic	Low	High	Fungal culture, biopsy of involved tissue with micro	Direct visualization of the organism via microscopy
Histoplasmosis	Hyphae large macroconidia and smaller infectious microconidia. At temperatures <35°C yeast form. Hyphal elements possible.	Normal	High	Mononuclear	Low	High	Fungal smear and culture, antigen titers	Fungal culture from involved organ, antigen titers
Aspergillosis	Septate hyphae branched at 45-degree angles with conidiophores. Hyphae develop terminal buds forming small conidia.	Normal	High	Early neutrophil, lymphocytic	Low	High	Fungal culture, biopsy of affected tissue with micro, PCR	Galactomannan and beta-D-glucan. Microscopy, culture, or PCR from bronchoalveolar lavage or affected tissue.

Tuberculosis	Intracellular aerobic gram-positive acid-fast pleomorphic bacillus	High	High or normal	Mixed pleocytosis	Low	High	AFB smear and culture, PCR; GeneXpert, MODS	QuantIFERON, PPD, BAL for AFB smear and culture
Syphilis	Spirochetal bacterium	Normal	High or normal	Lymphocytic	Normal	High or normal	Darkfield microscopy, VDRL, PCR	RPR, VDRL, (FTA-ABS) and <i>Treponema pallidum</i> particle agglutination tests (MHA-TP)
Borreliosis	Spirochetal bacterium	Normal	High	Lymphocytic	Normal	High or normal	Darkfield microscopy, IgG and IgM antibody index, PCR	Two-tier testing (ELISA and IgM/IgG immunoblot)

LP, lumbar puncture; CSF, cerebrospinal fluid; WBC, white blood cell; CrAg, cryptococcal capsular polysaccharide antigen; PMN, polymorphonuclear; PCR, polymerase chain reaction; AFB, acid-fast bacillus; MODS, microscopic observation drug susceptibility; PPD, purified protein derivative; VDRL, Venereal Disease Research Laboratory; RPR, rapid plasma reagin; FTA-ABS, fluorescent treponemal antibody absorption; Ig, immunoglobulin; ELISA, enzyme-linked immunosorbent assay.

TABLE 64.3 Treatment of Chronic Infectious Meningitis

Condition	Treatment	Alternatives and Other Considerations
Cryptococcosis	Amphotericin B (AmB) 0.7-1 mg/kg/day IV plus flucytosine 100 mg/kg/day × 14 days then fluconazole 400 mg PO daily × 8 wk then fluconazole 200 mg daily lifelong	Repeat LP to keep opening pressures in normal range; CSF shunting when needed.
Coccidioidomycosis	Induction therapy with oral fluconazole 400-800 mg/day, followed by 200-400 mg/day indefinitely	Itraconazole 400-600 mg/day or amphotericin B 0.5-0.7 mg/kg/day. Intrathecal amphotericin B in addition to an azole. Shunting for hydrocephalus when needed.
Blastomycosis	Liposomal amphotericin B, 5 mg/kg/day for 4-6 wk, followed by an oral azole. Possible options for azole therapy include fluconazole (800 mg/day), itraconazole (200 mg two or three times per day), or voriconazole (200-400 mg twice per day) for at least 12 months and until resolution of CSF abnormalities.	Surgical drainage of any epidural abscess
Histoplasmosis	Liposomal amphotericin B (5.0 mg/kg daily for a total of 175 mg/kg given over 4-6 wk). Fluconazole (800 mg/day) should be continued for 9-12 mo.	Chronic fluconazole maintenance therapy (800 mg/day) in relapsing patients. Intrathecal amphotericin B.
Aspergillosis	Voriconazole 6 mg/kg IV twice a day on day 1 followed by 4 mg/kg IV twice daily. Followed by maintenance therapy of voriconazole 200 mg every 12 h.	Voriconazole plus caspofungin for invasive disease
Tuberculosis	Intensive four-drug regimen × 2 mo then continuation two-drug regimen × 10 mo based on resistance patterns	Choice of treatment should be directed by resistance patterns. Steroids should be considered for meningitis.

Syphilis	Aqueous penicillin G 18-24 million U/day administered as 3-4 million units IV every 4 h or as continuous infusion for 10-14 days	Procaine penicillin 2.4 million units IM daily with probenecid 500 mg orally four times daily for 10-14 days
Borreliosis	Ceftriaxone 2 g IV daily for 14 days	IV cefotaxime or IV penicillin G. Oral doxycycline.

IV, intravenous; PO, by mouth; LP, lumbar puncture; CSF, cerebrospinal fluid; IM, intramuscular.

Treatment

A combination of antifungal medication and aggressive management of hydrocephalus is integral to the successful treatment of patients with cryptococcal meningitis. Amphotericin B (AmB) plus flucytosine, as compared with AmB alone, is associated with improved survival of patients with cryptococcal meningitis. Elevated intracranial pressure (ICP) can be managed through a variety of treatments. Patients should initially undergo daily lumbar punctures to reduce opening pressure until normal opening pressure is consistently maintained; some patients may require multiple daily lumbar punctures. For patients requiring frequent lumbar punctures, placement of a lumbar drain or ventriculostomy can provide a temporary means for controlling ICP. Ventriculoperitoneal shunt can be considered for patients with persistently elevated ICP. A recent retrospective study of elevated ICP in patients with cryptococcal meningitis determined by aggressive management of ICP during the initial 5 days of illness was associated with lower mortality than initial antifungal management alone.

Although guidelines for treatment of cryptococcal disease are based primarily on data from *C. neoformans* infections in HIV and solid organ transplant patients, these guidelines are intended to apply to patients with *C. neoformans* or *C. gattii* infections. A limited number of *C. gattii*-specific recommendations were included for the first time in the 2010 Infectious Diseases Society of America guidelines and are based on data from *C. gattii* infections in historically endemic areas. These recommendations pertain mainly to patients with cryptococcomas, which previous data have suggested are more common in patients infected with *C. gattii* than *C. neoformans*, and include consideration of surgery for patients with large cryptococcomas, increased radiologic and follow-up evaluations for those with cryptococcomas or hydrocephalus, and possible use of amphotericin B/5 flucytosine (AmB/5FC) in patients with large and/or multiple pulmonary cryptococcomas.

Outcomes

Poor prognostic factors include low CSF glucose concentration, high CSF cryptococcal antigen titer (>1:1,024), high CSF lactate level, altered level of consciousness, hydrocephalus, and elevated ICP.

COCCIDIOIDOMYCOSIS

Epidemiology and Pathobiology

Coccidioides immitis is a fungus endemic to the southwestern United States, Northern Mexico, and areas of South America. The mycelial phase of *Coccidioides* spp. is able to withstand extreme desert climates and after rainfalls will multiply to form arthroconidia. Infection in humans occurs when aerosolized arthroconidia are inhaled. Once inhaled, *C. immitis* usually results in a self-limited respiratory infection, commonly known as *valley fever*. In susceptible populations, a pulmonary infection can progress to severe disseminated disease. Dissemination is more likely to occur in patients of African or Asian descent, pregnant women, and people who are immunocompromised, especially due to HIV infection or long-term immunosuppressive therapy.

FIGURE 64.1 Axial brain MRI. **A:** T2 fluid-attenuated inversion recovery (FLAIR) with leptomeningeal hyperintensity in the posterior frontal lobe. **B:** Diffusion-weighted imaging (DWI) demonstrating pus in the posterior horn of the lateral ventricle. **C and D:** T1 post contrast with avid leptomeningeal enhancement.

Clinical Features

Similar to tuberculosis, chronic meningitis due to *C. immitis* classically involves the basilar meninges. The most common symptom is headache, which is present in over 75% of patients. Other presenting signs and symptoms are related to elevated ICP and include nausea and vomiting (40%); altered mental status (39% to 73%); focal neurologic deficits, including ataxia, gait disturbance, diplopia, or facial palsies (33% to 80%); and nuchal rigidity (20%).

In patients with HIV infection, coccidioidomycosis can resemble *Pneumocystis jirovecii* pneumonia, producing a unique reticulonodular diffuse infiltrative pulmonary disease and constitutional symptoms of dyspnea, fever, and night sweats. Coccidioidomycosis frequently disseminates in patients with HIV infection, with common sites of dissemination including the meninges, lymph nodes, and skin. Although patients who are HIV-positive can present with unique symptoms, most HIV-infected patients present with symptoms similar to those seen in immunocompetent patients. Hydrocephalus, cerebral infarction, and vasculitis are potential complications of *C. immitis* meningitis. Communicating hydrocephalus is a well-known complication of basilar meningitis, secondary to obstruction of arachnoid villi blocking reabsorption of CSF and may develop during the initial or later stages of the infection. Hydrocephalus develops in about 20% to 50% of patients with *C. immitis* meningitis and is associated with a 12-fold increased risk of mortality. Cerebral infarction, as well as venous and dural thrombosis, has been reported during the initial and later stages of infection. Perivascular inflammation is typically associated with infarction of the basal ganglia, thalamus, and cerebral white matter.

Diagnosis

Coccidioidomycosis can be diagnosed using serologic testing, histopathology, or culture of tissue or fluid from the infected site. Identification of *C. immitis* spherules in tissue, sputum, and bronchoalveolar lavage (BAL) fluid, or a positive culture from any location in the body, is diagnostic of coccidioidal infection. Definitive diagnosis of *C. immitis* meningitis requires identification or culture of the organism from the brain or CSF. Unfortunately, CSF culture is often negative and presumptive diagnosis is typically made through a combination of CSF and serologic testing. CSF is typically abnormal, with a lymphocytic pleocytosis with early neutrophil predominance, and low glucose concentration. Of note, this pathogen may cause a CSF eosinophilia in up to 70% of patients with meningitis, a finding that is relatively uncommon with other fungal pathogens. Detection of antibodies to *C. immitis* in the CSF using the complement fixation antibody assay is the most sensitive test for confirming meningeal infection. Repeated CSF sampling is sometimes required to confirm the diagnosis, as antibody test results can be negative early during the course of infection (71% to 94% sensitive). Enzyme immunoassay for IgM and IgG and latex agglutination tests are less sensitive in CSF samples. Although polymerase chain reaction (PCR) assays have been used to detect *C. immitis* infection, they are not routinely available.

Treatment

Oral fluconazole is recommended for the treatment of *C. immitis* meningitis. Practice guidelines recommend high-dose induction therapy with oral fluconazole 400 mg/day to 800 mg/day, followed by 200 mg/day to 400 mg/day indefinitely. Itraconazole, administered in dosages of 400 to 600 mg/day, has been reported to be comparably effective. Some physicians also initiate therapy with intrathecal AmB in addition to an azole based on their belief that responses are more prompt with this approach.

Hydrocephalus nearly always requires a neurosurgical shunt for decompression. Patients who do not respond to fluconazole or itraconazole are candidates for intrathecal AmB therapy with or without continuation of azole treatment. The most common life-threatening complication of coccidioidal meningitis is CNS vasculitis leading to cerebral ischemia, infarction, and hemorrhage. Some physicians endorse the use of concomitant high-dose, intravenous, short-term corticosteroids, but larger randomized studies are lacking.

Outcomes

Approximately 66% to 80% of patients treated with oral azoles alone achieved initial clinical improvement or remission of meningitis. However, up to 75% of patients relapse; therefore, lifelong prophylaxis with fluconazole 400 mg/day is recommended. Without treatment, the frequency of relapse is high and outcome poor.

BLASTOMYCOSIS AND HISTOPLASMOSIS

Epidemiology

Blastomyces dermatitidis and *Histoplasma capsulatum* are dimorphic fungi endemic to the Mississippi and Ohio river valleys. Although isolated cases of infection have been reported outside this geographic area, most patients reside within these areas. *Histoplasma* and *Blastomyces* species are ubiquitous environmental organisms, existing in the mycelial phase and then converting to the yeast phase

P.531

at body temperature. Both organisms produce a large spectrum of disease, ranging from subclinical infection to disseminated disease.

Pathobiology

B. dermatitidis, a thick-walled yeast with broad-based budding daughter cells, is endemic to the Great Lakes and Mississippi and Ohio river valleys. Like histoplasmosis, infection with blastomycosis is acquired via inhalation of spores into the lung and can manifest as pulmonary or extrapulmonary disease. Chest radiographs commonly demonstrate nodular or lobar infiltrates with cavitations. If the organism evades nonspecific host defense mechanisms in the lungs, it will convert into the yeast phase and multiply. The organism then spreads hematogenously to other organs. Cutaneous involvement is seen in 60% of patients with blastomycosis, manifesting as verrucous or fungating lesions with irregular borders. Other sites less frequently involved include bones, joints, genitourinary system, and the CNS.

H. capsulatum, like *B. dermatitidis*, is primarily found in the Mississippi and Ohio river valleys, and infection is acquired via inhalation. Histoplasmosis may produce an acute pulmonary infection with fever, chills, and pulmonary opacities. Patients with impaired cellular immunity, such as HIV-infected individuals, typically present with chronic pulmonary symptoms with progression to severe disseminated disease. Infection disseminates hematogenously to distant sites, such as the liver, spleen, and CNS. Bone marrow involvement is common and often manifests as thrombocytopenia, anemia, or leukopenia.

Clinical Features

CNS infection with blastomycosis occurs in less than 10% of people with disseminated disease and manifests as solitary or multiple abscesses and acute or chronic meningitis. Unlike other fungal CNS infections, blastomycosis is more likely to present with focal neurologic deficits, seizures, and altered mental status, whereas symptoms of fever, headache, and meningismus are less common. Although intracranial infection results most frequently from hematogenous seeding of the brain parenchyma from the lungs, epidural extension from overlying vertebral or skull osteomyelitis have been described.

Most patients with pulmonary histoplasmosis are asymptomatic and have resolution of the infection without therapy. It is common for individuals in the Mississippi and Ohio river valleys to have asymptomatic pulmonary nodules. Dissemination occurs during both primary infection and reactivation of latent infection. CNS involvement occurs in less than 20% of patients with disseminated infection and most frequently affects patients with severely impaired cellular immunity, such as people who are HIV-infected. Presenting symptoms typically include headache and altered mental status; although less common, patients may also present with focal neurologic deficits, seizures, ischemic stroke, and mass lesions.

Diagnosis

Direct visualization of blastomycosis via microscopy is the only method of rapid diagnosis but has variable sensitivity. Lumbar puncture typically reveals elevated opening pressure, and CSF is notable for elevated protein concentration, low glucose concentration, and a pleocytosis with neutrophilic predominance early in the disease course followed by a lymphocytic predominance. The gold standard for diagnosis remains CSF culture, which is positive in 70% of patients with blastomycosis. Growth of *B. dermatitidis* on culture media can occur within 5 to 10 days but may take 2 to 4 weeks for definitive identification of the organism. More invasive procedures, such as brain biopsy and ventricular sampling of CSF, are more likely to provide sufficient material for definitive diagnosis and are often needed for diagnosing intracranial disease. The use of CSF and serum antigen titers and antibodies are useful, although as with histoplasmosis, significant cross-reactivity occurs with other dimorphic fungi.

In histoplasmosis meningitis, CSF frequently demonstrates a mononuclear pleocytosis, increased protein concentration, and decreased glucose

concentration. CSF culture is not sensitive for diagnosing histoplasmosis. The use of CSF and serum antigen titers and antibodies are useful, although as with blastomycosis, significant cross-reactivity occurs with other dimorphic fungi. Because meningitis is typically the result of disseminated infection, testing for the organism in the blood or bone marrow should also be considered.

Treatment

AmB should be given for blastomycosis infection as a lipid formulation at a dosage of 5 mg/kg/day for 4 to 6 weeks, followed by an oral azole. Possible options for azole therapy include fluconazole (800 mg/day), itraconazole (200 mg two or three times per day), or voriconazole (200 to 400 mg twice per day) for at least 12 months and until resolution of CSF abnormalities. Patients with immunodeficiency due to HIV or immunosuppressive therapy have high rates of relapse and should be maintained on long-term secondary prophylaxis with fluconazole indefinitely. For selected patients with neurologic dysfunction caused by focal CNS blastomycosis, surgery may be beneficial. Surgical drainage of an epidural abscess may be necessary for reducing morbidity and mortality from this disorder.

Treatment of CNS histoplasmosis is challenging. Despite treatment with AmB, mortality ranges from 20% to 40% of patients with meningitis, and up to half of responders relapse after therapy is discontinued. The optimal treatment for *H. capsulatum* meningitis is liposomal AmB (5.0 mg/kg daily for a total of 175 mg/kg given over 4 to 6 weeks). To reduce the risk of relapse, fluconazole (800 mg/day) should be continued for 9 to 12 months after completion of AmB. Chronic fluconazole maintenance therapy (800 mg/day) should be considered for patients who relapse after completing a full course of therapy. Itraconazole, although more active against *H. capsulatum* in animal models, does not cross the blood-brain barrier in adequate amounts to treat CNS infection. Intrathecal administration of amphotericin directly into the ventricles, cisterna magna, or lumbar arachnoid space should be reserved for severe infections that do not respond to conventional therapy.

ASPERGILLOSIS

Epidemiology and Pathobiology

Aspergillus species are ubiquitous soil inhabitants that grow and survive on organic debris. This organism sporulates abundantly, releasing conidia into the atmosphere in large quantities. The conidia are small in diameter, making it possible to reach smaller areas of the lung, including the alveoli. Although humans inhale several hundred conidia per day, inhalation of organisms rarely results in disease because the conidia are efficiently eliminated by host immune mechanisms. Alveolar macrophages and neutrophils constitute the first line of host defense against aerosolized conidia.

Historically, disease was limited to individuals with repetitive exposure to pathogens, producing a mild condition known

P.532

as *farmer's lung*. *Aspergillus* spp. can also produce lung aspergillomas, characterized as an overgrowth of fungus in preexisting cavitory lung lesions. More recently, the incidence and severity of *Aspergillus* spp. infections has increased due to a growing number of people living with immunosuppression, leading to the disease known as *invasive aspergillosis*. Populations significantly at risk for invasive aspergillosis include patients undergoing treatment for hematologic malignancies, recipients of allogeneic hematopoietic stem cell transplant and solid organ transplant, people who are HIV infected, and individuals with chronic granulomatous disease.

Clinical Features

Cerebral aspergillosis occurs in approximately 10% to 20% of patients with invasive disease and results from hematogenous dissemination of the organism or via direct extension from rhinosinusitis. CNS infection can present as a solitary mass lesion, cavernous sinus thrombosis, multiple intracranial abscesses, acute or chronic basilar meningitis, vasculitis, or myelitis. Pathologically, cerebral aspergillosis has a propensity for vascular invasion, infarction, hemorrhage, and aneurysm formation; as a result, the clinical presentation may mimic cerebral vasculitis, ischemic or hemorrhagic infarction, or subarachnoid hemorrhage. In patients with suspected cerebral aspergillosis, it is important to examine the lungs and sinuses for evidence of infection and potential sites for obtaining biopsy or culture material.

Diagnosis

Diagnosis of aspergillosis in immunocompromised patients remains difficult. As with many invasive fungal CNS infections, diagnosis is often achieved through examination of the primary entry site of infection. Thus, in patients with suspected CNS aspergillosis, it is important to examine the lungs and sinuses for evidence of infection and potential sites for obtaining biopsy or culture material. MRI of the brain typically reveals a manifestation of infection, such as cerebral infarction, hemorrhagic lesions, solid-enhancing aspergillomas, or ring-enhancing abscesses. Dural enhancement is usually seen in lesions adjacent to infected paranasal sinuses and indicates direct extension of disease.

Several serum laboratory markers can aid in the diagnosis of invasive aspergillosis. Enzyme-linked immunosorbent assay (ELISA) testing for the fungal cell wall constituents galactomannan and beta-D-glucan should be considered. CSF galactomannan assay using latex agglutination or ELISA may be a useful adjunct to serum testing; however, data is limited to small sample sizes with variable performance and reliability (sensitivity of 70% to 90%). Several PCR assays can detect *Aspergillus* spp. in blood and BAL fluid samples; a recent study to detect *Aspergillus* spp. in fresh tissue and BAL fluid reported a sensitivity and specificity of 86% and 100%, respectively. Experience with PCR to detect *Aspergillus* spp. in CSF samples is limited.

Treatment

Unfortunately, cerebral aspergillosis, especially in an immunocompromised patient, is difficult to treat and has a high mortality rate. The use of voriconazole, a newer antifungal agent, has reduced the mortality of an infection that was previously associated with almost universal mortality. Clinical trials have demonstrated that voriconazole is more effective than AmB as initial therapy for invasive aspergillosis and is associated with

significantly improved survival (71% vs. 58%, respectively). *In vitro* studies evaluating combination therapy with voriconazole and caspofungin for *Aspergillus* spp. have provided promising results in patients with invasive aspergillosis.

TUBERCULOSIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Mycobacterium tuberculosis is an intracellular aerobic gram-positive acid-fast pleomorphic bacillus that can cause chronic meningitis. Transmission occurs primarily by inhalation of airborne droplet nuclei into the lungs. *M. tuberculosis* multiplies in alveolar macrophages, and within weeks, the bacilli can hematogenously disseminate to extrapulmonary sites, including the meninges and adjacent brain parenchyma. Tuberculous meningitis is an aggressive form of extrapulmonary disease that is more common in patients infected with HIV.

CLINICAL FEATURES

Meningitis is typically preceded by nonspecific symptoms of malaise, anorexia, fatigue, weight loss, fever, myalgia, and headache. In immunocompetent patients, headache, vomiting, meningeal signs, focal deficits, vision loss, cranial nerve palsies, and raised ICP are characteristic clinical features. Cerebral vessels may be affected by adjacent meningeal inflammation, producing vasospasm, constriction, and eventually thrombosis with cerebral infarction. As the disease progresses, the patient will become comatose from elevated ICP and obstructive hydrocephalus.

DIAGNOSIS

Despite its many limitations, tuberculin skin testing remains in widespread use. The Centers for Disease Control and Prevention (CDC), the American Thoracic Society, and the Infectious Diseases Society of America's guidelines recommend that one should not obtain a tuberculin skin test unless treatment would be offered in the event of a positive test result. Negative results from the purified protein derivative test do not rule out tuberculosis (TB); if the 5-tuberculin skin test result is negative and suspicion for TB is high, the test can be repeated with the 250-tuberculin test. Note that this test is often nonreactive in persons with tuberculous meningitis.

Diagnosing tuberculous meningitis can be difficult and typically involves a combination of neuroimaging, serologic studies, and CSF analysis. Meningitis in the setting of concomitant pulmonary TB is highly suggestive of tuberculous meningitis. Both CT and MRI of the brain are valuable for diagnosing TB meningitis and evaluating for complications. The hallmark pathologic feature of tuberculous meningitis is the presence of a thick exudate most prominent in the basilar meninges. Characteristic abnormalities include enhancement of the basilar meninges, thick exudates, obstructive hydrocephalus, and periventricular infarcts. Characteristic imaging abnormalities for TB meningitis can be found in [Figure 64.2](#). Chest CT is sensitive for detecting pulmonary abnormalities in patients with tuberculous meningitis. Mediastinal and hilar lymphadenopathy, miliary pattern, and bronchopneumonic infiltrate are frequently noted.

Characteristic CSF abnormalities include a mononuclear pleocytosis, low glucose concentration, and elevated protein concentration. CSF pleocytosis can be lower in HIV-infected patients. Of note, 16% of patients with confirmed cryptococcal meningitis, 5% with TB, and 4% with bacterial meningitis will have normal CSF cell counts and biochemistry. Although CSF acid-fast bacillus

P.533

(AFB) smear and culture are crucial for making a diagnosis of tuberculous meningitis, there is a wide range of reported sensitivities for AFB smear; sensitivities can reach as high as 52% when large volume CSF samples (>6 mL) are evaluated by microscopy for at least 30 minutes. Conventional CSF culture for *M. tuberculosis* on Lowenstein-Jensen medium is positive in approximately 45% to 90% of cases but usually takes several weeks for a positive result. Detection of *M. tuberculosis* DNA in CSF by PCR assay is a useful ancillary diagnostic test, with nearly 100% specificity, but sensitivity varies between 30% and 50%, thus limiting its usefulness. Other assays that may prove more sensitive include detection of intracellular bacteria by a modified Ziehl-Neelsen stain and early secretory antigen target (ESAT)-6 in CSF leukocytes. In addition, the World Health Organization has concluded that tests such as GeneXpert and microscopic observation drug susceptibility (MODS) assay are useful for the diagnosis of TB. The GeneXpert relies on DNA-PCR technique for detection of TB and rifampicin resistance while producing results in only 3 hours. The MODS was recently endorsed for rapid screening of multidrug-resistant TB. This technology uses an inverted light microscope to examine liquid culture for growth of the characteristic "cord"-like structures of TB. This can be completed in 7 to 10 days, compared to conventional solid culture that takes several weeks.

FIGURE 64.2 Axial brain MRI. **A and B:** T1 post contrast with multiple ring-enhancing lesions seen in miliary TB. **C and D:** T1 post contrast with large L frontal tuberculoma. **E and F:** T1 post contrast demonstrating avid basilar meningitis with leptomeningeal enhancement.

TREATMENT

Empiric treatment should be initiated when tuberculous meningitis is initially suspected, as the organism grows slowly, speciation can take weeks, and earlier treatment is associated with better outcomes. First-line antituberculous medications include rifampicin, isoniazid, pyrazinamide, ethambutol (RIPE), and streptomycin. Most first-line antituberculosis drugs (except ethambutol) achieve satisfactory levels in the CSF. Multidrug-resistant and extremely drug-resistant (XDR) TB pose a serious growing problem, and treatment should be individualized based on sensitivity testing. Adjunctive corticosteroids significantly reduce death and disabling residual neurologic deficits and should be used regardless of HIV status, although evidence for added benefit for HIV-infected patients is inconclusive.

NEUROSYPHILIS

Neurosyphilis has played an important role in the evolution of modern neurology. Paretic neurosyphilis was the first psychiatric disorder for which a specific cerebral pathology and treatment was reported. Erb described spinal syphilis *tabes dorsalis* in 1892. Quincke introduced lumbar puncture, and CSF examination was used to diagnose infection, even in asymptomatic people. *Treponema pallidum* was identified in the brain by Noguchi and Moore in 1913. The first effective treatment came in 1918 when Wagner-Jauregg gave fever therapy for paresis. He was the first neurologist to win the Nobel Prize. Then came arsenical chemotherapy, the first planned use of a drug that would attack the organism without harming host tissues; this was Ehrlich's concept of "the magic bullet." Safer and more effective therapy came in 1945 with the introduction of penicillin, which has been in use since and has revolutionized the disease. Following the introduction of penicillin in the 1940s and 1950s, the incidence of neurosyphilis declined for two main reasons: (1) Fewer people spread the disease because those affected were being identified and treated and (2) many neurosyphilis infections were prevented because penicillin was being used to treat gonorrhea and other infections. For instance, the frequency of neurosyphilis as a cause of first admission to a psychiatric hospital plummeted from 5.9 cases per 100,000 population in 1942 to 0.1 cases per 100,000 in 1965. New cases became so rare that many hospitals discarded routine testing to detect syphilis.

During the next few decades, some investigators detected a shift in clinical patterns, but this finding was debated. The population at highest incidence was young homosexual men. Finally, in 1981, the AIDS epidemic occurred. The incidence of primary and secondary syphilis rose from 13.7 cases per 100,000 in 1981 to 18.4 cases per 100,000 in 1989, an increase of 34%. In the ensuing years, the incidence of syphilis declined. In 1997, fewer than 8,000 cases of early syphilis were reported in the United States, the lowest rate in 38 years and a sixfold decline from 1990. In addition to this alarming increase in the incidence of syphilis in industrialized countries,

syphilis, like HIV, is an enormous health problem in developing countries. For instance, syphilis seropositivity among pregnant women in sub-Saharan Africa may be higher than 10%. Since 2000, there has been an unexpected increase in new cases of primary and secondary syphilis in the United States. Trends in Western Europe, Brazil, and Canada were similar, presumably because of a resurgence of unsafe sexual practices. Even before the HIV era, there had been a shift in clinical manifestations because of the widespread use of antibiotics. Previously common parenchymal forms became rare, whereas the incidence of meningeal (including meningitis, radiculitis, and cranial neuritis) and vascular syndromes have increased.

EPIDEMIOLOGY AND PATHOBIOLOGY

Syphilis is caused by the thin, motile corkscrew bacterium *T. pallidum*. This organism cannot be routinely cultured in the laboratory and is difficult to visualize using traditional light microscopy. Transmission is primarily via sexual contact with an infected individual or by vertical transmission from mother to fetus. Without treatment, the disease will inevitably progress through a series of clinical stages. In general, syphilis can be classified as early or late infection. Early infection encompasses primary, secondary, and early latent syphilis. Late infection refers to tertiary syphilis.

CLINICAL FEATURES

After sexual exposure to the organism, an asymptomatic incubation period of approximately 3 weeks occurs, followed by the development of a painless genital ulceration or chancre. If left untreated, the chancre will resolve in 3 to 5 weeks and the disease will progress to secondary syphilis. Secondary syphilis is a syndrome of fever, lymphadenopathy, headache, malaise, myalgia, and a macular or pustular rash of the palms and soles. During this stage, involvement of other organ systems produces clinical symptoms, including mucosal lesions, renal failure, hepatitis, and neurologic symptoms. The signs and symptoms of secondary syphilis typically resolve in 4 to 10 weeks, and the patient is deemed latently infected. About one-third of patients with untreated latent syphilis will progress to develop late or tertiary syphilis, which can affect any organ in the body, particularly the nervous system, manifesting with a variety of symptoms.

T. pallidum spreads hematogenously to the CNS early in the course of disease, and clinical signs and symptoms are not limited to stage of disease. Patterns of meningitis or vascular disease may be more common earlier in disease, whereas late disease presents as parenchymal or spinal cord pathologies. Although neurosyphilis can produce a wide variety of manifestations, including general paresis, psychiatric illness, cognitive decline, tabes dorsalis, or vascular disease, this section will limit the discussion to syphilitic meningitis.

Syphilitic meningitis typically presents in the secondary stage of syphilis within 2 years of acquiring infection. Although meningitis is less common than other forms of neurosyphilis, abnormal CSF with pleocytosis and elevated protein concentration occurs in up to 25% of patients. The most common presenting symptoms include headache, photophobia, nausea and vomiting, meningismus, and cranial nerve deficits. Although any cranial nerve can be affected, cranial nerves VII and VIII are most commonly affected.

DIAGNOSIS

The diagnosis of neurosyphilis is typically made through a combination of history, physical examination, and results of serologic and CSF analyses. The first step in diagnosis is performing serologic testing for syphilis using Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin assays. These assays detect IgG and IgM antibodies to a cardiolipin-lecithin cholesterol antigen and remain positive in patients who have had syphilis, regardless of treatment. Treponemal assays, including the fluorescent treponemal antibody absorption (FTA-ABS) and *T. pallidum* particle agglutination tests (MHA-TP) measure treponemal antibodies and are used for confirming infection. Treponemal assays should also be positive in patients with neurosyphilis. The sensitivities of treponemal-specific tests (TST), although in the range of 80% for primary syphilis, are believed to be nearly 100% in cases of secondary syphilis. False-positive TST are infrequent.

In syphilitic meningitis, CSF typically has a mononuclearpredominant pleocytosis, elevated protein concentration (>45 mg/dL), and normal or decreased glucose concentration. Although CSF immunologic tests, such as VDRL, are usually abnormal in syphilitic meningitis (70% sensitivity), a negative result does not rule out neurosyphilis. More recently, PCR assays have been developed to detect *T. pallidum* in the CSF, but 50% of patients with syphilitic involvement of the CNS have a negative PCR. Other new techniques include using CSF-FTA and percentage of CSF B cells when CSF-VDRL is negative to aid in establishing the diagnosis of neurosyphilis.

TREATMENT

Penicillin is the first-line therapy for neurosyphilis. The CDC recommends 18 million units to 24 million units of aqueous penicillin G per day administered as 3 million units to 4 million units intravenous (IV) every 4 hours or as continuous infusion for 10 to 14 days. An alternative is procaine penicillin 2.4 million units intramuscular (IM) daily with probenecid 500 mg orally 4 times daily for 10 to 14 days [Level 1].¹

LYME DISEASE

EPIDEMIOLOGY

Lyme disease is the most common tickborne infection in the United States. The CDC reports that 300,000 cases of Lyme disease are diagnosed in the United States each year, with 96% of cases concentrated in 13 states (Connecticut, Delaware, Maine, Maryland, Massachusetts, Minnesota, New Hampshire, New Jersey, New York, Pennsylvania, Vermont, Virginia, and Wisconsin). In humans, the signs and symptoms of Lyme borreliosis most frequently appear in spring, summer, and early autumn, coinciding with the activity of nymphs and with the increasing recreational use of tick habitats by the public.

PATHOBIOLOGY

North American Lyme borreliosis, or Lyme disease, is caused by *Borrelia burgdorferi*, which is transmitted by specific *Ixodes* spp. ticks. In Europe, at

least five species of Lyme *Borrelia* (*Borrelia afzelii*, *Borrelia garinii*, *B. burgdorferi*, *Borrelia spielmanii*, and *Borrelia bavariensis*) can cause the disease, leading to a wider variety of possible clinical manifestations in Europe than in North America. Transmission of the organism occurs through injection of tick saliva during feeding. A feeding period of more than 36 hours is usually required for transmission of *B. burgdorferi* by *Ixodes scapularis* or *Ixodes pacificus*. In North America, the only species of Lyme *Borrelia* known to cause human disease is *B. burgdorferi*.

CLINICAL FEATURES

Initial infection is typically manifested by a skin lesion known as *erythema migrans*. Erythema migrans consists of an area of erythroderma that enlarges over days to weeks, often reaching several

P.535

inches in diameter. Spirochetes initially proliferate at the site of the tick bite. When sufficiently numerous, they slowly migrate centrifugally from the site of inoculation, typically for up to 30 days after the bite. Depending on the location on the body, the rash may be round or elliptical. Central pallor may be present.

Early disseminated disease is usually characterized by a multifocal rash, with each new focus representing a nidus of spirochetes that spread hematogenously from the initial site. The bacterial dissemination is accompanied by the usual host inflammatory reaction to bacteremia: fever, diffuse aches and pains, headaches, malaise, fatigue. Up to 5% of infected individuals develop heart block, known as *Lyme carditis*, sometimes requiring a temporary pacemaker. Early dissemination affects the nervous system in 10% to 15% of patients, primarily in the first few months after the initial infection, during what is often termed *acute disseminated infection*. Most commonly, patients present with an aseptic lymphocytic meningitis, cranial neuritis, or painful polyradiculitis. First described in Europe, Garin-Bujadoux-Bannwarth syndrome is now considered to include all or part of a classic triad: lymphocytic meningitis, cranial neuritis, and polyradiculitis. Cranial and peripheral nerve involvement can occur anywhere along the course of affected nerves, not preferentially in the subarachnoid space. Approximately three-fourths of patients with Lyme-associated cranial neuropathies present with a facial nerve palsy. Early studies suggested this could be bilateral in up to one quarter of cases.

Late Lyme disease can manifest as arthritis or the skin disorder known as *acrodermatitis chronica atrophicans*, a tissue paper thinning of the skin. Neurologic manifestations of late Lyme disease include myelitis, encephalitis, and neurobehavioral changes. Much attention has focused on patients who have persistent fatigue and cognitive difficulty after receiving treatment for Lyme disease with regimens that should be highly effective even for severe infections, a disorder often referred to as *post-Lyme syndrome*. This topic is controversial and is beyond the scope of this chapter.

DIAGNOSIS

Typical erythema migrans is usually sufficiently distinctive to allow a clinical diagnosis in the absence of a supporting laboratory test. Serologic assays for antibodies to Lyme *Borrelia* are positive infrequently at this stage, and thus should be obtained only in atypical cases, and then in conjunction with convalescent phase serologic testing 2 to 6 weeks after obtaining the acute sample. Treatment at this stage will prevent progression to neurologic Lyme disease.

The majority of patients with early Lyme disease are seropositive on serum two-tier testing (ELISA and IgG immunoblot). Those who are seronegative at presentation will convert in 2 weeks after acute phase. CSF testing for intrathecal antibody production and lumbar puncture showing lymphocytic meningitis are useful to confirm diagnosis. CSF PCR is insensitive for the diagnosis of neurologic Lyme disease and should not be routinely used. Late neurologic Lyme disease requires a positive serum two-tier (ELISA and IgG immunoblot) seropositivity and evidence of intrathecal antibody. CSF examination generally supports an active infection with a lymphocytic meningitis, elevated protein concentration, and normal glucose concentration.

TREATMENT

For adult patients with early Lyme disease and the acute neurologic presentation of meningitis or radiculopathy, ceftriaxone 2 g IV daily for 14 days is recommended [Level 1].² Parenteral therapy with cefotaxime or penicillin G may be acceptable alternatives [Level 1].² Oral doxycycline has good oral absorption and CNS penetration and may also be an alternative. Late neurologic Lyme disease may present as encephalomyelitis, peripheral neuropathy, or encephalopathy. These patients should be treated with ceftriaxone 2 g IV once daily for 2 to 4 weeks. Cefotaxime or penicillin G may be acceptable alternatives. Retreatment is not indicated for persistent or recurrent symptoms.

INTRODUCTION

Parasitic infections are a tremendous public health burden in tropical and subtropical regions. Parasitic tropical diseases of the nervous system can be found anywhere in the world due to the exponential increase in international travel, tourism, and migration. One important factor is the disregard of tourists and business travelers for the prophylactic measures recommended before traveling to parts of the world where potential exposure to endemic parasitic diseases may occur. When travel history precedes the onset of the disease, neurologists should have a high index of suspicion based on basic knowledge of the most common parasitic neurologic diseases ([Table 65.1](#)) in order to diagnose and treat these exotic conditions.

TABLE 65.1 Parasitic Infections of the Nervous System

Name	Agent	Reservoir	Transmission
Metazoan Infections			
Neurocysticercosis	<i>Taenia solium</i>	Pigs, humans	Human <i>Taenia</i> carriers
Gnathostomiasis	<i>Gnathostoma spinigerum</i>	Fish, poultry, dogs, cats	Undercooked fish, poultry
Hydatid cysts	<i>Echinococcus</i> species	Dogs, foxes, sheep, cows	Dogs' feces
Larva migrans	<i>Toxocara canis</i> , <i>Toxocara cati</i> , <i>Ascaris</i> species	Dogs, cats	Dogs' and cats' feces
Baylisascariasis	<i>Baylisascaris procyonis</i>	Raccoon (<i>Procyon lotor</i>)	Raccoons' feces
Paragonimiasis	<i>Paragonimus westermani</i>	Fresh water crustaceans, snails	Eating uncooked crustaceans
Schistosomiasis/bilharziasis	<i>Schistosoma</i> species	Fresh water snails	Skin penetration by larval forms (cercariae) in infected water

Sparganosis	<i>Spirometra mansoni</i>	Reptiles, amphibians	Eating uncooked frogs or snakes
Strongyloidiasis	<i>Strongyloides stercoralis</i>	Human	Infected soil contact
Trichinosis	<i>Trichinella spiralis</i>	Pigs	Eating undercooked pork
Protozoan Infections			
African trypanosomiasis Sleeping sickness	<i>Trypanosoma brucei</i>	Ungulates	Tsetse flies (<i>Glossina</i>)
American trypanosomiasis Chagas disease	<i>Trypanosoma cruzi</i>	Opossum, dogs	Triatomine bugs
Amebiasis	<i>Entamoeba histolytica</i>	Human	Ingestion of food contaminated with feces
Primary amebic meningoencephalitis	<i>Naegleria</i> species	Warm fresh water ponds	Nasal route while swimming
Granulomatous amebic encephalitis	<i>Acanthamoeba</i> species	Fresh and brackish water	Nasal route while swimming
Cerebral malaria	<i>Plasmodium falciparum</i>	Human	<i>Anopheles</i> mosquitoes
Toxoplasmosis	<i>Toxoplasma gondii</i>	Cat	Cats' feces in contaminated soil or vegetables

Parasitic diseases are divided into *protozoan infections* caused by unicellular organisms (malaria, trypanosomiasis, amebiasis) and *metazoan infections* caused by worms (helminths), mainly cestodes or tapeworms (cysticercosis), nematodes or round worms (larva migrans, baylisascariasis, gnathostomiasis, strongyloidiasis), and trematodes or flukes (paragonimiasis). Not included in this chapter are neurologic diseases transmitted by ectoparasites, such as ticks and other arthropods, including Lyme disease (a spirochetal infection caused by *Borrelia burgdorferi*) (see [Chapter 64](#)); other forms of borreliosis presenting as relapsing fevers transmitted to humans by lice or ticks (see [Chapter 64](#)); and gram-negative bacterial infections, such as the Rickettsial typhus group (caused by *Rickettsia prowazekii* and *Rickettsia typhi*, transmitted respectively by the body louse *Pediculus humanus* and the rat flea *Xenopsylla cheopis*), as well

as the spotted fevers transmitted by ticks and caused by *Rickettsia rickettsii* (see [Chapter 63](#)). *Toxoplasma gondii* infection is discussed in the context of HIV infection (see [Chapter 67](#)).

PROTOZOAN INFECTIONS OF THE NERVOUS SYSTEM

CEREBRAL MALARIA

Cerebral malaria is an acute encephalopathy caused by *Plasmodium falciparum*, the most virulent of the four *Plasmodium* species that infect humans when a female *Anopheles* mosquito inoculates the protozoan parasites through the skin. Parasites are carried to the liver where they mature and multiply to enter the red cells in the bloodstream.

According to the Centers for Disease Control and Prevention (CDC), malaria causes 660,000 deaths each year, mainly among young children in sub-Saharan Africa. In 2011, the number of malaria cases reported in the United States was the largest since 1971, representing a 48% increase from 2008. Most malaria infections occurred among travelers to regions with active malaria transmission.

Clinical Features

Malaria presents with typical bouts of intermittent fever with chills, rigors, and anemia. Cerebral malaria may be heralded by headache, vomiting, and a clinical picture of encephalopathy developing over days in a febrile patient, accompanied by confusion, decreased responsiveness, and somnolence rapidly progressing to stupor and coma. Psychomotor agitation and psychiatric manifestations may precede cerebral malaria. Focal findings are uncommon, except when stroke occurs. In children, tonic-clonic seizures occur, followed by postictal unresponsiveness.

In adults, cerebral malaria may occur in the setting of severe malaria presenting with acute respiratory distress; pulmonary edema; acute renal failure and hemoglobinuria ("blackwater fever"); jaundice and liver failure; severe anemia; thrombocytopenia; disseminated intravascular coagulation; and bleeding complications, including intracranial hemorrhages. Severe hypoglycemia must be assumed to be present in children with cerebral malaria and should be treated promptly and aggressively.

Retinal hemorrhages and exudates are usually seen on funduscopic examination and reflect the cerebral small-vessel vasculopathy. Meningeal signs do not occur and cerebrospinal fluid (CSF) is normal; however, spinal tap is mandatory to exclude other causes of encephalopathy. Brain imaging may show evidence of brain swelling and herniation or small hemorrhages.

Treatment

The drugs of choice for treatment of cerebral malaria are the derivatives of artemisinin, such as artesunate, artemether, or arteether. Quinine is an equivalent alternative for cerebral malaria. Development of drug resistance to artemisinin derivatives has occurred and combination therapy for *P. falciparum* malaria with other antimalarial drug is recommended. Cerebral malaria is a critical condition and requires intensive care treatment; complications such as hypoglycemia, respiratory distress syndrome, and acute renal and liver failure must be promptly recognized and treated. Severe anemia or bleeding diathesis may require blood transfusions. Steroids are not recommended in cerebral malaria. Despite treatment, the mortality is over 25%, but survivors usually recover without sequelae; however, residual hemiplegia, extrapyramidal symptoms, blindness, psychiatric symptoms, and epilepsy may occur.

There is intensive research on the immune mechanisms of cerebral malaria leading to vascular occlusion by parasitized erythrocytes, vasoconstriction, and alterations of the blood-brain barrier with decreased cerebral blood flow, edema, demyelination, ischemia, hypoxia, acidosis, and death. Potential therapies based on nitric oxide bioavailability, high levels of endothelin-1, and angiopoietin dysfunction appear promising.

Malaria prevention relies on avoiding exposure to mosquitoes using repellents and insecticide-treated bed nets and prophylactic use of antimalarial drugs prior to, during, and after travel to endemic malaria regions.

A viable malaria vaccine is yet to succeed.

TRYPANOSOMIASIS

Two human infections with protozoa of the genus *Trypanosoma* have neurologic importance: African trypanosomiasis (sleeping sickness) and American trypanosomiasis (Chagas disease); both are transmitted by infected arthropods, the tsetse fly (*Glossina* species) in Africa, and triatomine (reduviid) bugs in South America.

African Trypanosomiasis

This fatal encephalitis is caused by infection with *Trypanosoma brucei rhodesiense* and *Trypanosoma brucei gambiense*, endemic respectively to East and West Africa. Tsetse fly infests one-third of Africa's landmass representing a problem of appalling magnitude. African trypanosomiasis or *sleeping sickness* is a chronic encephalitis, with diencephalic involvement resulting in disruption of the circadian sleep/wake cycle manifested by excessive daytime sleepiness, sleep attacks similar to those of narcolepsy, and nocturnal insomnia. There are also psychiatric manifestations, seizures, coma, and finally death. CSF shows lymphocytic pleocytosis and moderate increase in protein concentration and immunoglobulins (Ig), especially intrathecal IgM. African trypanosomes can be identified by fine needle aspirate of enlarged cervical lymph nodes, as well as in blood and CSF. The combination of nifurtimox and eflornithine appears to be a promising treatment.

American Trypanosomiasis

Human infection with *Trypanosoma cruzi* (Chagas disease) affects an estimated 10 million people in Latin America causing about 50,000 annual deaths. Presence of infected asymptomatic blood donors in the United States led blood banks to perform routine trypanosome screening with radioimmunoprecipitation.

Acute infection following the triatomine bite causes subcutaneous swelling typically located in the orbital region (Romaña sign), cervical lymph node enlargement, and acute myocarditis or encephalitis. A striking feature of Chagas disease is the selective neuronal destruction with denervation of the myenteric plexus of the intestine causing megaesophagus and megacolon and denervation of the ganglionic neurons in the conduction system of the heart leading to a chronic dilated cardiomyopathy. The dilated heart becomes an important cause of embolic stroke. At autopsy, one-third of patients with chronic Chagas disease have left ventricular thrombi.

T. cruzi can be demonstrated in blood or CSF or by serologic testing. Treatment of acute disease or reactivations includes nifurtimox, benznidazole, or itraconazole. There is no effective therapy for chronic Chagas disease. Secondary prevention of stroke with long-term anticoagulation is recommended.

AMEBIC MENINGOENCEPHALITIS

Primary amebic meningoencephalitis is due to infection with the free-living amoeba *Naegleria fowleri*. Infection is acquired by swimming in warm bodies of natural or man-made fresh water.

P.539

The organisms penetrate the cribriform plate and reach the brain causing acute meningoencephalitis and brain abscess. The clinical presentation is typical of purulent meningitis. The organisms are seldom isolated. Treatment with intravenous and intrathecal amphotericin B, intravenous and intrathecal miconazole, and oral rifampin should be started based on clinical suspicion in patients with meningitis and history of swimming in warm fresh waters.

A chronic granulomatous form of amebic meningoencephalitis often accompanied by cutaneous infection and keratitis is caused by infection with the opportunistic free-living amoebae *Balamuthia mandrillaris* and by several species of *Acanthamoeba* affecting immunosuppressed patients, transplant recipients, or malnourished individuals. Treatment is often unsuccessful.

METAZOAN INFECTIONS OF THE NERVOUS SYSTEM

NEUROCYSTICERCOSIS

Neurocysticercosis is the human infection with larval forms (cysticerci) of the pig tapeworm *Taenia solium*. Neurocysticercosis is the most common neurologic infection caused by helminthes (cestodes) in humans. Contrary to common belief, consumption of poorly cooked pork infected with *T. solium* cysticerci does not cause neurocysticercosis but results in intestinal tapeworm infection or human taeniasis. Neurocysticercosis occurs from human-to-human transmission of fertilized *T. solium* eggs from a human carrier of intestinal *Taenia*. Humans become intermediate hosts in the life cycle of *T. solium* by ingesting *Taenia* eggs due to fecal contamination of water or food. Failure of intestinal *Taenia* carriers to wash their hands after defecation is the most common source of infection.

Pathobiology

Ingested eggs hatch in the intestine, enter the bloodstream, and are carried into the host tissues including heart, muscles, and the brain and spinal cord where cysticerci develop into cystic forms called *Cysticercus racemosus* (Latin *racemus*, bunch of grapes). Neurocysticercosis can be prevented with hand washing, clean water, and environmental sanitation.

Cysticerci are found in the brain parenchyma, the subarachnoid spaces, the ventricular system, the eye, the spinal cord and intrathecal nerve roots, as well as in the heart, the muscles, and subcutaneous tissues. Although many cysticerci fail to elicit a foreign body reaction, inflammation around each cysticercus eventually develops, accompanied by edema, reactive gliosis, and formation of dense exudates in the subarachnoid space composed of collagen, lymphocytes, multinucleated giant cells, eosinophils, and hyalinized parasitic membranes found in parenchymal lesions but also causing eosinophilic meningitis, ventriculitis, and radiculitis. Stroke may result from involvement of the blood vessels by the inflammation. Even calcified lesions may develop perilesional edema associated with seizure activity.

Clinical Features

Neurocysticercosis is the most common cause of epilepsy in tropical areas of Latin America, Africa, and Asia. It results in 50,000 deaths per year and is a frequent cause of chronic neurologic disorders due to irreversible brain or spinal cord damage. Neurocysticercosis is becoming increasingly prevalent in industrialized countries because of travel and migration. In the United States, 1,494 patients with neurocysticercosis were reported between 1980 and 2004, making it the most common imported disease of the nervous system.

Cysticercosis is a pleomorphic disease capable of producing epilepsy, stroke with focal neurologic deficits, intracranial hypertension, and reversible dementia. Diagnostic criteria have been clearly established. Reported cases in the United States presented with seizures (66%), hydrocephalus (16%), and headaches (15%) due to parenchymal neurocysticercosis brain lesions (91%); the remainder had ventricular cysts (6%), subarachnoid cysts (2%), and spinal cord lesions (0.2%).

Diagnosis

The diagnosis of neurocysticercosis is based on clinical findings, a history of travel to endemic regions or potential exposure to *Taenia* carriers, and immunologic tests. The possibility that a patient harbors an intestinal *Taenia* should be explored with repeated examinations of stools for ova and parasites. On neuroimaging, parenchymal neurocysticercosis shows single or multiple cysts in the parenchyma, with the typical "hole-in-donut" appearance with presence of the radiodense scolex of the parasite. In subarachnoid neurocysticercosis, there is abnormal enhancement of the leptomeninges, hydrocephalus, and cystic

lesions located at the sylvian fissure or basal cisterns. Multiple calcified lesions (“starry sky”) on computed tomography (CT) indicate spontaneous resolution. CSF usually shows lymphocytic pleocytosis, presence of eosinophils, increased protein (up to 2,000 mg/dL), and normal glucose. Serum immunoblot and CSF enzyme-linked immunosorbent assay (ELISA) are useful confirmatory tests.

Treatment

The recommended treatment for patients with viable subarachnoid or parenchymal cysts is albendazole for 8 to 15 days, usually in combination with dexamethasone to avoid the risk of stroke or brain edema. Dexamethasone administration should begin prior to the start of albendazole therapy and should be prolonged for several days. Isolated intraventricular cysts in the fourth ventricle are best treated with endoscopic surgery. Shunt placement must be considered before the start of albendazole in patients with hydrocephalus.

LARVA MIGRANS AND EOSINOPHILIC MENINGITIS

Infection of the nervous system by nematodes or roundworms occurs when humans become hosts to the parasite and the moving worms migrate producing the clinical syndrome called *larva migrans* usually accompanied by eosinophilic meningitis. The severity of the infection depends mainly on the size and vitality of the parasite, ranging from the severe meningoencephalitis or myelitis caused by the tracts of the spike-covered worm *Gnathostoma spinigerum* in Thailand or the highly motile *Ascaris* of the North American raccoon *Baylisascariasis procyonis* or by to the relatively benign eosinophilic meningitis caused in Southeast Asia by *Angiostrongylus cantonensis*, the rat lungworm.

Pathobiology

A history of travel is usually elicited because humans become hosts to the parasite by ingestion of contaminated Japanese-style raw fish, such as sushi and sashimi, and consumption of natural and exotic foods, such as raw mollusks, shrimp, freshwater crustaceans, snails, snakes, frogs, or insufficiently cooked chicken or duck contaminated with the infective larvae of the parasite. Once ingested, the highly motile larvae cross the intestinal wall and migrate to subcutaneous tissues causing cutaneous larva migrans,

P.540

continuing to visceral larva migrans with involvement of internal organs, skeletal muscles, the eye, and the nervous system. [Table 65.2](#) summarizes the main geographic forms of the larva migrans syndromes and eosinophilic meningitis.

TABLE 65.2 Nematode (Round Worm) Infections of the Nervous System Causing Larva Migrans Syndrome and Eosinophilic Meningitis

Name	Agent	Geographic Location	Clinical Presentation
Angiostrongyliasis Eosinophilic meningitis	<i>Angiostrongylus cantonensis</i> <i>Angiostrongylus costaricensis</i>	China, Southeast Asia, Taiwan, Thailand, Vietnam, Australia, South Pacific islands Costa Rica, Central America	Eosinophilic aseptic meningitis

Gnathostomiasis	<i>Gnathostoma spinigerum</i>	Southeast Asia	Meningoencephalitis, myelitis, eosinophilic meningitis, cutaneous and visceral larva migrans
Baylisascariasis	<i>Baylisascaris procyonis</i>	North America	Meningoencephalitis, myelitis, eosinophilic meningitis, eye involvement, cutaneous larva migrans
Toxocariasis Larva migrans	<i>Toxocara canis</i> , <i>Toxocara cati</i> <i>Ascaris</i> spp.	Worldwide	Eosinophilic meningitis, eye involvement, myelitis, encephalitis, cutaneous larva migrans

These conditions usually present with eosinophilic pleocytosis in the CSF demonstrated with the use of the Giemsa or Wright stain showing greater than 10 eosinophils per mL or more than 10% of the total CSF leukocyte count. Eosinophils are effectors of the adaptive immune response (helper T cell type 2) directed against destruction of metazoan multicellular parasites.

Clinical Features

Neurologic forms of presentation include the relatively benign eosinophilic meningitis of angiostrongyliasis to the more severe cases with encephalitis, transverse myelitis, seizures, meningitis, subarachnoid hemorrhage, and focal neurologic deficits associated with parenchymal brain hemorrhages that occur with larger parasites causing gnathostomiasis and baylisascariasis.

Diagnosis

CSF examination may range from the normal appearance and mild eosinophilic meningitis of angiostrongyliasis to the usually bloody and xanthochromic CSF of gnathostomiasis and baylisascariasis, with severe eosinophilic pleocytosis (up to 3,000 cells/mm³), mild increase in protein concentration, and normal glucose concentration. Blood eosinophilia is usually present. Neuroimaging shows the tracts of the parasites as long or multiple parenchymal brain hemorrhages or evidence of multiple foci of myelitis. Diagnosis is confirmed by identification of the larvae in CSF or tissue samples.

Treatment

The recommended treatment of eosinophilic meningomyelitis is a combination of antihelmintics and intravenous corticosteroids, such as albendazole with intravenous dexamethasone.

SCHISTOSOMIASIS (BILHARZIA)

Human schistosomiasis is a parasitic disease caused by trematode flukes of the genus *Schistosoma*. Some 230 million people worldwide are infected with *Schistosoma* spp. The geographic distribution of different agents of schistosomiasis is summarized in [Table 65.3](#). Parasitic adult worms remain in the venous circulation for years, evading the immune system and excreting over 100,000 fertile eggs daily. Immune responses of the host to the

parasites' eggs explain the pathology of schistosomiasis. Some *Schistosoma* species cause chronic liver damage with portal hypertension, whereas others produce bladder and urogenital lesions in chronic carriers.

Pathobiology

Neurologic involvement occurs during the early postinfective stage when *Schistosoma japonicum* eggs reach the brain causing meningoencephalitis; infection with *Schistosoma mansoni* and *Schistosoma haematobium* produce preferential involvement of the spinal cord (myelitis and myeloradiculitis), particularly of the conus medullaris, cauda equina, or the spinal cord. *Schistosoma* ectopic eggs reach the central nervous system (CNS) through retrograde venous flow into the Batson venous plexus. This parasitic myelopathy can be manifested as an acute painful flaccid paraplegia with areflexia, sphincter dysfunction, urinary incontinence, impotence, and sensory disturbances; acute transverse myelitis, spastic paraplegia, painful lumbosacral radiculopathy with backache, and cauda equina syndrome also occur.

Diagnosis

The diagnosis must be suspected on the basis of a clinical presentation of acute painful lumbosacral myelopathy or conus medullaris syndrome with imaging findings suggestive of bilharziasis in a patient with history of travel or exposure to *Schistosoma cercariae* after swimming in fresh water. The diagnosis is confirmed by demonstration of *Schistosoma* antibodies in serum and/or CSF and presence of *Schistosoma* eggs in biopsy of rectal mucosa or in stools and urine.

Treatment

Schistosomal myelitis usually responds to treatment with the schistosomicidal drug praziquantel in combination with steroids; other schistosomicidal drugs are oxamniquine and metrifonate. Surgery with decompressive laminectomy and debridement is usually

P.541

reserved for cases of acute myelitis that deteriorate despite intensive schistosomicidal treatment. Preventive measures in countries affected include the use of chemotherapy, snail control measures, and behavioral modification.

TABLE 65.3 Clinical Syndromes and Geographic Distribution of Schistosomiasis

Clinical Syndromes	Agent	Geographic Location
Parasitic myelitis (conus medullaris)	<i>Schistosoma mansoni</i>	Africa, Middle East, Caribbean, Brazil, Venezuela, Suriname
Intestinal schistosomiasis	<i>Schistosoma japonicum</i>	China, Indonesia, Philippines
Liver fibrosis with portal hypertension		
Meningoencephalitis	<i>Schistosoma haematobium</i>	Africa, Middle East
Urogenital schistosomiasis	<i>Schistosoma intercalatum</i>	West Africa
Squamous cell carcinoma of the bladder	<i>Schistosoma guineensis</i>	East Africa Mekong river basin

Viral Infections

Shibani S. Mukerji

Jennifer L. Lyons

"The single biggest threat to man's continued dominance on the planet is a virus."

--- Joshua Lederberg, Nobel Prize winner

INTRODUCTION

Viral infections of the central nervous system (CNS) are a diverse group of diseases that have plagued mankind for centuries. Infections can occur in the spinal cord (myelitis), cerebrum (encephalitis), meninges (meningitis), brain stem (rhombencephalitis), or any of these in combination. Additionally, viral infections at disparate sites may damage the CNS indirectly through a misguided immune response. This chapter highlights the common causes of CNS viral infections (aside from HIV, which is discussed in a separate chapter), discusses the clinical manifestations and the methods of detection, and when applicable, reviews treatment options.

Viruses invade humans by a variety of mechanisms. This can include skin penetration, infection of mucosal membranes, such as in respiratory or gastrointestinal epithelium, or by direct inoculation into the bloodstream. After primary inoculation, neurotropic viruses gain entry into the CNS by one of a number of mechanisms.

Experiments with several viral strains show that replication occurring in tissue, such as skeletal muscle or skin, allows access to peripheral nerve endings. Some neurotropic viruses are able to infect nerves and then spread by retrograde transport to the sensory ganglia. Characteristic of this is the herpes simplex virus, which replicates in the skin and infects adjacent sensory nerve endings. The virus is then able to tether its capsid onto the host's transport complex, travel toward the dorsal root ganglia, and establish latency.

On the other hand, infection within the bloodstream is dependent on the site of inoculation and ability to infect endothelial cells or cell populations within plasma (e.g., HIV infection of T lymphocytes). Once in the blood, a virus must cross the blood-brain barrier (BBB) to spread into brain parenchyma. In cases like HIV, when infected inflammatory cells, such as lymphocytes or macrophage mononuclear cells cross the BBB, the virus gains entry in a process termed the *Trojan horse*. In other cases, high viremic loads lead to passive transport into the brain or spinal cord. Individual viruses can use multiple mechanisms of viral CNS entry, and in fact, many viruses are able to spread to the CNS using both neural and hematogenous pathways as will be discussed with poliovirus and varicella-zoster virus (VZV).

The widespread availability of viral nucleic acid amplification has revolutionized diagnostics in CNS viral infections and reduced the need to perform open brain biopsies. The polymerase chain reaction (PCR) technique is ideally suited for organisms that are difficult to culture and can retain its sensitivity even after small doses of antiviral therapies. However, this technique relies on a viral load high enough for detection by PCR, a factor not always present in cerebrospinal fluid (CSF), leading to false negatives. False negatives also occur when heme breakdown from a bloody lumbar puncture interferes with nucleic acid detection. False-positive CSF PCR results occur with viruses that associate themselves with peripheral blood cells and enter the CNS during an inflammatory process but are themselves not the source of the CNS disorder. This phenomenon occurs with Epstein-Barr virus (EBV), as peripheral blood mononuclear cells are latently infected. EBV's relevance as a pathologic agent in the CSF can be unclear and is discussed further in this chapter.

Additional diagnostic methods for CNS viral infections include detection of virus-specific immunoglobulin (Ig) M that relies on the host's ability to mount an immunologic response to the infecting agent. The detection of virus-specific antibodies requires a competent immune system and sufficient time to develop antibodies. Interpretation of antibody levels can be confusing, as some serum antibodies last for months or even years after infection that is often asymptomatic, as seen in West Nile virus where IgM-specific antibodies can persist for months and is not reflective of acute infection. Occasionally, antibody cross-reactivity can also lead to false-positive detection. In contrast to serum antibodies, the presence of virus-specific IgM antibodies in CSF is indicative of intrathecal synthesis and diagnostic of neuroinvasive disease.

Serum virus-specific IgG can be helpful when a corresponding rise in titer between acute and convalescent phases occurs. One limitation here is in the setting of postinfectious complications, where antibody detection in the acute phase was not pursued. Isolated IgG detection, especially in infections that are common and usually asymptomatic, is of limited use.

Antiviral agents are few in number, and treatment in many cases of CNS viral infections remains supportive. Herpes simplex virus, VZV, cytomegalovirus, HIV, and influenza have targeted therapies with varying efficacy. The lack of options in many cases leads physicians to focus on managing the complications of these diseases, often including use of anti-inflammatory agents, such as corticosteroids, to suppress immune-mediated injury. As seen in almost every aspect of medicine, prevention is the best approach to combatting viral diseases and requires comprehensive vaccination programs, mosquito repellents, appropriate protective gear, animal surveillance programs, and education.

PICORNAVIRUS

Picornaviruses are some of the oldest and most diversified viruses to cause human disease. The picornavirus family has four primary groups resulting in human pathogenesis: enteroviruses (e.g., polioviruses, coxsackieviruses, and echoviruses), rhinoviruses (RV), hepatoviruses (e.g., hepatitis A), and parechoviruses. These viruses are nonenveloped, single-stranded RNA viruses. It is estimated that the majority of viral meningitis cases globally are caused by picornaviruses, specifically enteroviruses, as are most cases of acute flaccid paralysis.

P.543

ENTEROVIRUSES

Poliomyelitis

Poliomyelitis is a disease that plagued the world in the late 19th and early 20th century, as widespread epidemics resulted in paralysis or death. The name poliomyelitis is derived from two Greek words, *polios* ("gray") and *myelon* ("marrow" or "spinal cord"). The control of polio following the development of both the inactivated polio vaccine (IPV) and live-attenuated oral vaccines (OPV) is a remarkable achievement in science. In the United States, the last case of naturally occurring polio was in 1979. There continues to be endemic areas, namely in Afghanistan, Nigeria, and Pakistan, with additional occasional outbreaks elsewhere.

The worldwide eradication of polio is the goal of the World Health Organization (WHO) and many countries, as well as nonprofit organizations.

PATHOBIOLOGY

Poliomyelitis virus is an enterovirus whose main route of human infectivity is via the gastrointestinal tract. There are three serotypes (types 1, 2, and 3), with all serotypes being neurotropic. Poliovirus type 1 is the most frequently encountered in human infections around the world. Although the disease occurs in all age groups, it is rarely seen before 6 months of age. Infections are spread via the fecal-oral route and are highly influenced by hygiene standards. The virus replicates initially in the gastrointestinal tract's lymphatic system (Peyer patches), followed by viremia and immune activation. How the virus gains access to the nervous system remains uncertain. One hypothesis is the poliomyelitis virus, which is able to replicate in skeletal muscles, can spread into peripheral motor axons, and access anterior horn cells of the spinal cord via retrograde transport. This hypothesis has been tested in mouse models with expression of transgenic poliomyelitis virus receptor. A second hypothesis is by direct spread from the blood due to a breakdown in the BBB. These mechanisms for CNS entry are not mutually exclusive.

CLINICAL MANIFESTATIONS

Although CNS complication is the most feared outcome of polio infection, it is not a common occurrence when evaluating poliomyelitis infections as a whole. Nearly 90% of infections are asymptomatic and recognized only by isolation of the virus from the oropharynx or in feces. Approximately 4% to 8% of those infected will have a minor, self-limited illness similar to other enteroviral infections with headache, anorexia, abdominal pain, and a sore throat. These cases are typically identified during epidemics. In 1% to 2% of infected individuals, there are the more severe clinical manifestations of fever, headache, and evidence of meningismus. Frank paralysis occurs in only 0.1% of all poliovirus infections, and the clinical course can be divided into two phases. A prodromal phase of sore throat, fever, and symptoms suggestive of upper respiratory infection is most common in young patients. Mild abdominal upset and meningeal irritation are more common in adults. There is a short recovery period for 2 to 3 days before an abrupt onset of fever, chills, myalgias, headache, and symptoms consistent with meningitis. Paresthesias and muscle fasciculations can precede muscle weakness and paralysis. When paralysis occurs, it is typically asymmetric, and the lower extremities are more commonly involved than the upper extremities. When quadriplegia occurs, it is more frequently seen in adults than infants. Paralysis of the diaphragm and intercostal muscles in spinal poliomyelitis occurs more often in young adults than in the extreme age groups. Bulbar paralysis is due to weakness of muscle groups innervated by cranial nerves, and in polio, the glossopharyngeal and vagus nerves are most commonly affected, followed by the oculomotor nerve. Older adults are more likely to have medullary involvement, and these patients are at high risk for aspiration and need for mechanical ventilation.

DIAGNOSIS

The diagnosis of paralytic polio is clinically suspected with the development of asymmetric acute flaccid paralysis following a febrile illness. It is more likely to be suspected in those who are unvaccinated coming from endemic countries or those with immunodeficiencies. Other viruses to consider in the differential are other enteroviruses, especially enterovirus 71, and arboviral infections, such as West Nile virus (discussed later in the chapter).

CSF pleocytosis is evident as early as meningeal symptoms are present, with an initial polymorphonuclear profile that eventually shifts to a lymphocytic predominance. An increased protein concentration is most prominently seen if there is severe paralysis. These abnormalities are not distinguishable from other viral causes of aseptic meningitis and thus, identification of the poliomyelitis virus is necessary to confirm the diagnosis. Isolation of poliomyelitis virus by CSF culture is challenging and is not typically performed. Polio is more easily isolated from oral secretions and feces, and with rapid identification of polioviruses by genomic amplification using PCR, clinicians can distinguish poliomyelitis viral infections from other enteroviruses or other infectious causes.

TREATMENT

There are no antiviral drugs for treatment of poliomyelitis, and symptom management is the primary focus. Respiratory muscle paralysis or cases of bulbar poliomyelitis frequently require mechanical ventilation and aggressive management of secretions. Bowel function also requires special attention in spinal poliomyelitis. Long-term management of physical and psychiatric sequelae obliges a comprehensive team of both physical and occupational therapy along with orthopedic services and psychiatry.

The inactivated and oral poliomyelitis vaccinations have been used effectively for controlling paralytic poliomyelitis but differ in terms of asymptomatic viral shedding and risk of contracting vaccine-related disease. IPV is an injectable preparation containing antigen units for all three polio serotypes. In the United States, the IPV is the only version administered and is typically given with other childhood vaccines at 2, 4, 6 to 18 months, and 4 to 6 years. Children develop little to no secretory antibody response to the IPV. If exposed to live polioviruses, these children are more likely to have asymptomatic infections but still shed virus in their feces, exposing nonimmunized contacts. Most oral poliomyelitis vaccine (OPV) preparations also immunize against all three serotypes. The prevalence of poliomyelitis-specific antibody to all three serotypes following three doses of OPV is approximately 96%. Nonimmune OPV recipients will shed vaccine viruses in feces and the oropharynx that can be spread to nonimmunized children. This aspect can be advantageous in poorly vaccinated communities, as children can develop OPV-specific antibodies despite not having received the vaccine. A rare event is the development of vaccine-associated paralytic poliomyelitis, an occurrence in 1 per 2.6 million vaccine doses and is only associated with OPV. The WHO still recommends the use of the trivalent OPV in underdeveloped nations because of cost, ease of administration, and greater secretory immunity in the gastrointestinal tract.

P.544

OUTCOME

The prognosis of paralytic poliomyelitis depends on age (infants and children are more likely to recover) and severity of paralysis (i.e., partial vs. complete paralysis). Permanent weakness from polio paralytic infections occurs in approximately two-thirds of patients. Complete recovery is unlikely in cases with severe acute flaccid paralysis or in those requiring mechanical ventilation. Increased mortality is typically seen in those with polio encephalitis, bulbar involvement due to glossopharyngeal and/or vagus nerve impairment, and/or respiratory muscle paralysis.

Following the epidemics in the early 20th century, some individuals with partial or full recovery from paralytic polio experienced a new onset of neuromuscular weakness, pain, and fatigue. In such cases, muscle weakness and atrophy were identified in muscles that had been previously affected. These symptoms have been collectively called the *postpolio syndrome* and, in those with slowly progressive weakness, atrophy, and fasciculations, termed *postpolio progressive muscular atrophy* (PPMA; discussed separately).

Enteroviruses 70 and 71

Acute hemorrhagic conjunctivitis was first recognized in 1970 and is the result of either enterovirus 70 or an antigenic variant of coxsackievirus A24. The disease is characterized by the rapid onset of painful conjunctivitis and subconjunctival hemorrhage. Complete recovery is typically seen within 1 to 2 weeks. Epidemics predominantly occur in tropical and subtropical regions lasting several months and will affect large populations.

Neurologic complications of acute hemorrhagic conjunctivitis primarily include an asymmetric acute flaccid paralysis. Those affected appear clinically similar to those with spinal poliomyelitis except for the preceding association with acute hemorrhagic conjunctivitis. Prodromal symptoms for acute hemorrhagic conjunctivitis-associated paralysis include fever and malaise then an acute, severe radicular pain. This is followed by flaccid, asymmetric weakness of the legs with proximal muscles (e.g., quadriceps muscle) more affected. Reflexes are diminished or absent. Permanent paralysis or residual weakness is present in over half the cases. The virus is difficult to isolate in the CSF by PCR when neurologic symptoms arise, but high titers of virus-specific antibodies are typically detectable in the CSF in those with paralysis.

Enterovirus 71 has been the etiologic agent responsible for several encephalitis epidemics throughout the world, resulting in substantial mortality and morbidity. The largest enterovirus 71 epidemic occurred in Taiwan in 1988, resulting in 1.5 million people affected, of which 405 children developed serious neurologic complications with 78 deaths. Every 2 to 3 years, large enterovirus 71 outbreaks occur around the Asia-Pacific rim, affecting thousands. As such, enterovirus 71 is now recognized as an emerging neurotropic virus. Enterovirus 71 can cause hand-foot-and-mouth disease as well as upper respiratory infections and gastroenteritis. In those affected neurologically, manifestations include myoclonic jerks, tremors, ataxia, cranial nerve palsy, meningitis, and meningoencephalitis. Polio-like flaccid paralysis occurs in about 10% of patients. Fulminant neurogenic pulmonary edema and apnea from rhombencephalitis occurred in epidemics affecting children in Taiwan and Malaysia, and these disease manifestations are the primary cause of death in enterovirus 71-infected individuals. Most of the patients had magnetic resonance imaging (MRI) T2-weighted high-intensity lesions in the brain stem. Diagnosis may be made by virus isolation from throat, feces, or vesicles; by antibody studies; and CSF reverse transcriptase polymerase chain reaction (RT-PCR).

COXSACKIEVIRUS AND ECHOVIRUSES

Neurologic manifestations of human viral infections caused by group A and group B coxsackieviruses and echoviruses primarily are meningitides. Historically, group B coxsackieviruses and echoviruses are the most frequently implicated serotypes in meningitis; exceptions include when a single serotype causes a widespread outbreak. For example, coxsackievirus A9 was responsible for most cases in an outbreak in the Gansu Province, China in 2005 and Alberta, Canada in 2010.

The symptoms and signs of meningeal involvement of coxsackieviruses and echoviruses are similar to other viruses that cause meningitis. The severity of disease varies, with the extremes of life having the more severe meningitis. Headache is frequent, and if meningismus is present, it can vary in severity and typically begins 24 to 48 hours following onset of symptoms. In infants, the dominant symptoms are fever and irritability, with less than 10% having evidence of meningeal irritation. Frequently, there is a prodromal or associated upper respiratory tract infection or symptoms. Acute CNS complications include febrile seizures, elevated intracranial pressure, and coma. When considering alternate diagnoses for enterovirus meningitis, bacterial meningitis needs to be considered and should be treated empirically with broad-spectrum antibiotics. Arboviruses, acute HIV, herpesviruses, Lyme borreliosis, leptospirosis, and lymphocytic choriomeningitis virus are other infectious etiologies in the differential.

CSF analysis typically demonstrates clear fluid with normal to mildly elevated pressure. There is a mild to moderate pleocytosis that ranges from 10 to 500/mm³ and rarely exceeds 1,000/mm³. Initial differential cell counts demonstrate a high percentage of neutrophils but an eventual shift to a lymphocytic predominance. The CSF glucose concentration is generally normal and protein concentrations are normal to slightly elevated. PCR is the primary means of virus detection with greater than 95% sensitivity and specificity. Viral cultures are infrequently used, as they are insensitive and can take days for results to return.

Treatment is largely symptom management. Containment during outbreaks is critical, with good hygiene practices and protective equipment for high-risk groups. The broad-spectrum antipicornaviral agent pleconaril is an orally administered inhibitor of enterovirus replication. There have been two placebo-controlled clinical trials that showed a shortened course of illness compared to placebo, but the benefit was modest. The drug has not been approved for use in the United States.

Although encephalitis is not commonly caused by coxsackievirus or echovirus (with the exception of enterovirus 71), it can occur in immunocompromised patients. The severity of encephalitis is variable, with seizures, hemichorea, and acute cerebellar ataxia being described. In patients with agammaglobulinemia, hematopoietic transplantation, or B-cell depletion with immunotherapy agents, enterovirus can cause a chronic, severe, and fatal meningitis and encephalitis. In such cases, enterovirus can be recovered in the CSF by PCR at different time points throughout the disease course. Intravenous immunoglobulin (IVg) and pleconaril have been used with some success.

Sporadic cases of acute flaccid paralysis have been seen with coxsackieviruses and are typically less severe than in poliovirus-associated disease. For example, in an 11-year program monitoring of acute flaccid paralysis in the Slovak Republic as part of the WHO strategy for polio eradication, coxsackievirus B and echoviruses were the most common etiologies for acute flaccid paralysis in the post-polio vaccine era. These viruses are also reported etiologies for oculomotor palsies, Guillain-Barré syndrome (GBS), opsoclonus-myoclonus, and transverse myelitis.

P.545

ARBOVIRUSES

Arboviruses comprise a group of viruses from four genera that all have in common transmission to humans via arthropods: alphaviruses, flaviviruses, bunyaviruses, and reoviruses. Human infection due to arboviruses follows patterns of vector activity. That is to say that seasons and years when the insects are most abundant logically see higher rates of infections. Most arboviruses have vertebrate reservoirs, such as birds or small mammals, and are transmitted by mosquitoes or ticks. Continuation of the life cycle relies on a constant interaction between hosts (e.g., birds, mammals) and vectors (e.g., ticks, mosquitoes). Animals that act as hosts maintain high enough levels of viremia and are able to retransmit infections back to arthropods when bitten. However, humans and horses are “dead-end” hosts, as they are not able to sustain elevated levels of viremia without succumbing to disease. Endemicity varies widely, as do outcomes. [Figure 66.1](#) demonstrates highly endemic areas for many encephalitis-associated viruses.

Arboviruses are important causes of encephalitis worldwide, and neuroinvasion is usually coupled with an intense inflammatory reaction and/or edema, the effects of which can be devastating. Alternatively, neurologic disease can occur as a parainfectious inflammatory disorder in the setting of systemic disease without specific evidence of nervous system infection per se. Fortunately, for the most part, exposure leads to asymptomatic seroconversion or a mild self-limited illness; typically, only a fraction progress to severe neurologic disease and/or death.

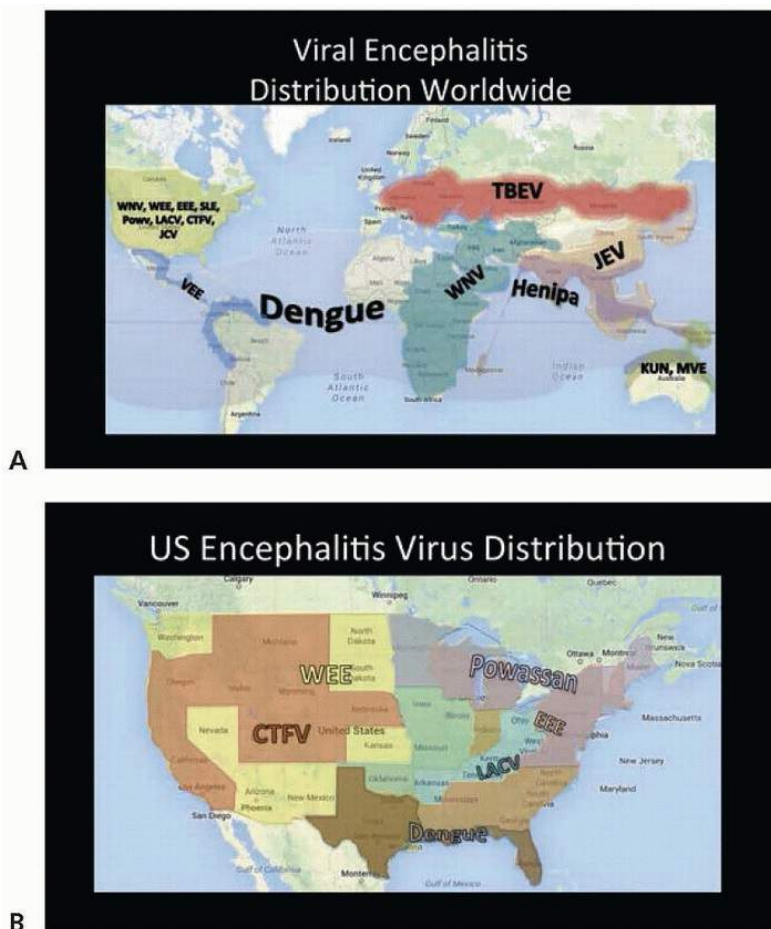

FIGURE 66.1 A: Global distribution of viral etiologies of encephalitis. Herpesviruses and rabies are excluded, as these are all ubiquitous around the globe. United States and Canada are endemic to multiple viruses but most vary by region. **B:** Distribution of nonherpes, non-WNV, and non-SLE viral encephalitis viruses in the United States. WNV has been reported from all continental states, and St. Louis has only not been seen in New England.

Acute arboviral infections are diagnosed typically by serum and/or CSF antibody detection via enzyme-linked immunosorbent assay (ELISA) for virus-specific IgM antibodies. Given the high prevalence of asymptomatic infection and potential for persistence of IgM in serum, antibody detection must be confirmed with a fourfold titer increase in IgG between the acute and convalescent phase (4 weeks post the acute phase). In general, though, the presence of CSF virus-specific IgM antibodies is indicative of intrathecal synthesis and is diagnostic for neuroinvasive disease. CSF RNA detection is highly specific for active infection, but its sensitivity in arboviral infections is not nearly as high as seen in herpes simplex DNA detection. CSF PCR can be especially helpful in immunocompromised people who are unable to mount or have a delayed antibody response. Culturing arboviruses is not routinely performed, as they are difficult to isolate due to low levels of viremia in humans. There are no specific antiviral therapies for the treatment of neuroinvasive arboviral infections and the focus remains on supportive care and exposure prevention.

FLAVIVIRUSES

Flaviviruses are positive-sense, single-stranded, enveloped viruses with icosahedral capsids. Many have the capability of neuroinvasion and severe damage throughout the neuraxis. Inflammatory reactions accompany infection. [Table 66.1](#) outlines the most consistently described statistics for flaviviruses that cause neurologic disease.

Dengue

There are four serotypes of this flavivirus, and infection with one does not confer protection from infection with the others. Dengue is carried by the *Aedes* mosquito and can be acquired throughout Central and South America, Puerto Rico, Africa and the Middle East, Southeast Asia and the Pacific, and Australia (see [Fig. 66.1A](#)). The southern United States occasionally sees cases as well. Millions are infected each year. Vertical transmission is also known, as is spread through infected blood and organ donation.

PATHOBIOLOGY

As with other flaviviruses, inoculation proceeds to local immune cell infection and carriage to a lymph center, where replication occurs and viremia results. The virus makes its way to the CNS, although mechanisms of infection are not well understood. Virus is detected in the CNS, although it is not known if this occurs passively across an altered BBB or as an active infection. Vasogenic edema results, and a systemic inflammatory response can elicit immune-mediated damage of multiple organs and the neuraxis.

CLINICAL MANIFESTATIONS

After exposure and subsequent incubation of several days to just over a week, those who are symptomatic will experience fever, myalgias, and malaise most commonly, occasionally with a rash. Severe systemic disease can follow over a matter of days, characterized by thrombocytopenia, multifocal hemorrhage, shock, and death. Neurologic manifestations can accompany severe disease and range from encephalopathy to direct nervous system infection accompanied by an inflammatory response causing meningoencephalitis and/or myelitis to a parainfectious immune diseases

such as GBS and acute disseminated encephalomyelitis (ADEM). Up to 50% of those who are symptomatic will develop neurologic complications. Risk factors for developing severe disease include young age, certain HLA genotypes, female gender, and superinfection with a second serotype. Serotypes 2 and 3 are associated more so with neuroinvasive disease than are the others.

TABLE 66.1 Nervous System Disease Caused by Flaviviruses

Virus	Endemic Locale	No. of Infections Annually	Systemic Symptomatic Disease (% of Infections)	Neurologic Disease (% Symptomatic Infections)	Neurologic Manifestations	Case Fatality Rate	Long-term Sequelae	Preventive Strategies
Japanese encephalitis virus	Southeast Asia, Japan, Pacific Islands	30,000-50,000	0.30	0.001-0.02	Encephalitis with brain stem and occasionally spinal cord involvement	25%	30%	Vector control, vaccine
West Nile virus	Africa, Middle East, Continental United States, Puerto Rico	~150,000 (United States)	20	1	Meningoencephalitis and/or acute flaccid paralysis	10% overall, 15%-30% in age older than 70 yr	50%	Vector control, blood and organ donation restrictions
Dengue virus	Central and South America, Puerto Rico, Africa, Middle East, India, Southeast Asia, Pacific Islands, Northern Australia	50-400 million	0.5-1	4-50	Meningoencephalitis, ADEM, GBS, CNS hemorrhage	4%-5%	~25%	Vector control
Murray Valley encephalitis virus	Northern Australia, New Guinea	Occurs in outbreaks	Outbreaks of 21-114 cases	0.1-0.7 of all infections	Meningoencephalitis	20%-40%	30%-50%	Vector control
Tick-borne encephalitis virus	Europe, Southern Russia, East Asia	~35,000	2-33	25-30	Meningoencephalitis	1%-2% (Western Europe) 30%-40% (Eastern Russia)	35%-60%	Vector control, vaccine
Kunjin virus	Northern Australia, New Guinea	Occurs in outbreaks	Minority	Minority	Mild meningoencephalitis or encephalomyelitis	<1%	NA	Vector control
St. Louis encephalitis virus	Continental United States	~1,000; higher in outbreaks	<1	>60	Meningoencephalitis	5%-15%	Up to 50%	Vector control
Powassan virus	Canada, Northern United States, Russia	NA; seroprevalence 0%-5% in endemic areas	Minority	NA; <50 cases reported 2001-2012 but incidence	Meningoencephalitis and/or encephalomyelitis	10%	50%	Vector control

ADEM, acute disseminated encephalomyelitis; GBS, Guillain-Barré syndrome; CNS, central nervous system; NA, not applicable.

DIAGNOSIS

Given the protean neurologic complications, there is no specific neuroimaging finding related to dengue, and computed tomography (CT) or MRI of the brain may be entirely normal. Similarly, CSF may be normal or only demonstrate elevated protein concentration; this appears to relate to the type of neurologic complication present. Opening pressures can also be elevated. If there is a pleocytosis, it is generally lymphocytic. If caught early, RNA can be detected from the blood and/or CSF; otherwise, antibody detection from blood and/or CSF demonstrating active or recent production is diagnostic. In endemic areas, a tourniquet test to assess capillary fragility can be performed at the bedside in the appropriate clinical context to make a presumptive diagnosis.

TREATMENT

No vaccine or specific therapies exist for dengue infection, although aggressive supportive treatment early on, with platelet transfusions, rehydration, and management of elevated intracranial pressure, may improve survival. Case fatality rate is 4% to 5%, although some 25% of survivors will suffer residual neurologic deficits (see [Table 66.1](#)).

Tick-Borne Encephalitis Virus

Tick-borne encephalitis virus is carried by the *Ixodes* tick. It is found across Europe and Asia and is responsible for thousands of infections each year (see [Fig. 66.1A](#)). Men are more commonly affected than women. Viral infection results in replication in lymphatic cells, vascular dispersion, and entry into brain parenchyma by means of brain microvascular endothelial cells. Viral presence in the brain incites an inflammatory reaction that precipitates widespread damage throughout the cerebrum, cerebellum, brain stem, and sometimes the spinal cord. After an incubation period of about a week, patients develop a fever that lasts several days and then progresses to headache, nausea, and occasionally meningismus. They can further develop encephalopathy and brain stem dysfunction several days later, and in the most severe cases, severe back pain and upper more so than lower extremity paresis can occur. Diagnosis is best made by demonstration of intrathecal tick-borne encephalitis virus-specific antibody production; serum antibodies can be useful in the patient who has never received vaccination. CSF usually shows a modest lymphocytic pleocytosis and elevated protein concentration, although in some cases, a polymorphonuclear pleocytosis has been demonstrated.

Treatment of tick-borne encephalitis virus is supportive. Mortality varies by location, at 1% to 2% for Western Europe but up to 40% for Eastern Russia (see [Table 66.1](#)). Long-term neuropsychiatric sequelae occur in more than half of the survivors. An effective vaccine exists, but for a variety of reasons, vaccination rates overall remain low.

Japanese Encephalitis Virus

Japanese encephalitis virus is transmitted by the *Culex* mosquito. It was first identified in Japan in 1871 but now includes much of Southeast Asia (see [Fig. 66.1A](#)). Like its sibling flaviviruses, initial replication is in lymphoid tissue followed by transient viremia that carries the virus to the brain; once inside the CNS, it imparts damage both by infection and reactive inflammation.

Most Japanese encephalitis virus infections are asymptomatic; about 1 in 300 is clinically apparent. Somewhere between 1 and 20 in 1,000 produce neuroinvasive disease. This translates, though, into some 50,000 cases of encephalitis a year, with a mortality rate of about 25%. Children and young adults are at highest risk.

In symptomatic cases, after an incubation period of a little over a week, fever sets in, along with chills, myalgias, and occasionally meningismus. In children, abdominal pain and nausea are common. Symptoms can quickly progress to limb weakness and extrapyramidal signs and subsequently to coma and death. Imaging and pathologic specimens show thalamic and cerebral peduncular involvement, but viral involvement is typically widespread throughout the brain and even into the spinal cord occasionally. CSF typically shows a lymphocytic pleocytosis of up to 1,000 cells/ μ L and a modestly increased protein concentration. Diagnosis is usually by antibody detection from CSF or by serologic increases between acute and convalescent phases; RNA isolation from CSF is diagnostic, as well. As with other flavivirus infections that are usually asymptomatic and/or have vaccines available, a single positive IgG in endemic areas may not indicate active disease.

Treatment is supportive, keeping in mind that death commonly is secondary to cerebral edema and increased intracranial pressure. Of those who survive, about 30% will have long-term deficits (see [Table 66.1](#)), again making prevention strategies key. These include vector control and vaccination; there is a highly effective vaccine for Japanese encephalitis virus, but vaccination campaigns are unfortunately currently lacking.

West Nile Virus and Kunjin Virus

West Nile virus was originally isolated in Africa but since introduction to New York in 1999 has been endemic in the United States (see [Fig. 66.1A](#)). Its vector is the *Culex* mosquito, although infected donated blood has been another mode of transmission. As of 2012, all 48 contiguous states in the United States had reported cases. Most cases of West Nile virus are asymptomatic and go unreported; there were an estimated 1.8 million infections in North America between 1999 and 2010. Hundreds to thousands of symptomatic cases are reported to the Centers for Disease Control and Prevention (CDC) each year. As such, seroprevalence of West Nile virus IgG in endemic areas is actually quite high. Of the symptomatic cases, the most common symptoms are fever and malaise. Less than 1% will go on to develop what is considered neuroinvasive disease: meningitis, encephalitis, or myeloradiculitis. Risk factors for developing neuroinvasive disease are age older than 50 years, immune suppression, homelessness, chronic renal disease, hepatitis C infection, and CCR5 mutations.

PATHOBIOLOGY

West Nile virus has an incubation period of 2 to 14 days, after which replication occurs in lymph tissue, followed by viremia and carriage to the CNS, where it infects neurons and anterior horn cells. How it does so remains elusive, as receptors have not been identified. Nor is it known how the virus crosses the BBB. As with many viral CNS diseases, though, its mechanism of neuronal injury and death is not only directly related to viral infection but also to the intense inflammatory reaction that imparts bystander damage to the delicate resident cells in the brain and spinal cord.

West Nile virus neuroinvasive disease presentation depends on the part of the neuraxis that is involved. Fever, headache, meningismus, and encephalopathy herald meningoencephalitis, whereas radicular pain and flaccid asymmetric limb paralysis accompany anterior horn cell infection. New parkinsonism points to basal ganglia involvement.

DIAGNOSIS

Diagnosis can be made by detection of West Nile virus RNA in the CSF, although this is fleeting and insensitive after about 48 hours, or by CSF IgM or by a fourfold increase in antibody titers from acute to convalescent phase. CSF otherwise should demonstrate a lymphocytic pleocytosis with moderately elevated protein concentration and normal glucose concentration; however, neutrophilic predominance can also be seen. Although West Nile virus RNA can be detected in urine, use of this assay in acute disease is not standard. Neuroimaging may be normal or may demonstrate leptomeningeal enhancement; radicular enhancement; and/or T2 hyperintensities in the subcortical white matter, deep gray matter structures, and/or the spinal cord parenchyma.

TREATMENT

As with many viruses, West Nile virus is a monophasic illness for which there is no proven specific therapy other than supportive therapy. IVIg, West Nile virus-specific IgG, and ribavirin all have been not clearly beneficial, but corticosteroids are commonly used to modulate inflammation. Long-term sequelae are the rule for survivors of neuroinvasive disease, and about 10% die (see [Table 66.1](#)), making prevention of mosquito bites the most logical management strategy.

Kunjin is a subtype of West Nile virus isolated in northern Australia that primarily causes disease in horses; human disease has been reported and is similar to but much milder than West Nile virus neuroinvasive disease (see [Fig. 66.1A](#)). It can be transmitted to humans, also by the *Culex* mosquito, and occurs typically in small outbreaks (see [Table 66.1](#)).

Murray Valley Encephalitis Virus

Murray Valley encephalitis virus is carried by the *Culex* mosquito and is endemic to Northern Australia and Guinea (see [Fig. 66.1A](#)). It mostly has occurred in outbreaks with case numbers in the teens to low hundreds, making it much less of a threat than most other flaviviruses. Four outbreaks may have occurred in the early part of the 20th century under the moniker "Australian X" disease, and in 1951, the virus was isolated during the first documented Murray Valley encephalitis virus outbreak. Subsequent outbreaks occurred in 1956, 1974, and 2011. There have been sporadic cases additionally. A study conducted immediately after the 2011 outbreak demonstrated 2.2% seroprevalence in endemic areas, with higher numbers coming from those born before 1974.

Incubation time averages 2 weeks. The vast majority of cases are asymptomatic or gives rise to a mild febrile illness with headache that does not come to medical attention. About 1 out of 150 to 1,000 infections develop more severe symptoms several days later of lethargy, encephalopathy, and occasionally seizures that can progress to brain stem symptoms, flaccid paralysis due to myelitis, and death. The case fatality rate is 15% to 30%, and about 30% to 50% suffer long-term neurologic deficits (see [Table 66.1](#)).

In severe cases, T2-weighted MRI of the brain shows bilateral thalamic and brain stem hyperintensities. Pathologically, virus has been recovered from brain tissue, and additionally, there is a striking widespread reactive inflammatory infiltrate throughout the gray matter.

Diagnosis is often by serology, suggesting that specific Murray Valley encephalitis virus IgM appears several days after infection and persists for months. Antibodies can also be evaluated in CSF, as well, and there are Murray Valley encephalitis virus RNA assays for detection in serum. Management is supportive.

St. Louis Encephalitis Virus

St. Louis encephalitis virus is carried by *Culex* species mosquitoes and is a cause of epidemic encephalitis in both North and South America but mostly in the United States (see [Fig. 66.1B](#)). Epidemics typically occur during the summer season. The vast majority of individuals have asymptomatic infections. Otherwise, presenting symptoms mimic a flu-like illness and include fever, headache, and lethargy. Neurologic features can include seizures, ataxia, confusion, hemiparesis, and myoclonus.

CSF analysis demonstrates a predominantly lymphocytic pleocytosis. St. Louis encephalitis virus is rarely isolated from blood or serum and diagnosis largely requires demonstration of St. Louis encephalitis virus-specific CSF IgM. MRI can show T2-hyperintensities in the basal ganglia and in some cases, abnormal signal is seen within the substantia nigra. Pathology in St. Louis encephalitis virus cases includes perivascular, meningeal, and capillary lymphocytic infiltrates and activated microglia in gray and white matter. There are widespread neuronal degenerative changes, more obvious in cortex, basal ganglia, and cerebellum. A few St. Louis encephalitis virus cases have evidence of inflammation and neuronal loss in the spinal cord.

Treatment is supportive. Mortality varies considerably in case series and has been reported as high as 20%; long-term morbidity occurs in up to 50% of cases (see [Table 66.1](#)). Prognosis is worse with those who develop seizures.

Powassan Virus

This flavivirus is carried by the *Dermacentor* spp. and *Ixodes* ticks and is endemic in Canada, the northern United States, and parts of Russia (see [Fig. 66.1B](#)). It derives its name from the town in Canada where disease was first identified in 1958. Like Murray Valley encephalitis virus and St. Louis encephalitis virus, its epidemiologic significance pales in comparison to other flaviviruses.

Symptoms occur after an incubation period of 1 to 4 weeks and begin with malaise, fever, and pharyngitis but can progress to hemiplegia, vomiting, marked brain stem dysfunction, coma, and death. CSF studies, as with nearly all viral encephalitides, usually demonstrate a moderate lymphocytic pleocytosis and modestly elevated protein concentration. RNA and antibodies can be detected in blood and/or CSF, although the tests are not widely available; referral to state laboratories in the United States is advised.

Pathologic studies demonstrate intense lymphocytic infiltrates and necrosis of gray matter mostly in the basal ganglia, thalamus, and mesial temporal lobes, although involvement is widespread. Neuronal cells demonstrate eosinophilic inclusion bodies. There is no specific therapy for this disease, and treatment is supportive. About half of the survivors suffer permanent sequelae (see [Table 66.1](#)).

BUNYAVIRUSES

Bunyaviruses are negative-sense, single-stranded helical RNA viruses that are encapsulated. Although some are arboviruses, several

are spread by rodents and are not associated with significant neurologic disease. Those that do result in encephalitis have less epidemiologic significance than most of the flaviviruses, which are found in densely populated areas, are widespread globally, and/or are much more neurovirulent.

Lacrosse Virus

Lacrosse virus is transmitted by the *Aedes triseriatus* mosquito. Lacrosse virus is endemic to the United States, and symptomatic cases are most commonly seen across the Ohio River Valley, mid-Atlantic, and Midwest. In these areas, the incidence is about 10 to 30 per 100,000 population but only about 0.3% to 4% are symptomatic. Most cases are reported in children, with only about 3% occurring beyond the age of 20 years.

Initial infection causes viral replication in muscle followed by viremia and CNS invasion. The mechanism of entry into the CNS is unknown, but neurons and glial cells in the frontal, temporal, and parietal lobes are mostly affected. Presentation is of headache and fever, which progresses over days to seizures and encephalopathy about 25% to 50% of the time. CSF demonstrates a lymphocytic pleocytosis with modestly elevated protein concentration, although results can be entirely normal. Lacrosse virus IgM in CSF is diagnostic; otherwise, diagnosis comes from fourfold increase in IgG antibody titers from acute to convalescent phase. Alternatively, antigen detection on biopsy specimen provides the diagnosis. Treatment is supportive and the disease monophasic; mortality is less than 1%.

Jamestown Canyon Virus

This virus infects many species of mosquitoes and flies and is found throughout the United States into Canada. It is an extremely rare cause of mild meningoencephalitis, with less than a score of cases reported. However, seroprevalence has been reported as high as 27%, suggesting neurovirulence is very low. Symptoms mirror those of other arboviruses, with onset of a mild febrile illness followed by severe headaches. Serologic studies are diagnostic when a fourfold rise in IgG is seen between acute and convalescent phases; treatment is supportive.

REOVIRUSES

Reoviruses are a family of double-stranded, nonenveloped RNA viruses with icosahedral capsids. As with bunyaviruses, these infections are considerably more isolated than most flavivirus infections.

This Reoviridae genus includes Colorado tick fever virus, California hare coltivirus, Salmon River virus, and the European Eyach virus. All are associated with human disease, but Colorado tick fever virus causes the majority of human infections. It is carried by *Dermacentor andersoni* ticks and is mostly seen in the Rocky Mountains and western United States into Canada at elevations of 4,000 to 10,000 feet. Men are more often infected than women, likely due to lifestyle characteristics leading to exposure. There have been some 200 to 300 cases reported, but the incidence is likely much higher, as most infections are thought to be asymptomatic. Presentation after an incubation period of about 3 to 5 days is of acute fever, headache, nausea, myalgias, and in some, a maculopapular rash. About a week later, a meningoencephalitis may develop (mostly children). There can be additional systemic involvement of the heart, liver, testes, epididymis, and lungs. Only a couple of deaths have been reported, and these have been due to hemorrhagic shock complicating disease. This monophasic illness resolves after another week.

CSF often shows a lymphocytic pleocytosis and modestly elevated protein concentration. Diagnosis is made by viral isolation from blood or CSF or serologies and treatment is supportive, with special care to avoid antiplatelet agents given the potential for hemorrhagic complications.

TOGAVIRUSES

Togaviruses are positive-sense, single-stranded, enveloped viruses with icosahedral capsids. There are two genera: *Alphavirus* and *Rubivirus*. *Alphavirus* species are arboviruses, whereas *Rubivirus* contains rubella, which is transmitted via droplet or mother-child transmission.

Alphavirus (Equine Encephalitis)

There are three types of equine encephalitis, all belonging to the genus *Alphavirus*, that occur in the Americas (see Fig. 66.1A): Eastern equine encephalitis (EEE), Western equine encephalitis (WEE), and Venezuelan equine encephalitis (VEE). These viruses affect horses primarily but in 1938 were found to cause human disease in those having close contact with affected animals.

Equine encephalitides are rare human infections and occur either in isolated cases or in short-lived epidemics when environmental conditions favor viral amplification. WEE and EEE are seen on the western and eastern coasts of the United States and into Canada with some overlap into the Midwest and Great Lakes regions (see Fig. 66.1B). VEE occurs throughout Central America into the northern part of South America.

EEE is the most severe of the equine encephalitides, frequently progressing to coma and death. The disease begins with a short prodrome (~5 days) of a flulike illness: fever, headache, malaise, nausea, and vomiting. This quickly is followed by confusion, stupor or coma, and possibly seizures. Focal neurologic signs can be present, including tremor, cranial nerve palsies, and plegia. In a recent case series, the median CSF white blood cell count was 370 cells/mm³ (median 70% neutrophils). The median total protein concentration was 97 mg/dL, and the CSF glucose concentration was normal. Diagnosis of EEE encephalitis relies on the detection of IgM antibodies in the serum and/or CSF. PCR and genomic amplification is available for EEE, and virus isolation from CSF or brain remains the diagnostic gold standard. The majority of those with EEE and neurologic symptoms have abnormal brain MRI. Lesions are best seen on T2-weighted sequences with the basal ganglia and thalamus most affected (Fig. 66.2).

Pathologic findings on gross examination in EEE are notable for diffuse cerebral edema. There is typically acute or chronic perivascular and meningeal inflammation seen within the basal ganglia, thalamus, cortex, brain stem, and spinal cord. Inflammatory infiltrates, neuronal death, and rarefied tissue can correlate to changes seen on MRI. EEE immunohistochemistry has shown clusters of infected cells primarily in gray matter with neurons as the predominant cell type affected (Fig. 66.3). In cases of myelitis, anterior horn cells are affected.

Estimates of case fatalities of EEE range from 30% to 70%. In children, length of prodrome was statistically associated with clinical outcome at the time of discharge, with longer prodromes having more favorable outcomes. This relationship is not as clear in adults, although patients with more favorable outcomes tended to have longer prodromes. In patients who recover, the morbidity from EEE is high, with sequelae ranging from intellectual disabilities, cranial nerve palsies, hemiplegia, aphasia, and seizures.

WEE and VEE infections are less severe. The vast majority of children and adults have a flulike illness with fever and malaise lasting up to 2 weeks. The extremes of age are at risk for neuroinvasive disease but less than 10% progress to coma. Hemiparesis,

tremors, and cranial nerve palsies may occur with long-term sequelae that include cognitive decline and intellectual disabilities.

FIGURE 66.2 Axial T2 fluid-attenuated inversion recovery (FLAIR)-weighted MRI in a patient with encephalitis due to EEE shows hyperintensities in the basal ganglia bilaterally.

Rubivirus

RUBELLA

Rubella, also known as the *German measles*, is caused by a positive sense, single-stranded RNA virus. The name *rubella* is derived from Latin, meaning “little red,” as it generally produces a mild exanthematous disease in children and adults. However, infection occurring during pregnancy, particularly in the first trimester, can result in severe consequences including miscarriage, stillbirth, or infants born with congenital malformations and severe neurologic deficits, known as *congenital rubella syndrome*. Rubella also produces a rare chronic form of progressive encephalitis termed *progressive rubella panencephalitis*, which can be seen in children with congenital rubella syndrome or those with postnatal infections.

FIGURE 66.3 Histopathologic features in EEE. **A:** Hematoxylin and eosin-stained section of thalamus showing perivascular cuffing (*arrow*) (magnification $\times 20$). **B:** Hematoxylin and eosin-stained section showing neuronal degeneration and inflammation. **C:** EEE virus-specific antibody stained section of frontal cortex. (Courtesy of Dr. Pedro Ciarliani.)

In the 1970s, rubella infections occurred in epidemics in the United States approximately every 6 to 9 years prior to licensing of the rubella vaccine. The last U.S. epidemic in 1964 to 1965 resulted in over 12.5 million cases of rubella, with 20,000 infants born with congenital rubella syndrome. In 2004, after implementation of a universal vaccination program, elimination of endemic rubella virus transmission was documented in the United States. Rubella infections are still prevalent worldwide, as the virus continues to circulate where vaccination programs have not been established. Transmission of the virus is by the respiratory route and replication occurs in the nasopharynx and lymph nodes.

There can be severe neurologic morbidity from rubella arising when a pregnant woman is infected. The frequency of congenital defects is highest in the first trimester of pregnancy and falls as gestation advances. For a long time after birth, infants with congenital rubella syndrome may shed virus from the nasopharynx, eye, or CSF, producing a chronic, persistent infection in the fetus. Neurologic abnormalities are observed by 18 months of age. Infants with rubella encephalitis are hypotonic, inactive, and irritable with a typically full anterior fontanel. Eventually, opisthotonic posturing, rigidity, paresis, seizures, and developmental delays can occur. The syndrome includes sensorineural hearing loss, cardiovascular anomalies, congestive heart failure (CHF), cataracts, thrombocytopenia, and areas of

hyperpigmentation about the navel, forehead, and cheeks.

In postnatal infections, rubella results in a mild systemic illness with an incubation of period of 2 to 3 weeks. Lymphadenopathy is often the initial clue with a subsequent erythematous rash on the face and trunk. The neurologic symptoms are rare, occurring in less than 0.1% of rubella cases. Rubella can produce

P.551

an encephalitis, meningitis, or myelitis. There are sporadic case reports of GBS following the presence of rash.

Serum abnormalities seen with rubella infections include leukopenia with atypical lymphocytosis or thrombocytopenia. The CSF in postnatal rubella or in congenital rubella syndrome contains a lymphocytic pleocytosis and moderately increased protein concentration. Diagnosis of rubella is supported by detecting rubella-specific IgM and confirmed by detecting rubella virus in throat washings or rubella virus RNA in CSF or urine by using RT-PCR. Rubella virus can be recovered from the CSF of approximately 25% of patients and may persist in the CSF for more than 1 year after birth. On MRI of the brain in congenital rubella syndrome, there are basal ganglia, periventricular and cortical calcifications, multifocal T2-hyperintensities, and evidence of delayed myelination.

Prevention is the primary method of combating rubella. The rubella vaccine is a live attenuated virus that is usually given as part of the MMR (measles, mumps, and rubella) vaccine. Due to risk of congenital rubella syndrome, rubella vaccination is particularly important for nonimmune women who may become pregnant.

PROGRESSIVE RUBELLA PANENCEPHALITIS

Progressive rubella panencephalitis is an extremely rare and fatal neurodegenerative disorder that can follow either congenital or postnatal rubella infections. The insidious development of neurologic deterioration following years after a rubella infection was first described in the *New England Journal of Medicine* in two consecutive papers in 1975. Several clinical and neuropathologic features seen in progressive rubella panencephalitis mirror that of subacute sclerosing panencephalitis following measles infections (SSPE; discussed under “Measles Encephalitis”). Progressive rubella panencephalitis is typically seen in the second decade of life. The syndrome begins with a dementing illness and ataxia, the latter being the most consistent neurologic sign in progressive rubella panencephalitis. As the disease progresses, the ataxia worsens with dysmetria, dysdiadochokinesia, and truncal titubation. Dysarthria is prominent. The development of pyramidal tract involvement, retinopathy, seizures, and multifocal myoclonus can occur over a protected period of time over 8 to 10 years. Headache and meningismus are not seen.

Progressive rubella panencephalitis and SSPE occur in people who have elevated antiviral antibodies and apparent intact cellular immunity. In the cases reported of progressive rubella panencephalitis, there were high titers of rubella-specific IgG in CSF and sera. The high ratio of CSF-to-sera of rubella-specific antibodies suggests intrathecal synthesis. The rubella virus is rarely isolated. In these cases, it is important to rule out the presence of measles-specific antibodies given the similarity in presentations. Electroencephalogram (EEG) reveals diffuse slowing but without the characteristic pattern in SSPE.

The neuropathologic features of progressive rubella panencephalitis on gross examination show atrophy of the rhombencephalon, centrum semiovale, and basal ganglia with ventricular dilatation, particularly in the fourth ventricle. Microscopically, the cerebellum has atrophy of all cell layers. Neuronal loss is present and widespread. Inclusion bodies seen in SSPE are not present in progressive rubella panencephalitis. There is evidence of chronic inflammation and demyelination with diffuse astrogliosis of the white matter with perivascular lymphocytic and plasma cell infiltrates. Progressive rubella panencephalitis produces a picture consistent with vasculitis. There are IgG deposits in cerebral vessels as well as the presence of multinucleated giant cells and lymphocytes in vessel walls. Most of the extracted IgG is specific to rubella.

The diagnosis of progressive rubella panencephalitis is easier in children with congenital rubella syndrome. In those who had postnatal rubella infections, the differential should include SSPE as well as dementing illness of childhood. However, with the onset of ataxia, the diagnosis is clearer and demonstration of CSF and sera rubella-specific antibodies is diagnostic. The emphasis remains on preventative measures through vaccination programs, as there are no specific treatments.

ORTHOMYXOVIRUSES: INFLUENZA VIRUS

Influenza is a negative-sense RNA virus with three subtypes (A, B, and C). Further delineation is based on hemagglutinins (H) and neuraminidases (N). The majority of symptomatic infections result in a monophasic, febrile, respiratory illness, but certain hemagglutinin and neuraminidase types confer particularly severe virulence, raising morbidity and mortality.

Neurologic complications are most severe with influenza A and are more commonly seen in children but overall are rare. Additionally, direct CNS infection by influenza is rare, and parainfectious or postinfectious autoimmune and toxin-mediated diseases are the most common neurologic complications. Febrile seizures, encephalopathy, Reye syndrome, GBS, and encephalitis have all been described. Encephalopathy and encephalitis may be clinically indistinguishable and as such are typically described interchangeably, although the pathophysiology of these two entities differs greatly.

Influenza is seen worldwide, but the most commonly reported neurologic complications of encephalopathy/encephalitis come from Japan, where the usual population affected is children younger than 5 years old. This age group accounts for some 80% of influenza-associated encephalopathies. Fatality rate is about 25% to 35%, and another 20% to 40% have residual neurologic deficits after convalescence.

The pathophysiology of influenza-associated encephalopathy is unknown. Virus can be recovered from brain tissue or CSF occasionally, but this is rare. More plausible is a scenario of overwhelming cytokine production, inciting edema and necrosis involving the brain stem and deep gray matter structures of the cerebrum. CT and MRI frequently demonstrate abnormalities in these regions or more widespread edema; it is uncommon in influenza-associated encephalopathy for neuroimaging to be normal.

Influenza-associated encephalopathy typically presents early in the course of the respiratory disease about 1 to 2 days after fever onset. Depressed level of consciousness is invariable. Seizure occurs some 80% of the time, and EEG is abnormal. Symptoms can progress to coma and death. For neurologic complications, neuraminidase inhibitors are used, but again because these are thought not to be directly due to viral invasion of the brain, this approach is to minimize the complicating triggers. Treatment for the neurologic complications is aimed at reducing inflammation and edema.

PARAMYXOVIRUSES

HENIPAVIRUSES

Hendra virus and Nipah virus are single-stranded, enveloped, negative-sense RNA paramyxoviruses. In the CNS, they cause encephalitis. Their reservoir is the *Pteropus* fruit bat, which resides in Southeast Asia, Madagascar, India, and northern Australia

P.552

(see Fig. 66.1A). These are primarily nonhuman viruses: Hendra is an equine virus and Nipah a swine virus, but human transmission has occurred due to both

exposure to the fruit bat and exposure to infected animals, usually via saliva. This is extremely rare.

Pathogenesis in the CNS is related both to parenchymal infection and widespread, severe vasculitis. Initial invasion of the CNS seems to occur in a retrograde fashion through the trigeminal nerve or directly across the BBB.

Presentation of Hendra or Nipah virus infection is that of a rapidly progressive encephalitis occurring 1 to 2 weeks after exposure, starting as a fever perhaps with myalgias progressing to confusion, seizure, coma, and death over the course of several days. Mortality rate is 40% to 75%, and no definitive treatment exists.

MEASLES ENCEPHALITIS

Measles virus is a small single-stranded RNA virus belonging to the genus *Morbillivirus* of the family Paramyxoviridae. Measles virus is highly infectious, spreading rapidly between individuals primarily through aerosolized respiratory droplets over short distances. Measles virus can also be suspended in the air for long periods of time via small-particle aerosols. Infection spread can occur swiftly in a sparsely vaccinated population due to poor herd immunity. The most common manifestation of measles is a febrile childhood exanthem.

Infection with measles virus is associated with a robust cell-mediated immune response and downstream upregulation of cytokines. The virus does not usually replicate extensively in brain tissue, and it is thought that key mutations may be needed to confer a neurovirulent phenotype. Hypothesized viral routes to CNS include migration of infected leukocytes through the BBB, via endothelial cells, or through neuronal viral transport. The virus and subsequent immune response can result in severe brain injury.

There are three main neurologic complications that can arise from measles infections: post measles encephalomyelitis (PME), measles inclusion body encephalitis (MIBE), and SSPE. Toxic encephalopathy and acute infantile hemiplegia rarely occur with measles infections and are more likely related to complications of severe febrile illnesses of childhood and are not specific to measles.

PME is akin to ADEM and is seen weeks after a measles infection. Symptoms include headaches, changes in mental status, and seizures, and most PME cases had preceding morbilliform rash and fever that are typically seen with measles virus. In patients with myelitis, back pain with bladder and bowel dysfunction is prominent. CSF analysis can show a mild lymphocytic pleocytosis and elevated protein concentrations. MRI scans demonstrate T2 hyperintensities in the white matter of the brain and spinal cord. In histopathologic studies of the brain, there is evidence of inflammation and demyelination; however, measles virus is not present, suggesting that PME is likely a postviral autoimmune phenomenon.

MIBE, also known as *immunosuppressive measles encephalitis*, typically occurs months after a measles infection and affects immunocompromised individuals who are unable to clear measles virus. The disease has been described in those with hematologic malignancies, HIV, and solid organ and stem cell transplantation. Nearly all reported MIBE cases have altered mental status and seizures. The seizures are typically refractory focal motor seizures, but generalized seizures and *epilepsia partialis continua* have been reported. Focal motor deficits, speech impairment, and visual symptoms are also seen. There is progressive deterioration in the level of consciousness typically leading to coma and death in weeks to months. CSF analysis is usually normal, but a mild pleocytosis and elevated protein concentration may be seen. Brain biopsy is necessary to establish a definitive diagnosis. Measles hemagglutinin and matrix proteins can be visualized by immunohistochemical staining, and intranuclear and intracytoplasmic paramyxovirus particles are seen in neurons, glia, and endothelial cells with electron microscopy. In cases of MIBE and SSPE, it is thought that the virus is likely replication-defective making culturing measles virus difficult and the presence of measles is best demonstrated by RT-PCR. The measles vaccine has been implicated as a cause in immunocompromised patients with MIBE.

General supportive measures are the primary treatment. The role of postexposure Ig prophylaxis is unclear. In several patients, intravenous ribavirin treatment has resulted in temporary improvement but is not approved for the treatment of measles. The measles vaccine has been successfully used without serious complications in many immunocompromised patients including those with HIV who do not have evidence of severe immunosuppression.

SUBACUTE SCLEROSING PANENCEPHALITIS

SSPE is a rare, slowly progressive, fatal disease of the CNS typically occurring in children and young adults. SSPE develops in immunocompetent persons after a prolonged latent period following a measles infection. There is a higher risk of SSPE associated with a measles infection before the age of 2 years. The disease follows a stereotypic pattern beginning with behavioral changes after a period of weeks to months. Eventually, there is the appearance of myoclonus and focal deficits (speech disorder, ataxia, paresis, or vision loss). If epilepsy is present, generalized tonic-clonic seizures are the most common. As the disease progresses, there is increased pyramidal and extrapyramidal tone and whole-body myoclonic jerks. There have been very few reports of remission; the disease is typically prolonged over months to years and ends in death.

The presence of periodic complexes on EEG is classic for SSPE, with a spike and delta wave component of 0.5- to 3-second duration and intercomplex intervals of 4 to 30 seconds. These complexes are recognizable in the early stages. Those affected with SSPE have elevated levels of measles-specific IgG antibodies in the CSF and serum, unlike in MIBE. There are no specific MRI findings for SSPE. Striking histologic features of SSPE are hypertrophic astrocytes and microglial proliferation. A perivascular infiltration occurs in the cortex and white matter with plasma and other mononuclear cells. Patchy areas of demyelination and gliosis occur in the white matter and deeper layers of the cortex. The neurons of the cortex, basal ganglia, pons, and inferior olives show degenerative changes. Intranuclear and intracytoplasmic eosinophilic inclusion bodies contain measles virus nucleocapsids. The measles virus extracted from brain tissue in SSPE is highly defective due to lack of membrane protein production, which renders the virus incapable of being fully assembled and shed from the cell surface.

No drug treatments are available to clear the persistent measles virus from the CNS. Intraventricular interferon with intravenous or intraventricular ribavirin has resulted in clinical improvement or stopped progression in case reports but has not cured the disease. No controlled studies have been performed for SSPE. The focus remains on symptomatic and supportive treatments including treatment of myoclonus and seizures, but the disease and its sequelae are entirely preventable by maintaining measles immunization rates greater than 90% in populations.

RHABDOVIRUS: RABIES

Rabies is one of the most deadly and feared viruses with fatality rates essentially at 100%. The disease is present in all continents, except in Antarctica, with the predominant burden of illness in Asia and Africa. It has a variable incubation period followed by pain or paresthesia at the site of the bite and ultimately a progressive encephalomyelitis and death.

EPIDEMIOLOGY

Rabies is underreported in many areas around the world. The estimated worldwide mortality from rabies is approximately 60,000 per year, which is more than any other single zoonotic disease. The route of transmission is typically via the bite of an infected animal, allowing breakdown of the dermal barrier and deposition of the virus into tissues. Dogs remain the principle vector for human rabies, and dog bites are responsible for over 95% of cases. During 2012, the United States and

its territories reported 6,162 rabid animals to the CDC, including raccoons, bats, skunks, foxes, cats, cattle, and dogs. Humans are considered dead-end hosts, with human-to-human transmissions occurring only in rare circumstances, such as in transplantations. Airborne transmission of rabies has been reported in spelunkers of bat-infested caves and laboratory workers with no known bat bites.

PATHOBIOLOGY

Rabies is derived from a negative sense, single-stranded RNA virus belonging to the genus *Lyssavirus*. The virus is enveloped and bacilliform (bullet-shaped). Once transcribed by the host, viral replication and transcription occur in cytoplasmic inclusions within neuronal cells termed *Negri bodies*. The virus then is able to use the host cell machinery to travel retrograde by axonal transport mechanisms to the dorsal root ganglia or cell bodies in the spinal cord or brain stem. In the CNS, viral replication is enhanced and clinical disease develops.

CLINICAL FEATURES

There are two clinical forms of rabies traditionally described: encephalitic (furious) and paralytic (dumb) (Table 66.2). The earliest symptom reported is pain or paresthesia at the site of infection in about half of patients due to viral replication in the local dorsal root ganglia. Other symptoms include fever, headache, and lethargy. The encephalitic course is heralded by hypersalivation, alternating patterns of agitation and lucidity, and hydrophobia leading to pharyngeal spasms, all ultimately leading to coma and death. The paralytic form classically begins with limb weakness early; there are no convulsions or laryngeal spasms. The paralysis results in flaccid tone and can spread to involve other limbs. The paralytic form of rabies has a longer prodromal period and a more protracted course. The typical incubation period is 1 to 6 months. Longer incubations of up to 8 years post exposure have been reported with evidence of genetic data to exclude the possibility of reexposure.

DIAGNOSIS

Diagnostic tests rely on the widespread dissemination of the virus. MRI of the affected brain shows a pattern of mild T2 hyperintensities primarily in the brain stem, hippocampus, thalamus, and cerebral white matter (Fig. 66.4). Postcontrast enhancement in the brain is observed late in the course. In paralytic rabies, the brachial plexus can enhance in the prodromal phase. The MRI changes seen in rabies are preferential to the brain stem.

The diagnosis can be made by fluorescent antibody staining of corneal smears or nuchal skin biopsies, although both false-negative and false-positive results occur, and/or by the detection of viral nucleic acid using RT-PCR in biologic fluids including saliva and CSF. Although viral shedding in saliva is used for testing, sensitivity on single sample testing can be as low as 70%. This is attributed to intermittent shedding, and thus multiple successive saliva samples or skin biopsies reach sensitivities greater than 95%.

Histopathologic diagnosis of rabies was for many years dependent on visualization of Negri bodies in infected neurons on biopsies. These are inclusions, which are classically round or ovoid eosinophilic bodies with basophilic stippling. Negri bodies are most prominent in the brain stem, hippocampus, and in Purkinje cells but can be seen in cortical neurons and spinal ganglia. A histologic picture of encephalitis and/or myelitis can occur but is not universal, as considerable variability in the inflammatory response may be due to differences in the infecting rabies virus strain. Perivascular lymphocytic inflammation and microglial activation are typically found in the brain stem and spinal cord but can be widespread. In paralytic rabies, inflammation is most evident in the anterior horn. Rabies viral antigen is frequently identified in cases where Negri bodies are absent and can be shown in non-CNS tissue including the cornea and nasal mucosa.

TREATMENT

No effective therapies exist for rabies after the development of symptoms. Of the individuals who have survived, one received preexposure immunization and eight received postexposure prophylaxis prior to the onset of symptoms. There has been a single case of a 15-year-old girl who was in contact with a bat 1 month prior to symptom onset and did not receive postexposure prophylaxis who survived after treatment with a combination of medical therapies, which included therapeutic coma with ribavirin, amantadine, benzodiazepines, and ketamine, dubbed the "Milwaukee protocol." This paradigm with case-by-case modifications for the treatment of rabies remains controversial, as at least 26 subsequent cases have failed to repeat this isolated success. Additional therapies for rabies, including Ig plus vaccination, ribavirin, and interferon α , have not been successful to date. Thus, the best approach to rabies is exposure avoidance and vaccinating those anticipating potential exposure. Access to postexposure prophylaxis may be lifesaving for those who do become exposed.

ARENAVIRUSES

This is a large family of negative-sense RNA viruses that infect rodents asymptotically. Human contact with the animal or its excrement results in viral transmission. "Old world" arenaviruses include Lassa virus, found in Africa, and lymphocytic choriomeningitis virus, found throughout the world. "New world" arenaviruses include Whitewater Arroyo virus found in North America, Junin virus found in Argentina, and Machupo virus found in Bolivia and parts of Paraguay. Lymphocytic choriomeningitis virus causes a variety of neurologic manifestations described in the following section. Lassa, Whitewater Arroyo virus, Junin, and Machupo all cause hemorrhagic fever, with mortality rates of 15% to 35%. Infection is via droplet inhalation, escort by alveolar macrophages to lymph nodes, subsequent replication, and dissemination. Symptoms start as a febrile illness that can progress

P.554

P.555

to encephalopathy and severe thrombocytopenia and platelet aggregation inhibition, resulting in multifocal hemorrhage. These infections tend to occur in outbreaks, and men are more frequently affected than women, a feature thought to be related to exposure patterns.

TABLE 66.2 Features of Furious versus Paralytic Symptoms in Patients Infected with Rabies Virus

	Furious	Paralytic
General Features in Patients Infected with Dog RABV Variants		
Prevalence	2/3 (67%)	1/3 (33%)

Average survival without intensive care support	5-7 days (<i>n</i> = 80)	11 days (<i>n</i> = 35)
Location of bite and relation to unsuccessful immunization	Anywhere; not related	Anywhere; not related
Prodromal symptoms	Nonspecific with local neuropathic pain in a third of patients	Nonspecific with local neuropathic pain in a third of patients
Rabies characteristics^a	Present but might not be seen at all stages	None or minimal, phobic spasms in only half, inspiratory spasms might not be obvious due to weakness of neck muscles and diaphragm; percussion myoedema at deltoids and chest wall (in the absence of hyponatremia, renal failure, hypothyroidism, and severe cachexia)
Sensory deficits	At bitten segment due to ganglionitis; loss of pinprick sensation followed by loss of joint position sense	At bitten segment due to ganglionitis; loss of pinprick sensation followed by loss of joint position sense
Flaccid weakness with areflexia	Appears only when comatose	Ascending pure motor weakness, predominantly involving proximal and facial musculature as initial manifestation, whereas consciousness is fully preserved
Electrophysiologic features	Subclinical anterior horn cell dysfunction; sensory neuronopathy in patients with local neuropathic symptoms	Evidence of peripheral demyelination or axonopathy; sensory neuronopathy in patients with local neuropathic symptoms
MRI Findings in Patients Infected with Dog RABV Variants		
Prodromal phase	Enhancing hypersignal T2 changes along the brachial plexus and associated spinal nerve roots at levels corresponding with the bitten extremity; nonenhancing ill-defined mild hypersignal T2 changes of the spinal cord, temporal lobe cortices, hippocampal gyri, and cerebral white matter	Enhancing hypersignal T2 changes along the brachial plexus and associated spinal nerve roots at levels corresponding with the bitten extremity; nonenhancing ill-defined mild hypersignal T2 changes of the spinal cord, temporal lobe cortices, hippocampal gyri, and cerebral white matter
Acute neurologic (noncomatose) phase	Progression of abnormal hypersignal T2 changes	Progression of abnormal hypersignal T2 changes
Comatose phase	Moderate gadolinium enhancement, especially in limbic structures, thalamus, substantia nigra, tectal plates, brain stem, deep gray matter, cranial nerve nuclei, spinal cord, and cranial and spinal nerve roots	Moderate gadolinium enhancement, especially in limbic structures, thalamus, substantia nigra, tectal plates, brain stem, deep gray matter, cranial nerve nuclei, spinal cord, and cranial and spinal nerve roots
General Features of Early-Stage Rabies in Naturally Infected Dogs		
Viral load in brain structures	Several times greater than paralytic at all 12 regions examined	Several times lower than furious at all 12 regions examined
Cytokine or chemokine mRNA transcripts	Barely detected; TNF- α detectable but at nonsignificant concentration	TNF- α , interferon γ , and interleukin 1 β
FLAIR signal abnormality indicative of macrocellular damage revealed by MRI	Faint signal in cervical cord, brain stem, temporal lobes, and cerebral hemispheres	Moderate to intense signal in hypothalamus, brain stem, cervical cord, and temporal lobes
Blood-brain barrier status (examined by presence or absence of contrast-enhanced lesion)	Intact; no contrast-enhanced lesion	Intact; no contrast-enhanced lesion

Neuropathology

Caudal-rostral polarity of viral antigen; greater viral antigen reported in many regions, including frontal and occipital cortices and most spinal cord levels; inflammation generally mild throughout the CNS

Prominent inflammation in brain stem, in association with lower extent of viral antigen; caudal-rostral polarity of viral antigen

^aChange in consciousness, phobic spasms, spontaneous inspiratory spasms, and autonomic dysfunctions.

RABV, rabies virus; MRI, magnetic resonance imaging; TNF- α , tumor necrosis factor-alpha; FLAIR, fluid-attenuated inversion recovery; CNS, central nervous system.

From Hemachudha T, Ugolini G, Wacharapluesadee S, et al. Human rabies: neuropathogenesis, diagnosis, and management. *Lancet Neurol*. 2013;12(5):498-513.

FIGURE 66.4 Axial diffusion-weighted imaging (**far left**), apparent diffusion coefficient (**middle**), and T1-weighted MRI after administration of gadolinium (**right**) at the level of the caudate heads in a patient with rabies encephalitis demonstrate diffusion restriction within the subcortical white matter (*arrows*) and diffuse leptomeningeal enhancement (*arrowheads*). The white matter diffusion restriction is thought secondary to wallerian degeneration and leptomeningeal enhancement to leptomenigitis.

LYMPHOCYTIC CHORIOMENINGITIS VIRUS

Of the arenaviruses, lymphocytic choriomeningitis virus can be found throughout the world. In addition to murine transmission, outbreaks in the setting of solid organ transplantation have also been reported, albeit rarely, but with uniformly fatal outcomes. Vertical transmission is also known to occur. The more common mode of infection is via exposure to infected rodent excrement, and most often the infection is asymptomatic if the host is immune competent. Indeed, the donors of those solid organ transplant recipients who died from infection were unaware of their infection, and one even had a lymphocytic choriomeningitis virus-infected pet hamster.

Initial incubation time is 1 to 3 weeks. Lymphocytic choriomeningitis virus is neurotropic, and viremia results in carriage of virus to brain. The most common neurologic complication is viral meningitis that is self-limited; more severe encephalitis is rare, although in a study of undiagnosed encephalitides, 2.3% were found to be due to lymphocytic choriomeningitis virus, suggesting potential underdiagnosis. Other complications include orchitis, arthritis, pericarditis, and pancreatitis. CSF studies in the immunocompromised may be acellular, but in cases of viral meningitis, there is usually a strongly predominantly lymphocytic pleocytosis and elevated protein concentration. Lymphocytic choriomeningitis virus RNA can occasionally be detected in blood or CSF, but diagnosis is more reliably made by serology in the correct clinical setting. Treatment is supportive.

Lymphocytic choriomeningitis virus has also been reported as an important teratogen, and many of the cases reported have been in the United States. About half of the mothers had symptomatic infection and one-third had rodent exposures, which suggests an education potential for prevention purposes. Children born to these mothers suffered chorioretinitis, hydrocephalus, and/or periventricular calcifications.

ADENOVIRUS

Adenovirus is a nonenveloped, double-stranded DNA virus with an icosahedral capsid belonging to the family Adenoviridae. Infection primarily occurs in mucocellular cells of the respiratory tract, conjunctiva, and gastrointestinal tracts, followed by lymphoid tissue replication and subsequent viremia. Infections can be monophasic, but the virus can alternatively establish latency and oncologic transformation.

Adenovirus infection of the nervous system is rare and described in terms of case reports. Most are in the setting of bone marrow transplant. Adenovirus infection occurs in both children and adults; case reports have additional commonalities of immune suppression and co-occurring CSF virus detection. Presentation is of meningoencephalitis that may progress to involve the spinal cord. Encephalopathy, headache, and fever are present initially with progression to stupor, coma, and death. CSF may just show elevated protein concentration and detectable adenovirus DNA. Pathology demonstrates adenovirus widespread gliosis, neuronal loss, and adenoviral neuronal inclusions most prominent in the brain stem and diencephalon, with the posterior horns predominantly affected in myelitis. T2-weighted MRI of the brain demonstrates hyperintensities predominantly in the brain stem and deep gray matter structures. Reported outcomes have been dismal, but no reliable epidemiologic data exists.

HERPESVIRUSES

The human herpesvirus group consists of neurotropic viruses that establish latent infections within the nervous system for the lifetime of their host. These viruses contain double-stranded DNA molecules. The family consists of eight members: herpes simplex virus 1 and 2 (HSV-1, HSV-2), VZV, cytomegalovirus, EBV, and human herpesvirus 6, 7, and 8 (HHV-6, HHV-7, HHV-8). These are pleiotropic viruses that are capable of causing tissue injury, vasculitis, angiogenesis, and

tumorigenesis.

HERPES SIMPLEX VIRUS 1 AND 2

The herpes simplex virus (HSV) is a common virus with two closely related types, HSV-1 and HSV-2, sharing 70% genomic homology. HSV-1 and HSV-2 establish latent infections in dorsal root ganglia and can reactivate years later, causing meningitis (HSV-2) or encephalitis (HSV-1 primarily). In adults, seroprevalence for HSV-1 and HSV-2 is 50% to 90% and 4% to 40%, respectively.

Herpes Simplex Virus Encephalitis

Herpes simplex virus encephalitis (HSE) is the most commonly identified cause of sporadic encephalitis in the United States, Europe, and Australia. The incidence is estimated at about three cases per million population but with bimodal age distribution. The majority of patients are younger than 20 years old or older than 50 years, with a peak incidence between 60 and 64 years of age. There is no sex preference or seasonal variability. In immunocompetent adults, more than 90% of cases are due to HSV-1. HSV-2 can be responsible for HSE and is typically seen in immunosuppressed individuals or in neonates. The pathogenesis for HSE is either reactivation within the trigeminal ganglion with axonal spread into the frontal and temporal lobes, reactivation of latent virus within the CNS, or a primary infection of the CNS. These are not mutually exclusive.

CLINICAL MANIFESTATIONS

The clinical presentations of HSE is headache and fever, with personality or behavioral changes, disorientation, and/or seizures. The combination of fever and headache with personality changes or confusion is seen in the majority of cases, although only rarely will an individual have the complete triad of symptoms.

DIAGNOSIS

The CSF is abnormal in more than 95% of HSE patients, revealing a moderate pleocytosis with predominately mononuclear cells. Red blood cells are frequently present. There can be a moderate increase in CSF protein concentration, whereas hypoglycorrhachia is seen only occasionally and not expected. PCR for HSV-1 is 98% sensitive and 94% specific. False-negative results can be seen during the first 72 hours of illness and testing can turn positive 1 to 2 days later. PCR results can remain positive even while on treatment in 40% of HSE patients, although by and large, these statistics do not come from therapy with acyclovir. The CSF white blood cell count in immunocompromised hosts may not be elevated, and in general, immunocompromised patients have lower white blood cell count numbers in comparison to those with healthy immune systems. EEG changes are nonspecific and classically demonstrate periodic lateralized epileptiform discharges or seizures. MRI is the superior imaging modality, demonstrating abnormalities 24 to 48 hours earlier than CT. The diagnosis of HSE is supported by T2 hyperintensities in cortical and subcortical regions of the medial temporal lobes, insula, orbitofrontal, and cingulate gyri (Fig. 66.5). There may be additional evidence of subacute hemorrhages within edematous brain tissue. Restricted diffusion correlates with cytotoxic edema and is present early in disease.

FIGURE 66.5 Axial T2-weighted FLAIR MRI at the level of the superior cerebellar peduncle and tentorium cerebelli in a patient with limbic encephalitis due to HSV-1 demonstrates T2 hyperintensity and edema in the anterior temporal lobe on the right.

TREATMENT

The introduction of acyclovir in 1984, which prevents viral replication by DNA polymerase inhibition, resulted in dramatically reduced mortality rates from HSE. Acyclovir for HSE is dosed at 10 mg/kg every 8 hours for 21 days in patients with normal renal function; relapse is an issue in undertreated patients. If the patient is not clinically improving, foscarnet can be substituted for acyclovir.

Resistance to acyclovir is very uncommon in treatment-naïve patients, with overall prevalence of resistant HSV-1 estimated to be about 0.3%. Acyclovir resistance stems from viral thymidine kinase mutations in 95% of cases or in viral DNA polymerase genes. These mutations result in decreased or absent HSV thymidine kinase production, altered affinity of the thymidine kinase, or HSV DNA polymerase for the active phosphorylated acyclovir. In immunocompromised people who are receiving long-term prophylactic acyclovir, the risk of acyclovir-resistant HSV and VZV increases. In these patients, treatment with foscarnet and cidofovir are second-line agents.

OUTCOME

HSE is a medical emergency, as prognosis is dependent on early initiation of treatment. Despite highly favorable results with acyclovir, treatment initiation continues to be delayed primarily due

P.557

to failure to recognize the disease early, and predictors of adverse outcomes despite treatment include age (older than 30 years old), Glasgow Coma Scale score less than 6, and duration of symptoms prior to starting acyclovir.

Neonatal Herpes Simplex Virus 2 Encephalitis

Neonatal HSV infections are some of the most life-threatening infections in newborns. In the United States, neonatal HSV encephalitis affects approximately 1,500 to 2,220 babies per year. HSV-2 accounts for 70% of these cases. The majority of infected infants acquire HSV in the peripartum period during delivery.

HSV infections in infants are grouped into three categories: disseminated disease, CNS involvement, and limited disease to the skin, eyes, and/or mouth. This classification system is predictive of morbidity and mortality. Factors influencing outcomes in neonatal HSE include prematurity, seizures, and multiple dermatologic infections of the skin. Almost one-third of neonates with HSV infection have CNS disease. The clinical manifestations include nonspecific signs of encephalitis/meningitis such as lethargy, poor feeding, labile temperature, seizures, opisthotonus, and bulging fontanelles. The median age of presentation for HSV-2 encephalitis is day 16 to 19 of life.

Neonatal CSF HSV PCR is highly sensitive and specific for herpes DNA. HSV DNA is detectable in the first week of illness even while on antiviral therapy. Initiation of acyclovir before the development of CNS disease, disseminated disease, or depressed consciousness improves outcomes. The first-line treatment for neonatal HSE is intravenous acyclovir at 60 mg/kg/day divided three times a day for 21 days. It is recommended to obtain a repeat CSF HSV PCR at the end of therapy and if HSV DNA is still present, to continue therapy. There is higher morbidity and mortality associated with prolonged HSV infection despite therapy. Mortality in the era of antiviral therapy is 4% for CNS HSV disease at 1 year. Long-term neurologic consequences include cerebral palsy, intellectual disabilities, attention deficits, and epilepsy.

Benign Recurrent Lymphocytic Meningitis

A syndrome of recurrent episodes of benign, self-limited, sterile meningitis were first described by Mollaret in 1944. For years, the condition was referred to as *Mollaret meningitis*.

PATHOBIOLOGY

Benign recurrent lymphocytic meningitis is a syndrome that appears to be related to infection with a variety of herpes simplex viruses. In recent years, detection of herpes simplex virus type 2 genome by PCR has been most often, but not uniformly, reported. Other cases have been linked to varicella-zoster infection. CNS epidermoid cysts can give rise to Mollaret meningitis especially with surgical manipulation of cyst contents. A familial association, where more than one family member had Mollaret, has been documented.

CLINICAL MANIFESTATIONS

The syndrome is characterized by repeated, short-lived, spontaneous, remitting attacks of headache and nuchal rigidity. Between attacks, the patient enjoys good health. The meningitic episodes usually last 2 or 3 days. Most are characterized by mild meningitis without associated neurologic abnormalities. The patient's body temperature is moderately elevated with a maximum of 104°F (40°C). Neck stiffness and the signs of meningeal irritation are present. The first attack may appear at any age between childhood and late adult years. Both sexes are equally affected. The episodes usually recur for 3 to 5 years.

DIAGNOSIS

During the attacks, there is CSF pleocytosis and slight elevation of the protein concentration. The CSF glucose concentration is normal. The cell count ranges from 200 to several thousand cells per cubic millimeter; most cells are mononuclear. Large, fragile endothelial cells are found in the CSF in the early phases of the disease; their presence is variable and is not considered essential for the diagnosis.

DIAGNOSIS AND TREATMENT

Patients with Mollaret meningitis always recover rapidly and spontaneously without specific therapy. There is no effective therapy for shortening the attack or preventing additional attacks, although in some anecdotal reports, acyclovir was beneficial.

VARICELLA-ZOSTER VIRUS

VZV is a human herpesvirus that causes both a primary infection (chickenpox) and can reactivate, producing shingles (zoster), meningitis, and encephalitis. After primary infection, the virus persists in a latent form within cranial nerve or dorsal root ganglia and has intermittent periods of reactivation and shedding. VZV reactivation primarily occurs from the spinal ganglia, with the thorax being the most common site of latent infection, followed by lumbar, cervical, and then sacral regions.

VZV encephalitis is more common in those with immunodeficiency or immunosenescence (waning T-cell immunity to varicella). Encephalitis can occur in the absence of a rash. Diagnosis is confirmed with either VZV DNA or anti-VZV IgM detection in the CSF. Intravenous acyclovir 10 to 15 mg/kg every 8 hours for 10 to 14 days is the generally recommended treatment.

Symptomatic ataxia can occur with primary varicella infections and is traditionally seen in children. Acute cerebellar ataxia is due to either direct viral infection of the cerebellum or is a parainfectious process. Ataxia can be antecedent to or present up to 14 days after the onset of a primary varicella rash. In one of the largest series of children with acute cerebellar ataxia due to viral causes, boys are more likely to be affected than girls and have worse gait disturbances and associated cranial nerve involvement. Those with varicella-related acute cerebellar ataxia tended to have worse ataxia than seen in other viral syndromes but have more rapid rates of recovery with good neurologic outcomes.

Herpes Zoster

Herpes zoster primarily is seen in healthy individuals older than age 50 years and in immunocompromised people, particularly those with HIV or recipients of bone marrow transplant. The incidence rate of zoster ranges between 3 and 5 per 1,000 person-years in North America, Europe, and Asia. There is an age-specific rise in incidence rates in those older than age 80 years to 8 to 12 per 1,000 person-years. It is estimated the number of zoster infections worldwide is rising because the general population is aging, the availability of antiviral treatment has had the effect of more people being diagnosed, and because those who are immunocompromised are living longer.

Pain typically heralds the onset of zoster. The pain of zoster is described as severe, sharp, lancinating, radicular pain in the distribution of the affected nerve root. The pain can be associated with pruritus and paraesthesia. A unilateral dermatomal vesicular rash in the area supplied by the affected root or roots typically follows days later. The vesicles are usually clustered and contain clear fluid, which then desquamate and scab within 5 to 10 days. Occasionally, the pain

P.558

is present without the ensuing rash in a condition known as *zoster sine herpete*. Treatment choices for uncomplicated zoster include oral acyclovir, valacyclovir, or famciclovir with preferential use of valacyclovir or famciclovir due to similar dosing and better CNS pharmacokinetics. A 7- to 10-day course of antiviral therapy is recommended.

Cranial ganglia are affected in approximately 20% of people. In those with cranial nerve involvement, the trigeminal nerve is most often affected. Zoster ophthalmicus, within the V1 distribution of the trigeminal nerve, is often accompanied by keratitis and can lead to blindness. A vesicular rash at the tip of the nose (Hutchinson sign) is a strong predictor of ocular involvement, indicating involvement of the nasociliary branch of V1, which also supplies the cornea and conjunctiva. A herpes zoster rash can precede optic neuritis or ophthalmoplegia. The combination of facial palsy and vesicles in the external auditory canal, tympanic membrane, or on the ipsilateral anterior tongue or hard palate is termed *Ramsay Hunt syndrome*. This syndrome is an indicator of zoster involvement of the facial nerve. The facial palsy in Ramsay Hunt can be severe and those affected are less likely to recover.

The most common complication of zoster is the development of postherpetic neuralgia (PHN). The definition of PHN varies but is generally defined as continued pain in the affected dermatome that persists beyond 4 to 6 weeks after resolution of a rash. The risk of developing PHN varies and is highest in the elderly as well as those who are immunocompromised. Several prospective studies report that 30% to 50% of patients with PHN experience pain lasting over 1 year and with some experiencing pain lasting up to 10 years. The central mechanisms for PHN remain unknown. Treatment of PHN is difficult, and pain can be refractory to multiple analgesics. Combinations of topical treatments (lidocaine or capsaicin) and oral analgesics (tricyclic antidepressants, anticonvulsants, and opioids) are typically used. Interventions such as sympathetic nerve blocks, epidural injections of lidocaine or steroids, or pulsed radiofrequency have either failed to demonstrate benefit or the data is not robust to recommend these procedures.

VZV infection can rarely result in muscle weakness affecting bulbar, limb, or truncal muscles and is typically within the distribution predicted by the rash. For example, peripheral facial weakness is seen with VZV oticus or unilateral diaphragmatic paresis when affecting the cervical myotomes. Neurogenic bladder and loss of anal sphincter control can follow sacral herpes zoster. Segmental zoster paresis is highly associated with PHN. In patients with postganglionic lesions, an MRI can show T2 signal hyperintensity within the affected plexus or nerve, enlargement of the nerve, or enhancement.

FIGURE 66.6 Midsagittal T2-weighted (**far left**) and postcontrast T1-weighted (**middle**) of the thoracic spine from a patient with varicella-zoster myelopathy show multiple levels of intrinsic cord T2 hyperintensity (**left**) with patchy enhancement (**middle**) from T10 to T12 (**arrow**); axial T2-weighted image at the level of T12 demonstrates both white and gray matter involvement by the lesion.

Additionally, the VZV is emerging as a relevant ischemic and hemorrhagic stroke risk factor. Large population studies in the United Kingdom and Taiwan show an increase in the incidence of stroke or transient ischemic attack (TIA) the year following herpes zoster, with a greater relative risk (4.5-fold higher) after herpes zoster ophthalmicus. In pediatric populations, nearly one-third of ischemic arteriopathies are associated with varicella infections.

The hypothesis is that reactivation from ganglia results in viral spread to the adventitia of local blood vessels and eventual transmural migration into the media. Inflammatory cells including neutrophils in early VZV vasculopathy and T cells are directed to the infected sites secreting inflammatory factors that result in remodeling of the vessel. Pathology demonstrates evidence of multinucleated giant cells, Cowdry A inclusion bodies, and herpesvirus in arteries. VZV vasculopathy affects small and large arteries with an emphasis on small artery involvement. In contrast, immunocompromised hosts can develop the entire spectrum of small, large, and mixed artery involvement with VZV vasculopathy.

Those affected with VZV vasculopathy do not necessarily have a history of zoster or varicella rash. In cases when a zoster rash is present, there was often a time delay of an average of 4 months between the rash and neurologic symptoms. Anti-VZV IgM in the CSF is more sensitive than CSF VZV DNA for detecting VZV-

associated vasculopathy. When VZV vasculopathy is suspected or confirmed, treatment with intravenous acyclovir for a minimum of 14 days is suggested based on category 3 evidence (expert opinion). Oral prednisone at 1 mg/kg for 5 days without taper has been given as an adjuvant to suppress the inflammatory response in arteries, but this dosing is arbitrary.

Myelitis may complicate acute varicella infection or can be a consequence of reactivation. Clinical features include paraparesis with a sensory level approximately 1 to 2 weeks following a dermatomal rash. MRI T2-weighted images can show focal areas of hyperintense lesions (Fig. 66.6). Immunocompromised hosts have a more progressive, insidious course that can be ultimately fatal. Gross histopathology shows areas of necrosis and inflammation

P.559

with invasion of the spinal cord by VZV. Diagnosis is confirmed by presence of VZV DNA and/or anti-VZV IgM in the CSF. Aggressive treatment with intravenous acyclovir and consideration of corticosteroids may produce a favorable response, although evidence is lacking.

In the United States, the herpes zoster vaccine has been licensed since 2006 for use in patients older than the age 60 years without primary or acquired immunodeficiency. The attenuated VZV vaccine reduces the incidence of HZ and can reduce the severity of complications including PHN.

EPSTEIN-BARR VIRUS

EBV is a double-stranded, helical DNA gamma herpesvirus that infects B lymphocytes primarily and subsequently establishes latency. In the nervous system, primary infection is associated with meningitis, encephalitis, myelitis, radiculitis, cerebellar ataxia, GBS, and ADEM. These entities and associations are rare. CNS disease due to reactivation is primarily seen in the setting of profound immune suppression, whereby primary CNS lymphoma is precipitated by EBV-mediated B-cell transformation; this is most closely associated with advanced HIV infection. However, there are case reports of meningoencephalomyelitis occurring in the setting of apparent reactivation.

EBV is one of the most common infections worldwide. Primary inoculation occurs usually by adolescence through infected saliva transfer. The virus replicates in the pharyngeal tonsils and transforms short-lived B lymphocytes to prevent their apoptosis. Primary infection is usually asymptomatic, but infectious mononucleosis can also occur about a month into infection. This is characterized by profound fatigue, lymphadenopathy, splenomegaly, and fever. The nervous system complications mentioned earlier rarely follow. In ADEM or GBS, pathophysiology is due to parainfectious inflammation. For the other entities, there is at least a component of inflammation, and the degree of direct viral pathogenesis is unknown but likely small if any.

Diagnosis of primary EBV infection is by serology. The detection of viral capsid antigen (VCA) IgM indicates recent infection; in chronic/latent infection, this antibody wanes in favor of VCA IgG and EBV nuclear antigen. EBV DNA can be detected in blood and CSF as well, but this does not necessarily indicate pathogenic connection to the disease at hand. Treatment is supportive aside from EBV-associated primary CNS lymphoma, which is treated as a neoplasm with chemotherapy and/or radiation. In the setting of primary infection nervous system complications, treatment often involves corticosteroids, IVIg, and/or plasmapheresis.

Pathologic studies of CNS EBV infections unrelated to primary CNS lymphoma are lacking. Although the virus is detectable in CSF, its positive predictive value is actually quite low. Furthermore, replication can occur in the setting of other infections or illnesses, which makes caution in interpreting results of paramount importance, as this finding could very well be an epiphenomenon. In AIDS-related disease, however, detection of EBV DNA from CSF has a very high sensitivity and specificity for CNS lymphoma.

CYTOMEGALOVIRUS

Cytomegalovirus (CMV) is a common cause of viral opportunistic infections in persons who are immunocompromised from either HIV (CD4 counts <50 cells/mm³) or those who have undergone transplantation. CMV is also the most common cause of congenital viral infection resulting in neurologic impairments. In the general population, CMV seroprevalence varies considerably, ranging from 50% to 80% in sexually active adults. It is seen in almost all homosexual men with HIV. Symptomatic CMV infections of the nervous system in adults can result in retinitis, encephalitis, polyradiculitis (usually of the lumbosacral nerve roots), myelitis, or vasculitic mononeuritis multiplex. Since the advent of antiretroviral therapy, the incidence of CMV infections affecting the CNS has decreased considerably.

CMV encephalitis clinically presents as a subacute encephalopathy with features of disorientation, lethargy, apathy, and possibly fever. Focal neurologic deficits include seizures and cranial nerve palsies. Clinical signs of brain stem or cerebellar involvement occur in about 30% of those affected. MRI of the brain can show periventricular enhancement or increased T2 hyperintensity on the ependymal surfaces or can be entirely normal. CSF pleocytosis is rare, and if present, it is a mild lymphocytic pleocytosis with an elevation in CSF protein concentration. The diagnosis in the correct clinical setting is strongly supported by a positive CSF CMV PCR (sensitivity 60% to 100%; specificity 89% to 100%).

Additionally, CMV can produce a lumbosacral polyradiculopathy that is often associated with concurrent infection elsewhere. Those with polyradiculopathy develop subacute lower extremity weakness, paresthesia, and lumbar pain with progression to flaccid paraplegia and areflexia. Ascending sensory loss is often asymmetric. Sacral involvement includes urinary retention and fecal incontinence. If perianal anesthesia is present, there is likely anal sphincter dysfunction and conus medullaris involvement, similar to Elsberg syndrome most commonly seen in the setting of HSV-2 reactivation. CSF studies typically reveal a high polymorphonuclear pleocytosis, elevated protein concentration, and hypoglycorrhachia. CSF RT-PCR is positive for CMV in many cases. In the absence of therapy, progressive rubella panencephalitis is a progressive illness and is fatal.

Anti-CMV treatments can be effective if given early in the disease course. The treatment guidelines for CMV infections affecting the nervous system in the adult suggest combination therapy with IV ganciclovir 5 mg/kg and IV foscarnet 90 mg/kg twice daily to stabilize disease. The duration is continued until neurologic improvement is evident which can take weeks to months. Oral valganciclovir is recommended for CMV infections as maintenance therapy for life or until evidence of immune recovery (i.e., >100 cells/ μ L for at least 3 to 6 months) with antiretroviral therapy is demonstrated. Oral agents for active CNS infection are unlikely to be effective.

Congenital CMV infections are largely asymptomatic, with 10% to 15% of infants presenting with symptoms. The incidence varies in different populations around the world with rates ranging from 0.2% to 3% of all births. Vertical CMV transmission can result from primary maternal infection in pregnancy, can follow reactivation of a previous infection, or can be seen by reinfection with a new strain. Long-term sequelae include sensorineural hearing loss, microcephaly, chorioretinitis and/or optic atrophy, seizures, and a wide range of intellectual developmental disorders. Therapeutic interventions preventing fetal CMV infections with proven efficacy in cases of documented maternal infection are lacking, and no preventive vaccine exists.

HUMAN HERPESVIRUS 6

HHV 6 (Roseolovirus) is a double-stranded, enveloped DNA betaherpesvirus that has two subtypes: A and B. Exanthem subitum is caused by type B. Primary infection typically occurs in childhood, and latency is established in lymphocytes.

a limbic encephalitis and occasionally myelitis. Mori (2010) found an incidence of about 4% after first transplantation and 11% in the setting of a second transplant.

Patients with HHV 6 encephalitis will develop headaches and encephalopathy, usually consisting of disorientation, short-term memory dysfunction, seizure, and depressed consciousness, which in the scenario of immune suppression should always raise red flags toward intracranial pathology. HHV 6 replication can be detected in CSF, and especially when disparate to that in blood, this along with characteristic neuroimaging and clinical scenario support the diagnosis. The caveat is that HHV 6 reactivation is common in this setting, and so isolated detection of viral DNA is not unilaterally diagnostic.

Neuroimaging typically demonstrates bilateral mesial temporal hyperintensities perhaps with extension into the thalamus; pathologic examination has correlated increased HHV 6 DNA to these areas. Antiviral treatment, typically with foscarnet and/or ganciclovir, can reduce viral burden and prevent mortality, although long-term deficits frequently remain.

POLYOMAVIRUS

JOHN CUNNINGHAM VIRUS

John Cunningham virus (JCV) is a double-stranded, circular DNA polyomavirus with an icosahedral capsid and no envelope. It is ubiquitous throughout the world and only infects human cells, making animal study a challenge. There are seven types and multiple subtypes of JCV, all originating in Africa, resulting in trackable migration patterns.

Pathobiology

Initial infection is usually asymptomatic and usually occurs in the first two decades of life. By adulthood, nearly 80% of any given population is seropositive. Latency is subsequently established in kidneys or peripheral blood mononuclear cells, although periodic viral shedding in urine is known to occur. Reactivation is precipitated in the setting of immune compromise, and the virus makes its way to the brain parenchyma, where it productively infects oligodendroglial cells and produces the pathologic entity that is known as *progressive multifocal leukoencephalopathy* (PML).

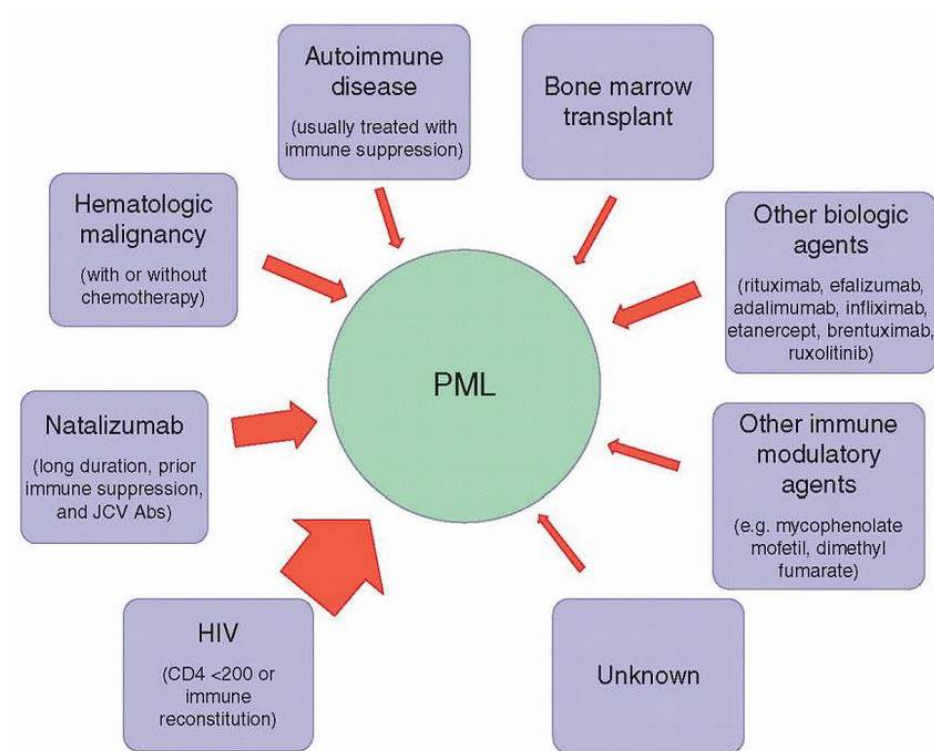

FIGURE 66.7 Predisposing factors for PML. Relative number of cases is depicted by arrow size. By far, advanced HIV infection or immune reconstitution has been the most frequent predisposing factor. Natalizumab therapy for the treatment of multiple sclerosis has emerged in the 21st century as an important risk factor, with duration of treatment, prior immune suppression, and JCV antibody positivity on treatment conferring highest risk. Hematologic malignancy has been the longest standing risk factor. Autoimmune diseases, bone marrow transplant, and other biologic or immune modulatory agents predispose as well, although autoimmune disease contribution unilaterally is controversial, as patients with PML in this setting are nearly always treated with corticosteroids or immune modulatory agents. Finally, some cases are idiopathic.

The predisposing immune suppression for PML since the 1980s is most commonly in the setting of advanced HIV infection with a CD4 count of less than 200. However, the original cases of PML were described in lymphoproliferative disorders, and this still occurs. Additionally, certain biologic agents used to treat autoimmune disease and even autoimmune diseases in and of themselves have been associated with immune suppression sufficient to trigger JCV reactivation and PML. A diagram of such predisposing factors and their relative risk can be found in [Figure 66.7](#). Notably, natalizumab and other immunomodulating agents used in the treatment of multiple sclerosis, although far behind HIV-related cases to date, is an important scenario in which PML occurs.

JCV entry into the brain is not well understood. If indeed the latency is in peripheral blood mononuclear cells, these may be chaperoned across the BBB to their target glial cells. Once across this immunologic barrier, the virus binds cell surface glycoproteins and secondarily serotonin (5HT_{2A}) receptors to gain entry. Clathrin-coated vesicles initiate transport into the cell, where virus travels in a retrograde fashion to the nucleus in order to establish productive infection. As mentioned earlier, oligodendrocytes are the primary targets of infection in the brain, but certain variants have the capability to infect cerebellar granule cells or pyramidal neurons in the cortex. These latter two types of infection are very rare. By and large, productive infection leads to cell destruction, demyelination, and

macrophage infiltration to mop up the debris. This occurs at multiple foci in the brain initially, but as the infection spreads, plaques form and coalesce, thus making the descriptor PML apropos.

Clinical Features

Clinically, symptoms manifest with dependence on localization of demyelination. Typical presentations are that of a subacute process over several weeks. Cortical weakness and ataxia are common, but language disturbance, visual disturbance, hemispatial neglect, and impaired gait are also well described. Headache is a common accompaniment, but notably absent are signs/symptoms localizable to the spinal cord, which is spared in this entity.

P.561

FIGURE 66.8 Axial T2-weighted FLAIR (left) and T1-weighted MRI after administration of gadolinium (right) at the level of the middle cerebellar peduncles in a patient with PML in the setting of advanced HIV demonstrate T2 hyperintensity and T1 hypointensity within the pons extending into the middle cerebellar peduncles bilaterally.

JCV is a known precipitant of the immune reconstitution inflammatory syndrome (IRIS) seen with rapid viral clearance upon initiation of combination antiretroviral therapy (cART) in advanced HIV infection (also in the setting of natalizumab withdrawal). This entity is rare in the CNS but occurs in about 1% of treated HIV infections; when opportunistic infection is present at the time of HIV diagnosis, reduction in antigen load prior to initiation of cART is one strategy to prevent IRIS. In the setting of PML IRIS, however, this is not possible, as there are no known treatments available for reducing antigen burden. As such, there is no good way to prevent PML IRIS at this time. If it does occur, treatment is supportive and most commonly albeit counterintuitively involves corticosteroids to manipulate the intracranial inflammatory response.

Diagnosis

Diagnosis of PML has evolved from pathologic to laboratory and imaging-based. That is to say, although biopsy is gold standard, this is now reserved for cases whose imaging or laboratory data are unclear. Biopsy will show enlarged, bizarre astrocytes, multifocal but coalescent demyelination, and oligodendroglial nuclear inclusions that stain for JCV by immunohistochemistry. However, more commonly, the combination of brain MRI and CSF detection of JCV DNA in the correct clinical context clinch the diagnosis. In fact, if JCV DNA is not detected but the imaging and scenario are highly suspicious, repeat testing should be performed. CSF studies otherwise can be normal or can show a modest lymphocytic pleocytosis with normal or slightly elevated protein concentration. These findings notably are all but indistinguishable from acute or chronic HIV meningitis. Hypoglycorrhachia is not found. MRI shows multiple T1-weighted hypointense and T2-weighted hyperintense plaques in the subcortical white matter that involve the subcortical U-fibers but do not involve the cortical ribbon. Middle cerebellar peduncular involvement is common (Fig. 66.8). In the setting of immune compromise, gadolinium enhancement is seen only about 15% of the time, whereas in the setting of immune reconstitution, this number increases but only to about 40%.

Treatment

There are no specific treatments for PML except to reconstitute the immune system. Potential viral-targeted therapies have included 5HT2A antagonists; mefloquine; and antivirals such as acyclovir, cidofovir, zidovudine, vidarabine, and cytarabine. These have largely been evaluated separately and have failed. In natalizumab-associated PML, plasmapheresis has been used to rapidly remove drug from the system. In HIV, cART has changed the epidemiology from 1-year survival of less than 10% to greater than 50%. Those with higher CD4 counts at diagnosis have more favorable outcomes.

INTRODUCTION

Acquired immunodeficiency syndrome (AIDS) is the most devastating pandemic of the 20th and early 21st centuries. It was first recognized in 1981 through a growing number of reports of rare opportunistic infections, including *Pneumocystis carinii* pneumonia (PCP), and malignancies, such as Kaposi sarcoma, occurring in previously healthy gay men. Similar cases were discovered in intravenous (IV) drug users, and in 1982, the Centers for Disease Control and Prevention (CDC) proposed epidemiologic surveillance criteria. In 1983, human immunodeficiency virus (HIV) type 1 was isolated from human peripheral blood lymphocytes, and shortly thereafter, this retrovirus was established as the cause of AIDS. As the worldwide magnitude of the HIV pandemic became clear, the pace of research grew. The virus was sequenced and its structure elucidated by x-ray crystallography. The life cycle of the HIV, with the discovery of binding to the CD4 glycoprotein receptor, leading to the immune dysregulation was discovered soon after initial viral identification. Further understanding of the mechanisms of human infection and pathogenesis and development of successful drug therapies occurred. Central nervous system (CNS) complications due to infection by HIV-1 were first described early in the epidemic, when severe neurocognitive disease attributable to the virus was common in individuals with profound immunodeficiency.

CLASSIFICATION OF HIV DISEASE

In 1986, the CDC proposed staging criteria for HIV infection. These were modified in 1987 to include HIV-associated dementia and myelopathy among the 23 AIDS-defining illnesses. Revisions, in 1993, added three laboratory categories that are stratified by CD4 cell numbers and three clinical categories ([Table 67.1](#)).

AIDS-defining illnesses were expanded to include positive HIV serology and pulmonary tuberculosis (TB), recurrent bacterial pneumonia, invasive cervical carcinoma, or a CD4 lymphocyte count less than 200 cells/mm³. These revisions define the end stage of HIV infection and clarify the relationship of specific clinical syndromes, especially those affecting the nervous system that are not themselves diagnostic of AIDS, to advanced immunosuppression. In contrast to the CDC system, the World Health Organization (WHO) Clinical Staging and Disease Classification System revised in 2006 can be used readily in resource-constrained settings without access to CD4 cell count measurements or other diagnostic and laboratory testing methods ([Table 67.2](#)).

The WHO system classified HIV disease on the basis of clinical manifestations that can be recognized and treated by clinicians in diverse settings and by clinicians with varying levels of HIV expertise and training. This classification system guides medical management of HIV-infected persons. CD4 lymphocyte count levels and viral load assays have mostly supplanted staging criteria for decisions about antiretroviral therapy. Staging is still useful for prognosis and decisions about opportunistic infection prophylaxis and identifying patients most at risk for opportunistic infections and malignancy.

EPIDEMIOLOGY

HIV infection is still an enduring pandemic affecting virtually all population groups and countries. According to the

2013 UNAIDS report, in 2012, there were 35 million people worldwide living with HIV infection. Among these HIV-positive individuals, 25 million (71%) are living in sub-Saharan Africa and 1.3 million live in North America. HIV-2 is restricted to West Africa and those countries with historical and socioeconomic ties to the region and commonly co-occurs with HIV-1. Retrospective analysis of banked blood showed that HIV was present in the United States in the 1970s. In 2013, the CDC estimated the prevalence of HIV/AIDS at 1.1 million Americans (Table 67.3). Estimates were that 16% of infected individuals were unaware of their HIV status. Cumulative deaths due to AIDS totaled 636,000, with 15,529 deaths in 2010.

In 2000, AIDS became the leading cause of death among African-American men aged 35 to 44 years and women aged 25 to 34 years. The disproportionate representation of African-American and Hispanic men is related to IV drug use: African-Americans represent approximately 12% of the U.S. population

P.566

but accounted for an estimated 44% of new HIV infections in 2009. African-Americans also accounted for 44% of individuals living with HIV infection in 2009. Hispanic/Latinos represent 16% of the U.S. population but accounted for 19% of individuals living with HIV infection in 2009. Although affected by drug use, unprotected heterosexual activity has become the predominant transmission risk for minority women. There has also been a significant increase in the incidence of HIV infection among the elderly. By 2015, it is anticipated that 50% of HIV-seropositive individuals will be older than age 50 years.

TABLE 67.1 1992 Centers for Disease Control and Prevention Classification of HIV Infection

Laboratory Categories

Category 1—CD4 lymphocyte count >500 cells/mm³

Category 2—CD4 lymphocyte count from 200 through 499 cells/mm³

Category 3—CD4 lymphocyte count <200 cells/mm³

Clinical Categories

Category A—asymptomatic infection, persistent generalized lymphadenopathy, and acute primary HIV infection

Category B—symptomatic conditions not included in the CDC 1987 surveillance case definition of AIDS that are judged by a physician to be HIV related or where medical management is complicated by HIV infection (e.g., sepsis, bacterial endocarditis, pulmonary TB, cervical dysplasia or carcinoma, vulvovaginal candidiasis)

Category C—any of the 23 conditions listed in CDC 1987 case definition for AIDS

CDC, Centers for Disease Control and Prevention; TB, tuberculosis.

Adapted from United States Congress, Office of Technology Assessment. *The CDC's Case Definition of AIDS: Implications of the Proposed Revisions-Background Paper*. Washington, DC: US Government Printing Office; 1992.

TABLE 67.2 World Health Organization Clinical Staging of Established HIV Infection

HIV-Associated Symptoms	WHO Clinical Stage
Asymptomatic	1
Mild symptoms	2
Advanced symptoms	3
Severe symptoms	4

Adapted from World Health Organization. *WHO Case Definitions of HIV for Surveillance and Revised Clinical Staging and Immunological Classification of HIV-Related Disease in Adults and Children*; 2007.

The introduction of combination antiretroviral therapy (cART) in 1996 profoundly changed HIV/AIDS epidemiology in the United States and other resource-rich countries. Since the introduction of cART, there has been a 38% decline in incident AIDS cases and a 67% decline in deaths from AIDS in the United States. Progress in some developing countries remains hampered by limited access to formal cART programs. Through the U.S. President's Emergency Plan for AIDS Relief (PEPFAR), UNAIDS, the WHO, as well as nongovernmental organizations and local ministries of health, there has been an increase in formal cART programs in many developing regions, with the hopes of disease stabilization in the next 5 to 10 years.

TABLE 67.3 Epidemiology of HIV/AIDS: United States and Global Data: 2012 and 2013

United States—through 2012	
Adults/adolescents	1,144,500
Pediatric (<13 yr)	10,834
Total	1,155,334
Demographics (Adult)	
<i>Race</i>	
African-American	44%
Non-Hispanic white	34%

Hispanic	21%
<i>Gender</i>	
Men	75%
Women	25%
Global—2008	
Total cases through 2012	35,300,000
Sub-Saharan Africa	25,500,000
South and Southeast Asia	3,900,000
Number of new HIV infections in 2007	2,300,000
Deaths due to AIDS in 2012	1,600,000
Children with AIDS (<15 yr) in 2012	3,300,000
Adapted from Centers for Disease Control and Prevention. www.cdc.gov . 2013; 2013 World Health Statistics. World Health Organization. www.who.int .	

The major routes of HIV transmission include sexual contact, mother-to-child, injection drug use with contaminated needles, and exposure to infected blood or blood products, with sexual transmission being the most common route of exposure worldwide. Worldwide, heterosexual activity is the most common mode of transmission. In the United States, homosexual activity is the most common risk behavior (45%) followed by high-risk heterosexual behavior (27%) and injection drug use (22%). The fastestgrowing populations with AIDS in the United States are women (who account for 26% of cases), African-American and Hispanic minorities, and IV drug users.

Recipients of blood products or clotting factor for hemophilia, or other coagulation/blood disorders, account for less than 1% of adult AIDS cases. In the United States, routine testing of blood products has largely eliminated this source of infection. Occupational exposure with validated transmission and seroconversion is well documented but rare. Most percutaneous or mucocutaneous exposures have been to blood or bloody fluid. Prospective studies of known exposures estimate the average risk for HIV transmission following percutaneous exposure (“needlestick”) to be approximately 0.3% and after mucous membrane exposure, 0.09%.

AIDS IN CHILDREN

This topic is discussed more fully in Chapter 147. By the end of 2012, nearly 4,500 children in North America younger than the age of 15 years were living with HIV infection. Most children are infected perinatally. Since 1992, perinatal transmission in the United States has declined sharply, from a peak of 1,000 to 2,000 cases annually to only 38 cases in 2006 resulting from successful implementation of CDC guidelines for maternal counseling, testing, and antiretroviral treatment.

Worldwide, however, perinatal transmission continues to post a large burden on worldwide incidence of HIV infection. There are an estimated 3.3 million HIV infections in children in 2012, with 260,000 new infections in 2012. Among these new infections in children, 88% of them are in sub-Saharan Africa. Perinatal infection of children depends on maternal viral load and the stage of pregnancy during which the infection is acquired. After delivery, a substantial number of children return to seronegative status.

Hallmarks of early infection include developmental delay and cognitive dysfunction, loss of previously acquired milestones, and vasculopathy that can cause stroke or hemorrhage. In Africa, some studies show no difference in neuropsychological measures and school success in HIV-positive children compared with HIV-negative controls who have similar nutritional and socioeconomic status. However, a mortality rate of 61% by age 4 years for very ill children must qualify such a comparison.

ETIOLOGY

HIV is an enveloped RNA lentivirus. It contains an RNA-dependent DNA polymerase (reverse transcriptase) that produces a provirus capable of integrating into host cell DNA. In the target cell, the virus exists in both free and integrated states.

P.567

Human HIV infection is considered a cross-species (zoonotic) infection, arising from monkeys infected with simian immunodeficiency virus (SIV) through multiple independent transmissions. Of the two recognized viral species, HIV-1 is found worldwide and is more prevalent, whereas HIV-2 is found in Western Africa and in Europe among African immigrants and their sexual partners. Sporadic cases of HIV-2 occur in the United States, but they are rare in comparison to HIV-1. A variety of evidence suggests that the AIDS pandemic most likely originated in equatorial Western Africa. HIV-1 is characterized by extensive genetic diversity and can be divided into three classes: group M (major), group O (outlier), and group N (new, non-M, and non-O). Group M is responsible for 90% of cases of HIV infection globally and is represented by nine major subtypes or clades. The HIV-1 subtypes in the United States and Europe differ from the subtypes seen elsewhere in the world. In the United States and Europe, clade B is the predominant subtype, whereas in sub-Saharan Africa, clades A, C, and D are predominant subtypes.

PATHOBIOLOGY

The primary infectious event includes breach of a mucosal barrier, enhancing viral entry. Viremia drives infection and massive depletion of CD4 T cells, particularly in the gut-associated lymphoid tissue (GALT). The immune reaction to the virus causes activation of CD8 T cells and virus-specific antibody production, which in turn promotes rebound of CD4 T cells and slowed viral replication, although importantly the mucosal lymph system does not recover to its preinfective condition. Progression of HIV is caused in part by this constant immune activation that detrimentally affects the immune system through a combination of direct loss of infected CD4 T lymphocytes and bystander cell killing. Infection of CD4 lymphocytes by HIV, mediated by viral attachment to the cell surface CD4 receptor, leads to cell death. In humans, the CD4 receptor is expressed on several cell types, including neurons and glia in the brain, but there is no evidence of viral replication in cells other than lymphocytes, macrophages, monocytes, and their derivatives. In 1996, a chemokine receptor was identified as a coreceptor that is necessary for viral entry into cells. In acute and early HIV infection, an M-tropic viral strain that prefers to replicate in macrophages with the chemokine receptor CCR5 predominates (R5 strain). In advanced infection, a T-tropic viral strain that prefers T cells with the chemokine receptor CXCR4 evolves and becomes predominant (X4 virus). Genetic variation in the chemokine receptor may affect susceptibility to HIV infection. Relative resistance to infection is observed in individuals who are homozygous for a 32 base-pair deletion in CCR5. Progression rates in AIDS may be affected by changes in the presentation of viral epitopes by infected cells to cytotoxic T lymphocytes. Accelerated progression to AIDS is associated with a single amino acid

substitution in the HLA-B35 allele (HLA-B*35-Px). However, the predictive value of observations about the effect of HLA polymorphisms on disease progression might be restricted to specific populations. Primary HIV infection can be asymptomatic or, in 50% to 70% of the cases, results in an acute, self-limited mononucleosis-like illness with fever, headache, myalgia, malaise, lethargy, sore throat, lymphadenopathy, and maculopapular rash. Painful ulceration of the buccal mucosa may impede swallowing (odynophagia).

Acute infection is characterized by viremia, high viral replication rates (up to 1 million RNA molecules per milliliter), viral isolation from peripheral blood lymphocytes, and high serum levels of a viral-core antigen, p24. Cytotoxic lymphocytes and soluble factors from CD8 lymphocytes are effective in reducing viral load to a set point that differs for each individual. Despite the effective early immune response, there is almost simultaneous immune dysfunction. Neutralizing antibodies, initially immunoglobulin (Ig) M and later IgG, appear in 2 to 6 weeks, resulting in clearance of viremia and a decrease in serum p24 levels. Rarely, antibodies do not appear for several months or, exceptionally, not at all.

Adverse immunologic effects occur early and are more severe in symptomatic persons. An early absolute lymphopenia affects both CD4 helper and CD8 suppressor cells with lymphocyte hyporesponsiveness to mitogens and antigens and thrombocytopenia. Lymphocytosis, especially of CD8 lymphocytes, usually follows with inversion of the CD4/CD8 ratio. Atypical lymphocytes are sometimes seen. Early changes in the CD4/CD8 ratio are usually transient, but reversion to more normal values is accompanied by persistent functional abnormalities. Cutaneous anergy is a direct result of the viral effects on CD4 cells.

After acute infection and seroconversion, clinical latency may last several years before onset of symptoms due to development of secondary infection, malignancy, or neurologic disease. There is no biologic latency, however. HIV infection is a chronic, persistent infection of variable viral replication rate.

The viral load set point after acute infection correlates with rate of progression to symptomatic infection or AIDS. Several proprietary assays provide quantitative measurement of plasma HIV RNA. The branched (b)DNA assay detects as few as 20 to 50 copies per milliliter. Recognition of acute infection is important because early antiretroviral treatment may prevent extensive seeding of lymphoid tissues or even eliminate infection. Without treatment, viral replication is robust and even in the absence of a decline in CD4 count may cause cardiovascular disease, nephropathy, and non-AIDS-related cancers.

It is estimated that 10 billion virions enter the plasma daily in untreated people. Virus is found mainly in tissues, not plasma; total lymphoid viral burden is three times that of plasma, the majority in follicular dendritic cells within germinal centers, where virus is passively adherent. The total body viral load is 100 billion HIV RNA copies. Approximately 10% of latently infected cells contain replication-competent provirus. Cellular destruction of lymphoid tissue is mediated by direct HIV-cytopathic effects, autoimmunity, and other mechanisms. Eventually, the lymphoid system is overwhelmed by the viral burden, which increases with advancing disease and culminates in AIDS.

Other factors that may augment HIV replication and the onset of symptoms include the following: the biologic variability of HIV and the appearance of increasingly virulent strains; host immunogenetics; and interactions with concomitant infection by cytomegalovirus (CMV), herpes simplex virus, hepatitis B and C viruses, human herpesvirus (HHV)-6, and human T-lymphotropic virus type 1 (HTLV-1) that upregulate expression of HIV and cell-killing ability by cytokines. Cytokines and chemokines are released by immune cells in response to infection and may upregulate or downregulate viral replication.

Other immunologic abnormalities in AIDS are caused by effects of HIV on B cells or macrophages, which result in hypergammaglobulinemia, impaired antibody responses to new antigens (including encapsulated bacteria), and increased levels of immune complexes. Antibodies to platelets may cause thrombocytopenia.

cART and specific prophylaxis have reduced the incidence of AIDS-related opportunistic infections and

States and other countries where treatment is readily available. cART refers to the use of three or more antiretroviral drugs from two antiretroviral drug classes. The major classes of antiretroviral drugs include nucleotide reverse transcriptase inhibitors, nonnucleotide reverse transcriptase inhibitors, protease inhibitors, integrase inhibitors, entry inhibitors, and fusion inhibitors. These antiretroviral drug classes interfere with different stages of HIV replication. The types of infections or neoplasms that complicate HIV infection have not changed and are similar worldwide, with varying frequencies depending on local factors. In untreated HIV infection, PCP is the most common opportunistic pathogen. Other opportunistic infections are often multiple and include fungal, viral, bacterial, and parasitic organisms. Many of these infections involve the CNS, usually secondarily but sometimes as the primary infection. For example, the papovavirus that causes progressive multifocal leukoencephalopathy causes a primary brain infection. Infections that are common in developing countries, such as trypanosomiasis, cysticercosis, and malaria, are sometimes seen in recent immigrants to the United States. Hepatitis B and C infections are important comorbid conditions, especially among those who acquire HIV from injection drug use. Kaposi sarcoma (an AIDS defining erythematous macular or nodular patch typically involving the face, oral mucosa, or upper trunk), Hodgkin and non-Hodgkin lymphoma, and cervical cancer, the most commonly encountered neoplasms related to immunosuppression, have become very rare in the setting of effective antiretroviral treatment. Non-AIDS-defining malignancies are now more common in treated populations, including anal cancer, lung cancer, liver cancer, and cancers of the head and neck. With the use of cART, HIV-positive individuals live significantly longer, and indeed more than 75% of HIV-positive individuals older than 50 years of age now die from non-HIV-related causes.

CENTRAL NERVOUS SYSTEM PATHOGENESIS

HIV enters the CNS at the time of primary infection and can result in no apparent disease, in acute self-limited syndromes, or in chronic disorders. Neurologic disorders are found in up to 70% of patients in clinical series, and more than 80% of autopsy series, of AIDS patients. In 10% to 20% of patients, the neurologic disorder is the first manifestation of AIDS. Uncommonly, a neurologic disorder is the sole evidence of chronic HIV infection and the cause of death. A high prevalence of neurologic disorders is observed in all populations studied, including those in sub-Saharan Africa and Asian regions bordering the Pacific Ocean. Despite the reduction in incidence of primary HIV-related syndromes, autopsy series of cART-treated patients who died of AIDS or unrelated causes show abnormalities in most brains, which in some cases were the cause of death. Cognitive impairment or HIV-associated neurocognitive disorder (HAND) is the most important HIV-related clinical syndrome.

Evidence of early CNS invasion includes isolation of virus from cerebrospinal fluid (CSF) or neural tissue (brain, spinal cord, peripheral nerve) and intrathecal production of antibodies to HIV. How HIV enters the CNS is not known. Possible mechanisms include intracellular transport across the blood-brain barrier within infected macrophages, as free-virus seeding of the leptomeninges, or as free virus after replication within the choroid plexus or vascular epithelium. In vitro studies using a proteomic platform suggest that HIV-1-infected monocyte-derived macrophages upregulate a large number of human brain microvascular endothelial cells, causing blood-brain barrier dysfunction that facilitates the development of CNS disease. Chemokines seem to play an important role in enhanced transmigration of HIV-infected lymphocytes across the blood-brain barrier. In vitro studies show enhanced HIV-infected leukocyte transmigration in response to the chemokine CCL2 (monocyte chemoattractant protein [MCP]-1) with disruption of the blood-brain barrier, enhanced permeability, reduction of tight junction proteins, and expression of the matrix metalloproteinases MMP-2 and MMP-9. In the brain, viral infection is detected only in microglial cells or macrophages by in situ hybridization techniques; it is not found in neurons or glial cells, even though these cells have CD4 and chemokine receptors.

The high frequency of neurologic disorders in HIV infection has led to the designation of HIV as a *neurotropic*

virus. The term *neurotropic* implies selective vulnerability and targeting of brain by the virus. Alternatively, the high frequency of neurologic disorders may be explained by the chronicity of infection, which results in continued seeding of the CNS and chronic immune activation. Specific neurotropism is not needed for continued accrual of neurologic damage. It has been difficult to establish correlation of neurologic syndromes with productive viral replication in the affected tissue. There is, however, an increase in the viral burden or viral load with advancing disease that parallels dementia and other neurologic syndromes. The mechanism of neurologic injury is believed to be indirect. Potential mechanisms include immune-mediated indirect injury; restricted persistent cellular infection; cellular injury due to cytokines released by infected monocytes and macrophages; excitotoxic amino acid injury; voltage-mediated increase of intracellular calcium; free radical damage; potentiation of inflammatory damage by chemokines and lipid inflammatory mediators (arachidonic acid and platelet-activating factor); direct cellular toxicity of HIV gene products, such as the envelope gp120, tat, and gp41; and cross-reacting antibody to an HIV glycoprotein binding a cell membrane epitope, resulting in cell receptor blockade. Studies show the involvement of double-stranded RNA-activated protein kinase in apoptotic neuronal death due to HIV-gp120. This enzyme is elevated in brain tissue of patients with HIV dementia. More than one mechanism may be important. Genetic changes in the virus in the host may result in noncytopathic CNS virus with enhanced replicative capacity in monocytes and macrophages, leading to a greater viral burden in the CNS than is apparent in the periphery. Phenotypic and viral load discordance is documented in several studies of plasma and CSF.

This compartmentalization of virus may explain the occurrence of neurologic syndromes when peripheral viral replication appears to be well controlled.

CLINICAL MANIFESTATIONS

HIV-RELATED SYNDROMES

Neurologic disorders may occur at any stage from seroconversion to AIDS. Dementia and myelopathy are diagnostic of AIDS even without opportunistic infections; neuropathy is the most common direct HIV-related neurologic disease. All levels of the neuraxis may be affected, including multisystem disorders. Neurologic disorders are likely to be transient in early HIV infection, but they become progressive or chronic with persistent infection and worsening immunosuppression.

The neurologic syndromes in early HIV infection are indistinguishable from disorders that occur with infection by other viruses (Table 67.4). These include aseptic meningitis, reversible encephalopathy, leukoencephalitis, seizures, transverse myelitis, cranial and peripheral neuropathy (Bell palsy, Guillain-Barré

P.569

syndrome), polymyositis, and myoglobinuria. Brachial neuritis and ganglioneuritis have been reported only rarely. The course is typically self-limited, and patients often experience full neurologic recovery. A recent study from the Multicenter AIDS Cohort Study suggests that older HIV-positive individuals in the cART era experience a higher incidence of neurologic disease compared to age-matched HIV-negative individuals. In addition, HIV-positive individuals experience neurologic diagnoses at an earlier age compared to HIV-negative individuals. Excess neurologic disease was found in the categories of nervous system infections, dementia, seizures/epilepsy, and peripheral nervous system disorders in this study.

TABLE 67.4 Primary HIV-Related Neurologic Syndromes: Acute Infection

Transverse myelitis

Cranial and peripheral neuropathies

Bell palsy

Acute inflammatory demyelinating polyneuropathy of the Guillain-Barré type

Polymyositis

Myoglobinuria

CSF abnormalities (pleocytosis up to 200 cells/mm³ and oligoclonal bands) differentiate HIV syndromes from postinfectious disorders. Tests for HIV antibody may be negative because these syndromes may precede or accompany seroconversion, and the tests must be repeated in several weeks. If acute HIV infection is strongly suspected, p24 antigen and viral load assay should be considered if serology is negative. Hepatitis B and hepatitis C serology should be determined in all HIV-seropositive patients. Early antiretroviral therapy may be offered to decrease the high viral load typical of acute infection quickly, thereby lowering the viral load set point. No specific treatment is indicated for these self-limited disorders except that plasmapheresis or immunoglobulin is used in cases of Guillain-Barré syndrome and steroids for polymyositis.

In chronic HIV infection, neurologic disorders may accompany systemic HIV disease or secondary disorders ([Table 67.5](#)).

Chronic or recurrent CSF pleocytosis sometimes occurs with meningeal symptoms but is often asymptomatic. Chronic pleocytosis does not predict any specific neurologic complication. Ascribing CSF pleocytosis to HIV infection requires exclusion of secondary pathogens or tumor. In a cross-sectional study, HIV-related CSF pleocytosis was uncommon in individuals with blood CD4 counts below 50 cells/ μ L or in those on effective antiretroviral therapy.

HIV-Associated Neurocognitive Disorder

Cognitive impairment is a well-recognized complication of chronic HIV infection in all populations; it can range from mild to severe ([Table 67.6](#)). Its prevalence may be underestimated in resource-limited settings. Despite some success, there are enormous challenges to developing special dementia scales for use in resource-limited settings, including multiple languages, regional dialects, and low formal education rates. The International HIV Dementia Scale is a brief screening test that can be performed by nonneurologists and has been validated as a potential screening test for dementia in HIV-positive individuals in resource-limited settings. There are several scales for classification of HIV cognitive impairment, including revision of the AIDS Task Force of the American Academy of Neurology (AAN) criteria.

TABLE 67.5 Primary HIV-Related Neurologic Syndromes: Chronic Infection

Persistent or recurrent meningeal pleocytosis with or without meningeal symptoms

Diffuse and focal cerebral syndromes

Dementia, static or progressive with or without motor signs

Mild cognitive impairment, neuropsychological test criteria only

Organic psychiatric disorder

Cerebrovascular syndromes

Cerebellar ataxia

Seizure disorder

Multisystem degeneration

Chronic progressive myelopathy

Cranial and peripheral neuropathies

Bell palsy

Hearing loss

Phrenic nerve paralysis

Lateral femoral cutaneous nerve

Chronic inflammatory demyelinating polyneuropathy

Distal symmetric sensory neuropathy

Mononeuritis multiplex

Autonomic neuropathy

Myopathy

Minor motor signs, usually motor slowness or tremor, may be present. HIV-associated dementia, known variously as *HIV-1-associated dementia complex*, *HIV dementia*, or *AIDS dementia complex*, is diagnostic of AIDS. Older

designations are subacute encephalitis, subacute encephalopathy, or HIV encephalitis. HIV dementia refers to HIV-positive individuals with moderate to severe cognitive impairment on neuropsychological testing and marked difficulties in activities of daily living due to the cognitive impairment. In the pre-cART era, HIV dementia, the most severe stage of HAND, was a common stage of cognitive impairment among HIV-positive individuals with advanced immunosuppression. In HIV-positive individuals on cART, HIV dementia is rarely seen, and less severe stages of HAND such as HIV-associated mild

P.570

neurocognitive disorder (MND) are the most common clinically recognized stage of cognitive impairment. HAND including all three stages (asymptomatic neuropsychological impairment [ANI], MND, and HIV dementia) may be seen in 40% to 50% of HIV-positive individuals with advanced infection in some studies, with ANI and MND being the most common stages. Peripheral neuropathy coexists in 25% of patients.

TABLE 67.6 HIV-1-Associated Neurocognitive Disorder

Severe Manifestations

HIV-1-associated dementia

Mild Manifestations

HIV-1-associated mild neurocognitive disorder

Asymptomatic neuropsychological impairment

HIV dementia in the absence of cART is an insidiously progressive subcortical dementia. Early symptoms include apathy, social withdrawal, diminished libido, slow thinking, poor concentration, and forgetfulness. Psychiatric syndromes, such as psychosis, depression, or mania, are sometimes profound and may be the first manifestation of HIV infection. Motor signs include slow movements, tremor, parkinsonian features, leg weakness, and gait ataxia. There may also be headaches, seizures, or frontal release signs. Although the disorder is usually progressive in HIV-positive individuals not on cART, some patients on cART develop a static level of disability, and others may improve in response to medical treatment for HIV or complicating disorders. When progressive, the disease culminates in akinetic mutism, an immobile bedridden state with global cognitive impairment and urinary incontinence.

In children, there may be a similar static or progressive encephalopathy. Most affected children meet criteria for AIDS, but progressive encephalopathy can occur before immunologic dysfunction is severe. Neurologic findings include intellectual deterioration, microcephaly, loss of developmental milestones, and progressive motor impairment that may culminate in spastic quadriplegia and pseudobulbar palsy. Seizures are usually due to fever. Myoclonus and extrapyramidal rigidity are rare.

The CSF is usually normal or shows mild pleocytosis, protein elevation, and oligoclonal bands. Virus can be cultured from CSF. In HIV-positive individuals not on cART, both CSF and plasma viral load correlate with occurrence of dementia but may be discordant in some cases where CSF load is greater than plasma. In HIV-positive individuals on cART, CSF and plasma viral load do not correlate with HAND stage. CSF markers of immune activation, HIV p24 antigen, β_2 -microglobulin, tumor necrosis factor, and antomyelin basic protein in cART-treated HIV-positive individuals do not correlate with severity of dementia. None of these markers is

predictive of, or specific for, dementia. CSF and serum markers such as neopterin and tryptophan levels and CSF serotonin metabolites and quinolinic acid levels lack predictive value or specificity but can correlate with severity of dementia. Elevated levels of CSF neurofilament protein, a marker of axonal injury, are found in HIV-infected patients with dementia. Levels decline in individuals who have a clinical response to antiretroviral therapy, suggesting its possible use as an indicator of drug efficacy. Efforts to identify markers for progression to dementia have been disappointing. A recent study suggested that increased levels of sphingomyelin and ceramide and the accumulation of lipid peroxidation products are associated with declining cognitive status. Further studies are needed to confirm these findings.

FIGURE 67.1 HIV-positive subject with progressive dementia. **A:** T1-weighted and **(B)** T2-weighted MRI scans show ventricular enlargement and cortical atrophy, particularly in the frontal lobe. There is also some mild periventricular T2 hyperintensity.

In adults, computed tomography (CT) or magnetic resonance imaging (MRI) scans show cortical atrophy and ventricular dilatation, sometimes with white matter changes. On CT, there is attenuation of white matter; MRI shows hyperintense white matter lesions on T2-weighted and proton density sequences ranging from discrete foci to large confluent periventricular lesions (Fig. 67.1).

CT in children shows basal ganglia calcification and cerebral atrophy. MRI white matter changes may not correlate with dementia and may disappear spontaneously or with antiretroviral therapy.

Abnormalities in functional neuroimaging are detected in HIV-infected individuals whether they have dementia or not. The abnormalities become worse or change with progressive cognitive

P.571

impairment. ^{18}F -fluorodeoxyglucose-positron emission tomography (PET) shows relative hypermetabolism in the thalamus and basal ganglia in HIV-infected individuals. Progressive dementia is accompanied by cortical and subcortical hypometabolism. Singlephoton emission computed tomography (SPECT) shows multifocal cortical perfusion deficits in the frontal lobes, worse in those with dementia. Cerebral metabolite abnormalities demonstrated by magnetic resonance spectroscopy (MRS) include elevated myoinositol and choline levels in frontal white matter indicative of glial proliferation in patients with mild cognitive impairment. Severe dementia is associated with decreased levels of *N*-acetylaspartate, a neuronal marker. Dynamic cerebral blood volume

(CBV) studies by functional MRI show increased CBV in deep and cortical gray matter in HIV-positive individuals and even greater increases in the deep gray matter of those with dementia. Continuous arterial spin label MRI showed reduced caudate blood flow and volume in patients with cognitive impairment. Abnormalities may improve with antiretroviral treatment.

Pathologic abnormalities in brain include microglial nodules, multinucleated giant cells, focal perivascular demyelination and gliosis, and neuronal loss in frontal cortex. Although there is often no correlation between the severity of these pathologic changes and the severity of dementia, recent studies suggest that neuronal injury may be missed by standard pathologic survey techniques. In a prospective study, severity of neurocognitive impairment was correlated with microneuroanatomic injury to dendritic structures that resulted in dendritic simplification but not to viral burden or presence of microglial nodules and multinucleated giant cells. Astrocyte cell death through apoptotic mechanisms may reduce the neuroprotective functions of this cellular population. In vitro studies show that soluble Fas ligand (sFasL) from HIV-infected macrophages triggers apoptosis of uninfected astrocytes. A study of pre-cART HIV-infected patients with dementia showed elevated CSF sFasL levels in this group compared with HIV-negative controls and HIV-positive nondemented patients. More prospective data are needed to understand the role of apoptosis in HIV dementia and the use of markers for apoptosis as predictors of dementia.

The incidence of HIV dementia is lower than the frequency with which pathologic abnormalities are found. The CDC reported a prevalence of 7.3% for the diagnosis of HIV encephalopathy in 1987 through 1991. The Multicenter AIDS Cohort Study Group reported a 4% prevalence of dementia diagnosis, with a 7% annual rate and 15% overall probability of dementia before death. There are increased mortality rates among demented patients. A subset of individuals may show clinical progression in their HAND stage. Some HIV-positive individuals on cART may demonstrate ongoing CNS changes as identified by subcortical atrophy on MRI studies in the absence of clinical changes. Other HIV-positive individuals may show clinical deterioration on neuropsychological testing. Some HIV-positive individuals may show clinical improvement which is sustained. Additional HIV-positive individuals with HAND may have a fluctuating course from abnormal to normal and then abnormal neuropsychological test performance again. HIV dementia now is rarely seen in the United States where cART is commonly used. However, in resource-limited countries, many HIV-positive individuals are not on cART. In 2012, according to UNAIDS, around 9.7 million people living with HIV infection had access to antiretroviral therapy in low- and middle-income countries. This number represents 61% of people eligible for treatment under the 2010 WHO guidelines and only 34% of people eligible under the 2013 WHO guidelines. In sub-Saharan Africa, where 70% of the world's HIV-positive population resides because HIV-positive individuals are frequently not on cART, the frequency of HIV dementia may be much higher than the prevalence in the United States. Studies in Uganda suggest that the frequency of HIV dementia among antiretroviral-naïve HIV-positive individuals presenting to an infectious disease clinic may be as high as 31% to 41%. If this proportion is seen throughout resource-limited countries, then HIV dementia may be among the most common forms of dementia globally along with Alzheimer disease and vascular dementia. The question of whether specific HIV subtypes are associated with an increased risk of dementia is unresolved, with some studies showing an increased risk for dementia in HIV subtype D-infected individuals compared to HIV subtype A-infected individuals in Uganda, whereas other studies show no association of HIV subtype with risk of dementia. Similarly, initial studies suggested that HIV subtype C may have a decreased risk of dementia compared to subtype B, but recent studies suggest no difference between HIV subtypes B and C and risk of dementia.

The diagnosis of HIV-associated dementia requires exclusion of secondary opportunistic infections or neoplasms. Other confounding variables include drug use, vitamin B₁₂ deficiency, metabolic disorders, concurrent infections such as hepatitis C infection, CNS side effects of medications (e.g., efavirenz, which can cause CNS side effects in 50% of HIV-positive individuals after initiation), and age-related comorbidities in an

aging HIV-infected population due to successful antiretroviral treatment. Older survivors of HIV are at risk for vascular disease and degenerative disorders associated with dementia such as Alzheimer disease. In most studies, antiretroviral therapy reduces the incidence and mortality of AIDS dementia. In general, the prevalence of HAND in HIV is expected to increase with longer survival and the aging of HIV-positive individuals. The primary treatment for HAND is cART, which is associated with cognitive improvement in the majority of antiretroviral-naïve HIV-positive individuals. Treatment of comorbid conditions frequently associated with HAND such as depression is also beneficial. Clinical trials of adjunctive therapies such as selegiline, a monoamine oxidase type B inhibitor, and minocycline have showed no benefit. Antioxidants and agents that block gp120 are ineffective. Neuropsychological test abnormalities can accrue with advancing disease. Those showing a decline in neuropsychological test performance, however, have an increased risk of death. In an early multicenter study of 19,462 HIV-infected people, the strongest predictors of significant dementia were CD4+ T-lymphocyte counts of less than 100 cells/ μ L, anemia, and an AIDS-defining infection or neoplasm (18.6% to 24.9% risk in 2 years). In the post-highly active antiretroviral therapy (HAART) era, HAND is often independent of advanced immunosuppression.

Antiretroviral therapy using drugs with good CNS penetration may benefit the symptomatic patient with CNS virologic escape, but some studies suggest that the beneficial effect of treatment is independent of CNS penetration. A randomized clinical trial of cART with good CNS penetration compared to cART with poor CNS penetration showed no clinical benefit for the group randomized to cART with good CNS penetration. Suppression of viral replication in both the blood and CSF is critical for effective treatment of HAND. Initiation of cART is usually associated with immune system recovery and cognitive benefits. However, some HIV-positive individuals after initiation of cART may experience clinical deterioration despite recovery of the immune system from immunodeficiency, a condition known as *immune reconstitution inflammatory syndrome* (IRIS). When IRIS involves the CNS, opportunistic infections of the CNS such as cryptococcal meningitis or progressive multifocal leukoencephalopathy may present.

P.572

In addition, an acute syndrome of fulminant HIV encephalitis can occur in rare cases in which cognition worsens despite virologic suppression and immune system recovery. Risk factors for IRIS include a low CD4 nadir at initiation of cART, the presence of an underlying opportunistic infection, and a sharp decline in viral load after starting cART. Corticosteroids have been used in HIV-positive individuals with noninfectious encephalitis after cART initiation, with clinical improvement in some cases. Additional studies of the role of corticosteroids for the treatment of IRIS are needed.

Further work is needed to understand the pathogenesis and risk for HAND in the post-cART era.

Stroke

Most studies show an association with stroke incidence and HIV status in the post-cART era that extends beyond traditional risk factors including hypertension, dyslipidemia, diabetes mellitus, and smoking. Although modification of these risk factors is an important strategy to decrease stroke risk among HIV-infected individuals, studies have demonstrated an excess risk of stroke in HIV infection. Multiple mechanisms unique to HIV infection may cause an increased stroke risk. Impaired fibrinolysis resulting in a hypercoagulable state may occur. Intracranial vasculopathy has been described in untreated, severely immunocompromised HIV infected individuals with and without strokes, often in combination with aneurysmal arteriopathy and, at times, with concomitant infections including varicella-zoster virus and CMV. Marked clinical and radiographic improvement of vasculopathy documented after initiation of cART suggests that this mechanism is likely of considerably less clinical relevance for virologically suppressed individuals on cART. In addition, cumulative exposure to cART may lead to a rise in vascular risk over time. Impaired glucose metabolism due to antiretroviral therapy may also add to stroke risk. In addition, stroke syndromes may follow secondary infections or neoplasms, such as

cryptococcus or other fungi, toxoplasmosis, TB, herpes zoster, CMV, syphilis, or lymphoma. Other causes include HIV-related vasculitis, cardiogenic emboli, thrombogenic conditions such as hyperviscosity, disseminated intravascular coagulation, and the presence of lupus anticoagulant. Cerebral hemorrhage may follow HIV-associated thrombocytopenia or toxoplasmosis.

Evaluation of cerebrovascular syndromes includes screening for classical risk factors including high blood pressure, impaired glucose tolerance, and hyperlipidemia. Additional studies that should be obtained include imaging; CSF examination; cultures for viruses, bacteria, mycobacteria, and fungi; serum and CSF antibodies for cryptococcus, syphilis, and toxoplasmosis; plasma and CSF HIV viral load; polymerase chain reaction (PCR) of CSF for suspect pathogens; echocardiography; carotid Doppler; lipid profiles; coagulation profiles; platelet count; and determination of procoagulants. If vasculitis is suspected, angiography or brain or meningeal biopsy may be useful. Management is directed to the underlying mechanism and may include a change in antiretroviral therapy.

Seizures

Seizure activity complicating HIV infection should raise the suspicion for an underlying structural brain lesion, especially in the setting of focal seizure activity, in patients whose CD4 counts are less than 400 cells/ μ L, and if focal neurologic signs are present on examination. If seizures are generalized, common etiologies include an underlying metabolic derangement or diffuse meningoencephalitis. Underlying infectious and noninfectious causes to consider, especially in those patients with low CD4 counts, include toxoplasmosis, cryptococcoma, primary CNS lymphoma, and progressive multifocal leukoencephalopathy. In a study of 100 consecutive cases, secondary pathogens were identified in 53% and HIV encephalopathy in 24%; there was no identified cause in 23%. In another study, status epilepticus was associated with CNS infection in a third of patients, most commonly toxoplasmosis. Seizures in HIV-infected patients have been reported in 4% to 14% of patients and are a common disease-defining presentation. The diagnosis of seizures in HIV patients includes basic laboratory parameters, drug levels if available, neuroimaging, lumbar puncture, and electroencephalogram (EEG). If antiepileptics are indicated, one should consult recent guidelines for the initiation of antiepileptic medications and dosage adjustments of antiretroviral drugs due to antiepileptic drug-antiretroviral drug interactions by a joint panel of the AAN and the International League Against Epilepsy.

Leukoencephalopathy

Leukoencephalopathies in acute or chronic HIV infection include acute fulminating and fatal leukoencephalitis, multifocal vacuolar leukoencephalopathy presenting as rapid dementia, and a relapsing-remitting leukoencephalitis that may simulate multiple sclerosis. The pathogenesis of these syndromes is uncertain. A severe demyelinating leukoencephalopathy with intense perivascular infiltration by HIV-gp41 immunoreactive monocytes/macrophages and lymphocytes is described in patients who failed HAART treatment despite good virologic response in one case. Some speculate this illness is a form of IRIS.

Movement Disorders

Movement disorders in patients with HIV infection were frequently described in the pre-cART era, including patients presenting with tremors, chorea, dyskinesias, and athetosis, most commonly associated with opportunistic infections such as toxoplasmosis. In the post-cART era, movement disorders can also be present, specifically tremors and parkinsonism, which may arise as a consequence of primary infection or side effects of medications. In the current cART era, movement disorders are most commonly described in the setting of HAND. Cognitive decline typically precedes tremor and gait disturbance. Interestingly, there appears to be a greater susceptibility to drug-induced parkinsonism in HIV-infected patients likely related to dopaminergic neuron dysfunction from primary HIV infection which occurs early in infection. Movement disorders related to peripheral neuropathy have also been frequently described in HIV, including restless legs syndrome as well as painful legs

and moving toes syndrome.

Myelopathy

Chronic progressive myelopathy, an AIDS-defining illness, is characterized by progressive spastic paraparesis, ataxia, and sphincter dysfunction. Vascular myelopathy presents with a subacute onset of clinical signs and symptoms, developing over weeks to months. Common symptoms include bilateral lower extremity weakness with spasticity. Patients also experience bowel, bladder, and erectile dysfunction with variable sensory disturbances. Deep tendon reflexes are hyperactive with an extensor plantar response. Pathologic findings are similar to those of subacute combined degeneration due to vitamin B₁₂ deficiency and include vacuolar change with intramyelin swelling or demyelination that is most severe in the lateral and posterior columns. Microglial nodules and giant cells are sometimes seen, and HIV can be sometimes cultured or detected by hybridization techniques. Pathologic abnormalities are more common than clinical symptoms. Diagnosis requires ruling out causes by measuring serum vitamin B₁₂ levels, copper levels,

P.573

rapid plasma reagin (RPR), and HTLV-1 antibodies before making the diagnosis. Lumbar puncture should be performed to rule out infection with herpes simplex virus, varicella-zoster virus, CMV, and neurosyphilis. In HIV-associated vacuolar myelopathy, the CSF may be normal, or it may show mild pleocytosis with mild elevation in protein. Neuroimaging should be performed, although it is important to note that the spinal MRI may be normal or it may show spinal atrophy or patchy abnormalities on T2-weighted images. Somatosensory evoked potentials (SEP) help to confirm myelopathy, whereas nerve conduction studies can detect coexistent neuropathy if present. No specific treatment is available for myelopathy. The impact of cART is unknown. Antispasticity drugs such as baclofen or bladder relaxants such as imipramine must be used cautiously to avoid sedation or exacerbating weakness.

Motor Neuron Disease

Several cases of an amyotrophic lateral sclerosis (ALS)-like illness have been reported as the initial neurologic syndrome in patients with varying degrees of immunosuppression, ranging from profoundly reduced to near-normal CD4 lymphocyte levels. Clinically, HIV-associated ALS differs from sporadic ALS in that the patients present with symptoms at a younger age, have a more rapid progression, have a high CSF protein, and may recover after initiation of cART. Electromyographic (EMG) features have been shown to be consistent with ALS in one series of six patients. It is important to note that because of the potential reversibility of ALS-like symptoms in HIV infection, testing for HIV infection is generally recommended in younger patients presenting with motor neuron symptoms.

Peripheral Neuropathy

Distal sensory polyneuropathy (DSPN) is the most common neurologic manifestation of HIV infection, with more than 50% of patients with advanced HIV having evidence of DSPN on neurologic examination. Risk factors for development of sensory neuropathy include advanced age, lower CD4 nadir, current ART use, and past “D-drug” use (specific dideoxynucleoside analog antiretrovirals, that is, ddI [didanosine], ddC [zalcitabine], and d4T [stavudine]). Overall, the incidence of neuropathy has increased because of the longer survival of HIV-infected patients, likely related to comorbidities including diabetes mellitus, alcohol abuse, and vitamin B₁₂ deficiency.

Symptoms are typically symmetric, predominantly distal and sensory. Patients may experience numbness, tightness, pain, burning, or hyperalgesia in the feet. Signs include stocking-glove sensory loss, mild muscle wasting and weakness, and loss of ankle jerks. Conduction studies show sensorimotor neuropathy with mixed axonal and demyelinating features. Clinically, HIV-related DSPN is indistinguishable from the neuropathy due to nucleoside reverse transcriptase inhibitors. Pathologic findings include axonal degeneration, loss of large

myelinated fibers, and variable inflammatory cell infiltration. CSF may be normal or show mild pleocytosis and elevated protein. HIV can rarely be cultured from nerve, but the cellular localization of the virus is not known. The neuropathy may be mediated by the binding of gp120 envelope viral glycoprotein to sensory ganglion cells.

Neuropathic pain is associated with significant disability in daily activities, unemployment, and overall reduced quality of life. It is sometimes responsive to anticonvulsants (gabapentin, pregabalin, lamotrigine), tricyclic antidepressants, selective serotonin-norepinephrine reuptake inhibitors (duloxetine), topical anesthetic patches or creams, high-concentration capsaicin patch, and nonsteroidal or narcotic analgesics. Immune globulin is sometimes used in refractory cases, but reports of success are only anecdotal. Clinical trials have shown that recombinant human nerve growth factor is effective, but it is currently unavailable. There are also reports that smoked cannabis is effective for pain but may be associated with CNS side effects.

Other clinical manifestations of HIV infection include mononeuropathies, mononeuritis multiplex, inflammatory demyelinating polyneuropathy, and ganglioneuritis. Inflammatory demyelinating polyneuropathy may occur in its acute form early in the course of disease as part of the acute retroviral syndrome. Chronic inflammatory demyelinating polyneuropathy may also occur early in infection when there is immune dysregulation. It is distinguished from Guillain-Barré syndrome by a subacute or progressive course and variable response to corticosteroids, intravenous immunoglobulin (IVIG), or plasmapheresis. Electrodiagnostic studies show demyelination with variable axonal damage. Histopathologic studies reveal epineurial inflammatory cell infiltrates, demyelination, and axonal degeneration. CSF may show a pleocytosis, but findings are nondiagnostic. Mononeuropathies due to entrapment neuropathies are also commonly seen in patients with HIV infection. It is important to note that focal cranial neuropathies warrant further evaluation including neuroimaging and CSF analysis. Mononeuropathy multiplex due to peripheral nerve infarction associated with vasculitis is rarely described secondary to primary HIV infection and is more frequently described with CMV opportunistic infection as described later in this chapter.

Myopathy

HIV-associated myopathy may range from mild symptoms to severe rhabdomyolysis, with HIV-associated polymyositis being the most frequent clinical syndrome. HIV-associated polymyositis is clinically and pathologically similar to autoimmune polymyositis and is characterized by proximal limb weakness, mild creatine kinase elevation, and myopathic features on EMG. The mechanism by which HIV leads to inflammatory myopathy is not fully understood, but a T-cell-mediated and MHC I-restricted cytotoxic process triggered by HIV has been proposed. HIV-associated myopathy has also been described as part of an IRIS. Although treatment is not established in HIV-associated myopathy, patients may respond to steroids or IVIG. Other differentials to consider include myopathies related to cART or infectious etiologies. Stavudine (d4T) can cause HIV-associated neuromuscular weakness syndrome (HANWS) which is characterized by a rapidly progressive weakness, resembling Guillain-Barré syndrome, with associated lactic acidosis due to mitochondrial dysfunction. Zidovudine may also cause a clinically similar myopathy due to its effects on mitochondria. Muscle biopsies show ragged red fibers and deficient cytochrome oxidase. Some patients respond well to steroid therapy without accelerated progression of HIV disease.

OPPORTUNISTIC INFECTIONS

The spectrum of viral, bacterial, and fungal opportunistic infections, well described for their devastating consequences prior to the cART era, remain prevalent in many countries where cART medications remain poorly accessible, in patients not adherent to their HIV drug regimen, and as immune reconstitution phenomenon ([Table 67.7](#)).

Meningitis may be caused by such viruses including herpes simplex virus, varicella-zoster virus, CMV, and Epstein-Barr virus (EBV); fungi (*Cryptococcus*, *Histoplasma*, *Coccidioides*, *Candida*); bacteria

(*Listeria*, *Treponema pallidum*, atypical or conventional mycobacteria, pyogenic bacteria such as *Salmonella*, *Staphylococcus aureus*); and neoplasm (carcinomatous meningitis due to lymphoma).

TABLE 67.7 Secondary Neurologic Syndromes in HIV Infection and AIDS: Opportunistic Infections and Neoplasms

Leptomeninges

Viral	CMV, HSV, VZV, EBV, hepatitis B
Fungal	<i>Cryptococcus</i> , <i>Histoplasma</i> , <i>Coccidioides</i> , <i>Candida</i>
Bacterial	<i>Listeria</i> , <i>Treponema pallidum</i> , pyogenic bacteria (<i>Salmonella</i> , <i>Staphylococcus aureus</i>), atypical or conventional mycobacteria
Neoplasm	Lymphoma

Cerebral Syndromes

Diffuse Encephalopathy or Encephalitis

Viral	CMV, HSV, VZV, hepatitis C
Bacterial	Atypical mycobacteria
Parasitic	<i>Acanthamoeba</i> , <i>Toxoplasma</i>
Neoplasm	Lymphoma

Focal Cerebral Syndromes

Viral	HSV, VZV, PML
Fungal	Abscess due to <i>Cryptococcus</i> , <i>Candida</i> , <i>Zygomycetes</i> , <i>Histoplasma</i> , <i>Aspergillus</i>
Bacterial	Abscess due to pyogenic bacteria, mycobacteria (tuberculoma), <i>Listeria</i> , <i>Nocardia</i>
Parasitic	<i>Trypanosoma cruzi</i> , <i>Taenia solium</i> , <i>Toxoplasma</i>
Neoplasm	Primary or metastatic lymphoma, glioma, metastatic Kaposi sarcoma

Cerebrovascular Syndromes and Seizures

Viral	VZV, HSV, rarely PML
Fungal	<i>Cryptococcus</i> , <i>Aspergillus</i>
Bacterial	<i>T. pallidum</i> , <i>Mycobacterium tuberculosis</i>
Parasitic	<i>Toxoplasma</i>
Neoplasm	Lymphoma, lymphomatoid granulomatosis, metastatic Kaposi sarcoma
Other	Cerebral hemorrhage, cardiac emboli, vasculitis

Movement Disorders

Viral	PML, HIV
Bacterial	CNS Whipple disease
Parasitic	<i>Toxoplasma</i>

Spinal Cord Syndromes

Viral	VZV, CMV, HSV, HTLV-1
Bacterial	Mycobacteria, myogenic bacteria, <i>T. pallidum</i>
Parasitic	Toxoplasmosis
Neoplasm	Lymphoma, Kaposi sarcoma

Cranial and Peripheral Neuropathy

Viral	CMV (retinitis, polyradiculitis, mononeuritis multiplex)
Fungal	<i>Candida</i> (retinitis)
Parasitic	<i>Toxoplasma</i> (retinitis)

Myositis

Bacterial	<i>S. aureus</i> , mycobacteria
Parasitic	<i>Toxoplasma</i>

CMV, cytomegalovirus; HSV, herpes simplex virus; VZV, varicella-zoster virus; EBV, Epstein-Barr virus;

PML, progressive multifocal leukoencephalopathy; CNS, central nervous system; HTLV-1, human T-lymphotropic virus type 1.

Focal brain syndromes may be caused by *Toxoplasma*, progressive multifocal leukoencephalopathy, abscesses related to *Nocardia*, *Listeria*, *Taenia solium*, *Candida*, *Cryptococcus*, *Histoplasma*, *Aspergillus*, *Coccidioides*, *Mycobacterium tuberculosis*, atypical mycobacteria, and pyogenic bacteria.

VIRAL INFECTIONS

The pattern of opportunistic viral infection associated with AIDS has changed since the introduction of effective HIV therapy. Early in the AIDS epidemic, syndromes such as shingles or recurrent aseptic meningitis raised suspicion of an immunodeficient state, and the encephalitis eventually attributed to HIV itself was initially attributed to CMV infection. In contrast, contemporary concerns include facilitation of HIV spread by simultaneous herpes genital infection, use of vaccinations in households of AIDS patients, and other epidemiologic considerations. However, in severely immunosuppressed patients, viral infections of the nervous system remain prominent. For further information about viral infections, see [Chapter 66](#).

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) was recognized early in the HIV pandemic as a complication of AIDS in profoundly immunosuppressed patients. PML is caused by JC virus (JCV), which is a ubiquitous polyomavirus. CNS disease is characterized by lytic infection of oligodendrocytes, causing demyelination. Clinically, patients develop a subacute neurologic decline with focal neurologic symptoms and signs. Localization is hemispheric in 85% to 90% of cases; the posterior fossa is affected in the remainder. Focal or generalized seizures occur in 6% of patients. Imaging shows hypodense subcortical lesions on CT and T2-hyperintense lesions on MRI that spare the cortical gray matter ([Fig. 67.2](#)). In PML-IRIS, MRI may show contrast enhancement on T1 postgadolinium sequences, most commonly associated pathologically with CD8+ T cells infiltrating the perivascular spaces. CSF analysis should be performed for JCV detectable on PCR, although a negative study does not exclude the diagnosis, and repeat testing is often recommended if clinical and radiographic imaging is consistent with the diagnosis.

FIGURE 67.2 A 38-year-old woman with a history of HIV/AIDS recently resumed antiretroviral medication with CD4 count rising from 23 to 78 cells/ μ L in 2 months, viral load of 340,000, presenting with left-sided weakness that became worse after 2 weeks, and diagnosed with PML as a complication of IRIS. **A:** Fluid-attenuated inversion recovery (FLAIR) hyperintense lesions in bilateral frontoparietal white matter extending to the subcortical regions, larger on the right than left, associated with **(B)** irregular peripheral enhancement. (Courtesy of Dr. Doris Lin, Department of Radiology, Johns Hopkins University School of Medicine.)

In AIDS patients, PML lesions may stabilize spontaneously, and they may also respond to antiretroviral therapy. cART has led to significant improvement in survival, although patients are often left with serious neurologic sequelae. Despite anecdotal reports of efficacy, clinical trials have not shown any benefit from IV or intrathecal cytosine arabinoside, topotecan, and cidofovir. Immune reconstitution following antiretroviral therapy favorably impacts the clinical course in some but not all patients with PML. This may be explained by a selective loss of JCV-specific CD4 cells. The IRIS with either emergence or clinical progression of PML has been reported. When PML is the AIDS-defining illness, improved prognosis is associated with CD4 cell counts greater than 300 cells/ μ L, evidence of inflammatory response indicated by gadolinium enhancement on MRI, and reduction in the JCV viral load in CSF.

P.576

Varicella-Zoster Virus

Varicella-zoster virus (VZV), the causative agent of varicella (chickenpox) and herpes zoster (shingles), is common in the general population with a lifetime prevalence of 15% to 30%. A ubiquitous latent virus, VZV remains dormant in the dorsal root ganglia after primary infection, characterized by fever and vesicular rash, most commonly occurring in early childhood. In severely immunosuppressed patients, the infection is reactivated, leading, in some cases, to disseminated diseases with manifestations including pneumonia, diffuse rash, and visceral involvement. Neurologic syndromes resulting from reactivation of VZV in the immunocompromised patient also include shingles, transverse myelitis, meningoencephalitis, and vasculitis.

Shingles beginning with painful dysesthesias or paresthesias (often described as itching) is followed in 7 to 10 days by a contagious vesicular rash that eventually crusts. The acute phase lasts up to a month and may be followed by chronic neuralgic pain for years, although this is less likely if effective antiviral treatment is started promptly. Location is most commonly thoracic, followed by cervical and trigeminal dermatomal distributions. Neurologic complications in addition to postherpetic neuralgia include large or small-vessel stroke due to vasculitis induced in the vessel wall by the virus, myelitis, segmental myoclonus, and meningitis or encephalitis. *Zoster ophthalmicus*, which involves the first division of the trigeminal nerve, can lead to blindness from corneal scarring.

Diagnosis is made by CSF PCR analysis or antibody detection. VZV antibodies can be detected in 2.5% to 7% of HIV-infected patients with meningitis, encephalitis, myelitis, or retinitis who have a history of shingles. MRI of the brain or spinal cord may show focal or meningeal enhancement. In patients with encephalitis, CSF shows a mononuclear pleocytosis, increased protein, and, sometimes, low glucose.

Treatment of VZV complications with acyclovir or famciclovir should be started within 72 hours of the rash to prevent pain. Vaccination with two doses of live attenuated virus is recommended even in HIV-infected patients if their CD4 cell count is greater than 200 cells/ μ L, as this may decrease future complications.

Herpes Simplex Viruses

Herpes simplex virus (HSV) is a neurotropic virus, causing encephalitis in both immunocompetent and immunosuppressed patients. The virus targets structures of the mesial temporal lobe, producing symptoms

including headache, fever, confusion, language and memory impairment, and, in severe cases, depressed consciousness and status epilepticus. In those who are immunosuppressed, a more indolent course may present due to the limited inflammatory response that can be mounted. Diagnosis is made with multiplex PCR on CSF instead of brain biopsy, although false-negative CSF PCR has occurred. It is important to note that CSF pleocytosis may be absent in HIV-positive patients. Quantifying the viral load offers prognostic information: Mortality is 22% in patients who have greater than 100,000 copies per microliter, whereas sequelae are mild to moderate (seizures, permanent memory impairment) in those with fewer viral copies. Neuroimaging may show edema and hemorrhagic necrosis in the temporal lobes and basal frontal lobes, reflecting the path of viral entry from its latent presence in the trigeminal nerve. In a retrospective analysis, immunocompromised adults had more extensive involvement of the brain with involvement of the brain stem, cerebellum, and atypical regions including scattered lesions in the cerebrum, sometimes in the absence of temporal lobe involvement. EEG shows focal slowing, often with periodic complexes or other epileptiform discharges in the same areas. Abundant viral inclusions (Cowdry type A bodies) can be seen in patients without necrosis or hemorrhage on pathologic examination. Serum antibodies to herpes simplex 1 are present in up to 70% of the general population and to herpes simplex 2 in 16% to 33%. Because of this, the presence of antibodies does not help in diagnosis. Morbidity and mortality of HSV encephalitis in HIV patients remain high despite acyclovir, as patients may present atypically and may have associated acyclovir resistance.

HHV-6 and HHV-7 are important causes of encephalitis, meningitis, and myelitis in patients with AIDS that also have predilection for the temporal lobes. HHV-8 is responsible for Kaposi sarcoma, which rarely involves the CNS.

Cytomegalovirus

CMV is typically a manifestation of severe immunocompromised state (CD4 count <50 cells/ μ L) and most commonly presents with retinitis and gastrointestinal symptoms but may also present with a primary neurologic syndrome including rhombencephalitis, ventriculitis, or polyradiculopathy. CMV-associated polyradiculopathy is a common neurologic presentation with rapid development of flaccid paraplegia, urinary retention, and pain radiating into the lumbar and sacral root distributions. CMV encephalitis may present with subcortical diffuse white matter abnormalities and may be clinically difficult to differentiate from HIV-associated encephalopathy. A neuropathology study of HIV-infected patients reported 28 (17%) cases of CMV encephalitis, most of them with premortem diagnosis of HIV-associated cognitive decline.

Diagnostic workup should include ophthalmologic examination, as 30% of patients with neurologic CMV complications present with concomitant CMV retinitis, and CSF should be tested for CMV-PCR. Treatment recommendations for neurologic CMV complications vary and include ganciclovir, foscarnet, or both. Induction therapy is recommended for at least 4 weeks, with maintenance therapy for at least 6 months with monitoring of CSF PCR and immune reconstitution.

Human T-Lymphotropic Virus Types 1 and 2

HTLV is also neurotropic and a member of the same family of retroviruses as HIV. There is conflicting evidence on whether HTLV-1 coinfection accelerates or slows HIV infection and whether HIV coinfection predisposes to clinical manifestations of tropical spastic paraparesis. HTLV-1 causes a chronic spastic paraparesis with gradual onset, and its most frequent symptoms are gait disturbance and urinary symptoms. Contrary to the conflicting evidence of HTLV-1 coinfection, it is generally accepted that HTLV-2 coinfection exerts a negative effect on HIV-1 replication by modulating the cellular microenvironment, favoring its own viability and inhibiting HIV-1 progression. Therapy for HTLV-1/2 remains symptomatic using medications to improve spasticity. Treatment with cART including zidovudine/lamivudine may decrease HTLV-1 viral load and improve neurologic function, although no randomized control trials have been conducted.

Hepatitis B and C

Due to shared mode of transmission, coinfection of HIV and HBV is common, with an estimated 4 million people worldwide being coinfecting. Neurologic conditions caused primarily by hepatitis B infection including peripheral neuropathy and encephalopathy related to hyperammonemia may increase the severity of cognitive decline and peripheral neuropathy symptoms seen with primary HIV infection. HIV and hepatitis C virus (HCV) share large worldwide populations

P.577

as well with an estimated 25% to 40% of individuals being coinfecting in the United States, with the highest number in those who are IV drug users. HCV alone is known to be neurotoxic, and there is evidence that with coinfection, the neurotoxic effects of HCV and HIV infection are additive, although one of the major issues in studying this population is the many confounders including history of IV drug use, sex, and educational status. In one study, clinically significant HIV-associated neurocognitive decline and peripheral neuropathy are not exacerbated by active HCV infection in the setting of optimally treated HIV infection, although the long-term consequences of HCV coinfection remain important and incompletely understood. HCV coinfection has been also correlated with an increased risk of primary intracranial hemorrhage, although the role for HCV coinfection in the risk of ischemic stroke is less well-defined.

FUNGAL INFECTIONS

Fungal infections and their treatment are discussed in detail in Chapter 64, so only those aspects important for HIV-infected patients are presented here.

Cryptococcosis

Cryptococcal infection, the most common cause of meningitis in AIDS, was a presenting illness in 25% to 50% of AIDS patients in older clinical series and remains prevalent in many regions worldwide. The yeast is a ubiquitous environmental encapsulated fungus found in soil and bird feces and enters the body via inhalation. CNS involvement emerges from latent infection most commonly when CD4 counts fall below 100 cells/ μ L.

Cryptococcal meningitis most commonly presents as a subacute meningitis or meningoencephalitis. Some patients demonstrate more severe symptoms such as seizures, lethargy, and coma resulting from elevated intracranial pressure (ICP). In protracted meningeal infection, small cryptococcomas can be found, and stroke may occur due to vasculitis. CT and MRI can be normal early on but show hydrocephalus and meningeal enhancement as the infection evolves. Cryptococcomas can be visualized near the ventricles and adjacent to subarachnoid spaces. CSF should be tested for cryptococcal antigen and cultured for fungus. In resource-limited settings, India ink staining is frequently used, as cryptococcal antigen testing may not be available. CSF opening and closing pressure should be measured, as it is elevated in the majority of patients with cryptococcal meningitis. The principles of treatment for patients with cryptococcal meningitis include (1) antifungal therapy, (2) lowering elevated ICP, (3) initiating or optimizing antiretroviral therapy to improve immune function, and (4) management of immune reconstitution if it develops. Induction therapy includes amphotericin B plus flucytosine. Fluconazole is the basis of maintenance therapy and must be continued until there is recovery of immune function. Patients with elevated opening pressure should undergo daily therapeutic lumbar punctures with measurement of closing pressures until pressures have normalized.

Primary prophylaxis using fluconazole or another azole may be instituted if the CD4 count falls below 200 cells/ μ L. Early initiation of antiretroviral therapy in the setting of cryptococcal meningitis has been shown to increase mortality, and treatment is typically delayed for at least a few weeks after treatment of fungal infection.

Candidiasis

Candida is a rare cause of meningitis in severely immunosuppressed patients. Autopsies have occasionally

shown *Candida* in brain parenchyma. Resistant organisms may emerge in patients who have been treated with fluconazole for primary prophylaxis.

Coccidioidomycosis

Coccidioidomycosis is endemic to the southwestern United States and certain areas of Mexico and Central and South America. Immunosuppressed patients more commonly develop disseminated infection, although rarely present with CNS involvement. Basilar meningitis is the most common presentation in those with neurologic involvement, which is typically accompanied by a reticulonodular diffuse infiltrative pneumonia. As the organism is often difficult to grow on CSF culture, presumptive diagnosis is often made through identification of *Coccidioides immitis* spherules in tissue, sputum, bronchoalveolar lavage (BAL) fluid, or other body fluid. Chronic meningitis due to *C. immitis* occurs in about 10% of patients from endemic areas with CD4 counts less than 200 cells/ μ L. The most common symptoms are headache and slowly worsening mental status changes. Symptoms are usually severe only in patients who develop endarteritis obliterans or hydrocephalus. Treatment of disseminated coccidioidomycosis includes systemic antifungal therapy with amphotericin B or azoles. Amphotericin B remains the drug of choice for life-threatening disease.

Histoplasmosis

Histoplasma capsulatum var *capsulatum* (*H. capsulatum*) primarily affects those living in the valleys of the Ohio and Mississippi rivers in the United States and those living in Latin America. *H. capsulatum* var *duboisii* is described only in Africa and is a common endemic mycosis in HIV-positive patients. In patients with advanced HIV infection, histoplasmosis typically manifests with disseminated disease, as opposed to the asymptomatic or limited pulmonary infection observed in the majority of healthy individuals exposed to *H. capsulatum*. Neurologic symptoms include headache and encephalopathy, with findings of a lymphocytic meningitis and focal parenchymal lesions in the brain or spinal cord.

Aspergillosis

Aspergillus fumigatus is a rare cause of brain abscess in HIV patients. *Aspergillus* is an angiotropic fungus that causes a necrotizing angitis in the brain. Secondary thrombosis and hemorrhage can occur, with the anterior and middle cerebral arteries being most commonly involved. Evolving hemorrhagic infarcts convert into septic infarcts with associated abscesses and cerebritis. Mycotic aneurysms may develop, or intra-arterial thrombosis may present with subarachnoid hemorrhage. Intracranial spread of *Aspergillus* infection occurs less frequently through direct or contiguous spread. Direct extension from the sinuses or orbit has been reported, causing abscess formation in the frontal lobes. Meningitis, less frequent than abscess, tends to involve the base of the brain. *Aspergillus*, myelitis, and invasion of the cavernous sinus have all been reported in AIDS patients. *Mucorales* can cause a similar picture, but this organism is not increased in frequency in AIDS patients.

Neuroimaging should be obtained prior to lumbar puncture to determine whether there is abscess formation. Organisms are rarely found in CSF, and surgical removal of *Aspergillus* abscesses may be the only manner of diagnosis. Amphotericin B combined with flucytosine and treatment of the source of infection is the treatment of choice.

PARASITIC INFECTIONS

The geographic and patient ecologies of parasitic and HIV infections intersect in many areas including the tropical environments of sub-Saharan Africa, Central and South America, Thailand, and

India, which foster the presence of malaria and other parasitic infections. Discussion in the following sections focuses on the interaction of parasitic infections in HIV-positive patients.

FIGURE 67.3 A: FLAIR MRI and **(B)** contrast-enhanced CT in an HIV-positive patient with toxoplasmosis. Extensive bilateral white matter T2 hyperintensity and multiple contrast-enhancing lesions are present.

Toxoplasmosis

For many years, toxoplasmosis was the most common cause of brain lesions in patients with AIDS and a frequent cause of death. Today, *Toxoplasma gondii* accounts for less than 2% of AIDS deaths in the United States, although it remains a major contributor to death in HIV-positive patients worldwide. Most of this gain is due to effective antiretroviral treatment, but effective and well-tolerated drugs for both treatment and prophylaxis of toxoplasmosis infection have also contributed. Although 95% of cases represent reactivation of latent infection, seronegative patients should avoid consumption of raw meat, unpasteurized milk, and exposure to cats and cat litter. Neurologic symptoms are referable to the sites of mass lesions. These most often occur at the gray-white junction and in the thalamus or basal ganglia. With multiple lesions, the clinical picture may appear nonfocal with seizures and signs of increased ICP. Meningitis, ventriculitis, and hydrocephalus have been described in the AIDS population, although they are less common presentations than focal mass lesions. Fever and headache are present in up to 70% of patients. CT and MR scans demonstrate ring-enhancing or nodular lesions with marked surrounding edema. With MRI, lesions have decreased signal with T1-weighted sequences but increased signal on T2-weighted images (Fig. 67.3). Multiple lesions are seen in 60% of cases. Thallium brain SPECT shows decreased uptake with a toxoplasmosis abscess which can be helpful in distinguishing CNS toxoplasmosis from primary CNS lymphoma, which shows increased uptake. A radiologic and clinical response to treatment should be seen in 7 to 10 days after the initiation of treatment. As a result, most cases are now diagnosed by therapeutic response rather than brain biopsy. Because severe immunosuppression may result in a false-negative response, *Toxoplasma* serology should be obtained as soon as a diagnosis of HIV infection is made. PCR for *Toxoplasma* can be done on CSF, but it has a low yield.

Treatment is with sulfadiazine or sulfadoxine and pyrimethamine. Folic acid should be given to avoid vitamin B deficiency in the patient. Inadvertent substitution of folic acid will allow survival of the parasite. Patients allergic to sulfa can undergo desensitization or receive atovaquone, clindamycin plus pyrimethamine, or cotrimoxazole, which can also be used for primary prophylaxis. Maintenance therapy can be stopped when the CD4 cell count exceeds 100 cells/ μ L.

Malaria

Malaria is widespread in many of the same areas where HIV is prevalent, although the effects of coinfection are poorly understood. Patients at highest risk for cerebral manifestations of malaria include those with a lack of acquired immunity toward *Plasmodium falciparum*. When it involves the brain, *P. falciparum* infection causes seizures, including status epilepticus; cerebral edema; alteration of consciousness and coma; and signs of brain stem dysfunction. The pathogenesis of cerebral malaria remains incompletely understood, but key factors include cerebral capillary blockade and parasitized red blood cell (pRBC) sequestration, the host's immunologic status and immunologic response to infection, and pathogen-related antigen expression and release of toxins that interact with cerebral endothelial structure and may contribute to secondary parenchymal changes. In children, sequelae in severe cases include developmental delay, cognitive dysfunction, epilepsy, attention deficit disorder, and poor school performance. Prevention includes reducing opportunities for exposure to mosquitos using insecticides and protective netting as well as prophylactic drug regimens determined

P.579

by local sensitivity patterns. Treatment includes parental antimalarial treatment, preferably with IV artesunate as well as supportive management.

Trypanosomiasis

Infection by *Trypanosoma brucei gambiense* or *rhodesiense* causes sleeping sickness in Africa, and *Trypanosoma cruzi* causes Chagas disease in South America; in AIDS patients, it may rarely lead to mass lesions or meningoencephalitis.

Cysticercosis

Immunosuppression does not affect the virulence and prevalence of *Taenia solium* infection, but neurocysticercosis should be considered in the differential of an HIV-positive patient from a region endemic for cysticerci. Lesions are most often calcified, although cysts containing live organisms in the larval state are occasionally seen. Anticonvulsant drugs are necessary to treat seizures, but antiparasitic agents, such as praziquantel and albendazole, are rarely needed.

BACTERIAL AND MYCOBACTERIAL INFECTION

Syphilis

Neurosyphilis, which is caused by *T. pallidum*, occurs with greater frequency in individuals coinfecting with HIV. Although not an opportunistic infection, syphilitic infection behaves differently in the presence of AIDS, and genital syphilis facilitates acquiring HIV infection. About 15% of patients with primary syphilis are seropositive for HIV. Conversely, positive serology for syphilis may occur in over 35% of some HIV-infected populations. Progression from primary syphilis (painless chancre) to later stages is typically more rapid in HIV-infected patients with lower CD4 counts. Syphilis can affect many parts of the nervous system including the meninges, brain, brain stem, spinal cord, nerve roots, and cerebral and spinal blood vessels. Syndromes of early neurosyphilis are more common than late syndromes (general paresis and tabes dorsalis). Syphilitic meningitis is the earliest neurologic complication of syphilis and is caused by invasion of the meninges by the spirochete. These can sometimes lead to cerebral vasculitis and stroke, most commonly involving the middle cerebral artery (MCA). Late stages of neurosyphilis include meningovascular involvement of the medium and large vessels as well as parenchymatous disease. Parenchymatous neurosyphilis is typified by tabes dorsalis, involving the dorsal roots and posterior columns, and general paresis. All patients who are HIV positive and also seropositive for syphilis require an analysis of CSF to detect and treat neurosyphilis before it has permanent and disabling consequences. Although a positive CSF serology using fluorescent treponemal antibody (FTA) or Venereal Disease Research Laboratory (VDRL) is enough to initiate treatment, the CSF in neurosyphilis also usually

contains white blood cells (WBCs) (usually mononuclear) and may also have increased protein. CSF VDRL, however, may be negative. Treatment with IV penicillin or 4 weeks of doxycycline or minocycline should be continued until there is a fourfold drop in serum titers. Ceftriaxone has a 23% failure rate, so its use is not recommended. HIV patients should have serology tested monthly for 3 months and at 3-month intervals thereafter. Lumbar puncture should be repeated after 6 months to ensure an adequate response to treatment. If serologic titers remain stable or rise, retreatment is indicated. Complete normalization of CSF VDRL reactivity is less likely in those with higher baseline values and peripheral blood CD4 counts less than 200 cells/ μ L.

Mycobacteria

MYCOBACTERIUM AVIUM-INTRACELLULARE

Mycobacterium avium-intracellulare was one of the earliest opportunistic infections described in patients with AIDS, although neurologic involvement was usually detected only at autopsy. The organism has been responsible for cases of immune reconstitution syndrome when antiviral treatment is started. Patients with disseminated *M. avium-intracellulare* may develop meningoencephalitis, cranial neuropathies, and epidural abscess, but defining neurologic syndromes due to *M. avium-intracellulare* has been difficult due to coinfection with several opportunistic organisms.

MYCOBACTERIUM TUBERCULOSIS

Worldwide, over 14 million people are coinfecting with TB and HIV. In 2012, an estimated 1.3 million died of TB, including 320,000 coinfecting with HIV. Tuberculous meningitis (TBM), which is the most deadly form of the disease, is five times more frequent in HIV-positive patients. The elevated risk of TB in HIV-infected persons is due in part to impairment of T-cell-mediated immunity, with TB risk increasing as CD4 cell count declines. In addition, the Beijing strain of TB, which has particularly high virulence, is associated with HIV infection and multidrug resistance.

The Beijing genotype *Mycobacterium tuberculosis* is significantly associated with HIV infection and multidrug resistance in cases of TBM.

CNS manifestations of TB occur from hematogenous dissemination of the bacteria from primary lung involvement, with formation of small subpial and subependymal foci. In HIV-positive patients, clinical presentation is typically similar to those who are HIV negative, although those who have very low CD4 counts can present atypically with more disseminated disease and altered consciousness. The most common presentation is meningitis, which is frequently a subacute or chronic presentation, followed by tuberculomas. Meningitis preferentially involves the basilar meninges and is associated with hydrocephalus, multiple cranial neuropathies, and ischemic stroke. TB may also present with spine disease, affecting the vertebral bodies (Pott disease) or the spinal cord. Diagnosis can be particularly challenging, as the clinical picture often mimics other opportunistic infections, including cryptococcal meningitis. CSF may show an early neutrophilic response followed by lymphocytic predominance, low glucose, and elevated protein, although studies have shown that there is a reduced CSF WBC count in HIV-infected adults not receiving cART compared to HIV-uninfected adults. CSF protein has also been noted to be normal in HIV-positive patients. When cultured from CSF, the organism takes 3 to 4 weeks to grow and can be difficult to detect. AFB can also be detected by PCR, although the sensitivity is low. Recent discovery of the use of CSF gene expert may be particularly beneficial in TBM, although ongoing studies are needed to determine its sensitivity and specificity in the HIV-positive population. Treatment for TBM is extrapolated from clinical trials for pulmonary TB and includes rifampicin, isoniazid (INH), pyrazinamide, and streptomycin (or ethambutol) for intensive phase followed by rifampicin and INH for maintenance along with adjunctive corticosteroids. Recent studies have shown that high-dose rifampicin and a fluoroquinolone early in treatment may decrease mortality. It is important to note that there is an increased risk for drug resistance to INH

and rifampicin in HIV-positive patients with TB, causing further challenges to treatment. For those who are cART naïve, delay in treatment initiation is recommended.

NEOPLASMS

Lymphoma incidence has declined markedly, from a range of 0.6% to 3% of patients in pre-cART clinical series to rare or no occurrence in post-cART series. Clinical signs are nonspecific and include focal neurologic signs, seizures, cranial neuropathy, and headache. CT may be normal or show hypodense lesions as well as single or multiple lesions with patchy or nodular enhancement. Thallium SPECT shows increased uptake in lymphoma, which aids in distinguishing it from toxoplasmosis which shows decreased uptake. EBV DNA is found in PCR studies of CSF but is not predictive of the diagnosis. Brain biopsy is required for diagnosis. Response to therapy with radiation and chemotherapy is improved by current antiretroviral regimens, with longer survivals and reports of complete tumor regression, although this is rare. Opportunistic infections may coexist with tumor and should be excluded by appropriate studies.

Other neoplasms reported rarely in AIDS patients include metastatic Kaposi sarcoma (associated with HHV-8) and primary glial tumors, but their incidence has also been dramatically decreased by cART. Non-AIDS-defining malignancies are now more important in the treated HIV population and occur with increased frequency compared with the uninfected population. An elevated risk is reported for the following cancers: anal, vaginal, Hodgkin lymphoma, liver, lung, melanoma, oropharyngeal, leukemia, colorectal, and renal. Routine cancer screening and smoking cessation are therefore important in this population.

NUTRITIONAL AND METABOLIC CONSEQUENCES

Nutritional deficiency may result from inadequate amounts of thiamine, vitamin B₁₂, folic acid, and glutathione which in turn may cause encephalopathy, dementia, neuropathy, or spinal cord disorders. Metabolic abnormalities often occur in late-stage disease and are reversible causes of encephalopathy. Testosterone deficiency is increasingly recognized in long survivors and may contribute to encephalopathy.

DIAGNOSTIC EVALUATION

The diagnostic evaluation of patients with a suspected HIV-related illness includes an enzyme-linked immunosorbent assay (ELISA) for HIV serology. Positive results are confirmed by Western blot. Depending on local laws, serologic tests may require informed consent and counseling. In patients with otherwise typical viral syndromes, such as aseptic meningitis or transverse myelitis, HIV infection must be suspected even in the absence of known high-risk behavior. Absence of antibodies during the acute illness does not negate the diagnosis because these disorders typically occur at the time of seroconversion. Other helpful diagnostic studies include determination of CD-lymphocyte subset ratio, plasma HIV viral load, serum protein electrophoresis, quantitative immunoglobulins, and platelet count.

Evaluation for specific neurologic syndromes should be preceded by a general physical examination to assist in excluding opportunistic infections or tumor. Evaluation may require biopsy of skin, lymph nodes, or bone marrow as well as chest radiography. Blood culture for viruses and fungi may also prove necessary.

Accurate neurologic diagnosis requires systematic evaluation, including assessment for the possibility of multiple diseases. Thorough neurologic examination should be performed. CSF is most helpful in syphilis, viral, and fungal infections. PCR of CSF can be helpful for pathogenic diagnosis of HSV, VZV, CMV, toxoplasma, and PML, but negative results do not exclude infection. CSF abnormalities are common in asymptomatic HIV infection and must be interpreted with caution in considering other possible conditions. CT and, especially, MRI are useful in distinguishing focal from diffuse brain lesions. MRS and thallium SPECT can help in distinguishing tumor from infection. Proton MRS and other functional imaging may also be useful in HIV-associated cognitive impairment.

Brain biopsy may be required for differential diagnosis. Stereotactic biopsy is a low-risk procedure in experienced hands. For solitary lesions not causing herniation, it is reasonable to treat for toxoplasmosis. Biopsy is reserved for patients who do not respond to appropriate treatment and for PCR and seronegative cases.

Myelopathy is evaluated by MRI with gadolinium to exclude a compressive lesion. CSF is a useful adjunct test to rule out infectious etiologies. EMG and nerve conduction studies are useful in evaluating chronic inflammatory demyelinating polyneuropathy, anterior horn cell disease, polyradiculopathy, peripheral neuropathy, and myopathy. Nerve or muscle biopsy may be required.

TREATMENT, COURSE, AND OUTCOME

Potent cART has transformed the course of AIDS from a fatal disease to a chronic illness. Even before cART, prophylactic treatment of common opportunistic infections had reduced AIDS deaths. Improved medical care has also reduced the need for hospital admissions in this population.

Antiretroviral drugs improve morbidity due to HIV and extend survival. More than 40 drugs in 7 classes, including combination drugs, have been approved for use, and more are in clinical trials or development (Table 67.8). New drugs are in development that target various phases of the viral cycle and include attachment inhibitors and chemokine receptor inhibitors.

Current recommendations regarding initiation of cART include starting antiretroviral therapy for all HIV-positive patients with a CD4 count ≤ 500 cells/mm³. Deliberately delaying initiation of antiviral treatment (e.g., until the CD4 count is below 500 cells/mm³) contributes to non-AIDS events, such as cardiovascular, renal, and hepatic disease, that can occur as a result of an infection's ongoing inflammatory effects and is associated with higher mortality.

ADVERSE NEUROLOGIC EFFECTS OF DRUG TREATMENT FOR HIV INFECTION

The most important adverse effect of initiation of cART in an immunosuppressed patient is immune reconstitution syndromes.

Vaccination of patients with HIV infection (or their household contacts) is considered worth the risk if the percentage of CD4 lymphocytes is above 15% in children, or greater than 200 cells/mm³. With varicella vaccine, clinicians should be prepared to use acyclovir if symptoms of varicella infection develop. Measles vaccine has rarely led to subacute sclerosing panencephalitis. Other antimicrobials used for prevention or maintenance therapy of fungal and parasitic infections can have neurologic side effects, such as testosterone deficiency with azole use, neuropathy with INH if supplemental vitamin B₆ is not given, and seizures from ganciclovir. Increased sensitivity to psychotropic drugs leading to prominent extrapyramidal effects is seen in AIDS patients. As new medications with different mechanisms of action are introduced, it is important that any adverse effects be reported using systems such as the U.S. Food and Drug Administration (FDA's) Sentinel

P.581

P.582

Initiative to detect trends that will allow practitioners to best balance risks and benefits in treating HIV infection.

TABLE 67.8 Categories of Drugs Used to Treat HIV

Former	Brand	Year
--------	-------	------

Name	Name	Name	Side Effect	Introduced
Nucleoside Reverse Transcriptase Inhibitors				
Abacavir	—	Ziagen	Cognitive, myopathy, seizures	1998
Didanosine	DDI	Videx	Neuropathy, myopathy	1991
Lamivudine	<3TC>	Epivir	Neuropathy, lactic acidosis	1995
Stavudine ^a	<d4T>	Zerit	Neuropathy, myopathy	1994
Zalcitabine ^a	<ddC>	Hivid	Neuropathy	1992
Zidovudine	<AZT>	Retrovir	Neuropathy, myopathy, cognitive, seizures	1987
Nucleotide Reverse Transcriptase Inhibitors				
Emtricitabine	<FTC>	Emtriva	Lactic acidosis	2003
Tenofovir	—	Viread	Encephalopathy	2001
Nonnucleoside Reverse Transcriptase Inhibitors				
Delavirdine	—	—	Rescriptor	1997
Efavirenz	—	Sustiva	Cognitive, insomnia, hallucinations	1998
Etravirine	<TMC-125>	Intelence	—	2008
Nevirapine	—	Viramune	—	1996
Rilpivirine	—	Edurant	—	2011
Protease Inhibitors				
Amprenavir ^a	—	Agenerase	Lipodystrophy, metabolic syndrome,	1999

			myopathy (if combined with statins)	
Atazanavir	—	Reyataz	Same	2003
Darunavir	—	Prezista	Same	2006
Fosamprenavir	—	Lexiva	Same	2007
Indinavir ^a	—	Crixivan	Same plus neuropathy	1996
Nelfinavir	—	Viracept	Same plus visual symptoms	1997
Ritonavir	—	Norvir	Same plus neuropathy and visual symptoms	1996

^aRarely used in the United States.

Table 67.8 lists medications in current use by class, with neurologic toxicities. The following is a brief summary of the most important toxicities.

Zidovudine causes a mitochondrial myopathy with ragged red fibers with muscle energy failure. Severe anemia (which can be corrected using erythropoietin growth factor) also contributes to fatigue.

The “D-drugs,” didanosine (ddl), zalcitabine (ddC), and stavudine (d4T), cause a sensory neuropathy that is often painful and sometimes difficult to distinguish from the neuropathy caused by HIV itself. D-drugs are now rarely used because of the risk of sensory neuropathy.

Efavirenz, a nonnucleoside reverse transcriptase inhibitor, causes sleep disruption and nightmares that can lead to its discontinuation by patients.

Protease inhibitors (Pis) such as ritonavir and nelfinavir cause lipodystrophy. The cosmetic consequences often result in patients avoiding these drugs. The associated metabolic syndrome contributes to higher rates (16% per year) of myocardial infarction and, presumably, other vascular disease in long-term users. Some PIs, including indinavir, saquinavir, and ritonavir, are also associated with neuropathy, probably resulting from effects on dorsal root ganglia.

Muscle necrosis with myoglobinuria has been reported with raltegravir, an integrase inhibitor. Lactic acidosis is associated with some nucleoside reverse transcriptase inhibitors.

PRECAUTIONS FOR CLINICAL AND LABORATORY SERVICES

Strict observation of contamination management procedures or universal precautions is mandatory. Hospital patients with known or suspected HIV infection are not isolated unless they have respiratory infection, such as TB, or severe neutropenia. Strict precautions should be observed in handling all waste, body fluids, and surgical specimens. Gloves must be worn to prevent skin and mucocutaneous contact with blood, excretions, secretions, and tissues of infected patients. Goggles or glasses should be used if heavy aerosol contamination with blood or other secretions is anticipated (e.g., in the operating room). Masks are not needed unless the patient requires respiratory isolation for other reasons. Needles and other sharp instruments in contact with infected blood should be disposed of in proper safety containers. Health care workers should not recap needles to avoid needlestick injury.

The risks to health care workers are small but real. HIV seroconversion has been documented following

needlestick injury or mucocutaneous exposure. The converse risk to patients from infected workers is exceedingly small, but HIV-positive workers should not perform or assist with invasive procedures in which cuts may occur. Postexposure prophylaxis with two drugs is recommended for HIV exposure through percutaneous or mucosal routes and with three drugs for significant blood exposure (visibly contaminated needle or device with deep penetration). HIV and hepatitis B and C serologies should be determined immediately. Problems encountered with postexposure prophylaxis include side effects of therapy, lack of efficacy, and false-positive HIV tests on rapid screening assays. Postexposure treatment is estimated to reduce HIV transmission risk by 80%.

HIV is readily inactivated by heat and standard sterilization solutions, including 70% alcohol. Special sterilization procedures may not be necessary but are often used.

OUTCOME

HIV-infected patients treated optimally can survive more than 20 years. They may die of HIV infection, causes unrelated to HIV infection, or of complications related to treatment. All patients need rigorous evaluation for systemic and neurologic syndromes irrespective of the stage of infection because of the risk for multiple, coexistent, or sequential problems, including disorders unrelated to HIV.

FUTURE DIRECTIONS

Great strides have been made in the medical management of HIV infection, with the prevalence of some neurologic sequelae seen with profound immunosuppression reduced. Nonetheless, HIV infection remains a serious diagnosis with common neurologic manifestations and is rapidly fatal in countries where access to effective treatment is limited. Therapy does not eliminate latent provirus and may fail if resistant mutants arise. Candidate vaccines are in clinical trials in areas of high seroprevalence and seroconversion. The complex biology of the virus and the host immunogenetic response to infection pose significant challenges to successful vaccine development. Additional strategies to “cure” HIV infection include the “shock and kill” strategy, which uses drugs to “shock” latent HIV virus into replicating, and then the active virus and cells producing the active virus would be “killed” by antiretroviral therapy, normal immune system processes, or other interventions designed to kill infected cells. Elimination of viral reservoirs including the CNS remains as potential problems to this strategy for “cure” and is a subject of significant active investigation.

Prion Diseases

Lawrence S. Honig

INTRODUCTION

Prion diseases are a less common group of neurodegenerative disorders. There are several disorders distinguished by clinical presentation and pathoetiologic basis but marked by spongiform neurodegeneration and an unusual protein-based molecular pathogenesis. The particular agents responsible for the diseases are not nucleic acids, viruses, or living organisms but rather “proteinaceous infectious particles” or *prion* molecules, a concept developed and established through the groundbreaking research of Stanley Prusiner, who was awarded a Nobel Prize for this work. The prion protein is a specific, relatively small translational product of just over 200 amino acids length. This neuronal protein (prion protein [PrP]) is present in cells in its usual, “normal” cellular conformation (known as PrP^C) with a protein secondary structure consisting of about 45% alpha helical segments and very little beta sheet internal structure. However, in prion diseases, there is an abnormal “scrapies” or protease-resistant conformation (known as PrP^{Sc} or PrP^{res}), which is marked by 40% beta-pleated sheet molecular architecture and has only about 30% alpha helical structure. In the prion diseases, there is an accumulation of the abnormally folded PrP^{res} protein causing nervous system dysfunction and destruction, through protein-protein interactions presumably within cells but ultimately spreading between cells. Specifically, misfolded copies of the protein cause conformation changes in normal PrP^C , converting it, in turn, to the abnormal form. There is an exponential increase in brain accumulation of abnormal prion protein, leading to rapidly escalating progressive nervous system destruction.

Prion diseases have a plural epidemiology: They may occur in both sporadic, nongenetic forms and genetic, familial forms, like many neurodegenerative disorders, but they may also occur as “acquired diseases,” through transmission by iatrogenic, surgical, or cannibalistic exposures of persons to nervous system tissue of affected individuals. Hence, they are also known as *transmissible spongiform encephalopathies*. The archetypical and most common of these uncommon disorders is Creutzfeldt-Jakob disease (CJD), named after two neurologists who described some cases of rapidly progressive dementia in the early part of the 20th century (which may not necessarily all have represented prion disorders). Although prion disease is sometimes easily recognizable, the differential diagnosis is often broad, particularly early in the course of the disease. The rapidity of symptom progression, together with the fact that different alternative diagnoses may have specific effective treatments, makes expeditious recognition and diagnosis particular important for this set of disorders.

TABLE 68.1 Prion Disease Classification

Category	Name of Disorder or Syndrome	Abbreviation	Subtypes
Sporadic	Sporadic Creutzfeldt-Jakob disease	sCJD	Includes Heidenhain and Brownell-Oppenheimer variants
	Sporadic fatal insomnia	sFI	
	Variable protease-sensitive prionopathy	VPSPr	—
			—

Genetic	Familial CJD	fCJD	Missense, octapeptide repeat mutations
	Gerstmann-Sträussler-Scheinker syndrome	GSS	—
	Fatal familial insomnia	FFI	—
Acquired	Variant CJD	vCJD	—
	Kuru	Kuru	—
	Iatrogenic CJD	iCJD	Human growth hormone, dural and corneal transplants, reused depth electrodes

EPIDEMIOLOGY

Prion diseases can be classified by their clinical-epidemiologic bases. Prion diseases may occur as sporadic genetic or acquired forms (Table 68.1). The hallmark of sporadic CJD (sCJD) is generally a rapidly progressive dementia, typically with gait dysfunction, although there are other rarer clinical phenotypes such as sporadic fatal insomnia (sFI). There are three distinct clinical forms of genetic prion diseases: Familial CJD (fCJD) clinical presentation is like that of sCJD; Gerstmann-Sträussler-Scheinker (GSS) disease is typically marked more by ataxia; and familial fatal insomnia is marked by severe insomnia and autonomic changes. Acquired CJD, transmitted through exposure to prions, was first described in the disease Kuru, discovered in New Guinea during the mid-20th century. Transmitted by ritual cannibalism, this disease has fortunately since vanished. Other forms of acquired disease include iatrogenic CJD (iCJD) transmitted through medical products, grafts, or transplants and variant CJD transmitted via consumption of tissues of cows who had bovine prion disease.

CJD occurs across all human populations, with an incidence of about 1.5 cases per million individuals per year, or about 400 persons per year in the United States. It is an uncommon

P.585

dementia. Compared to the approximately 1.5 per thousand individuals per year (500,000 in the United States) who develop Alzheimer disease, CJD is a condition with a thousandfold less common incidence. However, because the survival after a diagnosis of CJD is typically less than 1 year, whereas that for Alzheimer disease may be 20 years, the prevalence of CJD among living persons is still rarer. Among the 6 million Americans with dementia, the large majority of whom have Alzheimer disease, only about a few hundred have CJD, or about 1 in 20,000. Conversely, because of the short survival time for CJD, a higher proportion, nearly 1 in 1,000 deaths of persons with dementia each year are due to CJD. As a proportion of the total number of deaths in the nation, CJD represents about 1 in 10,000 deaths, despite having an incidence of only about 1.5 in a million. There has been increased attention and interest in the prion disorders, but there is no evidence that sCJD has had increased incidence over the decades. There has been a mildly increasing secular trend in the annual death rate in the United States over the past 30 years from about 0.9 cases per million to about 1.5 cases per million population, but this is almost certainly due to increased ascertainment rather than increased disease incidence.

SPORADIC CREUTZFELDT-JAKOB DISEASE

sCJD represents approximately 85% to 90% of prion disease. This disorder occurs without any known risk factor other than age. sCJD is very uncommon before the fourth decade of life and is principally found in the age range of 50 to 80 years. However, it is likely that the disease is clinically overlooked in the extreme elderly, so although it is clear that the age-specific incidence increases in the middle years, from age 30 to 60 years, it is not certain that the age-specific incidence declines among the older old (e.g., older than age 80 years). CJD incidence and prevalence are equal regarding gender, affecting males and females equally. U.S. statistics do show a somewhat

higher rate of CJD in whites than African-Americans, but this may be due to disparities in dementia care and diagnosis. Because there are no known environmental risk factors, it is not known why individuals develop sCJD, but presumably the disease represents the consequence of a stochastic accident in which there was age-dependent initial abnormal folding of prion protein, leading to inexorable disease. There is a single nucleotide polymorphism at the prion protein codon 129, with alleles coding for either methionine (M) or valine (V), which does affect risk. CJD is more common among codon 129 homozygotes (MM or VV) than heterozygotes (MV). In the North American and European populations, only about 50% of the individuals are homozygotes at codon 129, whereas over 80% of sCJD cases are homozygous at codon 129. Thus, there is some protection for persons from being heterozygous at the codon 129 polymorphism.

PRION DISEASE OF GENETIC ORIGIN

Whether presenting as dementia (fCJD) or ataxia (GSS), genetically transmitted prion disease represents only about 10% to 15% of prion disease cases. In genetic or familial prion disease, there is a mutation in the prion protein gene (PRNP) which causes with very high likelihood the eventual production of misfolded prion proteins leading to the progressive spongiform disease. There are about 30 such mutations, nearly all missense mutations and there is one portion of the gene which has an octapeptide repeat of variable length. Penetrance of the prion mutations is usually complete. The clinical expression of fCJD is less affected by codon 129 homozygosity, but for certain mutations, the clinical phenotype may depend on the cis-genotype at codon 129. Overall, the phenotype of fCJD is similar to sCJD, but onset is often at an earlier age (e.g., 30 to 50 years) and the disease course for some mutations may be more protracted in duration—up to more than 20 years.

ACQUIRED CREUTZFELDT-JAKOB DISEASE

iCJD in which CJD is acquired through transmission of infective prions via medical substances or procedures is very uncommon, currently representing less than 1% of prion disease in the United States. Rare events of transmission of CJD by exposure to contaminated neurosurgical instruments, electroencephalography (EEG) depth electrodes, or corneal transplants have been described. The vast majority of iCJD occurred as a consequence of administration of human-derived pituitary growth hormones, before modern recombinant DNA-based pharmaceutical production, and from the neurosurgical use of human dural grafts. Since the understanding of these risks, iCJD has nearly vanished. Human-to-human transmissibility of prion disease was first evident in the disease kuru, a predominantly ataxic disorder in certain tribal regions of New Guinea. This disorder arose in the 1950s, reaching a prevalence in certain tribes as high as 2% but has now been eliminated, with the recognition that this disorder was due to exposure of individuals to brain tissue prepared because of ritual cannibalistic practices, since discontinued. There is no demonstrated risk of CJD transmission from saliva, tears, urine, or feces. Blood has not shown any transmissibility for sCJD, although there is evidence that variant CJD can be transmitted through blood transfusions. Studies have not shown any increased risk of CJD to medical personnel.

VARIANT CREUTZFELDT-JAKOB DISEASE

Variant CJD disorder typically affects younger persons. It first appeared in the United Kingdom in the 1990s and was rapidly linked to the immediately prior epidemic in the same nation of prion disease in cows, known as *bovine spongiform encephalopathy* (BSE). It is clear that exposure of people to abnormal cow prions, almost certainly through the human gastrointestinal tract, caused a tiny proportion of individuals so exposed to develop a lethal prion disease, originally known as *new variant CJD*, now known as *variant CJD* (vCJD). Initially, there were enormous fears that this disease might spread widely. However, over the past 20 years, this epidemic of disease has been small, amounting to a world total of less than 300 cases, including about 200 in the United Kingdom, and scattered cases elsewhere in the world. There has not been one “endogenous” case in the United States, that is, in persons who have not also lived in affected regions such as the United Kingdom. The

incidence of vCJD in the United Kingdom rose to as high as 20 to 30 persons per year but is now less than 1 person per year. The epidemiology of this disorder was different from sCJD, in that the disease affected younger persons, almost all between the ages of 10 and 50 years and only affected persons homozygous at prion codon 129, with apparent complete protection by heterozygosity (MV genotype) at codon 129.

PRION DISEASES IN OTHER SPECIES

Scrapie, a disease of sheep and goats, has likely been known since biblical times. Cows can develop BSE. Other ungulate mammals also have prion disease, including deer, elk, and moose, which develop the cervid disorder, chronic wasting disease (CWD). Experimentally, or through consumption of prion disease-affected animal tissues, prion disease can be seen in a numerous species. These diseases include transmissible mink encephalopathy (TME), feline spongiform encephalopathy (FSE), and exotic ungulate spongiform encephalopathy (EUE) in nyala, oryx, and greater kudu.

P.586

PATHOBIOLOGY

Prion protein is a normal cellular protein, which is most expressed in the nervous system, and localizes to the synaptic regions, although its function is unknown. Prion protein belongs to the larger family of genes known as *cluster of differentiation* (CD) genes, many of whose members are found in cells of the immune lineage and whose functions may include cell-cell interactions and signaling. Presence of prion protein in various other bodily tissues likely relates to expression in cells of lymphatic lineage. The relative paucity of prion protein in non-neural tissues likely explains the confinement of prion disease symptoms to the nervous system. It also explains the lack of any demonstrable transmission from person to person, other than through exposure to nervous system tissues (which have included brain, pituitary, dura, and cornea). It is likely that in individuals developing sCJD, chance explains a rare spontaneous conversion of PrP^C to PrP^{res}. However, once PrP^{res} is formed, there is an escalating production of more PrP^{res} through the process of protein-protein induced conformational change mentioned earlier. This process can be shown to occur in vitro, in culture, and in animal models.

A number of observations have established the protein-based nature of the disease process. Injection of PrP^{res} into experimental animals in their brains or even elsewhere (in sufficient quantities) results in prion degenerative brain disease. The transmissible agents are not destroyed by nuclease enzymes that inactivate DNA or RNA nor by ultraviolet or X-irradiation and because of its folded state, is resistant to proteases. However, prions are inactivated by destructive/denaturing agents such as concentrated formic acid, phenol, bleach, or sodium hydroxide (lye) as well as by extreme dry heat (600°C). Although injected PrP^{res} causes prion degeneration and death in normal mice, mice that are genetic knockouts for the prion gene do not have prion degeneration, regardless of the amount of PrP^{res} they are administered, because they have no PrP^C which can be converted.

Prion proteins are highly conserved, but interspecies differences do provide a barrier to transmissibility. Exposure to or consumption tissues from sheep with prion disease (scrapies) has never been associated with human prion disease. In addition, in experimental animal systems, it can be shown that there is a greater barrier to transmission if the prion agent is from a molecularly more distant species. However, it is clear that bovine prion protein is sufficiently similar to human prions, as to allow transmission of BSE to humans. The small but prolonged epidemic of vCJD resulted from a preceding epidemic of BSE in cattle. Evidence to date indicates that in some persons, consumption of bovine material, likely containing nervous system tissue, led to vCJD, through a process of transluminal gastrointestinal lymphatic-mediated transmission to the nervous system. In vCJD, but not sCJD or fCJD, abnormal prion protein can be shown to be present in lymphoid-containing extraneural tissues, including blood, tonsils, and appendix.

CLINICAL MANIFESTATIONS

SPORADIC CREUTZFELDT-JAKOB DISEASE

The classic clinical manifestations of CJD are the triad of rapidly progressive dementia, myoclonus, and ataxia. At earliest presentation, only one or none of these symptoms may be present. However, in any patient with rapid appearance of one of these symptoms, without other obvious explanation, particularly in the age range of 40 to 80 years, the possibility of prion disease should be considered. The most important clinical manifestation is unexplained rapid but incremental (noncatastrophic) progressive cognitive or motoric impairment over a period of weeks to months. However, the earliest symptoms may be very vague, constitutional (fatigue, insomnia, anorexia), or neuropsychiatric (apathy, depression, anxiety, personality change, or emotional lability).

Symptoms

The dementia of sporadic and fCJD is typically “cortical” with impairments in memory, concentration, language, praxis, or visuoperception. However, true episodic memory impairment, as seen in Alzheimer disease, is usually less evident until later in the disease. Psychiatric abnormalities, including various behavior changes, and psychotic symptoms including hallucinations and delusions are not uncommon. Focal neurologic deficits including visual disturbances, focal weakness or sensory symptoms, and ataxia are common. Ataxia is usually of a cerebellar type, with gait imbalance more common than appendicular or ocular signs. Myoclonus is a striking sign, particularly as the rapid development of this movement disorder is uncommon in the absence of metabolic or drug effects. A particularly prominent feature in the later stages of CJD is startle myoclonus, in which an auditory or other sensory stimulus results in more or less generalized myoclonic movement. By the later stages of disease, myoclonus is present in more than 80% of patients.

Clinical Course

Neurologic deterioration proceeds with increasing rapidity in CJD. Caregivers often describe day-by-day deterioration, and physicians can observe this in hospitalized patients. Rapid evaluation is mandatory for anyone with suspected CJD. Ultimately, the entire course of disease from first symptoms to spastic quadriparesis, akinesia, and mutism and then to death, typically occurs within 6 to 12 months. It is not uncommon for it to occur in 2 to 6 months. In general, the clinical manifestations of sCJD and fCJD are similar, with similar disease courses. fCJD may present at earlier ages. For many mutations, the course from symptom onset to death is equally brief as for sCJD, but for some mutations, there may be more prolonged course that can range to as long as more than 20 years from symptom onset to death. Recent years have also identified a form of sCJD due to “variably protease resistant prion protein,” and this form of disease may also have more protracted course than the more common sCJD due to completely protease resistant prion protein accumulation.

Variant Presentations

Distinctive clinical “variant” presentations of sCJD have been described according to the dominant symptoms at presentation, but these varieties of sCJD should not be confused with vCJD, a transmissible disorder related to BSE. The Heidenhain variant is marked by initial symptoms that are primarily visuoperceptual, including visual hallucinations or illusions, and/or the rapidly progressive development of cortical blindness. It is not uncommon for persons to have ophthalmologic evaluations and/or cataract procedures due to misdiagnosis of the symptoms as ocular rather than cerebral. Cerebral involvement of the occipital cortex is responsible for these symptoms. The Brownell-Oppenheimer variant is marked by prominent cerebellar symptoms, including ataxia of gait, and reflects greater early cerebellar involvement. Some clinicians refer to other variants of disease based on initial symptoms as “cognitive” or “affective” variants.

KURU

Kuru was the first transmissible neurodegenerative disease to be identified in humans. This condition, and its transmissible nature, was elucidated after its identification as an increasing epidemic among the Fore tribal peoples of Papua New Guinea in the mid-20th century. Carleton Gajdusek, who received a Nobel Prize for his discovery, showed with colleagues that the disease was spread through brain tissue and that it could be experimentally transmitted to primates. Kuru was marked by an asymptomatic incubation period of years to decades, followed by rapidly progressive symptoms of ataxia, gait disorder, instability, anorexia, and “shivering” (tremors and myoclonus). Subsequent progression included dysarthria progressive to muteness, dysphagia, urinary and bowel incontinence, and increasing cognitive impairment and dementia. Total duration of disease typically was about 1 to 2 years after symptom onset. The disease was disproportionate in women and children. It became evident that the disease was transmitted from person to person during the preparation, manipulation, and presumed consumption of human brain tissue from deceased individuals as part of ritualistic mortuary practices. These practices were eliminated after increasing Western exposure, and the disease slowly disappeared.

VARIANT CREUTZFELDT-JAKOB DISEASE

vCJD was first recognized in 1996 in Great Britain when cases of young-onset spongiform disease were identified. Typical symptoms differ from those of other prion disorders. Age of onset is typically age 10 to 40 years, almost nonoverlapping with sCJD. Painful sensory symptoms including lancinating paresthesias are common. Psychiatric symptoms including apathy, depression, and psychosis are common, occurring in nearly 90% of individuals at presentation. Neurologic symptoms develop, including increasing cognitive impairment, cerebellar ataxia, and often abnormal movements including dystonia, chorea, and myoclonus. Progressive neurologic deterioration results in death often 1 to 2 years after onset but sometimes with much greater duration of disease of some years. With the appropriate symptoms, vCJD should be suspected particularly in individuals who lived in the United Kingdom or other European countries between 1980 and the present, but the worldwide incidence is now less than five cases per year. All affected persons with vCJD are homozygous for methionine at codon 129. Other than the effects of age and codon 129 genotype, it is unclear why so few persons in the United Kingdom developed vCJD, given the very large exposure of the population to cows affected by BSE. There were hundreds of thousands of affected cows, and there was likely much exposure prior to recognition of BSE, its hazards, and control of the bovine epidemic, through elimination of ruminant tissues from cow food stocks and aggressive herd culling. There is frequent confusion by the public between sCJD and vCJD, known popularly as *mad cow disease*. Although vCJD does represent the only known trans-species transmission to humans of neurodegenerative disease, there has not yet been documented an endogenous case in the United States, originating from exposure to U.S. bovine products.

FAMILIAL CREUTZFELDT-JAKOB DISEASE

fCJD may present identically to sCJD. The presence of a family history, and/or an earlier age of onset, may be the only clinical indication. Genetic testing can confirm the familial, inherited basis. Familial disease is present in the United States and worldwide in about 10% to 15% of cases of CJD, but certain ethnic groups have increased prevalence of mutations. Specific mutations may present with particular phenotypes. For many fCJD cases, symptoms and duration of disease may be much like that of sCJD, although as mentioned, age of onset may be earlier, and sometimes duration of disease may be longer. GSS syndrome is a rare prion disease characterized by ataxia and spasticity. Representing less than 5% of CJD cases (or an incidence less than 5 cases per 100 million), most cases are associated with mutations in codons 102, 105, 117, or 198 of the PRNP gene, which have 100% penetrance. Typically, individuals carrying a GSS mutation develop symptoms at age 40 to 70 years,

and despite dominance of ataxia, there is heterogeneity of symptoms, partly depending on the mutation. In the most common form (codon 102 mutation), cerebellar ataxia and gait disturbance (ataxia, spasticity, rigidity) are the predominant symptoms, with dementia occurring later in disease, and myoclonus less common. In other forms, spasticity (codon 105 mutation), dementia (codon 117 mutation), or parkinsonism (codon 117 and 198 mutations) may be more prominently discriminating features. Typically, GSS is a slower prion illness, with duration of disease of 5 to 10 years before death.

FATAL FAMILIAL INSOMNIA

This very rare disease is transmitted through an autosomal dominant mutation occurring at PRNP codon 178 in the setting of a cysteine at codon 129. Age of onset is typically 40 to 60 years. Symptoms include progressive sleep disturbance and dysautonomia. Over the course of months to years, ataxia and dementia ensue. The sleep disturbance is characterized by a loss of normal circadian sleep-activity patterns. In addition to decreased sleep duration, dreamlike confusional states may occur during waking hours. Autonomic dysfunctions may include irregular blood pressure and heart rate, hyperthermia, hyperhidrosis, and excessive lacrimation. Pathologically, thalamic involvement is prominent.

DIAGNOSIS

Diagnosis of CJD or other prion diseases is based on clinical history and examination. Rapidly progressive neurologic symptoms without clear metabolic, infectious, or inflammatory cause should always prompt consideration of this category of disease. Although the triad of rapidly progressive dementia, ataxia, and myoclonus may be highly suspicious for prion disease, there are other disorders that can present similarly and prion diseases may present atypically without the classic set of progressive symptoms. Thus, paraclinical imaging and laboratory studies can be very useful.

DIFFERENTIAL DIAGNOSIS

Prion disease should be considered in the differential diagnosis of all rapidly progressive neurologic disorders. Demographic information can be useful in assessing the likelihood of sCJD because this disease is more common above age 40 to 50 years. Family history is key in ascertaining the likelihood of fCJD or GSS, which may present in the third or fourth decade of life. Typically, the history of acuity and symptom onset is most important. Although CJD presents with rapid deterioration, with a typical history of the patient being completely normal some months prior, there are other neurodegenerative disease that may have the appearance of rapidity, including Lewy body degeneration, which may be marked by fluctuations, and even unrecognized Alzheimer disease. However, more commonly, the diagnostic possibilities include neurodegenerative disease due to CJD versus some infectious or inflammatory condition. Although herpes or rabies encephalitis, or tuberculous, HIV, fungal, or other meningoencephalitides should be in the differential diagnosis, they are usually most easily diagnostically established or eliminated from consideration by history, blood tests, and, most importantly,

P.588

cerebrospinal fluid examination. Most challenging in the differential diagnosis of rapid progressive neurodeterioration are the immune-mediated and other inflammatory encephalitis (see [Chapter 71](#)). *N*-methyl-D-aspartate (NMDA)-receptor antibody encephalitis typically occurs in persons younger than the age of 30 years so is uncommonly a strong consideration, depending on symptoms. However, voltage-gated potassium channel antibody encephalitis and other immune-mediated syndromes marked by antineuronal antibodies may strongly be in the differential. In rare cases, epileptic syndromes with persistent subclinical activity or syndromes of ischemic or metabolic changes may

mimic CJD. Appropriate use of biomarker and imaging studies is key to rapid and accurate diagnosis; judicious use of brain biopsy may be extremely helpful.

CEREBROSPINAL FLUID ANALYSIS

Lumbar puncture classically was the first diagnostic test performed when the possibility of prion disease was considered. This is because so many other rapidly progressive dementias are marked by the presence of a pleocytosis or other signs of infection or inflammation. In addition, the presence of significant white cells in the cerebrospinal fluid (CSF) is virtually exclusionary of prion disease (unless a concomitant condition is present). In prion disorders, the CSF cell counts are normal, as is glucose level. Protein level may be normal or mildly elevated. A variety of biomarker proteins may be elevated in the CSF of patients with prion disease, relating to the ongoing acute neurodegeneration. Specifically, elevations of CSF 14-3-3 protein and tau protein, both neuronal proteins, may support the diagnosis of CJD if used in the proper clinical setting. However, the levels of these proteins increase in CSF following acute neuronal damage of various causes, including infectious, inflammatory, traumatic disorders. These biomarker proteins are not the prion proteins themselves, and presence of abnormal levels of these proteins does not exclude other diagnoses, nor do normal levels exclude diagnosis of CJD. These CSF tests are much less sensitive, and may be normal in vCJD, and in more indolent cases of CJD including GSS, fCJD, and iCJD. Other marker proteins including neuron-specific enolase (NSE) are even less useful. Newly developed tests such as the real-time quaking-induced conversion (RTQuIC) assay attempt to actually assay extremely low levels of prions in CSF or other fluids such as urine or nasal mucosal brushings but are still unproven in both sensitivity and specificity. For the differential diagnosis of the patient with dementia, it is notable that typically in CJD, beta-amyloid 42 may be low, along with high total tau levels—thus, the pattern of these two markers may be similar to that of Alzheimer disease. However, usually tau levels in CJD are much higher than in Alzheimer disease, and phosphorylated tau is not elevated in CJD (unless there is concomitant Alzheimer disease).

FIGURE 68.1 EEG tracings show pseudoperiodic generalized paroxysmal discharges. The EEG montage shows generalized paroxysmal discharges with a sharp, often triphasic, morphology that occur in a nearly periodic fashion of about one per second. Amplitude is somewhat greater in the frontal regions.

ELECTROENCEPHALOGRAPHY

Abnormal EEG findings typically occur during the course of disease, but even “typical” abnormalities are not specific for prion disease. In sCJD, nonspecific background slowing is often seen early in the disease. Periodic, or pseudoperiodic, synchronous, biphasic or triphasic sharp wave complexes are common features (Fig. 68.1). They may be seen in the middle to late stages of the disease in up to

P.589

75% of patients. A slow background rhythm is noted universally in the terminal stages but is nonspecific. In the proper clinical setting, presence of periodic sharp wave complexes may strongly support the diagnosis of sCJD, although apparently identical-appearing complexes can appear in hepatic encephalopathy, herpes encephalitis, and rabies encephalitis, among other acute brain illnesses. Periodic sharp wave complexes are infrequently seen in iCJD and fCJD, and usually not observed in vCJD.

NEUROIMAGING

Magnetic resonance imaging (MRI) has become the most reliable marker of prion disease. Abnormal diffusion-weighted imaging (DWI) signal occurs in the majority of cases at disease presentation. The particular appearance of increased DWI signal abnormality with regional abnormalities in the cortical ribbon, and commonly, concomitant signal increased in the deep gray nuclei including caudate, putamen, and thalami may be quite characteristic (Fig. 68.2). Typically, there is little or no increased signal on corresponding T2-weighted images, particularly as seen on fluid-attenuated inversion recovery (FLAIR) sequences. Although, particularly later in disease, there may be some increased FLAIR signal in addition to the abnormal DWI signal. Despite the sensitivity of these signal abnormalities, they are not completely specific, with a variety of other ischemic, encephalitic, or epileptic conditions able to produce similar gray matter DWI signal abnormalities without significant T2 signal change. Thus, although MRI has become the marker most used for diagnosis of CJD, interpretation requires the appropriate clinical situation, and MRI does not alleviate the need for additional testing.

FIGURE 68.2 The three rows shown are from three different patients, each with definite CJD, having pathologic confirmation of CJD. These rows show the variable involvement of cortex and basal ganglia in different affected individuals. Each row shows six contiguous axial slices obtained using a DWI sequence. In the patient imaged in the *top row*, prominent increased signal can be seen in the parietooccipital cortical ribbon bilaterally, but there is no clear signal abnormality in the basal ganglia. In the patient imaged in the *middle row*, there is prominent DWI signal abnormality in the basal ganglia and thalami bilaterally but much less so in the cortical ribbon. In the *bottom row*, the patient's images show significant abnormalities in both basal ganglia and cortical ribbon.

BRAIN BIOPSY

Biopsy has the potential to provide definitive diagnosis of prion disorders. Because of the transmissibility of prions, biopsy is done under general anesthesia, through an open, not stereotactic, neurosurgical approach through a small skull opening, using nonreusable equipment and full operating room infection control precautions. Risk of patient morbidity or mortality from brain biopsy is low and relates principally to general anesthesia and respiratory status. The histopathologic examination of brain biopsy tissue may not be definitive. Like for CSF, the presence of a robust inflammatory picture, including lymphocytic, microglial, or macrophage accumulations, strongly militates against a diagnosis of CJD. The typical findings in CJD may range from subtle to prominent—with spongiform change, including a diffuse vacuolation of the neuropil, as well as variable degrees of astrocytic gliosis and neuronal loss (Fig. 68.3). Prion-containing amyloid plaques consisting of aggregated prion

protein may rarely be seen. However, despite the lack a robust histopathologic readout, the availability of biochemical tests on biopsy brain tissue has resulted in near elimination of any “false-negative” biopsy results. Biochemical tests on biopsy brain tissue, including electrophoretic Western blot testing and

immunohistochemistry for PrP^{res} are highly sensitive and completely specific for CJD and also enable molecular “typing” of the condition. In the United States, the National Prion Disease Pathology Surveillance Center performs Western immunoblot analysis to detect the presence of abnormal PrP. Different electrophoretic banding patterns have been elucidated through the work of Pierluigi Gambetti and colleagues in the United States and John Collinge and colleagues in the United Kingdom based on electrophoretic mobility due to the glycosylation status of PrP. These gel-visualized subtypes can be combined with codon 129 genotype (MM, MV, or VV) to further molecularly categorize the prion disorder. Different subtypes have somewhat different histopathologies, brain regional predilections, and clinical course, especially duration. The advantage of brain biopsy is that a definitive diagnosis of CJD may be made, or alternatively, an alternate diagnosis may be established. The disadvantage of biopsy is that it is a surgical procedure with low, but some attendant risk, and that it is quite possible that a diagnosis will be made for which there are no disease-modifying treatment options. However, the value of a definitive diagnosis should not be underestimated because it obviates the need for any further clinical evaluations and investigations and gives certainty to families and medical professionals.

FIGURE 68.3 **A** and **B** show stained histologic sections of frontal cortex and cerebellar cortex, respectively, stained with hematoxylin, eosin, and Luxol fast blue. **C** and **D** show immunohistochemically stained sections of frontal cortex and cerebellar cortex, respectively, stained with monoclonal antibody 3F4, specific for PrP^{res}. **A** and **C** are oriented with white matter up and pial surface downward. **A** shows prominent vacuolation of the gray matter more than the white matter, typical of prion-related spongiform change. **C** shows brown staining of granular deposits of abnormal prion protein, variably aggregated but more prominent in gray matter than white matter. **B** and **D** are oriented with cerebellar molecular layer up and granular cell layer downward. **B** shows minimal spongiform change but a prominent kuru plaque (*arrow*). **D**

shows brown staining of granular deposits of abnormal prion protein in the molecular layer. (A and B courtesy of Dr. Jean Paul Vonsattel, Columbia University; C and D courtesy of Dr. Pierluigi Gambetti, Case Western Reserve University.)

GENETIC TESTING

Genetic tests have the ability to definitively diagnose prion disorders only in those cases in which there is a familial inherited prion disease. Furthermore, despite increased speeds in genetic testing, it is not uncommon to have a patient die of disease before the genetic

P.591

results are available. Thus, barring a completely clear family history of a known mutation, with clear clinical syndrome, other testing should still be pursued. Even in persons without family history, it is possible due to early parental demises from other causes, uncertain parentage, or even spontaneous mutation, that a genetic form of prion disease might be present. Thus, it is reasonable to offer all patients and their families, the option of genetic testing of the affected patient, after full genetic counseling of family members. Genetic testing can most conveniently be performed on DNA from blood leukocytes but can also be performed on biopsy or autopsy tissue to examine the PRNP gene for polymorphisms or mutations. For patients with a known family history of CJD, the presence of a known pathogenic mutation in the symptomatic patient is diagnostic.

TREATMENT AND OUTCOME

Prion disease is particularly feared, perhaps more than possibly any medical disorder, because of its combination of rapidity and inevitable lethality. The disease is not cataclysmic, in that death can be anticipated over a period of weeks to months. However, it is so rapid that usually neither patients nor families have time to reflect, arrange affairs, or fully anticipate the disease progress and mortal outcome. Arriving at a definitive diagnosis during life, through brain biopsy, or in the case of familial disorders through genetic testing, can be helpful to patients and families, in obviating guilty thoughts regarding potentially missed avenues of investigation or treatment. Once a diagnosis of prion disease is well-established, there is no legitimate medical role for non-indicated medications such as antivirals, antibiotics, glucocorticoids, or plasma exchange. It is clear that such treatments never provide benefit, and indeed, they may often provide risk of side effects, in addition to being medically inappropriate.

Supportive care is important. This includes social support, with appropriate dissemination of information, and involvement of hospice services, whether at home or institutional. Medical supportive care includes physical aspects such as wheelchairs, hospital beds, and hoists as well as pharmacologic interventions including anticonvulsants such as levetiracetam or valproate to treat seizures or myoclonus, benzodiazepines to treat anxiety and myoclonus, neuroleptics to assist in agitation and insomnia, glycopyrrolate to treat excessive secretions, and other comfort measures. Discussion of end-of-life issues should not be ignored. It is important to address family concerns regarding nutrition, and to discuss for this disorder, the lack of any clear medical benefit in enteral feeding, and the futility of resuscitative measures in the face of accelerating catastrophic nervous system failure. Although the wishes of patients and their families are paramount, adequate educational efforts are important for optimal medical care. Prion diseases are, in most jurisdictions, illnesses that have mandated reporting to the public health authorities. Brain autopsy is encouraged because of its benefits with regard to disease categorization, surveillance, and confirmation of cases for families and physicians, particularly when biopsy has not been performed during life. Brain autopsy is also an important tool in the research and study of these diseases. Genetic counseling should be provided in families for whom the disease has a suspected familial or genetic basis.

There are no drugs or treatments proven to affect the outcome of established prion disease in either animals or humans. It can be theoretically proposed that disease-modifying treatment might be based on (1) preventing abnormal prion conformational change, (2) preventing prion-prion interactions, (3) removing abnormal prion proteins from the nervous system, or (4) alleviating the deleterious effects of abnormal prion protein. To date, a few small trials have been based on in vitro and animal model data suggesting that heterocyclic compounds might impede abnormal prion folding or induced conformational changes. Two trials of quinacrine, a drug, which may impede abnormal prion protein folding, have failed to show any evident beneficial effect on human prion diseases. Similarly, trials of tetracycline drugs have also not shown evidence of efficacy. There is substantial interest in the possibility of clearing prion protein through immunization strategies, as is being tested in other neurodegenerative diseases such as Alzheimer disease. In prion disease, to date, such investigations are preclinical, using animal models.

Multiple Sclerosis and Allied Demyelinating Diseases

Claire S. Riley

INTRODUCTION

Among demyelinating diseases, multiple sclerosis (MS) is the most common and widely recognized. It is the leading cause of nontraumatic neurologic disability in young people. The identification of a pathologic autoantibody has definitively separated neuromyelitis optica (NMO) from MS, where it was previously considered an MS subtype. Marchiafava-Bignami disease, a rare demyelinating condition often associated with alcoholism, is discussed here as well, although the mechanism is thought to be toxic rather than inflammatory. The discussion that follows considers each disease state separately with the unifying pathophysiology of demyelination.

MULTIPLE SCLEROSIS

MS is a chronic inflammatory demyelinating disease of the central nervous system (CNS) of unknown cause. The course is extremely variable, but most patients initially experience relapses with complete or near-complete recovery interspersed with periods of clinical remission. Although a minority of patients has only minimal symptoms, many become disabled in time as a result of incomplete recovery from relapses or conversion to a progressive form of the disease.

EPIDEMIOLOGY

MS affects approximately 400,000 people in the United States and 2.5 million worldwide. It is a leading cause of nontraumatic disability in young adults. The disease typically begins between the ages of 20 and 40 years. The first symptoms rarely occur before age 10 years or after age 60 years. Women are affected approximately twice as often as men except in individuals with the primary progressive form of the disease where there is no gender preponderance.

PATHOBIOLOGY

The etiology of MS is unknown. It probably results from complex interactions between environmental factors and susceptibility genes, which lead to an aberrant immune response and damage to the myelin sheath, oligodendrocytes, axons, and neurons.

Studies in a mouse model of MS, experimental autoimmune encephalomyelitis (EAE), histopathologic studies of MS lesions, and immunologic markers in serum and cerebrospinal fluid (CSF) of MS patients suggest that MS is an immune-mediated disease. A virus, bacterium, or other environmental toxin might induce an immune response in genetically susceptible persons. Antigen-presenting cells (APCs) provide relevant antigens to CD4+ T-helper cells in the periphery, which lead to their activation and the subsequent generation of autoreactive proinflammatory T-helper (Th) 1 and 17 subsets. B cells and monocytes are also activated. These autoreactive T cells interact with adhesion molecules on the endothelial surface of CNS venules and, with antibodies and monocytes, cross the disrupted blood-brain barrier with the aid of proteases (e.g., matrix metalloproteinases) and chemokines. Within the CNS, target antigens are recognized (putative antigens include myelin basic protein, myelin-associated glycoprotein, myelin-oligodendrocyte glycoprotein, proteolipid protein [PLP], α B-crystallin, phosphodiesterases, and S-100 protein), T cells are reactivated, and the immune response is amplified. Proinflammatory T-helper cells proliferate and B cells continue their maturation to antibody-secreting plasma cells, whereas monocytes become activated macrophages. Together, these immune cells produce inflammatory

cytokines (e.g., interleukin [IL]-12, IL-23, interferon γ , tumor necrosis factor [TNF]- α), proteases, free radicals, antibodies, nitric oxide, glutamate, and other stressors that collectively lead to damage of myelin and oligodendrocytes. In the appropriate cytokine milieu, CD4+ Th2 cells proliferate and secrete anti-inflammatory cytokines (e.g., IL-4, IL-5, IL-13, and transforming growth factor- β) that suppress the immune response. Depending on the location and extent of damage, demyelination may impair or block nerve conduction and result in neurologic symptoms. With a loss of trophic support from oligodendrocytes, axons may degenerate to cause irreversible neurologic deficits. Spontaneous improvement of symptoms is attributed to resolution of inflammation, adaptive mechanisms (e.g., reorganization of sodium channels), or remyelination.

It had long been thought that Th1 and Th2 subsets arose from the terminal differentiation of the CD4+ T cells. However, a third pathway has been identified, induced by IL-1, IL-6, and transforming growth factor- β , and then expanded and maintained by IL-23, which is secreted by APCs. This third subset, a proinflammatory T-helper cell, is known as *Th17* because it produces IL-17. Th17 cells secrete a number of cytokines, including TNF- α and granulocyte macrophage colony stimulating factor (GM-CSF), which are critical for the development of EAE. MS patients have monocyte-derived dendritic cells that secrete higher levels of IL-23 than healthy controls. Higher levels of IL-17 mRNA-bearing mononuclear cells are found in the serum of MS patients having relapses than in patients in remission.

Although MS is typically considered a T-cell-mediated disease, a growing body of evidence supports a pathogenic role of B cells, including the frequent observation of intrathecal production of immunoglobulin in MS patients, identification of antibodies that react to specific myelin antigens within MS lesions, a pathologic pattern of MS characterized by antibody-associated demyelination (see the following text), and the discovery of B-cell follicles in the meninges of patients with secondary progressive MS. Pathologic studies have shown that B-cell clones are shared between the meninges and parenchyma of individual MS patients. Furthermore, B cells

P.594

are efficient APCs and B-cell depletion is a promising therapeutic approach in MS.

Chronic demyelinating plaques appear translucent, sharply demarcated, and are most frequently found in the periventricular white matter, brain stem, cerebellum, and spinal cord. Lesions are characterized by extensive demyelination, gliosis, variable axonal loss, and a minimal inflammatory infiltrate consisting of T lymphocytes and macrophages. Demyelination accompanied by a perivascular infiltrate consisting predominantly of T cells, lipidladen macrophages, and prominent reactive astrocytes are typical features of actively demyelinating lesions. Although demyelination with relative preservation of axons is often considered the pathologic hallmark of MS, axonal transection is common, especially in areas of active inflammation and demyelination. In autopsies of 52 MS cases, prominent cortical demyelination was seen with a mild but diffuse inflammatory infiltrate with microglial activation in normal-appearing white matter of patients with secondary or primary progressive MS. Cortical demyelination was rare in patients with relapsing-remitting MS.

Lucchinetti and colleagues identified four distinct pathologic patterns in an immunohistopathologic study of actively demyelinating MS lesions in 83 cases (51 biopsies and 32 autopsies). All four patterns contained an inflammatory infiltrate consisting of T lymphocytes and macrophages. The most common type, pattern II, was characterized by the deposition of immunoglobulin and complement. Pattern I was characterized by macrophage-associated demyelination. In patterns III and IV, demyelination was due to an oligodendrogliopathy. Pattern III was differentiated from pattern IV by a preferential loss of myelin-associated glycoprotein. Multiple active lesions were discovered in 27 autopsy cases. The same lesion pattern was observed within each patient, but there was marked heterogeneity between patients, suggesting that MS might have multiple pathogenic mechanisms. However, the results of this study were challenged by another autopsy series of 12 relapsing-remitting MS patients who died in the setting of an acute relapse. Most cases, including one who died 17 hours after an exacerbation, included lesions characterized by extensive oligodendrocyte apoptosis with intact myelin

sheaths and slight or no inflammatory infiltrate. More than one of the aforementioned patterns were observed in some patients. The investigators concluded that pattern III lesions represent an early stage of lesion formation that precedes inflammation and demyelination. However, biopsy and some autopsy studies are susceptible to inherent selection bias and the findings may not be representative of typical MS.

Genetic Risk Factors

The strongest known genetic factor influencing MS susceptibility is the human leukocyte antigen (HLA)-DRB1*1501 haplotype. However, it is not essential for the development of MS, increases the risk two- to fourfold, and is present in 20% to 30% of normal individuals. Linkage and association analysis of 931 family trios (individuals with MS and their parents) screened 300,000 single-nucleotide polymorphisms and identified two genes outside of the HLA region, interleukin-2 receptor alpha gene (IL2RA) and interleukin-7 receptor alpha gene (IL7RA), which also increase the risk of MS. IL2RA encodes the alpha chain of the IL-2 receptor, which is essential for regulation of T-cell responses and has been implicated in the pathogenesis of other autoimmune diseases, including Graves disease and type 1 diabetes mellitus. IL7RA encodes the alpha chain of the IL-7 receptor. IL-7 functions in the homeostasis of memory T cells and may play a role in the generation of autoreactive T cells in MS patients. The effect of these allelic variants on overall MS risk is small but statistically significant. Additional genome-wide association studies have identified 110 MS risk variants in 103 loci, which are not within the major histocompatibility complex.

Additional evidence for a genetic predisposition includes increased risk in some ethnic groups (e.g., Caucasians of northern European ancestry) and decreased risk in others (e.g., Native Americans), varying prevalence rates among different racial groups in the same geographic location, a 20% to 40% increased risk of MS in first-degree relatives, whereas adopted children of MS patients have a risk similar to the general population, and 25% to 30% concordance in monozygotic twins compared to 5% in dizygotic twins. However, 70% of identical twins are discordant for MS, so environmental factors and other unknown influences must contribute to susceptibility.

Environmental Influences

In general, there is a latitudinal gradient with an increased prevalence of MS further from the equator in both hemispheres. Large differences in the frequency of MS are observed in some homogenous populations living at different latitudes. Several regions with similar latitude have vastly different MS prevalence rates, which in some instances can be accounted for by differences in ethnic susceptibility (e.g., Great Britain and Japan lie at the same latitude, but the prevalence in Britain is approximately 60 times more than in Japan).

Further evidence of an environmental effect comes from migration studies and apparent epidemics and disease clusters. In general, immigrants who move from one area to another before the age of 15 years acquire the MS prevalence rate of the new region. The altered risk develops gradually and may be imperceptible in the immigrants themselves but is obtained by their children. Notable exceptions include Israeli-born children of European and American immigrants who have a frequency of MS similar to that of their parents. Therefore, genetics may sometimes be more important than the environment. Migrating after age 15 years does not affect the risk of MS.

Apparent MS epidemics occurred in Iceland and the Faroe Islands after World War II, suggesting an infectious or other environmental cause. The arrival of British troops to the Faroe Islands in 1940 also brought the first neurologist to the islands, so that increased awareness of the disease and better case ascertainment may have led to the apparent "epidemic." However, the onset of the disease occurred after 1942 in all of the identified cases except for a few who had spent time away from the islands.

More than the expected number of MS cases has been reported in several areas, including Key West, Florida; Orange County, California; Los Alamos County, New Mexico; Hordaland, Norway; and Colchester County, Nova

Scotia, raising the possibility of a shared environmental exposure causing the disease. Mercury toxicity, zinc, viruses, and other toxins have been suggested but no credible evidence has explained these clusters, which may have occurred by chance.

Multiple environmental factors may influence the risk of MS, including vitamin D, which has emerged as one compelling possibility. The active form of vitamin D, 1,25-dihydroxyvitamin D₃, has immunomodulatory properties and can prevent or ameliorate experimental allergic encephalomyelitis (EAE), a mouse model of MS. Numerous studies have found an inverse correlation between sunlight exposure (the most common source of vitamin D) and dietary intake of vitamin D and the risk of MS. The relationship to sunlight exposure may help explain the latitudinal variation of MS prevalence. Furthermore, a study of U.S. military personnel found that higher serum levels of 25-hydroxyvitamin D₃ (25[OH] D₃) were associated with a lower risk of MS. Similar findings in the

P.595

Netherlands were reported, but only in women, as well as a negative correlation between 25(OH)D₃ levels and disability. However, it is not known whether vitamin D supplementation modifies the disease in people already diagnosed with MS.

High-salt diet has been shown to increase severity of EAE and induce pathogenic TH17 cells in humans and mice *in vitro*. This has been hypothesized to explain in part the increasing incidence of MS and other autoimmune diseases in countries with “Western diet.”

Among the possible infectious causes, the case for EBV is of interest. The frequency of MS is low in people who are seronegative for EBV, but the risk is increased in those who have had infectious mononucleosis. The evidence for other microbial agents is less compelling, but it is possible that a number of viruses or bacteria might act as a nonspecific trigger of MS in genetically susceptible individuals.

Physical trauma or psychological stress might precede the onset of either MS or MS exacerbations. Although temporal associations are common, a clear causal relationship is lacking. The Therapeutics and Technology Assessment Subcommittee of the American Academy of Neurology concluded that there is no significant association between trauma and MS onset or exacerbation. The committee also concluded that, although possible, there is no clear relationship between antecedent psychological stress and the onset of MS or exacerbations. However, a study in Israel concluded that stress associated with the 2006 war between Israel and Lebanon increased exacerbations in civilians with MS.

CLINICAL MANIFESTATIONS

A clinically isolated syndrome (e.g., optic neuritis, transverse myelitis, or a brain stem or cerebellar syndrome) heralds the onset of the disease in approximately 85% to 90% of all cases. A relapsing-remitting course ensues and is often followed by a progressive phase of the disease. Symptoms, which depend on lesion location and extent of tissue destruction, range from mild and intermittent to severe and persistent or progressive (Table 69.1). The disease begins insidiously and gradually worsens in the remaining 10% to 15% of patients, termed *primary progressive multiple sclerosis*.

TABLE 69.1 Classic Signs and Symptoms of Relapsing Multiple Sclerosis

Symptom	Sign	Localization
Blurred vision	Relative afferent pupillary defect Disc pallor Papillitis	Optic nerve

Red desaturation

Diplopia	Nystagmus Internuclear ophthalmoplegia One-and-a-half syndrome	III, IV, and VI nerve nuclei and outflow tracts MLF PPRF
Vibratory or electrical sensation with neck flexion	None—"Lhermitte sign" is a symptom	Cervical spine
Paroxysmal dystonia	Brief, often painful, usually unilateral muscle spasms May manifest as paroxysmal dysarthria or facial spasms	Corticospinal tracts
Pseudobulbar affect	Laughing or crying uncontrollably without emotional congruence with the displayed affect	Brain stem, also frontal and parietal subcortical white matter

MLF, medial longitudinal fasciculus; PPRF, paramedian pontine reticular formation.

Acute optic neuritis is one of the most common manifestations. Patients typically note unilateral visual loss that evolves over a few days and is preceded or accompanied by orbital pain that occurs with or is exacerbated by eye movement. Progressive visual failure over many years is uncommon. On examination, visual loss varies from mild to severe. Visual acuity of 20/200 or worse is found in about 33% of patients, but complete loss of vision is rare. Dyschromatopsia and a central scotoma or other visual field defects are common. A relative afferent pupillary defect (RAPD), which may be the only clinical evidence of optic neuritis, is invariably present unless there is a prior history of or current optic neuritis in the opposite eye. The absence of a RAPD in a person with acute visual loss raises the possibility of uveitis, which occurs with increased frequency in MS. Funduscopy in optic neuritis is often normal, but swelling of the optic disc is observed in 35% of patients. Retinal hemorrhages and exudates are uncommon.

Spontaneous recovery of vision usually occurs within the first month, even when visual loss is severe. Lack of improvement suggests an alternative diagnosis because 98% of patients with visual acuity 20/50 or worse improve at least three lines on a Snellen letter chart within 6 months after the onset of symptoms. Optic atrophy is frequently found after the acute episode resolves.

Temporary worsening of vision with physical activity was originally described by Uhthoff in 1890. Uhthoff phenomenon now refers to new or worsening neurologic symptoms that occur in some patients with elevations in temperature (often during exercise or a hot shower). Symptoms are transient and attributed to reversible conduction block along demyelinated nerve fibers.

Oculomotor abnormalities are common. Diplopia usually results from a sixth nerve palsy or internuclear ophthalmoplegia. Other forms of nystagmus (e.g., gaze-evoked or pendular) are also common. Smooth pursuit and saccadic eye movement abnormalities may be observed. Third or fourth nerve palsies, the one-and-a-half syndrome (reflecting damage to the parapontine reticular formation or the sixth nerve nucleus causing ipsilateral gaze palsy as well as impaired adduction in contralateral gaze due to damage to the medial longitudinal

Facial numbness and vertigo can be difficult to distinguish from peripheral vestibular dysfunction, or facial weakness that is usually of the upper motor neuron type, but may mimic an idiopathic Bell palsy. Sudden hearing loss is uncommon and should raise the possibility of Susac syndrome. Intractable hiccups are rare but may result from lesions in the medulla or upper cervical spine. Intractable hiccups or vomiting should raise the possibility of NMO. Dysphagia is uncommon except in advanced MS. Limb weakness is common in MS and may occur during an acute exacerbation or incomplete recovery from an acute attack. The legs are more often affected than the arms and hands.

Approximately 70% of patients have some spasticity, which most commonly involves the legs. Spasticity is often accompanied by painful spasms and upper motor neuron signs. Spasticity often impairs mobility and activities of daily living and disrupts sleep. Gait abnormalities are common and usually a result of ataxia, weakness, or spasticity. However, in some instances, spasticity of the leg extensors permits weight bearing and improves gait. In nonambulatory patients, spasticity may interfere with transfers and personal hygiene.

An extensor plantar response is seldom the only evidence of corticospinal tract dysfunction. Demyelinating lesions in the anterior horn cells and dorsal root entry zones occasionally result in atrophy and hyporeflexia.

Paresthesias, dysesthesias, hypesthesia, or the Lhermitte sign (whereby neck flexion generates an electric sensation that usually radiates from the back of the neck to the lower back and possibly into one or more limbs) are common initial manifestations of MS and occur in most patients at some time.

An action tremor of the arms is common in MS patients. It is often accompanied by other signs of cerebellar disease, including gait ataxia, dysmetria, dysdiadochokinesia, and dysarthria. Tremor of the head, trunk, and legs is much less frequent. Incapacitating tremor, scanning speech, and truncal ataxia are seen in advanced disease.

Paroxysmal symptoms in MS are brief, repetitive, stereotyped attacks of neurologic dysfunction that are thought to result from ephaptic spread of abnormal electrical discharges from partially demyelinated nerve fibers ("cross-talk"). These discharges can arise from areas with acute inflammation and demyelination or chronic tissue damage. The symptoms usually last a few seconds to a few minutes and may occur anywhere from a few to 200 times per day. Attacks may occur spontaneously or be provoked by sudden noises, emotion, movement, hyperventilation, or tactile stimulation. The most common symptoms are trigeminal neuralgia and tonic spasms. Paroxysmal dysarthria, ataxia, diplopia, itching, paresthesias, pain, hemifacial spasm, and glossopharyngeal neuralgia are less frequent.

Trigeminal neuralgia occurs in about 2% of MS patients. The character and quality of the pain is usually indistinguishable from idiopathic trigeminal neuralgia. However, trigeminal neuralgia in MS is more likely to involve both sides of the face and is often accompanied by trigeminal neuropathy or other signs of brain stem dysfunction.

Paroxysmal dystonia, or tonic spasms, the second most common movement disorder in MS (only tremor occurs more frequently), are stereotyped, sometimes painful attacks of unilateral dystonic posturing of the limbs. They are occasionally bilateral and rarely involve the face. The attacks last between 30 seconds and 2 minutes and can occur up to 60 times a day. Tonic spasms are probably caused by demyelinating lesions involving the corticospinal tract. However, they are not pathognomonic for MS and are occasionally seen in patients with cerebral ischemia or spinal cord trauma.

Pseudobulbar affect is characterized by episodes of laughing or crying that do not coincide with the individual's emotional state. This can cause significant emotional distress to both patients and caregivers.

Fatigue is one of the most common and disabling MS symptoms. It is out of proportion to physical activities and is typically worse in the afternoon. Fatigue may precede the first clinical demyelinating event by months or years in one-third of patients. The etiology of MS-related fatigue is poorly understood. No association exists between fatigue and disease course; disability; brain volume; or MRI lesion load, location, or activity.

Bladder dysfunction, which can result in failure to store or empty urine, or a combination of the two, affects approximately 75% of patients. In 15%, symptoms are severe enough to prevent the patients from leaving home or attending social activities. Demyelinating lesions above the level of the pons may result in detrusor hyperreflexia with uninhibited bladder contractions, which causes urinary urgency that is often accompanied by frequency, nocturia, and urge incontinence. Lesions involving the reticulospinal pathways above S2 and below the pons may also lead to involuntary bladder contractions or cause simultaneous contraction of the bladder wall and urethra, a condition known as *detrusor-sphincter dyssynergia*. Patients with detrusor-sphincter dyssynergia have storage and emptying dysfunction and a combination of urgency, frequency, difficulty initiating voiding, incomplete emptying, and incontinence. Damage to the upper urinary tract and kidneys as a result of increased intravesicular pressure is rare. Hypocontractility and failure of the bladder to empty properly occurs with demyelination of the lower sacral anterior horn cells. Complete inability to void is uncommon.

Bowel dysfunction often coexists with bladder dysfunction and is present in up to 70% of patients. Constipation, which may be caused by immobility, decreased fluid intake, or medication side effects (especially those used to treat bladder dysfunction), is common.

Sexual dysfunction is present in up to 90% of patients. It is most likely to occur in progressive MS but affects up to two-thirds of patients with relapsing-remitting disease. The most common symptoms among men are erectile and ejaculatory dysfunction. Women have difficulties achieving orgasm, decreased vaginal lubrication, and reduced vaginal sensation. Both men and women may have reduced libido. Physiologic (e.g., fatigue, weakness, spasticity, pain, hypesthesia) and psychological factors (e.g., depression, anxiety about bladder and bowel dysfunction) may interfere with sexual activity. Many of the medications commonly used to treat other MS symptoms, including anticholinergics, antidepressants, and baclofen, can adversely affect sexual function.

Depression is clearly the most common affective disorder in MS with a lifetime prevalence of 50% before age 60 years. Some patients experience depressive symptoms but do not meet diagnostic criteria for major depression. The etiology of depression is likely multifactorial with psychosocial and biologic factors contributing to such a high frequency. There is concern that the β -interferons may cause or exacerbate depression. Episodes of major depression may occur during periods of exacerbations, remission, or disease progression. Although much less common than depression, bipolar disorder, anxiety, pseudobulbar affect, and euphoria are also prevalent in patients with MS.

Cognitive impairment occurs in up to 65% of patients with MS. Short-term memory, attention, concentration, verbal intelligence, visuospatial skills, and information processing are the domains most commonly affected. Disturbances of language and immediate and long-term memory occur less frequently. Disability and disease duration are generally poor predictors of cognitive dysfunction, which can occur early in the course of MS. However, cognitively impaired patients have more lesions, more severe tissue

P.597

damage, and smaller brain volumes than unimpaired patients as measured by conventional and nonconventional MRI techniques. Changes detected by magnetization transfer imaging in normal appearing brain tissue may have a stronger correlation with cognitive dysfunction than T1 or T2 lesion load.

In most patients, cognitive dysfunction is subtle and goes undetected in the neurologist's office. The Mini-Mental State Examination is not useful because it may fail to identify nearly 75% of MS patients deemed to be cognitively impaired by detailed neuropsychological testing.

Approximately 70% of patients experience pain at some time. Pain can occur during an acute exacerbation (e.g., ocular pain with optic neuritis or dysesthesias with demyelinating plaques involving spinal cord), but almost half of MS patients have chronic pain. It is not a major problem for most, but 20% have severe pain. In addition to painful muscle spasms, paroxysmal phenomena, and the sensory symptoms discussed earlier, MS patients are more likely to have joint, muscular, and extremity pain than age- and sexmatched controls. Many patients also complain of neck and back pain, which may be due to posture or gait abnormalities.

Disease Course

No biologic markers or MRI features distinguish the several forms of MS. The current classification system is based on consensus and relies on the clinical course (Fig. 69.1). Appropriate classification of patients is imperative for appropriate treatment with the disease-modifying drugs (see the following text).

FIGURE 69.1 The course of MS has been divided into four subtypes based on consensus of specialists. Most patients begin with a relapsing-remitting course (RRMS). Many of these eventually follow a secondary progressive pattern (SPMS). Approximately 10% to 15% of patients have primary progressive disease (PPMS), whereas the progressive relapsing form (PRMS) is very uncommon. The *top two lines* show that disease is labeled as RRMS irrespective of whether recovery from relapses is complete (*first line*) or incomplete (*second line*), as long as a stable baseline is reestablished. The *next two lines* demonstrate that disease is called *secondary progressive multiple sclerosis* irrespective of whether relapses continue, as long as the disease is gradually worsening either between attacks or in the absence of attacks. The *next two lines* show that disease may steadily worsen (*first line*) or there may be periodic plateaus (*second line*). The *bottom line* shows progression from onset followed by the development of relapses. (Reprinted with permission from Lublin FD, Reingold SC. Defining the clinical course of multiple sclerosis: results of an international survey. *Neurology*. 1996;46:907-911.)

Relapsing-remitting MS is the initial form of the disease in 85% to 90% of patients. It is characterized by acute relapses interspersed with clinical remissions. Symptoms from a relapse typically evolve over several days to a week before reaching a nadir. Recovery is variable, but approximately 40% of relapses result in persistent neurologic deficit and patients may accumulate disability in a stepwise fashion. When left untreated, most patients with relapsing-remitting MS ultimately enter the secondary progressive phase of MS, which is

characterized by gradual deterioration with or without occasional superimposed relapses.

Ten percent to 15% of patients have primary progressive MS, which is characterized by continuous and usually gradual deterioration of neurologic function (e.g., a slowly progressive monoparesis). There may be plateaus and slight fluctuations, but relapses do not occur. Fifteen percent to 40% of patients who start with the primary progressive form later have an acute relapse, which may not occur for many years after the original symptoms. This type of MS is referred to as *progressive relapsing multiple sclerosis* and is the least common form.

Different mechanisms may be responsible for symptomatic worsening. An inflammatory component may result in relapses, whereas neurodegeneration may be responsible for progressive disease.

Pregnancy

Pregnancy is protective in MS, particularly during the third trimester when there is a 70% reduction in the annualized relapse rate compared with the year prior to pregnancy. However, when MS is left untreated, about 30% of women have a relapse in the first 3 months postpartum before the risk returns to the prepregnancy rate 4 to 6 months after delivery. These effects may be the result of changes in Th1 and Th2 immune responses mediated by estriol or vitamin D, both of which are markedly elevated during the final trimester of pregnancy and fall abruptly after delivery; other hormonal changes that occur during pregnancy may also play a role.

Women with relapses during pregnancy or in the year prior to pregnancy are more likely to have a relapse in the first 3 months postpartum than women without relapses during these periods, but it is impossible to accurately predict who will have a relapse. In an uncontrolled study, intravenous immunoglobulin (IVIG) ameliorated the increased risk of postpartum exacerbations. However, the results of a subsequent randomized, double-blind trial were not as encouraging. Furthermore, there is now good evidence from well-designed, large, placebo-controlled trials that IVIG is an ineffective therapy for relapsing-remitting and secondary progressive MS. Breastfeeding does not affect the postpartum course of MS.

Vaccination

Infections, including minor upper respiratory infections, increase the risk of MS exacerbations. Strategies that minimize the risk of infection should be incorporated. Concerns that vaccinations may trigger MS exacerbations are based on anecdotes. However, a prospective, randomized, double-blind, placebo-controlled trial, showed that influenza immunization does not increase the risk of relapse or disease progression and patients should be routinely vaccinated. Hepatitis B, tetanus, and varicella vaccines appear to be safe in MS patients. There are few data regarding the safety of other vaccines in MS, but patients who meet the CDC guidelines should be advised to have them. Patients treated with fingolimod or mitoxantrone should not receive live attenuated vaccines, as there is some risk of developing the infection the vaccine is meant to prevent, or they may have an

P.598

attenuated response to the vaccination. It is probably best to delay immunizations for 4 to 6 weeks in the setting of an MS relapse because the goal of relapse management is to diminish the immune system's reactivity, and vaccination has the opposite effect.

DIAGNOSIS

The diagnosis of MS is established based on clinical criteria usually in combination with MRI. Examination of the CSF may be helpful. However, no single test result is pathognomonic of MS.

Imaging

Brain MRI abnormalities are present in more than 95% of recently diagnosed MS patients. Five to 10 new or enlarging gadolinium-enhancing or T2 brain lesions are identified for every one clinical exacerbation in patients with relapsing MS. Spinal cord lesions are detected by MRI in 75% to 90% of those with

established MS.

Fifty percent to 70% of clinically isolated syndrome patients have asymptomatic T2 brain lesions, and 27% to 42% have clinically silent spinal cord lesions. However, conventional MRI lacks pathologic specificity, and areas of edema, demyelination, axonal damage, gliosis, and remyelination all appear as T2 hyperintensities. Furthermore, there is poor correlation between disability and T2-weighted abnormalities. Nonconventional MRI techniques, including diffusion tensor imaging, magnetic transfer imaging, and proton magnetic resonance spectroscopy (MRS), have more pathologic specificity than conventional MRI and can detect and quantify tissue damage within visible T2 lesions and normal-appearing brain tissue. These techniques may enhance the ability to monitor disease evolution and understanding of the mechanisms that lead to irreversible disability.

FIGURE 69.2 Brain MRI from relapsing-remitting MS patients. Axial (**A and B**) and sagittal (**C**) fluid-attenuated inversion recovery (FLAIR) images demonstrate multiple periventricular white matter lesions. Many of the lesions are oriented perpendicular to the lateral ventricles and are the MRI correlate of “Dawson fingers,” which was originally a pathologic description of MS plaques. Also note the juxtacortical lesion in the right parietal lobe (**A**). The location and morphology of the lesions is characteristic of MS.

On T2-weighted imaging, brain lesions are typically 3 to 15 mm in diameter, round or ovoid, and located in the periventricular white matter, corpus callosum, centrum semiovale, juxtacortical regions, pons, floor of the fourth ventricle, cerebellar peduncles, or cerebellar hemispheres (Figs. 69.2 and 69.3). Larger lesions in the cerebral hemispheres associated with mass effect, edema, or ring enhancement, which resemble tumors and are known as

P.599

tumefactive lesions, are occasionally observed (Fig. 69.4). Cortical lesions are not well visualized by standard MRI techniques.

FIGURE 69.3 Brain MRI of the posterior fossa in an MS patient. An axial T2-weighted image (A) reveals multiple infratentorial lesions consistent with MS. The lesions are not well visualized on the FLAIR image (B). Although FLAIR is a more sensitive sequence than T2 for demonstrating supratentorial lesions, it is suboptimal for detecting infratentorial lesions.

In patients with relapsing MS, gadolinium enhancement, which represents active inflammation and disruption of the blood-brain barrier, is the earliest phase of lesion development seen on conventional MRI (Fig. 69.5). Almost all new brain T2 lesions demonstrate enhancement on postgadolinium T1-weighted imaging, and 65% to 80% are hypointense on the corresponding pregadolinium T1-weighted sequence. Gadolinium enhancement typically resolves after 2 to 4 weeks. Persistent enhancement raises

P.600

the possibility of neurosarcoidosis or neoplasm because only 3% to 5% of MS lesions enhance for more than 8 weeks. T2 lesions may become smaller, but they rarely disappear, whereas the majority of T1-hypointense lesions become isointense in 6 to 12 months, presumably as a result of resolution of edema and remyelination. However, 30% to 45% of hypointense lesions remain hypointense and are called *chronic black holes* (Fig. 69.6). Chronic black holes represent areas of extensive demyelination and axonal damage and have a much better correlation with disability than T2 lesions, especially in patients with secondary progressive MS.

FIGURE 69.4 Brain MRI from a patient with relapsing-remitting MS. Axial FLAIR (**A**) and postgadolinium T1-weighted (**B**) images reveal a large ring-enhancing mass-like lesion with surrounding vasogenic edema in the left hemisphere. There is also a much smaller nonenhancing lesion in the right hemisphere. The findings are consistent with tumefactive MS.

FIGURE 69.5 Brain MRI from a relapsing-remitting MS patient. A postcontrast T1-weighted image reveals multiple gadolinium-enhancing lesions. Gadolinium enhancement, which represents disruption of the blood-brain barrier and active inflammation, is the earliest phase of lesion development that can be detected on conventional MRI.

FIGURE 69.6 Brain MRI from a patient with secondary progressive MS. A sagittal FLAIR image (**A**) reveals

multiple periventricular white matter lesions consistent with MS. Note that many of the lesions are hypointense on the gadolinium T1-weighted image (**B**). Persistent T1-hypointense lesions (“black holes”) represent areas of significant demyelination and axonal damage and have a stronger correlation with disability than T2-hyperintense lesions, especially in patients with secondary progressive MS.

Spinal cord lesions are more common in the cervical than thoracic spine, appear hyperintense on T2-weighted imaging, and have a predilection for the white matter in the lateral and posterior columns. Adjacent gray matter is commonly involved. Lesions typically occupy less than half of the cross-sectional area of the cord and extend fewer than two vertebral segments (**Fig. 69.7**). Hypointense lesions on T1-weighted spinal cord MRI are uncommon in MS patients. Unlike gadolinium-enhancing brain lesions, active spinal cord lesions are frequently accompanied by clinical symptoms. However, asymptomatic spinal cord lesions are also common. Clinically silent spinal cord lesions are particularly useful for diagnosing MS in patients with vague neurologic symptoms and nonspecific findings on brain MRI because intramedullary cord lesions are rare in healthy people.

In general, relapsing-remitting MS patients have more gadolinium-enhancing lesions than those with progressive disease. Patients with secondary progressive MS tend to have more chronic black holes than those with the relapsing-remitting or primary progressive disease. Primary progressive MS patients are more likely to have few T2 brain lesions and diffuse spinal cord abnormalities. However, MRI characteristics are not diagnostic of the subtypes of MS—these remain clinically based.

Biomarkers

Examination of the CSF can aid in the diagnosis of MS and helps to exclude alternative diagnoses. CSF contains fewer than six white blood cells (WBCs) per cubic millimeter and normal protein content in most patients with a clinically isolated syndrome or established MS. A mild lymphocytic pleocytosis or elevated protein level is seen in about 35%. More than 50 WBCs per cubic millimeter or a protein content over 100 mg/dL are rarely observed and raise the possibility of an alternative diagnosis.

P.601

FIGURE 69.7 Cervical spine MRI from a relapsing-remitting MS patient. Axial (**A**) and sagittal (**B**) T2-weighted images reveal intramedullary lesions at C5-C6 consistent with demyelination. Also note the lesion at the cervicomedullary junction.

CSF immunoglobulin abnormalities are common. The immunoglobulin (Ig) G index, which measures

intrathecal production of IgG, is elevated in 70% to 85% of MS patients. Isoelectric focusing followed by immunoblotting detects oligoclonal bands (OCBs) in more than 95% of patients (two or more bands detected in the CSF that are not present in the serum are considered abnormal). Unfortunately, many U.S. clinical laboratories use older and less sensitive methods to identify OCBs. Treatment with corticosteroids lowers the IgG index but has no effect on OCBs. An elevated IgG index and the presence of OCBs are not restricted to MS and are observed in 20% to 40% of patients with other inflammatory, demyelinating, or infectious diseases and occasionally other neurologic disorders, including the Guillain-Barré syndrome and other peripheral neuropathies. Therefore, CSF abnormalities should always be considered in conjunction with the clinical and MRI findings.

A single immunoglobulin band restricted to the CSF is of unclear significance and may be found in healthy individuals, as well as a variety of illnesses, including clinically isolated syndromes, MS, infectious and inflammatory diseases, CNS lymphoma, peripheral neuropathy, or migraine headaches. However, when the CSF is reexamined after an average of 6 months, one-third of patients, the majority of whom have demyelinating disease, show a change from a monoclonal to oligoclonal pattern.

A high CSF level of myelin basic protein indicates damage to myelin and is not useful in differentiating MS from other illnesses, including cerebrovascular disease, infections, neoplasms, or inflammatory diseases.

Visual-evoked potentials (VEPs) are sensitive for detecting clinically silent lesions in the anterior visual pathways although they are no longer included in the MS diagnostic criteria. VEPs are abnormal (prolonged P100 latency or greater than 6 milliseconds interocular difference if the latencies are normal) in approximately 30% of patients with clinically isolated syndromes other than optic neuritis and more than 50% of MS patients without a history of visual symptoms or clinical evidence of optic nerve dysfunction. However, abnormal VEPs may be observed in patients with other disorders, including compressive lesions of the optic nerve or chiasm, glaucoma, retinal disease, vitamin B₁₂ deficiency, infectious diseases (e.g., neuroborreliosis, neurosyphilis), systemic lupus erythematosus (SLE), and neurosarcoidosis.

VEPs are prolonged in almost all patients with a recent episode of optic neuritis, and routine testing for diagnostic purposes is not indicated. However, latencies shorten (presumably as a result of remyelination or ion channel reorganization) between 3 months and 2 to 3 years after acute optic neuritis and return to normal in about 25% of patients, so normal responses do not exclude the possibility of prior optic neuritis. Multifocal VEPs, which simultaneously record responses from multiple regions of the visual field are more sensitive than conventional VEPs but are not currently widely available.

MRI has largely supplanted the use of somatosensory and brain stem auditory-evoked potentials, which are rarely useful for identifying patients at increased risk for developing MS and are not included in the MS diagnostic criteria.

Optical coherence tomography (OCT) is a noninvasive technique that uses low-frequency infrared light to measure retinal nerve fiber layer thickness (RNFL) and macular volume. OCT, which has been used by ophthalmologists since 1990 to monitor glaucoma, is now used in MS. Thinning of the RNFL occurs after optic neuritis as a result of loss of retinal axons. The eyes of MS patients without a history of optic neuritis also undergo thinning of the RNFL. OCT is used as a secondary and tertiary outcome measure in clinical trials and by some neurologists and ophthalmologists to follow patients with or without a history of optic neuritis.

Diagnostic Criteria

New MS diagnostic criteria, referred to as the *McDonald criteria* (after the late Ian McDonald), were established in 2001 and revised in 2005 and 2010 ([Table 69.2](#)). MRI abnormalities may be used to demonstrate dissemination in space and time, provided an individual has had one episode of neurologic dysfunction consistent with demyelinating disease (see the following text). This has allowed for an earlier

diagnosis. Eighty percent of patients diagnosed with MS based on MRI criteria will develop *clinically definite multiple sclerosis* (CDMS), a term formerly used to indicate two clinical demyelinating attacks separated in time and space, within 3 years if they

P.602

are left untreated. Early diagnosis is of great importance because MS disease-modifying drugs seem to be most effective when given early in the disease and a delay in treatment can result in irreversible neurologic damage.

TABLE 69.2 Multiple Sclerosis Diagnostic Criteria

Clinical Presentation	Additional Data Required for MS Diagnosis
Two or more attacks with objective evidence of two or more lesion on clinical examination or objective clinical evidence of one lesion with reasonable historical evidence of a prior attack	None
Two or more attacks with objective evidence of one lesion on clinical examination	Dissemination in space demonstrated by one of the following: a. DIS on MRI ^a b. Second clinical attack
One attack with objective evidence of two or more lesions on clinical examination	Dissemination in time demonstrated by one of the following: a. MRI ^b b. Second clinical attack
One attack with objective evidence of one lesion on clinical examination	Dissemination in space demonstrated by one of the following: a. MRI ^a b. Second clinical attack <i>and</i> Dissemination in time demonstrated by one of the following: a. DIT criteria for MRI ^b b. Second clinical attack
Insidious neurologic progression suggestive of MS (i.e., a clinical presentation consistent with primary progressive MS)	One year of disease progression <i>and</i> two of the following: a. Dissemination in space in brain according

- to 2010 McDonald
criteria
- b. Spinal cord MRI with
two T2 lesions
 - c. Positive CSF^c

If all criteria are fulfilled and alternative diagnoses have been excluded, the diagnosis is MS. If there is a suspicion of MS but only some of the criteria are met, the diagnosis is “possible MS.”

^aSee [Table 69.3](#) for MRI criteria for dissemination in space.

^bSee [Table 69.4](#) for MRI criteria for dissemination in time.

^cPositive CSF: two or more oligoclonal bands detected in the CSF that are not present in the serum or an elevated IgG index.

MS, multiple sclerosis; DIS, dissemination in space; MRI, magnetic resonance imaging; DIT, dissemination in time; CSF, cerebrospinal fluid.

Adapted from Polman CH, Reingold SC, Banwell B, et al. Diagnostic criteria for multiple sclerosis: 2010 revisions to the “McDonald Criteria.” *Ann Neurol.* 2011;69:292-302.

The diagnosis of relapsing-remitting MS requires at least one episode of neurologic dysfunction consistent with inflammation and demyelination occurring in the absence of fever or infection and lasting at least 24 hours along with objective evidence of lesions disseminated in space and time. Dissemination in space may be demonstrated by two anatomically distinct lesions on examination that are consistent with CNS demyelination (e.g., an extensor plantar response and optic atrophy) or a focal lesion on examination along with MRI evidence of dissemination in space ([Tables 69.2](#) and [69.3](#)). In the absence of two clinical attacks, dissemination in time may be demonstrated by subclinical disease evolution on MRI ([Table 69.4](#)). The diagnosis of primary progressive MS requires at

P.603

least 1 year of insidious neurologic progression combined with variety of MRI and CSF abnormalities (see [Table 69.2](#)).

TABLE 69.3 Magnetic Resonance Imaging Criteria for Dissemination in Space

T2 lesion in at least two of the four following areas:

- Periventricular
- Juxtacortical
- Infratentorial
- Spinal cord

If brain stem or spinal cord lesion is symptomatic, it is excluded from lesion count for DIS.

TABLE 69.5 Radiologically Isolated Syndrome

CNS white matter abnormalities meet the following criteria:

- Ovoid well circumscribed and homogeneous foci with or without involvement of corpus callosum
- T2 hyperintensities $>3 \text{ mm}^2$ and meeting three of four Barkhof criteria for dissemination in space
- CNS anomalies do not fit vascular pattern

No history of remitting clinical symptoms consistent with neurologic dysfunction

MRI anomalies do not account for clinically apparent impairments

MRI anomalies not related to toxic substances or medical condition

MRI anomalies not better accounted for by another disease

Exclusion of MRI phenotypes of leukoaraiosis or extensive white matter involvement without involvement of corpus callosum

CNS, central nervous system; MRI, magnetic resonance imaging.

Adapted from Okuda D, Mowry EM, Beheshtian A, et al. Incidental MRI anomalies suggestive of multiple sclerosis: the radiologically isolated syndrome. *Neurology.* 2009;72(9):800-805.

Characteristic MS lesions are occasionally discovered on MRI in individuals with no history of neurologic symptom and a normal examination. In the absence of clinical evidence of demyelination, even if MRI abnormalities are accompanied by the presence of CSF OCBs, an elevated IgG index, and delayed VEPs, a diagnosis of MS cannot be established. Formal criteria for this, termed *radiologically isolated syndrome*, were established in 2009 ([Table 69.5](#)).

DIFFERENTIAL DIAGNOSIS

In the absence of a definite diagnostic test, MS remains a diagnosis of exclusion. Most of the disorders that

may mimic MS can be excluded by a detailed history, thorough examination, and appropriate laboratory tests and diagnostic studies.

Infections that may mimic MS include neuroborreliosis, neurosyphilis, and rarely progressive multifocal leukoencephalopathy. Human T-lymphotropic virus type-1 (HTLV-1) and HIV should be considered in patients with a progressive myelopathy. Acute disseminated encephalomyelitis may be impossible to distinguish from a first attack of MS. However, it is more likely to follow an infection or vaccination; more common in children; and generally includes encephalopathy, which is a rare manifestation of MS. Although patients with sarcoidosis may initially present with neurologic symptoms, evaluation usually reveals evidence of systemic sarcoidosis. Other autoimmune diseases that should be considered include Behçet syndrome, Sjögren syndrome, SLE, vasculitis, and the antiphospholipid antibody syndrome. Susac syndrome is an autoimmune microangiopathic endotheliopathy that affects brain, retina, and cochlea and results in encephalopathy, hearing loss, and branch retinal artery occlusions. It may be mistaken for MS because of prominent white matter lesions that are observed on brain MRI. Drug-induced demyelination is a strong possibility in patients with Crohn disease or rheumatoid or psoriatic arthritis treated with antitumor necrosis factor therapies. NMO and the NMO spectrum of disorders may be difficult to distinguish from MS, particularly early in the disease, in patients with recurrent optic neuritis and minimally abnormal brain MRI, or in patients with brain MRI findings more characteristic of MS. NMO-IgG seropositivity may help differentiate the diseases. Neoplasms (especially primary CNS lymphoma and gliomas) occasionally enter the differential diagnosis. Hyperacute onset of symptoms suggests stroke. Primary lateral sclerosis may simulate primary progressive MS but does not relapse and is monosymptomatic. MRI and CSF analysis usually help differentiate the two diseases. Hereditary spastic paraparesis should be considered in patients with a progressive spastic paraparesis, especially if there is a family history of similar illness. Other causes of a progressive myelopathy that should be considered in patients suspected of having progressive MS include adrenomyeloneuropathy, vitamin B₁₂ deficiency, copper deficiency, spondylotic myelopathy, spinal cord tumors, and a spinal dural arteriovenous fistula.

TREATMENT

Therapy for MS consists of treatment of acute exacerbations, disease-modifying drugs, and symptomatic therapies. Optimal management often requires a multidisciplinary approach with pharmacologic and nonpharmacologic measures.

Treatment of Acute Exacerbations

High-dose intravenous (IV) corticosteroids hasten recovery from acute exacerbations but do not seem to affect the degree of recovery. A typical regimen consists of a 3- to 5-day course of 1,000 mg of IV methylprednisolone with or without an oral prednisone taper. Some patients with severe attacks seem to respond better to an additional 2 to 5 days of treatment. Because treatment does not seem to affect long-term outcome, not every MS exacerbation (e.g., mild sensory symptoms) requires treatment. In the Optic Neuritis Treatment Trial, patients who received oral prednisone 1 mg/kg/day did not improve any faster than the placebo-treated group. Furthermore, treatment with oral prednisone was associated with an increased risk of subsequent optic neuritis. Therefore, there does not appear to be a role for low-dose oral corticosteroids in the treatment of MS acute exacerbations [**Level 1**].¹

Fever and infections, including asymptomatic urinary tract infections, can cause transient worsening of MS symptoms without a corresponding worsening of the underlying disease. This is known as a *pseudoexacerbation*. Infections should be excluded in the setting of new or worsening symptoms before treatment with corticosteroids is initiated and fevers should be treated aggressively.

Plasma exchange may be warranted for the treatment of acute relapses that result in significant residual disability despite high-dose IV corticosteroid therapy. In a small, but well-designed study, 42% of patients with severe demyelinating events that did not respond to high-dose IV corticosteroids had marked functional improvement after seven plasma exchanges. Patients who responded were treated an average of more than 40 days after the onset of symptoms. The investigators of a larger retrospective study reported similar results and concluded that plasma exchange may be effective when initiated more than 60 days after the onset of an acute demyelinating event.

Disease-modifying Drugs

The β -interferons and glatiramer acetate are commonly used relapsing-remitting MS therapies. They are modestly effective in reducing relapses and have positive effects on a variety of disability and MRI measures [Level 1].^{2,3,4,5,6} Studies have also shown that these agents are effective (and possibly even more so) when initiated at the time of an initial clinical demyelinating event in patients with

P.604

at least two or three asymptomatic brain lesions (i.e., prior to an MS diagnosis), and delaying treatment results in irreversible neurologic deficit [Level 1].^{7,8,9,10} The interferons and glatiramer acetate clearly alter the short-term course of MS. Anecdotes along with retrospective and prospective open-label studies suggest a long-term treatment benefit, but controlled studies are lacking.

In head-to-head studies, the clinical effectiveness of glatiramer acetate was similar to the high-dose interferons (i.e., interferon β -1b 250 μ g administered subcutaneously every other day and interferon β -1a 44 μ g administered subcutaneously thrice weekly) in patients with relapsing-remitting MS.

The advent of oral therapies for relapsing MS, with the U.S. Food and Drug Administration (FDA) approval of fingolimod in 2010, followed by teriflunomide and dimethyl fumarate in 2012 and 2013, respectively, dramatically increased the options, with 10 therapies approved for the most common form of MS as of 2014. Table 69.6 summarizes available therapies for relapsing forms of MS.

TABLE 69.6 Overview of Disease-Modifying Therapies for Relapsing Forms of Multiple Sclerosis

Treatment	Dosage	Potential Side Effects	Monitoring
IFN β -1b	250 μ g	Flulike symptoms	CBC
IFN β -1a	SC	LFT abnormalities	LFTs
IFN β -1a	q.o.d. 30 μ g IM q.wk. 22 μ g or 44 μ g SC t.i.w.	Leukopenia Neutralizing antibodies Depression Injection site necrosis (rare)	TFTs
Glatiramer acetate	20 mg SC daily	Site reactions Lipoatrophy Immediate	None

	or 40 mg SC t.i.w.	postinjection reactions	
Mitoxantrone	12 mg/m ² IV q12wk	Heart failure Promyelocytic leukemia Bone marrow suppression Alopecia	MUGA scan annually after completion, assess ejection fraction prior to each dose. CBC Lifetime maximum dose: 140 mg/m ²
Natalizumab	300 mg IV q4wk	Progressive multifocal leukoencephalopathy LFT abnormalities Hypersensitivity reaction	JCV Ab MRI brain LFTs
Fingolimod	0.5 mg PO daily	Bradycardia at first dose LFT abnormalities Lymphopenia Macular edema Reactivation of herpes virus (zoster, oral or genital herpes)	First-dose observation with ECG before and 6 h after dosing and hourly vital signs, VZV immunity, baseline macula exam with follow-up eye exam 3-4 mo after initiation
Teriflunomide	7 mg or 14 mg PO daily	Gastrointestinal side effects Hair thinning LFT abnormalities (black box warning: hepatic failure) Hypertension Tuberculosis reactivation	Monthly LFTs for 6 mo after starting treatment Quantiferon gold or TB skin test
Dimethyl fumarate	240 mg PO b.i.d.	Gastrointestinal upset Flushing LFT abnormalities Lymphopenia	CBC with differential LFT

IFNB, interferon β ; SC, subcutaneous; IM, intramuscular; LFT, liver function test; CBC, complete blood count; TFT, thyroid function test; IV, intravenous; MUGA, multigated acquisition; JCV, John Cunningham virus; MRI, magnetic resonance imaging; ECG, electrocardiogram; VZV, varicella-zoster virus; PO, by mouth.

The therapeutic effects of interferon may be due to its antiproliferative action, downregulation of costimulatory molecules, decrease of proinflammatory cytokines, or through effects on matrix metalloproteinases and adhesion molecules, which reduce the permeability of the blood-brain barrier and limit trafficking of T lymphocytes into the CNS. The beneficial effects of glatiramer acetate, a synthetic polypeptide composed of the four amino acids L-alanine, L-glutamic acid, L-lysine, and L-tyrosine, may result

P.605

from reactive Th2 cells that cross the blood-brain barrier and increase the secretion of suppressor-type cytokines and downregulate inflammatory activity within the CNS, a process known as *bystander suppression*.

Natalizumab is a humanized monoclonal antibody that is highly effective for reducing relapse rate and new T2 and contrast-enhancing lesions on MRI in relapsing MS [Level 1].^{11,12} However, because it is associated with a low risk of progressive multifocal leukoencephalopathy (PML), it is used in conjunction with antibody testing for John Cunningham virus to predict risk of PML. Natalizumab likely exerts its therapeutic effects by blocking the binding of the $\alpha 4$ -subunit of $\alpha 4 \beta 1$ integrin expressed on the surface of activated T cells with its receptor vascular cell receptor molecule-1 (VCAM-1) on the vascular endothelial surface at the blood-brain barrier. The interaction between $\alpha 4$ and VCAM-1 is critical in order for T cells to gain access into the CNS.

Fingolimod is a functional antagonist of the sphingosine 1 phosphate receptor, which prevents egress of lymphocytes from peripheral lymph nodes. Reduction in relapse rate and MRI outcomes was significant compared to placebo and to weekly intramuscular interferon β -1a in two large randomized, double-blind, placebo-controlled trials [Level 1].^{13,14} Teriflunomide is a pyrimidine synthesis inhibitor, which slows expansion of activated lymphocytes. Modest efficacy in relapse rate reduction as well as reduction in sustained disability production was shown in large double-blind placebo-controlled trials [Level 1].^{15,16} Dimethyl fumarate is a fumaric acid ester shown to be effective in reducing relapse frequency and MRI activity in relapsing forms of MS [Level 1].^{17,18} Mechanism of action is hypothesized to be related to scavenging free radicals and acting through modulation of NF- κ B and Nrf2 pathways.

Initial treatment decisions should be individualized and based on a combination of efficacy, route of administration, and potential side effects particularly related to concomitant medical issues.

Neutralizing antibodies (NAbs) develop in 15% to 25% of patients treated with interferon β -1a 44 μ g subcutaneously three times a week and 25% to 40% treated with interferon β -1b. Interferon β -1a 30 μ g administered intramuscularly is clearly less immunogenic with NAbs occurring in only 2% of patients. NAbs typically develop between 6 and 18 months after the initiation of treatment and only rarely after more than 2 years of therapy. Although they may be transient, persistent high-titer NAbs (>100 NU/mL) are associated with a reduced therapeutic effect. Six percent of patients develop persistent anti-natalizumab antibodies, which are associated with a clear loss of efficacy and an increased risk of infusion-related hypersensitivity reactions.

Secondary progressive MS is more difficult to treat than the relapsing-remitting form of the disease. The high-dose interferons and a double dose of once-weekly intramuscular interferon β -1a reduce the number of relapses and MRI activity but do not have a consistent effect on disability progression. Patients with superimposed relapses, gadolinium-enhancing lesions, or rapidly accumulating disability may be most likely to respond to treatment. In a small study, glatiramer did not prevent progression of disability in patients with primary or secondary progressive MS.

Periodic pulses of IV methylprednisolone are not effective in preventing disability in patients with secondary progressive MS. However, in one study of patients with mild relapsing-remitting MS, they had a favorable effect on disability, brain atrophy, and T1-hypointense lesions.

Mitoxantrone is an anthracenedione with immunosuppressive and immunomodulatory properties and the only FDA-approved therapy for secondary progressive MS. However, its effects are modest and safety is a concern, so risks and benefits need to be carefully considered before treatment is initiated. Mitoxantrone is also effective in highly active relapsing MS. Six monthly infusions of 20 mg of mitoxantrone combined with 1 g of IV methylprednisolone dramatically reduce gadolinium-enhancing brain lesions and seem to decrease relapses and disability in patients with rapidly worsening relapsing-remitting and secondary progressive MS and active brain MRI.

There are no proven therapies for primary progressive MS. Mitoxantrone and interferon appear to be ineffective. Glatiramer acetate was evaluated in a large clinical trial, but the study was stopped prematurely because of futility. A trial with rituximab, a monoclonal antibody directed against the CD20 antigen on the surface of B cells, also yielded negative results. However, post hoc analyses of the two studies suggest that glatiramer acetate may be beneficial in men and a possible treatment effect with rituximab in several subgroups, including patients younger than age of 51 years and in those with baseline gadolinium-enhancing lesions.

Symptom Management

Therapies to alleviate the daily symptoms of MS are integral part of patient care. Successful treatment often involves a combination of pharmacotherapy with nonpharmacologic measures, such as rehabilitation, exercise, or lifestyle and environmental modifications. See [Table 69.7](#) for an overview of symptomatic management of common MS symptoms.

Management of spasticity includes evaluation and treatment of potentially exacerbating factors. Once exacerbating factors are minimized, a combination of physical therapy interventions and pharmacologic management is optimal. The most commonly used agents are baclofen and tizanidine alone or in combination. Common adverse effects of baclofen include limb weakness, sedation, and confusion. At higher doses, weakness may negate the benefit of spasticity reduction. Abrupt discontinuation of baclofen can result in seizures, confusion, hallucinations, and a marked increase in muscle tone. The use of tizanidine is mainly limited by drowsiness. Increased weakness is usually not a problem. Gabapentin may also be effective. The use of benzodiazepines has largely been supplanted by baclofen and tizanidine, which are better tolerated. Botulinum toxin may be effective for focal spasticity. Intrathecal baclofen may be beneficial for patients with severe leg spasticity that does not respond to oral agents at the highest tolerable dose.

Occupational and physical therapy are the mainstays of treatment for motor impairment. The potassium channel blocker dalfampridine, which is a sustained release formulation of 4-aminopyridine, enhances conduction across demyelinated nerve fibers. It improved leg strength and walking speed in some patients with relapsing and progressive forms of MS in two therapeutic trials. Dalfampridine increases the risk of seizures, especially at higher doses, and is contraindicated in those with history of seizures or impaired kidney function. The risk of seizure appears to be low with the effective dose of dalfampridine, which is 10 mg twice daily [**Level 1**].¹⁹

Depression responds well to psychotherapy and antidepressants, alone or in combination. Amitriptyline is effective for pseudobulbar affect (pathologic laughing or crying), as is a mixture of dextromethorphan and quinidine [**Level 1**].²⁰

To date, there is no clearly effective treatment for MS-related cognitive impairment. Some patients may

benefit from cognitive remediation and strategies to compensate for deficits. Donepezil improved memory in one small, controlled trial in MS patients

P.606

P.607

with mild to moderate cognitive impairment. In an open-label pilot study, donepezil was also effective in improving attention, memory, and executive functioning in severely cognitively impaired patients with MS who were residents of a long-term care facility. In another randomized, double-blind trial, low-dose (4.5 mg daily) naltrexone, an opioid receptor antagonist, improved self-reported cognitive function in MS patients. Disease-modifying drugs that minimize lesion development, tissue destruction, or brain atrophy may limit cognitive decline.

TABLE 69.7 Management of Multiple Sclerosis Symptoms

Symptom	Nonpharmacologic Approaches	Pharmacologic Approaches (Starting Dosage)
Spasticity	Physical and occupational therapy Exercise Evaluation of aggravating factors which may include the following: <ul style="list-style-type: none"> • Urinary tract infection • Decubitus ulcers • Pain • Constipation • Tight-fitting garments • Interferon β 	Baclofen (oral 10 mg t.i.d. or intrathecal) Tizanidine (4 mg q.h.s.) Benzodiazepines (varies) Botulinum toxin Gabapentin (300 mg t.i.d.)
Weakness	Physical and occupational therapy	Dalfampridine (10 mg b.i.d.)
Depression	Psychotherapy Support groups	Selective serotonin reuptake inhibitors Serotonin-norepinephrine reuptake inhibitors
Pseudobulbar affect	Psychotherapy to manage triggers	Dextromethorphan/quinidine (20/10 mg b.i.d.) Amitriptyline (10 mg q.h.s.)
Fatigue	Improve sleep habits Energy conservation techniques Evaluation of other causes of fatigue including the following: <ul style="list-style-type: none"> • Anemia • Thyroid dysfunction • Sleep apnea • Side effects of other medications 	Amantadine (150 mg b.i.d.) Modafinil (100 mg q.d.) Armodafinil (150 mg q.d.) Methylphenidate (10 mg q.d.)

- Elevated core body temperature

Sexual dysfunction	Psychotherapy and relationship counseling to help couples manage sexual difficulties Mechanical vibrators and vacuum devices to enhance blood flow, increase lubrication, and stimulate orgasm	Selective phosphodiesterase 5 inhibitors for erectile dysfunction Estrogen creams for vaginal dryness
Cognitive impairment	Neuropsychological testing to define areas of deficit, identify areas of relative strength for compensatory strategies Cognitive remediation	No clearly effective pharmacotherapy
Urinary dysfunction	Urodynamic studies to define specific type of dysfunction— failure to store or empty Biofeedback Evaluate for infection Clean intermittent catheterization	Anticholinergics Mirabegron (25 mg q.d.) α -Adrenergic antagonist Botulinum toxin Desmopressin for nocturia 0.1 mg q.h.s.
Bowel dysfunction	Biofeedback Dietary changes to increase fiber Increase water intake for constipation Scheduled defecation	Stool softener Stimulant laxative Osmotic laxative
Tremor	Deep brain stimulation	Primidone (25 mg q.h.s.) Propranolol (20 mg b.i.d.) Clonazepam (0.5 b.i.d.) Ondansetron (8 mg b.i.d.)
Paroxysmal symptoms (trigeminal neuralgia, paroxysmal dystonia)	Avoidance of triggers	Carbamazepine (100 mg b.i.d.) Acetazolamide (250 mg b.i.d.) Phenytoin (100 mg t.i.d.) Lamotrigine (100 mg q.d.) Baclofen (10 mg t.i.d.)
Pain	Avoidance of triggers	Gabapentin (300 mg t.i.d.) Pregabalin (75 mg b.i.d.) Amitriptyline (25 mg q.h.s.) Duloxetine (30 mg daily) Venlafaxine (37.5 mg b.i.d.)

Bladder dysfunction in MS can be well characterized by a urologic evaluation and urodynamic studies. A combination of anticholinergic therapy and an α -adrenergic antagonist (doxazosin, prazosin, tamsulosin,

terazosin) may facilitate emptying in individual with sphincter detrusor dyssynergia. Clean intermittent catheterization combined with an anticholinergic agent may be necessary for some patients. Those unable to tolerate medications or perform self-catheterization may require an indwelling catheter. Catheterization is the mainstay of therapy in patients with detrusor hypocontractility and emptying difficulties. Patients with good upper extremity function are usually able to perform clean intermittent catheterization. An indwelling catheter may be necessary for patients who cannot perform self-catheterization because long-term intermittent catheterization by a caregiver is usually not practical. Urologic follow-up is necessary for patients with a chronic indwelling catheter to monitor for the development of urinary tract and genital complications.

Numerous medications have been reported to be successful in treating MS tremor, including carbamazepine, clonazepam, gabapentin, levetiracetam, primidone, ondansetron, propranolol, and tetrahydrocannabinol. However, these agents are rarely effective and tremor can be the most difficult MS symptom to treat. Thalamic deep brain stimulation may result in dramatic improvement. Stable MS patients with disabling tremor for at least 1 year despite medical therapy who have no significant cognitive dysfunction, speech or swallowing problems, or other deficits in the affected limbs may be good candidates. If treatment is warranted, dysesthesias and pain usually respond to anticonvulsants and antidepressants, either used alone or in combination. Gabapentin, pregabalin, amitriptyline, nortriptyline, and duloxetine commonly provide relief. Myelopathic pain responds to opioids, which may be necessary in some patients. Referral to a pain specialist may be helpful for patients with refractory pain.

OUTCOME

MS is an extremely variable illness. Therefore, counseling patients with clinically isolated syndromes and early MS poses a major challenge for clinicians. However, brain MRI abnormalities after an initial clinical demyelinating event provide important prognostic information regarding the development of MS. Fifty-one percent of patients who initially have optic neuritis and at least three brain MRI T2-hyperintense lesions develop CDMS within 5 years compared to only 16% who have normal brain MRI. CDMS develops within 20 years in 82% of CIS patients with at least one brain MRI T2 lesion compared with 21% with a normal baseline brain MRI. Forty-one percent to 50% of placebo-treated patients in the interferon β or glatiramer acetate clinically isolated syndrome trials, which required at least two or three asymptomatic brain lesions for entry, developed CDMS within 2 to 3 years. In those studies, the risk of MS at 18 to 24 months was greatest in patients with more than eight T2-hyperintense lesions or at least one gadolinium-enhancing lesion on a baseline brain MRI.

In general, the larger the number of baseline brain MRI lesions at the time of a clinically isolated syndrome, the greater the risk of long-term disability. There is also a modest correlation between the change in MRI T2 lesion volume in the first 5 years and long-term disability. However, possible outcomes are wide ranging. In one natural history study, 45% of those with at least 10 lesions on initial brain MRI had reached Expanded Disability Status Scale (EDSS) 6 after 20 years, but 35% had only mild disability.

Although the course of MS is essentially impossible to predict in an individual patient, female sex, younger age at onset, and little disability 5 years after onset are generally favorable prognostic signs. Male sex, older age at onset, frequent attacks early in the course of the disease, a short interval between the first two attacks, incomplete recovery from the first attack, rapidly accumulating disability, cerebellar involvement as a first symptom, and progressive disease from onset are associated with worse outcome. Optic neuritis as a first attack is associated with a favorable short- and intermediate-term outcome, but 20-year disability is similar among patients who present with optic neuritis, brain stem, or spinal cord

syndromes. African-Americans have a lower prevalence of MS than whites but tend to accumulate disability more rapidly.

In one natural history study, 24% of patients with a clinically isolated syndrome who were followed for an average of 4 years reached an EDSS score of 6 or more (EDSS 6 is defined as unable to walk 100 m without unilateral assistance) and 40% of those followed for 6 to 15 years entered the secondary progressive phase of the disease. In another study, the natural course of the disease was less aggressive with only 24% of patients reaching EDSS of 6 or more and 39% developing secondary progressive MS 20 years after the onset of their first clinical demyelinating event.

Some patients have a very mild form of relapsing-remitting MS with minimal or no disability at least 10 years after disease onset, which is often referred to as *benign multiple sclerosis*. Although natural history studies have yielded conflicting results, most suggest that many of these patients will develop significant disability and enter the secondary progressive phase of the disease within 20 years. There are no reliable predictors to identify which patients will continue to have a mild course. Furthermore, neuropsychological testing reveals cognitive impairment in approximately 20% to 45% of patients considered to have benign MS. Therefore, the diagnosis of benign MS should include an assessment of cognitive function and only be considered in retrospect and after prolonged follow-up.

The Marburg variant of MS is a rare, fulminant, and usually monophasic illness that typically results in death within 1 year. It can be difficult to differentiate from severe acute disseminated encephalomyelitis. Pathologically, it is characterized by robust macrophage infiltrate and destruction of axons as well as demyelination and prominent tissue necrosis.

Schilder disease, or myelinoclastic diffuse sclerosis, is a vanishingly rare pediatric form of demyelinating disease characterized by formation of bilateral plaques in the centrum semiovale with pathology consistent with MS without additional lesions in the CNS in the setting of normal peripheral nervous system function, normal adrenal function, and no deficit in very long-chain fatty acids. A handful of cases have been reported since the original description by Schilder in 1912. There is controversy regarding the potential contamination of case series with children eventually found to have adrenoleukodystrophy.

NEUROMYELITIS OPTICA SPECTRUM DISORDER

Neuromyelitis optica spectrum disorder (NMOSD) is a severe inflammatory demyelinating disease of the CNS that is distinct from MS. Originally considered a monophasic illness characterized by the co-occurrence of acute or subacute optic neuritis and transverse myelitis, it is now recognized that NMOSD patients typically have recurrent attacks, and the disease is not always limited to the optic nerves and spinal cord. Although there is overlap with the presentation of MS, the disease has a distinct pathologic antibody and the features of the optic neuritis and myelitis are distinct from MS. The most common clinical syndrome is longitudinally extensive transverse myelitis, as opposed to the relatively short segments of spinal cord that tend to be involved in MS myelitis. Optic neuritis may be unilateral or bilateral and is often severe with poor recovery. A third clinical hallmark is intractable nausea, vomiting, or hiccups.

EPIDEMIOLOGY

The true incidence and prevalence of NMOSD are unknown. However, the disease is much less common than MS; estimated prevalence rate is about 1% to 2% that of MS in the United States. NMOSD usually begins late in the fourth decade, but the onset may occur during childhood or after age 70 years. Women are affected four to nine times as often as men, and nonwhite individuals are more commonly affected than whites.

PATHOBIOLOGY

Aquaporin 4-IgG is both a sensitive and highly specific serum autoantibody that is present in about 70% of NMOSD patients in either serum or CSF. Pathogenicity of the aquaporin 4-IgG has been demonstrated by passive transfer in animal models.

Acute NMO lesions are characterized by extensive demyelination and axonal damage and contain an inflammatory infiltrate consisting mainly of macrophages, B lymphocytes, eosinophils, and granulocytes. T lymphocytes are sparse. Immunoglobulin and products of complement activation are deposited in a distinctive perivascular rim and rosette pattern. Intramedullary lesions typically extend over several spinal levels, involve both gray and white matter, and are often necrotic. Gliosis, cystic degeneration, cavitation, and atrophy are typical of chronic spinal cord and optic nerve and chiasmal lesions.

Aquaporin-4 (AQP4), which is the main water channel in the CNS, is the target antigen in NMOSD. AQP4 is located primarily in perivascular and subpial astrocytic foot processes and expressed in high levels within the optic nerves, hypothalamus, brain stem, periventricular regions, and gray matter of the spinal cord. AQP4 loss may impair water homeostasis and glutamate transport and lead to oligodendrocyte injury, demyelination, and axonal damage. The circumventricular organs around the third and fourth ventricles contain high density of AQP4 and this may explain the presentations of intractable nausea, vomiting, hiccups, as well as hypothalamic dysfunction.

A marked loss of AQP4 immunoreactivity is observed in all NMO demyelinating lesions regardless of location, stage, or degree of necrosis and occurs in regions with extensive vasocentric immunoglobulin and complement deposition.

CLINICAL MANIFESTATIONS

Patients typically experience frequent and severe exacerbations of optic neuritis or myelitis interspersed with periods of remissions. See [Table 69.8](#) for a description of classic NMOSD presentations. A secondary progressive course with continuous worsening between exacerbations is uncommon, occurring in only 2% of patients.

At onset, patients usually present with unilateral optic neuritis or myelitis. In approximately 50% of patients, the initial attack is severe with visual acuity reduced to finger counting or worse or Medical Research Council (MRC) grade 3 or 4 weakness in at least one extremity. There is often considerable improvement after the

P.609

first attack, but a second episode occurs in 55% of patients within 1 year and in 90% within 5 years.

TABLE 69.8 Classic Presentations of Neuromyelitis Optica Spectrum Disorder

Symptom	Sign	Localization
Blurred vision Pain with eye movement	Relative apparent pupillary defect Red desaturation	Optic nerve
Leg weakness	Paraparesis or monoparesis	Spinal cord
Intractable vomiting or hiccups		Area postrema

Disease outside of the spinal cord and optic nerves occurs in 10% to 15% of patients. Symptoms include vomiting, intractable hiccups, narcolepsy, facial weakness or numbness, diplopia, vertigo, dysarthria, trigeminal neuralgia, tremor, ataxia, hearing loss, hemiparesis, and encephalopathy.

The prognosis of untreated NMOSD is poor, with the potential for profound visual loss and weakness developing early in the course of the disease as a result of incomplete recovery from attacks. Myelopathic pain, spasticity, dysesthesias, tonic spasms, as well as bowel and bladder dysfunction are common. In a cohort of patients seen at the Mayo Clinic, 60% were legally blind in at least one eye and more than 50% had either a mono- or paraplegia within 8 years of disease onset. The 5-year survival rate was only 68%, and all deaths were attributable to respiratory failure from acute intramedullary cervical spine lesions.

DIAGNOSIS

The diagnosis of NMO is established by clinical features that are supported by MRI and, sometimes, serologic findings. A new set of diagnostic criteria for NMOSD has been proposed by an expert consensus panel and is likely to be published in 2014. Current diagnostic criteria are listed in [Table 69.9](#). In a patient with a history of optic neuritis, myelitis extending over three or four spinal cord segments, and an unremarkable brain MRI, the diagnosis is usually straightforward. However, diagnostic uncertainty often exists when patients initially present with severe optic neuritis and a normal or minimally abnormal brain MRI or a longitudinally extensive transverse myelitis. The latter may be defined as NMOSD after infectious and collagen-vascular diseases, sarcoidosis, tumors, and vascular myelopathies are excluded. These patients have a *form fruste* of the disease with optic neuritis or longitudinally extensive transverse myelitis and unremarkable brain MRI.

Initial brain MRI is normal or reveals fewer than three or four white matter lesions in 97% of patients. If not already present, subsequent imaging often reveals clinically silent nonspecific white matter lesions. However, at least 10% of patients eventually develop lesions characteristic of MS.

Approximately 7% of AQP4-IgG seropositive patients develop brain lesions that are considered characteristic of NMO but atypical of MS. These lesions tend to occur in the hypothalamus, thalamus, brain stem, and around the third and fourth ventricles, which are all sites of high AQP4 expression. Large lesions in the cerebral hemispheres are occasionally observed.

In the setting of a recent myelitis, spinal cord MRI is the most sensitive diagnostic test for NMO. Longitudinally extensive T2 lesions involving more than three vertebral segments, and frequently more than six, are characteristic of NMO ([Fig. 69.8](#)). Preferential central gray matter involvement as well as gadolinium enhancement and spinal cord swelling are common. Lesions often become smaller over weeks to months, either spontaneously or in response to corticosteroids, and spinal cord atrophy may develop.

FIGURE 69.8 NMOSD patient with an acute myelitis. Sagittal T2-weighted image (A) of the cervical spine shows an intramedullary lesion extending from C1 to T1 accompanied by spinal cord swelling. A second lesion is seen in the visualized portion of the upper thoracic spine. A follow-up MRI (B) 8 months later shows marked improvement.

TABLE 69.9 Neuromyelitis Optica Diagnostic Criteria

Required criteria:

1. Optic neuritis
2. Acute myelitis

At least two of three supportive criteria:

1. Spinal cord MRI lesion extending three or more contiguous vertebral segments
2. Initial brain MRI with fewer than four white matter lesions or three lesions if one is periventricular
3. NMO-IgG seropositivity

MRI, magnetic resonance imaging; NMO-IgG, neuromyelitis optica immunoglobulin G.

Adapted from Wingerchuk DM, Lennon VA, Pittock SJ, et al. Revised diagnostic criteria for neuromyelitis optica. *Neurology*. 2006;66:1485-1489.

The morphology of acute NMO spinal cord lesions is unlike MS lesions, which rarely involve more than one-and-a-half vertebral segments or gray matter. Although characteristic of NMO, longitudinally extensive lesions are not specific and are seen in a variety of illnesses, including infectious and other inflammatory diseases, as well as in patients with vascular lesions and tumors (Fig. 69.9).

Biomarkers

AQP4-IgG is detected in 73% of patients with NMO and has a 91% specificity in differentiating NMO from MS patients who present with myelitis and optic neuritis. The antibody appears to be even more specific in distinguishing NMO from classic MS and a variety of other autoimmune and inflammatory neurologic

disorders.

In patients with a history of optic neuritis, a longitudinally extensive myelitis, and a minimally abnormal brain MRI, AQP4-IgG testing is not necessary to establish a diagnosis of NMO, as negative serology does not exclude it. Serologic testing may be most useful in patients who have a history consistent with NMO but atypical brain lesions or MRI findings characteristic of MS.

AQP4-IgG is also detected in 45% of patients at high risk for developing NMO (i.e., patients with recurrent optic neuritis or

P.610

longitudinally extensive transverse myelitis and brain MRI findings that do not fulfill criteria for MS).

Seropositivity predicts the development of NMO or recurrent longitudinally extensive transverse myelitis and provides the rationale for AQP4-IgG testing in these individuals.

FIGURE 69.9 Longitudinally extensive spinal cord lesions in other diseases. Sagittal **(A)** and axial **(B)** T2-weighted images of the cervical spine show an intramedullary lesion predominantly involving gray matter from C2 to C6 in a patient with neuroborreliosis. A sagittal T2-weighted image **(C)** of the cervical spine shows an intramedullary lesion extending from C4 to T1 and spinal cord swelling at C5-C6 in a patient with neurosarcoidosis. A sagittal T2-weighted image **(D)** of the distal spinal cord and conus medullaris shows

increased signal in the lower thoracic spinal cord, a small hemorrhage (*arrow*) at the conus tip, and numerous flow voids along the posterior spinal cord surface in a patient with a dural arteriovenous fistula.

Although not part of the current NMO diagnostic criteria, CSF analysis may be informative in some patients and useful to exclude alternative diagnoses. When examined within 4 weeks of the onset of an exacerbation, the CSF typically reveals a mild pleocytosis and an elevated protein. However, approximately 35% of patients have greater than 50 WBC per cubic millimeter and there may be more than 1,000 WBC per cubic millimeter. In addition, more than 5 neutrophils per cubic millimeter are present in the CSF in up to 60% of patients. Neutrophilic pleocytosis or more than 50 WBC per cubic millimeter in the CSF are uncommon findings in MS. Oligoclonal bands are present in about 20% to 30% of NMO patients and are not useful in differentiating NMO from MS.

Serum non-organ-specific autoantibodies, especially antinuclear or extractable nuclear antibodies, are frequently detected in NMO patients. Rheumatoid factor or double-stranded DNA antibodies are less commonly observed. The clinical significance of these antibodies is unclear, as the coexistence of NMO with SLE, Sjögren syndrome, or other autoimmune diseases with the exception of thyroid disease, is rare. However, their presence is another indication of aberrant humoral immunity.

TREATMENT

NMO exacerbations are usually treated with intravenous methylprednisolone 1 g daily for 5 to 7 days. Plasma exchange, which is indicated for severe exacerbations that do not respond to high-dose intravenous corticosteroids, results in functional improvement in up to 60% of patients.

There are ongoing early phase controlled therapeutic trials in NMO with monoclonal antibodies including the complement inhibitor eculizumab and the IL-6 receptor inhibitor, tocilizumab. Level 1 treatment evidence is lacking in NMO and NMOSD. Treatment with immunosuppressive or immunomodulatory therapies aimed at altering the course of the disease is based on anecdotes and small open-label studies. Interferon- β and glatiramer acetate appear to worsen the course of NMOSD. Mycophenolate mofetil or the combination of prednisone and azathioprine may be beneficial in some patients. Mitoxantrone was reported to have some benefit in a study of five patients, but treatment is limited to 2 to 3 years due to dose-related irreversible cardiotoxicity. Treatment-associated leukemia is also a concern, as it is in MS. The results of an open-label study with rituximab, a monoclonal antibody directed against the CD20 antigen on the surface of B cells, are encouraging. However, B-cell depletion does not prevent severe disease activity and a randomized controlled trial is needed.

Therapies aimed at treating spasticity, pain, sphincter dysfunction, and other chronic NMOSD symptoms play an integral part in patient management and are similar to the ones used to treat some of the daily symptoms of MS.

MARCHIAFAVA-BIGNAMI DISEASE

Primary degeneration of the corpus callosum is characterized clinically by altered mental status, seizures, and multifocal CNS signs. Demyelination of the corpus callosum without inflammation is the primary pathologic feature but other areas of the CNS may be involved. The disease was first described by Marchiafava and Bignami in 1903 in three Italian red wine drinkers.

EPIDEMIOLOGY

A few hundred cases have been described in the world's literature, but the disease is probably more common.

death because the symptoms and findings are nonspecific. Genetic susceptibility has been suspected because of the frequency of reports in Italian men. Onset is usually in middle age or later.

FIGURE 69.10 Marchiafava-Bignami disease. Acute necrosis of corpus callosum and neighboring white matter of the frontal lobes. (From Merritt HH, Weisman AD. Primary degeneration of the corpus callosum [Marchiafava-Bignami's disease]. *J Neuropathol Exp Neurol.* 1945;4:155-163.)

PATHOBIOLOGY

The cause is not known. The condition was first noted in middle-aged and elderly Italian men who consumed red wine. It has been described worldwide, however, and is not confined to red wine. In some cases, alcohol consumption was not a factor. Nutritional deficiencies have also been implicated. The syndrome is rare, however, even in severe malnutrition. Toxic factors have been suggested, but no agent has been implicated.

The sine qua non is necrosis of the medial zone of the corpus callosum. The dorsal and ventral rims are spared. The necrosis varies from softening and discoloration (Fig. 69.10) to cavitation and cyst formation. Usually, all stages of degeneration are found. In most cases, the rostral position of the corpus callosum is affected first. The lesions arise as small symmetric foci that extend and become confluent. Although medial necrosis of the corpus callosum is the principal finding, there also may be degeneration of the anterior commissure (Fig. 69.11), posterior commissure, centrum semiovale, subcortical white matter, long association bundles, and middle cerebellar peduncles. All these lesions have a constant bilateral symmetry. Usually spared are the internal capsule, corona radiata, and subgyral arcuate fibers. The gray matter is not grossly affected.

FIGURE 69.11 Marchiafava-Bignami disease. Medial necrosis of the corpus callosum and anterior commissure with sparing of the margins. (Courtesy of Dr. P. I. Yakovlev.)

Few diseases have such a well-defined pathologic picture. The corpus callosum may be infarcted as a result of occlusion of the anterior cerebral artery, but the symmetry of the lesions, sparing of the gray matter, and occurrence of similar lesions in the anterior commissure, long association bundles, and cerebellar peduncles are found only in Marchiafava-Bignami disease. The microscopic alterations are the result of a sharply defined necrotic process with loss of myelin but relative preservation of axis cylinders in the periphery of the lesions. There is usually no evidence of inflammation aside from a few perivascular lymphocytes. In most cases, fat-filled phagocytes are common. Gliosis is usually not well advanced. Capillary endothelial proliferation may be present in the affected

P.612

area, but no thrombi are seen. The disease has been reported with central pontine myelinolysis or Wernicke encephalopathy in alcoholics and in nonalcoholic persons, thus suggesting a possible common pathogenesis.

CLINICAL MANIFESTATIONS

The onset is usually insidious, and the first symptoms are so nonspecific that the time of onset is difficult to determine. There is a mixture of focal and diffuse signs of cerebral disease. In addition to memory loss and confusion, manic, paranoid, or delusional states may occur. Depression and extreme apathy are typical.

DIAGNOSIS

Marchiafava-Bignami disease is suspected when insidiously developing dementia, multifocal neurologic signs, and seizures occur in elderly men, particularly alcohol abusers. CT and MRI are accurate in diagnosis, but MRI is preferred in showing the callosal lesions and symmetric demyelinating lesions in

subcortical white matter. In the original reports, status epilepticus was prominent and, in modern times, an acute form may be seen. The differential diagnosis includes Wernicke encephalopathy, which may occur simultaneously, manifested by ataxia, ophthalmoplegia, and nystagmus as well as dementia or delirium. In a review of 153 cases reported between 1981 and 2012, CSF pleocytosis was reported in 0% of the confirmed minimal brain damage (MBD) cases. Elevated CSF protein was found in only 8%.

TREATMENT

Generally, the outlook for recovery is poor. However, spontaneous recovery has been reported, and some patients improve with thiamine or corticosteroid therapy. Metabolic recovery may be documented by MRS.

OUTCOME

The disease is slowly progressive and results in death within 3 to 6 years. Rarely, fever lasts days or weeks, or a temporary remission may be seen.

Pontine and Extrapontine Myelinolysis

Gary L. Bernardini

Elliott L. Mancall

INTRODUCTION

In 1959, Adams, Victor, and Mancall described a distinctive, previously unrecognized disease characterized primarily by the symmetric destruction of myelin sheaths in the basis pontis. They called it *central pontine myelinolysis* (CPM). The general term *myelinolysis* may be more appropriate because the condition affects extrapontine brain areas as well. The term *osmotic demyelination syndrome* has also been applied. CPM can occur alone or in combination with extrapontine myelinolysis (EPM) in 10% to 20% of cases; isolated EPM may also be found.

Myelinolysis is a neurologic complication that can develop after too rapid correction of hyponatremia to normal or supranormal levels. Chronic alcoholism and undernutrition are frequently associated with this condition. Pontine myelinolysis has been seen, however, in hyponatremic nonalcoholic patients, including conditions of dehydration resulting from vomiting, diarrhea, or diuretic therapy, with postoperative overhydration or with psychogenic water intoxication. Severe malnutrition, including that resulting from extensive burn injuries, may be a predisposing condition. In addition, pontine myelinolysis occurs in chronic alcohol users with profound hypophosphatemia. There may also be an association between hyponatremia and hypokalemia in some cases. Some reports of myelinolysis have been in patients with alcoholic cirrhosis or after interferon therapy who had normal serum sodium. However, in most cases, the main factor underlying development of myelinolysis appears to be too rapid correction of serum sodium levels. Correction after hypernatremia rather than hyponatremia has also been encountered. The condition has been described with increasing frequency in patients undergoing orthotopic liver transplantation. Pontine myelinolysis is found in 0.28% to 9.8% of these cases. In liver failure, lack of sufficient energy for adequate glial cell function, deficiency of important organic osmolytes such as myoinositol to protect the brain from sudden changes in serum osmolality, or negative nitrogen balance decreasing amount of amino acids to form essential organic osmolytes are possibilities that predispose these patients to develop CPM. Similarly, rapid correction of hyponatremia has led to myelinolysis in the uremic patient on hemodialysis. However, a more benign form of pontine myelinolysis may occur without hyponatremia in alcoholic binge drinkers or some with anorexia nervosa. This syndrome has good clinical outcome, and magnetic resonance imaging (MRI) abnormalities disappear. EPM incidence appears to be increasing possibly due to sensitivity in detection through improved quality MRI.

EPIDEMIOLOGY

Predisposing factors associated with CPM include alcoholism, chronic malnutrition, and sodium imbalances. In large case series of patients with CPM, Lampl and Yazdi found that 39.4% were alcoholics, 21.5% had too rapid correction of hyponatremia, and 17.4% were liver transplant recipients. Studies have reported CPM to occur in cases of rapid correction of hyponatremia or hypernatremia. In addition, the incidence of CPM increases in alcoholic patients even with normonatremia. An association of hypokalemia with hyponatremia has been implicated in this disease, with suggestion of correcting hypokalemia prior to correcting low sodium levels in treating these patients.

CLINICAL MANIFESTATIONS

The clinical manifestations vary from asymptomatic to comatose, although patients may present with generalized

encephalopathy associated with low levels of serum sodium. Neurologic signs and symptoms of myelinolysis usually appear within 2 to 3 days after rapid correction of sodium levels. Classically, initial symptoms of dysarthria and dysphagia with initial flaccid quadriplegia (later to become spastic) can be seen on examination after correction of hyponatremia. Other findings are mutism, behavioral abnormalities, frank psychosis, ophthalmoparesis, bulbar and pseudobulbar palsy, hyperreflexia, seizures, and coma. Typically, rapidly progressive corticobulbar and corticospinal syndrome may be noted in debilitated patient, often during an acute illness with associated electrolyte imbalance and correction or overcorrection of hyponatremia. Although the patients are mute, coma is unusual. The patients may be “locked in,” and communication by eye blinking can sometimes be established. The course is rapid, and death generally ensues within days or weeks after onset of symptoms.

EPM can lead to ataxia, irregular behavior, visual field deficits, parkinsonism, choreoathetosis, dystonia, or paroxysmal kinesigenic dyskinesias. The movement disorders can appear with or without radiographic evidence of EPM. Movement disorders as result of EPM may represent treatable form with some improvement noted after dopaminergic therapy. In EPM, bilateral symmetric involvement may affect white matter of basal ganglia (caudate/putamen), cerebellum, thalamus, midbrain (substantia nigra), corpus callosum, subcortical white matter, claustrum, hypothalamus, lateral geniculate bodies, amygdala, subthalamic nuclei, or medial lemnisci with sparing of the pons and globus pallidus.

DIAGNOSIS

Although historically, most cases have been diagnosed only at autopsy, the syndrome can now be diagnosed in life through neuroimaging along with clinical presentation. Computed tomography (CT) scans may be normal, especially early in the course, but CT abnormalities include symmetric areas of hypodensity in the basis pons and extrapontine regions without associated mass effect. MRI is more sensitive and typically shows symmetric increased signal intensity in the central pons (described as *trident-shaped*) on T2-weighted and fluid-attenuated inversion recovery (FLAIR) images; lesions appear hypointense on T1-weighted images and typically do not enhance (Fig. 70.1). MRI diffusion-weighted imaging (DWI) may be even more sensitive testing because it

P.617

demonstrates increased signal of restricted diffusion of water in the central pons within 24 hours of onset of symptoms of myelinolysis. Lesions seen within the basis pons typically spare the tegmentum and may extend to ventral midbrain but rarely involve medulla.

FIGURE 70.1 Central pontine myelinolysis on MRI. Axial T1- and T2-weighted MRI in 23-year-old alcoholic after rapid correction of severe hyponatremia, showing hypointense (**A**) and hyperintense (**B**) “trident-shaped” basis pontine lesion consistent with pontine myelinolysis. **C**: Sagittal T1-weighted MRI showing hypointensity in area of pons consistent with demyelination. (Courtesy of Dr. William Wagle.)

Even though conventional imaging with CT and MRI may lag behind clinical manifestations by up to 2 weeks, MRI DWI remains the most sensitive technique for early diagnosis. However, in clinically suspicious cases with initial negative neuroimaging, repeat MRI is recommended within 2 weeks of symptom onset. Other studies with magnetic resonance spectroscopy, with decreased *N*-acetylaspartate (NAA)/creatine (Cr) ratio, increased choline (Cho)/Cr ratio may be helpful in the acute phase with diagnosis of CPM. Brain stem auditory-evoked responses may demonstrate prolonged III to V and I to V latencies consistent with bilateral pontine lesions. An electroencephalogram (EEG) may show slowing and low voltage. Cerebrospinal fluid (CSF) levels of protein and myelin basic protein may be elevated.

FIGURE 70.2 Central pontine myelinolysis. Histologic section through rostral pons showing characteristic lesion. (Courtesy of Dr. J. Kepes.)

PATHOBIOLOGY

The principal pathologic change is demyelination; within affected areas, there is degeneration with loss of oligodendrocytes but nerve cells and axon sheaths are spared, blood vessels are unaffected, and there is no inflammation. The pathophysiology seems caused by physiologic imbalance of osmoles in the brain. Apoptosis may deplete supply of energy to glial cells and Na^+/K^+ adenosine triphosphatase (ATPase) pumps, thus impairing cellular adaptation to osmotic stress. In animal studies, the initial event after administration of hypertonic saline in hypotonic rats seems to be opening of the blood-brain barrier, followed sequentially by swelling of the inner loop of the myelin sheath, oligodendrocyte degeneration, and release of macrophage-derived factors leading to the eventual breakdown of myelin. Histologically, the lesion begins in the median raphe and may involve all or part of the base of the pons (Fig. 70.2). The lesion may spread into the pontine tegmentum or superiorly into the mesencephalon or involve bilateral extrapontine areas with or without concurrent basis pontis lesions. Microscopically, lesions resemble those of Marchiafava-Bignami disease (demyelination of corpus callosum and other commissural fibers, commonly seen in the context of chronic alcoholism and malnutrition).

The exact cause of myelinolysis is uncertain. In those with hyponatremia that has been rapidly corrected to normal or supranormal levels, it is not clear whether the low sodium, the rate of correction, or absolute change in serum sodium content is causative factor. However, symptoms are more likely to develop with rapid correction of chronic (>48 hours) rather than acute hyponatremia. In experimental animals, pontine myelinolysis developed in hyponatremic rats, rabbits, or dogs treated rapidly with hypernatremic saline. Animals left with untreated hyponatremia did not develop neuropathologic changes. Therefore, attention has focused on rate of correction of

the hyponatremia rather than on hyponatremia itself as inciting mechanism of myelinolysis. A recent study has suggested loss of activity of brain aquaporins (specifically aquaporins 1 and 4) affecting redistribution of water and osmolytes across various brain compartments may be seen in pontine myelinolysis.

PREVENTION AND TREATMENT

Prevention of myelinolysis includes judicious correction of hyponatremia with normal saline and free-water restriction, discontinuation of diuretic therapy, and correction of associated metabolic abnormalities and medical complications. At present, there are no clinical trials providing Level 1 evidence for the appropriate treatment of CPM. Hyponatremic patients who are asymptomatic may not require saline infusion. Those with agitated confusion, seizures, or coma should be treated with normal saline until the symptoms improve. Caution should be used in giving hypertonic saline to patients with symptomatic hyponatremia; frequent laboratory evaluations of serum sodium should be used as a guide to avoid too rapid correction of low sodium levels.

Stepwise correction of hyponatremia is shown in [Table 70.1](#). Some have reported success in treating CPM with high-dose pulse therapy with methylprednisolone (1 g/day for 5 days), plasmapheresis, or immunoglobulins. Based on clinical data and animal studies, there is low incidence of myelinolysis if increase in serum sodium is less than or equal to 12 mmol/L in 24 hours. Late appearance of tremor, dystonia, or cognitive and

P.619

behavioral changes has been reported in survivors. Prognostic factors that are favorable for recovery include absence of coexisting hypokalemia, less severe hyponatremia, and less severe clinical syndrome on admission and discharge. Full recovery has also been seen.

TABLE 70.1 Stepwise Correction of Hyponatremia

- | | |
|----|--|
| 1. | Calculate total sodium deficit.
$\text{Sodium deficit} = (140 - \text{serum sodium}) \times \text{total body water (TBW = 0.6 [men] or 0.5 [women])} \times \text{kg lean body mass}$ |
| 2. | Determination of rate of sodium infusion Depending on desired rate of increased serum sodium (i.e., ≤ 12 mmol/L/day) and effect of 1 L of any infusate on serum sodium levels
Use the formula: $\text{change in serum sodium} = (\text{infusate sodium} + \text{infusate potassium}) - \text{serum sodium} / \text{TBW} + 1$ |
| 3. | Maximum desired sodium increase over 24 h: ≤ 12 mmol/L |

Autoimmune Meningitis and Encephalitis

Lawrence S. Honig

INTRODUCTION

Meningitis and encephalitis are defined as inflammatory conditions of the meninges or brain, and often occur together as meningoencephalitis, affecting both meninges and cerebrum. Meningitis may present with various symptoms including headache, fever, painful eye movements, neck stiffness, and cranial or limb radiculopathies. However, it is specifically defined by evidence of cellular infiltration of the meninges. As such, it is generally evident through laboratory testing, finding abnormal numbers of white blood cells in the cerebrospinal fluid (CSF), and sometimes also evident radiologically through abnormal densities or enhancements of the meninges. Encephalitis is more difficult to define clinically, as the symptoms may include varying degrees and regional involvements of brain dysfunction. Indeed, many disorders are described as encephalitis even when they may involve a subacute injurious process to the brain that does not specifically include inflammation per se. (These include toxic, metabolic, mitochondrial, prion, or neoplastic disorders discussed in other chapters that best would be termed *encephalopathies*, rather than encephalitides.) The gold standard for defining encephalitis is brain biopsy, but this is required infrequently. Encephalitis can generally be inferred by the presence of abnormal clinical findings referable to the brain, with accompanying evidence of inflammation of the brain, often by neuroimaging. Supportive features can include electroencephalographic findings suggesting acute brain injury, and accompanying meningitis. Classically, meningitis and encephalitis were perceived as attributable to infectious etiologies. Causative organisms included more or less relatively identifiable typical or atypical bacteria, fungi, or parasites or often less identifiable viruses. However, recent decades have brought with them the advent of increasing general good health, decreasing infectious causes of these disorders, and increasingly potent molecular tools allowing better diagnosis. Thus, it has become clear that a significant fraction of meningitis and encephalitis, particularly after the period of infancy, and particularly in the developed world, has no apparent infectious cause. In recent years, a number of inflammatory syndromes without known external organismal causative underpinnings have been defined as clinicopathologic entities. The acute multiple sclerosis-like syndrome, involving mostly white matter, called *acute disseminated encephalomyelitis* (ADEM), still has no clear pathoetiology. However, improvements of molecular assay techniques have led to the categorization of a number of other clinical encephalitis syndromes, mostly involving cerebral gray matter, through identification of the presence in serum and/or CSF of characteristic antibodies to nervous system proteins. The antigens to which these antibodies are directed include intraneuronal proteins (Hu, Yo, Ma), synaptic proteins, and cell surface proteins. The cell surface antigens are actually the most common and most notably include the voltage-gated potassium channel complex (VGKCC) receptor and glutamate *N*-methyl-D-aspartate receptor (NMDAR). Despite incomplete understanding of their pathogenic basis, these various encephalitic disorders characterized by presence of antineuronal antibodies are best termed the *immune-mediated encephalitides*. They may be further categorized as being of autoimmune idiopathic nature or autoimmune and associated with a neoplasm. These latter are termed *paraneoplastic syndromes*. However, because so many of the same syndromes occur in the presence or absence of a neoplasm, it is most useful to consider these disorders as immune-mediated, with or without an identified underlying associated factor such as a malignancy.

EPIDEMIOLOGY

The incidence and prevalence of encephalitis is not well established due to differences in populations, diagnosis, and reporting. Recent studies suggest an overall incidence rate across all age ranges of about 50 cases of all-

cause encephalitis per million persons. Of these, about 40% are infectious, 40% unknown cause, 10% ADEM, and 5% each are NMDAR and VGKCC antibody encephalitis. A number of studies have suggested that, excluding infants and excluding epidemics, NMDAR encephalitis is more common than any other single sporadic viral encephalitic etiology. Thus in adults, the incidence of VGKCC and NMDAR antibody disorders probably is each somewhat similar to that of Creutzfeldt-Jakob disease with an incidence rate of about two per million persons per year. VGKCC antibody encephalitis occurs more often in persons older than the age of 50 years and affects men more than women (about 65% men). NMDAR encephalitis is increasingly recognized in the pediatric population, and more than half of cases occur in children. A series of about 500 cases has shown a median age of onset of 21 years with a range of 8 months to 85 years. There is a strong female predominance (81%), but among patients younger than 12 years, or older than 45 years, as many as 40% of cases are male. Only about 40% of patients have tumors, but of those with tumors, more than 95% are women. Tumors are more common among patients of Asian or African ancestry. Individuals with tumors that are resected improve more quickly, require less treatment, and are much less likely to relapse. With or without tumor, 2 years after treatment, there is a good outcome in 80% of cases, with independent living, without disability, or only mild symptoms or disability. However, there is also a fatality rate of about 5%.

PATHOBIOLOGY

The general defining feature of the immune-mediated meningoencephalitides are the presence of specific autoantibodies directed toward nervous system antigens. It is not entirely clear that the antibodies themselves are pathogenic, and some have suggested that they might be bystanders in disease pathogenesis. For the antibodies directed toward intraneuronal antigens, evidence is indeed weak that the antigen relates to the syndromes and that the antibodies themselves are pathogenic; perhaps cytotoxic T cells are more responsible for disease pathogenesis and neural destruction. For the cell surface antigens, a variety of observations are suggestive

P.621

that the antibodies themselves may play an important part in the pathogenesis of the disorders. Antibody levels may correlate with disease activity; procedures to reduce immune response may result in clinical improvement; and in some cases, animal models have been developed mimicking the effects of antigen depletion. The genesis of these disorders is generally conceptualized as beginning with the development of an immune response to an autoantigen in the nervous system, either spontaneously due to exposure of the immune system to antigens displayed by a tumor, virus, or microbe or due to unmasking of otherwise privileged nervous system antigens due to brain injury or infection. The antigen provoking the response may be the actual neural antigen or a cross-reacting closely related molecule due to "molecular mimicry." Once an immune response has occurred, there is immune-mediated attack on normal nervous system tissue. Such attack may occur after any inciting infection or injury has already resolved.

Immune-mediated encephalitides may be associated with antibodies to cell surface proteins, such as the VGKCC, NMDAR, α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor, or to γ -aminobutyric acid-B (GABA_B) or glycine (GLY) receptors or may be associated with antibodies to synaptic proteins such as glutamic acid decarboxylase (GAD) or amphiphysin or may be associated with intraneuronal proteins such as Hu, Yo, Ma, or Ri (Table 71.1). Any of these syndromes may occur in the context of paraneoplasia, in which presumably some onconeural antigen on the tumor prompted the immune response, or "spontaneously" without the presence of a tumor. In general, the presumed deleterious effects of an antibody may relate simply to interference with neural transmission or to the development of immune-mediated attack on the patient's neural tissue. NMDAR encephalitis is associated with the presence of anti-NR1 subunit antibodies, which apparently bind the NMDAR causing internalization of these receptors important for neurotransmission, particularly in the hippocampus. Pathologic studies of biopsies performed on patients with NMDAR antibody encephalitis often

additionally show mild inflammation with perivascular infiltrates, which likely brings to the region injurious cytokines, but neurons and their connections are often intact. To the extent that there is only loss of neurotransmitter function and/or presence of noxious inflammatory molecules, elimination of the injurious antibody and the inflammatory response can allow for cellular production of new receptor proteins providing for complete recovery of function. To the extent that there is an immune attack on neurons, recovery is unlikely. In paraneoplastic cerebellar degeneration due to anti-Yo, pathologic studies show complete destructive depletion of all Purkinje cells, severely, and permanently impairing cerebellar function. Likewise in anti-Hu syndrome, there appears to be hippocampal atrophy with loss of neurons.

TABLE 71.1 Immune-mediated Meningoencephalitides

Antigen Category	Antigen	Syndrome	Tumor	Reversible
Cell surface protein	VGKCC (LGI1, CASPR2, contactin-2)	LE, hyponatremia	Lung, thymus, thyroid, ovary, kidney	+
	NMDA receptor	LE, oral dyskinesias	Teratoma	+
	AMPA receptor	LE	Lung, breast, thymus	+
	GABA _B receptor	LE	SCLC	+
	mGluR5 receptor	LE, SPS	Lymphoma	+/-
	GLY receptor	Dysautonomia, LE?, Cblm?	Thymus, lymphoma	+/-
	Ganglionic AChR		Breast, others	
Synaptic protein	GAD	LE, SPS, Cblm	Various	+/-
	Amphiphysin	LE, SPS	Breast, SCLC	+/-
Intraneuronal antigen	Hu	LE, sensory ataxia	SCLC, others	-
	Yo	Cblm	Breast, ovary	-
	Ri	LE, Cblm, myoclonus, opsoclonus	Breast, SCLC	-
	CRMP5/CV2	LE, Cblm, uveitis	SCLC, thymus	+/-
	Ma2 (Ma/Ta)	LE, opsoclonus	Testes	+/-
Other antigens	P/Q calcium channel	LE?	SCLC	+
	Thyroglobulin, microsomal	Meningoencephalitis?		+

LE, limbic encephalitis; SPS, stiff person syndrome; SCLC, small cell lung cancer; Cblm, cerebellar disorder.

CLINICAL MANIFESTATIONS

The clinical hallmarks of the immune-mediated meningoencephalitides are subacute deterioration of central nervous system function, accompanied typically by some evidence of an inflammatory process in the central nervous system on CSF testing and/or neuroimaging. It is often the speed, rather than the particular clinical characteristics that indicates an immune-mediated meningoencephalitis. Rapidly progressive central neurologic dysfunction, in the face of no clear evidence of toxic, vascular, neoplastic, or infectious nervous system involvement, should promptly raise the suspicion of an immunemediated or prion-mediated (see [Chapter 68](#)) disorder.

Diagnostic testing, reviewed in the following text, is essential to interpret the clinical findings. Magnetic resonance imaging (MRI) of the brain in these immune-mediated disorders may show MRI signal abnormalities in gray or white matter on T2-weighted or fluid-attenuated inversion recovery (FLAIR) imaging sequences. Signal abnormalities may also be seen on diffusion-weighted imaging (DWI) of the cortical ribbon and deep nuclei, similar to changes seen in prion diseases or ischemic disorders. However,

P.622

the distinguishing feature of the immune-mediated disorders is inflammation. Even if DWI signal abnormalities are seen, they are accompanied by more extensive FLAIR or T2-weighted imaging abnormalities not common in prion disease. And contrast-enhanced imaging may show areas of breakdown of the blood-brain barrier, definitely inconsistent with prion disease but common in inflammatory disease. But it is CSF and blood studies that best help define the immune-mediated disorders. CSF may show evidence of central nervous system inflammation such as the presence of pleocytosis and elevated protein. Cellular fluid is not characteristically seen in prion disease. Blood and CSF studies may identify marker antibodies that characterize distinct clinicopathologic entities with characteristic diagnostic, prognostic, and therapeutic features. Some of these immune syndromes are sufficiently recognizable disorders through their clinical phenotype, even though it may take some days to weeks to confirm an immune-mediated disorder with an antibody test. Other syndromes may not be as easily recognized but nonetheless may show a somewhat consistent epidemiology and clinical presentation.

LIMBIC ENCEPHALITIS

Limbic encephalitis is a syndrome in which there is subacute affliction that principally involves the deeper, medial forebrain structures of the temporal, and to a lesser extent frontal and parietal, lobes, specifically the hippocampal formation and amygdala, parahippocampal regions, and insular and cingulate cortices. Clinical symptoms of limbic encephalitis are subacute, over days to weeks to months. Typically, decline in memory is a predominant feature, with confusion and disorientation, occurring over a less prolonged time period than typical for mild cognitive impairment (MCI) and neurodegenerative disorders such as Alzheimer disease. Memory dysfunction is often lateralized and may be more verbal, involving left hippocampus, or more visual, involving right hippocampus. Patients may repeat themselves and may have confusional episodes but often neuropsychiatric symptoms are more noticeable to friends and relatives. Personality and/or behavioral changes, including depression, apathy, irritability, aggression, disinhibition, and impulsiveness, are common, as well as frank psychosis with delusions and paranoia. These symptoms reflect involvement of the limbic structures. Seizures are common. Indeed, frequently, the first clinical feature that prompts consideration of organic neurologic disease, as opposed to psychiatric interpretation, may be new onset of complex partial or generalized seizures. Changes in eating habits and sexual desire may also occur as well as sleep disturbance. Limbic encephalitis was first described in the last two decades of the 20th century as relating to antibodies to intraneuronal antigens such as Hu, Ma, or Yo and often associated with a cancer. Thus, limbic encephalitis almost became synonymous with paraneoplastic encephalitis. However, during the first decade of the 21st century, a whole new family of limbic encephalitis disorders was described, in which the antibodies are specific

for neuronal cell surface antigens (see [Table 71.1](#)). These syndromes, associated with antibodies to cell surface antigens, are more common than the prior family. The antigens are usually expressed throughout the nervous system but tend to be particularly enriched in the hippocampus, and in some cases the cerebellum, and thus are associated with limbic encephalitis and sometimes cerebellar dysfunction. The cell surface antigens include those of the VGKCC, which includes antigens LGI1 (leucine-rich glioma inactivated 1 protein also known as *epitempin*), CASPR2 (contactin-associated protein 2) and contactin-2, to glutamate receptors including the NR1 subunit of the NMDAR or the GluR1 or GluR2 subunits of the AMPA receptor or to GABA_B or GLY receptors. Each syndrome tends to have its own symptomatology, although symptoms overlap. The two most important such entities, each relatively recognizable from their clinical syndromes, are VGKCC antibody encephalitis and NMDAR antibody encephalitis.

Voltage-gated Potassium Channel Complex Encephalitis

This typically affects individuals older than age 50 years and typically is a relatively “pure” limbic encephalitis that affects both mesial temporal lobes but is usually asymmetric in presentation, affecting one cerebral hemisphere more than the other. There are several clinical presentations. One common presentation involves clinical hallmarks of memory loss with occasional generalized seizures and sometimes brief seizures lasting only 1 to 2 seconds and involving speech arrest or brief facial contortion. Typically, patients and/or observers may be aware of these spells, but other than a brief interruption of activities, the spells themselves may not significantly impede patient function. Initially, unilateral hippocampal involvement is most common but usually progresses to involve both hippocampi clinically and by imaging. These patients may also have significant neuropsychiatric symptoms including personality change or apathy or aggression. Another archetypical presentation is with faciobrachial seizures or spasms, which typically last 2 to 5 seconds and involve unilateral grimacing and dystonic or mild myoclonic movements of the ipsilateral arm in addition to the face. With this presentation, most often the motor symptoms are first noted before informants report marked memory or personality changes. Subsequently, memory is involved. Serum is usually positive for antibody specific to LGI1, part of the VGKCC. Frequently, electroencephalography may be abnormal with slowing but does not show any electroencephalogram (EEG) surface sharp waves even during these clinically seizure-like events. A psychiatric cause is often posited because of the bizarre nature of the events, without surface electrode-based electrographic concomitant. However, the spells are quite responsive to anticonvulsants, particularly phenytoin. Generalized convulsive seizures may also occur but are less common. The third, least common presentation of VGKCC encephalitis is one of Morvan syndrome, frequently associated with the CASPR2 antibody, with severe sleep disturbance, most marked by insomnia but also by daytime sleep attacks. Other features include confusion and hallucinations, and autonomic disturbances including tachycardia, hypertension, incontinence, constipation, and hyperhidrosis. Rash may occur and peripheral nervous system features including stiffness and muscle twitching that represents neuromyotonia. Although these three presentations may recognizably occur, some patients have overlapping features. Another common feature of VGKCC encephalitis is hyponatremia. Serum sodium levels in the 120 to 130 mEq/L range, or occasionally lower, are common, occurring in 60% of cases. This electrolyte abnormality can itself exacerbate the cognitive symptomatology and decrease seizure threshold. Typically, oral sodium chloride supplementation is required to maintain adequate serum sodium levels. MRI typically (i.e., in 80% of cases) shows T2 and T2 FLAIR hyperintensity, usually without marked DWI signal abnormality nor necessarily any contrast enhancement upon delivery of gadolinium contrast agents. Lumbar puncture typically (i.e., in 80% of cases) shows at least a mild pleocytosis, with cell counts ranging from 5 to 100 white blood cells/ μ L but absent red blood cells and normal or only mildly elevated protein and normal glucose. The differential diagnosis often includes herpes encephalitis, and clues that herpes family virus is not the etiology include the

somewhat more subacute history of weeks to months (rather than days), the characteristic brief EEG-negative seizures if present, the lack of red blood cells in CSF or hemorrhage by MRI, and the frequently relatively “inactive” EEG (often without frank epileptiform activity). Nonetheless, antiviral therapy for herpes simplex virus (HSV) is appropriate until CSF is proven negative for HSV DNA by rapid polymerase chain reaction (PCR) testing. Presence of VGKCC antibody should prompt search for a tumor, particularly in the lungs, although only about 10% of cases are tumor-associated. Immune treatments are often very effective, commonly with significant or complete neurologic recovery from limbic encephalitis due to VGKCC antibody. Disease relapses, depending on definition, are infrequent, occurring in at most 5% to 10% of cases, but in some cases, a propensity for seizures may persist, requiring continued treatment with antiepileptic agents.

N-methyl-D-aspartate Receptor Antibody Encephalitis

This presents as a subacute encephalopathy, sometimes preceded by a prodromal nonspecific or “viral” illness but then developing prominent neuropsychiatric symptoms. Symptoms of psychosis, with disorganized or paranoid thoughts, atypical behavior, and social withdrawal may occur early on. This disorder occurs principally in young women, although now recognized in both children and men. Because of these demographics, it is common for the disorder to first be the subject of psychiatric investigations and treatment; a diagnosis of “catatonia” is often tendered. Development of more profound confusion, motor symptoms including focal dystonia, weakness, ataxia, tremors, myoclonus, and chorea, and onset of seizures prompts neurologic evaluation. Frequently, the nonepileptic motor symptoms are confused for seizures, but seizures are also common, and the seizures of this disorder do typically have an EEG correlate, although not usually classic spike and wave discharges. EEG also frequently shows characteristic abnormalities such as the “extreme delta-brush” pattern in adults, which are almost pathognomonic for this disorder. MRI is abnormal only in about half of cases and may show focal areas of T2 or FLAIR signal abnormality in limbic regions, or cortical regions, and sometimes areas of frank inflammation with contrast enhancement. CSF typically shows a pleocytosis, commonly with 5 to 100 white blood cells/ μL , and sometimes mildly elevated protein and oligoclonal bands. Respiratory depression, sometimes requiring mechanical ventilation, may occur in up to half of cases, and the disease may progress to coma. Autonomic dysregulation is common, with persistent tachycardia, punctuated by episodic bradycardia and sinus pauses (asystole up to 10 seconds), the latter often in the context of nasogastric tube placement, orotracheal suctioning, or other vagal stimulatory maneuvers. Flushing, sweating, and urinary and bowel changes may also occur. The most pathognomonic clinical finding is oral, buccal, lingual, and facial dyskinesias, which may occur in fragmentary and intermittent fashion or may be nearly continuous. Often there is a rhythmic, myoclonic nature to these movements. They can also be extremely intense, with injuries to tongue and lips from biting. Any case of *N*-methyl-D-aspartate receptor antibody encephalitis (NMDARAE) should prompt immediate search for a teratoma. In women, ovarian teratomas occur in about 50% of cases, and prompt removal of a discovered tumor is generally the most effective therapy. The encephalitic illness can be extremely prolonged, even with aggressive treatments. However, it is common to have marked or complete recovery over a period of 4 to 12 months, although cases have been described with recovery proceeding over years. Relapses, depending on the definition, occur in up to 25% of cases, often in the first year; cases associated with tumors that are resected extremely rarely relapse, absent a diagnosis of additional tumor.

Other Neuronal Cell Surface Receptor Antibody Encephalitides

These are less common than those associated with antibody to VGKCC or NMDAR. But limbic encephalitides with some similarity to VGKCC-associated disorders may be marked by antibodies to non-NMDA glutamate receptor such as the AMPA, GABA_B, or GLY receptors. These disorders do not have as consistent phenotypes as VGKCC antibody encephalitis but also typically involve memory dysfunction, behavioral dysfunction, and epileptic seizures. Seizures may be complex partial or generalized convulsive seizures. Unexplained new-onset

epilepsy in a younger or middle-aged patient, somewhat more commonly female than male, age 30 to 60 years, is a not uncommon presentation of these rarer disorders.

Limbic Encephalitis Associated with the Antineuronal Anti-Hu Antibody

This typically presents with subacute memory disorder. Generally, the course is one of several months, sometimes associated with behavior change but less commonly with seizures. Sensory ataxia due to proprioceptive losses, due to dorsal root ganglionopathy, occurs commonly in about half of cases. Other symptoms can include cerebellar dysfunction, brain stem signs, and autonomic symptoms including gastrointestinal pseudo-obstruction. In about 90% of cases, there is an associated tumor, which is usually a lung tumor, and is often small cell lung cancer. The neurologic syndrome virtually always precedes the discovery of the tumor, and the tumor may often be quite small and limited. Tumor removal more often than not does result in stabilization of the neurologic symptoms, particularly if there is complete tumor resection. However, limited recovery occurs in only about a third of cases, and significant improvement is very rare.

SUBACUTE CEREBELLAR DEGENERATION

This is a clinically recognizable disorder in which over a period of days to weeks or several months, there is increasingly severe ataxia. Gait ataxia, appendicular ataxia with intention tremor, and dysarthria are all common features. Other brain stem signs such as nystagmus, diplopia, oscillopsia, hyperreflexia, and nausea and vomiting may occur. Serum testing reveals antibodies directed against cerebellar neuronal antigens, typically the anti-Yo antibody, although anti-Ri, anti-Hu, anti-Ma, anti-GAD, anti-PCA-2, and other antibodies have been identified less commonly. Anti-Ri syndrome usually is marked by opsoclonus. The CSF may have evidence of pleocytosis and high protein, and in such cases, steroid treatment may be more useful. Search for a tumor is mandatory. In women, more than 80% of cases have a carcinoma of breast or ovary, or occasionally other locations. Like anti-Hu encephalitis, tumors in anti-Yo encephalitis are often small, more limited, and usually not identified until neurologic presentation and associated investigations. Like anti-Hu syndrome, stabilization may occur with tumor removal. However, meaningful recovery does not occur.

OTHER IMMUNE-RELATED MENINGOENCEPHALITIDES

These are associated with antineuronal antibodies in subacute retinal degeneration due to CAR antibody and syndromes associated with antibodies to Ma2 (Ma/Ta), ganglionic acetylcholine receptors, mGluR5 receptor, and CRMP5/CV2. Antibodies to synaptic

P.624

antigens such as GAD and amphiphysin likewise are associated with encephalitides. Hashimoto encephalitis is a meningoencephalitic illness presenting with confusion, headaches, and seizures and marked by antimicrosomal and antithyroglobulin antibodies. This controversial entity is now referred to as *steroid-responsive encephalitis* because the condition often responds markedly to steroid therapy. CSF typically shows mild evidence of meningitis, often with high CSF protein, and sometimes pleocytosis. The role of thyroid antibodies is unclear. Other meningoencephalitic disorders that appear immune-mediated relate to systemic inflammatory conditions including Behçet disease, Vogt-Koyanagi syndrome, systemic lupus, and other disorders. Acute disseminated encephalomyelitis, postinfectious and postvaccination inflammatory disorders, and unidentifiable aseptic meningitides, and the syndromes of newonset refractory status epilepticus (NORSE) or febrile infection-related epilepsy syndrome (FIRES) also bear similarities to the disorders described earlier but are generally not accompanied by sensitive or specific disease biomarkers.

DIAGNOSIS

The diagnosis of immune-mediated encephalitides starts with clinical history and examination. Typically, the

disorder is subacute to acute but sometimes the disorders may develop over a background of some mild, nonspecific, and not clearly related symptoms ongoing for some years. More commonly, there is an escalating course de novo and rapidly, of cognitive, behavioral, and/or epileptic dysfunction without metabolic, infectious, or systemic inflammatory causes. Typically, this rapid progression of symptoms should prompt an aggressive diagnostic evaluation to provide the information required for appropriate categorization of the disorder. This is because the various disorders, although poorly understood, still have particular empirically established treatment options. Although imaging is often helpful in localization, and neurophysiologic studies are helpful in assessing the contributions of epileptic activities, it is laboratory studies of blood and CSF that may be most useful.

Blood testing can be of great diagnostic use. Antibody tests for VGKCC antibodies or other antibodies termed *paraneoplastic* (see [Table 71.1](#)) can often be highly sensitive and specific. The major limitation of these tests is that reporting of results may take some days to weeks.

It is essential to also perform CSF analysis to assess for the presence of inflammation; the results of this are available within hours. CSF cell counts are informative as to whether there is an inflammatory cellular component. Cytologic examination permits exclusion of neoplastic cell involvement. Microbiologic and serologic tests allow for determination of whether bacterial or viral infectious elements are present. Antibody panels may be used, particularly for NMDARAE. Of the immune-mediated encephalitides, most disorders are most easily diagnosed in the blood, although the NMDA disorder may present with antibodies only evident in the CSF. For monitoring purposes, CSF antibodies may have use, whereas blood NMDAR antibody levels do not seem to correlate with symptoms and improvement. Thus, CSF is diagnostically important but also the ability to follow CSF cell counts and protein and antibody levels in the case of NMDAR antibody provide key metrics for monitoring the status of treatment.

Electroencephalography (EEG) is important to exclude the possibility that subclinical epileptic activity is responsible for abnormalities in mental status or motoric function. EEG provides help when there are frequent subclinical seizures in assisting the choice and dosage of antiepileptic medications.

Neuroimaging has become a somewhat reliable marker for limbic encephalitis, particular in the mid to late stages of VGKCC disorders ([Fig. 71.1](#)). Frequently, there are T2 and T2 FLAIR abnormalities in hippocampal or other limbic regions, and in some cases evidence of restricted diffusion on DWI imaging, indicating water content changes associated with presumed acute injury. NMDAR encephalitis is less likely to show MRI abnormalities, although in some cases, there are clear areas of injury. For some of the encephalitides, there may be imaging evidence of meningitis and/or evidence of inflammatory cortical or subcortical lesions, which may show contrast enhancement. When abnormalities are present, their evolution can be used as a gauge of the progress of treatment. Nuclear medicine metabolic (fluorodeoxyglucose positron emission tomography [PET]) or perfusion (^{99m}Tc -hexamethyl propylene amine oxime [HMPAO] or ^{99m}Tc -ethyl cysteine dimer [EDC] single-photon emission computed tomography [SPECT]) scans of patients with limbic encephalitides may be normal or show areas of decreased metabolism/perfusion but more often show hypermetabolism and hyperperfusion in the affected temporal lobes, presumably due to overactivity.

Systemic body imaging can become important in the diagnostic evaluation of these disorders because of the possibility of a distant tumor prompting an antibody response, which then is associated with nervous system dysfunction. The presence of VGKCC, NMDAR, or anti-Hu antibodies should respectively prompt thorough examination of the lungs, ovaries, or breasts and ovaries.

Brain biopsy has the potential to provide specific pathoetiologic information in cases where blood and CSF studies are noninformative. In particular, some infectious processes, including viral and other infectious disorders can be detected on brain biopsy. If prion disease, such as Creutzfeldt-Jakob disease, is within the

differential diagnosis, then brain biopsy is valuable in establishing or excluding that diagnosis. However in general, brain biopsy is often diagnostically unrevealing in the immune-mediated encephalitides. Biopsy may reveal lymphocytic infiltrates in the parenchyma, vasulocentric involvement, and may confirm the presence and relative involvement of gray and white matter. However, lacking an infectious organism, these pathologic findings are usually insufficiently specific to be helpful. Thus, specific settings in which brain biopsy should be considered are as follows: (1) Prion disease is within the differential diagnosis; (2) infectious disease not otherwise discoverable is being considered; and (3) inflammatory disease is strongly suspected but it is not clear if there is active disease or a burned out process. In this latter situation, the limitation is that a brain biopsy, even if directed at a neuroimaged lesional area, may not be representative of other areas.

TREATMENT AND OUTCOME

Treatment of the immune-mediated encephalitides includes both symptomatic treatment for seizures and immune-related therapies. Immunomodulatory therapies are warranted in this family of syndromes, but in general, only the cell surface antibody-mediated syndromes, such as VGKCC, NMDAR, and related antibody-mediated encephalitides are highly responsive. The syndromes associated with intraneuronal antigens, such as anti-Hu, usually show little benefit from treatment.

Immune treatments include “first-line treatments,” which consist of high-dose intravenous corticosteroids, intravenous immunoglobulin infusions, and plasma exchange. Second-line treatments comprise more potent immunosuppressive therapies, including rituximab, mycophenolate, azathioprine, and cyclophosphamide.

P.625

There are to date no published controlled trials of these various therapeutic approaches, so all such therapies are both empiric and off-label (unapproved) at this time. Complicating interpretation of therapeutic interventions are the fact that a number of the immune-mediated encephalitides may have a monophasic course and eventually, even if only after months or years, show spontaneous recovery without specific therapy (e.g., NMDARAE) and the fact that the different antibody syndromes do appear to have different responsiveness to different therapeutic interventions.

FIGURE 71.1 Neuroimaging in immune-mediated encephalitis. **Top row** shows MRI imaging of a patient with VGKCC encephalitis with T2 FLAIR sequences 1 month after onset of symptoms (*top left*) and 5 months later after treatment. Prominent left hippocampal hyperintensity and swelling on initial image has essentially resolved after treatment. **Bottom row** shows two patients with NMDAR encephalitis. *Bottom left* shows essentially normal MRI imaging on T2 FLAIR sequence of patient with severe symptoms. *Bottom right* shows DWI sequence on a different patient, showing subtle increased signal on left greater than right parietal cortical ribbon.

Corticosteroid course is frequently the first treatment for these disorders and presumably acts both by decreasing the inflammatory response and decreasing antibody production. Steroid actions start within hours but also cease within hours to days of termination of therapy. It is particularly useful for limbic encephalitis associated with VGKCC antibodies and some of the other cell surface antibodies. It is less obviously efficacious in NMDARAE, particularly when there is not such an inflammatory component (e.g., in individuals with little degree of pleocytosis). Typical steroid dosages are 1,000 mg methylprednisolone intravenously daily for 5 days. For VGKCC encephalitis, intravenous steroids are followed by oral treatment, often with a relatively prolonged taper. Prednisone at doses of about 1 mg/kg can be given, with a taper

over months. If there is no reemergence of symptoms, patients may be able to have complete discontinuation of steroids by 4 to 12 months, although

P.626

some patients require chronic treatment with either steroids or second-line agents discussed in the following text. Chronic steroid treatment is not of evident use in NMDARAE. Side effects of steroids may be limiting even in the acute setting, including behavioral dysfunction, euphoria, and insomnia. Side effects of chronic treatment must also be monitored, including weight gain, facial plethora, diabetes, and fungal and other infections.

Intravenous human immunoglobulin (IVIG) infusion is the other first treatment for these disorders.

Presumed mechanism of action is interference through competition or binding with circulating pathogenic antibodies and/or immunoregulatory effects. Typical dosage is 0.4 g/kg for 5 days, for a total dosage of 2 g/kg. MIG has a plasma half-life of about 28 days and therapeutic span of weeks to months. Frequently, cotreatment with both methylprednisolone and MIG is performed as first-line treatment. Retreatment with IVIG for relapses may be performed after 1 or more months.

Plasma exchange (plasmapheresis) is another putative first-line treatment for immune-mediated disorders. Exchange in five plus sessions over 2 weeks may have some use. Most often considered in persons presenting with respiratory failure, this intervention is less often used for several reasons. For NMDARAE, antibody production is apparently principally in the central nervous system, so it is theoretically, as well as practically less clear that removal of plasma antibody is effective. Other reasons why plasma exchange is less used, include that it is less expeditious, requiring multiple treatments over many days, and more arduous for the patient requiring large venous cannulas in persons who may be agitated. Furthermore, if IVIG infusion is contemplated, then plasmapheresis would be counterproductive, removing the infused therapeutic immunoglobulin.

Second-line treatments for these disorders are generally used either as steroid-sparing agents in cases that appear to be steroiddependent or IVIG-dependent or in cases where steroids and/or IVIG treatment is not accompanied by evidence of recovery over about 4 weeks. These second-line treatments include targeted specific immunosuppression with rituximab or nonspecific immunosuppression with mycophenolate, azathioprine, or cyclophosphamide. Rituximab is a chimeric mouse/human monoclonal antibody directed against the human lymphocyte cell surface antigen CD20. It eliminates B cells and is a proven treatment for lymphopietic malignancies, as well as proven treatment by randomized controlled trials in the nonmalignant inflammatory disease rheumatoid arthritis. In nonmalignant conditions, a single infusion of 1,000 mg, given with appropriate premedications and monitoring, over hours results in near certain complete elimination of all B lymphocytes. This elimination typically occurs within several days. Although the half-life of the drug is only weeks, the B-cell depletion last months (typically 6 to 9 months, particularly after first treatment, although in a small percentage of patients up to several years). This results in substantial reductions in antibodyproducing cells. The advantage of the treatment is that, aside from occasional infusion reactions, this focused immunosuppression is well tolerated and easily monitored (by counts of peripheral CD19-positive B cells). The therapy is not reversible, except through passage of time. However, if neurologic recovery is incomplete, or if there is a relapse, retreatment with rituximab will again deplete any recovered B cells. In many cases, a single treatment is adequate, presumably because the body's repopulated antibody-producing cells do not include the clones producing the pathogenic antibody. Experience seems to indicate that rituximab may be particularly successful second-line treatment for NMDARAE, with beginning of improvement in symptoms often occurring some weeks following therapeutic infusion. Side effects of rituximab can include potentially serious or even lethal infusion reactions (which however are very uncommon in nonmalignant conditions), chronic immunosuppression, and in rare cases progressive multifocal leukoencephalopathy. Mycophenolate and azathioprine can also be used as more general

immunosuppressants following steroids and/or IVIG. Mycophenolate levels can be monitored, and white blood cell counts can be monitored during treatment with these drugs. Cyclophosphamide is a more toxic chemotherapeutic agent that can be used to achieve a higher degree of immunosuppression in refractory cases. There are no large therapeutic series with these agents.

John C. M. Brust

INTRODUCTION

Sarcoidosis is a multisystem, granulomatous disease of unknown cause. Sarcoid granulomas resemble those of tuberculosis but lack tubercle bacilli or caseation, although central necrosis is sometimes seen. Active lesions contain epithelioid and multinucleate giant cells; such lesions may resolve but more often become fibrotic.

EPIDEMIOLOGY

Sarcoidosis occurs worldwide, with estimated incidence ranging from 3 to 50 cases per 100,000 population. Incidence is especially high among African-Americans, in whom the disease is more likely to be chronic and severe. Susceptibility to sarcoidosis is polygenetically influenced, and different polymorphisms involving the major histocompatibility complex predict the severity of disease. Onset is most often in the third or fourth decade, but the disease also affects children and the elderly. Sarcoid granulomas are attributed to heightened immune responses to unidentified exogenous antigens. An infectious cause remains elusive. Sarcoidosis is described in patients with HIV infection treated with highly active antiretroviral therapy (HAART), reflecting what is known as the *immune reconstitution inflammatory syndrome*. Sarcoidosis has also developed following interferon alpha therapy for hepatitis C.

PATHOBIOLOGY

The disorder is mediated primarily by CD4+ T-helper 1 (Th1) cells and mononuclear phagocytes, with participation of numerous cytokines and chemokines that include interleukins, adhesion molecules, interferon gamma, tumor necrosis factor (TNF)-alpha, and transforming growth factor-beta. Lesions may affect any organ, especially lungs, lymph nodes, skin, bones, eyes, and salivary glands. Although nearly 20% of patients with neurosarcoidosis lack systemic symptoms or signs, workup reveals systemic sarcoidosis in as many as 97%. When nervous system disease complicates systemic sarcoidosis, it usually does so within 2 years of onset.

In the central nervous system (CNS), sarcoid granulomas most often involve the meninges, especially at the base of the brain, with secondary infiltration of cranial nerves and obstruction of cerebrospinal fluid (CSF) flow. Lesions tend to be perivascular and thereby may spread intraparenchymally, frequently affecting the hypothalamus and, less often, other CNS structures, including the spinal cord. Granulomas also occur in peripheral nerves and muscle.

CLINICAL MANIFESTATIONS

Given the unpredictable dispersal of lesions, sarcoidosis is a clinically protean disease systemically and neurologically. Nearly 50% of patients with neurosarcoidosis have more than one neurologic complication, with relative frequencies varying among different clinical series ([Table 72.1](#)).

TABLE 72.1 Symptoms and Signs in Neurosarcoidosis

Signs and Symptoms	(%)
Cranial neuropathy	50-75

Aseptic meningitis	10-20
CNS parenchymal disease	5-15
Peripheral neuropathy	5-10
Myopathy	10
Hydrocephalus	10
CNS, central nervous system.	

Although any cranial nerve may be affected, the most frequently affected is the seventh, sometimes in association with uveitis and parotitis (uveoparotid fever) but usually alone, thus suggesting Bell palsy. Facial weakness may be bilateral and either simultaneous or sequential and may recur after recovery. Eighth nerve involvement, the second most common cranial neuropathy in sarcoidosis, causes deafness (often bilateral) and vestibular symptoms. Optic nerve involvement causes papillitis or retrobulbar neuritis and eventually optic atrophy. Trigeminal nerve involvement causes either sensory loss or neuralgia.

Granulomas involve the hypothalamus more often than the pituitary, thereby producing combinations of endocrinologic and nonendocrinologic symptoms that include diabetes insipidus, decreased libido, galactorrhea, amenorrhea, abnormal sleep patterns, altered appetite, temperature dysregulation, and abnormal behavior. Cerebral granulomas may be scattered diffusely, with some too small to be detected on computed tomography (CT) or magnetic resonance imaging (MRI), or they may consist of one or larger masses that mimic a brain neoplasm. Seizures are common in such patients. Cognitive and behavioral symptoms include dementia, depression, psychosis, hallucinations, and delirium. Rarely, sarcoid vasculitis causes cerebral infarction (or even intracranial hemorrhage) in a pattern clinically and pathologically indistinguishable from what is commonly called *granulomatous angiitis* of the nervous system. Autoantibodies to endothelial cells have been identified in patients with neurosarcoidosis.

Intraparenchymal or extraparenchymal spinal cord lesions can cause back pain, radiculopathy, and spastic paraparesis. Intramedullary lesions are often discontinuous and span several spinal segments.

Meningeal infiltration may be asymptomatic or may produce symptomatic aseptic meningitis, cauda equina signs, hydrocephalus (which can rapidly and fatally decompensate), and ependymitis with encephalopathy. Meningeal or dural mass lesions can be mistaken for meningiomas. Skull base lesions can mimic an acoustic or trigeminal schwannoma.

Peripheral nerve lesions cause mononeuropathy; mononeuropathy multiplex; and sensory, motor, or sensorimotor polyneuropathy,

P.629

either chronically progressive or resembling Guillain-Barré neuropathy. Most common is a chronic axonal sensorimotor neuropathy. Small-fiber sensory and autonomic neuropathy is also described.

A positive muscle biopsy has been reported in as many as 75% of patients with sarcoidosis, and muscle granulomas may be seen on MRI. Muscle granulomas are usually asymptomatic, although they sometimes cause palpable nodules or progressive diffuse polymyositis.

DIAGNOSIS

In patients known to have sarcoidosis, the appearance of neurologic symptoms usually poses no diagnostic problem, but alternative possibilities must be kept in mind. The differential diagnosis of neurosarcoidosis includes infection, autoimmune and inflammatory disorders, neoplasm, and demyelinating disease (Table 72.2). Altered mental status could be caused by hypercalcemia, corticosteroid effects, or systemic organ involvement and metabolic derangement. Progressive multifocal leukoencephalopathy has been reported in at least 30 patients with sarcoidosis. Patients with neurologic symptoms require both systemic and neurologic investigation. CNS granulomas, symptomatic or asymptomatic, are apparent on either T2-weighted or contrast-enhanced MRI; they are sometimes calcified. Leptomeningeal MRI enhancement is common, and imaging may reveal hydrocephalus and spinal cord, cauda equina, or optic nerve involvement.

Multiple periventricular and white matter lesions on T2 and fluid-attenuated inversion recovery (FLAIR) MRI may suggest multiple sclerosis. Multiple sclerosis plaques do not enhance with gadolinium beyond the acute inflammatory stage; sarcoid granulomas may not enhance in patients receiving corticosteroids. These lesions might represent either granulomas or small infarcts secondary to granulomatous vasculitis. Consistent with the latter is occasional contrast enhancement along nearby blood vessels. The CSF may contain as many as a few thousand white blood cells (WBCs) (usually with lymphocytic preponderance), as well as elevated protein levels, low sugar content, elevated immunoglobulin G (IgG) and IgG index, oligoclonal bands, elevated angiotensin-converting enzyme (ACE) levels (neither sensitive nor specific), and an elevated CD4 +to-CD8+ cell ratio.

Other studies, tailored to need with individual patients, include chest radiographs (revealing either asymptomatic hilar adenopathy or, more ominously, fibronodular disease and abnormal in nearly 90% of patients with sarcoidosis), pulmonary function studies, identification of a high ratio of CD4+to-CD8+ T cells on bronchiolar lavage, serum calcium (elevated in about 20% of patients with sarcoidosis), urinary calcium (elevated in 50% of patients), serum ACE (elevated in 65% of patients), serum gamma globulin (elevated in 50% of patients), serum sodium, and endocrinologic studies (thyroid function tests, cortisol, gonadotropins, testosterone or estradiol, and prolactin). Serum-soluble interleukin-2 receptor levels are also nonspecific but have been found to correlate with disease activity.

TABLE 72.2 Differential Diagnosis for Sarcoidosis

CNS infection, especially tuberculous and fungal meningitis

CNS neoplasm, especially carcinomatous and lymphomatous meningitis

Demyelinating disease

Vasculitis

Peripheral neuropathy, including mononeuropathy multiplex

Myopathy

CNS, central nervous system.

About two-thirds of patients are anergic to tuberculin-purified protein derivative, mumps, and other antigens, and those who are positive are usually only weakly so. Ophthalmologic or otolaryngologic consultation may disclose unsuspected lesions. Systemic or brain gallium scanning may be positive but is nonspecific. Wholebody 2-fluoro-1-deoxyglucose positron emission tomography (PET) may identify sites of inflammation not seen on MRI or with gallium scanning.

Diagnosis ultimately depends on histology; biopsy sites include lymph nodes (including transbronchial), salivary glands, conjunctiva, skin, liver, and, as a last resort, meninges or brain.

COURSE AND TREATMENT

About two-thirds of patients with neurosarcoidosis have a self-limited monophasic illness; the rest have a chronic, remitting-relapsing course. With treatment, death from neurologic disease is unusual. Although controlled studies are lacking, corticosteroids appear to reduce symptoms and size of granulomas; it is unclear whether they affect the natural history. Their use depends on the clinical setting. Short-term therapy may be given to patients with aseptic meningitis or isolated facial palsy. Long-term treatment is often necessary for intraparenchymal lesions, hydrocephalus, optic or other cranial nerve involvement, peripheral neuropathy, or symptomatic myopathy. A daily dose of 40 to 80 mg prednisone may be given for a few weeks and then slowly tapered, either to a lowest possible maintenance dose or, if possible, to discontinuation. Higher initial doses may be necessary in some patients. Anecdotally reported adjunctive immunosuppressive treatment for refractory patients includes mycophenolate mofetil, azathioprine, methotrexate, cyclophosphamide, rituximab, thalidomide, cyclosporine, chloroquine, hydroxychloroquine, and the TNF-alpha antagonists infliximab and adalimumab. Radiation therapy has been used but with uncertain benefit.

Surgery should be considered a last resort for patients with intracranial mass lesions unresponsive to pharmacotherapy or with hydrocephalus.

Elan D. Louis

INTRODUCTION

Essential tremor (ET) is a chronic, progressive neurologic disease. The hallmark motor feature is a 4- to 12-Hz kinetic tremor (tremor occurring during voluntary movements, such as writing or eating) that involves the arms and hands (Fig. 73.1). Tremor may eventually spread to involve the head (i.e., the neck), voice, and jaw. Given the presence of etiologic, clinical, and pharmacologic response profile and pathologic heterogeneity, there is growing support for the notion that ET may be a family of diseases whose central defining feature is kinetic tremor of the arms and which might more accurately be referred to as *the essential tremors*.

EPIDEMIOLOGY

ET is among the most prevalent adult-onset movement disorders, although it may occur at any age, and pediatric cases, with age of onset in the first decade of life, have been reported. In a recent meta-analysis of data from 28 population-based prevalence studies in 19 countries, the pooled prevalence of ET across all ages was 0.9%. The prevalence increases markedly with age and especially with advanced age. In the meta-analysis, prevalence among persons aged 65 years and older was 4.6%, and in some studies, the prevalence among persons aged 95 years and older reached values in excess of 20%. The rate at which new ET cases arise (i.e., the incidence rate) has been estimated as 619 per 100,000 person-years among individuals age 65 years and older; this incidence rises with age. Established risk factors for ET include older age and family history of ET.

FIGURE 73.1 Spirals drawn by patients with ET who have moderate arm tremor (**A**) and severe arm tremor (**B**).

ETIOLOGY

Both genetic and environmental (i.e., toxic) factors are likely contributors to disease etiology. Many large kindreds show an autosomal dominant pattern of inheritance, and first-degree relatives of ET patients are

approximately 5 times more likely to develop the disease than are members of the population and 10 times more likely if the proband's tremor began at an early age.

The prevalence of a family history of ET is high in ET patients seen in neurologic clinics and even higher in younger onset than older onset ET cases. A variant in the Lingo-1 gene has been most consistently associated with ET; however, no major causal genes have been identified so far, and this is likely due to phenocopies, incomplete penetrance, bilineal inheritance, or possibly other modes of inheritance. The existence of sporadic cases (i.e., cases without apparent family history), variability in age at onset in familial cases, and lack of complete disease concordance in monozygotic twins all argue for nongenetic (i.e., environmental) causes as well. A number of environmental toxins are under investigation, including β -carboline alkaloids (e.g., harmine, a dietary toxin) and lead. One epidemiologic study indicated a possible protective role of cigarette smoking and another suggested that higher levels of premorbid ethanol consumption raise the risk of developing ET with the presumed mechanism being Purkinje cell toxicity. The identification of modifiable risk factors would have important implications in terms of disease prevention.

PATHOBIOLOGY

The olivary model of ET, first proposed in the early 1970s, posited that a tremor pacemaker in the inferior olivary nucleus was driving the tremor in ET. However, there are major problems with this model, including the absence of direct empirical support and, therefore, there has been trend to move away from this model. In more recent years, mechanistic research on ET has focused more on the cerebellum and the role it seems to play in the biology of ET. Interest in the cerebellum was initially motivated by neuroimaging studies, which strongly implicate the importance of this brain region in ET, and clinical studies, which frequently note the presence of cerebellar signs in patients with ET. More recently, controlled postmortem studies have revealed an array of degenerative changes in the cerebellar cortex, primarily involving the Purkinje cells and surrounding neuronal populations, in the majority of ET cases (Fig. 73.2). In some studies, there is actual Purkinje cell loss. A smaller group of ET cases demonstrates a pattern of Lewy bodies that are relatively restricted to the locus ceruleus. Of mechanistic interest is that the noradrenergic neurons of the locus ceruleus project to the cerebellum and synapse with Purkinje cells. Hence, there is growing support for the notion that the cerebellum may be central to disease pathobiology and that the pathobiology is neurodegenerative.

FIGURE 73.2 A: Calbindin-stained section of the cerebellar vermis of an ET case (100 \times). Torpedoes (two arrows, ovoid swellings of the proximal portion of the Purkinje cell axon) occur in significantly greater numbers in ET cases than controls and are markers of an abnormal Purkinje cell biology. **B:** Calbindin-stained section of the cerebellar cortex of an ET case (200 \times). From left to right, one can see the Purkinje cell body (arrow), the normal

thin initial axonal segment (*long, thin arrow*), the torpedo (*arrowhead*), and the thickened axon with recurrent collateral formation (*dotted arrow*) and terminal branching of the Purkinje axon. These morphologic changes occur to a greater degree in ET cases than controls and are markers of an abnormal Purkinje cell biology. **C:** Calbindin-stained section of the cerebellar cortex of an ET case (200×). Hypertrophy of the basket cell processes is seen (*two arrows*, “hairy baskets”); in some instances, there is Purkinje cell loss and the baskets are empty (*two arrowheads*). These changes occur to a greater degree in ET cases than controls and are markers of both an abnormal Purkinje cell biology and reactive changes in the surrounding neuronal populations.

CLINICAL MANIFESTATIONS

Symptoms and signs of ET can begin at any age, and about 5% begin in childhood, although the incidence increases markedly with advancing age, and most prevalent cases are age 60 years or older.

The cardinal feature of ET is kinetic tremor, evidenced during a variety of activities on neurologic examination (e.g., finger-nose-finger maneuver, spiral drawing) (Video 73.1). The tremor is generally mildly asymmetric, affecting one arm more than the other, with on average an approximate 30% difference between sides; in approximately 5% of patients, the tremor is markedly asymmetric or even unilateral. In approximately 50% of patients, the tremor has an intentional component, worsening on finger-nose-finger maneuver as the patient approaches the target. Intention tremor is not limited

P.633

to the arms; in 10% of patients, it is detectable in the head when the patient's head approaches a target (e.g., while drinking from a cup or a spoon). Postural tremor also occurs in patients with ET and is generally worse in the wing-beat position than when the arms are held straight in front of the patient. The tremor in the two arms is generally out of phase, creating a seesaw effect when the arms are held in a wing-beat position and contributing to the observation that functionality may improve when two rather than one hand is used (e.g., while holding a cup). The postural tremor of ET is generally greatest in amplitude at the wrist joint rather than more proximal or distal joints and generally involves wrist flexion extension rather than wrist rotation supination. As a rule, the amplitude of kinetic tremor exceeds that of postural tremor, and the converse pattern should raise questions about the diagnosis. Tremor at rest, without other cardinal features of parkinsonism, occurs in approximately 20% of patients with ET attending a specialty clinic, but in contrast to that of Parkinson disease (PD), it is a late feature and it has only been observed in the arm rather than the arm and leg. Another motor feature of ET, aside from tremor, is gait ataxia, which is in excess of that seen in similarly aged controls. In most patients, this is mild, although in some, it may be of moderate severity. There is some evidence that gait ataxia is more pronounced in patients with midline cranial tremors (e.g., neck, jaw, voice). Saccadic eye movement abnormalities have also been detected in ET patients in several physiologic studies, although these are of a subclinical nature.

Recent years have witnessed an increasing appreciation of the presence of nonmotor features in ET patients, which may broadly be classed into cognitive, psychiatric, and sensory. Cognitive changes are in excess of those seen in similarly aged controls and range from mild changes across several domains, but especially executive function, to mild cognitive impairment and dementia, both of which occur to a greater extent than in age-matched controls. The pathobiology of these cognitive changes is unclear at present. Psychiatric manifestations include secondary anxiety and depression. The presence of a primary mood disturbance, which precedes the motor manifestations, is supported by at least one prospective study. A harm avoidant personality has been reported in studies that have assessed personality traits in ET, and this may be one feature, which makes patients reluctant to undergo therapeutic surgery even in the setting of severe and disabling tremor. Sensory changes include diminished hearing in excess of that seen in age-matched controls and a mild olfactory deficit in some although not all studies.

Initially, the tremor may be mild and asymptomatic and it may not worsen for years, but in most individuals, the

tremor worsens over time. Several patterns of progression have been described (Fig. 73.3). The two most common are (1) late life onset and (2) early life onset with mild, stable tremor for many years and then a late life worsening. The least common pattern is that of early life onset with marked worsening over the ensuing years to decade. There are few prospective, longitudinal natural history studies, but the best estimates of rate of change indicate that arm tremor worsens by 2% to 5% per year. With the progression of time, there is a tendency for the spread of tremor beyond the arms, such that patients develop cranial tremors (neck, voice, jaw), particularly in women with ET, among whom the risk of neck tremor is severalfold higher than that of men with ET. The prevalence of neck tremor is the highest of these, with voice tremor being less so and jaw tremor being even less so. Neck tremor is generally of a “nono” (i.e., horizontal) variety but can also be a “yes-yes” (i.e., vertical) tremor or a more complex tremor with a rotatory component. Unless severe, the neck tremor, which is a postural tremor, should subside and resolve when the patient is recumbent. Isolated neck tremor, with minimal or no accompanying arm tremor, is extremely rare and should raise suspicion that the diagnosis is dystonia rather than ET. A curious feature of the neck tremor is that patients are often unaware of its presence, particularly when it is mild. The presence of dystonic postures in ET cases is controversial, although it is likely that the presence of mild dystonia in some cases does not preclude a diagnosis of ET, especially when the dystonia is a late finding in a case with long-standing and severe ET.

FIGURE 73.3 Three patterns of progression in ET. The two most common are (1) late life onset (*blue dashed line*) and (2) early life onset with mild, stable tremor for many years followed by late life worsening (*purple dotted line*). The least common pattern is that of (3) early life onset with marked worsening over the ensuing years to decade (*red solid line*).

Although in the past ET was often viewed as a “benign” problem, the term *benign essential tremor* is no longer considered appropriate. Indeed, the majority of patients have tremor-related disability, and 15% to 25% are sufficiently motorically disabled by high-amplitude shaking that they cannot continue to work.

ET patients have about a fourfold increased risk of developing incident PD, thereby developing what is referred to as *essential tremor-Parkinson disease* (ET-PD). The pathobiology of this connection is not fully understood.

DIAGNOSIS

Thirty percent to 50% of “ET” cases are misdiagnosed and do not have ET, with many of these cases having dystonia or PD. Differentiation may be made readily, however, by the absence of rigidity or bradykinesia or other signs of parkinsonism (e.g., hypomimia) in these cases. The characteristics of the tremor are also important in distinguishing an ET patient from one with PD (Table 73.1). The presence of isolated postural tremor (with minimal kinetic tremor), a postural tremor involving the metacarpophalangeal joints rather than the wrist, and a postural tremor characterized by greater wrist rotation than flexion and extension are all indicators that the likely diagnosis is emerging PD rather than ET (see Table 73.1). Reemergent tremor is a postural tremor that commences after a brief latency, rather than immediately, and is a feature of PD. Dystonia in the arm is characterized by dystonic posturing (e.g., “spooning of the fingers” [i.e., the tendency during arm extension to flex the wrist and hyperextend the metacarpophalangeal and phalangeal joints]) and the presence of a tremor that is neither rhythmic nor oscillatory. The possibility of neck dystonia should be assessed and is characterized by head tilt or rotation with head tremor,

P.634

hypertrophy of the sternocleidomastoid muscle, the presence of a tremor null point, and a sensory trick by history (Table 73.2). Absence of cerebellar speech (i.e., either scanning or dysarthric) and nystagmus distinguishes ET from the spinocerebellar ataxias. Hyperthyroidism or the use of medications such as lithium or valproate is usually excluded by clinical history. A difficult differential is between a mild case of ET and enhanced physiologic tremor, although the presence of neck tremor should exclude the latter. Computerized tremor analysis, with inertial loading, can assist with this differential. In patients with a tremor of central origin (ET), the primary tremor frequency should not change with inertial loading.

TABLE 73.1 Clinical Examination Features that Help Distinguish Essential Tremor from Parkinson Disease

	ET	PD
Rest tremor (arms)	+ ^a	+
Rest tremor (legs)	- ^a	+
Kinetic tremor (arms)	++	+ ^b
Postural tremor (arms)	+	+ ^c
Intention tremor (arms)	Common	Rare
Reemergent tremor		+
Head tremor	Common	Rare
Jaw tremor	+ ^d	+
Voice tremor	+	-

Rigidity	^e -	+
Bradykinesia	^f -	+
Hypomimia	-	-
Tachyphemia	-	+

^aWhen present, rest tremor generally occurs in ET cases with disease of longer duration and greater severity rather than mild cases of short duration. It is restricted to the arms.

^bThe kinetic tremor of ET is generally of higher amplitude than that of PD, although this is not always the case.

^cA postural tremor involving the metacarpophalangeal joints rather than the wrist and a postural tremor characterized by greater wrist rotation than flexion and extension are both indicators that the likely diagnosis is emerging PD rather than ET. An isolated postural tremor (with minimal or no kinetic tremor) is a feature of PD rather than ET. The presence of flexed posturing of the wrist and/or fingers is often a sign of PD.

^dThe jaw tremor in ET generally occurs when the mouth is open (e.g., while talking or while saying “ahhhh”); in PD, it generally occurs while the mouth is closed.

^eDuring passive movement, the movement may be ratchety, with cogwheeling, but there should be no rigidity.

^fOlder ET patients may have ratings of 1 on the motor portion of the Unified Parkinson's Disease Rating Scale.

+, present; -, absent; ET, essential tremor; PD, Parkinson disease.

TREATMENT

The tremor may be severe enough to result in embarrassment and functional disability, and these are the main motivations for treatment. β -Blockers (especially propranolol) [Level 1]¹ and primidone [Level 1]² alone or in combination, are the most effective pharmacologic therapies, although many patients chose to discontinue these medications due to their limited efficacy. Propranolol has been used in doses up to 360 mg daily, although doses in excess of 100 mg are rarely tolerated in the elderly. Asthma is a relative contraindication to the use of propranolol but is not an absolute contraindication and must be assessed on a case-by-case basis. Primidone is given in doses up to 1,500 mg daily, although lower doses are often effective. An acute nausea and/or ataxia is observed in approximately 25% of patients who are prescribed this medication, and preloading the patient with phenobarbital (e.g., 30 mg twice a day [b.i.d.] for 3 days) is one method that is used to avoid this unwanted side effect. These drugs reduce the amplitude of tremor in

30% to 70% of patients, but they do not abolish it unless the tremor is mild. Other agents that have been used include topiramate [**Level 1**],³ gabapentin [**Level 1**],⁴ and benzodiazepines (alprazolam or clonazepam) [**Level 1**].⁵ Many patients note that tremor is temporarily suppressed by drinking ethanol, but a rebound exacerbation sometimes follows the next day. High-frequency thalamic stimulation markedly reduces the severity of the tremor and has replaced stereotactic thalamotomy as the treatment of choice for severe pharmacologically refractory tremor. Several other emerging surgical therapies are currently under evaluation.

TABLE 73.2 Clinical Examination Features that Help Distinguish Essential Tremor from Dystonia

	ET	Dystonia
Rhythmic and oscillatory tremor	+	+/-
Tremor has a directional quality	^a -	+
Tremor null point	^b -	+
Head tremor resolves while supine	+	-
Head tremor with little or no arm tremor	^c -	+
Head tilt or rotation	-	+
Hypertrophy of the sternocleido-mastoid or other neck muscles	-	+
Voice breaks with voice tremor	-	+/-
Dystonic posturing in hands (e.g., “spooning”)	-	+

^aDystonic tremor often has a directional quality seeming to move in one direction more than the opposite.

^bTremors, in general, are very positionally dependent in ET, but this should not be confused with a null point.

^cIsolated head tremor should be a clue that the diagnosis is likely to be dystonia rather than ET.

+, present; -, absent; ET, essential tremor.

Tics and Tourette Syndrome

Stanley Fahn

Daphne Robakis

INTRODUCTION

Tics are brief, sudden, repetitive movements (motor tics) or utterances (phonic or vocal tics) that are temporarily suppressible and are usually preceded by a strong urge to perform the tic. The distinction between motor and vocal tics is somewhat arbitrary because production of vocal tics requires the involvement of facial, oropharyngeal, or diaphragmatic musculature. The Gilles de la Tourette syndrome, named after the author of the seminal description and commonly shortened to *Tourette syndrome* (TS), is the most well-described tic disorder.

TS is a neurobehavioral disorder consisting of both multiple motor and phonic tics (not necessarily concurrently) that change in character over time, beginning before 18 years of age, and with symptoms that wax and wane but last more than 1 year. For the diagnosis of TS, these motor and phonic tics are not caused by exogenous factors such as cocaine or a medical condition such as encephalitis or trauma. Although the earlier definition as proposed by the American Psychiatric Association in its *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*), is a useful criterion for research on the disorder, it excludes chronic tics in the motor or vocal domains alone, which are likely milder expressions of the same condition ([Table 74.1](#)). Other causes of ticlike syndromes include neuroacanthocytosis, encephalitis, prior neuroleptic use, and head trauma. Many patients with TS have a behavioral component of obsessive-compulsive disorder (OCD), attention deficit disorder (ADD), anxiety, or poor impulse control. These behavioral features usually impose more disability than do the tics.

Primary tics not part of TS may be classified under chronic motor/vocal tic disorder, in which tics persist beyond 1 year, or transient motor/vocal tic disorder, in which tics last less than 1 year, the latter being the most common tic disorder in children. Most adults with tics had idiopathic tics as children, but primary or secondary tic disorders can develop in adulthood. Insult to the basal ganglia by diverse mechanisms including stroke, infection, trauma, autoimmune process, or neurodegenerative disease can cause the appearance of tics, possibly via disruption of dopamine circuits. Similar to tardive dyskinesias, tardive tics may appear after varying lengths of treatment with antipsychotics or as a consequence of discontinuation of treatment. Substances such as caffeine, stimulants, and certain antiepileptics (carbamazepine, lamotrigine) have been reported to exacerbate or provoke the emergence of tics. Tics generally follow an anatomic distribution more heavily weighted toward the craniocervical regions than the trunk and limbs. Tics are rarely of psychogenic origin but due to similar clinical features are often difficult to differentiate from organic tics.

TABLE 74.1 Tourette Syndrome—Diagnostic Criteria

Both multiple motor and one or more vocal tics (not necessarily concurrently)

The tics may increase or decrease in frequency but have persisted for more than 1 yr since first onset.

Onset before age 18 yr

No other direct causes, such as drugs, encephalitis, or neurodegenerative disorders

Data from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Arlington, VA: American Psychiatric Association; 2013.

EPIDEMIOLOGY

Estimates of prevalence rates of tics have varied broadly, depending on clinical definitions, the age range of participants, and other features of study design. Studies of children yield higher prevalence estimates than do studies of adolescents and adults, as tics typically attenuate in severity or remit entirely by young adulthood. Conservative estimates for lifetime prevalence rates are 1 per 1,000 in boys and 2 per 10,000 in girls. On average, tics begin around age 5 years and increase in severity, reaching a most intense period around age 10 years. After that, tics usually decline in severity until, by age 18 years, nearly half of the patients are virtually free of tics.

PATHOBIOLOGY

Research into the pathobiology of tics has focused mainly on Tourette but the causes of TS are still unknown. The search for genetic mutations has yielded modest evidence for linkage to chromosome 11q23 in a large French Canadian family and to 11q23-q24, 2p11, and 8q22 in Afrikaner families, although these findings generally have yet to be replicated. A de novo chromosomal inversion on chromosome 13q31.1 in a child with TS led to identification of a frameshift mutation in *SLITRK1*, a gene that promotes dendritic growth, as one rare cause of TS. Although early family studies suggested that the genetic transmission of TS is autosomal dominant with a strong sex-specific difference in penetrance, more recent studies have indicated that the mode of inheritance is more complicated than this, appearing semidominant and semirecessive and having greater penetrance in homozygotes than in heterozygotes.

Anatomic MRI has documented reduced volumes of the basal ganglia, particularly the caudate nucleus, as well as thinning of sensorimotor, primary motor, and premotor cortices in persons with TS. These findings are thought to represent hypoplasia in motor portions of the cortical-basal ganglia circuits, and these developmental disturbances contribute to the genesis of tic behaviors. Preliminary postmortem studies suggest the presence of reduced GABAergic interneurons in the basal ganglia, possibly contributing to excess excitability of these motor circuits. Separate circuits within the prefrontal and parietal cortices, and in the hippocampus, are thought to help modulate tic-generating activity in the basal ganglia and motor cortices, producing an activity-dependent hypertrophy of these brain regions. Although dopamine receptor-blocking drugs can suppress tics and have long suggested the presence of supersensitive

P.637

dopamine receptors, postmortem binding studies of dopamine receptors failed to provide support for this hypothesis. Positron emission tomography (PET) studies have provided inconsistent evidence for increased dopamine storage and release in striatum.

An immune hypothesis proposes that TS is sometimes caused by infection with β -hemolytic *Streptococcus*, as seen in children who develop Sydenham chorea. Known as a *pediatric autoimmune neuropsychiatric disorder associated with streptococcus infections* (PANDAS), evidence for this proposed etiology for a small minority of TS patients has been inconsistent and controversial.

CLINICAL FEATURES

As defined by *DSM-5*, a tic is a sudden, rapid, recurrent, nonrhythmic motor movement or vocalization. Tics range from intermittent simple brief jerks (simple tics) to a complex pattern of rapid, coordinated, involuntary

movements (complex tics) arising abruptly from a background of normal activity and often preceded by a vague, unpleasant sensation that is relieved by the movement (Video 74.1). Although tics usually can be suppressed for a short time, the inner sensation builds relentlessly, producing a burst of tic behavior when the patient stops suppressing them. Tics usually begin in the face (eye blinking, grimacing), neck (head shaking), and shoulders (shrugging), but they can also begin with sounds (sniffing, throat clearing, barking, words, or parts of words). They can progress to involve the thorax and limbs and foul utterances (coprolalia). Repeating sounds (echolalia) or movements (echopraxia) are sometimes seen. The speed of tics ranges from very fast (clonic tics) to sustained contractions (dystonic tics). Simple clonic tics resemble essential myoclonus, and the two conditions are difficult to distinguish. Dystonic tics need to be differentiated from primary torsion dystonia. Sydenham chorea is distinct in manifesting as a continuous restless type of movement pattern, and it is self-limited. Premonitory sensations, intermittency, and suppressibility help distinguish tics from most other movement disorders.

Behavioral or psychiatric symptoms are present in 90% of patients with TS and may be considered part of the clinical syndrome. Impulse control problems are common and can present as aggressivity, rage attacks, antisocial or inappropriate sexual behavior, or self-injury. Obsessive-compulsive symptoms associated with tics overlap with those seen in non-tic-related OCD but are less likely to manifest as compulsive washing or cleaning rituals and more likely to be characterized by obsessions with symmetry, the need to do and redo activities, and “just right” perceptions. Some complex tics can resemble compulsions. Attentional difficulties often precede the appearance of tics by several years and usually reflect coexisting Attention deficit hyperactivity disorder (ADHD) but may also be attributable to other factors such as cognitive fatigue from the effort to suppress tics, obsessions like mental counting, or mood disorders. TS patients have higher rates of sleep disturbances including difficulty falling asleep and staying asleep and have increased sleep latencies and arousals on polysomnography. Tics can persist during sleep, in contrast to most other hyperkinetic movement disorders, usually in an attenuated form. Alterations in sleep and wakefulness patterns may be intrinsic to the disease itself or may be caused by medications used to treat tics and comorbid conditions.

TREATMENT

In evaluating patients with tics, assessing the influence of tics on the person's emotional, social, scholastic, and occupational functioning is of central importance in deciding whether and when to intervene therapeutically. In TS, identifying and treating psychiatric comorbidities is often of greatest help, as frequently the symptoms OCD, ADD, depression, and anxiety are more disabling than are the tics. Treatment is aimed at achieving a tolerable degree of tic suppression. A supportive, individualized, multidisciplinary approach that involves neurology, psychiatry, and psychology, as well as education of the patient, parents, and teachers about the natural history of TS and its comorbidities, is usually indispensable to effective treatment.

When tics are mild and not socially or academically disabling, no treatment may be required. When they are more severe, the frequency and forcefulness of motor and phonic tics can sometimes be reduced with clonazepam, clonidine, or guanfacine [**Level 1**].^{1,2} Dopamine antagonists and depletors are more effective but often have more adverse effects [**Level 1**],^{3,4,5,6,7} including tardive dystonia, and thus are often reserved for second- or third-line treatments. Habit reversal therapy (HRT) and comprehensive behavioral intervention for tics (CBIT), which is based on HRT, have been used successfully as first-line treatments or in combination with pharmacotherapy [**Level 1**].^{8,9,10,11,12} OCD, ADHD, depression, and anxiety disorders, if present, all require specific therapies, including psychotherapies, behavioral therapies, and medication [**Level 1**].^{13,14} Pharmacologic options are listed in [Table 74.2](#).

Neurosurgery, using deep brain stimulation, is being applied to patients with severe and intractable tics that cause great disability [**Level 1**].^{15,16} Different targets in the brain are being tested, but no consensus has been reached as to the best target. Botulinum toxin may be helpful in patients with focal simple motor and vocal tics and for dystonic tics [**Level 1**].¹⁷

TABLE 74.2 Medications Used in the Treatment of Tourette Syndrome and Its Most Common Co-occurring Illness

Medication Type	Medication	Dose
Tics		
α-Agonists	Clonidine	0.1-0.3 mg/day
	Guanfacine	1-6 mg/day
Catecholamine depletors	Tetrabenazine	12.5-300 mg/day
Dopamine-blocking agents	Risperidone	0.5-6 mg/day
	Ziprasidone	20-100 mg/day
	Aripiprazole	2-30 mg/day
	Fluphenazine	50-400 mg/day
	Pimozide	1-6 mg/day
	Haloperidol	0.5-10 mg/day
	Thioridazine	150-300 mg/day
	Trifluoperazine	2-10 mg/day
	Thiothixene	1-15 mg/day
Olanzapine	5-20 mg/day	
Other	Clonazepam	1-4 mg/day
	Baclofen	30-60 mg/day
OCD		
SSRIs	Fluoxetine	20-60 mg/day
	Sertraline	50-200 mg/day
	Paroxetine	20-50 mg/day
	Fluvoxamine	100-300 mg/day
	Clomipramine	100-200 mg/day
ADHD		
Stimulants	Methylphenidate	10-60 mg/day
	Amphetamine	10-40 mg/day
	Atomoxetine	40-80 mg/day

OCD, obsessive-compulsive disorder; SSRI, selective serotonin reuptake inhibitors; ADHD,

OUTCOME

Primary tic disorders including TS are not neurodegenerative diseases and do not worsen after reaching maximum severity in the preteen years. Rather, the motor and phonic tics have disappeared by adulthood in the majority of patients. In some cases, tics will wax and wane in severity throughout life. It remains controversial whether factors such as tic severity or dysfunction caused by tics correlate with long-term outcomes, and therefore, individual outcomes cannot be reliably predicted. The prognosis for secondary tic disorders varies according to the underlying condition. For those who continue to manifest tics all their life, almost all with persistent tics have learned to live a normal life. In a few individuals, tics can remain a social embarrassment or occupational problem, such as those in acting or politics. Such individuals may require tic-suppressing medication and if that fails, be candidates for neurosurgical intervention. TS patients who suffer from significant social dysfunction often do so as a result of their behavioral symptoms rather than the tics. However, the combination of tics and comorbid psychiatric conditions can be debilitating and remain a challenge for many TS patients throughout their lives.

Videos can be found in the companion e-book edition. For a full list of video legends, please see the front matter.

Restless Legs Syndrome

William G. Ondo

INTRODUCTION

Restless legs syndrome (RLS), also known as *Willis-Ekbom disease* (WED), is clinically defined by the presence of four positive criteria: (1) an urge to move the limbs with or without sensations, (2) worsening at rest, (3) improvement with activity, and (4) worsening in the evening or night. The diagnosis of RLS is exclusively based on those symptoms. The diagnostic criterion for children relies mostly of description from the child's perspective, family history of RLS, and sleep disturbance. There is also an expanding literature linking RLS in children to attention deficit disorders.

Patient subjective semantic descriptions can be quite varied and tend to be suggestible and education dependent. The sensation is always unpleasant but not necessarily painful. It is usually deep within the legs and commonly between the knee and ankle. The key is to rephrase their description into a question asking if that sensation makes you want to move your legs. Essentially, all patients report transient symptomatic improvement from walking, although other movements also help. In general, harsh sensory stimuli can also mitigate RLS. Other clinical features typical for RLS include the tendency for symptoms to gradually worsen with age, improvement with dopaminergic treatments, a positive family history, and periodic limb movements while asleep (PLMS). Traditionally, the neurologic examination is normal in RLS; however, leg/feet stereotypies are sometimes present later in the day although usually suppressible.

In most cases, only a simple evaluation is justified for clinically typical RLS. Serum ferritin and iron-binding saturation for serum iron deficiency and electrolytes for renal failure should be obtained. It should be noted that severe iron deficiency may exist in the setting of a normal ferritin level because it is an acute phase reactant and increases with age. Nerve conduction velocities may be performed in atypical presentations (i.e., sensations beginning in the feet or superficial pain) or when physical symptoms and signs are consistent with a peripheral neuropathy. Polysomnographic evaluation is not generally needed. Several confounding diagnosis need to be considered ([Table 75.1](#)).

EPIDEMIOLOGY

Studies in predominantly Caucasian populations consistently show that between 5% and 15% of people have RLS, which is clinically significant in 2% to 3%. In general, northern European countries demonstrated the highest prevalence, followed by Germanic/Anglo-Saxon, then Mediterranean countries. The prevalence tends to decline the farther east one progresses, with lower rates in Asia. People from Africa have never been specifically studied but anecdotally, African-Americans only rarely present with RLS. Women usually have higher RLS rates; however, this female predisposition is lost in nulliparous women.

TABLE 75.1 Differential Diagnosis of Restless Legs Syndrome

Condition	How Different from RLS
Akathisia	Whole body urge to move, associated with dopamine blockers, not as circadian

Cramp	Chaotic visible/palpable muscle contraction, can be stopped by stretching muscle, no urge to move
Myalgia	Muscle ache, may be worse at night but no true urge to move
Neuropathic pain	Usually superficial, burning, electric, feet most involved
Radiculopathy	Usually asymmetric, more position dependent but not urge to move other than to move from painful position
Body positional discomfort	Can't get comfortable in any position but not a true urge to move
Moving toes, painful legs	Slow writhing dystonic movement of toes/feet, not suppressible
RLS, restless legs syndrome.	

PATHOBIOLOGY

Pathophysiologic studies show a number of objective abnormalities in RLS; however, our understanding is incomplete. The most robust observation is reduced central nervous system (CNS) iron stores, even in the setting of normal systemic iron studies. RLS patients show reduced cerebrospinal fluid (CSF) ferritin, reduced iron on magnetic resonance imaging (MRI), especially in the striatum and red nucleus, reduced iron on CNS ultrasonography in the substantia nigra, and most importantly, reduced iron and iron-related proteins at autopsy, including reduced H-ferritin staining, iron staining, and increased transferrin stains, but also reduced transferrin receptors. Researches also demonstrate reduced Thy-1 expression, which is regulated by iron levels. Substantia nigra dopaminergic cells are neither reduced in number nor are there markers associated with neurodegenerative diseases, such as tau or α -synuclein abnormalities.

Brain dopaminergic systems are also implicated in RLS by the dramatic improvement from dopaminergics. However, dopaminergic brain imaging studies are inconsistent and show modest or no abnormalities in a pattern that defies simple explanation and is interpreted by some to actually suggest increased dopamine turnover.

Iron and dopamine are intricately related. Although a number of theories explain the relationship, human data is lacking. The neural localization of RLS is also unknown. Functional involvement of the medial thalamus, cerebellum, and brain stem has been implicated

P.641

using functional MRI techniques. Spinal cord lesions often result in RLS and PLMS and animal models that lesion the diencephalospinal dopaminergic (A11) nucleus, which descends the spinal cord, mimic features of RLS in mice and rats, mostly increasing locomotor activity. Iron deprivation augments the phenotype.

Opioid pathways are implicated by clinical improvement seen with narcotics and pathologic data that shows reduced beta-endorphin-positive cells and Met-enkephalin-positive cells in six RLS patients compared to six controls. Glutamatergic activity is increased in the thalamus of RLS patients and correlates with arousal but not PLMS. Afferent systems are also implicated as shown by increased sensitivity to pinprick pain ratings (static hyperalgesia). These researchers felt this type of hyperalgesia was probably mediated by central sensitization to A-delta fiber high-threshold mechanoreceptor input, a hallmark sign of the hyperalgesia type of neuropathic pain.

In 40% to 60% of cases, a family history of RLS can be found, although this is often not initially reported by the patient. Twin studies also show a very high concordance rate. Many linkages have been identified in traditional familial studies but in no case has a specific gene mutation been identified. To date, six risk factor genes identified through genome-wide association studies have been published. The most robust associations include BTBDP, MEIS1, and PTPRD.

TABLE 75.2 Medications and Doses Used for Restless Legs Syndrome

Drug	Amount per Dose (mg)	Duration of Effect (h)	Comment
Dopaminergics: immediate effect, considered first-line therapy			
L-Dopa	100-250	2-6	Positive class 1 trials, fast onset, can use PRN, highest augmentation rates
Pramipexole	0.125-1	5-12	Positive class 1 trials, commonly used, slower onset but longer duration, extended release available
Ropinirole	0.25-4	4-8	Positive class 1 trials, extended release preparations available
Rotigotine	1-4	24	Positive class 1 trials, commonly used patch preparation
Pergolide	0.125-1	6-14	Well studied (class 2) but seldom used due to risk of cardiac valve fibrosis and other possible ergot adverse events (AE)
Apomorphine	1-3	1	Injection of short-acting powerful drug, anecdotal PRN use
Cabergoline	0.25-2	>24	Longest acting but may have same AEs as other ergot DAs
Bromocriptine	5-20	4-6	Rarely used in RLS
Opioids: Numerous opioids are used.			
Methadone	2-15	8-12	Open label data only, very good long-term tolerability and efficacy, several-day latency to benefit
Hydrocodone	5-10	4-10	Faster acting, shorter duration
Oxycodone	5-20	5-10	Best studied opioid

Alpha-2 delta blockers

Gabapentin	300-1,200	4-8	Small controlled trials, may help painful component of RLS
Pregabalin	50-300	6-12	Positive class 1 and 2 trials, not approved
Gabapentin enacarbil	600-1,800	8-16	Gabapentin prodrug with better absorption/bioavailability; positive class 1 trials, approved in the United States

Benzodiazepines: more beneficial for sleep than RLS, can be used in combination with other RLS medications. Clonazepam (0.5-2.0 mg) is traditionally used.

Oral iron	>50	?	No specific iron salt superior, titrate up as tolerated; minimal data of efficacy
IV iron	1,000	?	Usually not repeated before 3 months, several-day latency to benefit, long-term safety unknown, patients with normal serum ferritin equally responsive. Anecdotal evidence favors iron dextran preparations.

PRN, as necessary; DAs, dopamine agonists; RLS, restless legs syndrome; IV, intravenous.

The most common diseases associated with RLS include renal failure, systemic iron deficiency, neuropathy, myelinopathy, pregnancy, multiple sclerosis, and possibly Parkinson disease and essential tremor. There are reports associating RLS with many other conditions.

TREATMENT

The development of validated rating scales and standardized diagnostic criteria have vastly improved the quality of RLS treatment trials. Multiple medications have demonstrated efficacy in well-designed class I trials, especially dopaminergics, alpha-2 delta ligands, opioids, and iron (Table 75.2). With the possible exception of iron, all are felt to provide only symptomatic relief,

P.642

rather than any curative effect. Therefore, treatment should only be initiated when the benefits are felt to justify any potential side effects and costs. Over time, both dosing and drug changes may be required to maximize benefit and minimize the risk of side effects.

Dopamine agonists (DA) are the most best investigated consistently effective treatments for RLS. The improvement is immediate and often very dramatic. DA consistently demonstrate dramatic improvement in PLMS but modest or no improvement in other sleep parameters. No direct evidence favors any particular DA. Rotigotine patch, pramipexole, and ropinirole are best studied and all have class A evidence supporting their use. The dopamine precursor levodopa also effectively treats RLS and may have a more rapid onset of action. However, several comparative studies have favored DA over levodopa.

Immediate-release oral DA work best if administered at least 90 minutes before the onset of symptoms. The effect is immediate, so titration to the smallest effective dose can be fairly rapid. Based on

pharmacokinetics, many people may benefit from more than one dose, despite the formal indications, which recommend dosing 1 to 3 hours before bed. Extended-release preparations of pramipexole and ropinirole are also very effective but have not been formally studied. Nausea, sedation, and impulse control disorders can occur but hallucinations and hypotension rarely occur in RLS, making these drugs better tolerated in RLS compared to Parkinson disease.

The long-term use of DA for RLS is more problematic because some subjects develop tolerance, and others can develop augmentation. Augmentation is defined by an earlier phase shift of symptom onset, an increased intensity of symptoms, increased anatomic involvement, or less relief with movement. Levodopa has the worst augmentation, whereas augmentation with DA is modest at 1 year (2% to 9%) but seems to increase linearly over time. Risk factors for augmentation have been inconsistent but include lower serum ferritin, higher dose of a dopaminergic, worse RLS, a family history of RLS, and absence of neuropathy.

Drugs that bind to the alpha-2 delta subunit of the voltage-dependent calcium channel also improve RLS. As a class, they seem to improve International Restless Legs Scale (IRLS) scores similarly to DA; however, sleep studies show less improvement in PLMS but better sleep architecture. Gabapentin is the least studied but shows benefit. The gabapentin enacarbil sustained release tablet is a novel preparation that is absorbed much more effectively in the gastrointestinal tract and can achieve higher and more sustained serum levels of gabapentin. Multiple large class I trials have demonstrated efficacy, and the drug is approved for use in multiple countries. Pregabalin is also proven effective in high-quality studies but is not approved by regulatory agencies.

Opioid medications, also known as *narcotics*, have long been known to successfully treat RLS. Open-label trials consistently demonstrate good initial and long-term results, with relatively little tolerance, dependence, or addiction. Low-dose methadone especially shows excellent long-term efficacy and tolerability. However, only oxycodone has been evaluated in a placebo-controlled multicenter trial.

Although open-label oral iron supplementation has been reported to improve RLS, the only controlled study of oral iron supplementation failed to improve RLS symptoms. Oral iron, however, has numerous limitations related to absorption and tolerance. In contrast, the administration of high-dose (1 g) intravenous iron can dramatically increase serum ferritin levels. Clinical studies with different iron preparations have shown mixed but mostly favorable results.

Numerous other agents including other antiepileptic medications, benzodiazepines, clonidine, baclofen, tramadol, and magnesium have been reported to help RLS but suffer from limited data and cannot be recommended as either first- or second-line therapy. Physical measures that increase activity or create a sensory stimulus can also improve RLS but are often problematic when one desires sleep.

Dystonia

Stanley Fahn

INTRODUCTION

After parkinsonism, dystonia is the most common movement disorder encountered in movement disorder clinics. The term *dystonia* was coined by Oppenheim in 1911 to indicate that the disorder he was describing manifested hypotonia at one occasion and tonic muscle spasms at another, usually but not exclusively elicited on volitional movements. Although the term *dystonia* has undergone various definitions since 1911, the most recent definition is: "Dystonia is a movement disorder characterized by sustained or intermittent muscle contractions causing abnormal, often repetitive, movements, postures, or both. Dystonic movements are typically patterned, twisting, and may be tremulous. Dystonia is often initiated or worsened by voluntary action and associated with overflow muscle activation."

Limb, axial, and cranial voluntary muscles can all be affected by dystonia. The abnormal movements are often exacerbated during voluntary movements, so-called action dystonia.

If the dystonic contractions appear only with a specific action, it is referred to as *task-specific dystonia* (e.g., writer's cramp and musician's cramp). As the dystonic condition progresses, voluntary movements in parts of the body not affected with dystonia can induce dystonic movements of the involved body part, so-called overflow. Talking is a common activity that causes overflow dystonia in other body parts. With further progression, the affected part can develop dystonic movements while at rest, and sustained abnormal postures may be the eventual outcome.

Dystonic movements tend to increase with fatigue, stress, and emotional states; they tend to be suppressed with relaxation, hypnosis, and sleep. Dystonia often disappears during deep sleep, unless the movements are extremely severe. A characteristic and almost unique feature of dystonic movements is that they can be diminished by tactile or proprioceptive "sensory tricks" (*gestes antagoniste*). For example, patients with cervical dystonia (*torticollis*) often place a hand on the chin or side of the face to reduce nuchal contractions, and orolingual dystonia is often helped by touching the lips or placing an object in the mouth. Lying down may reduce truncal dystonia; walking backward or running may reduce leg dystonia.

Rapid muscle spasms that occur in a repetitive pattern may be present in torsion dystonia; when rhythmic, the term *dystonic tremor* is applied. Rarely, some children and adolescents with primary or secondary dystonia may experience a crisis, a sudden increase in the severity of dystonia, which has been called *dystonic storm* or *status dystonicus*. This can cause myoglobinuria with a threat of death by renal failure. These patients require treatment in an intensive care unit (ICU) using sedating agents such as propofol and midazolam, intrathecal baclofen, and in some cases, emergency deep brain stimulation of the internal globus pallidus.

EPIDEMIOLOGY

Epidemiologic studies in dystonia typically segregate patients with dystonia into primary (no known cause or no known lesion) and secondary (an environmental or hereditary lesion in the brain) and into focal, segmental, and generalized forms of dystonia. An epidemiologic study of primary dystonia in the population living in Rochester, Minnesota, found the prevalence of generalized dystonia to be 3.4 per 100,000 population and the prevalence of focal dystonia to be 30 per 100,000. The frequency of primary dystonia in the Ashkenazi Jewish population is much higher (between 1/6,000 and 1/2,000) because this population descends from a limited group of founders of the DYT1 mutation. The origin of the mutation was traced to the northern part of the historic Jewish Pale of

settlement (Lithuania and Byelorussia) approximately 400 years ago. Focal dystonia is more common than segmental dystonia, and generalized dystonia is very infrequent, about one-tenth as common as focal dystonia. The prevalence rate of focal dystonias varies in different countries, being slightly lower in Japan (between 6 and 14 per 100,000) than in Western Europe (between 11 and 14 per 100,000).

PATHOBIOLOGY

PATHOLOGY

Dystonia is considered a disorder of the central nervous system, with neuropathology showing structural lesions in degenerative forms of dystonia (e.g., Wilson disease and neurodegenerations with brain iron accumulation) and static lesions (e.g., post stroke, post trauma) and those with no structural lesion in the primary dystonias, some metabolic disorders (e.g., dopa-responsive disorder due to genetic mutations causing reduced synthesis of dopamine), and tardive dystonia (due to a persistent complication of dopamine receptor-blocking agents; see [Chapter 80](#)). When structural lesions are found in the brain associated with degenerative diseases and environmental insults, the putamen or its connections (including thalamus and cerebral cortex) are the regions affected.

ETIOLOGY

Dystonia can be caused by genetic mutations (inherited dystonia, discussed in the following section) and environmental insults

(acquired dystonia), but by far, the most common are dystonias without a known cause (idiopathic dystonia). The last group makes up the majority of focal dystonias. The acquired dystonias are listed in [Table 76.1](#). Most of the causes in this table result in structural lesions, but two do not—drug-induced and psychogenic dystonia.

GENETICS

A large number of gene mutations have been discovered to cause both primary (nonstructural) dystonia and degenerative dystonia.

[Table 76.2](#) lists the heredodegenerative dystonias. These are divided into autosomal dominant, autosomal recessive, X-linked, and mitochondrial disorders. Typically, these diseases result in progressive degenerative changes in the basal ganglia and their connections. These can usually be detected by magnetic resonance

P.645

imaging (MRI) and a metabolic workup. Neurodegenerations with brain iron accumulations (NBIA) are clinically detected by the presence of high iron content in the globus pallidus and other brain regions where there is decreased signal intensity T2-weighted images. [Table 76.3](#) lists the gene mutations in the NBIA.

TABLE 76.1 Causes off Acquiirred Dysttoniia

- | | |

i. Acute dystonic reaction

ii. Tardive dystonia

c. Ergotism

d. Anticonvulsants

16. Toxins—Mn, CO, carbon disulfide, cyanide, methanol, disulfiram, 3-nitropropionic acid

17. Metabolic—hypoparathyroidism

18. Psychogenic

Mn, manganese; CO, carbon monoxide.

The majority of patients with dystonia are without structural lesions in the brain. These so-called primary dystonias can be genetic or idiopathic. The genetic forms began to be classified by geneticists with a DYT1 label. But the labeling has become a mixed bag with both primary dystonias and one heredodegenerative dystonia being in this list. Unfortunately, the paroxysmal dyskinesias were also classified with a DYT label, when in fact these disorders should have been labeled as a separate entity. [Table 76.4](#) provides the DYT classification.

TABLE 76.2 Heredodegenerative Diseases (Typically Not Pure Dystonia)

Autosomal dominant

a. Huntington disease

b. Machado-Joseph disease (SCA3)

c. Other SCA subtypes (e.g., SCA2, 6, 17)

d. Familial basal ganglia calcification (Fahr disease)

Mitochondrial

a. Leigh disease

b. Leber disease

c. MERRF/MELAS

Complex etiology (multifactorial)

a. Parkinson disease

b. Progressive supranuclear palsy

c. Multiple system atrophy

d. Cortical-basal degeneration

SCA, spinocerebellar ataxia; NBIA, neurodegeneration with brain iron accumulation; PLAN, PLA2G6-associated neurodegeneration; MERRF, myoclonic epilepsy with ragged red fibers; MELAS, myopathy, encephalopathy, lactic acidosis, and stroke-like episodes.

Adapted and updated from Fahn S, Bressman SB, Marsden CD. Classification of dystonia. *Adv Neurol.* 1998;78:1-10.

PATHOPHYSIOLOGY

In the absence of overt evidence of neurodegeneration, investigation has turned to functional studies to better understand the pathophysiology of primary dystonia. Positron emission tomography (PET) has identified a range of changes including increased resting glucose metabolism in the premotor cortex and lentiform nucleus and decreased D2 dopamine receptor binding in the putamen. In DYT1 dystonia, two patterns of abnormal metabolic activity have been found. In nonmanifesting carriers and resting affected carriers, there is hypermetabolism of the lentiform nucleus, cerebellum, and supplementary motor cortex. On the other hand, in DYT1 patients having active muscle contractions, metabolic activity is increased in the

Although standard MRIs have not revealed structural pathology, diffusion tensor imaging (DTI) has shown subtle abnormalities in sensorimotor circuitry of dystonia patients. In DYT1 mutation carriers, there is reduced fractional anisotropy (FA) in subgyral white matter of the primary sensorimotor cortex, and in gene carriers manifesting dystonia, FA is also reduced in the pons in the region of the left superior cerebellar peduncle. Abnormal FA has also been observed in the lentiform nucleus and in white matter adjacent to this nucleus in patients with focal dystonia. Human and animal models of DYT1 dystonia reveal that a cerebellar outflow tract disruption between cerebellum and thalamus is associated with disease manifestations, provided that the remainder of the cerebellothalamocortical pathway is intact. In contrast, nonmanifesting DYT1 gene carriers have an additional disruption in this pathway between thalamus and cerebral cortex. Neurophysiologic studies demonstrate a variety of changes consistent with abnormalities in inhibitory control, sensorimotor integration, and brain plasticity. The electromyogram (EMG) in the dystonias shows cocontraction of agonist and antagonist muscles with prolonged bursts and overflow to extraneous muscles. Spinal and brain stem reflex abnormalities, including reduced reciprocal inhibition and protracted blink reflex recovery, indicate a reduced presynaptic inhibition of muscle afferent input to the inhibitory interneurons as a result of defective descending motor control. The sensorimotor cerebral cortex shows increased and disorganized receptive fields, and sensory temporal discrimination thresholds are increased in DYT1 mutation carriers with and without clinical dystonia. Further, tests probing brain plasticity, such as paired associated stimulation, reveal increased long-term potentiation.

TABLE 76.4 DYT Gene Nomenclature for the Dystonias

Name	Locus	Inheritance Pattern	Phenotype	Gene, Product
DYT1	9q34.11	AD	Early onset, limb onset (Oppenheim dystonia)	<i>TOR1A</i> , torsinA
DYT2	Unknown	AR	Early onset	Unknown
DYT3	Xq13.1	XR	Filipino, X-linked dystonia-parkinsonism (lubag)	<i>TAF1</i>
DYT4	19p13.3	AD	Generalized dystonia with spasmodic dysphonia	<i>TUBB4A</i> , beta-tubulin 4a
DYT5a	14q22.2	AD	DRD (Segawa disease)	<i>GCH1</i> , GTP cyclohydrolase 1
DYT5b	11p15.5	AR	DRD, infantile parkinsonism	TH, tyrosine hydroxylase
DYT6	8p11.21	AD	Mixed type, onset often with spasmodic dysphonia,	<i>THAP1</i>

Amish Mennonite and others

DYT7	18p	AD	Adult cervical	Unknown
DYT8	2q35	AD	Paroxysmal nonkinesigenic dyskinesia (Mount-Rebak)	Formerly called <i>myofibrillogenesis regulator 1</i> , now <i>PNKD</i> , PNKD protein
DYT9	1p34.2	AD	Paroxysmal choreoathetosis with episodic ataxia and spasticity	Now known to be the gene for GLUT1; same as DYT18
DYT10	16p11.2	AD	Paroxysmal kinesigenic dyskinesia (PKD) (EKD1)	<i>PRRT2</i> gene, proline rich transmembrane protein 2
DYT11	7q21.3	AD	Myoclonus-dystonia	<i>SGCE</i> , ϵ -sarcoglycan
DYT12	19q13.2	AD	Rapid-onset dystonia-parkinsonism (RDP)	<i>ATP1A3</i> , Na ⁺ /K ⁺ -ATPase alpha 3 subunit
DYT13	1p36	AD	Cervical-cranial-brachial	Unknown
DYT15	18p11	AD	Myoclonus-dystonia	Unknown
DYT16	2q31.2	AR	Early-onset dystonia-parkinsonism	PRKRA
DYT17	20p11.2-q13	AR	Juvenile onset with torticollis, spreading to segmental and generalized dystonia	Unknown
DYT18	1p34.2	AD	Paroxysmal exertional dyskinesia (PED)	<i>SLC2A1</i> , glucose transporter 1 (GLUT1)
DYT19	16q13-q21	AD	Paroxysmal kinesigenic dyskinesia without epilepsy (EKD2)	Unknown
DYT20	2q31	AD	Paroxysmal nonkinesigenic dyskinesia (PNKD2)	Unknown
DYT21	2q14.3-q21.3	AD	Adult-onset mixed dystonia, only in Sweden, so far	Unknown

DYT23	9q34.11	AD	Cervical dystonia	<i>CIZ1</i> (CDKN1A-interacting zinc finger protein 1)
DYT24	11p14.2	AD	Cervical-cranial-brachial dystonia (jerky torticollis)	<i>ANO3</i> (anoctamin 3)
DYT25	18p11.21	AD	Cervical-cranial dystonia	<i>GNAL</i> (guanine nucleotide-binding protein alpha-activating)

Genetic nomenclature is presented in the chronologic order named. The DYT1 gene has a deletion of one of a sequential pair of GAG triplets. DYT2 was set aside for any possible autosomal recessive forms of primary dystonia. DYT3 is associated with X-linked dystonia-parkinsonism, also known as *lubag*, and encountered in Filipino males and appears to be caused by mutations that lead to reduced expression of the transcription factor TATA-box binding protein-associated factors 1. It is the only disorder in this table that is a neurodegenerative disease. The other conditions in the table have not been associated with degeneration yet. DYT4 was labeled for an Australian family with dystonia, including a whispering dysphonia. DYT5a is for the GTP cyclohydrolase I gene mutations causing autosomal dominant DRD. DYT5b is for autosomal recessive DRD and infantile parkinsonism associated with mutations in the gene for tyrosine hydroxylase. DYT6 is the gene causing an adult- and childhood-onset dystonia of cranial, cervical, and limb muscles (mixed) initially discovered in a large Amish Mennonite kindred but now known to be worldwide. DYT7 is for familial torticollis in a family from northwest Germany. DYT8 to 10 are for paroxysmal dyskinesias: 8 is for nonkinesigenic type (PNKD) known as the *Mount-Rebak syndrome*; 9 is for a family with episodic choreoathetosis and spasticity, now recognized to be the same as DYT18; 10 is for PKD on chromosome 16. The same gene mutation can cause episodic ataxia and hemiplegic migraine. DYT11 has been named for mutations in the ϵ -sarcoglycan gene that causes myoclonus-dystonia. DYT12 is for the Na⁺K⁺-ATPase alpha 3 subunit gene mapped to chromosome 19q causing rapid-onset dystonia-parkinsonism. Speech is often involved. This gene mutation also can cause alternating hemiplegia of childhood. DYT13 is for gene mapped to 1p36 causing cervical-cranial-brachial dystonia in a family in Italy. DYT15 is for a myoclonus-dystonia family mapped to 18p11. DYT16 is for the stress response gene, PRKRA, which encodes the protein kinase, interferon-inducible double-stranded RNA-dependent activator identified in Brazilian families with early-onset dystonia-parkinsonism. DYT17 is for juvenile-onset cervical dystonia that can become generalized; DYT18 as PED due to a gene mutation in the glucose transporter. DYT19 causes another form of PKD without epilepsy. DYT20 causes a second form of PNKD. DYT21 was found in a Swedish family with dystonia. DYT23 causes familial cervical dystonia. DYT24 causes jerky torticollis. DYT25 results in cervical-cranial segmental dystonia.

AD, autosomal dominant; AR, autosomal recessive; DRD, dopa-responsive dystonia; M-D, myoclonus-dystonia; RDP, rapid-onset dystonia-parkinsonism; XR, X-linked recessive.

The functional and microstructural changes described earlier, although not always found in all forms of primary dystonia, point to altered motor control that may begin with abnormal inhibition or abnormal brain plasticity enhanced by feedback mechanisms. Because primary dystonia is etiologically heterogeneous, there are probably several different (possibly converging) pathways that lead to these changes, producing a common clinical picture of dystonic muscle contractions.

CLASSIFICATION OF TORSION DYSTONIA

To emphasize the twisting quality of the abnormal movements and postures, the term *torsion* is often placed in front of the word dystonia.

An updated classification of torsion dystonia organizes the dystonias into two major axes: clinical features and etiology. The clinical features axis has five sections, and the etiology axis has two sections (Table 76.5). Within the clinical features axis are age at onset, body distribution, temporal pattern, presence of other movement disorders, and presence of systemic manifestations. Age at onset is the most important factor related to prognosis of primary dystonia. As a general rule, the younger the age at onset, the more likely the dystonia will become severe and spread to multiple parts of the body. In contrast, the older the age at onset, the more likely dystonia will remain focal. Onset of dystonia in a leg is the second most important predictive factor for a more rapidly progressive course.

TABLE 76.5 Classification of Torsion Dystonia

Clinical Features

1. Age at onset

Infancy (birth to 2 yr)	Typically a metabolic disorder
Childhood (3-12 yr)	Commonly general or segmental, isolated or combined, inherited
Adolescence (13-20 yr)	Commonly general or segmental, isolated or combined, inherited
Early adulthood (21-40 yr)	Commonly segmental or focal, idiopathic or inherited
Late adulthood (older than 40 yr)	Commonly focal, idiopathic

2. Body distribution

- Focal (single body region)
- Segmental (two or more contiguous regions)
- Multifocal (two noncontiguous or more regions)
- Generalized (trunk + two or more other regions)
- Hemidystonia (unilateral arm + leg ± face)

3. Temporal pattern

Persistent	Can be inherited, idiopathic, secondary
Action-induced	Common onset of inherited and idiopathic (includes task-specific)
Diurnal	May be present in DRD
Paroxysmal	Paroxysmal dyskinesias

4. Associated features (other movement disorders are present in addition to dystonia)

Isolated dystonia	Dystonia is the only motor feature, with the exception of tremor.
Combined dystonia	Dystonia is combined with other movement disorders (such as myoclonus, parkinsonism, etc.).

5. Other neurologic or systemic manifestations

Examples: cognitive impairment in degenerative dystonia; psychiatric symptoms in Wilson disease

Etiology

Neuropathology

Degenerations

Static lesions

No structural lesion

Inherited or Acquired

Inherited

Acquired

Idiopathic

DRD, dopa-responsive dystonia.

Data from Albanese A, Bhatia K, Bressman SB, et al. Phenomenology and classification of dystonia: a consensus update. *Mov Disord.* 2013;28(7):863-873.

Because dystonia usually begins in a single body part, and because dystonia either remains focal or spreads to other body parts, it is useful to classify dystonia according to anatomic distribution. *Focal dystonia* affects only a single area. Frequently seen types of focal dystonia have specific labels: blepharospasm, torticollis, oromandibular dystonia, spastic dysphonia, writer's cramp, or occupational cramp. If dystonia spreads, it usually affects a contiguous body part. When dystonia affects two or more contiguous parts of the body, it is *segmental dystonia*. *Generalized dystonia* is a combination of trunk plus at least two other parts of the body. *Multifocal dystonia* fills a gap in the preceding designations, describing involvement of two or more noncontiguous parts. Dystonia affecting one-half of the body

P.649

is *hemidystonia*, which is usually symptomatic rather than primary. Adult-onset dystonia is often much more focal than generalized.

The most common focal dystonia is cervical dystonia (torticollis), followed by dystonias of cranial muscles: blepharospasm, spasmodic dysphonia, or oromandibular dystonia. Less common is arm dystonia, such as writer's cramp. The most common segmental dystonia involves the cranial muscles (Meige syndrome) or cranial and neck muscles (cranial-cervical dystonia).

The temporal pattern feature distinguishes between the great majority of dystonias that are continual even when the affected body part is at rest from the dystonia that appears only when that body part is voluntarily in motion. A diurnal pattern may be seen in dopa-responsive dystonia, being mild or absent in the morning and worsening as the day goes on. Paroxysmal dystonia is classified as part of a separate movement disorder, paroxysmal dyskinesias.

The associated features category separates those dystonias which are isolated (no other movement disorder present, with the exception of tremor) and those dystonias which are combined with other movement disorders, the most common being parkinsonism and myoclonus. Parkinsonism is commonly seen in DYT3, DYT5a, DYT5b, DYT12, and DYT16; myoclonus is present in DYT11 and DYT15 (see [Table 76.4](#)). Myoclonic jerks are sometimes seen in DYT1 and in tardive dystonia.

The etiologic classification includes pathology. Both pathology and etiology have been discussed earlier and in [Tables 76.1, 76.2, 76.3, 76.4](#).

CLINICAL MANIFESTATIONS

CARDINAL MOTOR FEATURES

Some clinical motor features of dystonia were described in the

“Introduction.” There are four more that are typical in dystonia.

Dystonic contractions are (1) of relatively long duration (compared to myoclonus and chorea), although short-duration contractions can occur in dystonia; (2) there is simultaneous contractions of agonist and antagonist muscles affecting the involved body part; (3) dystonic contractions usually result in a twisting of the affected body part (rather than simply flexion or extension); and (4) they involve the same muscle groups repetitively (called *patterned movements*). Myoclonus also has a patterned involvement, but chorea tends to flow from one body part to another. The speed of dystonic contractions can be slow or fast, even reaching the speed of myoclonus. The dystonia usually is activated or made worse when the involved body part moves voluntarily. But the voluntary movement can be highly selective. For example, a child with DYT1 dystonia may manifest twisting and elevation of a leg when walking forward but not when walking backward or running (or sitting or lying). As the disorder worsens, there is less selectivity, and the muscles can be involved even while at rest. Body position is another important factor. Dystonia may be absent when the patient is sitting and appear when the patient stands up. Dystonic tremor is usually not completely rhythmic, compared to parkinsonian tremor or essential tremor.

Cervical dystonia is often associated with arrhythmic tremor of the neck; the tremor is always in the horizontal plane. Some patients with primary dystonia may manifest tremor of the arms and hands that resemble essential tremor.

When evaluating a patient with dystonia, the first question is “Is dystonia present, or is the involved muscle tight because of guarding from pain or is it rigidity?” Then, determine if it is isolated dystonia (no other movement disorder present) or combined dystonia (another movement disorder present, often parkinsonism or myoclonus). This step will then focus the diagnosis to a considerable degree. The presence or absence of other neurologic signs is equally important because this would direct one into considering an acquired or neurodegenerative diagnosis. Then other features, such as age at onset, family history, rate of progression, body parts involved, and MRI results will guide the evaluator to a differential diagnosis. Some genes are available for testing commercially, and this should be pursued when those gene mutations are within the differential diagnosis. There are specific syndromes of various types of dystonia, and their patterns will help lead one to the correct diagnosis. These are discussed next.

OPPENHEIM DYSTONIA (DYT1)

The gene at the DYT1 locus has been identified and causes the dystonia described by Oppenheim. In most patients with DYT1 dystonia, symptoms begin in childhood or adolescence, and the mean age at onset is 13 years. Symptoms rarely begin after age 26, although onset as late as the seventh decade may occur. In most patients, first symptoms involve an arm or a leg (Video 76.1), with rare cases beginning in the cervical or cranial muscles. About 65% of all DYT1 patients progress to a generalized or multifocal distribution, but the proportion progressing is even higher for those with childhood onset. About 10% have segmental dystonia and 25% only focal involvement. Most of those with focal dystonia have writer's cramp, but isolated cervical (torticollis) and upper facial (blepharospasm) dystonias have been reported. In terms of body regions ultimately involved, one or more limbs are affected in the vast majority, with over 95% having an affected arm. The trunk and neck are affected in 25% to 35% of cases, and they may be the regions producing the greatest disability; the cranial muscles are less likely to be involved. Also, there may be great intrafamilial variability, ranging from no dystonia (70% of gene carriers have no dystonia) to mild writer's cramp to severe generalized dystonia. When dystonia begins in a leg, it usually starts as an action dystonia resulting in a peculiar twisting of the leg when the child walks forward, even though walking backward, running, or dancing may still be normal. Bizarre stepping or a bowing gait may be noted when the dystonic movements affect proximal muscles of the leg. Difficulty in placing the heel on the ground is evident when distal muscles are affected. As the disorder progresses, the movements may appear when the leg is at rest; the foot may be plantar flexed and ankle everted or inverted; the knee and hip often assume a flexed posture.

With arm involvement, action dystonia may interfere with writing; the fingers curl, the wrist flexes and pronates, the triceps contract, and the elbow elevates. Dystonic tremor of the arm is common, with features of both postural and action tremors. With progression, other activities of the arm are impaired; the arm often moves backward behind the body when the patient walks. Later, dystonia may be present when the arm is at rest.

As the dystonia becomes worse, the contractions become constant so that instead of moving, the body part remains in a fixed twisted posture. The trunk may develop wiggling movements and fixed scoliosis, lordosis, and tortipelvis. The neck may become involved with torticollis, anterocollis, retrocollis, or head tilt and shift. Facial grimacing and difficulties in speech may occur but are much less common. Although muscle tone and power seem normal, the involuntary movements interfere and make voluntary activity extremely difficult. In general, mental activity is normal, and there are no alterations in tendon reflexes or sensation. The rate of progression of this type of dystonia is extremely variable; in most cases, generalized spread occurs within the first 5 to 10 years followed by a static phase, but late worsening, especially more forceful

contractions in a body region already affected, may occur. The continuous spasms result in marked distortion of the body to a degree rarely seen in any other disease. With active treatment, it is now uncommon to encounter the severe deformities seen before the 1980s.

Oppenheim dystonia is an autosomal dominant disorder with markedly reduced penetrance of 30% to 40%. The *DYT1* gene is localized to chromosome 9q34.1 and encodes the protein torsinA. To date, there is only one clearly pathogenic *DYT1* mutation, namely, a GAG deletion in exon 5 of the *TOR1A* gene. The deletion results in the loss of a glutamic acid residue at position 302 or 303 in the 332-amino acid protein. There are several other coding variants in *TOR1A*, and one of these, a single nucleotide polymorphism (SNP) that results in coding for either aspartic or histidine at position 216, has recently been identified to modify clinical expression in *DYT1* GAG mutation carriers. The histidine allele, present in about 12% of the population, when inherited in trans, protects an individual carrying the GAG deletion from expressing dystonia.

TorsinA is a member of the AAA+ superfamily (ATPases Associated with a variety of cellular Activities). This family of proteins has many functions that are critical to assembly, disassembly, and operation of protein complexes. TorsinA is widely distributed in the brain; it is restricted to neurons and normally associated with the endoplasmic reticulum (ER). In cellular models, mutated torsinA relocates from the ER to the nuclear envelope (NE). Mutant torsinA expression is also associated with abnormal morphology and apparent thickening of the NE including altered connections between the inner and outer membranes, as well as generation of whorled membrane inclusions, which appear to “spin off” the ER/NE. Its aberrant localization and interactions may result in stress-induced abnormalities, including impaired dopamine release. It has also been shown that mutant torsinA interferes with cytoskeletal events, which may affect development of neuronal pathways in the brain.

Oppenheim dystonia affects most ethnic groups but is particularly prevalent in the Ashkenazi Jewish population, in which the prevalence is about 1 per 6,000, as mentioned in the epidemiology section.

Because all *DYT1* cases, Jewish and non-Jewish, have one recurring mutation, screening for the mutation is straightforward. Genetic testing is recommended for all patients with primary dystonia with an onset before age 26 years regardless of family history. It is also advised for those with later onset who have a relative with early onset. Genetic counseling should accompany testing; *DYT1* has low penetrance, which is affected by the presence of the histidine substitution described earlier. Further, there is variable expression, and importantly, *DYT1* does not account for all genetic causes of primary dystonia, even among those with early onset; these complex issues require discussion with patients and their family members.

OTHER EARLY-ONSET NON-DYT1 PRIMARY DYSTONIAS

DYT1 accounts for most childhood- and adolescent-onset primary dystonia in Ashkenazi Jews but only about 30% to 50% in non-Jews. Although some families are clinically similar to *DYT1*, other families have autosomal dominant inheritance of a somewhat different family phenotype. Dystonia begins on average several years later with a higher proportion having adult onset, and there is greater involvement of muscles in the cranial-cervical region. In two large related Amish Mennonite families with this phenotype, a gene locus (*DYT6*) was mapped to chromosome 8p and then the mutated gene identified as *THAP1*. A heterozygous 5bp (GGGTT) insertion followed by a 3 bp deletion (AAC) in exon 2 of the gene was detected in this large family. The mutation causes a frame shift at amino acid position number 44 of the protein resulting in a premature stop codon at position 73.

THAP1 is a member of a family of cellular factors sharing a highly conserved THAP domain, which is an atypical zinc finger. Associated with its DNA binding domain, *THAP1* regulates endothelial cell proliferation. In addition to the THAP domain at the N-terminus, *THAP1* possesses a nuclear localization signal at its C-terminus. One proposed disease mechanism is that *DYT6* mutations disrupt DNA binding and produce transcriptional dysregulation. Although this gene was initially thought to have a limited role, restricted to related Amish

Mennonite families, different *THAP1* mutations in families with diverse ancestries have now been identified. Despite the diversity of mutation types and ancestries, a similar phenotype has been observed thus far: with relatively early-onset (although the range is wide with a significant proportion having onset after 18 years) and commonly occurring cranial muscle involvement causing speech abnormalities. Many affected individuals in this kindred are disabled by dysphonia, dysarthria, and cervical dystonia.

ADULT-ONSET PRIMARY DYSTONIA

Most primary dystonias are of adult onset with estimates of prevalence ranging from 11.7 to 49 per 100,000. The adult dystonias usually remain localized to the muscles (and immediately contiguous muscles) first involved (i.e., focal and segmental dystonias). Common sites are neck (cervical dystonia), face (blepharospasm), jaw (oromandibular dystonia), vocal cords (spasmodic dysphonia), and arm (writer's cramp).

Family studies have demonstrated an increased rate of dystonia among family members, suggesting a genetic etiology. With equal rates in parents, offspring, and siblings, the pattern of transmission is consistent with autosomal dominant inheritance; however, it seems to be much less penetrant than childhood-onset dystonia, with penetrance rates of only 10% to 15% rather than 30% to 40% and few with higher penetrance. In one such family with cervical dystonia, a locus, *DYT7* on chromosome 18p, was mapped. This locus has been excluded in other adult-onset families, so its role in primary dystonia is not known. Because the majority of adult-onset dystonia patients do not have many affected relatives, association studies using cases and controls have been employed to find genetic risk factors. Adult-onset focal dystonias have been associated with polymorphisms in the D5 dopamine receptor gene and also with a *DYT1* haplotype, but these findings have not been consistently replicated.

Cervical dystonia, commonly known as *spasmodic torticollis* or *wry neck*, is the most common focal dystonia (Video 76.2). It occurs at any age, usually beginning between ages 20 and 60 years, and is more frequent in women. Any combination of neck muscles can be involved, especially the sternocleidomastoid, trapezius, splenius capitus, levator scapulae, and scalenus muscles. Sustained turning, tilting, flexing, or extending of the neck or shifting of the head laterally or anteriorly can result. Frequently, the shoulder is elevated and anteriorly displaced on the side to which the chin turns. Instead of sustained head deviation, some patients have jerking movements of the head. Neck pain occurs in about two-thirds of patients with cervical dystonia and usually responds successfully to injections of botulinum toxin at the site of the pain. A common sensory trick to relieve cervical dystonia is to place one hand on the back of the head or chin. About 10% of patients with cervical dystonia have a remission, usually within a year of onset; most remissions are followed by a relapse years later.

P.651

Some patients with torticollis have a horizontal head tremor that may be impossible to distinguish from essential tremor. Other considerations in the differential diagnosis of dystonic torticollis are congenital contracture of the sternocleidomastoid muscle, which can be treated with surgical release. In young boys after a full meal, extreme head tilt may be caused by gastroesophageal reflux (*Sandifer syndrome*), which can be treated either medically or by plication surgery. Other diagnostic considerations are trochlear nerve palsy; Arnold-Chiari malformation; malformations of the cervical spine, such as Klippel-Feil fusion or atlantoaxial subluxation; cervical infections; and spasms from cervical muscle shortening.

Blepharospasm is caused by contraction of the orbicularis oculi muscles. It usually begins with increased frequency of blinking, followed by closure of the eyelids, and then more firm and prolonged closure of the lids, which may produce functional blindness if untreated. Blinking and lid closure can be intermittent and are often temporarily suppressed by talking, humming, singing, or looking down. The condition is worsened by walking and by bright light. A common sensory trick that relieves contractions is placing of a finger just lateral to the orbit. Blepharospasm is usually accompanied by cocontraction of lower facial muscles, such as the platysma and

risorius. This type of focal dystonia sometimes becomes segmental by spreading to other cranial targets, such as the jaw (Video 76.3), tongue, vocal cords, or cervical muscles. The combination of blepharospasm with cervical or other cranial dystonias is called *craniocervical segmental dystonia* or *Meige syndrome*. Blepharospasm occurs more often in women than in men, usually beginning after age 50 years, although younger people may be affected. Abnormalities of the blink reflex have been found with blepharospasm and with other cranial or cervical dystonias.

The differential diagnosis of blepharospasm includes *hemifacial* spasm, which is unilateral. Rarely, hemifacial spasm is bilateral, but the contractions on the two sides of the face are not synchronous as they are in blepharospasm. *Blinking tics* can resemble blepharospasm, but tics almost always begin in childhood. *Sjögren syndrome* of dry eyes often causes the eyelids to close, but testing for tear production usually distinguishes this disorder. Injections of botulinum toxin into the contracting muscles are effective in more than 80% of patients with blepharospasm.

Writer's cramp of adult onset usually remains limited to one limb, often the dominant side (Video 76.4). In about one-third of cases, it spreads to the other arm. When it affects only writing, the patient may learn to write with the nondominant hand. For bilateral involvement or for dystonia that affects other activities (buttoning, shaving, or playing a musical instrument), carefully placed injections of botulinum toxin may be effective.

Dystonia of the vocal cords occurs in two forms. The more common type is *spasmodic adductor dysphonia*, in which the vocalis muscles contract, bringing the vocal cords together and causing the voice to be restricted, strangled, and coarse, often broken up with pauses. *Breathy (whispering) dysphonia* (spasmodic abductor dysphonia) is caused by contractions of the posterior cricoarytenoids (abductor muscles of the vocal cords) so that the patient cannot talk in a loud voice and tends to run out of air while trying to speak. Spasmodic dysphonia is often associated with tremor of the vocal cords. Essential tremor (with vocal cord tremor) is an important differential diagnosis; the presence of tremor in the hands or neck leads to such diagnosis. Injections of botulinum toxin can be dramatically effective for spasmodic adductor dysphonia but are less certain for breathy dysphonia. For each type, a physician must be experienced with the procedure of injecting the correct muscle. Some patients with the strangled voice of adductor dysphonia will compensate by speaking in a whisper, which could confuse the examiner into misdiagnosing abductor dysphonia. When encountering a patient with supposed breathy dysphonia, the examiner needs to inquire if whispering is done purposefully in order to talk fluently.

COMBINED DYSTONIA SYNDROMES

This category includes nondegenerative disorders in which parkinsonism (dopa-responsive dystonia and rapid-onset dystonia-parkinsonism) or myoclonus (myoclonus-dystonia) coexists with dystonia.

Dopa-Responsive Dystonia

A small minority of patients with childhood-onset dystonia have the autosomal dominant disorder dopa-responsive dystonia (DRD), sometimes called *Segawa disease*. Distinguishing DRD from primary isolated dystonia is important because DRD responds so well to treatment. It differs from primary dystonia by the signs of parkinsonism, which may be subtle. These include bradykinesia, cogwheel rigidity, and impaired postural reflexes. Other distinguishing features include diurnal fluctuations with improvement after sleep and worsening as the day wears on; a peculiar "spastic" straight-legged gait, with a tendency to walk on the toes; hyperreflexia, particularly in the legs and sometimes with Babinski signs; and a remarkable therapeutic response to low doses of levodopa that is sustained without the development of long-term fluctuations observed in Parkinson disease.

DRD usually begins between ages 6 and 16 years but can appear at any age. When it begins in infants, it resembles cerebral palsy. When it begins in adults, it often manifests as pure parkinsonism, mimicking Parkinson

disease, responding to levodopa, and having a generally benign course. DRD affects girls more often than boys, has a worldwide distribution, and is not known to have a higher prevalence in any specific ethnic group. Mutations in the gene for GTP cyclohydrolase 1 (*GCH1*) located at 14q22.2 are responsible for the majority of DRD. More than 60 different mutations have been reported; they are thought to have a dominant negative effect on enzyme activity. In some patients, other genetic etiologies can be found (e.g., recessively inherited mutations in tyrosine hydroxylase), but in others, no genetic cause can be identified.

GCH1 catalyzes the first and rate-limiting step in the biosynthesis of tetrahydrobiopterin (BH4), the cofactor required for the enzymes tyrosine hydroxylase, phenylalanine hydroxylase, and tryptophan hydroxylase. These hydroxylase enzymes add an -OH group to the parent amino acid and are required for the synthesis of biogenic amines. The genetic label for DRD owing to GCH1 mutations is DYT5a.

Pathologic investigations of DRD revealed no loss of neurons within the substantia nigra pars compacta, but the cells are immature with little neuromelanin. Neuromelanin synthesis requires dopamine (or other monoamines) as the initial precursor. Biochemically, there is marked reduction in dopamine concentration and tyrosine hydroxylase activity within the striatum in DRD.

Aside from mutations in GCH1, DRD can rarely be caused by mutations in other enzymes involved in dopamine synthesis including tyrosine hydroxylase and pterin synthesis deficiencies. DRD owing to tyrosine hydroxylase deficiency (DYT5b) is an autosomal recessive disorder that begins in infancy or early childhood. The phenotype may mimic DRD, but clinical features range from a mild syndrome of spastic paraparesis to severe parkinsonism, dystonia, and oculogyric crises. The pterin deficiency syndromes can include

P.652

other features such as ptosis, miosis, rigidity, hypokinesia, chorea, myoclonus, seizures, temperature disturbance, and hypersalivation. These latter features represent deficiencies of norepinephrine and serotonin in addition to dopamine; hyperphenylalaninemia is present, and the disorder may respond partially to levodopa.

Another disorder of infants is the autosomal recessive deficiency of the enzyme aromatic L-amino acid decarboxylase, which catalyzes the transformation of levodopa to dopamine. Levodopa is ineffective in this disorder, but patients respond partially to dopamine agonists coupled with a monoamine oxidase inhibitor.

The most important differential diagnosis of DRD is juvenile parkinsonism, a progressive nigral degenerative disorder usually caused by homozygous or compound heterozygous mutations in the *parkin* gene (*PARK2*). In this disorder, dystonia often precedes the parkinsonian features, which become the major clinical feature. Distinguishing laboratory tests include fluorodopa PET and β -CIT single-photon emission computed tomography (SPECT), which are normal in DRD but abnormal in juvenile parkinsonism, showing marked reduction in uptake in the striatum. Other differential features of DRD from juvenile parkinsonism and Oppenheim dystonia are listed in [Table 76.6](#).

TABLE 76.6 Differential Features between Dopa-Responsive Dystonia, Oppenheim Torsion Dystonia, and Juvenile Parkinson Disease

Features	DRD	DYT1	JPD
Average age at onset (range)	6 yr (infancy—sixth decade)	13 yr (4 yr—seventh decade)	Adolescence (7 yr—sixth decade)
Gender	Female > male	Female = male	Male = female

Initial signs	Leg > arm or trunk action dystonia, abnormal gait (scissoring, toe walking)	Arm or leg action dystonia, occasionally trunk or neck	Foot/leg > hand/arm dystonia, rest tremor (especially legs), akinesia/rigidity
Diurnal fluctuations	Often prominent	Rare	May occur
Bradykinesia	Yes (may be mild)	No	Yes
Postural instability	Occurs	No	Occurs
Response to L-dopa			
Initial	Excellent to very low to low dose	Inconsistent and usually not dramatic	Excellent to low to moderate dose
Long term	Excellent		Dyskinesias, may fluctuate
CSF			
HVA	↓	Normal	↓
Biopterin	↓	Normal	↓
Neopterin	↓↓	Normal	↓
F-DOPA PET	Normal or slightly reduced without worsening over time	Normal	Decreased and worsens over time
Inheritance	AD, reduced penetrance	AD, reduced penetrance	AR
Gene	Heterozygous mutations in <i>GCH1</i> in many, rarely recessive <i>GCH1</i> or <i>TH</i>	Heterozygous GAG deletion in <i>DYT1</i>	Homozygous or compound heterozygous <i>parkin</i> mutations
Testing	Screening for <i>GCH1</i> mutations in select labs	Commercially available	Commercially available
Prognosis	Return to near normal with treatment in most	Progresses at first, then tends to	Slow to moderate progression

stabilize after
several years

DRD, dopa-responsive dystonia; DYT1, Oppenheim torsion dystonia; JPD, juvenile Parkinson disease; CSF, cerebrospinal fluid; HVA, homovanillic acid; ↓, decreased; AD, autosomal dominant; AR, autosomal recessive.

One may also suspect DRD if a young patient with dystonia responds dramatically to low doses of anticholinergic agents. However, the most effective agent is levodopa. The suggested starting dose of carbidopa/levodopa for DRD is 12.5/50 mg two or three times a day, a dose low enough to avoid acute dyskinesias, which may sometimes occur if therapy is started with higher doses. The usual maintenance dose is 25/100 mg two or three times a day.

Rapid-onset Dystonia-Parkinsonism

Rapid-onset dystonia-parkinsonism (RDP) is a rare combined dystonia syndrome that begins during childhood or early adulthood. It is characterized by both dystonia and parkinsonism that usually begins suddenly, over hours to days, and may be associated with physical or emotional stress. Symptoms may, however, begin more insidiously and then have a period of rapid worsening. After the period of worsening, symptoms tend to stabilize, although improvement may occur. The phenotype resembles dystonic-parkinsonian Wilson disease, with prominent bulbar signs (including risus sardonicus), relatively sustained dystonic limb posturing, waxy effortful rapid successive movements, and postural instability. Inheritance is autosomal dominant, and de novo mutations have

P.653

been observed. The responsible gene, which maps to chromosome 19q13 (classified as DYT12), has been identified; it codes for Na⁺/K⁺-ATPase α3, a catalytic subunit of the sodium-potassium pump that functions to maintain an electrochemical gradient across the plasma membrane. In RDP patients, the cerebrospinal fluid (CSF) homovanillic acid concentration is low, there are no imaging abnormalities, and in two autopsies, no neurodegeneration was detected. However, subsequent cases in one family were found with changes in some subcortical regions. There is no effective treatment. The mutated gene has also been found to cause the disorder known as *alternating hemiplegia of childhood*.

Myoclonus-Dystonia

Although lightning-like movements occasionally occur in Oppenheim dystonia, they are a prominent feature in a distinct autosomal dominant disorder known as *myoclonus-dystonia* (M-D). In families with M-D, affected individuals have myoclonus as the primary sign, and it may occur with or without dystonia; rarely, dystonia is the only feature as writer's cramp or torticollis. Symptom onset is usually in the first or second decade; males and females are equally affected in most, but not all, families, and the pattern of inheritance appears autosomal dominant with reduced penetrance that is dependent on the transmitting parent. That is, most affected individuals inherit the disorder through their father, a finding consistent with a maternal imprinting mechanism. The neck and arms are involved most commonly, followed by the trunk and bulbar muscles, with less common involvement of the legs. The disorder tends to plateau in adulthood, and affected adults often report that the muscle jerks respond dramatically to alcohol. Also, there appears to be an excess of psychiatric symptoms, including obsessive-compulsive disorder (OCD), in family members, even those not affected with motor signs of M-D.

A large proportion of familial M-D is owing to mutations in the ε-sarcoglycan gene mapped to chromosome 7q21.3 (DYT11). The sarcoglycans are a family of genes that encode components of the dystrophin-glycoprotein

complex, and mutations in α -, β -, γ -, and Δ -sarcoglycan produce recessive muscular limb-girdle dystrophy. ϵ -Sarcoglycan, however, is expressed widely in brain, is located at the plasma membrane, and is imprinted. In a cellular model, the mutant protein is retained intracellularly, becomes polyubiquitinated, and is rapidly degraded by the proteasome. Furthermore, torsinA binds to and promotes the degradation of ϵ -sarcoglycan mutants when both proteins are coexpressed.

ϵ -Sarcoglycan mutations do not account for all familial M-D and probably are not responsible for most sporadic M-D. There is at least one other gene locus for M-D; in one family with M-D, a locus on 18p (DYT15) was mapped.

SECONDARY DYSTONIA

Secondary dystonia can occur as the result of an environmental injury (acquired dystonia) or a hereditary degenerative disorder (inherited degenerative or dystonia) that affects the brain, especially the basal ganglia. Spinal cord injury and peripheral injury are also recognized causes of dystonia. Examples of acquired dystonia include levodopa-induced dystonia in the treatment of parkinsonism; acute and tardive dystonia owing to dopamine receptor-blocking agents; and dystonias associated with cerebral palsy, cerebral hypoxia, cerebrovascular disease, cerebral infectious and postinfectious states, brain tumor, and toxicants such as manganese, cyanide, and 3-nitropropionic acid. Other acquired causes include psychogenic disorders, peripheral trauma followed by focal dystonia in the affected region, head injury, and delayed-onset dystonia after cerebral infarct or other cerebral insult. Prior history of one of these insults suggests the correct diagnosis, as does neuroimaging that shows a lesion in the basal ganglia or their connections.

A more complete listing of secondary dystonias was presented in [Tables 76.1](#), [76.2](#) and [76.3](#). A number of disorders in this group, such as the infectious and toxicant-induced neurodegenerations, are not limited to pure dystonia but show a mixture of other neurologic features, often the parkinsonian features bradykinesia and rigidity. *Tardive dystonia*, a persistent complication of agents that block dopamine receptors, is a common form of secondary dystonia. Tardive dystonia is usually focal or segmental, affecting the cranial structures in adults; in children and adolescents, however, it can be generalized, involving the trunk and limbs. It often is associated with features of tardive dyskinesia, especially oral-buccal-lingual movements (see [Chapter 80](#)). Clues suggesting a secondary dystonia are listed in [Table 76.7](#).

NBIAs were discussed in the section on genetics and are listed in [Table 76.3](#). An X-linked recessive disorder causing dystonia and parkinsonism affects young adult Filipino men. The Filipino name for the condition is *Iubag*. It has been designated as DYT3. It can begin with dystonia in the feet or cranial structures; lingual and oromandibular dystonias are common, sometimes with stridor. With progression, generalized dystonia often develops. Many patients develop parkinsonism; in some patients, the sole manifestation may be progressive parkinsonism. The abnormal gene is localized to the centromeric region of the X chromosome, and disease-specific mutations have been identified, which lead to a reduced expression of the general transcription factor TATA-box binding protein-associated factor 1 (*TAF1*). Pathologic study reveals a mosaic pattern of gliosis in the striatum. Patients respond only partially to levodopa, anticholinergics, baclofen, clonazepam, or zolpidem.

Psychogenic dystonia can be considered within the secondary dystonia category. For many decades, Oppenheim dystonia was considered psychogenic because of the bizarre nature of the symptoms, exaggeration in periods of stress, variability, and suppression by sensory tricks. This misdiagnosis often led to a long delay in identification of the nature of the disorder and to prolonged periods of needless psychotherapy. Awareness of the capricious nature of the disorder and serial observation of patients can avoid this pitfall. On the other hand, psychogenic dystonia does occur but in less than 5% of patients who otherwise would be considered

to have primary torsion dystonia. Clues suggestive of psychogenic dystonia are listed in [Table 76.8](#).

TABLE 76.7 Clues Suggestive of Symptomatic Dystonia

1. History of possible etiologic factor, for example, head trauma, peripheral trauma, encephalitis, toxin exposure, drug exposure, perinatal anoxia
2. Presence of neurologic abnormality aside from dystonia, for example, parkinsonism, dementia, seizures, ocular, ataxia, neuropathy, spasticity
3. Onset of dystonia at rest (instead of action)
4. Early onset of speech involvement
5. Leg involvement in an adult
6. Hemidystonia
7. Abnormal routine brain imaging
8. Abnormal laboratory workup
9. Presence of false weakness or sensory exam or other clues of psychogenic etiology (see [Table 76.8](#))

TABLE 76.8 Clues Suggestive of Psychogenic Dystonia

Clues relating to the movements

1. Abrupt onset
2. Inconsistent movements (changing characteristics over time)
3. Incongruous movements and postures (movements do not fit with recognized patterns or with normal physiologic patterns)
4. Presence of additional types of abnormal movements that are not consistent with the basic abnormal movement pattern or are not congruous with a known movement disorder, particularly rhythmic shaking, bizarre gait, deliberate slowness carrying out requested voluntary movement, bursts of verbal gibberish, and excessive startle (bizarre movements in response to sudden unexpected noise or threatening movement)
5. Spontaneous remissions
6. Movements disappear with distraction

7. Response to placebo, suggestion, or psychotherapy

8. Present as a paroxysmal disorder

9. Dystonia beginning as a fixed posture

10. Twisting facial movements that move the mouth to one side or the other (Note: Organic dystonia of the facial muscles usually does not move the mouth sideways.)

Clues relating to other medical observations

1. False (give-way) weakness

2. False sensory complaints

3. Multiple somatizations or undiagnosed conditions

4. Self-inflicted injuries

5. Obvious psychiatric disturbances

6. Employment in the health profession or in insurance claims field

7. Presence of secondary gain, including continuing care by a “devoted” spouse

8. Litigation or compensation pending

OTHER MOVEMENT DISORDERS WITH DYSTONIA

Dystonia can appear in disorders not ordinarily considered to be part of torsion dystonia ([Table 76.9](#)). These include dystonic tics that are more conveniently classified with tic disorders (see [Chapter 74](#)), paroxysmal dyskinesias more conveniently classified with paroxysmal dyskinesias, and hypnogenic dystonia that can be either paroxysmal dyskinesias or seizures.

PSEUDODYSTONIA

To complete the classification, [Table 76.10](#) lists disorders that can mimic torsion dystonia but are not generally considered to be true dystonias. These disorders typically manifest themselves as sustained muscle contractions or abnormal postures, which is why they are often mistaken for dystonia. However, these contractions are secondary to either a peripheral or a reflex mechanism or as a reaction to some other problem. For example, Sandifer syndrome is a result of gastroesophageal reflux, with apparent reduction in the gastric contractions when the head is tilted to the side; Isaacs syndrome is a result of continuous peripheral neural firing; orthopedic disease causes a number of postural changes; and seizures can result in sustained twisting postures.

TABLE 76.9 Other Movement Disorders in Which Dystonia May Be Present

Tic disorders with dystonic tics

Paroxysmal dyskinesias with dystonia

Paroxysmal kinesigenic dyskinesia

Paroxysmal nonkinesigenic dyskinesia

Paroxysmal exertional dyskinesia

Benign infantile paroxysmal dyskinesias

Hypnogenic dystonia (sometimes these are seizures)

TREATMENT

After levodopa therapy has been tested to be certain that DRD has not been overlooked, other oral medications may be effective and should be tried in people with dystonia not amenable or not adequately responding to botulinum toxin injections. The following

P.655

drugs have been reported to be effective in dystonia: high-dose anticholinergics (e.g., trihexyphenidyl), high-dose baclofen, benzodiazepines (clonazepam, diazepam), and antidopaminergics (tetrabenazine, dopamine receptor blockers).

TABLE 76.10 Pseudodystonias (Not Classified as Dystonia but Can Be Mistaken for Dystonia because of Sustained Postures)

Sandifer syndrome

Stiff person syndrome

Isaacs syndrome

Satoyoshi syndrome

Rotational atlantoaxial subluxation

Soft-tissue nuchal mass

Bone disease

Ligamentous absence, laxity, or damage

Congenital muscular torticollis

Congenital postural torticollis

Juvenile rheumatoid arthritis

Ocular postural torticollis

Congenital Klippel-Feil syndrome

Posterior fossa tumor

Syringomyelia

Arnold-Chiari malformation

Trochlear nerve palsy

Vestibular torticollis

Seizures manifesting as sustained twisting postures

Inflammatory myopathy

Test one drug at a time. The procedure can take months before a combination of medications can be found that are beneficial. Anticholinergics may be the most effective and is the only class of drugs other than botulinum toxin shown to be effective in a controlled clinical trial [Level 1].¹ Trihexyphenidyl is better tolerated in children than in adults. In both groups, start with a small dose (1 mg three times a day [t.i.d.]) and if tolerated, increase after 1 week to 2 mg t.i.d. The dose can be increased weekly at that rate until benefit or side effects are seen. The most common anticholinergic side effect is dry mouth and blurred vision due to dilated pupils. There could also be constipation and difficulty initiating a urinary stream. If a patient has glaucoma, pilocarpine eye drops need to be applied, and one should work with an ophthalmologist. Pilocarpine eye drops (1/4%) is also useful to overcome blurred vision due to dilated pupils. Dry mouth can be relieved with drinking more fluids or sucking on sugar-free hard candies. For urinary or bowel symptoms, adding pyridostigmine starting at 30 mg twice a day (b.i.d.) and increasing the dose to obtain relief often helps. A side effect that limits the use of anticholinergics is forgetfulness or short-term memory loss. The only relief is to lower the dose or discontinue the drug. The dose of trihexyphenidyl could reach over 120 mg/day in children. Adults may not tolerate more than 30 mg/day. Building the dosage up very slowly is the only way to achieve the effective high doses. If side effects occur, one can reduce the dose to the point at which the adverse effects have cleared while still achieving some benefit. If side effects occur without ever achieving benefit, it is best to titrate the dose downward over several days and eliminate it.

After the optimum dose of the anticholinergic agent has been reached, a second drug can be added. Baclofen, beginning at 10 mg at bedtime (h.s.), can be increased weekly by 10 mg until 10 mg four times a day (q.i.d.) is reached. If no adverse effects or benefit is seen, continue to increase the dose. As much as

90 to 120 mg/day may be necessary to see benefit. A major limitation is drowsiness, and a high dose may not be reached. If some benefit is seen, continue using it at a dose that is tolerated and then add a third medication. Clonazepam, diazepam, and tetrabenazine can all be tried using the same principle of starting with a low dose and building it up gradually until either side effects or benefit is seen.

For focal dystonias, such as blepharospasm, torticollis, oromandibular dystonia, and spastic dysphonia, local injections of botulinum toxin are beneficial [Level 1].^{2,3,4,5,6} This agent also can be used to treat generalized dystonia, with injections limited to the most severely affected focal site. This muscle-weakening agent can be effective for about 3 months before a repeat injection is needed. Current batches of the toxin contain less antigenic protein than the original batch, making it less likely that patients will develop antibodies to botulinum toxin, which would render that particular strain of toxin ineffective.

Stereotactic brain surgery may ameliorate dystonia and can be considered if medical therapies fail. Deep brain stimulation has mostly replaced ablative surgery, which had been thalamotomy and especially pallidotomy. The main target for deep brain stimulation is the globus pallidus interna. Bilateral deep brain stimulation of the pallidum appears to provide moderate to marked improvement for generalized primary dystonia without the high risk for dysarthria that occurs after bilateral thalamotomy, but dysarthria and other neurologic complications can sometimes occur. The subthalamic nucleus is being evaluated as another target for deep brain stimulation.

Hemifacial Spasm

Paul Greene

INTRODUCTION

In hemifacial spasm (HFS) there are involuntary contractions on one side of the face in muscles innervated by the facial nerve (cranial nerve VII) (Figs. 77.1 and 77.2). According to Digre and Corbett, the condition was first described in 1875 by Schultze but was first separated from other forms of facial twitching by Gowers in 1888. HFS is rare in this country. The age-adjusted incidence was 0.78 per 100,000 per year in Olmsted County, Minnesota, only 3% of the incidence of Bell palsy.

PHENOMENOLOGY

The contractions in HFS usually start as individual muscle twitches in the eyelids. Over time, twitches spread to other facial nerve-innervated muscles including the frontalis, paranasal muscles, zygomaticus major, perioral muscles, platysma, and occasionally, the periauricular muscles. Trains of twitches may develop and, when severe, there may be periods of sustained muscle contraction causing complete eye closure. Pain in HFS is very rare, usually from patients with concurrent involvement of the trigeminal nerve producing tic douloureux (the combination is called *tic convulsivo*).

Contractions in HFS diminish, but do not disappear, during sleep and patients often report worsening with stress. This is surprising for what is usually presumed to be a peripheral nerve disease (see the following discussion). HFS usually progresses slowly if at all but may produce facial weakness in patients with long duration of disease. About 1% of reported cases of HFS are bilateral (with twitching that is asynchronous from side to side). The majority of cases of HFS are sporadic, although there are occasional reports of familial cases (Video 77.1).

FIGURE 77.1 The anterior inferior cerebellar artery (*A*) runs between cranial nerves *VII* and *VIII* and compresses nerve *VII*. (From Ma Z, Li M, Cao Y, et al. Keyhole microsurgery for trigeminal neuralgia, hemifacial spasm and glossopharyngeal neuralgia. *Eur Arch Otorhinolaryngol*. 2010;267:449-454.)

DIFFERENTIAL DIAGNOSIS

There are few other diseases that produce twitches, trains of twitches, and occasionally, episodes of sustained muscle contraction ([Table 77.1](#)). Facial dystonia is usually more sustained and bilateral and muscle contractions are not usually synchronous. The rippling movements of facial myokymia are often unilateral but are slow and asynchronous. Motor tics in the face may be unilateral and rapid, but there is usually a warning sensation before the movements and the movements are usually suppressible, at least briefly. Synkinesis after Bell palsy or other cause produces synchronous contractions but only during blinking or voluntary movement. However, some patients develop HFS in addition to a synkinesis after nerve injury. Epilepsia partialis continua does mimic the movements of HFS precisely but usually involves the masseters (cranial nerve VII) and is rarely limited to the face.

PATHOGENESIS

The pathogenesis of HFS is thought to be compression of the facial nerve where it exits the brain stem (the root exit zone), usually by an aberrant artery, such as the anterior inferior cerebellar artery, posterior inferior cerebellar artery, or internal auditory artery, or a normal vein. Irritation of the nerve at this site is felt to generate

spontaneous electrical activity, causing muscle contractions, and “cross-talk” or simultaneous activation of axons going to different parts of the face. However, other causes of compression at the root exit zone besides normal arteries rarely occur, such as draining veins of arteriovenous malformations (AVMs), aneurysms, tumors, or plaques of multiple sclerosis in the central myelin at the root

P.658

exit zone of the facial nerve. For this reason, all patients with HFS should have a magnetic resonance imaging (MRI) with attention to the posterior fossa. If compression by aberrant arteries is the most common cause for HFS, it would be reasonable that arterial hypertension causing ectatic vessels might be a risk factor for HFS. Older studies suggested this, but recent carefully controlled studies failed to find such an association.

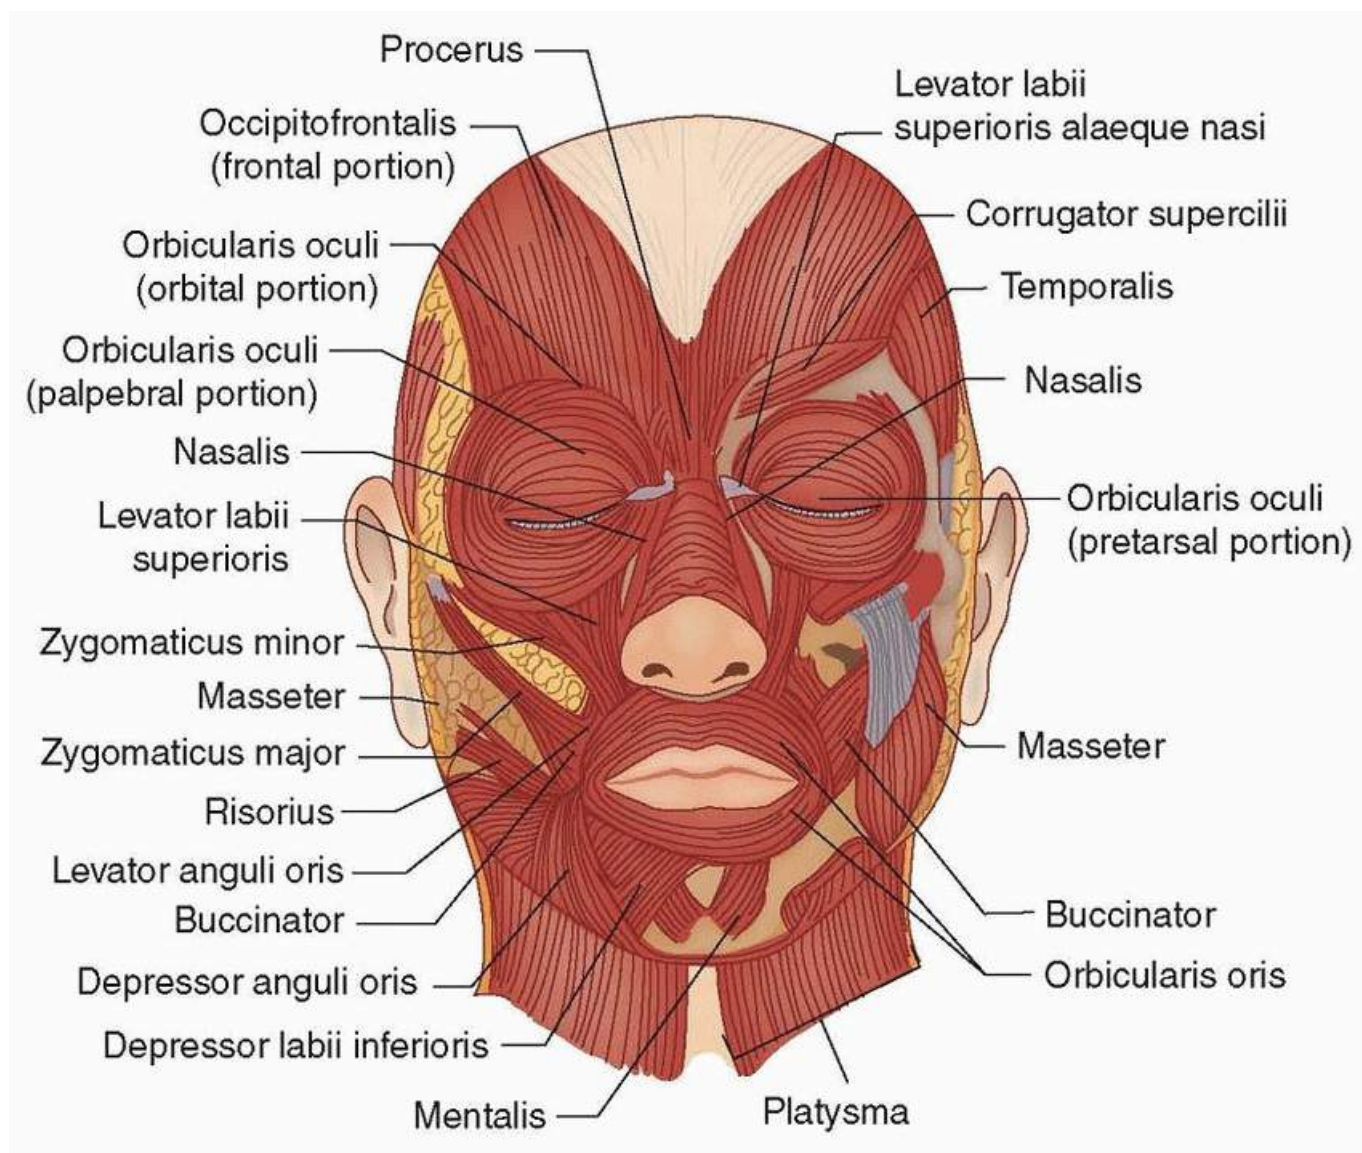

FIGURE 77.2 Muscles innervated by the facial nerve.

Occasionally, HFS has been seen after Bell palsy, bony overgrowth as in Paget disease pinching the stylomastoid foramen, and other peripheral lesions of the facial nerve. This has led to speculation that facial nerve compression induces a change in the facial nucleus, which is necessary for HFS to occur. The likelihood of such a facial nucleus change would increase as the site of compression gets closer to the nucleus. This alternative hypothesis is strengthened by the small number of cases of HFS associated with central lesions at the site of the facial nerve nucleus. In addition, there is evidence in HFS suggesting hyperexcitability of the facial nerve nucleus, including enhancement of F waves and other findings.

TABLE 77.1 Differential Diagnosis of Hemifacial Spasm

Condition	Similarities to HFS	Differences from HFS
Facial dystonia	May include rapid contractions	Very rarely unilateral. Mostly slower contractions. Spasms not usually synchronous in different facial muscles.
Myokymia	May be unilateral	Slower contractions. Spasms usually asynchronous in different muscles.
Motor tics	May be rapid, unilateral, and synchronous in different muscles	Usually an inner sensation before the movements. Movements usually suppressible at least briefly.
Synkinesis (e.g., after Bell palsy)	May be rapid, unilateral, and synchronous in different muscles	Spasms only occur with blinking or voluntary movement.
Epilepsia partialis continua (EPC)	May be rapid, unilateral, and synchronous in different muscles	Unlike HFS, may involve the masseter muscle. Usually involves extracranial muscles.
HFS, hemifacial spasm.		

TREATMENT

HFS can be treated with medications, botulinum toxin (BTX) injections, or by craniectomy and separation of an arterial loop from the root exit zone of the facial nerve (microvascular decompression). Medications are generally the least successful treatment. There is a single controlled study suggesting benefit from orphenadrine and dimethylaminoethanol, but this was never repeated and this treatment is rarely used today. Successful treatment of HFS in small numbers of patients has been reported with carbamazepine, clonazepam, baclofen, gabapentin, and felbamate but improvement was “rare” in several hundred patients treated with anticonvulsants in one large series. Even when spasms improve with medications, the improvement is usually temporary.

BTX has proved extremely useful in treating HFS, especially for orbicularis oculi contractions, for which most series report an almost 100% success rate (Table 77.2). The success rate is lower for lower facial muscles (although this is rarely reported) due to the

development of facial weakness before resolution of the spasms in some patients. Excess weakness of the orbicularis oculi is very rare, although leakage to the levator palpebrae causing ptosis is common. The risk of ptosis depends on the volume of toxin injected (greater volume produces greater risk) and the injection

site (closer to the insertion of the levator at the middle of the upper lid increases the risk). Other less common side effects include ecchymoses at the injection site, entropion of the lower lid, dry eye, excess tearing, and bagginess under the eye. Diplopia occasionally occurs, probably from spread of toxin to one or both lateral recti. All side effects from BTX injections are transient and there is no evidence that chronic BTX injections induce any permanent change. Benefit from BTX injections for HFS lasts 3 to 6 months, after which symptoms return and repeat injections are required.

TABLE 77.2 Botulinum Toxin Treatment of Hemifacial Spasm

A. Some people have dramatically different sensitivity to BTX, so initially inject just the muscle causing the most troublesome symptom (usually the orbicularis oculi [Oo]).

B. Optimal concentration of toxin, volume per injection, and number of sites per muscle are not known for most muscles (including the Oo). Most people use concentrations of 5-10 U/0.1 mL. The general rule is as follows: Use more dilute toxin to get a greater effect and use more concentrated toxin to get less spread to nearby muscles.

C. Major side effects are as follows:

- Ptosis (from leakage to the Levator palpebrae)
 - Ecchymoses
 - Dermatochalasis (usually in the lower lid)
 - Xerophthalmia or epiphora (usually short lasting)
 - Excess weakness of the injected muscle (not usually the Oo)
 - Diplopia (uncommon)—from lateral canthus injections
 - Entropion (rare)—from lower lid injections
-

D. In the Oo, avoid injecting the upper lid in the midline (to minimize the risk of ptosis). Lower lid injections are always necessary; injections in the orbital portion of the Oo are sometimes necessary.

E. Start with a small dose and increase the dose gradually to minimize side effects. Some reasonable starting doses are as follows:

- Orbicularis oculi—2.5 units per site with one site in the lower lid, lateral canthus, medial and lateral pretarsal components of the Oo, and orbital component of the Oo
 - Frontalis—2.5 units in two or three sites
 - Nasalis—2.5 units
 - Zygomaticus major—1 unit in one site
 - Depressor anguli oris, depressor labii inferioris, mentalis—2.5 units, one site in each
 - Platysma—2.5 units in three or four sites
-

F. Instruct patients to always notify you about problems arising after BTX injections: Patients may coincidentally develop an unrelated problem in the weeks following a BTX injection.

BTX, botulinum toxin.

Microvascular decompression, first popularized by Jannetta in the 1970s, appears to be the definitive treatment for HFS. When a vessel is compressing the facial nerve, a sponge is placed between the nerve and the vessel. In a large series, 1,327 patients were followed for up to 3 years and 90.5% were felt to have an excellent outcome after the first surgery. There were 2.3% of patients who did not improve and had a second surgery (in the opinion of the surgeons, the wrong vessel had been decompressed) and 90% of these were felt to have an excellent response. However, up to about 10% of patients experience return of spasms and require repeat operation, possibly when the sponge is dislodged. Serious complications (death, stroke, or cerebellar hematoma) occur in less than 1% in most series. Permanent facial weakness or hearing loss are uncommon, occurring in about 5%. Other rare surgical complications including wound infection or hematoma, cerebrospinal fluid leak (CSF), bacterial meningitis, and pseudomeningocele are also possible. However, vascular compression of the root exit zone of the facial nerve is not found in all cases, and current MRI techniques are not yet sufficient to guarantee that an offending vessel will be found. For all these reasons, many patients prefer to avoid surgery if possible, and BTX injections are the treatment of first choice for most patients.

Myoclonus

Pichet Termsarasab

Steven J. Frucht

INTRODUCTION

Myoclonus is characterized by lightning-like muscle jerks. Electrophysiologically, these jerks are associated with electromyographic discharges that are relatively short in duration compared to voluntary jerks. Myoclonic jerks may be positive due to active muscle contractions, or negative in which jerks occur due to lapses of postural tone (the classic example of this is asterixis).

EPIDEMIOLOGY

Myoclonus has a prevalence rate of 8.6 per 100,000, based on a study in Olmsted County published in 1999.

PATHOBIOLOGY

Although the electrophysiology of myoclonus is well understood, the actual pathophysiology is not. Myoclonus can be classified based on either anatomic localization or etiology. Anatomically, myoclonus can originate from either the central or peripheral nervous system. In the central nervous system, the location is further subdivided into cortical, subcortical, brain stem, and spinal cord origin.

Myoclonus is usually classified based on anatomic localization ([Table 78.1](#)). The etiology and clinical characteristics of myoclonus from each anatomic location will be discussed in the following text.

TABLE 78.1 Classification of Myoclonus

Clinical	Anatomic	Etiology
1. At rest	1. Cortical	1. Physiologic
Action	Focal	2. Essential
Reflex	Multifocal	3. Epileptic
2. Focal	Generalized	4. Symptomatic
Axial	Epilepsia partialis continua	Storage diseases
Multifocal	2. Thalamic	Cerebellar degenerations
Generalized	3. Brain stem	Basal ganglia degenerations
3. Irregular	Reticular	Dementias

Oscillatory	Startle	Infectious encephalopathy
Rhythmic	Palatal	Metabolic encephalopathy
4. Spinal		Toxic encephalopathy
	Segmental	Hypoxia
	Propriospinal	Focal damage

5. Peripheral

Myoclonus can be classified according to clinical features, by anatomic origin of the pathophysiology of the jerks, and by etiology.

CORTICAL MYOCLONUS

Myoclonus originating in the cortex has unique electrophysiologic features, as described in [Table 78.2](#). The first three are unique to cortical myoclonus and are not seen in subcortical or spinal myoclonus.

Back-averaging by electroencephalography (EEG) is very helpful in identifying cortical spikes prior to the jerks, but the technique is not routinely available. It is done by averaging at least 150 to

200 myoclonic jerks and capturing their preceding *cortical spikes*.

A short duration between the spike and the jerk indicates fast conduction from the cortex to the muscles via the corticospinal pathway, usually less than 50 milliseconds.

Giant somatosensory-evoked potentials (SEPs) are very large cortical potentials seen by SEP recording techniques such as by stimulation of the median nerve while recording EEG. A typical SEP has a negative (upward) phase followed by positive (downward) and negative phases, respectively. Only positive and the second negative phases are enlarged in cortical myoclonus. These phases are motor volleys, as compared to the first negative phase which is a sensory volley.

The *C-reflex* is a form of a long-latency reflex. When we stimulate muscle fibers, the afferent pathway is conducted through Ia sensory fibers, spinal cord, nucleus cuneatus, or gracilis and

P.661

ultimately to the primary sensory cortex. Then, the efferent pathway is conducted through the corticospinal tract to the alpha motoneuron. This typically takes about 40 to 50 seconds in the upper extremities. Therefore, when one electrically stimulates a muscle, the C-reflex will be seen on electromyography (EMG) recording about 40 to 50 milliseconds after the stimulation. Creflexes are typically enhanced in cortical myoclonus.

TABLE 78.2 Characteristic Electrophysiologic Features of Myoclonus from Different Anatomic Origins

Cortical Myoclonus

- Focal spikes or sharp waves of 10-40 ms duration preceding the jerk on back-averaged EEG

-
- Giant SEPs
-

- Enhanced C-reflexes
-

- EMG burst duration typically shorter than in subcortical or spinal myoclonus; <100 ms and usually 20-50 ms in duration
-

- Rostrocaudal recruitment pattern on polymyography with very fast spreading (jerks may appear almost at the same time on regular polymyography)
-

Subcortical Myoclonus Including Brain Stem Myoclonus

- EMG burst durations vary among subtypes, generally longer than that seen in cortical myoclonus, as long as 100 ms.
-

- Typical recruitment pattern:
-

- *Reticular reflex myoclonus* typically originates in the lower brain stem, most commonly CN XI-innervated muscles such as SCM. It spreads up to CNs VII-and V-innervated muscles and simultaneously down to muscles in the upper cervical levels.
-

- *Hyperekplexia* spreads between CN-innervated muscles. It can start from CN in the midbrain such as orbicularis oculi then spreading down to lower CN-innervated muscles. Jerks occur after somesthetic (touch), auditory, or, less commonly, visual stimuli.
-

Spinal Myoclonus

- EMG burst durations are typically longer than 100 ms.
-

- *Spinal segmental myoclonus*
-

- Recruitment pattern: Jerks start from one or two spinal segments and spread up and down along spinal segments. For example, jerking in the upper extremity from a structural lesion in the C7 spinal segment could be identified by an initial jerk of the ipsilateral triceps muscles with possible upward spreading to biceps and trapezius muscles and simultaneous downward spreading to C8-innervated intrinsic hand muscles.
-

- Velocity of spread is slower than in cortical myoclonus because it is not via fast-conducting corticospinal pathways.
-

- *Propriospinal myoclonus*
-

- Typical recruitment pattern up and down along axial muscles on polymyography. For example, jerks can originate in T12 rectus abdominis muscles and spread up and down to axial muscles above and below, respectively (e.g., up to higher level rectus abdominis and down to iliopsoas).

- Slow velocity of spread as it is conducted through the slow propriospinal fibers (slowest among all forms of myoclonus described above).

EEG, electroencephalography; SEP, somatosensory-evoked potential; EMG, electromyography; CN, cranial nerve; SCM, sternocleidomastoid muscles.

Multichannel EMG recording, also called *polymyography*, can also be helpful in visualization of patterns of spread from one muscle to another, called the *recruitment pattern*. Typical recruitment patterns in cortical myoclonus are described in [Table 78.2](#).

It is worth mentioning the Bereitschaftspotentials (BPs) here. The BP is a form of voluntary, movement-related potential seen on back-averaging EEG technique. It is also called a *premovement* or *readiness potential*. It is helpful in differentiating organic from psychogenic myoclonus; BPs are present in psychogenic movements but not in organic myoclonus.

SUBCORTICAL INCLUDING BRAIN STEM MYOCLONUS

The three main types of brain stem myoclonus are reticular reflex myoclonus, hyperekplexia, and palatal myoclonus. Myoclonus-dystonia syndrome or essential myoclonus also has a subcortical origin, as does myoclonus occurring after thalamic stroke (typically negative myoclonus or asterixis affecting one arm). The electrophysiologic findings are described in [Table 78.2](#).

Hyperekplexia, or exaggerated startle, has the nucleus gigantocellularis as a generator. It shows recruitment patterns, as described in [Table 78.2](#). Lack of habituation is a feature of hyperekplexia:

After repetitive stimuli, jerks will be less frequent and less severe clinically and electrophysiologically in the normal startle response but may fail to habituate in hyperekplexia.

SPINAL MYOCLONUS

Two major forms of spinal myoclonus exist: spinal segmental and propriospinal myoclonus. The typical recruitment pattern and the velocity of spread are described in [Table 78.2](#).

Spinal segmental myoclonus typically originates within a few or several adjacent spinal segments, typically cervical or lumbar.

Propriospinal myoclonus refers to axial jerks that originate in spinal cord segments, with spread up and down along the longitudinal axis of spinal cord. The very slow-conducting propriospinal pathway helps coordinate forelimb and hind limb movements in animals, such as cats, but the role of this pathway in humans is unclear.

It has been reported in the literature that BPs are associated with propriospinal myoclonus, and thus, a psychogenic cause has been proposed. However, there is evidence that there is disruption of fiber tracts in spinal cord seen on diffusion tensor imaging in patients with propriospinal myoclonus, suggesting that some forms of propriospinal myoclonus are organic.

PERIPHERAL MYOCLONUS

A typical example of peripheral myoclonus is hemifacial spasm, but peripheral myoclonus can also occur from irritation of spinal nerve roots, plexus, or peripheral nerves. The EMG burst duration varies, and there is lack of

CLINICAL MANIFESTATIONS

When myoclonus is observed, one should attempt to answer the following questions in order to elucidate the cause:

1. What is the distribution of myoclonus? What body part(s) is(are) affected? Is it focal, segmental (affecting multiple contiguous body regions), multifocal (multiple noncontiguous body regions), or generalized?
2. Is myoclonus positive or negative (due to lapse of muscle tone)? The classic example of negative myoclonus is asterixis, seen in hepatic encephalopathy or uremia. Negative myoclonus of the legs when standing can be seen in patients with posthypoxic myoclonus (Lance-Adams syndrome), producing a so-called bouncing gait.
3. Is myoclonus spontaneous (occurring at rest), action-induced, stimulation-induced, or reflex-induced? One example of stimulation-induced myoclonus is hyperekplexia, which is typically induced by somesthetic (typically in mantle area including forehead and nose), auditory and, less commonly, visual stimuli. Reflex-induced myoclonus (a hallmark of cortical myoclonus) can be tested by using the examiner's finger to tap a body region, such as a patient's finger, hand, or arm, which then would produce a myoclonic jerk. The latency between reflex stimuli and myoclonic jerks in cortical myoclonus is relatively short, suggesting efferent conduction via the corticospinal pathway. Longer latency would suggest slower conducting pathways such as the propriospinal pathway.
4. Is the myoclonus rhythmic or nonrhythmic? Is it synchronous?
5. Are there any other associated phenomena such as dystonia or ataxia?

CORTICAL MYOCLONUS

Cortical myoclonus can be focal, multifocal, or generalized. If it is focal, it usually affects the distal limbs such as the hands and fingers.

It can be positive or negative, may occur either at rest or with action, and is often stimulus-sensitive. It can be continuous and rhythmic, for example, *epilepsia partialis continua* in which patients have myoclonic jerks on one side of the body (Video 78.1). Cortical myoclonus may occur as a fragment of epilepsy (epileptic myoclonus, see “[Diagnosis](#)” section). Posthypoxic myoclonus is typically generalized, nonrhythmic, synchronous, and stimulus-sensitive (to tactile or auditory stimuli) but can also occur at rest (Video 78.2).

Familial cortical myoclonic tremor with epilepsy (FCMTE; also called *benign adult familial myoclonic epilepsy* [BAFME]) is a rare autosomal dominant genetic condition, characterized by small-amplitude myoclonic jerks in distal limbs that may look like and be misdiagnosed as essential tremor.

SUBCORTICAL MYOCLONUS

Subcortical myoclonus can originate from subcortical regions or the brain stem. *Myoclonus-dystonia syndrome*, previously called *essential myoclonus*, is a form of subcortical myoclonus (Video 78.3). Patients typically have myoclonic jerks mixed with dystonia, in the same or adjacent body regions. Myoclonus usually involves the neck and upper body such as the shoulders, arms, or hands. Dystonia seen in this condition also has similar involvement in the upper body such as the neck or hands (e.g., patients can present with writer's cramp).

Brain stem myoclonus, a form of subcortical myoclonus, includes hyperekplexia, reticular reflex myoclonus, and palatal myoclonus.

Hyperekplexia typically does not occur at rest, induced instead by a typical stimulus (Video 78.4). Patients

typically do not habituate to repeated stimuli. Nevertheless, we do not recommend examining patients with hyperekplexia with repetitive stimuli because repeated nose taps can lead to severe body stiffness especially in infants.

In *reticular reflex myoclonus*, patients usually have myoclonic jerks involving the sternocleidomastoid and facial and neck muscles with the pattern of spread correlating with electrophysiologic recruitment, usually rostral and caudal.

We describe the clinical features of *palatal myoclonus* in the “Diagnosis” section.

SPINAL MYOCLONUS

Spinal myoclonus includes spinal segmental myoclonus and propriospinal myoclonus.

In *spinal segmental myoclonus*, muscles in one or two adjacent spinal segments are typically affected. It can occur at rest or with action, may be rhythmic or nonrhythmic, but is usually not reflex-induced. When patients present with myoclonic jerks in one limb, one should always think about possible pathology in the spinal cord, such as a primary spinal cord malignancy.

Propriospinal myoclonus typically presents with axial jerks (Video 78.5). Patients typically have truncal flexion, usually nonrhythmic, at rest or with action or reflex-induced, with a relatively long latency due to slow conduction via propriospinal pathways. The differential diagnosis of axial jerks includes propriospinal myoclonus and reticular reflex myoclonus, but in the latter form, it usually involves a higher truncal region than propriospinal myoclonus.

PERIPHERAL MYOCLONUS

Peripheral myoclonus from nerve root, plexus, or peripheral nerve involvement typically affects a limb in the distribution corresponding to neural structures that are innervated. It usually occurs at rest and does change with action. Sometimes, it is difficult to differentiate from spinal segmental myoclonus, and spine imaging is required to rule out spinal pathology. *Hemifacial spasm* is a form of peripheral myoclonus (Video 78.6). It is characterized by clonic, sometimes tonic contraction of cranial nerve (CN) VII-innervated muscles, most commonly the orbicularis oculi, zygomaticus, and frontalis.

DIAGNOSIS

After one characterizes myoclonus phenomenologically, the next step is to identify the etiology. The etiologic classification of myoclonus of C. David Marsden, S. Fahn, and H. Shibasaki is most commonly used; *physiologic*, *essential*, *epileptic*, and *symptomatic myoclonus*. Here, we will integrate neuroanatomic classification with etiologic classification to show the correlation between these approaches.

PHYSIOLOGIC MYOCLONUS

Examples of physiologic myoclonus are jerks during sleep (hypnic jerks) and hiccups (diaphragmatic myoclonus).

CORTICAL MYOCLONUS

Cortical myoclonus can be epileptic or symptomatic. *Epileptic myoclonus* is fragments of epilepsy or myoclonic epilepsy and is cortical in origin. *Epilepsia partialis continua* can occur from a focal structural lesion typically seen in *Rasmussen encephalitis*, an autoimmune disorder leading to gliosis and hemiatrophy of one cerebral hemisphere (see Video 78.1).

The differential diagnosis of progressive myoclonic epilepsy is described in [Table 78.3](#). EEG is helpful in identifying epileptiform discharges. Investigations to confirm the diagnosis depend on the specific etiology,

for example, a skin biopsy to search for Lafora bodies in Lafora body disease, or a muscle biopsy to look for ragged red fibers in myoclonic epilepsy with ragged red fibers (MERRF). Genetic testing with appropriate genetic counseling is also used to confirm these entities.

Cortical myoclonus may be symptomatic, secondary to systemic or hereditary degenerative disorders, for example, storage diseases or mitochondrial disorders mentioned previously. On the other hand, symptomatic myoclonus may be either cortical, brain stem, spinal, or peripheral in origin. The list of symptomatic myoclonus disorders is lengthy and further workup depends on the suspected location and etiology. Patients with *posthypoxic myoclonus* have a history of mainly respiratory rather than cardiac arrest. Anoxic brain damage can be seen on neuroimaging. *Subacute sclerosing panencephalitis (SSPE)* is another example of symptomatic cortical myoclonus. EEG typically reveals generalized periodic discharges every 4 to 14 seconds. *Dentatorubral-pallidoluysian atrophy (DRPLA)* or Haw River syndrome, an autosomal dominant disorder of CAG repeat expansions, is another example in which patients can have cortical myoclonus associated with chorea, ataxia, dementia, and epilepsy. It was originally described in Japanese populations but is also found in other ethnic groups. The differential diagnoses of myoclonus associated with dementia also include *Creutzfeldt-Jakob disease (CJD)*, *corticobasal syndrome*, and *Alzheimer disease*, among others. Myoclonus can also be seen in *spinocerebellar ataxia type 14 (SCA14)*.

TABLE 78.3 Differential Diagnosis of Myoclonus Classified by Anatomic Localization

Cortical Myoclonus

- Epileptic

- Epilepsy partialis continua: Etiology can be Rasmussen encephalitis or focal cortical lesion.
-

- Progressive myoclonic epilepsy

- Unverricht-Lundborg syndrome (Baltic myoclonus, *EPM1* mutation, encoding for cystatin B)
-

- Lafora body disease (autosomal recessive, *EPM2A* mutation, encoding for laforin)
-

- Neuronal ceroid lipofuscinosis (NCL or Batten disease)
-

- Sialidosis
-

- Myoclonic epilepsy with ragged red fibers (MERRF, mitochondrial disorder)
-

- Symptomatic

- Posthypoxic myoclonus
-

- Secondary to systemic diseases or metabolic causes
-

- Renal or hepatic failure
-

- Infection-related
-

- Subacute sclerosing panencephalitis (SSPE), Creutzfeldt-Jakob disease (CJD)
-

- Myoclonus associated with neurodegenerative disorders
-

- Dentatorubral-pallidoluysian atrophy (DRPLA), corticobasal syndrome, and Alzheimer disease
-

- Heredodegenerative disorders
-

- Storage diseases
-

- Mitochondrial disorders
-

- Spinocerebellar ataxia (SCA), such as SCA14
-

Subcortical Myoclonus Including Brain Stem Myoclonus

- Subcortical
-

- Myoclonus-dystonia syndrome (essential myoclonus)
-

- Brain stem
-

- Physiologic
-

- Hypnic jerks
-

- Hiccups
-

- Hyperekplexia
-

- Variants include progressive encephalomyelitis, rigidity and myoclonus (PERM), and excessive startle syndromes.
-

- Palatal myoclonus

-
- Essential palatal myoclonus
-

- Symptomatic palatal myoclonus
-

- Opsoclonus-myoclonus (brain stem and cerebellum)
-

- Symptomatic: secondary to structural lesions in brain stem
-

Spinal Myoclonus

- Spinal segmental myoclonus
-

- Symptomatic: secondary to structural lesions in spinal cord
-

- Propriospinal myoclonus
-

Peripheral Myoclonus

- Hemifacial spasm
-

- Symptomatic
-

- Secondary to nerve root, plexus, or peripheral nerve lesions
-

This table lists the differential diagnoses of myoclonus, primarily classified by anatomic locations. We also integrate the original etiologic classification of C. David Marsden, S. Fahn, and H. Shibasaki, with the anatomic locations. Note that the list of symptomatic cortical myoclonus is extensive, and we include only examples. Symptomatic myoclonus (such as myoclonus from focal structural lesion) can occur anywhere within the neuraxis.

SUBCORTICAL MYOCLONUS

Subcortical myoclonus includes myoclonus-dystonia syndrome, hyperekplexia, and palatal myoclonus, among others. Here, we will also mention opsoclonus-myoclonus, which is due to dysfunction of brain stem and cerebellum.

Myoclonus-dystonia syndrome is also known as *essential myoclonus* or *DYT 11*. It is a form of subcortical myoclonus caused by a mutation in the *SCGE* gene (epsilon-sarcoglycan gene). This gene has maternal imprinting, that is, maternal allele does not express, and the abnormal gene is typically inherited from the father. In one rare condition, Russell-Silver syndrome where there is uniparental disomy, both alleles are from the mother, and therefore, both

can cause the phenotype of myoclonus-dystonia syndrome. Symptoms of myoclonus-dystonia syndrome are usually relieved by alcohol and associated neuropsychiatric features such as anxiety and obsessive-compulsive disorder are common.

Hyperekplexia, a form of brain stem myoclonus, may be hereditary or secondary. The genetics of hyperekplexia is complex: There are autosomal dominant and recessive forms. One of the well-known hereditary forms is autosomal dominant, caused by mutations in the glycine receptor gene, but other genes have also been reported. Secondary (i.e., symptomatic) hyperekplexia has been reported due to brain stem encephalitis from an autoimmune or paraneoplastic process. Sometimes, it can be associated with severe muscle rigidity and stiffness, also called *progressive encephalomyelitis, rigidity, and myoclonus* (PERM). Certain excessive startle syndromes may be culturally related and also can manifest as echolalia and automatic obedience. These syndromes are known by colorful regional names, such as *The Jumping Frenchmen of Maine* (Quebec), *myriachit* (Siberia), *Latah* (Indonesia, Malaysia), and *Ragin' Cajun* (Louisiana). These syndromes are not true forms of myoclonus because the movements are more prolonged in duration and subject to conscious suppression.

Palatal myoclonus is another form of subcortical myoclonus, with rhythmic jerky movements of the soft palate at the rate of 2 to 2.5 Hz. There are two forms of palatal myoclonus, essential and symptomatic. In essential palatal myoclonus (EPM), patients have ear clicks from contraction of the tensor veli palatini leading to movements of the opening of the eustachian tube. Symptomatic palatal myoclonus (SPM) is a delayed phenomenon that usually occurs weeks or months after a lesion in Guillain-Mollaret triangle, which is defined by the line between dentate nucleus, contralateral red nucleus, and contralateral inferior olivary nucleus (Fig. 78.1). The central tegmental tract runs between red nucleus and inferior olivary nucleus, which then sends fibers to contralateral dentate nucleus through the inferior cerebellar peduncle. Then, the dentate nucleus sends a projection to the red nucleus via the superior cerebellar peduncle. Lesions in this triangle may be ischemic, demyelinating, infectious, or postinfectious, among others. Hypertrophy and hyperintensity of the inferior olivary nucleus on T2 image on magnetic resonance imaging (MRI) can be seen in SPM. Unlike EPM, patients do not usually have ear clicks. Pendular nystagmus can also be seen in SPM. *Progressive ataxia with palatal tremor* (PAPT) is a syndrome that when seen suggests the possibility of adult-onset Alexander disease, a disorder caused by *GFAP* gene mutations. Sagittal view of the MRI in adult-onset Alexander disease can reveal atrophy of the spinal cord from the cervical portion down, giving the so-called tadpole sign. Diagnosis is confirmed by genetic testing.

Opsoclonus-myoclonus-ataxia syndrome (OMAS) (*Kinsbourne disease*) is diagnosed by a constellation of opsoclonus, myoclonus, and ataxia. In children, it can occur as a paraneoplastic process, typically seen with neuroblastoma associated with anti-Ri antibody, and abdominal imaging is required to screen for this cancer. In adults, it is associated with postinfectious (such as postviral), autoimmune, or paraneoplastic processes affecting the brain stem. Neuroimaging, cerebrospinal fluid (CSF) studies including paraneoplastic panel in blood and CSF are helpful in diagnosis. A course of steroids and/or intravenous immunoglobulin (IVIG) is warranted.

SPINAL MYOCLONUS

Spinal myoclonus includes spinal segmental myoclonus and propriospinal myoclonus. *Spinal segmental myoclonus* is symptomatic until proven otherwise; therefore, neuroimaging of the spine at appropriate levels is needed. In *propriospinal myoclonus*, we also suggest obtaining neuroimaging of the spine to rule out a structural lesion. There is controversy about a psychogenic versus organic origin of propriospinal myoclonus.

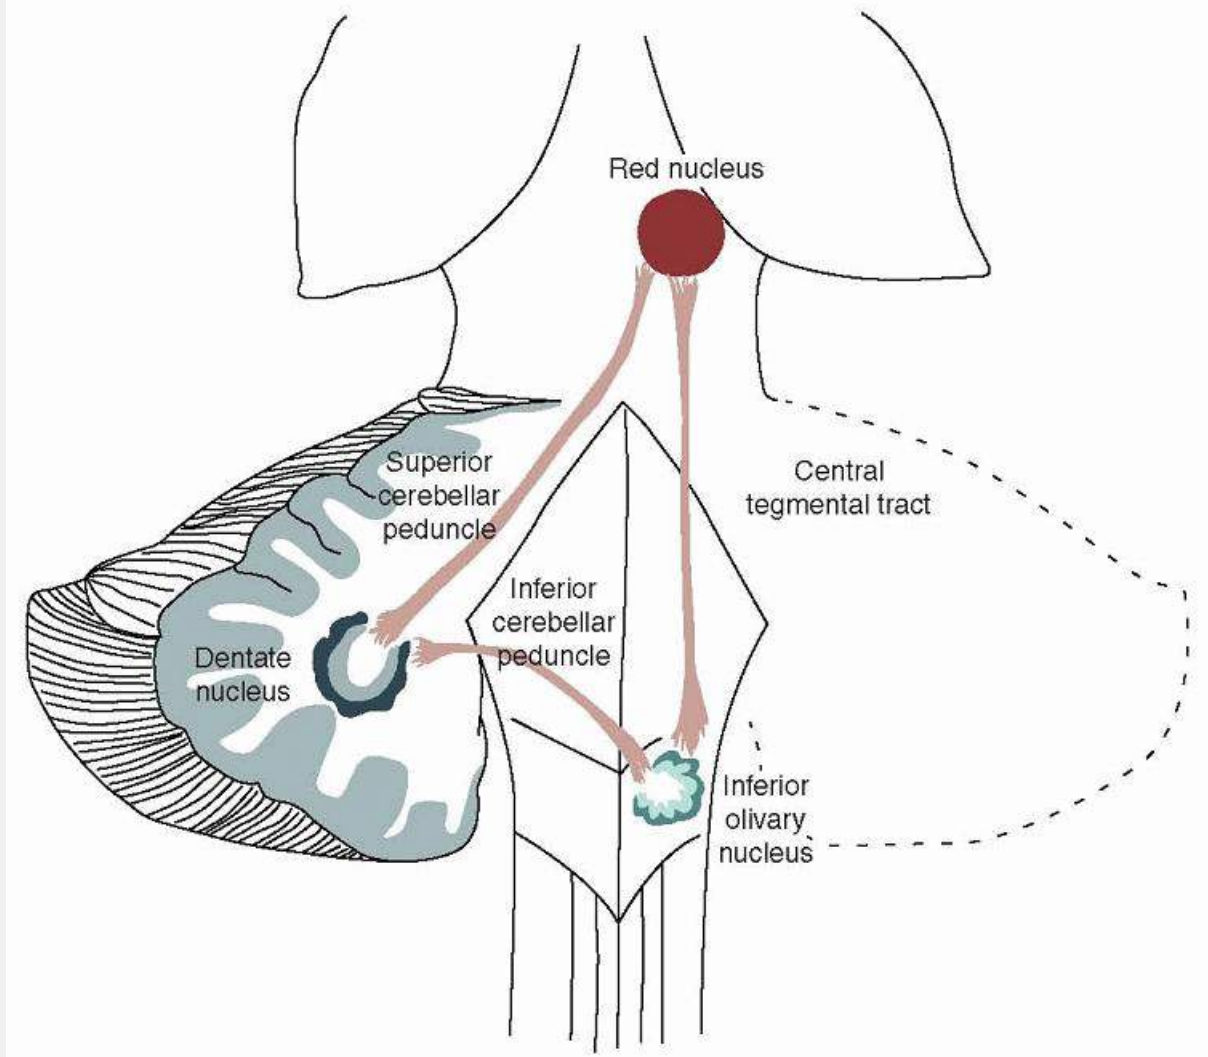

FIGURE 78.1 Guillain-Mollaret triangle. Red nucleus, inferior olivary nucleus, and dentate nucleus on contralateral sides form the three corners of this triangle. The central tegmental tract runs from the red nucleus to the inferior olivary nucleus, which sends the projection to the dentate nucleus via the inferior cerebellar peduncle. Dentate nucleus sends the projection through the red nucleus via superior cerebellar peduncle. Lesions in this triangle can lead to palatal myoclonus. (Courtesy of Thananan Thammongkolchai, MD.)

PERIPHERAL MYOCLONUS

Peripheral myoclonus of the limbs requires workup such as nerve conduction studies and EMG to confirm the location of the lesions, that is, neural structure involved or myotomal level. In hemifacial spasm, an MRI with visualization of the facial nerve and nearby vascular structures should be obtained. Sometimes, a vascular loop can be seen abutting the facial nerve.

TREATMENT

Specific treatment of myoclonus depends on the etiologic diagnosis, for example, treatment of hepatic encephalopathy in asterix or employing antiepileptic agents in myoclonic epilepsy. If specific treatment is not available, symptomatic treatment can be pursued. Pharmacologic treatments commonly employed are clonazepam, levetiracetam, and valproic acid. There are no clear guidelines regarding which medication should be initiated, although anatomic localization guides treatment. The treatment is shown in [Table 78.4](#).

OUTCOME

The prognosis and natural history of myoclonus depend on its specific etiology. For example, prognosis is good after treating an

P.665

underlying systemic disorder, removing a structural lesion, or treating an underlying autoimmune or paraneoplastic process. The outcome of other forms of myoclonus is variable.

TABLE 78.4 Treatment of Myoclonus

Specific treatment depending on the etiologies

Symptomatic treatment

- Pharmacologic treatment

- Levetiracetam (preferred in cortical myoclonus rather than subcortical or spinal); 1,000-3,000 mg/day divided twice a day; dose up to 4,000 mg/day has been used.
-

- Clonazepam (can be used in cortical, subcortical, and spinal myoclonus); starting dose 0.5-1 mg/day; typical dose 3 mg/day or more; sometimes up to 15 mg/day
-

- Valproic acid; typical dose 1,000-1,500 mg/day
-

- Zonisamide or primidone (used less commonly when the aforementioned conventional medications fail); dosing for zonisamide 100-200 mg/day; for primidone 500-750 mg/day but usually poorly tolerated at such high doses
-

- Others (nonconventional treatments)

- Sodium oxybate in some forms of myoclonus that responds to alcohol such as myoclonus-dystonia syndrome and posthypoxic myoclonus; average dose 6.5 mg/day, maximum 9 mg/day
-

- 5-Hydroxytryptophan in posthypoxic myoclonus
-

- Botulinum toxin injection
-

- Hemifacial spasm (treatment of choice)
-

- Deep brain stimulation (DBS)
-

- Pallidal DBS has been reported to improve both dystonia and myoclonus in myoclonus-dystonia syndrome, compared to Vim DBS, which improves only myoclonus but not dystonia. Data remains limited.

Specific treatment of myoclonus depends on the etiologic diagnosis. If specific treatment is not available, symptomatic treatment can be pursued. Vim DBS, ventrointermediate nucleus deep brain stimulation.

Videos can be found in the companion e-book edition. For a full list of video legends, please see the front matter.

Hereditary and Acquired Ataxias

Rachel Saunders-Pullman

Susan B. Bressman

Roger N. Rosenberg

INTRODUCTION

Ataxia is characterized by incoordination, and herein we describe ataxias that are due to lesions in the cerebellum and efferent or afferent connections. Cerebellar ataxias may be subdivided into three categories: acquired, nondegenerative ataxias; nonhereditary, degenerative ataxias; and hereditary ataxias. Hereditary ataxias can be further divided by mechanism of inheritance into those that are autosomal dominant, autosomal recessive, X-linked, and due to mitochondrial mutations.

The first autosomal recessive (AR) ataxias were described by Friedreich in the 1860s with clinical features including areflexia. In the early 1900s, cases that varied slightly from Friedreich ataxias (FRDA) were classified as *atypical FRDA*. Nosology was primarily based on pathologic features. Patients with markedly different clinical features might be diagnosed with “Marie” ataxia (retained reflexes and later onset than FRDA) or “Menzel” ataxia (olivopontocerebellar atrophy [OPCA] in autosomal dominant [AD] ataxia). Often, olivopontocerebellar atrophy was the term used for any non-FRDA cases as well as sporadic, late-onset ataxias. It was not until the later 20th century that Harding introduced firm clinical classification schema for hereditary ataxias. With the subsequent development of molecular genetics, loci for AR, AD, X-linked, and mitochondrial DNA mutations were discovered and added another level to classification. However, in populationbased studies, 33% to 92% of families with AD ataxias and 40% to 46% of families with AR ataxias remained without genetic diagnoses after systematic testing.

Prevalence estimates of ataxia depend on whether a clinical or genetic definition is proposed. Even when considering the rubric of clinical ataxia, worldwide prevalence is highly variable and difficult to determine because of region-specific genetic population effects, regional differences in testing and diagnosis, and limited reports from some countries. AD ataxias are the most prevalent hereditary ataxias, with a range of 0.0 to 5.6 per 100,000 and an average of 2.7 cases per 100,000. Spinocerebellar ataxia type 3 (SCA3)/Machado-Joseph disease is the most common AD ataxia, followed by SCA2 and SCA6. The prevalence of AR ataxias ranges from 0.0 to 7.2 per 100,000 with an average of 3.3 per 10,000. Among AR ataxias, Friedreich ataxia is the most frequent followed by ataxia with oculomotor apraxia or ataxia-telangiectasia.

This chapter will focus primarily on the hereditary ataxias, although the acquired ataxias will be covered in brief.

ACQUIRED ATAXIAS

Acquired etiologies of ataxia should be sought in all cases that are not clearly hereditary. Treatment for acquired ataxias is highly directed by etiology, and therefore etiologies of sporadic-appearing ataxias should be interrogated. Ataxia may be stable, progressive, or intermittent. The differential can be considered relative to rapidity of onset and includes exogenous or endogenous causes.

Acute-onset ataxia is more likely to be due to vascular disease, trauma, toxins (such as alcohol, toluene), multiple sclerosis and other demyelinating diseases, thiamine deficiency, cerebellitis (especially in children), and primary/metastatic tumor or paraneoplastic disease. It may be subacute or chronic, including due to tumor as well as paraneoplastic cerebellar degeneration (especially associated with ovary, breast, or lung neoplasm), thyroid disease, other immune-related diseases (including steroid-responsive encephalopathy thyroiditis), anti-glutamic

acid decarboxylase (anti-GAD) ataxia, gluten enteropathy, vitamin E deficiency (which may be secondary to a malabsorption syndrome), toxins (including alcohol, mercury, and medications such as phenytoin), infections (including prion disease, HIV, and Whipple), leptomeningeal metastasis, vitamin B₁₂ deficiency, and multiple system atrophy (a prominent cause of sporadic ataxia in adults associated with alpha-synuclein deposition in the pathognomonic glial cytoplasmic inclusions). In children with acquired ataxia, special concern must be given to intoxication (especially antiepileptics, lead, and alcohol), infectious or postinfectious cerebellitis (often attributable to enteroviral, picornavirus, or Epstein-Barr virus [EBV]), tumor, vascular disease, brain stem encephalitis, migraine, and hypothyroidism.

The first step in assessment for all ataxias should include neuroimaging with magnetic resonance imaging (MRI) to evaluate the cerebellum as well as additional structures and to determine the extent and etiology of cerebellar and noncerebellar disease. If acquired ataxias are not consistent with vascular, traumatic, or demyelinating disease, additional evaluation includes assessment of thyroid function, vitamin E and B₁₂, anti-GAD antibodies, and paraneoplastic antibodies. If suspicion of paraneoplastic etiology is present, additional work-up for assessment of a primary tumor should be considered, even in the absence of paraneoplastic antibodies. Most patients with gluten-related neurologic disease do not have associated gastrointestinal symptoms; therefore, assessment for gluten-related ataxia in an individual includes testing anti-gliadin immunoglobulin (Ig) A and IgG, antitransglutaminase-2 (anti-TG-2) and, if possible, TG-6 antibodies.

HEREDITARY ATAXIAS

Hereditary ataxias are generally progressive, although there is a subgroup of episodic hereditary ataxias, which is separately discussed.

The hereditary ataxias comprise heterogeneous disorders that share three features: ataxia, pathology involving the cerebellum or its connections, and heritability. The pathology usually affects more than the cerebellum, including also the posterior columns, pyramidal tracts, pontine nuclei, and basal ganglia, with corresponding additional neurologic signs. Clinical features may include ataxic gait and arm movements, as well as dysarthria, nystagmus, and signs of neuropathy. Within a family, clinical and pathologic features may differ and the heterogeneity creates problems for classification. Because the phenotypic range of hereditary ataxias is broad, with some family members demonstrating ataxia

P.667

and other different movement disorders or parts of a syndrome— such as mental retardation in a child in proband with fragile X tremor ataxia syndrome (FXTAS)—determination of family history should query for symptoms or diagnosis of chorea, dystonia, parkinsonism, tremor, mental retardation, neuropathy, epilepsy, visual loss, diabetes, and deafness.

Ataxia is often classified based on mode of inheritance, with broad separation between the autosomal dominant cerebellar ataxias (ADCAs), the AR ataxias, and those that are X-linked and mitochondrial. However, the mode of inheritance is not always clear, owing to variable penetrance, anticipation, new mutations, small family sizes, and nonpaternity. Hereditary ataxias should be considered in apparently sporadic cases without known etiology as well. Although cases with parent-child transmission are either dominant or (if maternally inherited) mitochondrial, those with only an affected sibling may be recessive, dominant, or mitochondrial.

AR ataxias are often of early onset, and dominant ataxias are of later onset. However, as many of one-third of individuals with FRDA, the most common recessive ataxia, may have late-onset disease, among the common ADCAs, especially SCA7, but also SCA1-3, 8, and 13 may begin in childhood or even infancy. Dominant ataxias are more often associated with DNA trinucleotide repeats, but FRDA is also a trinucleotide repeat disorder. Whereas the dominant ataxias are usually believed to be due to toxic gain-of-function events, it is believed that AR ataxias are due to decreased translation and loss of functional protein. Both dominant and recessive ataxias

may show cerebellar and extracerebellar neurologic features; however, nonneurologic manifestations, such as cardiomyopathy and diabetes (FRDA) and immunodeficiency (ataxia-telangiectasia [AT]), are more frequent in the recessive forms.

AUTOSOMAL DOMINANT ATAXIAS

Classification

In 1893, Marie applied the term *hereditary cerebellar ataxia* to syndromes that differed from Friedreich ataxia in their later-onset autosomal dominant inheritance, hyperactive tendon reflexes, and, frequently, ophthalmoplegia. Classification of ADCAs has been the subject of controversy since this time because nosology was based on pathology with poor clinical-pathologic correlation even within a single family. Harding challenged these confusing pathology-based schemes, lumping ADCAs, and then dividing them into clinical groups. With the mapping and cloning of autosomal dominant ataxia genes, emphasis has shifted to a genetic classification, incorporating clinical features when possible. A broad separation exists between those disorders that are chronic and progressive (the spinocerebellar ataxias, the SCAs) and those with primarily episodic appearance of ataxia (the episodic ataxias). Registration of SCA genes with the Human Genome Organization (HUGO) has led to a sequential numbering system of autosomal SCA loci, with 33 SCA loci and 21 known genes ([Table 79.1](#)). However, the numbering is based on the temporal order when SCA numbers were assigned and does not have clinical or pathologic significance. SCAs may be further subclassified into genetic groups (polyglutamine cytosine-adenine-guanine [CAG] repeat disorders, noncoding repeat expansions, and others), although the SCAs show tremendous clinical overlap. Nonetheless, for some SCAs, there are characteristic features which, when present, may be highly suggestive of a particular SCA. For example, seizures are prominent in SCA10, retinopathy in SCA7, and later age of onset and slower progression in SCA6 (see [Table 79.1](#)).

Epidemiology

Worldwide, ADCAs occur with a frequency of 1 to 5:100,000. Frequencies of specific SCAs vary by geographic region and this is attributed to founder effects in the populations. The most common ADCA worldwide is SCA3 (21%), then SCA2 and SCA6 (15% each), SCA1 (6%) and SCA7 (2%), and SCA8 (2-5%). The United States frequency pattern is very similar to that worldwide and SCA13 and SCA17 are also seen (less frequently than SCA8). SCA2 is common in Koreans. SCA3 is more common in Portugal, Japan, and Germany than in the United Kingdom. Dentatorubral-pallidoluysian atrophy (DRPLA) accounts for 20% of autosomal dominant SCA in Japan but is uncommon in the United States, where most cases are of African-American origin. SCA12 is common in eastern India but rare elsewhere.

Etiologic and Genetic Features

Although some distinct features can be discerned, most SCAs have many characteristics in common, and classification is complicated by intra- and interfamilial variation. Symptoms usually begin in early- or mid-adult years, but the age at onset varies from childhood to the eighth decade (see [Table 79.1](#)). The first and generally most prominent sign is gait ataxia, occasionally starting with sudden falls. Limb ataxia and dysarthria are also early symptoms. Hyperreflexia may be present initially, but tendon reflexes may later be depressed, and vibration and proprioception may be lost. Eye signs include nystagmus, slow saccades, and abnormal pursuit. Dementia, dystonia, parkinsonism, tremor, fasciculations, neuropathy, and distal wasting may occur, although the frequency of these features differs among the various SCAs. Anticipation and potentiation, earlier onset, and more severe symptoms in succeeding generations are observed in most of the SCAs (most dramatically in SCA7 and DRPLA but not in SCA6), and the majority are severely disabled 10 to 20 years after symptom onset (see [Table 79.1](#)). Some advocate classification of the ADCA by pathogenesis in those with known genes, dividing into those caused by (1) unstable CAG trinucleotide repeats in the protein-coding region leading many (poly) glutamine

repeats (these include SCA1, 2, 3, 6, 7, and 17 and DRPLA); (2) noncoding repeat expansions (SCA8, 10, 12, 31, and 36); and (3) those caused by more traditional genetic mechanisms, including single gene deletions (SCA15 and 16), duplications (SCA20), and point mutations (SCA5, 11, 13, 14, 23, 27, 28, and 35). Among this last class are genes associated with glutamate signaling (SCA5), tau regulation (SCA11 and 27), ion channel functions (SCA13 and 14), mitochondrial activity (SCA28), and calcium signaling (SCA15/16). Whereas ADCAs are generally progressive, the subgroup of episodic ataxias is predominantly intermittent. It is associated with mutations in ion channel genes (EA1, 2, and 5) or signaling (glutamate, EA6) and is separately discussed, although there is overlap with the other ADCAs, as SCA6 is due to CAG repeats in the calcium channel gene CACNA1A. In SCAs with repeat expansions, paternal and maternal transmissions differ, and in all but SCA8, there is a greater tendency for an increase in repeat size in paternally transmitted disease chromosomes. As a result, anticipation is more pronounced in paternally transmitted disease. In SCA8, most expansions occur during maternal transmission.

Coding CAG and Polyglutamine Disorders (Spinocerebellar Ataxia Types 1, 2, 3, 6, 7, and 17 and Dentatorubral-Pallidoluysian Atrophy)

SCA1, SCA2, SCA3, SCA6, and SCA7 are the most frequent etiologies of ADCAs in families worldwide, together accounting for

50% to 60%. As in other dominant disorders with trinucleotide

P.668

P.669

expansions (e.g., Huntington disease, DRPLA), there is generally an inverse relationship between repeat size and age at onset, with a threshold of expanded alleles needed for disease. However, in some of these there is an intermediate range of alleles, whereby the upper limit of normal overlaps with the lower range of abnormal repeats. These are now separated into “mutable normal” alleles where they are not disease causing but with transmission expand to cause disease and “reduced penetrance” alleles that may or may not cause disease. Another feature of the trinucleotide expansion disorders is meiotic instability and anticipation. In a parent-child transmission, the size of the repeat may change, either expanding or contracting; with expansion, there may be earlier onset or worse severity in subsequent generations (anticipation).

TABLE 79.1 Autosomal Dominant Ataxias

Disorder	Gene (Mutation Type/Locus)	Gene Product	Phenotype: Age of Onset (Years, Range) Some Typical Features^a
SCA1	SCA1 (CAG repeat)	Ataxin-1	30s (childhood to older than 60) Young adult onset; pyramidal signs; extrapyramidal signs; dysphagia; ophthalmoparesis; neuropathy; tongue atrophy, facial fasciculations
SCA2	SCA2 (CAG repeat)	Ataxin-2	20s-30s (infancy to 67) Young adult onset; very slow saccades; neuropathy; hyporeflexia; dementia; extrapyramidal signs; pyramidal signs rare; tongue atrophy, facial fasciculation

SCA3	MJD (CAG repeat)	Machado-Joseph disease protein 1	30s (6-70) Young adult onset; ophthalmoparesis; pyramidal and extrapyramidal signs; amyotrophy; sensory loss; very slow saccades
SCA4	SCA4 (chromosome 16q22.1)		30s (19-59) Sensory axonal neuropathy; deafness; pyramidal signs; generalized areflexia
SCA5	SCA5 (nonrepeat mutations)	Spectrin β chain, brain 2	30s (10-68) Slowly progressive
SCA6	CACNA1A (CAG repeat)	Voltage-dependent calcium channel α 1A subunit	48 (19-75) Older onset; slowly progressive; sometimes episodic; downbeat nystagmus
SCA7	SCA7 (CAG repeat)	Ataxin-7	30s (infancy to 60) Visual loss with optic atrophy and pigmentary retinopathy; ophthalmoparesis; pyramidal signs; extreme anticipation
SCA8	SCA8 (CAG-CTG)	Kelch-like 1	39 (18-65) Slowly progressive; hyperreflexia, decreased vibratory sense; maternal bias for transmission
SCA10	SCA10 (ATTCT repeat)	Ataxin-10	36 Seizures; polyneuropathy
SCA11	SCA11 (nonrepeat mutations)	—	30 (15-70) Slowly progressive; hyperreflexia; vertical nystagmus
SCA12	PPP2R2B (CAG repeat)	Serine/threonine protein phosphatase	33 (8-55) Early tremor; bradykinesia; dystonia; dementia; dysautonomia; hyperreflexia
SCA13	SCA13 (nonrepeat mutations)	—	Childhood Slowly progressive; mental retardation; short stature
SCA14	PRKCG (nonrepeat mutations)	Protein kinase C gamma	28 (12-42) Early axial myoclonus

SCA15/16	SCA15 (deletion of the 5' part of gene)	Inositol triphosphate receptor	Childhood to teen (childhood to 66) Slowly progressive ; dysarthria (pure ataxia); head tremor ; nystagmus
SCA17	TBP (CAA/CAG repeat mutation)	TATA-box- binding/transcription initiation (TFIID)	6-34 Dementia ; parkinsonism ; dystonia; chorea; myoclonus; seizures; cerebral and cerebellar atrophy on MRI
SCA18	7q22-q32	—	Teen Motor/sensory neuropathy
SCA19/22	1p21-q21	—	10-46 Slowly progressive ; tremor ; myoclonus; cognitive impairment
SCA20	— (260-kb duplication)	—	46 (19-64) Palatal tremor/myoclonus; dysarthria; hypermetric saccades; pyramidal signs; dentate calcification on CT
SCA21	—	—	6-30 Akinesia; rigidity; tremor ; cognitive impairment
SCA23	—	—	40-60 Dysarthria; abnormal eye movements; reduced vibration and position sense
SCA25	—	—	1-39 Sensory neuropathy
SCA26	—	—	(26-60) Dysarthria; irregular visual pursuits
SCA27	—	FGF14/fibroblast growth factor 14	11 (7-20) Early-onset tremor ; dyskinesia; dementia/cognitive deficits
SCA28	—	—	19 (12-36) Nystagmus; ophthalmoparesis; ptosis; hyperreflexia
SCA29	—	—	Childhood Learning deficits

DRPLA	DRPLA (CAG repeat)	Atrophin-1-related protein	30s (childhood to 70) Early-onset myoclonus and epilepsy; late-onset chorea; dementia in both
Episodic Ataxias			
EA1	KCNA 1	Voltage-gated potassium channel protein Kv1.1	Childhood (2-15) Exercise- or startle-induced ataxia; myokymia (attack duration: seconds to minutes); no vertigo
EA2	CACNA1A (nonrepeat mutations)	Voltage-dependent P/Q-type calcium channel subunit	Childhood (3-52) Stress- or fatigue-induced episodic ataxia (attack duration: minutes to hours); downbeat nystagmus; later permanent ataxia; acetazolamide responsive
EA5	CACNB4	Dihydropyridine-sensitive calcium channel subunit	—

^aAtaxia including dysarthria is common for all; features suggesting diagnosis are bolded.

SCA, spinocerebellar ataxia; MRI, magnetic resonance imaging; CT, computed tomography; DRPLA, dentatorubral-pallidoluysian atrophy; EA, episodic ataxia.

The CAG expansions result in an expanded polyglutamine tract because CAG codes for glutamine. Unlike the FRDA triplet expansion in the recessive Friedreich ataxia, which causes disease by inducing frataxin deficiency, the dominant SCA triplet expansions cause disease by altering the protein, a toxic gain of function. Polyglutamine protein inclusions are postulated due to impaired protein clearance and transcriptional dysregulation. As each polyglutamine disorder has distinctive clinical-pathologic features, some other feature, in addition to the polyglutamine, must play a role.

SPINOCEREBELLAR ATAXIA TYPE 1

The first ADCA locus, SCA1, was mapped to the short arm of chromosome 6 in 1974, and in 1993, the SCA1 mutation was identified as due to a trinucleotide (CAG) repeat expansion. The expansion was specifically sought because of the known anticipation in SCA1 families and the earlier identification of expanded trinucleotide repeats and anticipation in Huntington disease. The protein encoded by SCA1 is called *ataxin-1* (ATXN1), a ubiquitously expressed protein of unknown function. Mutated ATXN1 accumulates in the nucleus into aggregates, termed *nuclear inclusions*. These inclusions include ubiquitin, chaperones, and proteasomal subunits that are important for protein refolding and degradation, and abnormal protein clearance thus may mediate SCA1 pathogenicity.

Different trinucleotide repeats, those with cytosine-adenine-thymine (CAT), serve to stabilize the polyglutamine repeat from expanding. Normal SCA1 alleles have 6 to 44 CAG repeats, and the repeat configuration is interrupted by one to three CAT repeats when the allele contains 21 or more repeats. Abnormal alleles have 39 or more repeats without the CAT interruption. Mutable normal (intermediate) alleles are those with 36 to 38 CAG

repeats without the CAT interruption. Intermediate alleles appear to have no associated clinical signs but on transmission to offspring can expand

P.670

to the abnormal range. As with other polyglutamine disorders, the repeat size is overall associated with earlier age of onset and severity of disease, but approximately half of the variance in age at onset is not fully explained by repeat size alone; therefore, additional mechanisms are involved.

The prevalence of SCA1 is estimated at 1 to 2 per 100,000, varying in different populations. It is estimated to be responsible for 6% of ADCAs in North America, approximately 30% in Italy, England, and Serbia, and 40% in South Africa. SCA1 rarely accounts for ataxia in singleton or apparently recessive cases.

Typically, SCA1 starts in the third to fourth decade, but the range at onset is 6 years of age to late adulthood. Gait ataxia predominates and is often the first sign, usually with mild dysarthria, hypermetric saccades, nystagmus, and hyperreflexia. With progression, nystagmus may disappear and saccadic abnormalities and ophthalmoparesis (particularly upgaze) develop. Worsening limb, gait, and speech ataxia evolve. Hypotonia with decreased tendon reflexes and sensory loss are common later. Although mild dysphagia may occur early, bulbar manifestations including lingual atrophy, fasciculations, and severe dysphagia usually present late in the disease. Optic atrophy, dementia, personality change, dystonia, and chorea are less common. Maculopathy, more common in SCA7, has also been reported. Classically, SCA1 is more rapidly progressive than other SCAs, with progression to death in 10 to 30 years and early-onset disease more rapidly progressive. Lateonset disease may be restricted to a pure cerebellar disorder, as is seen in SCA6.

The pathology includes neuronal loss in the cerebellum, brain stem, spinocerebellar tracts, and dorsal columns with rare involvement of the substantia nigra and basal ganglia. Purkinje cell loss and severe neuronal degeneration in the inferior olive are seen; degeneration is also seen in the cranial nerve nuclei, restiform body, brachium conjunctivum, dorsal and ventral spinocerebellar tracts, posterior columns, and, rarely, the anterior horn cells. MRI shows atrophy of the brachia pontis and anterior lobe of the cerebellum and enlargement of the fourth ventricle, and spinal cord atrophy may be present.

SPINOCEREBELLAR ATAXIA TYPE 2

Mapped in ataxic patients from the Holguin province of Cuba who descended from an Iberian founder, SCA2 families were subsequently found in Italy, Germany, French Canada, Tunisia, and Japan. The SCA2 gene encodes the protein ataxin-2.

Normal individuals have 31 or fewer CAG repeats (with most containing 22), with 32 repeats of uncertain significance and CAG expansions of 33 or more associated with disease. Repeat length closely correlates with age at onset and severity. SCA2 may have marked anticipation, instability, and expansions. Large expansions over 200 and homozygosity are associated with retinitis pigmentosa, myoclonic encephalopathy, and early-onset parkinsonism. Intermediate length expansions may increase the risk of amyotrophic lateral sclerosis (ALS) and the atypical parkinsonism, progressive supranuclear palsy (PSP), and repeats of 33 or more or with a preserved CAA interruption may manifest as ALS or levodopa-responsive parkinsonism. The function of *ataxin-2*, the protein encoded by SCA2, is not known, but in normal and SCA2 brains, it is localized in the cytoplasm of neurons, especially Purkinje cells. Immunocytochemical studies suggest that the protein is associated with endoplasmic reticulum and may be involved in processing of mRNA and/or regulation of translation, and elevated repeats lead to aggregation of disease protein. Further, ataxin-2 knockout models suggest that it may play a role in modification of other neurodegenerative diseases, including not only ALS but SCA1 and 3 as well.

SCA2 is a relatively frequent cause of ADCA worldwide, ranging from 14% to 18% in German and American ADCA families, to 37% to 47% in Italian and English families, and more than 30% in ADCA families from eastern India. Rarely, it is found in families with apparent recessive inheritance (i.e., siblings but not parents affected) or

in sporadic cases, and some of this may be attributed to the tremendous anticipation whereby the child with markedly more repeats presents prior to the parent with fewer, albeit pathologic, repeats.

SCA2 usually begins in the third to fourth decade, but onset varies from infancy to the seventh decade. The most common clinical features are progressive gait and limb ataxia and dysarthria (Video 79.1). SCA2 is often described as a cerebellar-plus disorder, as other accompanying features are common and include depressed or absent tendon reflexes, slow saccades, kinetic or postural arm tremor, fasciculations, ophthalmoparesis, vibratory and position sensory loss, and sleep disturbances. Chorea and dystonia have been reported in 38% of cases and dementia in 37%. Less common features are leg cramps and leg hyperreflexia. Although levodopa-responsive parkinsonism is classically associated with SCA3, it may be present in SCA2 as well. Nystagmus is an initial feature that tends to disappear as slow saccades emerge. Although other SCA subtypes include these features, patients with SCA2 are most likely to have slow saccades and hyporeflexia. Many show electrophysiologic evidence of axonal neuropathy with severe involvement of sensory fibers. The highly variable phenotype occasionally seems to “breed true” in families (e.g., kindreds with dementia and extrapyramidal signs or with moderate ataxia, facial fasciculations, prominent eye signs that include lid lag, and retinitis). Abnormal motor control with periodic leg movements during sleep and rapid eye movement (REM) sleep without atonia are common.

Pathology, like clinical signs, is variable. Usually, there is severe neuronal loss in the inferior olive, pons, and cerebellum (OPCA). However, there may also be degeneration of the substantia nigra, dorsal columns, and anterior horn cells. Degeneration is rarely restricted to the cerebellum.

As with other SCAs, because there are overlapping clinical features, molecular genetic testing is necessary to confirm the diagnosis.

SPINOCEREBELLAR ATAXIA TYPE 3/MACHADO-JOSEPH DISEASE

Machado-Joseph disease (MJD) was first described in families of Azorean Portuguese descent, also seen in German, Dutch, African-American, and Japanese families, and eventually linked to chromosome 14q24.3-q32. Subsequent linkage to the same region was found in French families that were clinically similar to SCA1 or SCA2, and the locus was numbered SCA3. Because these French families were not of Azorean descent, and because there were several clinical differences (lack of dystonia and facial fasciculations), it was uncertain whether MJD and SCA3 were owing to different genes, different mutations in the same gene, or the varying phenotypic expressions of the same mutation in individuals with different ancestry. In 1994, an expanded and unstable CAG repeat was found in the coding region of the MJD gene and all 14q-linked families have the same unstable CAG repeat within the SCA3/MJD gene, so that now SCA3 and MJD are viewed as a single genetic disorder with a wide clinical spectrum. SCA3 is the most common ADCA worldwide. As with the other ADCA genes, there may be intrafamilial genetic modifiers (including differences within the SCA3/MJD gene) that influence the phenotype.

P.671

The normal repeat number is up to 43, and disease alleles in affected individuals range from 52 to 89 repeats. Intermediate allele size is between 48 and 54 repeats, is associated with meiotic instability and pathologic expansion in subsequent generations, and infrequently may manifest with restless legs syndrome, dysautonomia, and/or polyneuropathy. As in other CAG repeat diseases, there is a strong inverse correlation between the length of the repeat and age at onset, and there is instability in paternal meioses. Some, but not all, homozygous SCA3 individuals have early-onset severe disease, suggesting a gene dosage effect.

The SCA3/MJD gene encodes *ataxin-3*, a protein not related to ataxin-1 or ataxin-2. It binds and cleaves ubiquitin chains, suggesting that it may be a mixed linkage, ubiquitin chain-editing or regulatory enzyme linked to quality control and endoplasmic reticulum-associated protein degradation. It is ubiquitously expressed in the

cytoplasm of cell bodies and processes. In SCA3/MJD brain, there is aberrant nuclear localization and accumulation of ubiquitinated nuclear inclusions. The sites and burden of brain degradation in SCA3 is similar to SCA2.

Common signs, regardless of age at onset, include limb and gait ataxia, dysarthria, and progressive ophthalmoplegia. Findings that are more dependent on age at onset include pyramidal signs, dystonia and rigidity, amyotrophy, facial and lingual fasciculations, and lid retraction with bulging eyes. Four clinical subclasses have been proposed:

1. Adolescent or young adult onset: rapidly progressive with spasticity, rigidity, bradykinesia, weakness, dystonia, and ataxia
2. Mid-adult onset (ages 30 to 50 years): moderate progression of ataxia
3. Late-adult onset (ages 40 to 70 years): slower progression of ataxia, prominent peripheral nerve signs, and few extrapyramidal findings
4. Adult onset: parkinsonism and peripheral neuropathy

The pathology had been considered distinct with primarily spinopontine atrophy and involvement of pontine nuclei, spinocerebellar tracts, Clarke column, anterior horn cells, substantia nigra, and basal ganglia; the inferior olives and cerebellar cortex were thought to be always spared. With mutation screening, however, it is now evident that the olives and cerebellar cortex may be involved.

SCA3 is the most common cause of ADCA in many but not all populations. In the United States, about 21% of ADCA families have SCA3; in a study of mixed populations, 41% were SCA3, but this dropped to 17% when Portuguese families were excluded. SCA3 is common in Germany (accounting for 50% of ADCA cases), China, and Japan but uncommon in England and rare in Italy (Figs. 79.1 and 79.2).

SPINOCEREBELLAR ATAXIA TYPE 6

The SCA6 gene maps to chromosome 19p13 and encodes for an $\alpha 1A$ voltage-dependent calcium channel subunit (CACNA1A). It differs from other polyglutamine SCAs in the following: (1) Pathology is associated with a lower number of CAG repeats; (2) repeat is stable during transmission and anticipation is generally not observed; (3) there is a later onset, less severely progressive course, and the disorder tends to be more purely cerebellar; and (4) it is allelic with other generally nonprogressive channelopathies. There are three distinct phenotypes associated with different CACNA1A mutations. The SCA6 symbol is reserved for an adult-onset cerebellar syndrome with CAG repeat expansions. SCA6 CAG repeats are 20 to 33, with an average disease-causing length of 22. Normal expansions are 4 to 18, and 19 repeats are considered intermediate.

FIGURE 79.1 Patient JM of the Joseph family who, at age 38 years, shows dystonic posturing of his head, arms, trunk, and legs in association with prominent spasticity of his extremities. He has been symptomatic for 12 years. (From Rosenberg RN, Nyhan WL, Coutinho P, et al. Joseph's disease: an autosomal dominant neurological disease in the Portuguese of the United States and the Azores Islands. *Adv Neurol.* 1978;21:33-57.)

The two other phenotypes associated with *CACNA1A* mutations are familial hemiplegic migraine (FHM) and episodic ataxia type 2 (EA2). EA2 is caused by *CACNA1A* mutations that predict protein truncation, abnormal splicing, or, rarely, missense mutations, and about 50% of FHM is associated with *CACNA1A* missense mutations. In addition, a *CACNA1A* missense mutation, G293R, causes a more severe SCA6-like phenotype. Although most families “breed true” as SCA6, FHM, or EA2, phenotypic overlap may occur. SCA6 patients may also have episodes of ataxia. One family with CAG expansions had members with episodic ataxia and others with progressive ataxia and another with EA2 had members with hemiplegia or migraine during episodes of ataxia. The correlation between number of SCA6 repeats and age at onset is quite loose; 22 repeats, the most common expansion, is associated with

range of age at onset, even within sibships. Like MJD, the phenotype is more severe in homozygous individuals.

FIGURE 79.2 A 74-year-old man and grandson of the Joseph proband showed progressive disease for 12 years with truncal ataxia, cerebellar dysarthria, areflexia, distal sensory deficits, and distal atrophy. The degree of atrophy of the intrinsic hand muscles can be seen. Thus, he manifests a neurologic syndrome of late onset and, as a direct descendant of Antone Joseph, he suggests the possibility of a wide spectrum of disease. (From Rosenberg RN, Nyhan WL, Coutinho P, et al. Joseph's disease: an autosomal dominant neurological disease in the Portuguese of the United States and the Azores Islands. *Adv Neurol.* 1978;21:33-57.)

The molecular basis of disease is unknown, and thus far, studies suggest that expanded CAG repeats do not affect the functioning of the voltage-gated calcium channels but rather reflect a gain of function of the protein, although this remains an area of active research.

The clinical picture of SCA6 is fairly uniform. The average age at onset is somewhat older than other SCAs, about 45 to 50 years (range, 20 to 75 years). The first symptom is usually unsteady gait. Dysarthria, leg cramps, and diplopia can also be early symptoms. Occasionally, patients describe positional vertigo or nausea. Cerebellar signs include gait and limb ataxia (especially leg), cerebellar dysarthria, saccadic pursuit, and dysmetric saccades. Horizontal and downbeat nystagmus (most prominent on lateral gaze) are common eye signs, but very slow saccades are not observed. Noncerebellar signs occur with less frequency and usually less clinical impact than in other SCA disorders but include hyperreflexia, decreased vibration and position sense, impaired upgaze, and parkinsonism. Onset of ataxia may be episodic or apoplectic and resembles EA2 with attacks of unsteadiness, vertigo, and dysarthria that last for hours; between attacks, there are few if any symptoms or signs. The attacks may occur for years before progressive cerebellar signs emerge.

The course is slowly progressive, the least progressive of the SCAs and generally does not shorten life span. After 10 to 15 years, most affected individuals are no longer able to walk without assistance. MRI shows cerebellar atrophy but little brain stem or cortical atrophy. Pathologically, there is cerebellar atrophy with loss of Purkinje and granule cells and limited involvement of the inferior olives.

In the United States and Germany, SCA6 accounts for 10% to 15% of ADCA families. It is more common in Japan

(30%) and is uncommon in France, where only 1% of ADCA families harbor the mutation. Five percent to 6% of sporadic ataxia patients demonstrate SCA6 expansions. Some are new mutations, but it is also likely that some appear sporadic because of the late age at onset and relatively indolent course.

SPINOCEREBELLAR ATAXIA TYPE 7

SCA7 differs from other forms of ADCA by the associated severe retinal photoreceptor degeneration producing cone-rod dystrophy and is notable for unstable repeat length during meiosis. It is a result of the expansion of a coding sequence CAG repeat in ataxin-7, an integral component of the transcription coactivator complex involved in regulation of transcription. Normal alleles have up to 29 repeats. Abnormal alleles have from 36 to more than 450 repeats. Intermediate repeats are between 30 and 35. Alleles in this range are considered to be unstable, producing an increased risk of having a child with an abnormal repeat length but are not convincingly associated with a phenotype. Dramatic examples of anticipation, especially with paternal transmission, are due to repeat instability, which exceeds any other CAG repeat SCA, and is related to age at onset, rate of progression, and clinical signs.

SCA7 age at onset ranges from infancy to the seventh decade and averages around 30 years. The course varies with age at onset. A severe infantile form occurs with large expansions (>200) that are paternally inherited. These infants have hypotonia, dysphagia, visual loss, cerebellar and cerebral atrophy, and congestive heart failure with cardiac anomalies. This differs from childhood and adult forms, which are marked by early visual loss, moderately progressive limb and gait ataxia, dysarthria, ophthalmoparesis, and Babinski signs. In late-onset cases (fourth to sixth decade), ataxia may occur in isolation or it may precede visual symptoms (see [Table 79.1](#)). Affected individuals all have abnormal yellow-blue color discrimination (which in the mildest forms may be asymptomatic), and clinically, there is often optic disc pallor with granular and atrophic changes in the macula.

Degeneration affects the cerebellum, basis pontis, inferior olive, and retinal ganglion cells. Neuronal intranuclear inclusions containing the expanded polyglutamine tract are found in many brain regions, most frequently in the inferior olive. SCA7 accounts for almost all families with both ADCA and retinal degeneration and about 5% of all ADCA families.

SPINOCEREBELLAR ATAXIA TYPE 17

Initially described in a Japanese patient with childhood-onset ataxia and no family history, SCA17 has now been reported in Japanese and European kindreds. Age at onset ranges from 19 to 48 years, starting with gait ataxia and dementia. Psychiatric features sometimes precede the motor disorder. Limb ataxia, hyperreflexia, chorea, dystonia, myoclonus, parkinsonism (including tremor, bradykinesia, postural instability, and rigidity, sometimes mimicking MSA-C), as well as epilepsy have also been reported. MRI is notable for both cerebral and cerebellar atrophy. SCA17 is secondary to a CAG repeat expansion in the TATA-binding protein (TBP) gene, a transcription-initiating factor (TFIID). Normal repeat length is 29 to 42, and patients have 44 to 63 CAG repeats. Similar to SCA6, repeats are generally stable in subsequent generations. Neuropathology demonstrates Purkinje cell loss and intranuclear inclusions with polyglutamine expansions.

DENTATORUBRAL-PALLIDOLUYSIAN ATROPHY

DRPLA is most common in Japan where it constitutes 10% to 20% of ADCA families. Rare cases have been described in other groups. The pathology involves the dentate, red nucleus, subthalamic

nucleus, and the external globus pallidus; the posterior columns may be involved. The phenotype includes ataxia and dementia but varies in other features depending on age at onset. Early-onset cases (before age 20 years) tend to show severe and rapid progression of myoclonus, epilepsy, and cognitive decline, whereas later onset

cases display ataxia, chorea, dementia, and psychiatric problems (resembling Huntington disease; see [Table 79.1](#)). Anticipation is evident, and paternal transmission is associated with more severe early-onset disease. One clinical variant, the *Haw River syndrome*, was described in an African-American family in North Carolina. This variant includes all the aforementioned symptoms except for myoclonic seizures, and additional features include basal ganglia calcification, neuroaxonal dystrophy, and demyelination of the central white matter. MRI may show atrophy of the cerebral cortex, cerebellum, and pontomesencephalic tegmentum, with high signal in white matter of the cerebrum and brain stem.

The disorder is a result of an expansion of a CAG repeat in the DRPLA gene, which maps to chromosome 12p. There is an inverse relationship between repeat size and age at onset; normal subjects have up to 35 repeats and disease alleles have 48 or more (see [Table 79.1](#)). The gene is expressed in all tissues, including brain. The DRPLA gene product, *atrophin-1*, is found in neuronal cytoplasm. Ubiquitinated intranuclear inclusions are seen in neurons and to a lesser extent in glia. The neuronal inclusions are concentrated in the striatum, pontine nuclei, inferior olive, cerebellar cortex, and dentate.

Spinocerebellar Ataxias due to Noncoding Repeat Expansions (Spinocerebellar Ataxia Types 8, 10, 12, 31, and 36)

In contrast to the polyglutamine disorders, these SCAs are due to repeat expansions, usually trinucleotide, pentanucleotide, or hexanucleotide, which are transcribed to RNA but are not translated into protein.

SPINOCEREBELLAR ATAXIA TYPE 8

SCA8 has a slowly progressive course that begins at a mean of 39 years (range 1 to 65 years). The common initial findings include limb and gait ataxia and dysarthria and, compared to other SCAs, severe scanning dysarthria, truncal titubation, and leg ataxia are more common. Severely affected individuals are not able to walk by the fourth decade. Hyperreflexia, Babinski signs with spasticity, and ophthalmoplegia may also occur.

SCA8 is unique among the ataxia trinucleotide repeat disorders for several reasons: (1) The trinucleotide repeat is a cytosine-thymine-guanine (CTG) repeat rather than a CAG repeat, (2) the repeat length does not necessarily correlate with severity, (3) abnormal allele length has been reported in other ataxias as well as normal controls, and (4) allele expansion occurs with maternal transmission and contraction with paternal transmission. It is similar to SCA12 (a CAG trinucleotide repeat) but differs from other trinucleotide repeat disorders in that the product is a noncoding RNA. Abnormal CTG expansions (>44 repeats) have been reported in healthy and disease controls. The SCA8 transcript may downregulate the adjacent gene *Kelch-like 1 (KLHL1)*, leading to neurodegeneration. However, initial studies with transgenic mice suggest that CTG expansions produce an ataxic phenotype.

SPINOCEREBELLAR ATAXIA TYPE 10

SCA10 is caused by a large ATTCT pentanucleotide repeat expansion in intron 9 of *ataxin-10*, a new type of dynamic repeat expansion. Although the normal repeat range is 10 to 22 alleles, affected individuals have 800 to 4,500 repeats. The expanded repeat alleles are unstable with paternal transmission, and there is an inverse correlation between the repeat number and age at onset. An association between ataxia or seizure phenotype and allele size has not been established.

In 1999, two independent groups mapped this locus to chromosome 22q. The phenotype is marked by pure cerebellar signs and seizures. Most families are of Mexican or Brazilian ancestry suggesting a common, possibly Native American, founder population. Age at onset ranges from 12 to 48 years, with evidence of anticipation. There is slowly progressive ataxia with eventual difficulty sitting. Scanning dysarthria, dyscoordination of oral muscles, upper limb incoordination, and abnormal tracking eye movements also develop in most patients. Although seizures may be infrequently associated with SCA2 and SCA17, they are a prominent feature in

SCA10: between 20% and 100% of patients have recurrent partial complex and generalized motor seizures. Seizures usually start after the gait ataxia and are well controlled with anticonvulsants. Mild cognitive disorders, mood disorders, mild pyramidal signs, behavioral disturbances, and peripheral neuropathy may occur. Furthermore, nonneurologic features of hepatic failure, anemia, and/or thrombocytopenia were reported in one family. MRI demonstrates progressive pancerebellar atrophy, and interictal electroencephalogram shows evidence of cortical dysfunction with or without focal epileptiform discharges in some.

SPINOCEREBELLAR ATAXIA TYPE 12

SCA12 has been described in American European and Indian Asian families. It starts between ages 8 and 55 years, usually in the mid-30s. It differs clinically from other ADCAs with its frequent action tremor. The slowly progressive ataxia may not be disabling. Other features include hyperreflexia, subtle parkinsonism, focal dystonia, dysautonomia, dementia, and psychiatric features. MRI shows cerebral as well as cerebellar atrophy. Although the disorder is due to CAG repeat expansions, they are not translated and it is not believed to cause polyglutamine-related toxicity. Normal repeat length is 7 to 28 repeats, whereas it is greater than 65 repeats in affected individuals.

SPINOCEREBELLAR ATAXIA TYPE 13

SCA31 is due to a pentanucleotide repeat (TGGAA)_n insertion in the intron of BEAN/TK2. It is most frequently seen in those of Japanese descent and has been less frequently seen in individuals of East Asian background, including Korea and China. It is clinically characterized by pure cerebellar ataxia and pathologically by halolike structures surrounding the degenerating Purkinje cells, attributed to nuclear deformity and Golgi fragmentation. Because of its late age at onset, often in the 60s, and its pure cerebellar features, it is most compared to SCA6.

SPINOCEREBELLAR ATAXIA TYPE 36

SCA36 is also characterized by a late-onset slowly progressive ataxia in the 50s (range 29 to 65 years) and often with preserved gait even after 10 years but is a cerebellar plus syndrome. First symptoms are often balance difficulties, and dysarthria and appendicular cerebellar features are almost universal. SCA36 is associated with sensorineural hearing loss. There may be overlap with motor neuron disease, with muscle atrophy and denervation including lingual, often causing dysphagia. Frontal-subcortical

P.674

cognitive impairment may emerge. There is rare associated dystonia and parkinsonism. SCA36 is due to a hexanucleotide GGCCTG repeat expansion in NOP56. Six hundred fifty repeats or greater are associated with symptoms. Cases have been reported in Japan, Spain, and Italy, including singleton cases. Therefore, in areas with a founder mutation and the clinical features, molecular genetic testing may be considered even without a family history.

Spinocerebellar Ataxias due to Traditional Conventional Genetic Mechanism

These include point mutations (5, 11, 13, 14, 27, 28, 35, and 38), single gene deletions (SCA15/16), and duplications (SCA20).

SPINOCEREBELLAR ATAXIA TYPE 5

This locus was mapped to the pericentromeric region of chromosome 11q in a kindred descended from the paternal grandparents of President Abraham Lincoln. The affected gene β -III spectrin (SPTBN2) is highly expressed in Purkinje cells and is involved in glutamate signaling. Symptoms of this relatively benign, slowly progressive, cerebellar syndrome appear at 10 to 68 years with anticipation (see [Table 79.1](#)). All four juvenile-onset patients (10 to 18 years) resulted from maternal transmission rather than the paternal pattern seen in the other SCA syndromes. The juvenile-onset patients showed cerebellar and pyramidal tract signs, as well as bulbar

dysfunction.

SPINOCEREBELLAR ATAXIA TYPE 11

SCA11 has been reported in four families, including those with British, Pakistani British, French, and German ancestry. It presents with young onset, average age of 25 years (range 11 to 70 years), benign slowly progressive gait and limb ataxia, and with a normal life expectancy. It is primarily cerebellar except for mild pyramidal signs, although dystonia and peripheral neuropathy may be present. It is due to mutations in *TTBK2*, a gene that is widely expressed in the brain but particularly in Purkinje cells, granular cell layer, hippocampus, and midbrain, including substantia nigra. It phosphorylates tau protein and stabilizes Purkinje cells.

SPINOCEREBELLAR ATAXIA TYPE 13

SCA13 was initially observed in French and Filipino families and is due to mutations in the voltage-gated potassium channel *KCNC3*. It is present in both early-onset infantile and adult-onset forms. When onset is in infancy, it is characterized by cognitive impairment, severe cerebellar atrophy, and ataxia and motor deficits. Adult-onset cases are primarily characterized by progressive ataxia and cerebellar degeneration. Nystagmus and pyramidal features were also noted as well as, infrequently, seizures. Most adult-onset cases have mild progression.

SPINOCEREBELLAR ATAXIA TYPE 14

Initially described in a single Japanese family, individuals with early- (<27 years) and late-onset ataxia were described; those with early onset also have intermittent axial myoclonus, whereas those with late onset had pure ataxia. The gene was mapped to 19q13, and later an American family with overlapping linkage, but without any members demonstrating axial myoclonus, was reported. Mutations affect the protein kinase C gamma gene in American and Japanese families.

SPINOCEREBELLAR ATAXIA TYPES 19/22

This locus overlaps with SCA22 and was initially mapped through identification of the *KCND3* gene in a Dutch family with slowly progressive mild ataxia, nystagmus, infrequent cognitive impairment, myoclonus, sensory neuropathy, and irregular postural tremor (SCA19). Age of onset ranged from 20 to 45 years. MRI showed marked cerebellar hemispheric atrophy with mild vermian and cerebral atrophy. *KCND3* mutations are believed to cause ataxia through impairment of protein maturation and/or channel dysfunction.

SPINOCEREBELLAR ATAXIA TYPE 23

SCA23 is mapped to 20p13-p12.23 and was originally described in Dutch family. Age of onset ranged from 43 to 56 years and disease duration from 1 to 23 years. A classic pattern of gait difficulty, limb ataxia, and dysarthria was present. Neuropathology of one individual revealed pronounced Purkinje cell loss, especially in the vermis, dentate nuclei, and inferior olives. It is due to heterozygous mutation in the *PDYN* gene.

SPINOCEREBELLAR ATAXIA TYPE 27

Missense mutations in the gene encoding fibroblast growth factor 14 on chromosome 13q34 have been described in a Dutch pedigree with SCA27. Childhood-onset postural tremor and slowly progressive ataxia began in young adulthood.

SPINOCEREBELLAR ATAXIA TYPE 28

SCA28 is a slowly progressive disorder described primarily in Italian and French families. Mean age at onset is 30 years with ataxia, and there are frequent ophthalmologic features including slow saccades, ophthalmoparesis, and ptosis. It is caused by heterozygous mutation in the *AFG3L2* gene, which is hypothesized to lead to

protection of the cerebellum from degeneration and is allelic to the SPAX gene.

SPINOCEREBELLAR ATAXIA TYPE 35

SCA35 was described in two Chinese families with slowly progressive ataxia, generally affecting gait first with pyramidal signs in the legs, with onset in the 40s, and also associated with tremor, cervical dystonia, and ocular dysmetria. However, there was tremendous phenotypic variation in a third described family that included childhood onset of disease and mental retardation. SCA35 is due to missense mutations in transglutaminase 6 (TMG6).

SPINOCEREBELLAR ATAXIA TYPE 38

SCA38 is due to mutations in the ELOV5 gene, whose product is highly expressed in Purkinje cells and is involved in the synthesis of polyunsaturated fatty acids. Recently determined, missense mutations have been reported in Italian and French families. Ataxia is characterized as primarily slowly progressive cerebellar phenotype with onset in the 40s but with the majority also demonstrated mild to moderate axonal sensory neuropathy.

SPINOCEREBELLAR ATAXIA TYPES 15/16

SCA15 is characterized by late-onset slowly progressive cerebellar ataxia, action and postural tremor, dorsal column involvement, gaze impairment, overall slow progression, and vermian atrophy on MRI. It is due to a heterozygous deletion of the inositol 1,4,5,-triphosphate receptor type 1 (ITPR1) and resultant haploinsufficiency (although one missense mutation has been reported). This signaling protein

P.675

has been proposed as a unifying feature in cerebellar ataxias. The previously denoted SCA16 has now been merged with SCA15. Duplications:

SPINOCEREBELLAR ATAXIA TYPE 20

This syndrome was identified in an Australian family of Anglo-Celtic descent and is due to duplications on chromosome 11q12. Age at onset is 9 to 64 years with a mean of 47 years. Slowly progressive dysarthria and gait ataxia were typical. Most patients have a 2-Hz palatal tremor with some spread to lips and pharynx as well as dysphonia. Mild pyramidal features and hypermetric saccades are seen. MRI demonstrates dentate nucleus calcification. Two of nine individuals with imaging also had pallidal calcification and two had olivary calcification. Hence, pathology in the Mollaret triangle may account for the palatal tremor. No calcium metabolic etiology has been identified, and the syndrome differs from familial idiopathic brain calcification.

Additional Spinocerebellar Ataxias

Additional SCAs whose loci have been mapped but for which no gene has been determined include SCA4, 18, 21, 25, 26, and 30.

SPINOCEREBELLAR ATAXIA TYPE 4

SCA4 maps to chromosome 16q. The phenotype consists of lateonset (19 to 59 years) ataxia, prominent sensory axonal neuropathy, normal eye movements in most, and pyramidal tract signs and deafness in some.

SPINOCEREBELLAR ATAXIA TYPE 18

SCA18 is a syndrome of ataxia and hereditary sensorimotor neuropathy reported in an American family of Irish ancestry. Onset is usually in adolescence. All affected individuals developed gait ataxia, dysmetria, and nystagmus. This condition exemplifies the overlap between hereditary sensory neuropathies and the SCAs because sensory loss, pyramidal tract signs, and muscle weakness were also seen. In some patients, nerve

conduction studies showed sensory axonal neuropathy, and muscle biopsy revealed neurogenic atrophy. MRI demonstrated mild cerebellar atrophy. Linkage to 7q22-q32 was demonstrated.

SPINOCEREBELLAR ATAXIA TYPE 21

SCA21 is mapped to 7p15-21 and has been described in one French family. Age of onset ranged from 6 to 30 years with an average of 17 years. It is characterized by slowly progressive gait and limb ataxia and hyporeflexia, as well as parkinsonian features of akinesia, rigidity, tremor, or mild cognitive impairment.

SPINOCEREBELLAR ATAXIA TYPE 25

Localized to chromosome 2p, SCA25 was reported in a French family with ataxia and sensory neuropathy. Age at onset was 17 months to 39 years. Most patients had prominent ataxia, but some had a purely sensory neuropathy with minimal cerebellar involvement, and gastrointestinal symptoms were often present. The condition may mimic FRDA. Linkage to chromosome 2p was identified, and missense mutations affecting the potassium channel KCNC3 function have been identified, although the causative gene is not clear.

SPINOCEREBELLAR ATAXIA TYPE 26

Localized to chromosome 19p13.3, this disorder was reported in a Norwegian family. All affected members had a slowly progressive cerebellar ataxia, with age at onset ranging from 26 to 60 years and atrophy confined to the cerebellum.

SPINOCEREBELLAR ATAXIA TYPE 37

SCA37 is mapped to 1p32 and characterized by abnormal vertical eye movements.

Other Unmapped Autosomal Dominant Cerebellar Ataxias

The mapped and cloned SCA genes account for as much as 60% to 90% of ADCAs, depending on geographic region. Other loci for ADCA remain to be identified.

Genetic Testing for Autosomal Dominant Disorders

Genetic testing for a SCA is usually considered if the family history is consistent with dominant inheritance. Rarely, sporadic cases, especially SCA6 and SCA2, may be due to a SCA. Before embarking on SCA screening in a sporadic case, however, imaging and evaluation of acquired causes should be performed; if these are unrevealing, FRDA should be screened first, as this is a more likely cause than any SCA.

Consent for genetic testing is the patient's decision. Counseling is a critical part of the testing process so that patients and family members can learn the complexities of both positive and negative results. For example, comprehensive commercial ataxia testing does not screen for about 40% of genetic causes of ataxia; a negative result in these screens does not exclude genetic causation.

Molecular genetic clinical testing is now available for many of the SCAs, including DRPLA. Because testing all genes is expensive, clinicians may choose to prioritize tests on the basis of clinical features, such as retinopathy for SCA7, action tremor for SCA12, seizures for early-onset DRPLA or SCA10, and on ethnicity (see [Table 79.1](#)). However, there are often no distinguishing features to help choose the most likely SCA. Whole-panel testing may then be a reasonable alternative, or clinicians may choose a mini-panel with the most common disorders (which are also trinucleotide repeat disorders) SCA1, 2, 3, 6, and 7.

EPISODIC OR PAROXYSMAL ATAXIAS

Episodes of ataxia can be the first manifestation of metabolic disorders such as multiple carboxylase deficiencies or aminoacidurias. However, the term *episodic* or *paroxysmal ataxia* is generally applied when the major manifestations are self-limited episodes of cerebellar dysfunction with little evidence of fixed or progressive

neurologic dysfunction. Two major clinical-genetic subtypes are described: episodic ataxia with myokymia (EA1/myokymia) and episodic ataxia with nystagmus (EA2/nystagmus). Additional episodic ataxia genes have also been described but are less common than EA1 and EA2.

In EA1/myokymia, the attacks usually last a few minutes; they can occur spontaneously but are also provoked by startle, sudden movement, or change in posture and exercise (especially if the subject is excited, anxious, or fatigued). Usually, these are one or a few attacks each day. Onset is in childhood or adolescence; the disorder is not associated with neurologic deterioration, but myokymia appears around the eyes and in the hands. The Achilles tendon may be shortened and there may be a tremor of the hands. The attacks are often heralded by an aura of weightlessness or weakness; an attack comprises ataxia, dysarthria, shaking tremor,

P.676

and twitching. In some families, acetazolamide (1,000 mg/day) reduces the frequency of attacks; phenytoin and other anticonvulsants may reduce myokymia. This disorder is caused by missense point mutations in the potassium voltage-gated channel gene *KCNA1* on chromosome 12p (see [Table 79.1](#)).

EA2/nystagmus attacks last longer, usually hours or even days. Attacks are provoked by stress, exercise, fatigue, caffeine, fever, alcohol, and phenytoin. They do not generally occur more than once per day. Age at onset varies from infancy to 40 years and typically starts in childhood or adolescence. Unlike EA1/myokymia, the cerebellar syndrome may progress with increasing ataxia and dysarthria. Even when there is no progressive cerebellar syndrome, interictal nystagmus is often seen (see [Table 79.1](#)). During an attack, associated symptoms include headache, diaphoresis, nausea, vertigo, ataxia, dysarthria, tinnitus, ptosis, and ocular palsy. Acetazolamide is usually effective in reducing attacks. Most families with EA2 harbor mutations in the gene for brain-specific *CACNA1A*. In one family, the dihydropyridine-sensitive L-type calcium channel β -4 subunit was involved.

Different mutations in *CACNA1A* can also produce SCA6 or hemiplegic migraine, and some families have overlapping phenotypes. Most EA2 mutations are nonsense changes that result in truncated proteins and reduction in P/Q channel activity.

SPORADIC CEREBELLAR ATAXIA OF LATE ONSET

Many patients with ataxia beginning after age 40 years have no affected relatives. Some apparent sporadic cases with late-onset ataxia are a result of SCA mutations. Compared with ADCA, sporadic cases begin later (in the sixth decade), have a more rapid course, and are less likely to have ophthalmoplegia, amyotrophy, retinal degeneration, or optic atrophy. However, many of these patients have parkinsonism and upper motor neuron signs. Some also have autonomic dysfunction and are classified as having multisystem atrophy of the olivopontocerebellar type (MSA-C).

AUTOSOMAL RECESSIVE ATAXIAS

AR inheritance is usually suspected when siblings or cousins are affected but parents are not, in cases with parental consanguinity, or from populations with a founder mutation. Apparently, sporadic cases may also have AR inheritance.

Classification of recessive ataxias may be made on a pathogenic etiology, leading to a separation between those ataxias presumed related to (1) oxidative stress and mitochondria dysfunction, such as FRDA, ataxia with vitamin E deficiency (AVED), abetalipoproteinemia, Refsum disease, and others; (2) impaired DNA repair, such as AT, ataxia with oculomotor apraxia type 1 (AOA1) and type 2 (AOA2); (3) metabolic storage disorders (e.g., lysosomal) and others ([Table 79.2](#)); and (4) abnormal protein folding and degradation, such as autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS) and Marinesco-Sjögren syndrome (MSS). These groups also differ by phenotype: Among the disorders of mitochondrial dysfunction and oxidative stress, sensory

loss and areflexia are prominent, but little cerebellar atrophy is seen. In contrast, in the disorders of defective DNA repair, cerebellar dysfunction is the primary source of the ataxia, and oculomotor apraxia is common. Additional ataxias with different or unknown pathogenic mechanisms are listed in [Table 79.2](#) and include early-onset cerebellar ataxia with retained tendon reflexes, which is the second most common AR ataxia.

Classification

There are multiple potentially treatable forms of AR ataxia which, although uncommon, should be considered because of their potential response to dietary or other therapy. Additionally, these forms usually decline without treatment. These include any of the vitamin E-related ataxias, Refsum disease (which may be treated with a diet low in phytanic acid), other mild peroxisomal disorders (including that due to mutations in PEX10), biotinidase deficiency, cerebrotendinous xanthomatosis, possibly coenzyme 10 deficiency, and inborn errors of metabolism that may present with intermittent ataxia, including late-onset maple syrup urine disease, urea cycle defects, organic acidurias, Hartnup disease, pyruvate dehydrogenase deficiency, and glucose transporter type 1 (GLUT1) deficiency.

Epidemiology

The frequency and most common causes of AR ataxias vary with the ethnicity and geographic origin of the population studied. For example, FRDA, with a prevalence of 1 in 30,000 to 50,000 people is the most common form of hereditary ataxia in the United States and Europe but is not common in Mexico, China, and Japan. In Europe overall, ataxia with oculomotor apraxia type 2 (AOA2) is the second most frequent AR ataxia after FRDA. However, among AR ataxias in Portugal, the frequency of FRDA is 38% and AOA1 is 21%. AOA1 is the most common cause of AR ataxia in Japan. In the United States, there are few reports of AOA1 and AOA2, yet the frequency of AT is approximately 1 in 40,000 births.

Ataxias Associated with Oxidative Stress and Mitochondrial Dysfunction

Friedreich ataxia (FRDA), first described in 1863, is the most common early-onset ataxia and comprises a large proportion of the AR ataxias. The typical clinical features are juvenile onset (starting around puberty and usually by age 25 years) with progressive ataxia of gait and limbs, absent or hypoactive tendon reflexes in the legs, and extensor plantar responses. Other common features are dysarthria, corticospinal tract deficits, proprioceptive and vibratory sensory loss in the legs, and scoliosis. Approximately two-thirds have cardiomyopathy, up to 30% have diabetes mellitus with impaired glucose tolerance in another large proportion, and obstructive sleep apnea is present in about 20%. With the identification of the FRDA gene, FTX, and the ability to test a range of cases, it has become clear that there is an “atypical” phenotype as well: 25% of the cases have later age at onset, often with preserved tendon reflexes or slower course.

The prevalence of FRDA in North America and Europe is about 1 to 2 per 50,000, with a carrier frequency of about 1:60 to 1:120. Boys and girls are equally affected. Because the disorder is AR, parents are asymptomatic, and consanguinity is found in 5.6% to 28% of affected families. The risk for siblings is 25% and, in small families, only one person may be affected.

FXN maps to 9q and encodes a highly conserved, mitochondrial protein, frataxin. Ninety-six percent of FRDA patients are homozygous for an expansion of a GAA triplet repeat in the first intron of *FXN*, leading to a deficiency in the frataxin protein. About 4% are compound heterozygotes, with a GAA intronic expansion in one allele and an inactivating mutation in the other allele. Some, but not all, compound heterozygotes have milder disease.

Normal chromosomes have fewer than 34 triplets, and disease chromosomes have 66 to more than 1,700 repeats with the majority having between 600 and 1,200. Repeats in normal chromosomes

are stable when transmitted from parent to child, but expanded GAA repeats show meiotic instability, usually contracting after paternal transmission and either expanding or contracting with maternal transmission. Repeats of 34 to 65, which are rare, are termed *premutation alleles* because they may expand during parental transmission to produce causal mutations. Anticipation is generally not associated with FRDA. Alleles containing 44 to 66 GAA repeats can cause clinical but milder later onset disease, if the other allele is fully expanded to the disease range. The mechanism is thought to be somatic instability in the proportion of cells having 66 or more repeats.

TABLE 79.2 Other Hereditary Ataxias

Disorder	Gene (Mutation Type/Locus)	Gene Product	Phenotype: Age of Onset (Years, Range) Some Typical Features ^a
Autosomal Recessive Ataxias			
FRDA	<i>FXN</i> 9q13	Frataxin	Childhood to teen (infancy to 40) Hyporeflexia; proprioceptive loss; sensory loss; visual loss (optic atrophy, retinopathy); neuropathy; dysarthria; Babinski signs; cardiomyopathy; scoliosis; may be manifest by late-onset spastic paraparesis without much or any ataxia
AVED	<i>TTPA</i> 8q13.1-3	α -Tocopherol transferase protein	Childhood to teen (2-52) FRDA-like head titubation; retinitis pigmentosa; sensory neuropathy; acanthocytes
AT	<i>ATM</i> 11q22.3	Serine protein kinase ATM	Early childhood (infancy to 27) Oculocutaneous telangiectasia; immunodeficiency; elevated AFP; malignancy; oculomotor apraxia; chorea; athetosis
AOA1	<i>APTX</i> 9p13.3	Aprataxin	7 (2-16) Dysarthria; dysmetria; axonal neuropathy with areflexia; chorea; dystonia; oculomotor apraxia; low serum albumin and total cholesterol
AOA2	<i>SEXT</i> 9q34	Senataxin	15 (10-25) Sensory motor neuropathy; oculomotor apraxia; chorea; dystonia; elevated AFP; low serum albumin
ARSACS	<i>SACS</i> 13q12	Sacsin	Childhood Retinal striations; spasticity; peripheral neuropathy

IOSCA	<i>IOSCA</i> 10q24	Twinkle, Twinky	Infancy Peripheral neuropathy; chorea; optic atrophy; hearing loss
-------	-----------------------	--------------------	---

Marinesco-Sjögren	<i>MSS</i>	—	Infancy Cataracts, mental retardation, hypotonia, myopathy
-------------------	------------	---	---

Additional Autosomal Recessive Ataxias

Abetalipoproteinemia (**severe sensory neuropathy, GI biopsy**) and hypobetalipoproteinemia

Aminoacidurias

Ataxia-telangiectasia variant (ATV1)/Nijmegen breakage syndrome

Autosomal recessive cerebellar ataxia type 1 (ARCA1/SYNE related)

Biotinidase deficiency

Carboxylase deficiencies

Cerebrotendinous xanthomatosis (**cataracts**)

Ceroid lipofuscinosis

Childhood ataxia with CNS hypomyelination/vanishing white matter (CACH) (**MRI and transthyretin isoelectric focusing**)

Cockayne syndrome

Hexosaminidase deficiency

Hypoceruloplasminemia with ataxia and dysarthria (onset in 40s)

Late-onset Tay-Sachs disease

Leigh (also mitochondrial inheritance)

Leukodystrophies

Mitochondrial recessive ataxia syndrome (MIRAS)

Other recessive ataxias with hypogonadism, myoclonus, optic atrophy and mental retardation, deafness

Refsum disease

Sialidosis

Spinocerebellar ataxia with neuropathy (SCAN1) (**sensory motor neuropathy**)

Additional Autosomal Recessive Ataxias

Urea cycle defects

Wilson disease (**parkinsonism, tremor, dystonias, ceruloplasmin**)

Xeroderma pigmentosum

X-linked Ataxias

Ataxia with spasticity, mental retardation, deafness

Fragile X-associated tremor/ataxia syndrome (FXTAS)

Uncomplicated ataxia

X-linked sideroblastic anemia with ataxia

Mitochondrial Inheritance Ataxias

CoQ10 deficiency (**muscle biopsy, CoQ measurement**)

Leigh syndrome (also autosomal recessive)

Mitochondrial encephalomyopathies (MERRF, NARP, KSS)

^aAtaxia including dysarthria is common for all; onset usually before age 20 years, although some have late-onset forms; features suggesting diagnosis are bolded.

FRDA, Friedreich ataxia; AVED, ataxia with vitamin E deficiency; AT, ataxia-telangiectasia; AFP, α -fetoprotein; AOA1, ataxia with oculomotor apraxia type 1; AOA2, ataxia with oculomotor apraxia type 2; ARSACS, autosomal recessive spastic ataxia of Charlevoix-Saguenay; IOSCA, infantile-onset spinocerebellar ataxia; GI, gastrointestinal; CNS, central nervous system; MRI, magnetic resonance imaging; MERRF, myoclonus epilepsy and ragged red fibers; NARP, neuropathy, ataxia, retinitis pigmentosa; KSS, Kearns-Sayre syndrome.

The FTX expansion interferes with frataxin transcription and is associated with a great reduction of normally spliced FTX mRNA. Larger repeats more profoundly inhibit frataxin transcription and cause earlier onset and more severe symptoms. The amount of residual mRNA and thus the age at onset correlates with the shorter of the two expanded repeats. Cardiac disease and diabetes are also at increased frequency in patients with larger

repeat size (>500).

The pathology in FRDA is attributed to the deficiency of functional frataxin. Tissues with high levels of frataxin expression, such as heart, liver, skeletal muscle, pancreas, and spinal cord, are affected. Frataxin localizes to the inner mitochondrial membrane and is directly involved in regulating iron homeostasis. The absence of normal frataxin causes defects of mitochondrial oxidative phosphorylation. This ultimately leads to susceptibility to increased oxidative stress, mitochondrial iron accumulation, and lower levels of iron-sulfur proteins. Decreases in complex I to III activity and altered heme synthesis lead to reduced oxidative phosphorylation and accumulation of free radicals. Iron deposits have been demonstrated in the cardiac tissue of FRDA patients, consistent with defective responses to oxidative stress, including damage to iron-sulfur cluster respiratory enzymes.

In FRDA patients, the spinal cord may be thinner than normal. Degeneration and sclerosis are seen in the posterior columns, spinocerebellar tracts, and corticospinal tracts. Nerve cells are lost in the dorsal root ganglia and Clarke column. Peripheral nerves are involved, with fewer large myelinated axons. The brain stem, cerebellum, and cerebrum are normal except for mild degenerative changes of the pontine and medullary nuclei, optic tracts, and Purkinje cells in the cerebellum. Cardiac muscle, nerves, and ganglia are also involved.

Clinical features vary by age at onset and can be divided into early-onset FRDA, late-onset Friedreich ataxia (LOFA), and very late-onset Friedreich ataxia (VLOFA). Symptoms usually begin between ages 8 and 15 years but may start in infancy or after age 50 years. Like other triplicate repeat disorders, there is a correlation between the GAA repeat size and clinical features, particularly age at onset and rate of progression. However, the age at onset correlates with the shorter of the two alleles because FRDA, unlike other triplicate repeat disorders, is recessive (with expanded repeats in both alleles) and is a result of loss of frataxin function. The GAA size, however, does not entirely account for the variability in age at onset or clinical progression; somatic mosaicism and other genetic or environmental modifiers also play a role.

In typical early-onset FRDA, gait ataxia is the most common symptom and is usually the first. Although the gait disorder may be seen in children who have been walking normally, it is more common that children are slow to walk, the gait is clumsy and awkward, and they are less agile than other children. Within a few years, ataxia appears in the arms and trunk, a combination of cerebellar asynergia and loss of proprioceptive sense. Movements are jerky, awkward, and poorly controlled. Intention tremor, most common in the arms, may affect the trunk. Frequent repositioning or pseudoathetosis and true generalized chorea may occur. Speech becomes explosive or slurred and finally unintelligible. Dysphagia

P.679

is present in over 90%. Limb weakness is common, sometimes leading to paraplegia.

Vibratory loss is an early sign. Frequently, position sense is impaired in the legs and later in the arms. Loss of two-point discrimination, partial astereognosis, and impaired appreciation of pain, temperature, or tactile sensation are occasionally seen. Loss of leg reflexes and the presence of Babinski signs were once considered necessary for diagnosis; almost all patients with typical recessive or sporadic early-onset ataxia with these features have the *FXN* hyperexpansion.

Ocular movements are usually abnormal; fixation instability and square wave jerks are the most common abnormalities. Also frequent are jerky pursuit, ocular dysmetria, and failure of fixation suppression of the vestibular ocular reflexes. Nystagmus and optic atrophy are each seen in about 25% of patients, but severely reduced visual acuity is rare. Sensorineural hearing loss occurs in about 10%. Sphincter impairment may occur, especially when patients are bedridden; dementia and psychosis are unusual, and although motor planning is often impaired, the condition is not incompatible with a high degree of intellectual development. Worse cognition is correlated with larger GAA repeats. Skeletal abnormalities are common. Scoliosis or kyphosis, usually in the upper thoracic region, affects more than 75%. Pes cavus and equinovarus deformities occur in more than 50%.

Restless legs syndrome is reported in 30% to 50%.

Cardiac disease is found in more than 85%, with hypertrophic cardiomyopathy in two-thirds of patients. The electrocardiogram (ECG) most commonly shows ST-segment changes and T-wave inversions. Congestive heart failure occurs late and may be precipitated by atrial fibrillation. Diabetes mellitus is found in 10% to 30%.

The course is progressive, and most patients cease walking by 15 years after onset of symptoms. Life expectancy appears to be changing with more advanced management and recognition of milder phenotypes. Although older studies reported mean age at death in the mid-30s, resulting from infection or cardiac disease, in more recent studies, the average interval from symptom onset to death was 36 years.

Late-onset Friedreich Ataxia, Very Late-onset Friedreich Ataxia

With the advent of FRDA testing in large populations, it has become evident that the spectrum of FRDA includes slowly progressive disease, late-onset (after age 25 years, often with less than 500 GAA repeats), very late-onset (>40 years at onset, often with less than 300 GAA repeats), FRDA with retained reflexes (FARR), spastic paraparesis without ataxia, and FRDA without cardiomyopathy. The oldest age of onset reported is 80 years. In one study of ataxic subjects who were clinically thought not to have FRDA, 10% of those with recessive disease and 5% with sporadic disease had homozygous GAA hyperexpansions. To some extent, this variability, especially between families, is explained by the length of the GAA expansion. However, GAA expansion does not account for all the variation, particularly with repeat sizes above 500. For example, Acadian FRDA patients descend from a single founder and have the typical homozygous hyperexpansion with repeat lengths similar to those of other FRDA patients, but they have milder symptoms and cardiopathy is rare.

Clinical testing is currently available to screen for the GAA expansions, which in the homozygous form, account for 96% of cases. In cases with only a single expanded allele, further screening may identify deleterious mutations (nonsense or frameshift mutations that result in premature termination of translation or missense mutations in the highly conserved carboxy terminus) on the other allele.

Laboratory findings include characteristic ECG changes and echocardiogram evidence of concentric ventricular hypertrophy or, less commonly, asymmetric septal hypertrophy. Normal peripheral nerve conduction studies with absent or markedly reduced sensory nerve action potentials distinguish FRDA from Charcot-Marie-Tooth disease. Other common abnormalities are reduced amplitude of visual-evoked responses and small or absent somatosensory-evoked potentials recorded over the clavicle and delayed dispersed potentials at the sensory cortex. Computed tomography and MRI of the brain are usually normal in the early stages but may show cerebellar atrophy, especially with advanced or late-onset disease. Cervical spinal cord atrophy can often be detected on MRI. The cerebrospinal fluid is normal. Vitamin E levels should be assessed, as vitamin E deficiency is an important and treatable differential diagnosis and may mimic FRDA.

Specific treatment for FRDA includes physical therapy and walking aids, speech therapy, psychological support, and treatment of associated cardiac disease (cardiac arrhythmia is a major cause of death) and diabetes. Genetic counseling should be offered. No specific pharmaceutical for FRDA has yet been developed, although there is a range of studies underway.

Ataxias Related to Vitamin E Deficiency

Two forms of vitamin E-related ataxia are widely recognized, ataxia with vitamin E deficiency and abetalipoproteinemia. A third, Cayman ataxia, is likely due to the absence of binding to vitamin E-like compounds.

Ataxia with vitamin E deficiency (AVED) is an AR disorder characterized by progressive ataxia, proprioceptive loss, and areflexia. Additionally, decreased visual acuity due to retinitis pigmentosa, head titubation, Babinski sign, and dystonia may be present. Most individuals with AVED present in adolescence. AVED mimics FRDA

clinically; however, later onset, prominent titubation (28% of cases) and dystonia are more common than with FRDA.

Plasma vitamin E (α -tocopherol) is markedly reduced in the setting of a normal lipid and lipoprotein profile; as the normal range of vitamin E is very laboratory dependent, no universal normal range is given, but generally, the level is less than 4.0 $\mu\text{mol/L}$. Care should be taken in the preparation of the sample, as oxidation in room air may invalidate the results. Malabsorption can be excluded by normal vitamin A and D levels.

Deleterious mutations are found in the α -tocopherol transfer protein (*TTPA*) gene, which maps to chromosome 8q13. Mutation leads to impaired incorporation of α -tocopherol into very low-density lipoprotein (VLDL), which is needed for the efficient recycling of vitamin E. A milder phenotype, including retained reflexes and later onset, may occur with missense mutations that allow some residual TTP activity.

Treatment is with lifelong large-dose oral vitamin E replacement. It is believed that early treatment is associated with better outcome. Siblings should be evaluated for vitamin E deficiency, as presymptomatic treatment may prevent development of symptoms.

Abetalipoproteinemia (Bassen-Kornzweig) and cholestatic liver disease are also associated with vitamin E deficiency. In contrast to AVED, there is often malabsorption, and there are acanthocytes on peripheral smear.

Mitochondrial-Associated Ataxias

Nuclear mutations that encode mitochondrial proteins and mutations in mitochondrial-encoded proteins may also cause ataxia. Other ataxias such as Refsum disease may have mechanisms postulated to impair mitochondrial function.

P.680

Mitochondrial recessive ataxias include SANDO (sensory-ataxic neuropathy, dysarthria, and ophthalmoparesis) and *infantile-onset spinocerebellar ataxia* (IOSCA) and are due to mutations in genes for the nuclear-encoded mitochondrial enzymes DNA-polymerase gamma (POLG) and the mitochondrial helicase twinkle (*c10orf2*), respectively. IOSCA is a rare infantile-onset AR disorder, which was first mapped to chromosome 10q24 in Finnish families. Affected children develop ataxia, athetosis, and loss of tendon reflexes before age 2 years. This is followed by hypotonia, optic atrophy, ophthalmoplegia, deafness, and sensory neuropathy. Missense mutations in POLG cause predominantly sensory axonal neuropathy and ataxia, which is juvenile or adult in onset. There may be associated myoclonus, epilepsy, ophthalmoparesis, cognitive decline, cardiomyopathy, or liver failure.

Mitochondrial disorders due to mutations of the mitochondrial genome also account for progressive ataxia, particularly in children. Mitochondrial encephalomyopathy with ragged red fibers (MERRF) is characterized by ataxia, myoclonus, seizures, myopathy, and hearing loss. Maternal relatives may be asymptomatic or have partial syndromes, including a characteristic “horse collar” distribution of lipomas. Other mitochondrially inherited disorders, including coenzyme Q10 (CoQ10) deficiency; neurogenic muscle weakness, ataxia, and retinitis pigmentosa (NARP); Kearns-Sayre syndrome (KSS); and Leigh syndrome are described in Chapter 139.

Refsum disease is a childhood-onset ataxia syndrome characterized by sensory loss, areflexia, and absence of cerebellar atrophy. Other features include anosmia, early-onset retinitis pigmentosa with variable combinations of neuropathy, deafness, and ichthyosis. Mutations in the *PHYH* and *PEX7* genes cause changes in the phytanoyl-coenzyme A hydroxylase, and peroxisomal biogenesis factor-7 proteins, respectively. These lead to accumulation of phytanic acid and disturbance of peroxisomal function and mitochondrial dysfunction. This may be treated in part with a diet low in phytanic acid.

Ataxia-Telangiectasia and Other Ataxias Associated with Defective DNA Repair

Among AR ataxias, several have prominent oculomotor apraxia and are associated with impaired DNA repair. These encompass AT, where cerebellar degeneration is the most prominent feature, as well as ataxia with oculomotor apraxia, AOA1 and AOA2. These differ from FRDA and AVED, where the posterior columns and the spinocerebellar tracts are the major sites of degeneration, and the cerebellum is not primarily involved. Other AR ataxias associated with DNA repair malfunction, ataxia-like disorder (ATLD), spinocerebellar ataxia with axonal neuropathy (SCAN1), Cockayne syndrome, and xeroderma pigmentosum will also be briefly discussed.

Although AT, AOA1, and AOA2 are also childhood-onset disorders with prominent ataxia-like FRDA, they generally differ from FRDA in several ways: (1) There is prominent oculomotor apraxia in all three conditions but not in FRDA; (2) movement disorders—particularly dystonia and chorea—are frequent in these syndromes and less common in FRDA; and (3) cerebellar abnormalities are prominent, whereas in FRDA, MRI shows only mild cerebellar atrophy until late in the course of disease. Further, upper motor neuron features are uncommon in these conditions, except rarely in AOA1 and AOA2, whereas these are more frequent in FRDA. These conditions are also associated with abnormalities in α -fetoprotein (AFP) (increased in AT and AOA2), Igs (decreased in AT, may be increased in AOA2), carcinoembryonic antigen (CEA) (increased in AT), and albumin (decreased in AOA1).

Ataxia-telangiectasia is an early-onset AR ataxia that affects multiple body systems but whose hallmark feature is cerebellar degeneration. It is due to loss of function of the nuclear protein kinase, ataxia-telangiectasia mutated (ATM), which mediates the cellular repair response to double-stranded (DS) DNA breaks.

AT is characterized by progressive cerebellar ataxia starting at ages 1 to 4 years, oculomotor apraxia, and dysarthria. Later onset is uncommon, although cases with onset in early adulthood have been described. Although clinical symptoms and signs may vary, truncal ataxia in infancy, which becomes more obvious when the child learns to walk, is typical. With progression, the ataxia becomes more appendicular as well. Prominent oculomotor abnormalities include difficulty generating saccades, dependence on head thrusts to fixate, ocular dysmetria, and nystagmus. Facial hypomimia, chorea, dystonia, drooling, dysarthria, myoclonus, and peripheral neuropathy may appear in later childhood or in adolescence. Most AT patients require a wheelchair by their teens. Mild mental retardation has been reported in some cases.

Nonneurologic symptoms usually also appear. Cutaneous telangiectasias are characteristic but are not always present and generally do not appear in the first years of life; hence, they may come after the first neurologic symptoms. Telangiectasias involve the conjunctivae, face, ears, and flexor creases. Growth retardation and delayed sexual development may occur. Immune dysfunction is typical and includes recurrent respiratory and cutaneous infections, lymphopenia, and decreased concentrations of IgA and IgG. There may be progeria and premature graying. About 38% of patients develop malignancies, most frequently leukemia or lymphoma at a young age and epithelial malignancies at a later age. Increased sensitivity to ionizing radiation is a characteristic feature. The rate of cancer in heterozygote carriers is also increased.

The disease is progressive; with supportive care, most patients now live beyond age 20 years, and some live to the fifth or sixth decade. Ten percent to 15% of cases in a United Kingdom sample were noted to have a milder phenotype with later onset and slower course of neurologic deterioration. Therefore, AT may infrequently account for later onset progressive ataxia. Milder phenotypes with late onset or less progressive disease are generally attributable to mutations that permit some residual ATM kinase activity. However, cases with late-onset and absent protein have been reported, suggesting that genetic modifiers may also play a role in affecting the neurologic phenotype of AT. More slowly progressive “variant AT” with preservation of gait but prominent dystonia, myoclonus, and chorea has also been reported.

The gene *ATM* maps to chromosome 11 (see [Table 79.2](#)) and encodes the protein kinase ATM, a serine/threonine kinase that affects multiple substrates. Classic AT is usually caused by compound

heterozygosity or homozygosity for null *ATM* alleles that truncate or severely destabilize the ATM protein. Most mutations are truncating or splice mutations, and approximately 10% are missense mutations that inactivate the protein. Mutations may occur throughout the gene. "Leaky" splice mutations or presumed promoter deficits, associated with residual functional ATM protein, are usually associated with a milder phenotype and may contribute to some but not all of the phenotypic variability. ATM is a key regulator of multiple signaling cascades that respond to DSDNA breaks induced by damaging agents or by normal processes, such as meiotic recombination. The altered responses involve failure to activate cell checkpoints and repair DNA at G1, S, and G2/M. Molecular studies suggest that ATM is quickly engaged after DSDNA breaks are detected, and it phosphorylates multiple substrates involved in the response to DNA damage. The MRE11-RAD50-NBS1 (MRN) complex is one of the

P.681

initial sensors that detects the breaks and hence triggers ATM and the DNA repair response.

Insults that may cause DNA breaks are varied, including environmental triggers of ionizing and nonionizing radiation and radiomimetic chemicals, but it has also been hypothesized that the endogenous oxidative stress associated with the high metabolic demands of neurons may contribute to DNA damage and subsequent cell death in ATM-deficient neurons.

Mutations in the MRE11 nuclease, which is the first part of the MRN complex, may cause AT-like disease, and mutations in the NBS1 component of the MRN complex are associated with Nijmegen breakage syndrome (see later in the text).

Pathologically, loss of Purkinje cells is seen in the cerebellum with less prominent changes in the granule cell layer, dentate and inferior olivary nuclei, ventral horns, and spinal ganglia. MRI demonstrates cerebellar atrophy. Other laboratory abnormalities include elevated AFP (observed in <95% of patients), elevated CEA, decreased serum concentrations of IgA, IgE, and IgG2 (with normal to increased IgM), cytogenetic abnormalities including a 7;14 reciprocal chromosome translocation, decreased or absent ATM protein on immunoblotting, abnormal sensitivity to ionizing radiation and radiomimetic chemicals, and mutations in the ATM gene.

One percent of the population is heterozygous for an ATM mutation. As noted, there is genetic heterogeneity that contributes to AT. Population screening for the mutation is difficult because the gene is large and there are many different mutations; however, among different ethnic groups, founder effects lead to a small number of alleles accounting for most causal mutations and facilitates molecular genetic testing in those groups. In other individuals, which constitute the majority of patients, clinical functional assays for putative ATM problems are performed prior to mutation screening. After establishment of cell lines, immunoblotting for ATM protein can determine whether any or trace ATM protein is present. An assessment of protein levels may be difficult to quantify, so colony survival assay (CSA) is usually performed in addition. The CSA is a radiosensitivity assay performed on cultured cells, which assesses lymphoblastoid survival after irradiation. Although no treatment is curative, supportive treatment including caution about doses of ionizing radiation used, physical therapy, monitoring for malignancy and treatment of infection, and genetic counseling is beneficial. Multiple therapies are currently under investigation.

Ataxia-Telangiectasia-Like Disorders

SYNDROMES WITH ABNORMALITIES IN THE MRE11-RAD50-NBS1 COMPLEX

Ataxia-telangiectasia-like disorders (ATLD) resembles mild AT in that it is associated with later age of onset and a milder clinical course of disease. ATLD is caused by hypomorphic mutations in the MRE11 gene, which is part of the MRN complex described in the earlier text. ATLD patients have normal ATM levels but decreased amounts of the MRE11 protein.

Although *Nijmegen breakage syndrome*, also known as *AT variant 1*, is due to a deficiency in another part of the MRN complex, its neurologic manifestations are very different from AT, with microcephaly and mental retardation but not ataxia, ocular apraxia, or telangiectasia. Interestingly, the cellular manifestations mimic that of AT, with radiosensitivity and chromosome 7;14 translocations.

There are several AR ataxias presumed due to deficiencies in single-strand DNA (SSDNA) repair. Unlike AT and disorders of DSDNA repair, these do not appear to be associated with predisposition to cancer and, hence, are felt to attack primarily nondividing cells.

ATAXIA WITH OCULOMOTOR APRAXIA 1

AOA resembles AT and can be divided into two subtypes, AOA1 and AOA2. AOA1, also known as *hereditary motor and sensory neuropathy associated with cerebellar atrophy* (HMSNCA) and as earlyonset ataxia with oculomotor apraxia and hypoalbuminemia, is characterized by slowly progressive childhood-onset ataxia with subsequent oculomotor apraxia and a severe axonal motor neuropathy. The mean age at onset is 4 to 7 years and typically ranges from 2 to 16 years. The disease begins with gait instability, which is followed by dysarthria and appendicular ataxia and tremor. The oculomotor apraxia presents with limitation of ocular movements on command, abnormal fixation and head movement which precede eye contraversion, and hypometric saccades. This usually progresses to external ophthalmoplegia with vertical gaze lost first. The neuropathy begins with generalized areflexia and then proceeds to weakness followed by quadriplegia, wasting, and loss of ambulation. Usually, hands and feet are short and atrophic, and pes cavus is present in approximately 30%. Chorea is very common (approximately 80% of cases) and often regresses. Arm dystonia is present in approximately 50% of cases. Although cognition is normal in some, in others, there may be late cognitive decline. This has been described as a dysexecutive syndrome due to frontocerebellar pathway dysfunction. Although most patients are no longer ambulatory after 11 years of disease, some patients have had the disease as long as 20 years before needing a wheelchair. There are also occasional late-onset cases beginning at 28 and 29 years. There is generally a long life span, with survival to age 71 years.

Pathologically, there is cerebellar atrophy with marked significant Purkinje cell loss and posterior column and spinocerebellar tract degeneration as well as axonal neuropathy with marked loss of myelinated fibers. Hypoalbuminemia is present in 83% of individuals who have had the disease more than 10 to 15 years, and hypercholesterolemia is present in 70% of patients with disease of this duration. Milder forms with later age of onset, without apraxia and hypoalbuminemia and with pyramidal features, have been described. Diagnosis is based on MRI findings that demonstrate cerebellar atrophy in all and electromyogram (EMG)/nerve conduction (NC) studies that show axonal neuropathy, clinical features, and the exclusion of FRDA, AT, and AVED. In contrast to AT, AFP levels are normal.

The causative gene, *APTX*, encodes aprataxin, which may play a role in the repair of SSDNA. SSDNA breaks are believed to be common and elicited by endogenous processes, occurring as metabolic intermediates or as sequelae of oxidative stress. Aprataxin is a nuclear protein that catalyzes the hydrolysis of adenylate groups from 5' phosphate termini at nicks and gaps of SSDNA, thereby helping repair breaks. Unlike AT, the symptomatology is limited to the nervous system. Although the cells are not radiosensitive using the CSA for AT, they are sensitive to agents associated with SSDNA breaks, such as hydrogen peroxide. Most individuals have homozygous truncating mutations, although missense mutations have been reported, and these may be associated with later onset.

ATAXIA WITH OCULOMOTOR APRAXIA 2

A second form of AOA, AOA2 is associated with elevated AFP, like AT, but the increases are moderate (fivefold) compared with AT (10-fold increase). Symptoms of ataxia begin with gait imbalance and onset at a later age than AT and AOA1 (usually between 11 and 22 years, with mean age of onset of 15.6 years and a range of 3 to 30

years) and are the prominent cause of early disability. Oculomotor apraxia occurs frequently (approximately 47% of individuals) but less often than AOA1. Movement disorders, particularly

P.682

arm dystonia, chorea, and head or arm tremor, are common, with dystonia or chorea in 40%. Unlike AOA1, these are less likely to regress. Later, axonal sensory neuropathy with pes cavus is frequent, occurring in over 90% of cases. It is usually moderate in severity, leading to less disability than in AOA1 but nonetheless affects function. No extraneurologic features except early menopause have been reported.

Elevated AFP is present in over 90% of cases. Serum cholesterol is elevated in approximately 50% of cases. Serum creatine kinase may be elevated, and increased IgG and IgA have been reported in some families. In contrast to AT, ATM protein levels are normal. MRI demonstrates marked cerebellar atrophy. EMG/NC show axonal sensorimotor neuropathy. Sural nerve biopsy demonstrates axonal neuropathy with preferential loss of large myelinated fibers. Cerebellar atrophy is most prominent in the vermis and anterior lobe and with gracile and cuneate demyelination.

AOA2 is secondary to mutations in the gene encoding senataxin, an ortholog of yeast RNA helicase. ALS4 (amyotrophic lateral sclerosis 4) is also due to mutations in *SETX*. The disease is attributed to faulty repair in SSDNA breaks.

SPINOCEREBELLAR ATAXIA WITH AXONAL NEUROPATHY

SCAN1 clinically mimics FRDA, with ataxia, axonal sensorimotor polyneuropathy, distal atrophy, and pes cavus. SCAN1 differs from other DNA repair disorders in that it is not associated with oculomotor apraxia. It was first reported in a Saudi Arabian family and is characterized by prominent ataxia and peripheral axonal and sensory neuropathy resembling Charcot-Marie-Tooth. Symptoms usually begin in the second decade (13 to 15 years) with slowly progressive cerebellar ataxia with gait imbalance. Subsequently, nystagmus and dysarthria develop. These are followed by areflexia and sensory loss, with pain and touch involved initially, and later loss of vibratory sense ensues. Steppage gait develops, and most patients become wheelchair dependent. Mild hypoalbuminemia and mild hypercholesterolemia may occur. Like AOA1, pathology is limited to the nervous system, and there is no associated cancer predisposition. SCAN1 is caused by homozygous mutation in the *TDP1* gene, which is integral for TDP1 function to remove DNA-bound topoisomerase 1 and is important in SSDNA repair.

Finally, other AR ataxias which are associated with DNA repair include Cockayne syndrome and xeroderma pigmentosum.

Other Autosomal Recessive Ataxias

Autosomal recessive cerebellar ataxia 1 (ARCA1), described in a French Canadian cohort, is characterized by dysarthria, cerebellar atrophy, slow saccades in approximately 30%, and brisk reflexes. Age of onset is older than most AR ataxias, with mean age of 30 years (range 17 to 46 years), and it has slow progression. It is due to mutations in the *SYNE* gene, which encodes synaptic nuclear envelope protein, believed responsible for cytoskeleton integrity, and which may alter glutamate signaling.

ARSACS is phenotypically similar to the hereditary spastic paraplegias. *ARSACS* is an early childhood-onset disorder (12 to 18 months) characterized by ataxia, spasticity, dysarthria, distal muscle wasting, distal sensorimotor neuropathy mainly in the legs, and horizontal gaze nystagmus. Yellow streaks of hypermyelination, known as *retinal striations*, are noted in Quebec-born patients. Although initially described in eastern Canada, families in Japan, Italy, and Tunisia have now been reported, and the gene may be responsible for more cases of childhood-onset ataxia than previously recognized. The gene encodes a novel protein, saccin, which is similar to heat shock chaperone proteins, and although its function is not well understood, it may play a role in chaperonemediated protein folding.

Another early-onset recessive ataxia is the *Marinesco-Sjögren syndrome*, characterized by infantile onset, ataxia, bilateral cataracts, mental retardation, and short stature. It is due to mutations in *SIL1* encoding the SIL1 protein, which leads to disturbed chaperone dysfunction and disturbed protein folding. Other rare AR conditions include ataxia with pigmentary retinopathy, ataxia with deafness, and ataxia with hypogonadism.

The *Ramsay Hunt syndrome* is an etiologically heterogeneous syndrome characterized by myoclonus and progressive ataxia. It is most commonly a result of the mitochondrial syndrome MERRF.

The AR disorder Unverricht-Lundborg disease, or progressive myoclonus epilepsy (PME) type 1, which maps to chromosome 21q, may also cause Ramsay Hunt syndrome. The PME type 1 gene encodes cystatin B, which acts within cells to block the action of cathepsins, proteases that degrade other cell proteins.

Additional etiologies of AR ataxias are listed in [Table 79.2](#).

X-linked Hereditary Ataxias

X-linked inherited ataxias are rare except for the FXTAS associated with premutation expansions (55 to 200 CGG repeats) in the fragile X mental retardation gene (*FMR1*), which causes fragile X syndrome in the full mutation range (>200 repeats). This late-onset disorder of adult male carriers of premutation alleles has the core features of ataxia and intention or postural tremor. Additionally, there may be short-term memory loss, executive functional deficits, parkinsonism, peripheral neuropathy, proximal leg weakness, and autonomic dysfunction. Patients present after the age of 50 years, with a mean age of 60 years. MRI for most patients shows increased T2 signal at the middle cerebellar peduncles (MCP sign). Cerebral and cerebellar atrophy as well as increased T2 signal in deep and subependymal white matter may also be seen. Intranuclear, neuronal, and astrocytic inclusions are present in the brain and brain stem.

Penetrance is age related with 75% of male carriers older than 80 years expressing signs. Penetrance in female carriers is much lower, with infrequent cases of neurologic dysfunction, although there is a high rate of premature ovarian failure. The frequency of premutation carriers is 1:259 in women and 1:813 in men. Because of the high prevalence, it has been suggested that FXTAS may be one of the leading causes of neurodegenerative disease in men. However, the phenotype appears one of primarily ataxia plus the other features rather than with parkinsonism or tremor as the predominant early feature.

Rare syndromes of pure ataxia and spastic paraparesis with ataxia beginning in childhood, adolescence, or early adult years have an X-linked recessive pattern. An infant-onset X-linked form includes ataxia, deafness, optic atrophy, and hypotonia. X-linked sideroblastic anemia and ataxia is due to a mutation in *ABC7*, a mitochondrial iron transport protein. It may result in a nonprogressive or slowly progressive ataxia in boys, and anemia may be asymptomatic.

Diagnostic Evaluation of Early-onset Recessive Ataxia

The diagnostic workup of a patient with early-onset recessive ataxia depends on the constellation of clinical features in the family. If FRDA genetic testing is negative, other causes of sporadic or recessive ataxia need to be considered (see [Table 79.2](#)). Peripheral blood evaluation includes assessment of vitamin E, AFP, hexosaminidase A, very long-chain fatty acids and lipids, Igs, lactate and pyruvate, ceruloplasmin, and thyroid function. Additional studies including screens for amino and organic acids, biotinidase,

ammonia level, phytanic acid, electron microscopy (EM) for curvilinear bodies, and mitochondrial mutation screening may be indicated depending on clinical features. EMG/NC studies may help delineate the presence of a peripheral neuropathy and distinguish axonal from demyelinating neuropathy. Ophthalmologic evaluation may assist in diagnosis of retinitis pigmentosa, cataracts, and cherry-red spots. Depending on clinical features, skin or muscle biopsy may be warranted, for example targeting Niemann-Pick disease, type C (NPC), CoQ10

deficiency, and mitochondrial disorders. Finally, clinical molecular genetic testing is also available for AVED, abetalipoproteinemia, Refsum, AT, AOA1 and AOA2, POLG, and SACS, as well as the ADCA, which can occasionally present as sporadic or recessive disease.

OVERALL TESTING CONSIDERATIONS

Recommendations regarding testing include exclusion of acquired causes as noted earlier and focus depending on ethnicity, type of family history (dominant appearing, if parent-child inheritance, or recessive appearing if siblings only), age at onset of ataxia, and phenotype, especially features in addition to ataxia. Differences in ethnic groups, which are primarily due to founder mutations, are delineated in the suggested readings and may suggest prioritizing for particular genetic etiologies. Further, although some features strongly suggest certain etiologies, such as maculopathy in SCA7 and with prominent features described in [Tables 79.1](#) and [79.2](#), there is tremendous overlap, and molecular genetic testing is often required for diagnosis. Clinical molecular genetic testing is available for the ADCAs for SCA1, SCA2, SCA3, SCA5, SCA6, SCA7, SCA8, SCA10, SCA11, SCA12, SCA13, SCA14, SCA17, and DRPLA; for the episodic ataxias: EA1, EA2, and EA5; and the AR ataxias: AT, FRDA, AOA1, AOA2, MSS, AVED, FXTAS, and ARSACS.

If there is a positive dominant-appearing family history, in general, screening should be considered for the more common ADCAs, SCA1, 2, 3, 6, and 7 and in those of Asian descent, DRPLA as well. For recessive-appearing family history, focus first on Friedreich, then ataxiatelangiectasia, ataxia due to vitamin E deficiency, mitochondrial etiology including POLG and ataxia with oculomotor apraxia (AOA) types 1 and 2, and ARSACS. With onset older than age 45 years, screening for fragile X mental retardation 1 FMR1 premutations should be considered (see also [Chapter 34](#), Genetic Testing and DNA Diagnosis).

TREATMENT OF HEREDITARY ATAXIAS

Treatment of hereditary ataxias is focused on (1) treatment of identified deficits, such as vitamin E and biotin in AVED and biotinidase deficiency, and dietary restriction, such as of phytanic acid in Refsum; (2) supportive therapies for ataxia as well as comorbid features of a syndrome, such as lioresal for spasticity or botulinum toxin therapy for dystonia; (3) genetic counseling; (4) avoidance of toxins in certain conditions, such as unnecessary ionizing radiation in AT; and (5) pharmacotherapeutics directed to the ataxia, which are generally limited thus far.

Supportive therapies vary depending on the disorder but often include proper aids for mobility such as canes/walkers or wheelchairs as needed, ramps for wheelchairs, grab bars for safety, and weighted eating utensils. Physical therapy and occupational therapy may improve quality of life. In FRDA, orthopedic procedures are indicated for the relief of foot deformity. Speech and swallowing evaluations and therapy are usually indicated, including communication devices when needed. Additional supportive therapy includes treatment of conditions which may accompany the ataxia, including spasticity, movement disorders, bladder issues, depression, and pain. For example, levodopa may bring symptomatic relief of the parkinsonian features of rigidity, tremor, and bradykinesia; Lioresal or tizanidine may help spasticity. Doses are those used for respective treatment of parkinsonism and spasticity.

No specific pharmacologic treatments definitively benefit the hereditary ataxias. Symptomatic relief may occur for both riluzole (100 mg/day) and amantadine (300 mg/day), although level of evidence is not high (level B for riluzole and level C for amantadine). For FRDA, it has been suggested that antioxidant therapies may slow progression, especially cardiac manifestations, and, as noted, promising therapies are emerging but are not yet proven. Thus far, idebenone has not been demonstrated helpful. Varenicline (2 mg/day) may benefit SCA3 (level B evidence). Acetazolamide (1,000 mg/day) can control the attacks of the episodic paroxysmal cerebellar ataxias (EA1 and EA2), and phenytoin (200 mg/day) ameliorates the facial and hand myokymia associated with EA1. We can hope for novel specific therapies based on our increasing knowledge of the molecular mechanisms underlying the hereditary ataxias.

Videos can be found in the companion e-book edition. For a full list of video legends, please see the front matter.

Tardive Dyskinesia and Other Neuroleptic-Induced Syndromes

Un Jung Kang

Robert E. Burke

Stanley Fahn

INTRODUCTION

Antipsychotic drugs are commonly called *neuroleptics* because they often induce parkinsonism. They also cause other movement and sensory disorders, such as akathisia, acute dystonic reactions, neuroleptic malignant syndrome, and tardive dyskinesia syndromes, which are the most feared because they are persistent even after the offending drugs are discontinued (Table 80.1). The common pathophysiologic mechanism of neuroleptics is binding to and antagonizing dopamine D2 receptors. The dopamine receptor-blocking agents (DRBAs) are used not only as antipsychotic agents (e.g., the phenothiazines and the butyrophenones) but also for the treatment of gastrointestinal disorders (e.g., metoclopramide). Tardive and other neuroleptic-induced disorders are iatrogenic, and hence, the prescribing physician bears primary responsibility for causing these disorders. The physician to whom affected patients seek a consultation has the responsibility to make the diagnosis and institute appropriate treatment.

EPIDEMIOLOGY

The neuroleptic-induced neurologic complications are often referred to as *extrapyramidal syndromes* (EPS). Their prevalence ranges from 20% to 50% of exposed. Drug-induced parkinsonism is the most common form. Acute dystonic reactions occur in about 2% to 5% of patients, more commonly in younger patients and in males than females. Tardive syndromes may occur in about one-third of patients exposed to these drugs. Classic tardive dyskinesia is most common and estimates of prevalence range widely but mostly from 15% to 30% with an annual incidence rate of about 5% in the first 4 to 5 years. Prevalence and incidence increase with age; it is more severe among elderly women and more likely to occur with longer duration of exposure to antipsychotic drugs. Tardive dystonia is more rare than the classic type and is more common in younger patients. Other tardive syndromes, including tardive akathisia, account for about 10% of all tardive syndromes.

TABLE 80.1 Adverse Neurologic Effects of D2 Receptor-Blocking Agents

Extrapyramidal Syndromes

Acute dystonic reaction

Oculogyric crisis

Acute akathisia

Drug-induced parkinsonism

Neuroleptic malignant syndrome

Tardive Dyskinesia Syndromes

Withdrawal emergent syndrome

Classic orobuccolingual dyskinesia (some use tardive dyskinesia to refer to the classic type)

Tardive dystonia

Tardive akathisia

Tardive tics

Tardive myoclonus

Tardive tremor

PATHOBIOLOGY

The pathogenesis of the tardive dyskinesia syndromes is not well understood. Dopamine receptor supersensitivity occurs with these agents, but other drugs that induce similar supersensitivity, such as dopamine-depleting drugs (e.g., reserpine and tetrabenazine), do not cause tardive dyskinesia. The DRBAs that bind most tightly to the receptors are the ones most likely to induce tardive dyskinesia. To explain its delayed onset and persistence, maladaptive synaptic plasticity has been proposed as an underlying mechanism. Others proposed a neurodegenerative process triggered by oxidative stress or by the drugs binding to neuromelanin with resulting internalization of the cell membrane, but all these hypotheses remain to be validated. Genetic polymorphism studies have noted association of variations of monoamine receptors or metabolism genes with tardive dyskinesia, but these findings have not been consistently replicated.

So-called atypical neuroleptics (also called *second-generation antipsychotics*) have been developed and were initially thought to reduce the incidence of the various movement disorders, but subsequent studies have noted similar incidence of these complications from both second- and first-generation antipsychotics. Some second-generation antipsychotics, however, are definitely atypical in that they have less propensity to produce these movement disorders. Clozapine (Clozaril), a drug that predominantly blocks the D4 receptor and serotonin receptor subtypes, is free of these complications, except for acute akathisia. Quetiapine is also relatively free from the adverse effects listed earlier. The dopamine-depleting drugs, reserpine and tetrabenazine, can induce acute akathisia and drug-induced parkinsonism. Tetrabenazine has also been implicated in acute dystonic reactions and neuroleptic malignant syndrome. But neither drug has been convincingly implicated in causing persistent dyskinesias. In addition, calcium channel blockers, such as flunarizine and cinnarizine, and rarely selective serotonin reuptake inhibitors and lithium can produce parkinsonism and tardive syndromes, and the mechanism by which these drugs produce these complications is not known.

CLINICAL MANIFESTATIONS

It is important to recognize the different phenomenologies caused by the DRBAs; each requires specific treatment.

affect children and young adults, males more than females. Severe sustained twisting and uncomfortable postures of limbs, trunk, neck, tongue, and face are dramatic. *Oculogyric crisis* is a form of dystonia in which the eyes are deviated conjugately in a fixed posture for minutes or hours. *Acute akathisia* occurs within the first few days or weeks of drug use. It may also appear later in treatment when dosage is being increased. Akathisia consists of a *subjective* sense of restlessness or aversion to being still and is associated with *motor* features of restlessness.

These include frequent and repetitive stereotyped movements, such as pacing, repeatedly caressing the scalp, or crossing and uncrossing the legs. It can occur in subjects of any age. *Drug-induced parkinsonism* resembles idiopathic parkinsonism in manifesting all the cardinal signs of parkinsonism, including tremor.

The *neuroleptic malignant syndrome* is characterized by a triad of fever, signs of autonomic dysfunction (e.g., pallor, diaphoresis, blood pressure (BP) instability, tachycardia, pulmonary congestion, tachypnea), and a movement disorder (usually akinesia and rigidity). The level of consciousness may be depressed, eventually leading to stupor or coma; death may occur.

The *withdrawal emergent syndrome* may be a mild variant of tardive dyskinesia. “Emergent” implies that the symptoms emerge after abrupt cessation of the chronic use of an antipsychotic drug. The syndrome is primarily one of children, and it persists only for a few weeks before dissipating. The abnormal movements resemble those of Sydenham chorea; they are not stereotyped and repetitive, as seen in classic tardive dyskinesia.

The *persistent dyskinesia syndromes* are the most feared complications of antipsychotic medications because the symptoms are long-lasting and often permanent. *Classic tardive dyskinesia* consists of repetitive (stereotypic) movements. The lower part of the face is most often involved. This orobuccolingual dyskinesia resembles continual chewing movements, with the tongue intermittently darting out of the mouth (Video 80.1). Movements of the trunk may cause a repetitive pattern of flexion and extension (body rocking). The distal parts of the limbs may show incessant flexion-extension movements. The proximal muscles are usually spared, but respiratory dyskinesias may occur. If not accompanied by akathisia or dystonia, the patient may not be aware of the dyskinesia.

Several other important forms of tardive dyskinesia syndrome are now recognized. Unlike the classic oral dyskinesia described earlier, these other forms are frequently quite disabling. *Tardive dystonia* is a chronic dystonia caused by DRBAs (Video 80.2). Individuals of all ages are susceptible to tardive dystonia, and younger individuals are more likely to have a more severe generalized form. In older individuals, tardive dystonia is usually focal (affecting a single body part), often in the face or neck, and may remain confined to these regions or may spread to the arms and trunk. The legs are infrequently affected. Often, neck involvement consists of retrocollis and the trunk arches backward. The arms are typically rotated internally, the elbows extended, and the wrists flexed. The differential diagnosis includes all of the many causes of dystonia. Wilson disease, in particular, must be excluded specifically in any patient with psychiatric symptoms and dystonia.

Tardive akathisia is another important disabling variant of tardive dyskinesia. It is a chronic akathisia consisting of a subjective aversion to being still. Motor signs of restlessness include frequent, repeated, stereotyped movements, such as marching in place, crossing and uncrossing the legs, and repetitively rubbing the face or hair with the hand (Video 80.3). Patients may make moaning sounds. Patients may not use the word “restless” to describe their symptoms; instead, they may use expressions such as “going to jump out of my skin” or “jittery” or “exploding inside.” Akathisia can be expressed as focal discomfort, such as pain. It can be an exceedingly distressing symptom. In contrast to acute akathisia, the delayed type tends to become worse when antipsychotic medication is withdrawn, similar to the worsening of classic tardive dyskinesia on discontinuance of these drugs. As with other types of tardive dyskinesia syndrome, tardive akathisia tends to persist. Usually, tardive akathisia is associated with classic oral dyskinesia. Classic tardive dyskinesia, tardive dystonia, and tardive akathisia may

occur together. Less common variants of tardive dyskinesia include *tardive tics*, *tardive myoclonus*, and *tardive tremor*.

DIAGNOSIS

The diagnosis of tardive dyskinesia syndrome depends on the recognition of a typical pattern of abnormal involuntary movements or sensory symptoms plus documented use of the offending agents as discussed earlier. The symptoms should have either started while the patient was still taking the drug or within 3 months of discontinuing the drug.

[Table 80.2](#) lists movement disorders affecting the face. Huntington disease causing chorea and oromandibular dystonia are the major differential diagnoses of the oral dyskinesias. Oromandibular dystonia is probably the most common form of spontaneous oral dyskinesia. Clinical features differentiating these disorders from classic tardive dyskinesia are presented in [Table 80.3](#). Patients with Huntington disease are frequently treated with antipsychotic drugs; a resulting tardive dyskinesia may be superimposed on the chorea; the presence of akathisia or repetitive (stereotyped) involuntary movements suggests the additional diagnosis of tardive dyskinesia. Often, oromandibular dystonia takes the appearance of a repetitive opening and closing of the jaw as the patient attempts to overcome the muscle pulling. To discern if the repetitive movements are volitional or spontaneous, the examiner should ask the patient not to fight the movements but to let them come out as they want to. In dystonia, there will usually be a sustained contraction, such as jaw opening or clenching.

The diagnosis of drug-induced parkinsonism is based on the cardinal features of tremor at rest, bradykinesia, and rigidity, plus the history of current or recent discontinuation of a neuroleptic drug. In acute dystonic reactions, the features are sustained, twisting movements and postures of the cranial, cervical, and other body parts, plus the history of recent exposure to a DRBA. In neuroleptic malignant syndrome, the patient is usually rigid, obtunded, confused, and febrile, plus the history of recent exposure to a DRBA. Akathisia includes a sensory complaint, so the diagnosis depends on a description by the patient, plus the history of recent exposure to a DRBA. The most characteristic complaint is the inability to sit still. Often accompanying this complaint are some motor phenomenologies such as crossing and uncrossing legs, repetitive caressing of the scalp, and repetitive body rocking. The diagnosis of focal akathisia is often missed because the patient refers to the unpleasant symptom as pain. Painful or burning mouth or vagina is the most common focal akathitic complaint.

TREATMENT

Efforts should be made to prevent the tardive dyskinesia syndromes. Antipsychotic drugs should be given only when indicated, namely, to control psychosis or a few other conditions where no

P.688

other effective agent has been helpful, as in some choreic disorders or tics. These drugs should not be used indiscriminately, and when they are used, the dosage and duration should be as low and as brief as possible. If the psychosis has been controlled, the physician should attempt to reduce the dosage and even try to eliminate the drug, if possible. In nonpsychotic disorders, such as tics, other drugs should be tried first, and only if they fail should a DRBA be used.

-

- Parkinsonian tremor of jaw, tongue, and lips
-

- Idiopathic tremor of neck, jaw, tongue, or lips
-

- Cerebellar tremor of neck

Acute dystonic reactions are easily reversible with parenteral administration of antihistamines (e.g., diphenhydramine, 50 mg intravenously), anticholinergic drugs (e.g., benztropine mesylate [Cogentin], 2 mg intramuscularly), or diazepam (5 to 7.5 mg intramuscularly). Acute akathisia disappears on discontinuance of the offending drug. Acute akathisia sometimes improves with the β -adrenergic blocker propranolol given in doses of 20 to 80 mg/day or mirtazapine (15 mg/day) [**Level 1**].¹ Drug-induced parkinsonism does not respond to levodopa, probably because the dopamine receptors are blocked and occupied by the antipsychotic agent. Oral anticholinergic drugs (trihexyphenidyl 2 to 15 mg/day) and amantadine (up to 300

mg/day) are effective. On withdrawal of the offending antipsychotic drug, the symptoms slowly disappear in weeks or months. For neuroleptic malignant syndrome, a potentially lethal condition, treatment needs to be started immediately with hospitalization, withdrawal of the antipsychotic medication, and initiating supportive therapy, including intravenous hydration and cooling. Although controlled trials have not been conducted, numerous reports suggest that dantrolene sodium, a muscle relaxant, and levodopa or direct-acting dopamine agonists may be beneficial. Carbamazepine is also effective. In most patients, the antipsychotic medication can be restarted later without recurrence of the syndrome. The withdrawal emergent syndrome is self-limiting but may take weeks to resolve. Reintroducing the antipsychotic drug and then slowly tapering the dosage can eliminate the choreic movements.

Once a tardive dyskinesia syndrome has appeared, the logical treatment approach calls for eliminating the causative agents, DRBAs, if possible. It is best to taper the offending antipsychotic drug slowly and then discontinue it rather than stopping the DRBA suddenly if tardive dyskinesia is suspected. Sudden discontinuation has often precipitated full-blown tardive dyskinesia. The dyskinesia and akathisia of tardive dyskinesia may slowly subside in months or years without need for further treatment. Although these drugs cause tardive dyskinesias, paradoxically, they also mask the movements due to their D2 receptor blockade. Reducing the dosage or discontinuing the offending drug can therefore unmask or worsen the disorder, and reinstating the drug can suppress the movements. Tardive dyskinesias may increase transiently in the first few weeks after withdrawal. If the dyskinetic or akathitic symptoms are too distressing after stopping the DRBAs, treatment with dopamine-depleting drugs, such as tetrabenazine or reserpine, may suppress them. If it is not possible to stop the drugs because of active psychosis, then increasing the dosage or adding a dopamine-depleting drug, such as reserpine (0.75 to 1.5 mg/day) or tetrabenazine (25 to 150 mg/day), may suppress the dyskinesia and akathisia. The dosage should be increased gradually to avoid their side effects. Addition of α -methyltyrosine (500 to 1,500 mg/day) may be necessary to relieve symptoms, but this combination is more likely to cause postural hypotension and parkinsonism. With time, these dopamine-depleting drugs may eventually be tapered and discontinued. Tardive dystonia may be treated by dopamine depletion, but unlike oral tardive dyskinesia and akathisia, it may also be treated with anticholinergic drugs. In some patients with focal tardive dystonia, treatment with botulinum toxin injections is an option.

OUTCOME

Neuroleptic-induced movement disorders improve with reduction or discontinuation of the neuroleptics. There are few published data on remission rate of tardive syndromes after complete withdrawal of DRBAs; the remission rate is low, ranging from 2% to 13%, and improvement is seen in about 20% to 30%. Those who remain

P.689

on the DRBAs may also show apparent disappearance of tardive dyskinesia in up to 60% of cases, but their symptoms are likely masked by DRBAs, and their improvement is often associated with worsening of drug-induced parkinsonism.

Choreas

Joseph Jankovic

Stanley Fahn

INTRODUCTION

Chorea is a hyperkinetic movement disorder characterized by continual, jerk-like movements that flow randomly from one body part to another. Patients may be able to partially suppress the involuntary movements or “camouflage” them by incorporating them into semipurposeful activities (parakinesia). As a result of chorea, patients have difficulty maintaining a sustained voluntary contraction, such as tongue protrusion or a persistent hand grip, resulting in intermittent contractions and relaxations (milkmaid grip). Chorea should be differentiated from “pseudochoreoathetosis” due to loss of proprioception. Choreic movements can be associated with many disorders; the most common are listed in [Table 81.1](#).

SYDENHAM DISEASE AND OTHER CHILDHOOD CHOREAS

In 1686, Thomas Sydenham described the chorea now known by his name but originally called *St. Vitus dance*. His description was of children with a halting gait and jerky movements. Sydenham disease (acute chorea, St. Vitus dance, chorea minor, rheumatic chorea) is a disease of childhood characterized by chorea, which is often asymmetric or may be unilateral (hemichorea) in about 20% of the cases (Video 81.1). The abnormal movements give the child a restless appearance. The chorea, with some exceptions, is self-limited and fatalities are rare except as a result of cardiac complications. Because chorea is only one of many manifestations, including a variety of neurologic, psychiatric, cardiac, rheumatologic, and other problems, the term *Sydenham disease* is more appropriate than calling the disorder *Sydenham chorea*, an earlier term.

ETIOLOGY AND PATHOBIOLOGY

Sydenham disease is considered an autoimmune disorder, a consequence of infection with group A β -hemolytic *Streptococcus*. Unlike arthritis and carditis, which occur soon after the infection, chorea may be delayed for 6 months or longer. The *Streptococcus* is thought to induce antibodies that cross-react with neuronal cytoplasmic antigens of caudate and subthalamic nuclei, which apparently account for the symptoms characteristic of rheumatic chorea. These antineuronal antibodies are found in the serum of nearly all patients with Sydenham disease. Antibodies to cardiolipin, which have been found in chorea associated with lupus erythematosus, have not been found in Sydenham chorea. Postmortem changes in rare fatal cases that came to autopsy can be attributed to embolic phenomena due to associated carditis. A mild degree of inflammatory reaction has been found in a few patients.

Knowledge of the etiology and immunology of Sydenham chorea has spawned the concept of other pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS) and pediatric acute-onset neuropsychiatric syndrome (PANS). There is, however, considerable debate among the experts about the pathophysiologic mechanisms of PANDAS and PANS and its possible relationship to other movement disorders, including tics.

INCIDENCE

The incidence of Sydenham disease had fallen dramatically with the introduction of antibiotics and with better sanitary conditions.

It now is encountered infrequently in developed countries, but it is still common in developing countries. Acute

chorea is almost exclusively a disease of childhood; over 80% of the cases occur in patients between the age of 5 and 15 years. Onset of the first attack after the age of 15 years is uncommon. After spontaneous remission, some female patients have a recurrence during pregnancy, so-called chorea gravidarum, or with the use of oral contraceptives in the late teens and early 20s. All races are affected. Girls are affected more than twice as frequently as boys. The disease occurs at all times of the year but seems to be less common in summer.

CLINICAL FEATURES

In addition to the choreic movements and accompanying motor impersistence (inability to sustain certain simple voluntary acts such as protruding the tongue), Sydenham disease is associated with a variety of neurobehavioral problems, such as irritability; emotional lability; anxiety; obsessive-compulsive behavior and other neuropsychiatric manifestations; speech impairment; and, more rarely, encephalopathy, reflex changes, weakness, gait disturbance, headache, seizures, and cranial neuropathy.

The clinical features of the chorea in Sydenham disease differ from chorea in patients with Huntington disease (HD). In Sydenham, the chorea is manifested by a restless-appearing motor behavior, whereas in HD, the chorea consists of more isolated, jerky movements that become more flowing as the chorea worsens. Physiologic recordings in Sydenham chorea reveal the bursts of electromyographic (EMG) activity to last more than 100 milliseconds and to occur asynchronously in antagonistic muscles. These findings are in contrast to the chorea associated with HD, in which more frequent and shorter EMG bursts of 10 to 30 milliseconds and 50 to 100 milliseconds occur.

COMPLICATIONS

Other manifestations of the rheumatic infection may occur during the course of the chorea or may precede or follow it. Cardiac complications, usually endocarditis, occur in approximately 20% of patients. Myocarditis and pericarditis are less common. Vegetative endocarditis and embolic phenomena may occur but are rare. A previous history of rheumatic polyarthritis is common, but involvement of the joints during the course of the chorea is rare. Other infrequent complications include subcutaneous rheumatic nodules, erythema nodosum, and purpura. Persistent mental and behavioral effects can also result from Sydenham disease.

P.692

TABLE 81.1 Differential Diagnosis of Chorea

Developmental choreas

Physiologic chorea of infancy

Chorea minima

Idiopathic choreas

Buccal-oral-lingual dyskinesia and edentulous orodyskinesia

In older adults, senile chorea (probably several causes)

Hereditary choreas

Huntington disease

Benign hereditary chorea (*TITF-1* gene)

Neuroacanthocytosis (*VPS13A* gene)

Other heredodegenerations: Huntington disease-like (HDL) disorders (e.g., prion protein *PRNP*, *junctophilin*, or *JPH3* genes), dentatorubral-pallidoluysian atrophy (*DRPLA* gene), spinocerebellar ataxias (*SCA2*, *SCA17*), *C9orf72* expansions, ataxia telangiectasia, ataxia with oculomotor apraxia type 1 (aprataxin gene), ataxia with oculomotor apraxia type 2 (due to mutations in the *senataxin* gene), tuberous sclerosis of basal ganglia, pantothenate kinase associated neurodegeneration, other neurodegenerations with brain iron accumulation

Wilson disease, neuroferritinopathy, infantile bilateral necrosis

Neurometabolic disorders

Lesch-Nyhan syndrome, lysosomal storage disorders, amino acid disorders, Leigh disease, porphyria

Drugs

Neuroleptics (tardive dyskinesia, withdrawal emergent syndrome), dopaminergic drugs, anticholinergics, amphetamines, cocaine, tricyclics, oral contraceptives

Toxins

Alcohol intoxication and withdrawal, anoxia, carbon monoxide, manganese, mercury, thallium, toluene

Metabolic and endocrine disorders

Hypernatremia, hyponatremia, hypomagnesemia, hypocalcemia, hypoglycemia, hyperglycemia (nonketotic)

Pregnancy (chorea gravidarum)

Acquired hepatocerebral degeneration

Renal failure

Nutritional (e.g., ketogenic diet, beriberi, pellagra, vitamin B₁₂ deficiency, particularly in infants)

Infectious and postinfectious

Sydenham chorea

Encephalitis lethargica

Various other infectious and postinfectious encephalitis,

Creutzfeldt-Jakob disease

Immunologic

Systemic lupus erythematosus, antiphospholipid syndrome, chorea gravidarum

Henoch-Schönlein purpura, NMDA antibody encephalitis

AIDS

Vascular

Infarction or hemorrhage

Arteriovenous malformation, moyamoya disease

Polycythemia rubra vera

Antiphospholipid syndrome

Migraine

Following cardiac surgery with hypothermia and extracorporeal circulation in children
(choreoathetosis and orofacial dyskinesia, hypotonia, and pseudobulbar signs or CHAP syndrome)

Tumors

Trauma

Other secondary choreas

Cerebral palsy (anoxic), kernicterus, sarcoidosis, MS disease,

Behçet disease, polyarteritis nodosa, mitochondrial disorders

Miscellaneous

Paroxysmal dyskinesias (choreoathetosis), familial dyskinesia, and facial myokymia

NMDA, *N*-methyl-D-aspartate; MS, multiple sclerosis.

Modified from Fahn S, Jankovic J. *Principles and Practice of Movement Disorders*. Philadelphia: Churchill Livingstone/Elsevier; 2007.

DIAGNOSIS

The diagnosis is made without difficulty from the appearance of the acute or subacute onset of characteristic choreic movements in a child with relatively recent history of streptococcal infection, although such a history may not be always elicited. Helpful for diagnosis are the presence of associated behavioral changes and diffuse slowing on the electroencephalogram. Although serum antistreptolysin O (ASO) titers may be elevated, this and other immunologic tests, including rheumatoid factor, antinuclear antibodies, rheumatic B-cell alloantigen D8/17, and cerebrospinal fluid (CSF) oligoclonal bands are often negative (although CSF pleocytosis has been reported in a few cases). Magnetic resonance imaging (MRI) is usually normal except for occasional selective enlargement of the caudate, putamen, and globus pallidus. In contrast to many other types of choreic disorders, positron emission tomography (PET) scan in Sydenham disease reveals striatal hypermetabolism that returns to normal when the choreic movements abate.

Several other causes of symptomatic chorea presenting in childhood should be considered in the differential diagnosis of Sydenham disease (see [Table 81.1](#)). The *withdrawal emergent syndrome*, occurring in children when neuroleptic agents are suddenly discontinued, closely resembles the type of chorea seen in Sydenham, but a history of having taken these drugs should make the diagnosis rather easy. One condition that may be confused with the chorea of Sydenham is benign hereditary chorea, a childhood-onset, genetic, nonprogressive disorder (discussed later in the text).

Other dyskinesias in childhood also could present a problem in differential diagnosis, but the clinical distinctions between these and choreic movements should lead to the correct diagnosis. Tics may offer some difficulty, but these movements are more stereotyped

P.693

rather than random; they are usually temporarily suppressible, often preceded by a premonitory sensation, and associated with noises or phonic tics. Some genetic forms of dystonia begin in childhood, but the sustained and twisting movements are quite distinct from choreic movements. However, some dystonic movements are more rapid and these have been mislabeled as chorea. Dystonic movements are typically patterned, affecting the same body parts repetitiously. Also, childhood dystonia persists and does not have the self-limiting characteristic of Sydenham disease. Myoclonus-dystonia, also called *essential hereditary myoclonus*, can begin in childhood and sometimes could be difficult to distinguish from chorea. In contrast to chorea, which produces a jerk-like movement that affects different body parts in a random fashion, myoclonus tends to be more predictable affecting the same group of muscles.

Athetosis, a form of slow chorea consisting of writhing, nonpatterned movements, when it occurs in childhood is often seen in the setting of static encephalopathy (cerebral palsy) or some metabolic diseases and usually occurs in the first few years of life. One cause of cerebral palsy, particularly in underdeveloped countries is kernicterus due to bilirubin encephalopathy associated with neonatal jaundice. Besides delayed developmental milestones and choreoathetotic movements, patients with kernicterus often exhibit vertical ophthalmoparesis, deafness, and dysplasia of the dental enamel ([Fig. 81.1](#) and [Video 81.2](#)).

TREATMENT

There is no preventive treatment for the disease. Symptomatic therapy may be of great value in the control of the movements. When the severity of the movements interferes with proper rest, sedatives may be needed. If further treatment is necessary, a benzodiazepine, valproate, or corticosteroids may be effective. Although antidopaminergic drugs can suppress choreic movements, a dopamine receptor-blocking agent, such as a phenothiazine, should not be administered because of its potential to produce tardive dyskinesia or tardive dystonia. If the chorea is particularly troublesome by impairing motor coordination or balance, dopamine-depleting drug tetrabenazine may be very effective in reducing the amplitude of the chorea. Treatment generally consists of a full 10-day course of oral penicillin V therapy or an injection of benzathine penicillin G. Prophylactic administration of penicillin for at least 10 years is recommended to prevent other manifestations of rheumatic fever, of which Sydenham disease may be its sole manifestation.

FIGURE 81.1 MRI of an 11-year-old boy with kernicterus. The T2-weighted image shows abnormal pallidal signal (*arrows*). See also Video 81.2.

COURSE AND OUTCOME

Sydenham disease often is a benign condition, and complete recovery is the rule in uncomplicated cases.

The mortality rate of approximately 2% is due to associated cardiac complications. The duration of the symptoms is quite variable. In the average case, the motor symptoms persist for 3 to 6 weeks, but the neuropsychiatric symptoms may persist for years or may even be lifelong. Occasionally, the course may be prolonged for several months, and it is not unusual for involuntary movements of a mild degree to persist for many months after recrudescence of the more severe movements. Recurrences after months or several years are reported in approximately a third of the cases.

Susceptibility to *chorea gravidarum*, chorea from oral contraceptives, and even topical vaginal creams containing estrogen and increased sensitivity to levodopa-induced chorea are possible sequelae of Sydenham disease. Some cases of *chorea gravidarum* may have serum antibasal ganglia antibodies, supporting an immunologic basis of this disorder. Because patients with *chorea gravidarum* often have a prior history of Sydenham disease, also frequently associated with the presence of antibasal ganglia antibodies, the two disorders may overlap pathogenically. The end of pregnancy and the discontinuation of oral contraceptives or estrogen provide relief from the involuntary movements. A postmortem examination of a case of *chorea gravidarum* revealed neuronal loss and astrocytosis in the striatum.

P.694

AUTOIMMUNE CHOREAS

Chorea in *systemic lupus erythematosus* (SLE), often fluctuating and intermittent, has been associated with the presence of serum antiphospholipid antibodies (lupus anticoagulant), a heterogeneous group of antibodies that can cause platelet dysfunction and result in thrombosis. PET has not found caudate hypometabolism in SLE, in contrast to many other choreas. Treatment with antidopaminergic agents has been successful.

The primary antiphospholipid antibody syndrome also causes chorea, particularly in young women. Systemically, patients may have migraine, spontaneous abortions, venous and arterial thromboses, thickened cardiac valves, livedo reticularis, and Raynaud phenomenon. The central nervous system is involved with strokes, multi-infarct dementia, and chorea. Activated partial thromboplastin time is prolonged because of the presence of lupus anticoagulant, and high titers of anticardiolipin antibodies exist. Anticoagulation, immunosuppressive drugs, and plasmapheresis have had variable success; it is difficult to interpret the effectiveness of therapeutic interventions because spontaneous remission occurs frequently. Striatal hypermetabolism may be documented by PET scan.

Chorea associated with anti-*N*-methyl-D-aspartate (NMDA) receptor encephalitis is particularly important to recognize because if the diagnosis and treatment are delayed, it can be fatal. Often presenting as a subacute neuropsychiatric disorder, anti-NMDA encephalitis is characterized by a variety of neurologic and movement disorders including chorea, stereotypy, dystonia, and myorhythmia. A search for ovarian teratoma or other benign tumors should be initiated because their removal is a critical part of the treatment. Immunoglobulin G antibodies against the NR1 subunit of the NMDA receptor are often identified.

VASCULAR CHOREA AND BALLISM

Choreic movements confined to the arm and leg on one side of the body (hemichorea, hemiballism) may develop abruptly in middleaged or elderly patients. Ballistic movements are a more violent form of chorea and are characterized by large amplitude uncoordinated activity of the proximal appendicular muscles, so vigorous that the limbs are forcefully and aimlessly thrown about. Padding of the limbs or side rails may be necessary to prevent injury. The movements are present at rest and may be suppressed during voluntary limb movement.

The sudden onset suggests a vascular basis; indeed, it may be preceded by hemiplegia or hemiparesis. In such instances, the choreic or ballistic movements appear when motor function returns. This type of movement disorder is the result of a destructive lesion of the contralateral subthalamic nucleus or its connections. It has

also been seen with scattered encephalomalacic lesions involving the internal capsule and basal ganglia. Vascular lesions, hemorrhagic or occlusive in nature, are the most common cause, but hemiballism has been found in association with tumors and plaques from multiple sclerosis (MS) in the subthalamic nucleus and has occasionally followed attempted thalamotomy when the target was missed. In general, the movements tend to diminish over time, but they may be persistent and require therapeutic intervention. The agents noted previously for the control of choreic movements in general have proved effective.

A not uncommon cause of hemiballism/hemichorea in patients with AIDS is a toxoplasmosis lesion involving the subthalamic nucleus, which can also respond to antidopaminergic medication.

Chorea-ballism is a common feature of hyperosmolar hyperglycemic nonketotic syndrome, which appears related to hypoperfusion in the striatum.

Choreoathetosis as a sequela to surgery for congenital heart disease appears to be associated with prolonged time on pump, deep hypothermia, and circulatory arrest. In most cases of postpump syndrome, the chorea persists, and fewer than 25% improve with antidopaminergic therapy.

NEUROACANTHOCYTOSIS

Perhaps the most common hereditary chorea after HD is neuroacanthocytosis, formerly called *chorea-acanthocytosis*. The chorea is typically less severe than that seen with HD but occasionally can be just as severe. In addition to chorea, patients with neuroacanthocytosis often have tics, stereotypies, seizures, cognitive decline, amyotrophy, dysphagia, absent tendon reflexes, high serum creatine kinase, feeding dystonia (tongue pushes food out of the mouth), and self-mutilation with lip and tongue biting. Age at onset is typically in adolescence and young adulthood, but the range is wide (8 to 62 years). Like HD, a young age at onset is more likely to produce parkinsonism or dystonia rather than chorea. The diagnosis depends on finding more than 10% spiky erythrocytes (acanthocytes) in blood smears. Some authorities have proposed that detection of acanthocytes can be enhanced if a wet smear of blood is diluted 1:1 with normal saline (Fig. 81.2). Occasionally, electron microscopy is needed to confirm the presence of acanthocytes.

FIGURE 81.2 Acanthocytes in a patient with neuroacanthocytosis.

P.695

The cerebral pathology is similar to that of HD, with striatal degeneration causing caudate atrophy but without intranuclear inclusions immunostaining with antibodies against huntingtin protein. PET scan typically shows hypometabolism in the caudate nucleus as well as reduced fluorodopa uptake and decreased dopamine receptor binding in the striatum. Erythrocyte membrane lipids are altered. Tightly bound palmitic acid (C16:0) is increased, and stearic acid (C18:0) is decreased. Choline acetyltransferase and glutamic acid decarboxylase are normal in basal ganglia and cortex, substance P levels are low in the substantia nigra and striatum, and norepinephrine is elevated in the putamen and pallidum.

Neuroacanthocytosis has been found to be due to various mutations on the *CHAC* (chorea-acanthocytosis) gene, later renamed *VPS13A* on chromosome 9q21.2, coding for the protein named *chorein* (Fig. 81.3).

A rare patient with neuroacanthocytosis may have the McLeod phenotype, an X-linked (Xp21) form of acanthocytosis associated with chorea, seizures, neuropathy, liver disease, hemolysis, and elevated creatine kinase values.

DENTATORUBRAL-PALLIDOLUYSIAN ATROPHY

Once thought to be found mainly in the Japanese population, this autosomal dominant disorder is now known to be more widespread, thanks to discovery of expanded cytosine-adenine-guanine (CAG) repeats in the dentatorubral-pallidoluysian atrophy gene (*DRPLA* or *ATN1*) on chromosome 12p13.31 that codes for the atrophin-1 protein, which is phosphorylated by c-Jun NH-terminal kinase (JNK). The abnormal polyQ protein has reduced affinity for JNK. Also called the *Haw River syndrome* because of its occurrence in some African-Americans in North Carolina, DRPLA clinically overlaps with HD and manifests combinations of chorea, myoclonus, seizures, ataxia, and dementia. The phenotype varies according to triplet (CAG) repeat length, and anticipation and excess of paternal inheritance in younger onset cases with longer repeat lengths are seen. The neuropathologic spectrum is centered around the cerebellofugal and pallidofugal systems, but neurodegenerative changes can be found in many nuclei. In contrast to HD, DRPLA is typically associated with white matter degeneration.

FIGURE 81.3 Absence of chorein in patient (155a) with neuroacanthocytosis (Western blot). (Courtesy Dr. Benedikt Bader, Munich, Germany.)

HUNTINGTON DISEASE-LIKE SYNDROMES

In addition to neuroacanthocytosis and DRPLA, other syndromes that resemble HD have been reported, in which genetic linkage has been made to other gene markers. When the HD gene test is normal, one should consider these less common conditions. Huntington disease-like (HDL) 1 is an autosomal dominant disorder mapped to the prion protein gene (*PRNP*) on chromosome 20p with eight extra octapeptide repeats in the prion protein. The autosomal dominant HDL2 appears to be present exclusively or predominantly in individuals of African origin. It is due to cytosine-thymine-guanine (CTG) and CAG repeat expansions of the gene on chromosome 16q24.2, encoding junctophilin-3, a protein of the junctional complex linking the plasma membrane and the endoplasmic

reticulum. HDL3, although labeled as such, is an autosomal recessive neurodegenerative disease beginning at 3 to 4 years of age. It is manifested by chorea, dystonia, ataxia, gait disorder, spasticity, seizures, mutism, intellectual impairment, and bilateral frontal and caudate atrophy. HDL3 has been linked to 4p15.3. Although labeled as a spinocerebellar degeneration, SCA17 can present with chorea and manifest with other features of HD. SCA17 is due to an expanded CAG repeat in the gene on chromosome 6q27 for the TATA-binding protein, which has a transcription initiation function. Another relatively common HD phenocopy is C9orf72 expansion at 9p21.2.

BENIGN HEREDITARY CHOREA

This rare, childhood-onset, choreic disorder is nonprogressive and may even lessen in severity over time. This autosomal dominant disorder is caused by mutations in the *NKX2-1* (previously called *TITF1*) gene on chromosome 14q13.3, coding for a transcription essential for the organogenesis of the lung, thyroid, and basal ganglia. This syndrome has been also described in patients with deletion of not only the *NKX2-1* gene but also the contiguous *PAX9* gene. These mutations should be considered in children and adults with chorea, slight motor delay, gait ataxia, dystonia, myoclonus, tics, intellectual impairment, congenital hypothyroidism, and chronic lung disease, hence the term *brain-thyroid-lung syndrome*. Brain MRI has been generally reported to be unremarkable but

P.696

some cases showed hypoplastic pallida, lack of differentiation of medial and lateral components, and bilateral signal hyperintensities on T2-weighted MRI images. About half of the patients spontaneously improve in adulthood. Tetrabenazine and, paradoxically, levodopa improves troublesome chorea.

ESSENTIAL CHOREA

In the absence of a family history, a benign nonprogressive chorea without other neurologic features can be rarely encountered, so-called essential chorea. When it occurs in the elderly, the term *senile chorea* is sometimes used, but its nosology is uncertain, as some patients diagnosed with senile or essential chorea have been found to have a CAG expansion in the HD gene.

The movements usually begin insidiously, are mild, and usually involve the limbs. More complex movements of the lingual-facial-buccal regions, however, are on occasion encountered. Slow progression in the intensity and extent of the movements may occur. In addition to HD, many other cases have been later diagnosed with other disorders, such as the antiphospholipid antibody syndrome, hypocalcemia, tardive dyskinesia, and basal ganglia calcification. Still, a rare patient can remain undiagnosed despite extensive investigation and is left with the diagnosis of essential (senile) chorea. In such a case, pathologic changes are found in the caudate nucleus and putamen but not to the degree seen in HD. Significantly, degenerative changes in the cerebral cortex are absent. In general, the symptoms are mild and there is little need to resort to therapeutic measures. In those instances in which oral-facial and neck muscle involvement occurs, however, drugs used to control chorea as indicated previously may prove useful.

OTHER CHOREAS

It is beyond the scope of this review to describe all causes of choreas but the reader is directed to [Table 81.1](#) and suggested readings for less common forms of choreic disorders.

Treatment of chorea should focus on identification of specific and potentially treatable cause, such as drugs and infectious and autoimmune or paraneoplastic etiologies. Symptomatic relief of chorea is similar to that in patients with HD and typically involves the use of tetrabenazine, a monoamine depletor. Rarely, if chorea is disabling, pallidal deep brain stimulation may be considered.

Videos can be found in the companion e-book edition. For a full list of video legends, please see the front matter.

Huntington Disease

Karen S. Marder

INTRODUCTION

Huntington disease (HD) is an autosomal dominant neurodegenerative disorder caused by a cytosine-adenine-guanine (CAG) polyglutamine repeat expansion in exon 1 of the Huntington (HTT) gene on chromosome 4p16.3. The age of onset, defined based on the presence of a characteristic extrapyramidal movement disorder, is inversely related to CAG repeat length such that higher CAG repeat length is associated with earlier age at onset. HD is characterized by a triad of symptoms and signs including motor, cognitive, and psychiatric manifestations. Studies of premanifest HD have demonstrated changes in imaging biomarkers (putamen and caudate) that predate onset of motor signs more than 15 years prior to onset and cognitive changes that occur 10 years prior to motor onset. Symptomatic treatment for chorea but no diseasemodifying therapy is currently available. The development of imaging, biofluid, and quantitative cognitive and motor testing will facilitate clinical trial development in prodromal HD.

EPIDEMIOLOGY

James Huntington provided the first comprehensive description of the disease and its inheritance pattern in 1872. Since that time, it has been described worldwide. Prevalence of HD based on a meta-analysis of 13 “service-based” studies was 2.71 per 100,000 (95% confidence interval [CI], 1.55 to 4.72). Prevalence was significantly lower in Asia 0.4 per 100,000 compared to Europe, North America, and Australia 5.7 per 100,000. Among people of European ancestry, 4 to 7 per 100,000 people have HD, with far lower prevalence among Asians and Black Africans. Incidence based on four studies was 0.38 per 100,000 per year (95% CI: 0.16, 0.94), with incidence much lower in Asia compared to those of European ancestry. Seven common haplotypes have been identified in the *HTT* gene, with a single ancestral haplotype accounting for 50% of all European chromosomes, supporting the theory that HD may have originated in Northern Europe and spread worldwide.

PATHOBIOLOGY

GENETICS

Age of onset of HD, defined by the presence of extrapyramidal motor signs, occurs most often between 40 and 50 years (mean age 45 years); however, cases have been reported as young as age 2 years and as old as 85 years. Between 5% and 10% develop HD before age 20 years (juvenile HD) and about 10% after age 60 years. CAG repeat length is inversely correlated with age at onset and accounts for 50% to 70% of the variance in age at onset. Repeat lengths of 26 or less are normal. Repeats between 27 and 35 are considered intermediate or “high normal” and represent 3% to 5% of all “normal” alleles. Although carriers of 27 to 35 repeats will not develop manifest HD, this range confers meiotic instability, and parents, especially fathers, may transmit repeats to their children that are within the HD range. Carriers of 27 to 35 repeats may evidence subtle behavioral changes, an “endophenotype,” although they do not have motor or cognitive impairment. Repeats between 36 and 39 are associated with incomplete or reduced penetrance, meaning that some individuals will develop HD, generally late onset, and others will not. Diagnosis of HD in the 36 to 39 repeat range may be difficult due to confounding with age-associated signs. Individuals with 40 or more repeats will develop HD (fully penetrant) if they live long enough. Most individuals with HD have between 40 and 50 repeats. Those with juvenile HD usually have greater than 50 repeats, although greater than 100 repeats have been reported.

There is a greater chance for CAG expansion in sperm than in ova, which explains the concept of “genetic anticipation,” an earlier age at onset in the next generation. Mothers with HD pass on approximately the same number of repeats (± 3), whereas fathers with HD, because of meiotic instability, often pass on a higher CAG repeat length. Ninety percent of juvenile HD cases have inherited the disease from their fathers. Despite the inverse correlation with age, there is significant variability of age of onset of HD even among individuals with the same CAG repeat length.

NEUROPATHOLOGY

Neuronal loss begins in the striatum. A five-point grading system based on macroscopic and microscopic criteria correlates with the Shoulson-Fahn Total Functional Capacity scale ([Fig. 82.1](#)). The scale ranges from 0 (no pathology) to grade 4. The earliest changes are seen in the medial paraventricular portions of the caudate nucleus (50% of neurons are lost in grade 1), in the tail of the caudate, and in the dorsal putamen. Ninety-five percent of neurons are lost in grade 4. Astrocytes increase steadily from grade 2 to 4, with severe gliosis in stage IV. Although neuronal loss in the striatum is the hallmark of HD, extrastriatal involvement (globus pallidus, subthalamic nucleus, substantia nigra pars reticulata, thalamus, brain stem, and neocortex) occurs but is less severe than the striatum (see [Fig. 82.1](#)).

Microscopically, the caudate contains shrunken neurons and ubiquitinated, round intranuclear inclusions. These inclusions consist of large aggregates of abnormal huntingtin protein (HTT) ([Fig. 82.2B](#)). The normal function of HTT, a predominantly cytoplasmic protein, is not completely understood. HD is believed to arise primarily from a gain of toxic function from an abnormal conformation of mutant HTT; however, loss of function of HTT and toxicity from RNA may also contribute. HTT is essential for early embryonic development. Despite widespread expression of abnormal HTT, the striatum is relatively selectively vulnerable. Subcortical prefrontal white matter shows CD68-labeled microglial cells and macrophages, which probably reflects the slow ongoing widespread degenerative process involving the cortical neurons and their processes ([Fig. 82.2A](#)).

FIGURE 82.1 Gradations of Huntington disease pathology. Neuropathologic gradations of Huntington disease using a 5-point scale (0 to 4). **A-D**: Coronal sections passing through the nucleus accumbens including the head of the caudate nucleus and putamen. **A'-D'**: Coronal sections passing through the globus pallidus including the putamen and caudal segment of the head of the caudate nucleus. **A and A'**: Neuropathologic grade of severity 1 (HD1): (about 5% of all HD brains) there is minimal detectable change on gross examination at the sites shown in **A and A'**; however, the body and tail of the caudate nucleus are atrophic. **B and B'**: Neuropathologic grade of severity 2 (HD2): (about 15% of HD brains) the volume loss of the neostriatum is moderate with relative preservation of its shape. The medial outline of the head of the caudate nucleus is only slightly convex, but it still bulges into the lateral ventricle (**B**). The medial edge of the lenticular nucleus (**B'**) lost its medial convexity. **C and C'**: Neuropathologic grade of severity 3 (HD3): (about 50% of HD brains) the medial outline of the head of the caudate nucleus forms a straight line or is slightly concave medially (**C**). The volume loss of the lenticular nucleus (putamen and globus pallidus) is discrete, and its medial outline is parallel to the anterior limb of internal capsule or is slightly concave medially (**C'**). **D and D'**: Neuropathologic grade of severity 4 (HD4): (about 30% of HD brains) the striatum is severely atrophic. The medial contour of the head of the caudate nucleus is concave, as is the anterior limb of internal capsule (**D**). (Courtesy of JP Vonsattel, MD.)

NEUROCHEMISTRY

Up to 95% of the GABAergic medium spiny neurons that project to the globus pallidus and the substantia nigra are lost, whereas large cholinergic interneurons are selectively spared. Loss of the medium spiny neurons may be due to excessive stimulation of excitatory amino acid receptors, especially *N*-methyl-D-aspartate (NMDA) receptors. Although dopamine, glutamate, and γ -aminobutyric acid (GABA) are thought to be most affected in HD

and have been targets for therapy, multiple neurotransmitters and their receptors are involved. Cannabinoid and adenosine A2a receptor binding in the striatum and globus pallidus externa are affected early. There is typically loss of dopamine D1 receptors in the striatum as well as cannabinoid and D1 receptors in the substantia nigra as the disease progresses. Loss of substance P/dynorphin neurons occurs in the late stages and correlates clinically with dystonia.

CLINICAL MANIFESTATIONS

The triad of symptoms and signs associated with HD is an extrapyramidal movement disorder, cognitive impairment, and behavioral impairment (Table 82.1). Any one of the triad may occur first. Three carefully designed observational studies including individuals at risk for HD and early symptomatic HD (PHAROS, PREDICT HD, TRACK HD) have facilitated in-depth characterization of individuals followed longitudinally including the period of phenoconversion. The course of HD can be divided into several periods. During the premanifest period (from birth to approximately 10 to 15 years prior to phenoconversion), individuals are clinically indistinguishable from controls (presymptomatic phase). The prodromal phase, which follows, is characterized by subtle motor, cognitive, and psychiatric features leading up to phenoconversion. Phenoconversion is defined clinically, as unequivocally manifesting the extrapyramidal motor signs of HD, when HD is diagnosed.

MOTOR SIGNS

The extrapyramidal movement disorder is the defining feature of HD and is characterized by both involuntary movements (chorea, dystonia) and impairment in voluntary movements (eye movements, gait, swallowing). The Unified Huntington's Disease Rating Scale includes a 124-point assessment of the motor signs of HD including eye movements (reduced saccades and breakdown of smooth pursuit), fine motor coordination, chorea, dystonia, and gait and balance (Video 82.1). Chorea, derived from the Greek word "dance," is an involuntary movement that is brief but not as lightning-like as myoclonus. These random movements may be present in the limbs, face, or trunk (see Video 82.1). They are exacerbated with stress and are thought to disappear during sleep.

P.700

Chorea tends to be present in the early symptomatic phase, peak mid disease, and decline or disappear in the late phase of the disease. In contrast, bradykinesia, dystonia, and rigidity increase, particularly during the late stages of the disease, and affect voluntary movements. Most individuals need some assistance with walking, for example, assistive devices, approximately 7 years from onset of motor signs. Falls and choking are frequent mid- to late-stage events that may be life threatening. In addition to chorea, other motor features include motor impersistence. Examples include the inability to maintain tongue protrusion for 10 seconds or to maintain voluntary contraction while gripping, colloquially known as *milkmaid grip*. Impairments in fine motor activity that may include slowing and irregularity can be measured clinically or with quantitative motor assessment including speed of finger tapping and paced tapping. Variability of the inter tap interval or the pace of walking are among the earliest detectable signs of motor impairment, at a time when impairment is not detectable on neurologic examination or recognized by the individual. The earlier the disease onset, the less likely there will be chorea. Children presenting with HD present with an akinetic rigid form of the disease. Stiffness in the legs may also be accompanied by scissoring of gait, bradykinesia, and clumsiness. Seizures occur in 25% of juvenile HD cases.

FIGURE 82.2 Neuronal intranuclear inclusion. **A:** The presence of CD68-labeled microglial cells and macrophages within the subcortical prefrontal white matter (Brodmann area [BA] 9) is shown. **B:** Two neurons from putamen (HD3-neuropathologic staging) are shown. One of them exhibits a ubiquitinated, round nuclear inclusion. The other neuron is shrunken and diffusely labeled with antibodies directed against ubiquitinated proteins. (Courtesy of JP Vonsattel, MD.)

TABLE 82.1 Clinical Manifestations of Huntington Disease

Clinical Domain	Signs
Motor	Involuntary movements <ul style="list-style-type: none"> • Chorea, dystonia, dysphagia, dysarthria Voluntary movements <ul style="list-style-type: none"> • Slow saccade initiation and interrupted pursuit • Finger tapping/pronation supination, gait and balance
Cognitive	Processing speed, executive function, visuospatial perception, episodic memory, smell identification
Psychiatric	Irritability, obsessive-compulsive symptoms, perseverative behavior, depression, apathy, anosognosia

Clinical manifestations in HD occur in three domains: motor (defining feature of the disease), cognitive, and psychiatric.

COGNITIVE IMPAIRMENT

Although HD is diagnosed based on the presence of an extrapyramidal motor disorder, numerous cross-sectional and longitudinal studies have documented impairment primarily in executive function and psychomotor slowing that may begin 10 to 15 years prior to motor onset during the prodromal phase. Deficits in executive function including the ability to plan, organize, and monitor behavior are particularly prominent. These cognitive domains have been closely associated with the frontal lobes and the frontostriatal circuits and are similar to the cognitive impairment seen in Parkinson disease or vascular dementia. Patients with HD do not have a primary disorder of memory retention but have difficulty acquiring information efficiently or consistently retrieving it. In contrast to patients with Alzheimer disease (AD), patients with HD show marked improvement in response to cued recall, similar to that in other patients with frontal lobe disease. Unlike the cortical dementias, such as AD, HD does not prominently involve language until late in the illness. Among individuals who are in the premanifest stage, deficits in motor planning/speed (e.g., paced tapping, two-choice reaction time) and sensory-perceptual processing (emotional recognition and University of Pennsylvania smell identification test) best predict time to diagnosis after motor symptoms and CAG repeat

P.701

length and age. Using traditional neuropsychological tests, 40% of premanifest individuals meet criteria for mild cognitive impairment (MCI) (using cutoff scores 1.5 standard deviation [SD] below the mean of a comparison group in at least one domain) and displayed mild impairments in episodic memory, processing speed, executive functioning, and/or visuospatial perception. The prevalence of MCI increases over the 10 years prior to diagnosis, as individuals get closer to their estimated age at onset of diagnosis. The majority have nonamnesic MCI (18%), followed by amnesic MCI (7.5%) in premanifest HD. During the premanifest period, individuals may recognize subtle functional decline in capacity to perform their jobs and handle financial affairs. Children present a special case. They often have cognitive decline, manifesting as poor school performance, characterized by poor attention and may be misdiagnosed as attention deficit disorder.

BEHAVIORAL SIGNS

A range of psychiatric manifestations can be seen in both premanifest and manifest HD including most commonly irritability, obsessive-compulsive symptoms, depression (in up to 50%), and apathy. Apathy may increase significantly in premanifest HD and is associated with prediction of functional decline. Like apathy, obsessive-compulsive symptoms (OCS) are referable to frontostriatal circuits, in particular the orbitofrontal cortex. OCS also increase over time as the individual approaches phenoconversion. Perseverative behavior that is not ego dystonic, for example, getting stuck on an idea, may also be seen. Anosognosia is frequent in HD. Individuals with HD are less likely to report motor symptoms that are present on exam than Parkinson disease patients. Almost half of the participants in the PREDICT HD study who phenoconverted did not report motor symptoms, consistent with unawareness. Using the problem behavior assessment, three clusters of symptoms identified in manifest HD were depression, apathy, and irritability. Among HD patients, there is no clear relationship between psychiatric symptoms and disease progression, except for apathy, which correlates with disease duration. This may be due to the availability of effective treatment for affective symptoms and the episodic nature of these symptoms. Suicidal ideation and suicide are more common in HD compared to age-matched controls. Completed suicide has been reported to be 7- to 12-fold more common in HD than controls. Psychosis is rare. Critical periods for suicidal ideation have been identified close to the time of phenoconversion and early in the early symptomatic stage. In children, behavioral changes may include depression, aggression, impulsivity, and obsessions.

DIAGNOSIS

Diagnosis is based on the unequivocal presence of an extrapyramidal movement disorder in the setting of an expanded CAG repeat or a family history of HD based on autopsy or a close family member who has undergone genetic testing. The differential diagnosis of chorea is presented in Chapter 81. Individuals from confirmed HD families who present with signs and symptoms of HD should undergo a careful history and physical examination. As in sporadic cases, there should be consideration of causes of chorea including thyroid function tests, B₁₂, antinuclear antibody, antistreptolysin O, and HIV. Because HD is the most likely etiology of the extrapyramidal movement disorder in a family with a documented HD family, genetic testing for the expanded CAG repeat is a more cost-effective approach. It is essential that any individual (symptomatic or presymptomatic) who is considering genetic testing be offered genetic counseling performed according to published guidelines. A center specialized in HD with a team of professionals including a neurologist, psychiatrist, and a genetic counselor is preferable.

If there is no family history of HD, a careful medication history including dopamine antagonist exposure resulting in tardive dyskinesia should be sought. Additional tests would include complete blood count, thyroid function tests (hyperthyroidism), B₁₂ deficiency, a smear for acanthocytes and creatine phosphokinase to detect neuroacanthocytosis, a sedimentation rate (to rule out autoimmune disorders such as Sydenham chorea or lupus), and ceruloplasmin (for Wilson disease). Nonpaternity may also be an explanation for lack of a family history of HD.

There are several other causes of autosomal dominant slowly progressive chorea including HDL2 caused by a mutation in *JPH3* which is located on chromosome 16q24.3. *JPH3* that is responsible for making the protein junctophilin-3 and dentatorubral-pallidoluysian atrophy caused by a mutation in *ATN1* are reviewed in Chapter 81 along with a more complete differential diagnosis of chorea.

In individuals with HD, routine studies of blood, urine, and cerebrospinal fluid are normal. Structural magnetic resonance imaging (MRI) may show enlargement of the lateral ventricles due to atrophy of the caudate and putamen (Fig. 82.3). In a longitudinal study PREDICT HD, striatal volume decline was faster in premanifest and manifest HD compared to age-matched controls and was seen 10 years before diagnosis of “phenoconversion.” Structural MRI measures of striatal atrophy may be the earliest changes referable to HD but are not sufficiently sensitive or specific as a diagnostic marker for an individual patient. Diffusion tensor imaging, functional MRI, and fluorodeoxyglucose positron emission tomography are used in research settings as potential surrogate markers, however, are not yet useful for diagnostic purposes. In longitudinal studies, these structural and functional imaging markers correlate with calculated time to disease onset based on CAG and age, motor, and cognitive function and may also independently predict phenoconversion. In manifest HD, measures of striatal volume correlates with motor and cognitive function.

TREATMENT

No disease-modifying therapies have been approved for HD. Disease-modifying therapies have been directed primarily at oxidative stress and mitochondrial mechanisms of action. A 5-year phase III study including 600 HD participants randomized to CoQ10 2,400 mg or placebo was stopped early because of futility in 2014. A 3-year phase III study of creatine 40 mg/day was also stopped early in 2014 for futility. Small fetal transplant trials have been conducted, and one multicenter longitudinal study is ongoing. Preparatory work on RNA interference and antisense oligonucleotide-based therapies could be particularly effective in a highly penetrant single gene disorder such as HD. The design of neuroprotective trials in

premanifest individuals presents unique challenges associated with whether participants must know whether they have an expanded CAG repeat to participate and if not, whether it is ethical to randomize noncarriers to the active agent. A recent phase II study of 30 mg of creatine compared to placebo (PRECREST) demonstrated feasibility of randomizing both premanifest individuals who knew their mutation status as well as those who had not undergone clinical genetic testing in a prevention trial. This study also demonstrated the potential value of imaging as a more sensitive measure of change than clinical measures over an 18-month period [Level 1].^{1,2,3,4}

TREATMENT OF MOVEMENT DISORDER

Antidopaminergic Agents for Chorea

About 90% of people with HD develop chorea, but treatment is advised only if it is functionally or emotionally disabling. Tetrabenazine (TBZ) [Level 1]⁵ is the only U.S. Food and Drug Administration (FDA)-approved medication for the symptomatic treatment of chorea. In a double-blind placebo-controlled study (class I) including 54 HD randomized to TBZ up to 100 mg and 30 to placebo, chorea was reduced by 23.5% after 12 weeks. TBZ reversibly inhibits the central vesicular monoamine transporter type 2 (VMAT2) and depletes presynaptic dopamine more selectively than norepinephrine and serotonin. The highest binding density for TBZ is in the caudate, putamen, and nucleus accumbens, where HD pathology is the greatest. Starting dose of TBZ is 12.5 mg daily titrated to three times daily with a maximum dose of 100 mg. At 50 mg, the FDA requires that CYP2D6 genotyping be done. Poor metabolizers of CYP2D6 should not exceed the 50-mg dose. Because it is metabolized by Cyp2D6, drug interactions that might raise TBZ need to be considered. It is generally well tolerated but dose-dependent side effects include worsening depression, fatigue, parkinsonism, and akathisia. Tardive dyskinesia is not described.

Neuroleptics and atypical neuroleptics that block postsynaptic D2 receptors have been studied in smaller trials but may be limited by side effects especially tardive dyskinesia and worsening gait and swallowing.

Haloperidol, fluphenazine, and pimozide are high-potency atypical antipsychotics that can suppress chorea but do have dose-limiting side effects. Similarly, small trials of atypical neuroleptics such as olanzapine, risperidone, quetiapine, and ziprasidone have been performed with mixed results. Treatment with these typical and atypical antipsychotics rather than TBZ is advised if both motor and behavioral symptomatology is being addressed simultaneously.

Antiglutamatergic Therapy for Chorea

Glutamate toxicity resulting in degeneration of medium spiny striatal neurons is the concept behind treatment with NMDA receptor antagonists such as amantadine or compound that disrupt glutamate transmission such as riluzole. These have been shown to have none to minimal symptomatic or neuroprotective benefits in level 1 studies.

TREATMENT OF DYSTONIA

There have been no class 1 studies for dystonia in the setting of HD. Botulinum toxin injections can be also used for focal dystonia associated with HD.

TREATMENT OF VOLUNTARY MOTOR IMPAIRMENT (GAIT AND SWALLOWING)

There are no medical treatments for the voluntary motor impairments (gait, swallowing); however, physical, occupational, and swallowing therapy could provide benefit in terms of reduced fall risk and psychological well-being and increased caloric intake. There have been no randomized controlled trials of exercise in manifest or premanifest HD.

TREATMENT OF WEIGHT LOSS

Weight loss is also common as HD progresses. Increased caloric intake is necessary to maintain body mass index even in the presymptomatic state when there are no obvious movements to account for increased energy expenditure. In manifest HD, weight loss is correlated with rate of disease progression. Weight loss may not only be attributable to severity of the extrapyramidal movement disorder, decreased caloric intake due to dysphagia, or depression but may also be due to a hypermetabolic state associated with HD. Attention to increasing caloric intake to maintain weight, particularly as the disease progresses, is essential for well-being. Pureed foods and thickened liquids and frequent small meals may improve caloric intake. Feeding tube placement is an individual decision that should be discussed well before the need in the later stages of the disease.

TREATMENT OF COGNITIVE IMPAIRMENT

There are no approved treatments for cognitive impairment in HD. Small studies have been conducted with cholinesterase inhibitors

P.703

including donepezil and rivastigmine with no significant improvement. A randomized controlled trial of citalopram in nondepressed HD patients showed no change in executive function after 20 weeks; however, there was improvement in mood suggesting an effect on subsyndromal depression [Level 1].⁶ The largest study to date (class 1) included 403 HD participants at 64 centers followed for 6 months, randomized to latrepirdine (20 mg) versus placebo [Level 1].⁷ This agent thought to be a mitochondrial stabilizer did not show a difference in performance on Mini-Mental Status Examination or Clinician Interview-Based Impression of Change.

TREATMENT OF PSYCHIATRIC SYMPTOMS

The FDA-approved medications for depression, irritability, obsessive-compulsive behaviors, and general anxiety and aggression have been used to treat individuals with HD. Data is confined to case series and small open-label studies. There are no class I studies specifically for the treatment of psychiatric symptomatology.

OUTCOME

The course of HD is generally 15 to 20 years from the time of diagnosis based on the presence of an extrapyramidal syndrome consistent with HD. The course of juvenile HD rarely exceeds 15 years. The most frequent cause of death is aspiration pneumonia, although accidents, especially subdural hematoma, are common. Increasing attention to the benefits of weight maintenance and balance training may be life prolonging. The completion of three well-designed observational studies of at risk and early symptomatic individuals (PHAROS, TRACK HD, and PREDICT HD) will facilitate the design of new clinical trials that are adequately powered to detect change at all stages of the illness.

Parkinson Disease

Stanley Fahn

Un Jung Kang

INTRODUCTION

In 1817, James Parkinson described the major clinical motor features of what today is recognized as the symptom complex known as *parkinsonism*, manifested by any combination of six cardinal features: tremor at rest, rigidity, bradykinesia-hypokinesia, flexed posture, loss of postural reflexes, and the freezing phenomenon. At least two of these features, with at least one being either tremor at rest or bradykinesia, must be present for a clinical diagnosis of parkinsonism. The many causes of parkinsonism (Table 83.1) are divided into five categories—primary, symptomatic/secondary, Parkinson-plus syndromes, various heredodegenerative diseases in which parkinsonism is a manifestation, and parkinsonism with neurotransmitter enzyme deficit. An example of parkinsonism with dopamine enzyme deficit and a benign clinical course is the condition known as *dopa-responsive dystonia*, covered in the chapter on dystonia (see Chapter 76). Primary parkinsonism is known as *Parkinson disease* (PD), which can be sporadic or familial; it is the most common type of parkinsonism encountered by neurologists and is the second most common neurodegenerative disease after Alzheimer disease (AD). In addition to the motor features of PD, the importance of nonmotor features, ranging from fatigue, sleep, and behavioral disturbances to autonomic and sensory symptoms is increasingly appreciated as contributors to the overall disability of patients with PD.

The core biochemical pathology in parkinsonism is decreased dopaminergic neurotransmission in the basal ganglia. In most of the diseases in Table 83.1, degeneration of the nigrostriatal dopamine system results in marked loss of striatal dopamine content. In some, degeneration of the striatum with loss of dopamine receptors is present and is probably responsible for the lack of therapeutic effect by dopaminergic agents in these disorders. Drug-induced parkinsonism is the result of blockade of dopamine receptors or depletion of dopamine storage. It is not known how hydrocephalus or abnormal calcium metabolism produces parkinsonism. Physiologically, the decreased dopaminergic activity in the striatum leads to abnormal activities of the subthalamic nucleus and the globus pallidus interna (GPi), which is the predominant efferent nucleus in the basal ganglia. Understanding the biochemical pathology led to dopamine replacement therapy; understanding the physiologic change in brain network circuitry led to surgical interventions, such as deep brain stimulation of GPi, the subthalamic nucleus and ventrointermediate nucleus of the thalamus. Lesioning of these nuclei (pallidotomy, thalamotomy) is an alternative surgical technique. In addition, nondopaminergic system deficit is associated with many of the nonmotor symptoms.

EPIDEMIOLOGY

PD makes up approximately 80% of cases of parkinsonism listed in Table 83.1. The incidence and prevalence of PD increase with age. The mean age at onset is about 60 years. Onset at younger than 20 years is known as *juvenile parkinsonism*. Many cases are due to mutations in the *PRKN* gene, an autosomal recessive disorder without Lewy bodies in the degenerating substantia nigra. Some heredodegenerative diseases such as Huntington disease and Wilson disease can present as juvenile parkinsonism. Onset of primary parkinsonism between 20 and 40 years is defined as *young-onset PD*; some investigators extend the age to 50 years to account for higher genetic contribution than later onset cases. PD is more common in men, with a male-to-female ratio of 3:2. The prevalence of PD is approximately 160 per 100,000, and the incidence is about 20 per 100,000 per year. The prevalence and incidence increase exponentially with age, and at age 70 years, the prevalence is

approximately 550 per 100,000, and the incidence is 120 per 100,000 per year.

PATHOBIOLOGY

PATHOLOGY

The pathology of PD is distinctive. Degeneration of the neuromelanin-containing neurons in the brain stem occurs, especially dopamine-containing neurons in the ventral tier of the pars compacta in the substantia nigra and in the noradrenergic-containing neurons in the locus ceruleus; many of the surviving neurons in these nuclei contain eosinophilic cytoplasmic proteinaceous inclusions known as *Lewy bodies*, the pathologic hallmark of the disease. The nigral dopaminergic neurons project to the neostriatum (nigrostriatal pathway). By the time symptoms appear, the substantia nigra already has lost about 60% of dopaminergic neurons and the dopamine content in the striatum is about 80% less than normal. Incidental Lewy bodies seen at neuropathologic examination in individuals without PD symptoms or signs are thought to represent presymptomatic individuals who would have ultimately developed clinical manifestations of PD. Lewy bodies and Lewy neurites (intra-axonal aggregates) contain the protein, α -synuclein, and are present both in PD and dementia with Lewy bodies, which is associated with wide spread cortical pathology. Other synucleinopathies include multiple system atrophy (MSA) with oligodendrocyte inclusions containing α -synuclein and some forms of neurodegeneration with brain iron accumulation (NBIA), which shows axonal spheroids with α -synuclein deposition.

Staining for Lewy bodies and neurites with antibodies to α -synuclein indicates that the aggregation of α -synuclein first occurs in the olfactory apparatus and in the caudal brain stem, especially the dorsal motor nucleus of the vagus in the medulla even in cases without involvement of substantia nigra pars compacta or clinical PD symptoms. Braak proposed a staging system for PD pathology and proposed a hypothesis that the Lewy-related pathology progressively spread rostrally up the brain stem and then into the telencephalon and cerebral cortex (Fig. 83.1). However, Lewy pathology does not correlate with actual cell loss or function and there are many cases that do not fit the pattern

P.705

of hypothesized progression. The susceptible neurons containing Lewy neurites belong to the class of projection neurons with an axon that is disproportionately long, thin, and poorly myelinated or unmyelinated.

TABLE 83.1 Classification of Major Parkinsonian Syndromes

Extrapyramidal Syndromes

- Parkinson disease—sporadic and familial
-

Secondary Parkinsonism

- Drug-induced: dopamine antagonists and depleters
 - Hemiatrophy—hemiparkinsonism
 - Hydrocephalus; normal pressure hydrocephalus
 - Hypoxia
-

- Infectious; postencephalitic

- Metabolic; parathyroid dysfunction

- Toxin: Mn, CO, MPTP, cyanide

- Trauma

- Tumor

- Vascular; multi-infarct state

Parkinson-Plus Syndromes

- Corticobasal degeneration

- Dementia syndromes

 - Alzheimer disease

 - Dementia with Lewy bodies

 - Frontotemporal dementia

- Lytico-Bodig (Guam parkinsonism-dementia-ALS)

- Multiple system atrophy syndromes

 - Striatonigral degeneration (MSA-P)

 - Shy-Drager syndrome

 - Sporadic olivopontocerebellar degeneration (OPCA) (MSA-C)

 - Motor neuron disease-parkinsonism

- Progressive pallidal atrophy

- Progressive supranuclear palsy (PSP)

Hereditary Degenerative Diseases

- Neurodegeneration with brain iron accumulation (NBIA)
- Huntington disease (Westphal variant)
- Lubag (X-linked dystonia-parkinsonism)
- Mitochondrial cytopathies with striatal necrosis
- Neuroacanthocytosis
- Wilson disease

Parkinsonism with Neurotransmitter Enzyme Deficit

- Enzymatic deficiencies of dopamine synthesis

Mn, manganese; CO, carbon monoxide; MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine; ALS, amyotrophic lateral sclerosis; MSA-P, multiple system atrophy with predominant parkinsonism; MSA-C, multiple system atrophy with cerebellar features.

FIGURE 83.1 Six stages of PD based on distribution of Lewy neurites in the brain. Staining for α -synuclein in

Lewy neurites reveals their distribution. The *darkest color* represents the most intense deposition of Lewy neurites and their earliest appearance, which is in the olfactory tubercle and dorsal motor nucleus of the vagus. The substantia nigra develops Lewy neurites at stage 3, following which symptoms of PD appear (Braak stage 4). The neocortex is involved in stages 5 and 6. The susceptible neurons belong to the class of projection neurons with an axon that is disproportionately long, thin, and poorly myelinated or unmyelinated. (From Braak H, Bohl JR, Müller CM, et al. Stanley Fahn lecture 2005: the staging procedure for the inclusion body pathology associated with sporadic Parkinson's disease reconsidered. *Mov Disord.* 2006;21[12]:2042-2051.)

ETIOLOGY

The cause of PD in the vast majority of patients is unknown. Research has discovered both environmental and genetic factors. The discovery that the chemical agent 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) can cause parkinsonism raised the possibility that PD might be caused by an environmental toxin. No single environmental factor has emerged as essential, but growing up in a rural farming environment has been disproportionately frequent in some studies, suggesting potential role of pesticides, some resembling MPTP in chemical structures. Exposure to excess levels of manganese may produce a neurobehavioral syndrome that shares some of the cognitive and motor features of PD, but whether it increases the risk of idiopathic PD is controversial. Interestingly, decreased risk of PD in those with high level of caffeine consumption or cigarette smoking has been consistently noted. High uric acid levels are also associated with decreased risk and slower progression of PD.

GENETICS

Contribution of genetic factors has been recognized only since late 1990s. Studies of twins showed that onset of PD before age 50 years has a higher likelihood of a genetic cause. The first genetic form of PD was discovered in 1997 and now more than 20 different genetic forms of parkinsonism, labeled as PARK, have been discovered. Many of them are Parkinson-plus syndromes, and pathology is variable including some without Lewy body and some as NBIA. These are summarized in [Table 83.2](#). We will discuss well-established genetic forms with typical PD clinical phenotypes here.

TABLE 83.2 The Most Definitive Genetic Forms of Parkinson Disease

Name and Locus	Gene	Mode of Inheritance	Pathologic and Clinical Features	Protein Function	Where Found
PARK1 and 4 4q22.1	SCNA	Autosomal dominant	Lewy bodies; earlier onset and more aggressive course; L-dopa-responsive parkinsonism, dementia, hallucinations, autonomic dysfunction	α -Synuclein possibly synaptic vesicle trafficking, elevated in bird song learning	Families in Germany, Italy, United States (Contoursi kindred), Greece, Spain

PARK8 12q12	<i>LRRK2</i>	Autosomal dominant	Pathologic pleomorphism; indistinguishable from idiopathic PD		Worldwide
PARK2 6q26	<i>PRKN</i>	Autosomal recessive	Often juvenile onset without Lewy bodies; slowly progressive; no dementia	Parkin, a ubiquitin E3 ligase, attaches short ubiquitin peptide chains to a range of proteins, likely to mark degradation; supports mitophagy	Ubiquitous, originally in Japan, very common in juvenile onset
PARK6 1p36.12	<i>PINK-1</i>	Autosomal recessive	Juvenile onset	Mitochondrial kinase, modulates mitochondrial dynamics; supports mitophagy	Families in Italy, Spain, Philippines, Taiwan, Israel, Japan, Ireland, and North America
PARK7 1p36.23	<i>DJ-1</i>	Autosomal recessive	Early onset	Possible atypical peroxiredoxin and may play a role in apoptosis	Families in Holland, Italy, Uruguay
Glucocerebrosidase 1q22	<i>GBA</i>	Autosomal dominant; susceptibility gene; low penetrance; most common genetic risk factor gene	Indistinguishable from idiopathic PD	Lysosomal enzyme	About 13% of sporadic PD in Ashkenazi Jews, found in all ethnic groups

The first genetic cause of PD (PARK1) was discovered to be mutations in *SNCA* gene located on chromosome 4q22.1 coding for the protein α -synuclein. α -Synuclein is an abundant presynaptic protein. The resulting parkinsonism transmits in an autosomal dominant pattern. It is rare, being reported only in a small number of families originating in Greece, Italy, Germany, and Spain. However, single nucleotide polymorphisms have been associated with sporadic PD and the protein α -synuclein is present in Lewy bodies, even in patients with PD without genetic mutations, suggesting potential pathophysiologic role of α -synuclein in sporadic form of PD. It is not known if Lewy bodies contribute to neuronal degeneration or are a protective mechanism to slow neuronal death. Duplication and triplication of the α -synuclein gene also cause familial parkinsonism (PARK4), suggesting that overexpression of the normal (wild-type) protein suffices to provoke dopaminergic neurodegeneration.

Another gene defect causing familial PD is PARK8, which has been mapped to chromosome 12q12 and encodes for a previously unknown protein named *leucine-rich repeat kinase- 2* (LRRK2), also known as *dardarin*. This 2527 amino acid protein belongs to the family of the ROCO protein, contains a protein kinase domain, and is ubiquitously expressed in the central nervous system (CNS). About a dozen pathogenic *LRRK2* mutations have been identified, which have been found to be the most frequent genetic cause of PD, accounting to up to 5% of familial cases in the Caucasian population. Some ethnic groups have a particularly high prevalence; the most common mutation, G2019S, has an increased frequency among Ashkenazi Jews (18.3% of those with PD) and North African Berbers (39% of those with PD). *LRRK2* mutations result in an autosomal dominant parkinsonism that resembles late-onset idiopathic PD. Genome-wide association studies have shown significance of *LRRK2* polymorphism in sporadic PD as well. Although the neuropathology associated with *LRRK2* mutations is highly variable with some with Lewy bodies and others with neurofibrillary tangles, degeneration of substantia nigra neurons has been observed consistently.

The most commonly occurring gene defect causing juvenile familial parkinsonism is PARK2 (*PRKN*) on chromosome 6q26, coding for the E2-dependent E3 ubiquitin-protein ligase, parkin. Mutations in the parkin gene result in an autosomal recessive parkinsonism that is slowly progressive, with onset usually before age 30 years and with sleep benefit; rest tremor can be present. This cause of PD has a better prognosis for both motor and cognitive outcomes than idiopathic PD. There is degeneration of substantia nigra neurons, but in most instances, no Lewy body inclusions are found. Some typical adult-onset PD patients have been found to have a single heterozygotic mutation of the *PRKN* gene and with Lewy bodies at autopsy. Other recessive forms with similar juvenile

P.707

parkinsonism include those with PTEN-induced putative kinase 1 (*PINK1*; PARK6) and *DJ-1* (PARK7) mutations.

Glucocerebrosidase (*GBA*) gene mutations, when homozygous, cause autosomal recessive Gaucher disease. Heterozygous carriers are at increased risk for developing PD that is indistinguishable from idiopathic PD. PD patients with *GBA* mutations tend to have more cognitive problems, and about 13% of Ashkenazi Jews with PD have this mutation, but the same mutation causes PD in other ethnic groups as well.

PATHOGENESIS

Two major pathogenic hypotheses have emerged from epidemiologic and genetic evidences as well as postmortem examinations. One hypothesis proposes that mitochondrial dysfunction and oxidative stress are critical in the pathogenesis, whereas there is also evidence that misfolding and aggregation of proteins are instrumental in the PD neurodegenerative process. These two hypotheses are not mutually exclusive, and interactions among these pathogenic factors are likely to be important in understanding the mechanisms of

neurodegeneration in PD.

Environmental toxins associated with PD risk can damage mitochondria and generate oxidative stress. Postmortem biochemical observations also show that complex I activity of mitochondria is reduced in substantia nigra of patients with PD. Such a defect would decrease the synthesis of ATP and also lead to the buildup of free electrons, thereby increasing oxidative stress. Substantia nigra in patients with PD shows severe depletion of reduced glutathione, the major substrate required for the elimination of reactive oxygen species. This change is also seen in brains with incidental Lewy bodies and therefore could be the one of the earliest biochemical abnormalities of PD. It is not known, however, if this change is the cause or the result of oxidative stress. Iron in the substantia nigra may also play a critical role because it can catalyze the formation of the highly reactive hydroxyl radical from hydrogen peroxide. Recessive genes such as *PRKN* and *PINK1* have been shown to have wide ranging effects on mitochondrial quality control such as regulating mitochondria biogenesis, maintaining fission-fusion balance to remove damaged mitochondria, transport of mitochondria, and turnover of damaged mitochondria by recruiting autophagic machinery. Another recessive gene, *DJ-1* is implicated in a pathway handling oxidative stress. Endogenous factors may also predispose melanin-containing monoaminergic neurons to neurodegeneration. Cellular oxidation reactions (such as enzymatic oxidation and auto-oxidation of dopamine and other monoamines) result in the formation of reactive oxygen species such as dopamine quinone and other metabolic products that can damage the monoamine neurons. In addition, dopaminergic neurons and other susceptible neurons such as noradrenergic neurons in locus ceruleus are autonomous pacemakers and have long highly arborized axons, thereby subjected to high metabolic demands. A presence of a particular calcium channel may predispose these neurons to basal metabolic stress.

Most of the genes involved in PD seem to have multiple cellular functions. Nonetheless, genes producing recessive forms of PD have been implicated more in mitochondrial and metabolic pathways as noted earlier, whereas genes associated with autosomal dominant forms of PD have been noted to be involved in protein degradation homeostasis. Whether the hallmark of PD pathology, the Lewy body, which contains α -synuclein contributes to the toxicity or is a protective mechanism is not known. Evidence points to toxicity of protofibrillar forms of α -synuclein, and intriguing experimental evidence suggests that abnormal forms of α -synuclein may have the prion-like property of propagating its abnormal conformation and spreading the pathology along the neuronal projections and across the synaptic connections. α -Synuclein is involved in vesicle recycling. LRRK2 plays a role in vesicular trafficking and cytoskeletal function. Another PD gene, vacuolar protein sorting 35 (*VPS35*) was identified to cause autosomal dominant PD with typical features and good response to levodopa. This gene encodes a subunit of the retromer complex involved in endosomes and vesicular recycling. α -Synuclein and LRRK2 affects protein degradation pathways, including autophagy, a process of cell degradation of dysfunctional cellular components by lysosomes. Glucocerebrosidase is a lysosomal enzyme.

CLINICAL MANIFESTATIONS

CARDINAL MOTOR FEATURES

The clinical features of tremor, bradykinesia, rigidity, loss of postural reflexes, flexed posture, and freezing are the six cardinal motor features of parkinsonism. Not all need to be present, but at least two should be seen, either rest tremor or bradykinesia, before parkinsonism is considered clinically probable. *Rest tremor* at a frequency of 4 to 5 Hz is present in the extremities, almost always distally; occasionally, the rest tremor occurs in the proximal part of the limb instead of distally. The classic “pill-rolling” tremor involves the thumb and forefinger. Rest tremor disappears with action but sometimes reemerges as the limbs maintain a posture (Video 83.1). Rest tremor is also common in the lips, chin, and tongue. Rest tremor of the hands increases with walking and may be an early sign when others are not yet present. Stress or excitement worsens the tremor. Some patients will have an action tremor instead of or in addition to rest tremor. The biggest differential diagnosis of parkinsonian tremor

is essential tremor (ET). Ordinarily, these two causes of tremor are easy to distinguish. Tremor of PD is typically a rest tremor, whereas that of ET is a postural and action tremor. However, the manifestations of these tremors can overlap, with patients with severe ET having rest tremor. Not all patients with PD have tremor; when absent, the diagnosis is more difficult to make, and it usually takes longer after onset of symptoms to make a diagnosis. Eventually, bradykinesia worsens to the point of some disability, such as micrographia or dragging a leg when walking, that the patient seeks medical attention.

Akinesia is a paucity of spontaneous movement, but the term is often used interchangeably with *bradykinesia* and *hypokinesia*. Bradykinesia (slowness of movement, difficulty initiating movement, and loss of automatic movement) and hypokinesia (reduction in amplitude of movement, particularly with repetitive movements, so-called decrementing) are the most common features of parkinsonism, although they may appear after the tremor. Bradykinesia has many facets, depending on the affected body parts. The face loses spontaneous expression (masked facies, *hypomimia*) with decreased frequency of blinking. Poverty of spontaneous movement is characterized by loss of gesturing and by the patient's tendency to sit motionless. Speech becomes soft (*hypophonia*), and the voice has a monotonous tone with a lack of inflection (*aprosody*). Some patients do not enunciate clearly (*dysarthria*) and do not separate syllables clearly, thus running the words together (*tachyphemia*). Bradykinesia of the dominant hand results in small and slow handwriting (*micrographia*) and in difficulty shaving, brushing teeth, combing hair, buttoning, or applying makeup. Playing musical instruments is impaired. Walking is slow, with a shortened stride

P.708

length and a tendency to shuffle with loss of heel strike; arm swing decreases and eventually is lost. Difficulty arising from a deep chair, getting out of automobiles, and turning in bed are symptoms of truncal/body bradykinesia. Drooling saliva results from failure to swallow spontaneously, a feature of bradykinesia, and is not caused by excessive production of saliva. The patients can swallow properly when asked to do so but only constant reminders allow them to keep swallowing saliva. Similarly, arm swing can be normal if the patient voluntarily, and with effort, wishes to have the arms swing on walking. Pronounced bradykinesia prevents a patient with parkinsonism from driving an automobile when foot movement from the accelerator to the brake pedal is too slow.

Bradykinesia is commonly misinterpreted by patients as weakness. Fatigue, a common complaint in PD, particularly in the mild stage of the disease before pronounced slowness appears, may be related to mild bradykinesia or rigidity or may be an independent feature. Subtle signs of bradykinesia can be detected even in the early stage of parkinsonism if one examines for slowness in shrugging the shoulders, lack of gesturing, decreased arm swing, and decrementing amplitude of rapid successive movements. With advancing bradykinesia, slowness and difficulty in the execution of activities of daily living increase. A meal normally consumed in 20 minutes may be only half eaten in an hour or more. Swallowing may become impaired with advancing disease, and choking and aspiration are concerns. Bradykinesia is manifested in many ways depending on the body part affected ([Table 83.3](#)).

Rigidity is an increase in muscle tone that is elicited when the examiner moves the patient's limbs, neck, or trunk. This increased resistance to passive movement is equal in all directions and usually is manifested by a ratchety "give" during the movement. This so-called cogwheeling is caused by the underlying tremor even in the absence of visible tremor. Cogwheeling also occurs in patients with ET. Rigidity of the passive limb increases while another limb is engaged in voluntary active movement ("Froment maneuver").

Flexed posture commonly begins in the arms and spreads to involve the entire body. The head is bowed; the trunk is bent forward; the back is kyphotic; the arms are held in front of the body; and the elbows, hips, and knees are flexed. Deformities of the hands include ulnar deviation of the hands, flexion of the metacarpophalangeal joints, and extension of the interphalangeal joints (striatal hand). Inversion of the feet is

apparent, and the big toes may be dorsiflexed (striatal toe) and the other toes curled downward. Lateral tilting of the trunk commonly develops (Pisa syndrome), and extreme flexion of the trunk (camptocormia) is sometimes seen.

Loss of postural reflexes leads to falling and eventually to inability to stand unassisted. Postural reflexes are tested by the *pull test*, which is performed by the examiner, who stands behind the patient and gives a sudden firm pull on the shoulders after explaining the procedure and who checks for retropulsion (Videos 83.2 and 83.3). With advance warning, a normal person can recover within two steps. The examiner should always be prepared to catch the patient when this test is conducted; otherwise, a person who has lost postural reflexes could fall. The examiner should have a solid wall behind him or her in case a heavy patient falling backward also causes the examiner to fall backward. As postural reflexes are impaired, the patient collapses into the chair on attempting to sit down (sitting en bloc). Walking can be marked by festination, whereby the patient walks faster and faster, trying to move the feet forward to be under the flexed body's center of gravity and thus prevent falling.

The *freezing* phenomenon (motor block) is a transient inability to perform active movements. It most often affects the legs when walking but also can involve eyelid opening (known as *apraxia of lid opening* or levator inhibition), speaking (*palilalia*), and writing. Freezing occurs suddenly and is transient, lasting usually no more than several seconds with each occurrence. The feet seem as if "glued to the ground" and then suddenly become "unstuck," allowing the patient to walk again (Video 83.3). Freezing typically occurs when the patient begins to walk (start hesitation); turns while walking; or approaches a destination, such as a chair in which to sit (destination hesitation); it is often induced when the patient walks in crowded places (e.g., in the narrow confines of a theater row or when trying to go through a revolving door, or when suddenly confronted by a person coming into their path) and when there is a time restriction to the walking (e.g., trying to enter or exit an elevator before the door closes or when trying to cross a street before the traffic light turns to red). Freezing is often overcome by visual clues, such as having the patient step

P.709

over objects, and is much less frequent when the patient is going up or down steps than when walking on level ground. The combination of freezing of gait and loss of postural reflexes is particularly devastating because it often leads to falls. Falling is responsible for the high incidence of hip fractures in parkinsonian patients.

TABLE 83.3 Clinical Signs of Brradykinesia

Cranial

- Hypomimia (masked face)
- Staring expression with decreased blinking and retracted lids
- Hypometric saccades
- Impaired convergence
- Impaired upward gaze
- Hypophonia (soft voice)

-
- Aprosody of speech (loss of inflection of voice)
-

- Palilalia (repetition of first syllable)
-

- Sialorrhea (drooling of saliva)
-

Upper Limbs

- Reduced spontaneous movement (e.g., lack of gesturing)
-

- Decrementing amplitude with repetitive movements of opening and closing fists, pronating and supinating the forearms, and tapping a finger on the thumb
-

- Micrographia and slowness with handwriting
-

- Slowness in cutting food, dressing, and in hygienic care
-

- Decreased arm swing when walking
-

Lower Limbs

- Decrementing amplitude with repetitive movements of stomping feet or tapping toes
-

- Short, slow steps when walking
-

- Not elevating feet as high as normal when walking, tendency to shuffle
-

- Narrow base when walking
-

- Tendency to walk on toes; loss of heel strike
-

Body Bradykinesia

- Slowness in initiating movement on command
-

- Difficulty arising from a chair and turning in bed
-

- Difficulty carrying out two motor acts simultaneously
-

- Reduced shrugging of shoulders
-

SYMPTOMS AND SIGNS

The clinical signs and symptoms of PD can be divided into motor and nonmotor features of PD and those due to complications or adverse effects of the medications employed to treat the disease. The clinical motor features of PD are represented within the six cardinal features of parkinsonism discussed earlier. Of the six cardinal motor signs, tremor, bradykinesia, and rigidity occur early in the course of the disease, whereas flexed posture, loss of postural reflexes, and freezing of gait occur in more advanced stages. Falling is a late symptom. If these normally advanced signs and symptoms occur within 2 years of onset, one should suspect another cause of parkinsonism, such as progressive supranuclear palsy or MSA.

The onset of PD is insidious; tremor is the symptom first recognized in 70% of patients (Table 83.4). Symptoms often begin unilaterally; as the disease progresses, symptoms and signs become bilateral. The disease can remain confined to one side for several years before the other side becomes involved. The disease progresses slowly, and if untreated, the patient eventually becomes wheelchairbound and bedridden. Despite having severe bradykinesia with marked immobility, patients, when presented with a sudden stimulus, may rise suddenly and move normally for a short burst of motor activity, so-called kinesia paradoxa. The Hoehn-Yahr clinical staging (Table 83.5) captures the progression of the motor features of PD, from unilateral to bilateral, to loss of postural reflexes to disability. Disability in carrying out activities of daily living is scored on the Schwab-England scale. More detailed scoring of individual signs and symptoms of PD are captured in the Unified Parkinson's Disease Rating Scale (UPDRS) and its newer version that includes more nonmotor symptoms, the Movement Disorder Society (MDS)-UPDRS.

TABLE 83.4 Initial Symptoms in Parkinson Disease

Symptoms	No. of Cases (<i>n</i> = 183)	Percentage
Tremor	129	70.5
Stiffness or slowness of movement	36	19.7
Loss of dexterity and/or handwriting disturbance	23	12.6
Gait disturbance	21	11.5
Muscle pain, cramps, aching	15	8.2
Depression, nervousness, or other psychiatric disturbance	8	4.4
Speech disturbance	7	3.8
General fatigue, muscle weakness	5	2.7
Drooling	3	1.6
Loss of arm swing	3	1.6

Facial masking	3	1.6
Dysphagia	1	0.5
Paresthesia	1	0.5
Average number of initial symptoms per patient		1.4

TABLE 83.5 The Modified Hoehn and Yahr Staging Scale for Parkinson Disease

Stage 0	No signs of disease
Stage 1	Unilateral disease
Stage 1.5	Unilateral plus midline/axial involvement
Stage 2	Bilateral disease, without impairment of balance
Stage 2.5	Mild bilateral disease, with an abnormal pull test but with recovery to avoid falling
Stage 3	Mild to moderate bilateral disease; some postural instability (would fall on the pull test if not caught); physically independent
Stage 4	Severe disability; still able to walk or stand unassisted, but a walking aid is advisable to prevent falling
Stage 5	Wheelchair-bound or bedridden unless aided

From Fahn S, Elton RL, Members of the UPDRS Development Committee. The unified Parkinson's disease rating scale. In Fahn S, Marsden CD, Calne DB, et al, eds. *Recent Developments in Parkinson's Disease*. Vol. 2. Florham Park, NJ: Macmillan Healthcare Information; 1987:153-163, 293-304.

The nonmotor symptoms of PD ([Table 83.6](#)) can be more troublesome than the motor features of PD. Behavioral and personality changes include a reduced attention span, visuospatial impairment, and a personality that slowly becomes more dependent, fearful, indecisive, and passive. The spouse gradually makes more of the decisions and becomes the dominant partner. The patient speaks less spontaneously. The patient eventually sits much of

the day and is inactive unless encouraged to exercise. Passivity and lack of motivation are common and are expressed by the patient's aversion to visiting friends. The patient is more reticent to participate in conversations. Depression is frequent in patients with PD, with about 25% to 50% prevalence. Anxiety may be even more common, often with depression.

Cognitive decline is not an early feature but can become pronounced as the patient ages. Memory impairment, in contrast to AD, is not a feature of early PD; rather, the patient is just slow in responding to questions, so-called bradyphrenia. The correct answer can be obtained if the patient is given enough time. Subtle signs of bradyphrenia include tip-of-the-tongue phenomena from diminished verbal fluency and the inability to change mental set rapidly. In a cross section of patients with PD, 15% to 20% have a more profound dementia, but as many as 75% will develop dementia in their late 70s. Most of these patients have developed Lewy bodies in cortical neurons (Parkinson disease dementia [PDD]), and some have developed concurrent AD. These disorders are not always distinguishable, but dementia with Lewy bodies is often characterized by fluctuating hallucinations.

Sensory symptoms are fairly common, but objective sensory impairment is not seen in PD. Symptoms of pain, burning, and tingling occur in the region of motor involvement. A patient may have dull pain in one shoulder as an early symptom of the disease, which often is misdiagnosed as arthritis or bursitis, and even before clearcut signs of bradykinesia appear in that same arm. Akathisia (inability to sit still, restlessness) and the restless legs syndrome (RLS) occur in some patients with PD. In both syndromes, uncomfortable sensations disappear with movement, and sometimes, the two

P.710

conditions are difficult to distinguish. Akathisia, if present, is usually present most of the day; it may respond to levodopa but otherwise has not been treated successfully. The RLS develops late in the day with crawling sensations in the legs and may be associated with periodic movements in sleep, thereby disturbing sleep. Other sleep problems are fragmented sleep and rapid eye movement (REM) sleep behavior disorder (acting out one's dreams); the latter is usually successfully treated with clonazepam; melatonin may also provide relief. Other sleep problems are encountered with dopaminergic medications including excessive daytime sleepiness and sudden attacks of sleep without warning.

TABLE 83.6 Nonmotor Features of Parkinson Disease

Personality and Behavior

- Psychosis

-
- Punding

-
- Compulsive behaviors

-
- Nonmotor offs

Other

- Fatigue

REM, rapid eye movement.

Autonomic disturbances also are encountered. The skin is cooler, constipation is a major complaint, bladder emptying is inadequate, erection may be difficult to achieve, and blood pressure may be low. Orthostatic hypotension is not uncommon and is made worse with dopaminergic medications. A major diagnostic consideration is the dysautonomia of MSA, which often has features of parkinsonism and cerebellar dysfunction. Seborrhea and seborrheic dermatitis are common but can be controlled with good hygiene and facial cleansing.

Other nonmotor features of PD are reduced sense of smell (hyposmia), rhinorrhea, and excessive sweating.

Tendon reflexes are usually unimpaired in PD; an abnormal extensor plantar reflex suggests a Parkinson-plus syndrome, but an extension of the big toe “striatal toe” is seen in PD and can mimic a Babinski sign. More common is flexion of the toes on the involved side of the body; this can be the presenting complaint. An uninhibited glabellar reflex (Myerson sign) and palmomentar reflexes are common, even early in the disease.

DIFFERENTIAL DIAGNOSIS

The diagnosis of PD is based on the clinical features of parkinsonism; insidious asymmetric onset; slow worsening of symptoms; and the lack of other findings in the history, examination, or laboratory tests that would point to some other cause of parkinsonism (see [Tables 83.1](#) and [83.7](#)). The presence of rest tremor and substantial benefit from levodopa strongly support the diagnosis of PD. One of the most common disorders mistaken for PD is ET (see [Chapter 73](#)), which is characterized by postural and kinetic tremor, and not rest tremor unless the disease is advanced. Some patients with ET eventually develop PD. MRI is normal in PD, unless dementia or some other disorder is present. Dopamine transporter (DAT) single-photon emission computed tomography (SPECT) or positron emission tomography (PET) and 3,4-dihydroxy-6-18F-fluoro-L-phenylalanine (FDOPA) PET correlate with decreased dopaminergic nerve terminals in the striatum; the caudal putamen is affected first. DAT SPECT is available in United States and in most of the rest of the world.

P.711

P.712

It can be used to distinguish the diagnosis of PD from ET; the DAT scan is normal in ET. ¹⁸F-fluorodeoxyglucose (FDG)-PET reveals hypermetabolism in the lentiform nucleus and a progressive metabolic network pattern that correlates with disease worsening. A different metabolic network pattern is associated with declining cognition in PD and also in Parkinson-plus syndromes.

TABLE 83.7 Clues Indicate the Likely Type of Parkinsonism

Clinical	Alternative Diagnoses
Never responded to levodopa	Other than PD
Predominantly unilateral	PD; HP-HA syndrome; CBS
Symmetric onset	PD; most forms of parkinsonism
Presence of rest tremor	PD; secondary parkinsonism
Lack of rest tremor	PD; Parkinson-plus syndromes
History of encephalitis	Postencephalitic parkinsonism
History of toxin exposure	Parkinsonism caused by the toxin
Taking neuroleptics	Drug-induced parkinsonism

Shuffling gait much greater than upper limb bradykinesia	Normal pressure hydrocephalus; vascular parkinsonism
Severe unilateral rigidity	CBS
Cortical sensory signs	CBD
Unilateral cortical myoclonus	CBD
Unilateral apraxia	CBD
Alien limb	CBD
Early dementia	Dementia with Lewy bodies; AD; frontotemporal dementia
Psychotic sensitivity to levodopa	Dementia with Lewy bodies; AD
Early loss of postural reflexes	Progressive supranuclear palsy
Early falling	Progressive supranuclear palsy
Impaired downgaze	Progressive supranuclear palsy
MRI: caudate atrophy	HD; neuroacanthocytosis
MRI: decreased T2 signal in striatum	Multiple system atrophy
MRI: midbrain atrophy	Progressive supranuclear palsy
"Apraxia" of eyelid opening	Progressive supranuclear palsy
Deep nasolabial folds	Progressive supranuclear palsy
Furrowed forehead and eyebrows (quizzical look)	Progressive supranuclear palsy
Excessive hesitation between words when speaking	Progressive supranuclear palsy; CBD
Nuchal dystonia	Progressive supranuclear palsy
Abducted arms when walking	Progressive supranuclear palsy

Square wave jerks	Progressive supranuclear palsy; multiple system atrophy; CBS
Pure freezing	Progressive supranuclear palsy
Meaningful orthostatic hypotension	Multiple system atrophy
Urinary or fecal incontinence	Multiple system atrophy
Cerebellar dysarthria and dysmetria	Multiple system atrophy, SCA2, SCA3, SCA17
Laryngeal stridor (vocal cord paresis)	Multiple system atrophy
Lower motor neuron findings	Multiple system atrophy; neuroacanthocytosis
Upper motor neuron findings	Multiple system atrophy
Early orofacial dyskinesia with levodopa	Multiple system atrophy
Laboratory	
Fresh blood smear: acanthocytes	Neuroacanthocytosis
Grossly elevated creatine kinase	Neuroacanthocytosis
MRI: many lacunes	Vascular parkinsonism
MRI: "eye of the tiger" in pallidum	Pantothenate kinase-associated neurodegeneration (PKAN)
MRI: huge ventricles	Normal pressure hydrocephalus
Abnormal autonomic function tests	Multiple system atrophy
Denervation on sphincter EMG	Multiple system atrophy

PD, Parkinson disease; HP-HA, hemiparkinsonism-hemiatrophy; CBS, cortical-basal syndrome; CBD, cortical-basal degeneration; AD, Alzheimer disease; MRI, magnetic resonance imaging; HD, Huntington disease; SCA, spinocerebellar atrophy; EMG, electromyography.

Several clinical clues suggest that a patient with parkinsonism has some form of the syndrome other than PD itself (Table 83.7). In general, PD often presents with symptoms on only one side of the body, whereas patients with symptomatic parkinsonism or Parkinson-plus syndromes almost always have symmetric symptoms and signs (notable exceptions are cortical-basal syndrome and parkinsonism resulting from a focal brain injury, such as head trauma). Similarly, a rest tremor usually indicates PD because it much less

often seen in symptomatic parkinsonism or Parkinsonplus syndromes, except in drug-induced and MPTP-induced parkinsonism, which do include rest tremor. The patient who does not have unilateral onset or rest tremor, however, still can have PD that begins symmetrically and without tremor. Perhaps the most important diagnostic aid is the response to levodopa. Patients with PD almost always have a clear-cut, satisfactory response to this drug. If a patient never responds to levodopa, the diagnosis of some other form of parkinsonism is likely. A response to levodopa, however, does not confirm the diagnosis of PD because many cases of symptomatic parkinsonism (e.g., MPTP, postencephalitic, reserpine induced) and many forms of Parkinson-plus syndromes in their early stages (e.g., MSA) also respond to levodopa. [Table 83.7](#) provides a list of some helpful clues. Chapter 84 provides clinical descriptions of other parkinsonian disorders.

TREATMENT

At present, treatment is aimed at controlling motor and nonmotor symptoms of PD because no drug or surgical approach unequivocally prevents progression of the disease, although some clinical trials suggest that monoamine oxidase-B (MAO-B) inhibitors may slow clinical progression. Treatment is individualized because each patient has a unique set of symptoms; signs; response to medications; and a host of social, occupational, and emotional needs that must be considered. The goal is to keep the patient functioning independently as long as possible. Practical guides are the symptoms and degree of functional impairment and the expected benefits and risks of therapeutic agents. Much of the therapeutic effort in advanced PD involves controlling the motor adverse effects of levodopa, namely, dyskinesias and wearing-off.

Although pharmacotherapy is the basis of treatment, physiotherapy and exercise are also important [**Level 1**].¹ It involves patients participating actively in their own care, promotes exercise, keeps muscles active, preserves mobility, and improves balance. This approach is especially beneficial as parkinsonism advances because many patients tend to remain sitting and inactive. Psychiatric assistance may be required to deal with depression and anxiety and the social and familial problems that may develop with this chronic disabling illness. Electroconvulsive therapy may have a role in patients with severe intractable depression.

USEFUL DRUGS AND SURGICAL PROCEDURES

[Table 83.8](#) lists the drugs useful in parkinsonism according to mechanisms of action. It also lists some of the surgical approaches available. Selection of the most suitable drugs for the individual patient and deciding when to use them in the course of the disease are challenges for the treating clinician.

Because PD is chronic and progressive, treatment is lifelong. Medications and their doses change with time as adverse effects and new symptoms are encountered. Tactical strategy is based on the severity of symptoms.

TABLE 83.8 Therapeutic Choices for Parkinson Disease

Medications

- Dopamine precursor: levodopa ± carbidopa, standard and extended release
-
- Dopamine agonists: bromocriptine, pramipexole, ropinirole, apomorphine, cabergoline, rotigotine

- Catechol-O-methyltransferase inhibitors: entacapone and tolcapone

- Dopamine releaser: amantadine

- Glutamate antagonist: amantadine

- Monoamine oxidase type B inhibitors: selegiline and rasagiline

- Anticholinergics: trihexyphenidyl, benztropine, ethopropazine, biperiden, cycrimine, procyclidine. Weaker anticholinergics: diphenhydramine, orphenadrine, amitriptyline

- Muscle relaxants: cyclobenzaprine, diazepam, baclofen

- Peripheral antidopaminergic for nausea and anorexia: domperidone

- Antidepressants: amitriptyline and other tricyclics, fluoxetine and other serotonin uptake inhibitors

- Antianxiety agents: benzodiazepines

- Antipsychotics: clozapine, quetiapine

- Cholinesterase inhibitors for dementia: rivastigmine, donepezil

- REM sleep behavior disorder: clonazepam, melatonin

- Hypnotics: zolpidem, mirtazapine, amitriptyline, trazodone

- Antisoporific (daytime drowsiness): modafinil (Provigil), methylphenidate

- Anti-restless legs: dopamine agonists, pregabalin, gabapentin, opioids (e.g., propoxyphene, tramadol, oxycodone)

- Antisialorrhea: glycopyrrolate, propantheline, trospium (Sanctura), and other non-CNS-penetrating anticholinergics; botulinum toxin injection into salivary glands

- Antihypotensives: midodrine (ProAmatine), fludrocortisone, droxidopa

- Anticonstipation: high-fiber diet, polyethylene glycol (MiraLAX), and other laxatives

P.713

In [Table 83.8](#), *carbidopa* is listed as the peripheral dopa decarboxylase inhibitor, but in many countries, *benserazide* is also available. These agents potentiate the effects of levodopa, thus allowing about a fourfold reduction in dosage to obtain the same benefit. Moreover, by preventing the formation of peripheral dopamine, which can act at the area postrema (vomiting center), they block the development of anorexia, nausea, and vomiting. *Domperidone* is a dopamine receptor antagonist that does not enter the CNS; it is used to prevent nausea not only from levodopa but also from dopamine agonists. Domperidone is not available in the United States. Providing larger doses of carbidopa may also reduce gastrointestinal adverse effects.

Of the listed dopamine agonists, bromocriptine, pramipexole, ropinirole, rotigotine, and apomorphine are available in the United States; they are reviewed in a later section. Pergolide and cabergoline affect heart valve serotonin (5-hydroxytryptamine) 2B (5HT2B) receptors and can cause a fibrotic valvulopathy. Pergolide is no longer available in the United States. Because it is not absorbed through the intestinal tract and it is watersoluble, apomorphine is used as an injectable, rapidly acting dopaminergic drug to overcome “off” states (rescue effect). Subcutaneous apomorphine infusions are available in Europe, as are lisuride and cabergoline. Catechol-*O*-methyltransferase (COMT) inhibitors extend the elimination half-life of levodopa. Entacapone has a very short half-life and is given with each dose of levodopa. Tolcapone is longer-acting but requires monitoring for hepatotoxicity.

Amantadine, *selegiline*, *rasagiline*, and the anticholinergics are reviewed in following sections. Because the anticholinergics can cause forgetfulness and even psychosis, they should be used cautiously in patients most susceptible (those older than 70 years). The antihistaminics, tricyclics, and cyclobenzaprine have milder anticholinergic properties that make them useful in PD, particularly in the older patient who should not take the stronger anticholinergics. A number of medications listed in [Table 83.8](#) are used to treat the many nonmotor problems seen in PD; these are discussed in a later section. The surgical procedures are also covered separately.

Levodopa is uniformly accepted as the most effective drug available for symptomatic relief of many of the motor features of PD. If it were uniformly and persistently successful and also free of complications,

new strategies for other treatment would not be needed. Unfortunately, 75% of patients have serious complications after 5 years of levodopa therapy (Table 83.9).

TABLE 83.9 Five Major Outcomes after More Than 5 Years of Levodopa Therapy ($n = 330$ Patients)^a

Smooth good response	$n =$ 83 (25%)
Troublesome fluctuations	$n =$ 142 (43%)
Troublesome dyskinesias	$n =$ 67 (19%)
Toxicity at therapeutic or subtherapeutic dosages	$n =$ 14 (4%)
Total or substantial loss of efficacy	$n =$ 27 (8%)

^aThirty-six patients had both troublesome fluctuations and troublesome dyskinesias.

From Fahn S. Adverse effects of levodopa. In: Olanow CW, Lieberman AN, eds. *The Scientific Basis for the Treatment of Parkinson's Disease*. Carnforth, England: Parthenon; 1992:89-112.

TREATMENT ACCORDING TO THE STAGE OF PARKINSON DISEASE

EARLY STAGE

Authorities generally agree that in the early stage of PD when symptoms are noticed but not troublesome, symptomatic treatment is not necessary. All symptomatic drugs can induce side effects, and if a patient is not troubled socially or occupationally by mild symptoms, drug therapy can be delayed until symptoms become more pronounced. If disease-modifying therapies become available, they should be started at the time of diagnosis.

Selegiline delays the need for levodopa therapy by an average of 9 months. Because this MAO-B inhibitor provides a mild symptomatic effect, it has not been possible to conclude that selegiline also exerts a neuroprotective effect. However, a controlled study evaluating selegiline in the presence of levodopa therapy showed that those on selegiline performed better than subjects receiving placebo, including less development of

the freezing phenomenon, thus, selegiline should be considered as a therapeutic option at the time the diagnosis of PD is made [Level 1].^{2,3} Selegiline

(dose: 5 mg with breakfast and lunch) has few adverse effects when given without levodopa, but when given concurrently with levodopa, it increases the dopaminergic effect, allows a lower dose of levodopa, and contributes to dopaminergic-induced dyskinesias and hallucinations. *Rasagiline*, another irreversible propargylamine

MAO-B inhibitor, also provides mild symptomatic effect, and controlled studies suggest it might have some disease-modifying effect as well (dose: 1 mg per day) [Level 1].⁴ Exenatide showed promise of slowing progression in a pilot trial [Level 1].⁵

STAGE WHEN SYMPTOMS AND SIGNS REQUIRE SYMPTOMATIC TREATMENT

Eventually, PD progresses and symptomatic treatment must be used. The most common problems that clinicians consider important in deciding to use symptomatic agents are the following: threat to employment; threat to ability to handle domestic, financial, or social affairs; threat to handle activities of daily living; and appreciable worsening of gait or balance. In clinical practice, a global judgment for initiating such therapy is made in discussions between the patient and the treating physician.

The major decision is when to introduce levodopa, the most effective drug. All patients are likely to develop complications associated with long-term use (see Table 83.9). Younger patients, in particular, are more likely to show response fluctuations and dyskinesias, so other antiparkinsonian drugs, including dopamine agonists, could be used first to delay the introduction of levodopa in patients younger than age 50 years. This approach is known as the *levodopa-sparing strategy*. When symptoms threaten quality of life, levodopa is needed and should be administered at the lowest effective dose. High doses are more likely to induce the motor complications of dyskinesias and wearing-off. Concern that levodopa may hasten nigral dopaminergic neuronal degeneration has been largely diminished because a controlled trial, the ELLDOPA (earlier vs. later levodopa therapy in PD) study, showed that those with levodopa treatment actually are less impaired even after stopping medication for a few weeks (Fig. 83.2). The mechanism for this long-lasting improvement is not known.

The drugs used in the levodopa-sparing strategy are discussed first, for these are tolerated in younger patients, who are most prone to develop motor complications from levodopa and who can often respond to these other drugs. For patients older than

P.714

70 years or those who have some cognitive impairment, levodopa is the preferred drug because it is the most effective with the least risk of inducing psychiatric adverse effects.

FIGURE 83.2 Effect of different dosages of levodopa on the severity of PD based on changes in the Unified Parkinson's Disease Rating Scale (UPDRS). Data are from the ELLDOPA study in which subjects with early, untreated PD were randomized equally to one of three doses of levodopa (with carbidopa) or placebo. Treatment lasted 40 weeks, after which the medication was tapered to zero over 3 days, and the subjects were evaluated 7 and 14 days later. The changes in subjects treated with levodopa at different dosages or with placebo were determined on the basis of the total score of UPDRS. The scores were obtained by the blinded treating investigator who performed the evaluations before the morning dose of the daily dose of the study drug. The points on the curves represent mean changes from baseline in the total scores at each visit. Improvement in parkinsonism is represented by lower scores and worsening by higher scores. Negative scores on the curves indicate improvement from baseline. The bars indicate standard error. The last 2 weeks (weeks 40 to 42) allowed a return of symptoms and signs, but those on levodopa did not reach the same degree of worsening seen in those treated with placebo. (Data from Parkinson Study Group. Levodopa and the progression of Parkinson's disease. *N Engl J Med.* 2004;351[24]:2498-2508.)

Amantadine

Amantadine is a mild indirect dopaminergic agent that acts by augmenting dopamine release at storage sites and possibly blocking reuptake of dopamine into the presynaptic terminals. It also has some anticholinergic and antiglutamatergic properties. In the early stages of PD, it is effective in about two-thirds of patients. A major advantage is that benefit, if it occurs, is seen in a couple of days. The effect can be substantial. Unfortunately, its benefit in more advanced PD is often short-lived, with patients reporting a fall-off effect after several months of treatment. A common adverse effect is livedo reticularis (a reddish mottling of skin) around the knees (these are not harmful); other adverse effects are ankle edema and visual hallucinosis. Sometimes, when the drug is discontinued, a gradual worsening of parkinsonian signs may follow, thus indicating that the drug has been helpful. The usual dose is 100 mg two times per day, but

sometimes, a higher dose (up to 200 mg two times per day) may be required. Amantadine can be useful not only in the early phases of symptomatic therapy by forestalling use of levodopa or reducing the required dosage of levodopa but also in the advanced stages as an adjunctive drug to levodopa and the dopamine agonists. It can also reduce the severity of levodopa-induced dyskinesias, probably by its antiglutamatergic mechanism of action, and it is the most effective antidyskinetic drug available.

Anticholinergic (Antimuscarinic) Drugs

As a general rule, anticholinergic agents are less effective antiparkinsonian agents than are the dopamine agonists but may be more effective against tremor. The anticholinergic drugs are estimated to improve parkinsonism by about 20%. Many clinicians find that when tremor is not relieved by an agonist or levodopa, addition of an anticholinergic drug may be helpful. Trihexyphenidyl is a widely used anticholinergic agent. A common starting dose is 2 mg three times per day. It can be gradually increased to 15 mg or more per day.

Adverse effects from anticholinergic drugs are common, particularly in the age range of most patients with PD. Adverse cerebral effects are predominantly forgetfulness and decreased short-term memory. Occasionally, hallucinations and psychosis occur, particularly in the elderly patient; these drugs should be avoided in patients older than 70 years. If tremor is not relieved by dopaminergic drugs and one wishes to add an anticholinergic agent to the therapy for an elderly patient, amitriptyline, diphenhydramine, orphenadrine, or cyclobenzaprine is sometimes beneficial, with less CNS side effects of more potent agents. Diphenhydramine and amitriptyline can cause drowsiness and can be used as a hypnotic. For tremor control, the dose is increased gradually to 50 mg three times per day. A similar dose schedule is useful for orphenadrine. Cyclobenzaprine can be increased gradually until 20 mg three times per day is reached. Anticholinergics can reduce sialorrhea.

Peripheral side effects are common and are often the reason for discontinuing or limiting the dosage of anticholinergic drugs. Another approach is to treat peripheral adverse effects by appropriate antidotes. Pilocarpine eye drops can overcome dilated pupils that

P.715

can cause blurred vision and can be useful if glaucoma is present. Pyridostigmine, up to 60 mg three times per day, can help to overcome dry mouth, urinary difficulties, and constipation.

Dopamine Agonists

Controlled trials comparing dopamine agonists and levodopa have been carried out [Level 1].^{6,7} Dopamine agonists can be used as monotherapy in the early stage of the disease to delay introduction of levodopa or as conjunctive therapy with levodopa to potentiate an antiparkinsonian effect, to reduce the dosage needed for levodopa alone, and to overcome some of the adverse effects of long-term use of levodopa. Early use of dopamine agonists, by delaying the introduction of levodopa, delays the time to develop complications from chronic levodopa therapy such as motor fluctuations and dyskinesia. However, levodopa is added eventually for most patients on dopamine agonists and long-term follow-up studies show similar eventual prevalence of these complications in both groups [Level 1].⁸

The agonists are less effective than levodopa as antiparkinsonian agents, and most patients require the addition of levodopa within a couple of years. Bromocriptine, pergolide, lisuride, and cabergoline are ergot derivatives. As such, they could induce red inflamed skin (St. Anthony's fire), but this side effect is rare and is reversible on discontinuing the drug. Retroperitoneal, pleural, and pericardial fibrosis are more serious adverse, but also rare, events. Restrictive fibrotic cardiac valvulopathy may occur in up to one-third of patients taking pergolide (detected by echocardiography), due to its agonist effect on the heart valve

5HT_{2B} receptors, and this drug is no longer available in the United States. The nonergoline agonists, pramipexole and ropinirole, are the most commonly used dopamine agonists. They can cause excessive daytime sleepiness and ankle edema (with redness of the skin). Sleep attacks, including falling asleep without warning when driving a vehicle, are infrequent problems with dopamine agonists, but drivers need to be cautioned about such a serious possibility. Observing sleep attacks at home when just sitting in a chair is a warning sign not to drive. Defensive methods, such as delaying a dose of agonist or taking a stimulant such as modafinil or methylphenidate before a long drive, may be reasonable, but studies on whether these approaches are effective have not been carried out. Besides sleep effects and ankle edema, dopamine agonists are more prone than levodopa to induce hallucinations, particularly in the elderly who already may have some cognitive impairment.

A serious behavioral adverse effect from dopamine agonists is the development of impulse control problems in approximately 17% of subjects. These consist of pathologic gambling, hypersexuality, impulsive binge eating with weight gain, compulsive shopping, and excessive generosity, such as charitable contributions. Patients and their care providers need to be warned about this potential risk and the dosage markedly reduced or discontinued at the first sign of such a complication. Fortunately, the impulse control problem is reversible but usually requires discontinuation of these agents. Rapid elimination can induce a withdrawal reaction, so a gradual taper of the drug is preferred.

All agonists can induce anorexia and nausea. Orthostatic hypotension tends to occur when the drug is first introduced. Afterward, this complication is much less common. Therefore, the best starting regimen is a small dose at bedtime for the first 3 days (bromocriptine 1.25 mg, pramipexole 0.125 mg, ropinirole 0.25 mg) and then a switch from bedtime to daytime regimens at this dose for the next few days. The daily dose can be increased gradually at weekly intervals to avoid adverse effects (bromocriptine 1.25 mg, pramipexole 0.25 mg, ropinirole 0.75 mg) until a benefit or a plateau dosage is reached (bromocriptine 5 mg three times per day, pramipexole 0.5 mg three times per day, ropinirole 1 mg three times per day). If this plateau is not satisfactory, the dose either can be increased gradually until it is quadrupled or can be held constant while beginning carbidopa/levodopa. Extended-release tablets of pramipexole and ropinirole are also available and can be given once a day. The same total daily dose as the immediate release formulations provides similar effects.

Rotigotine is not absorbed via the intestinal tract but is absorbed transdermally. It is available as a dermal patch, with absorption over 24 hours. It is a weak dopamine agonist, but the once-a-day dermal patch application is convenient, and as such allows daylong plasma levels of the agonist, which theoretically could reduce wearing-off and nocturnal akinesia.

Besides the adverse effects listed earlier, there are subtle differences among the dopamine agonists. Cabergoline has the longest pharmacologic half-life and theoretically could be taken in once-a-day dosing, but valvulopathy is a risk. All agonists act at the D₂ receptor, which may account for most, if not all, of their anti-PD activity ([Table 83.10](#)). Pergolide acts at both the D₁ and D₂ dopamine receptors. Bromocriptine is a partial D₁ antagonist. Pergolide, pramipexole, and ropinirole also act at the D₃ dopamine receptor, but it is not clear what effect this has clinically, but it is conceivable that the D₂/D₃ ratio may be instrumental in causing the impulse control problems seen with these drugs. All three appear to be equally effective against PD; bromocriptine appears to have the weakest anti-PD effect. Dopamine agonists, when used in the absence of levodopa, rarely induce dyskinesias. Whether this is because of their longer half-life and possibly more continuous dopaminergic receptor stimulation or because they exert a different receptor effect than that of levodopa is unknown. If the agonists alone are not sufficiently effective, carbidopa/levodopa is needed.

Levodopa

In controlled trials comparing levodopa and agonists as initial therapy, levodopa produced a superior clinical response but more fluctuations and dyskinesias as noted earlier. Some clinicians prefer to begin therapy with carbidopa/levodopa for early symptomatic treatment and to add an agonist after a small dose has been reached (e.g., 25/100 mg three times per day). This approach is particularly useful if a patient already has some disability. The advantage of using levodopa at this stage in preference to a dopamine agonist is that a therapeutic response is virtually guaranteed. Nearly all patients with PD respond to levodopa and do so quickly. In contrast, only some benefit derives adequately from a dopamine agonist alone, and it may take months to discover

P.716

this because of a slower buildup of dosage. Therefore, if a definite response is needed quickly (e.g., to remain at work or to be self-sufficient), levodopa is preferable. On the other hand, if there is no particular urgency for a rapid clinical response and if the patient has no cognitive problems and is younger than 50 years of age, then beginning with a dopamine agonist allows one to use the levodopa-sparing strategy. Patients older than 70 years are less likely to develop response fluctuations with levodopa and more likely to develop confusion and hallucinations with dopamine agonists, so in this population, carbidopa/levodopa would be a good choice as a starting drug.

TABLE 83.10 Effect on Receptors by Dopamine Agonists

Agonist	D1	D2	D3	D4	D5	5-HT Receptor

Lisuride	+	++	?	?	?	+

+, activates; -, inhibits; 0, no effect; ?, uncertain.

STAGE WHEN SYMPTOMS AND SIGNS REQUIRE TREATMENT WITH LEVODOPA

When other antiparkinsonian medications are no longer bringing about a satisfactory response, levodopa is required to reduce the severity of parkinsonism. Levodopa is the most potent anti-PD drug. In treating patients with PD, the rule of thumb has been to use the lowest dosage that can bring about adequate symptom reversal, not the highest dosage that the patient can tolerate. As previously mentioned, the longer the duration of disease and the higher the dose, the greater the likelihood motor complications will occur. After 5 years of levodopa therapy, about 75% of patients with PD have some form of troublesome complication (see [Table 83.9](#)). On the other hand, a dose-response study showed a clear-cut dose-related clinical benefit, which is an advantage with

higher dosages (see [Fig. 83.2](#)) [**Level 1**].⁹

Combining levodopa with a peripheral dopa decarboxylase inhibitor (e.g., carbidopa) increases therapeutic potency and reduces gastrointestinal adverse effects, which can also be mitigated by increasing the dosage of levodopa slowly. A safe approach is to start with half tablet of 25/100 mg strength carbidopa/levodopa once a day. Continue for a week and weekly increase by another half tablet. By the sixth week, a plateau dose of 25/100 mg three times daily is reached. Giving levodopa with meals during this titration phase will reduce the risk for anorexia and nausea. If there is inadequate benefit, continue to increase the dose but at a faster rate. The 25/250-mg tablets can also be used, and a dose of 25/250 mg three or four times a day is common in patients with more advanced disease.

Extended-release forms of carbidopa/levodopa (Sinemet CR) and benserazide/levodopa (Madopar HBS) provide a longer half-life and a lower peak plasma level of levodopa. In the early stage of levodopa therapy, when complications have not yet developed, use of extended-release carbidopa/levodopa had not proven advantageous over the use of the standard preparation in a controlled trial because it did not delay motor fluctuations. However, it may be useful to start treatment with such an extended-release preparation in elderly patients to avoid too high a brain concentration of levodopa that might induce side effects such as drowsiness.

Once response fluctuations have developed, the extended-release preparation could reduce mild wearing-off. Also, a bedtime dose often allows more mobility during the night. Disadvantages are a delay in the response with each dose, less reliability of absorption, and the possibility of a late-in-the-day excessive dyskinesia response that can be prolonged. For a quick response on awakening, patients often take the standard (immediate release) preparation as the first morning dose in addition to the extended-release form. Some patients need a combination of standard and extended-release preparations of levodopa throughout the day to obtain a smoother response and minimize their motor complications.

The extended-release tablets of carbidopa/levodopa are available in two strengths: scored (50/200 mg, which can be broken in half) and unscored (25/100 mg). Neither should be crushed because the matrix of the tablet that delays solubilization would no longer be intact. When added to a dopamine agonist, a dose of 25/100 mg three to four times per day often suffices. When used alone, a starting dose of 25/100 mg three times per day often is necessary and can be increased as needed to 50/200 mg three or four times per day. For those desiring to produce a continuous dopaminergic stimulation effect, multiple dosing a day should be considered. If greater relief is required, a dopamine agonist or standard carbidopa/levodopa should be added.

It should be noted that the entire content of the extended-release formulation is not absorbed before the tablet passes through the duodenum and jejunum (the sites where levodopa is absorbed), so that an equivalent dose needs to be approximately 1.3 times greater than a dose of standard carbidopa/levodopa to achieve the same clinical efficacy. A combination of immediate and extended release carbidopa/levodopa in capsules (Rytary) has become available; it has a longer half-life and may offer advantages in some patients.

Some clinicians attempt to extend the plasma half-life of levodopa by adding a COMT inhibitor, such as entacapone, with each dose of levodopa. A clinical trial found such a combination resulted in earlier dyskinesias than levodopa alone.

INADEQUATE RESPONSE TO LEVODOPA TREATMENT

As a general rule, the single most important piece of information to help the differential diagnosis of PD and other forms of parkinsonism is the response to levodopa. If the response is nil or minor, the disorder probably is not PD. An adequate response, however, does not ensure the diagnosis of PD. All presynaptic disorders (e.g., reserpine-induced, MPTP-induced, postencephalitic parkinsonism) respond to levodopa. Also, a response to levodopa can occur in the early stages of MSA and progressive supranuclear palsy;

only later, when striatal dopamine receptors are lost, is the response lost.

Before concluding that levodopa is without effect in a given patient, an adequate dose must be tested. Not every symptom has to respond, but bradykinesia and rigidity respond best, whereas tremor can be resistant. Therefore, if rest tremor is the only symptom, lack of improvement does not exclude the diagnosis of PD. Tremor may never respond satisfactorily, even if adjunctive antiparkinsonian drugs are also used. Before concluding that *carbidopa/levodopa* is ineffective, a dose up to 2,000 mg levodopa per day should be tried if tolerated. If anorexia, nausea, or vomiting prevent attainment of a therapeutic dosage, the addition of extra carbidopa (additional 25 mg four times per day) or domperidone (10 to 20 mg before each levodopa dose) is usually effective in overcoming the adverse effect. If other adverse effects (drug-induced dystonia, psychosis, confusion, sleepiness, postural hypotension) prevent attainment of an effective dose, uncertainty about the diagnosis of PD will continue. In particular, dystonia induced by low doses of levodopa suggests a diagnosis of MSA. Similarly, drug-induced psychosis suggests PDD, diffuse Lewy body disease, or accompanying AD. Clozapine or quetiapine may suppress psychosis and allow the use of levodopa.

COMPLICATIONS OF LONG-TERM LEVODOPA THERAPY

Response fluctuations (wearing-off), dyskinesias, and behavioral effects are the major problems encountered with long-term levodopa therapy (Tables 83.11 and 83.12). These problems are features of an advanced stage of PD.

P.717

FLUCTUATIONS

Response to dopaminergic drugs consists of the short-duration response (SDR) within the time frame of hours and the long-duration response (LDR) that develops more slowly over weeks or longer. When levodopa therapy is initiated, the benefit from levodopa is usually sustained, with general improvement throughout the day and no dose-timing variations; mostly consisting of LDR. Skipping a dose is usually without loss of effect, and the response is evident on arising in the morning despite the lack of medication throughout the night. The pharmacokinetics of levodopa show a short initial distribution phase with a half-life of 5 to 10 minutes, a peak plasma concentration in about 30 minutes, and an elimination phase of about 90 minutes. Brain levels follow plasma levels. The mechanism for the LDR of levodopa is not known. It cannot be explained by a prolonged storage of dopamine from exogenous levodopa in residual nigrostriatal nerve terminals, and basal ganglia circuitry plasticity is probably responsible for this phenomenon.

With chronic levodopa therapy, however, most patients, including all patients with onset before age 40 years, begin to experience fluctuations. At first, fluctuations take the form of wearing-off (also known as *end-of-dose deterioration*), which is defined as a return of parkinsonian symptoms in less than 4 hours after the last dose. Gradually, the duration of benefit shortens further and the “off” state becomes more profound. The magnitude of the SDR to levodopa in patients with fluctuations may increase because the loss of the LDR leads to worse “off” states and patients notice fluctuations more readily due to greater difference between “on” and “off” states.

In some patients, these fluctuations become more abrupt in onset and random in timing; the condition is then the “on-off” effect and cannot be related to the timing of the levodopa intake. Motor “offs” are often accompanied by changes in mood (depression, dysphoria), anxiety, thought (more bradyphrenia), sensory symptoms (pain, akathisia), and dysautonomia (excessive sweating, urgency). Such behavioral, sensory, and autonomic “offs” can occur in the absence of motor “offs” and then they are difficult to recognize. Patients, in order to eliminate these unpleasant sensations, often take more frequent doses of levodopa, which has led some clinicians to call this the *dopamine disequilibrium syndrome*.

The brief peripheral half-life of levodopa, by itself, is not likely to be responsible for fluctuations. The half-life, present from the beginning of treatment, does not change. Also, no difference exists in the pharmacokinetics in patients with early disease who show a stable response and in those with advanced disease and fluctuations. Loss of striatal storage sites of dopamine by itself is not the sole cause of fluctuations either. The central effects on basal circuitry are likely to be involved. Some hypothesize that intermittent (compared with continuous) administration of levodopa contributes to the development of motor complications. These peaks and valleys of brain dopamine levels are thought to alter the striatal dopaminergic medium spiny GABAergic neurons and their synaptic connections with other striatal interneurons and cortical afferents that provide glutamatergic input.

- Depression, anxiety, panic, pain, akathisia, dysphoria

Once established, motor complications are seemingly irreversible. Substituting dopamine agonists for levodopa therapy or maintaining plasma concentrations at a constant therapeutic level by chronic infusion of levodopa diminishes the severity of the complications but does not eliminate them. Jejunal infusions of levodopa via a catheter inserted via the abdominal wall into the stomach and then passed into the jejunum, subcutaneous infusions of apomorphine, and hourly oral administration of liquefied levodopa have been used to “smooth out” the effect of levodopa. Selegiline, rasagiline, and COMT inhibitors are partially effective in treating mild wearing-off problems, probably by prolonging dopamine levels at the synapse [Level 1].¹⁰ The addition of these drugs to patients taking levodopa, however, may lead to dopaminergic side effects, including increased dyskinesias, confusion, and hallucinations. Another approach is to combine the slow-release forms of carbidopa/levodopa (Sinemet CR) with the standard (immediate-release) form. Again, this approach is effective mainly on wearing-off problems and not on complicated on-off fluctuations. Furthermore, the sustained-release formulation results in less predictable plasma levels of levodopa and often increases dyskinesias. Standard carbidopa/levodopa can be given alone by shortening the interval between doses. For the more severe state of on-off phenomenon, a more rapid and more predictable response sometimes can be achieved by dissolving the levodopa tablet in carbonated water or ascorbic acid solution because an acidic solvent can both dissolve levodopa and prevent its auto-oxidation. Liquid levodopa enters the small intestine faster, is absorbed faster, and can be used to fine-tune dosing. Patients with fluctuations often develop delayed “ons” and dose failures resulting from delayed entry of levodopa into the small intestine. Liquefying or crushing levodopa by the patient's teeth can help resolve this problem.

A large meal that slows gastric emptying and high-protein meals can cause dose failures in some patients. Levodopa is absorbed from the small intestine by the transport system for large neutral amino acids and thus competes with these other amino acids for this transport. Patients with this problem may benefit by taking levodopa before meals and also from special diets that contain little protein for the first two meals of the day, followed by a high-protein meal at the end of the day when they can afford to be “off.”

Direct-acting dopamine agonists, with their biologic half-lives longer than that of levodopa, can be used in combination with standard or slow-release forms of levodopa. The agonists are useful for treating both wearing-

off and on-off by reducing both the frequency and the depth of the “off” states. In yet another approach to treating on-offs, the patients inject themselves with apomorphine subcutaneously to quickly return to the “on” state. Trimethobenzamide or the peripheral dopamine receptor antagonist domperidone can be used to block nausea and vomiting from apomorphine.

DYSKINESIAS

Dyskinesias are commonly encountered with levodopa therapy but are often mild enough to be unnoticed by the patient. Severe forms, including chorea, ballism, dystonia, or combinations of these, can be disabling. The incidence and severity increase with duration and dosage of levodopa therapy, but they may appear early in patients with severe parkinsonism. Dyskinesias are divided into the following categories according to the timing of levodopa dosing:

1. Peak-dose dyskinesias appear at the height of antiparkinsonian benefit (20 minutes to 2 hours after a dose).
2. Diphasic dyskinesias, usually affecting the legs, appear at the beginning and end of the dosing cycle. Often, these may be mostly noticed by the patient at the end of the dose, blending into tremor that occurs during “off” state (see Video 83.4).
3. “Off” dystonia, which can be painful sustained cramps, appears during “off” states and may be seen at first as “early-morning dystonia” presenting as painful foot cramps; these are relieved by the next dose of levodopa.

Dyskinesias are usually seen in patients who have fluctuations, and some patients may move rapidly from severe peak-dose dyskinesias to severe “offs”; this process is known as *yo-yoing*. These patients may have only a brief “on” state. More commonly, they have good “ons” for parts of the day but are intermittently disabled by dyskinesias or “offs.” These diurnal variations are major problems; patients with this combination have a narrow therapeutic window for levodopa. The mechanisms for dyskinesias, fluctuations, and good response that lead to “on” are not well understood, and they may have common pathways as well as differential ones. For example, those with dyskinesias are usually good responders to dopaminergic agents and many drugs that reduce dyskinesia may make parkinsonism worse. On the other hand, sensitivity to dyskinesias is not altered by chronic infusion of levodopa, whereas fluctuations are suppressed. Because dopamine agonists are much less likely to cause dyskinesias, which have much less activation of the D1 receptor, increased sensitivity and response of the D1 receptor by dopamine derived from levodopa are thought to play a role in the production of dyskinesias.

Amantadine can reduce the severity of dyskinesias, but a dosage of at least 400 mg/day is required, and it is not known how long the benefit may last. Treatment of peak-dose dyskinesias also includes reducing the size of each dose of levodopa. If doing so results in more wearing-off, the levodopa can be given more frequently with smaller dosages, or a dopamine agonist or inhibitor of MAO-B or COMT can be added with the reduced dose of levodopa. Diphasic dyskinesias are more difficult to treat. Increasing the dosage of levodopa can eliminate this type of dyskinesia, but peak-dose dyskinesia usually ensues. A switch to a dopamine agonist as the major antiparkinsonian drug is more effective; low doses of levodopa are used as an adjunctive agent. The end-of-day dyskinesia is a part of the end-of-dose dyskinesia (part of diphasic dyskinesia). There is always a last dose of the day, and when that wears off, dyskinesias ensue. Medications such as amantadine and dopamine agonists rarely help end-of-day dyskinesias. Patients usually find that by taking the last dose of levodopa at home in the evening, and then allowing the dyskinesias to occur, lasting usually no more than 1 to 2 hours, the patient can live with this situation. Once the dyskinesia fades, the patient is then comfortable the rest of the evening. The principle of treating “off dystonia” is to try to keep the patient “on” most of the time. Here again, using a dopamine agonist as the major antiparkinsonian drug, with low doses of levodopa as an adjunct, can often be effective.

FREEZING

The freezing phenomenon is often listed as a type of fluctuation because of transient difficulty in initiating movement. But this phenomenon should be considered as distinct from the other types of fluctuations. “Off-freezing” must be distinguished from “on-freezing.” Off-freezing, best considered a feature of parkinsonism itself, was encountered before levodopa was discovered. The treatment goal of off-freezing is to keep the patient from turning “off.” Onfreezing remains an enigma; it tends to be aggravated by increasing the dosage of levodopa or by adding direct-acting dopamine agonists or selegiline without reducing the dosage of levodopa. Rather, it may be lessened by reducing the dosage of levodopa. There is no satisfactory treatment for on-freezing. Both on- and off-freezing seem to correlate with both the duration of illness and the duration of levodopa therapy. Patients with a combination of complicated fluctuations, dyskinesias, and off-freezing may respond to subthalamic nucleus stimulation. On-freezing does not respond to surgical therapy.

MENTAL AND BEHAVIORAL COMPLICATIONS

The adverse effects of confusion, agitation, hallucinations, delusions, paranoia, and mania are probably related to activation of dopamine receptors in nonstriatal regions, particularly cortical and limbic structures. Both levodopa and dopamine agonists can cause these complications, with the latter more prone to do so. Elderly patients and those with diffuse Lewy body disease or concomitant AD are sensitive to small doses of these dopaminergics. But all patients with PD, regardless of age, can develop psychosis if they take excessive amounts of levodopa or agonists to overcome “off” periods. Patients with pronounced behavioral/sensory offs tend to take more and more levodopa.

Although antipsychotic drugs can reduce levodopa-induced psychosis, adding neuroleptics that block D2 dopamine receptors worsens parkinsonism. Rather, quetiapine or clozapine, antipsychotic agents that preferentially block the dopamine D4 and serotonin receptors, can often treat psychosis without worsening parkinsonism. These drugs easily induce drowsiness, and they should be given at bedtime, starting with a dose of 12.5 mg. The dose can be gradually increased if necessary. Start with quetiapine to avoid the biweekly blood counts required with clozapine. Quetiapine is much less effective than clozapine, and it is not uncommon that clozapine is required. Because clozapine induces agranulocytosis in 1% to 2% of patients, patients must have blood counts monitored biweekly, and the drug must be discontinued

P.719

if leukopenia develops. If clozapine is not tolerated, other drugs, including small doses of olanzapine, molindone, pimozide, or other relatively weak antipsychotic drugs, can be used. If the antipsychotic drugs increase the parkinsonism, lowering the dosage of levodopa to avoid the psychosis is preferable to maintaining the antipsychotic agent at high dosage. Levodopa cannot be discontinued suddenly because the abrupt cessation may induce a neuroleptic malignant-like syndrome.

Impulse control problems (gambling, hypersexuality, excessive eating, and shopping) induced by dopamine agonists or less commonly by levodopa can be devastating to the patient and family. Patients and families need to be aware about these potential problems so they can inform the treating physician. Fortunately, these problems are eliminated by reducing the dosage but sometimes only by discontinuing the agonists. Levodopa would need to substitute for the agonists.

Punding is a behavioral disorder that has a resemblance to the impulse control problems discussed earlier. The term was first used in amphetamine abusers and refers to an abnormal motor behavior in which there is intense repetitive handling and examining of objects, such as picking at oneself, taking apart watches and radios, or sorting and arranging of common objects, such as lining up pebbles, rocks, or other small objects. Punding has been reported with levodopa and dopamine agonists. Treatment is problematic, but atypical antipsychotics have been suggested.

TREATING THE NONMOTOR PROBLEMS OF PARKINSON DISEASE

Although many nonmotor symptoms can appear before the classic cardinal motor features of PD (e.g., hyposmia, REM sleep behavior disorder, depression, anxiety, constipation), many do not appear until later in the disease. Cognitive decline occurs late and is probably the most devastating nonmotor problem. When dementia occurs, the patient is not able to tolerate dopaminergics because of the susceptibility for psychosis, especially hallucinations, but also paranoia. Treatment of psychosis was discussed in the preceding section. Dementia is difficult to treat, but some response can be seen with the cholinesterase inhibitors, rivastigmine 1.5 to 6 mg twice a day and donepezil 5 to 10 mg/day. Antidepressants are needed for treating depression. The serotonin uptake inhibitors are effective in treating depression of PD but may aggravate parkinsonism if antiparkinsonian drugs are not given concurrently. Tricyclics may be equally effective. Because of its anticholinergic and soporific effects, amitriptyline can be useful for these properties as well as for its antidepressant effect. Alprazolam, diazepam, and other benzodiazepines are usually well tolerated without worsening parkinsonism and can help to lessen tremor by reducing the reaction to stress that worsens tremor.

REM sleep behavior disorder, a condition where one moves while dreaming, is common in patients with PD. It is more troublesome for the bed partner than for the patient, but it can also cause the patient to fall out of bed and injure himself. It is extremely well treated with clonazepam at bedtime. Start with 0.5 mg and increase the dose if necessary. Sleep fragmentation is common in PD, and many patients have a difficult time falling back asleep after an arousal. A short-acting hypnotic given at that time (not at bedtime), such as zolpidem 5 mg, can provide relief. The other hypnotics listed in [Table 83.8](#) can also be effective. If the patient requires an antipsychotic for vivid dreams, quetiapine or clozapine, which cause drowsiness, can be used instead of the hypnotics listed in the table. Excessive daytime sleepiness is another type of sleep problem that is common in PD; it is due to medications. Dopamine agonists commonly cause drowsiness, and in older patients with cognitive problems, levodopa can cause drowsiness at the peak of the dose. Modafinil up to 200 mg morning and midafternoon or methylphenidate up to 10 mg three times a day may provide some relief.

Many patients with PD develop RLS, which consists of unpleasant crawling sensations in the legs, particularly when sitting and relaxing in the evening, and which disappear on walking. Whether RLS is an epiphenomenon of PD, because both conditions respond to dopaminergics, is not clear. It is possible that RLS is a result of the dopaminergic medications used to treat PD. Sporadic and familial RLS respond to dopamine agonists and levodopa, but these drugs can cause augmentation, a worsening of the restless legs symptoms—more severe unpleasant sensations, occurring earlier in the day and spreading to involve other body parts. Fortunately, pregabalin 300 mg/day is effective [**Level 1**].¹¹ Opioids are also effective in treating RLS and periodic movements in sleep, whether in patients with PD or those with sporadic and familial RLS. Tramadol 25 mg late in the day before the onset of symptoms is usually effective, and one can titrate up to 150 mg/day if necessary. Oxycodone 5 to 15 mg, methadone 5 to 20 mg, and codeine 30 to 60 mg are also effective.

The varied autonomic symptoms in PD need to be treated specifically. Orthostatic hypotension can respond to midodrine, starting with 10 mg/day and titrate up to three doses a day if necessary. If midodrine is not effective, fludrocortisone can be used as well as adding salt to the diet. Combinations of these agents may be needed. Supine hypertension can be an adverse effect, and the head of the bed may need to be elevated to avoid that. It is important that the patient's blood pressure, lying, sitting, and standing, be monitored by the family at home, reporting to the treating physician so the dosages of these agents can be properly adjusted. Droxidopa is a new agent approved for treating orthostatic hypotension. It is metabolized in the peripheral circulation to norepinephrine by the enzyme dopa decarboxylase. Thus, it will not be effective if more than 100 mg/day of carbidopa is being used.

Sialorrhea can be an annoying and embarrassing problem. Anticholinergics are effective, but most available agents are tertiary amines that enter the CNS and can impair memory or cause hallucinations in older patients.

Quaternary amines, such as glycopyrrolate and propantheline, do not penetrate the CNS, and they are preferable. If such drugs are not completely effective, injections of botulinum toxin into the salivary glands can be attempted; an overdose could impair swallowing, so an experienced physician should carry out the injections. Constipation is a common complaint. It should be treated with a high-fiber diet, supplemented by laxatives such as polyethylene glycol (MiraLAX).

SURGICAL THERAPY

Prior to the introduction of levodopa therapy, stereotactic surgery producing lesions in the thalamus or pallidum was common, resulting in reduction in tremor more than relief from other features of PD. Such surgery faded away after levodopa became available. But with the problems of motor complications from levodopa, there has been renewed interest in surgical therapy, mainly to treat these motor complications. The surgical approaches listed in [Table 83.8](#) are not considered in the early stages of PD but are reserved for patients who respond to levodopa and who have developed intractable motor complications from it. Stereotaxic lesions have been largely replaced by high-frequency electrical stimulation at the same targets because of safety concerns. *Thalamotomy and*

P.720

thalamic stimulation (the target for both is the ventral intermediate nucleus) are best for contralateral intractable tremor. Tremor can be relieved in at least 70% of cases. Although a unilateral lesion carries a small risk, bilateral operations result in dysarthria in 15% to 20% of patients. Thalamic stimulation seems to be safer and can be equally effective against tremor, but it runs the risks associated with foreign bodies and thin electronic wires that can break. *Pallidotomy and pallidal stimulation* (the target is the posterolateral part of the GPi) are most effective for treating contralateral dopa-induced dystonia and chorea but also have some benefit for bradykinesia and tremor. The target in the GPi is believed to be the site of afferent excitatory glutamatergic fibers coming from the subthalamic nucleus, which is overactive in PD.

Lesions of the subthalamic nucleus, although effective in relieving parkinsonism in animal models, are hazardous in humans because hemichorea or hemiballism may result. Instead, *stimulation of the subthalamic nucleus* is used and appears to be the most effective in reducing contralateral bradykinesia and tremor [**Level 1**].¹² Indeed, the most common type of surgery today is to use electrical stimulation of the subthalamic nucleus. Such deep brain stimulation (DBS) provides a reduction in not only tremor but also bradykinesia and rigidity, allowing a reduction in dosage of dopaminergic medication. The antiparkinsonian effect is never better than the best levodopa effect (except for tremor in which surgery seems superior). It is not effective against symptoms that do not respond to levodopa (with the exception of intractable tremor, which can respond to stimulation). Therefore, DBS can be useful in patients with a very good anti-PD response to levodopa but with uncontrollable response fluctuations. DBS has the potential to smooth out these fluctuations. This type of surgery often allows a marked reduction in levodopa dosage, thereby reducing dopa-induced dyskinesias as well as treating parkinsonian symptoms. The best results are seen with younger patients. DBS in the GPi is superior for controlling dyskinesias. The presence of cognitive problems and lack of benefit from levodopa are contraindications. Cognitive problems worsen with surgical penetration in the brain. DBS produces levodopa-like benefits probably by restoring the physiologic balance in the basal ganglia circuitry, bypassing the need to restore dopamine levels. In this concept, DBS could be considered an “electronic levodopa.” Adverse effects from the surgery include brain hemorrhage (rare), infection from a foreign body, speech impairment, dystonia, and breakage of the wires. Unfortunately, even in young patients, there can be impaired cognition, dysarthria, depression with suicide attempts, and incomplete control of fluctuations and dyskinesias. Targeting the GPi results in less dysarthria, depression, and cognitive impairment than the subthalamic nucleus. Experienced neurosurgeons and accurate placement of the electrodes are most important, and followup programming of the stimulators is an ongoing process to reach the ideal electrical settings. Exposure of the metallic stimulators to

diathermy can result in permanent brain injury.

Pilot trials suggest that stimulation of the pedunculopontine nucleus can reduce falling, but results have been inconsistent. Controlled trials are needed to determine if falling and freezing of gait respond to the stimulation of this target. Controlled surgical trials of *fetal dopaminergic tissue implants* have found the benefits to be less efficacious than initially reported in open-label investigations and have also led to the development of persistent dyskinesias. Until this problem can be solved, transplantation surgery is not a useful option. The same concern exists for the potential of cellular therapy with dopaminergic stem cells. On the other hand, intrajejunal infusion of levodopa is already available and it offers a smooth pharmacokinetic profile of levodopa that reduces clinical fluctuations and dyskinesias [Level 1].¹³ Percutaneous catheterization of the stomach with the catheter advanced into the jejunum avoids intracerebral penetration with its potential adverse effects.

OUTCOME

PD, being a neurodegenerative disease, worsens with time. Before the introduction of levodopa, PD caused severe disability or death in 25% of patients within 5 years of onset, in 65% in the next 5 years, and in 89% in those surviving 15 years. The mortality rate from PD was three times that of the general population matched for age, sex, and racial origin. Although no definite evidence indicates that levodopa alters the underlying pathologic process or stems the progressive nature of the disease, indications exist of a major impact on survival time and functional capacity. The mortality rate has dropped 50%, and longevity is extended by several years.

A debated point in the treatment of PD is the cause of declining efficacy from continuing treatment with levodopa seen in many patients. End-stage PD is denoted when the response to levodopa is inadequate to allow patient-assisted activities of daily living. Progression of the illness with further loss of dopamine storage sites in the presynaptic terminals cannot be the explanation for this outcome because loss of these structures in postencephalitic parkinsonism results in greater, not lower, sensitivity to levodopa. Perhaps as PD progresses, it is associated with loss of striatal dopamine receptors and loss of the presynaptic dopaminergic neuron.

After about 15 years of disease, most patients are seriously disabled, and the mortality rate increases compared to an age- and gender-matched population. Despite very effective medications for the early symptoms of PD, the motor symptoms of bradykinesia return and loss of postural reflexes constantly worsen, limiting ambulation. Falling and incurring fractures are common. In stage 5, patients require a wheelchair. Dysphagia with choking and aspiration and immobility with decubitus ulcers are common events. Dementia develops in most patients, rendering patients susceptible to psychosis with hallucinations and paranoid ideation. Patients become dependent on others for activities of daily living, and many are placed in nursing homes. Such a course emphasizes the importance of better understanding the pathogenesis and the need for disease-modifying therapy.

Parkinson-Plus Syndromes

Paul Greene

INTRODUCTION

Parkinson disease (PD) is the most common cause for a dopamine deficiency syndrome, but other causes for this syndrome had been identified from a small number of pathologic examinations since the early 20th century. It was not until the introduction of levodopa to treat PD in the late 1950s and early 1960s that clinicians began to identify patients who had dopamine deficiency signs but, unlike patients with PD, had minimal or no improvement with levodopa. Because multiple causes for levodopa-unresponsive dopamine deficiency states were soon identified, such patients were said to have parkinsonism or Parkinson-plus syndromes.

PROGRESSIVE SUPRANUCLEAR PALSY, MULTIPLE SYSTEM ATROPHY, CORTICOBASAL DEGENERATION

The three most common Parkinson-plus syndromes are progressive supranuclear palsy (PSP), multiple system atrophy (MSA), and corticobasal degeneration (CBD).

HISTORY

Progressive Supranuclear Palsy

In 1964, Steele, Richardson, and Olszewski reviewed autopsies of patients who had a syndrome of pseudobulbar palsy, supranuclear ocular palsy (chiefly affecting vertical gaze), axial rigidity and dystonia, early loss of postural reflexes, and dementia. They found a pattern of neuronal degeneration and neurofibrillary tangles (NFTs), chiefly affecting the pons and midbrain. This condition became known as the *Steele-Richardson-Olszewski syndrome* or PSP. As more autopsies became available, it became clear that this characteristic pathology could also produce other patterns of initial symptoms in addition to the originally described disease now called *Richardson syndrome*. In progressive supranuclear palsy-parkinsonism (PSP-P), patients in the early stage of the disease resemble idiopathic PD. However, occasional patients with PSP pathology may also present with corticobasal syndrome (see the following text), progressive nonfluent aphasia (PNFA), akinesia with gait freezing, primarily ataxia, or even pure dementia.

Multiple System Atrophy

It was noticed as early as 1900 that some patients with parkinsonian signs had additional signs and symptoms referable to other brain systems: cerebellar dysfunction (called *olivopontocerebellar atrophy* or OPCA) or autonomic dysfunction (termed *Shy-Drager syndrome* or SDS). Another syndrome of rapidly progressive parkinsonism with neuronal loss and gliosis primarily in the putamen and substantia nigra but no Lewy bodies on autopsy was termed *striatonigral degeneration* (SND). It was eventually noticed that some patients had elements of all these syndromes, and that patients with one clinical syndrome might have pathology overlapping with the other syndromes. The term *multiple system atrophy* (MSA) was introduced to indicate that SND, SDS, and OPCA were all part of a single disease spectrum. The later identification of a common pathology (synuclein-containing glial cytoplasmic inclusions) confirmed the suspicion that these conditions represented one disease (Table 84.2). Some patients with MSA have upper motor neuron signs and one of the original SDS patients had lower motor signs as well. It is not clear how many patients with parkinsonism and motor neuron disease have the pathology of MSA, so that the current criteria for MSA do not include the parkinsonism-amyotrophy syndrome. Because most patients have some degree of autonomic dysfunction, the disease is now characterized

according to the presenting motor dysfunction: MSA-P when parkinsonism dominates the picture and MSA-C when cerebellar dysfunction predominates.

Corticobasal Degeneration

Initially reported as corticodentatonigral degeneration with neuronal achromasia in 1967, this disorder was characterized clinically by a combination of levodopa-unresponsive parkinsonism with early loss of balance, severe unilateral limb dystonia, and almost any focal cortical deficit. The pathology was also characteristic: enlarged achromatic neurons in cortical areas (particularly parietal and frontal lobes) along with nigral and striatal neuronal degeneration without Lewy bodies. The syndrome, also called *cortical-basal ganglionic degeneration* in the past, is now usually called *corticobasal degeneration* (CBD). As with PSP, it is now recognized that this pathology can also present clinically in other ways: as a frontal behavioral-spatial syndrome, PNFA, a progressive supranuclear palsy-like syndrome (PSPS), and dementia without motor abnormalities. Because patients with the pathology of PSP may mimic CBD, the original clinical syndrome is now called *corticobasal syndrome*. The overlap in both pathology and clinical features between CBD and PSP has raised concerns that the two diagnoses may represent a spectrum of a single disease despite a small number of pathologic findings unique to each diagnosis.

EPIDEMIOLOGY

The reported prevalence of each syndrome varies dramatically. In part, this is because clinical studies tend to underestimate the prevalence, whereas autopsy studies tend to overestimate the prevalence (because unusual cases are more likely to come to autopsy). PSP is the most common, generally reported in clinical studies to have a prevalence of 1 to 20 per 100,000 (compared to 100 to 200 per 100,000 for PD). In a large autopsy study, of all patients diagnosed with parkinsonism, about 4% had a pathologic diagnosis of PSP, about 2% had MSA, and about 1% had CBD (compared with more than 60% with PD).

P.723

PATHOBIOLOGY

Progressive Supranuclear Palsy

Atrophy of the dorsal midbrain, globus pallidus, and subthalamic nucleus; depigmentation of the substantia nigra; and mild dilatation of the third and fourth ventricles and aqueduct are seen on gross visual inspection of the postmortem brain in typical PSP. Light microscopy shows neuronal loss with gliosis, numerous NFTs, and neuropil threads in many subcortical structures, including the subthalamic nucleus, pallidum, substantia nigra, locus ceruleus, periaqueductal gray matter, superior colliculi, nucleus basalis, inferior olive, red nucleus, oculomotor nuclei, and cerebral cortex, especially the prefrontal and precentral areas. The NFTs appear as skeins of fine fibrils, often globose in shape in brain stem neurons. Ultrastructurally, they are composed of short, straight 12- to 15-nm tubules arranged in circling and interlacing bundles containing neurofilament proteins and the neurotubule-associated protein tau. In PSP, inclusion of exon 10 of tau creates a predominance of four repeated microtubule-binding domains, compared with a mixture of three and four repeated domains in Alzheimer disease. The typical astrocytic lesion in PSP is the tufted astrocyte, in contrast to the astrocytic lesion in CBD, the astrocytic plaque (see following text). Coiled bodies consisting of NFTs are found in astrocytes in both PSP and CBD (Fig. 84.1).

Multiple System Atrophy

The full pathologic spectrum of MSA consists of neuronal loss and gliosis in the neostriatum, substantia nigra, globus pallidus, cerebellum, inferior olives, basis pontine nuclei, intermediolateral horn cells, corticospinal tracts, and, rarely, anterior horn cells. A characteristic pathologic feature is the presence of widespread glial

cytoplasmic inclusions, particularly in oligodendroglia. These argyrophilic, α -synuclein-positive, perinuclear structures are primarily composed of straight microtubules containing ubiquitin and tau protein. In SND, nerve cell loss and gliosis are found predominantly in the substantia nigra and neostriatum. In SDS, the preganglionic sympathetic neurons in the intermediolateral horns are lost. In addition, other areas may be affected, particularly the substantia nigra (to produce parkinsonism), the cerebellum (to cause ataxia), and the striatum (to cause lack of response to levodopa). In OPCA, there is degeneration of the olives, pons, and cerebellum as well as neuronal loss in the striatum and substantia nigra. Less often, the anterior horn cells are involved (to cause amyotrophy) (Fig. 84.2).

FIGURE 84.1 Pathology of PSP. The typical pathologic findings in PSP are tufted astrocytes (**A**), globose NFT (*inset* in **A**), and coiled bodies (**B**). (Modified from Dickson DW. Neuropathology of non-Alzheimer disease degenerative. *Int J Clin Exp Path.* 2010;3:1-23.)

Corticobasal Degeneration

In CBD there is asymmetric atrophy usually most severe in the frontoparietal region with relative sparing of the occipital lobes. Swollen vacuolated neurons are found in the atrophic cortical areas and to a lesser degree in the affected subcortical regions. These swollen or ballooned neurons contain phosphorylated neurofilaments and sometimes tau and ubiquitin. There is neuronal loss and gliosis in affected cortex and in the globus pallidus, putamen, red nucleus, thalamus, subthalamic nucleus, substantia nigra, locus ceruleus, and to a lesser degree in the dentate nucleus. Remaining neurons in affected areas contain the globose tangles common in PSP, in this setting called *corticobasal bodies*. As in PSP, white matter is affected with a variety of abnormalities including tau-containing fibrils coiling around the nuclei of oligodendroglia (coiled bodies). The typical glial finding in CBD is not the tufted astrocyte common in PSP but tau-containing processes surrounding astrocytes called *astrocytic plaques*. As in PSP, 4-repeat tau predominates but the insoluble tau fragments in CBD have a different ultrastructure from the insoluble fragments of tau in PSP (Fig. 84.3).

SYMPTOMS AND SIGNS

Progressive Supranuclear Palsy

Patients with classical PSP or Richardson syndrome have an akinetic rigid Parkinson-like syndrome with early loss of postural reflexes, falls, and dementia and usually have a supranuclear palsy early in the course. Rest tremor, asymmetric onset, and improvement with levodopa are uncommon. Axial rigidity often exceeds limb rigidity, and the posture may be erect. Patients have facial dystonia with deep nasolabial folds and furrowed brow (Procerus sign), an appearance of surprise or concern. When the patient walks, the neck may be extended, the arms abducted at the shoulders and flexed

at the elbows. Dysphagia and dysarthria usually appear early and become severe. The voice is slurred and hoarse, and some patients become anarthric as the disease progresses. Gait “freezing” may be prominent, and transient arrest of motor activity interrupts walking, speaking, and/or other actions.

FIGURE 84.2 Pathology of MSA. The typical pathologic findings in MSA are glial cytoplasmic inclusions (**A**), but they may be accompanied by neuronal inclusions (*arrow* in **B**) and α -synuclein-positive fibrillar neuronal inclusions (*inset* in **B**). (Modified from Dickson DW. Neuropathology of non-Alzheimer disease degenerative. *Int J Clin Exp Path.* 2010;3:1-23.)

The first visual symptoms in Richardson syndrome are failure to maintain eye contact in social interactions and difficulty with tasks requiring downgaze, such as reading, eating, or descending stairs. Hesitation on voluntary downgaze is found on examination accompanied by loss of vertical optokinetic nystagmus on downward movement of the target. Patients often complain of diplopia, blurred vision, or difficulty reading. Disturbances of eyelid motility are also common, including lid retraction (resulting in a staring expression), blepharospasm, and apraxia of eyelid opening or closing. Eyelid opening and closing apraxia (which are probably not true apraxia) are far more common in PSP than in any other extrapyramidal disorder. Fixation instability with coarse squarewave jerks and faulty suppression of the vestibulo-ocular reflex are common.

FIGURE 84.3 Pathology of CBD. The typical pathologic findings in CBD are astrocytic plaques (clusters of tau-positive processes around a central astrocyte) (**A**), ballooned neurons (*inset* in **A**) and threadlike processes (**B**). (Modified from Dickson DW. Neuropathology of non-Alzheimer disease degenerative.

The cognitive impairment of PSP syndromes has been considered the archetype of subcortical dementia. The striking features are severe bradyphrenia (slowed thought), impaired verbal fluency, and difficulty with sequential actions or shifting from one task to another. Cognitive tests that depend on visual performance are especially affected. Apathy and disinhibition are common. Impulsiveness compounds postural instability and often leads to behavior that accentuates fall risk. Emotional incontinence is dominated by inappropriate weeping or, less frequently, laughing.

P.725

The course of PSP is aggressive; 3 to 4 years after onset, patients cannot walk without assistance and at a median of 5 years after onset, they are confined to bed and chair. They succumb to infection (from aspiration or pressure ulcers) or the sequelae of falls. The course varies according to the clinical syndrome, but Richardson syndrome has inexorable deterioration, culminating in death in 6 to 10 years in most cases.

In PSP-P, falls, dementia, and supranuclear palsy develop later and patients are more likely to have an asymmetric onset, rest tremor, and response to levodopa early in the course (although these usually do not persist). In some patients with PSP pathology, depending on the distribution of pathology, language difficulty may precede motor signs, presenting as a dysarthric, slow expressive aphasia (called *primary progressive aphasia* or *progressive nonfluent aphasia*). In a small number of patients, variation in pathology may produce other initial syndromes: freezing and balance difficulty without significant rigidity (akinesia with gait freezing), pure dementia without significant motor deficits, cerebellar syndrome, or corticobasal syndrome (see the following text) (Videos 84.1 and 84.2).

Multiple System Atrophy

The defining symptoms of SND are those of parkinsonism without tremor. Progression is usually rapid, and beneficial response to levodopa is absent or slight, presumably because striatal neurons containing dopamine receptors are usually lost. Dystonic reactions are common following low-dosage levodopa therapy. Orthostatic hypotension is a common presenting symptom of SDS syndrome (sometimes with labile blood pressure), but other dysautonomic symptoms are also troublesome, including impotence, urge incontinence, incomplete bladder emptying, and gastrointestinal (GI) motility disorders. Laryngeal stridor (often at night but sometimes during the day as well) strongly suggests SDS syndrome and can be life threatening. Other sleep symptoms include dysrhythmic breathing, sleep, and central apnea. OPCA is characterized by a mixture of parkinsonism and cerebellar syndrome, including gait ataxia, dysmetria, scanning speech, nystagmus, hypometric saccades, supranuclear upgaze impairment, and other cerebellar eye movement abnormalities. The least common presentation of MSA involves amyotrophy mimicking amyotrophic lateral sclerosis (ALS) (often combined with parkinsonism). Some patients with pathologic MSA may have pure autonomic failure for many years before developing other symptoms (and some may have the pathology and eventually develop symptoms of Lewy body disease). Dementia in MSA is rarely severe. As noted earlier, combinations of these symptoms often occur. Most patients progress rapidly and are in a wheelchair by a median 6 to 7 years after onset, although patients with cerebellar deficit predominance seem to progress more slowly. As in other Parkinson-plus syndromes, patients die from pulmonary, urinary tract and pressure ulcer infections, and complications of falls. Unlike the other syndromes, patients with MSA are also at risk for cardiopulmonary arrest due to autonomic dysfunction.

Corticobasal Degeneration

The onset of CBD is insidious and typically unilateral, with focal cortical deficits, and often marked rigidity-dystonia in the involved arm and/or leg. Sustained postures leading to contractures are common. Bradykinesia is usually present but may be hard to detect in the dystonic limb or limbs. Cortical signs of apraxia, alien limb phenomenon, cortical sensory loss, cortical reflex myoclonus, and occasionally aphasia are usually dramatic. In addition to focal signs, global cortical dysfunction (dementia) is common. Speech is hesitant and dysarthric, gait

is poor, and occasionally action tremor is evident. Falls usually occur shortly after onset of the disease. The disease usually spreads slowly to involve both sides of the body, and supranuclear gaze difficulties can occur late in the course. Patients with CBD pathology may present with several other syndromes. In the frontalspatial syndrome, patients present with some combination of executive dysfunction, behavioral change, and visuospatial deficits. CBD at the onset may also look like PSP, PNFA, or a dementia without characteristic motor or focal cortical features (Video 84.3).

DIAGNOSIS

There have now been consensus criteria for the diagnosis of each of these syndromes. They were developed primarily for clinical research but are commonly used for clinical diagnosis as well (Tables 84.1, 84.2, 84.3).

Levodopa-unresponsive parkinsonism with early involvement of gait and balance suggests a Parkinson-plus syndrome, most commonly PSP, MSA, or CBD. There are two challenges: (1) Can we identify patients with signs and symptoms of one disease but the pathology of another? (2) Can we identify patients who seem to have idiopathic PD early in the course but actually have one of these syndromes?

It is not possible to predict the underlying pathology 100% of the time. Supranuclear vertical ophthalmoplegia suggests Richardson disease. Vertical eye movements are usually affected first in PSP whereas they develop late in CBD and are usually horizontal in MSA. Significant cerebellar deficits are most common in MSA but are rarely present in PSP. Autonomic failure is a hallmark of MSA and is uncommon in PSP and CBD but can be prominent in diffuse Lewy body disease (DLBD). Significant cognitive impairment is common in PSP and CBD but uncommon in MSA. Focal cortical deficits are a defining feature of CBD but occur in a minority of patients with PSP. Visual hallucinations and dopa-dyskinesias are more likely to be present in PD than in PSP-P or the other syndromes. Vascular parkinsonism often meets criteria for a Parkinson-plus syndrome and can be mistaken for PSP if eye movements are involved. Vascular parkinsonism can only be present with significant magnetic resonance imaging (MRI) abnormality, but white matter disease on MRI does not exclude PSP, MSA, or CBD. Frontotemporal lobar degeneration (FTLD)-parkinsonism can mimic any of these conditions, especially if the dementia lags behind the motor symptoms. PSP or CBD may present as dementia without motor abnormalities or as levodopa-responsive parkinsonism without incompatible signs and there may be no clinical way to correctly identify the disease until it progresses. Any patient with symmetric parkinsonian signs or where the lower body is more affected than the upper body may eventually develop a Parkinson-plus syndrome but this is neither sensitive nor specific.

¹⁸F-fluorodeoxyglucose (FDG) positron emission tomography (PET) can accurately distinguish between PD and all Parkinson-plus syndromes but is not generally available. There are other imaging markers for each of these syndromes but none is yet accepted as sensitive and specific. Midbrain atrophy can be quantified on computed tomography or MRI and is often different for PSP, MSA, and CBD. Rostral midbrain atrophy greater than pons atrophy may resemble the beak of a hummingbird in PSP. There may be hyperintensity in the dorsolateral margin of the putamen

P.726

(“putaminal slit” sign) and cruciform increased signal in the pons (“hot cross bun” sign) in MSA. Focal cortical atrophy suggests CBD. Autonomic failure in MSA affects preganglionic sympathetic neurons (plasma epinephrine is normal when the patient is supine but fails to rise when the patient stands), and this may differentiate it from orthostasis in DLBD.

TABLE 84.1 Diagnostic Criteria for Progressive Supranuclear Palsy

Inclusion Criteria for Possible or Probable PSP

Gradually progressive disorder with age at or older than 40 yr

Exclusion Criteria for Possible or Probable PSP

Recent history of encephalitis

Alien limb syndrome

Cortical sensory deficits

Focal frontal or temporoparietal atrophy

Hallucinations or delusions unrelated to dopaminergic therapy

Cortical dementia of the Alzheimer type

Prominent, early cerebellar symptoms

Unexplained dysautonomia

Evidence of other conditions that might explain symptoms

Supportive Criteria for Possible or Probable PSP

Symmetric proximal > distal akinesia or rigidity

Abnormal neck posture, especially retrocollis

Poor or absent improvement with levodopa

Early dysphagia and dysarthria

Early onset of cognitive impairment, including two or more of the following:

- Apathy
 - Impairment of abstract thought
 - Decreased verbal fluency
 - Use or imitation behavior
-

- Frontal release signs

Possible PSP

Either:

- Vertical supranuclear palsy
 - Slowing of vertical saccades and postural instability with falls after less than 1 yr of disease
-

Probable PSP

Vertical supranuclear palsy and prominent postural instability with the tendency to fall within the first year of disease

Definite PSP

Meets all criteria for possible or probable PSP and histopathologic confirmation at autopsy

PSP, progressive supranuclear palsy.

Modified from Litvan I, Bhatia KP, Burn DJ, et al. SIC task force appraisal of clinical diagnostic criteria for parkinsonian disorders. *Mov Dis.* 2003;18:467-486.

TABLE 84.2 Diagnostic Criteria for Multiple System Atrophy

Possible MSA

Gradually progressive sporadic disease starting older than age 30 yr

• At least one feature suggesting autonomic dysfunction:

- Unexplained urinary urgency, frequency, or incomplete bladder emptying

- Erectile dysfunction in males

- Significant orthostatic hypotension

• At least one additional feature of MSA (see below)

• Either:

- Parkinsonism (bradykinesia with rigidity, tremor, or postural instability)

- Cerebellar syndrome (gait ataxia with cerebellar dysarthria, limb ataxia, cerebellar oculomotor dysfunction)
-

Probable MSA

Gradually progressive sporadic disease starting older than age 30 yr

- Autonomic failure with either:
-

- Urinary incontinence (inability to control the release of urine from the bladder) with erectile dysfunction in men

- Orthostatic decrease of blood pressure within 3 min of standing by at least 30 mm Hg systolic or 15 mm Hg diastolic

- Either:
-

- Poorly levodopa-responsive parkinsonism (bradykinesia with rigidity, tremor, or postural instability)

- Cerebellar syndrome (gait ataxia with cerebellar dysarthria, limb ataxia, cerebellar oculomotor dysfunction)

Additional Features of Possible MSA

- Possible MSA-P or MSA-C
-

- Babinski sign with hyperreflexia

- Stridor

- Possible MSA-P
-

- Rapidly progressive parkinsonism

- Poor response to levodopa

- Postural instability within 3 yr of motor onset

- Gait ataxia, cerebellar dysarthria, limb ataxia, or cerebellar oculomotor dysfunction

- Dysphagia within 5 yr of motor onset

- Atrophy on MRI of putamen, middle cerebellar peduncle, pons, or cerebellum

- Possible MSA-C

- Parkinsonism (bradykinesia and rigidity)

- Atrophy on MRI of putamen, middle cerebellar peduncle or pons

- Hypometabolism on FDG-PET in putamen

- Presynaptic nigrostriatal dopaminergic denervation on SPECT or PET

MSA, multiple system atrophy; MSA-P, MSA-parkinsonism; MSA-C, MSA-cerebellar dysfunction; MRI, magnetic resonance imaging; FDG-PET, ¹⁸F-fluorodeoxyglucose-positron emission tomography; SPECT, single-photon emission computed tomography; PET, positron emission tomography.

Modified from Gilman S, Wenning GK, Low PA, et al. Second consensus statement on the diagnosis of multiple system atrophy. *Neurology*. 2008;71:670-676.

TABLE 84.3 Diagnostic Criteria for Corticobasal Degeneration

Probable CBD

- Insidious onset and gradual progression

- Onset on or after age 50 yr, present for at least 1 yr, less than two affected relatives

- Either:

- Probable CBS

- FBS

- NAV with at least one probable CBS feature (see below)

Probable CBS

Asymmetric presentation of both:

- At least two of the following:

- Limb rigidity or akinesia

- Limb dystonia

-
- Limb myoclonus
-

• At least two of the following:

- Orobulbar or limb apraxia
-

- Cortical sensory deficit
-

- Alien limb (more than just overflow levitation)
-

FBS Syndrome

Two of the following:

- Executive dysfunction
-

- Behavioral or personality change
-

- Visuospatial deficits
-

Nonfluent/Agrammatic Variant (NAV) of Primary Progressive Aphasia

Effortful, agrammatic speech with at least one of the following:

- Impaired grammar/sentence comprehension with relatively preserved single word comprehension
-

- Groping, distorted speech production (apraxia of speech)
-

PSP Syndrome (PSPS)

Three of the following:

- Axial or symmetric limb rigidity or akinesia
-

- Postural instability or falls
-

- Urinary incontinence
-

- Behavioral change
-

- Supranuclear vertical gaze palsy or decreased vertical saccade velocity
-

Possible CBD

-
- Insidious onset and gradual progression
-

- Present for at least 1 yr
-

- Either:
-

- Probable CBS
-

- NAV or FBS
-

- PSPS with at least one possible CBS feature (see below)
-

Possible CBS

Asymmetric or symmetric presentation of both:

- At least one of the following:
-

- Limb rigidity or akinesia
-

- Limb dystonia
-

- Limb myoclonus
-

- At least one of the following:
-

- Orobuccal or limb apraxia
-

- Cortical sensory deficit
-

- Alien limb (more than just overflow levitation)
-

CBD, corticobasal degeneration; CBS, corticobasal syndrome; FBS, frontal behavioural-spatial syndrome; NAV, non-fluent/aggramatic variant of primary progressive aphasia; PSP, progressive supranuclear palsy.

Modified from Armstrong MJ, Irene Litvan I, Lang AE, et al. Criteria for the diagnosis of corticobasal degeneration. *Neurology*. 2013;80:496-503.

In the past, these syndromes were thought to be sporadic, but recently a small number of genetic conditions have been identified that may be clinically diagnosed as PSP, MSA, or CBD.

TREATMENT

The treatment of all Parkinson-plus syndromes is difficult and the approaches are similar in PSP, CBD, and MSA and so are discussed together. Medications are usually ineffective for parkinsonian symptoms in these conditions but are more likely to be effective in MSA-C when the striatum is relatively spared. Levodopa, however, can exaggerate orthostatic hypotension in MSA. Measures to overcome this problem include wearing support hose, ingesting salt, and taking fludrocortisone, midodrine, and other hypertensive agents. Patients can sleep with head elevated to avoid nocturnal hypertension and, if this is a problem, the dose of fludrocortisone should be kept to a minimum. If the striatum becomes more involved, with presumed loss of dopamine receptors, the benefit of levodopa diminishes. Treatment with levodopa requires increasing the dose to the maximum-tolerated dose or up to 2 g/day (in the presence of carbidopa) to determine whether any therapeutic response can be obtained. Apraxia of eyelid opening (mainly in PSP) and painful dystonia or rigidity can be treated with botulinum toxin when the symptoms are relatively focal and the muscles can be located and injected. Tricyclic antidepressants or dextromethorphan/quinidine may suppress inappropriate crying or laughing. Anticholinergic drugs in modest doses or botulinum toxin injections may be useful in controlling drooling. Patients with Parkinson-plus syndromes are at high risk for swallowing difficulty, so botulinum toxin should be used with care. Antidepressants may be helpful for depression in all Parkinson syndromes (it is not known if some antidepressants are more effective than others), although most patients do not

P.728

tolerate dopamine receptor-blocking agents that are sometimes used to treat depression. 1-Deamino-8-D-arginine vasopressin at bedtime may help avoid nocturnal incontinence (and also help orthostasis). Constipation is managed as with idiopathic PD but may be less responsive to treatment. As with other Parkinson-plus syndromes, painful cramps may respond to botulinum toxin injections. Some families use enteric feeding when there is risk of aspiration. Gastric tubes do not prevent regurgitation followed by aspiration. Duodenal tubes do prevent aspiration but require continuous feeding, not bolus feeding ([Table 84.4](#)).

DRUG/TOXIN-INDUCED PARKINSONISM

DOPAMINE RECEPTOR BLOCKING DRUGS

Drugs that block striatal dopamine D2 receptors (e.g., phenothiazines, butyrophenones, thioxanthenes, and other centrally acting dopamine receptor blockers including some antiemetic medications and some calcium channel blockers) or deplete striatal dopamine (e.g., reserpine, tetrabenazine) can induce a parkinsonian state. It may take weeks to months for the parkinsonism to resolve after the offending agent is withdrawn. Parkinsonism that persists longer than 6 months after drug withdrawal is attributed to underlying PD that became evident during exposure to these antidopaminergic drugs. Anticholinergic drugs can ameliorate drug-induced parkinsonian signs and symptoms. The atypical antipsychotic agents, clozapine and quetiapine, are the antipsychotics least likely to induce or worsen parkinsonism.

1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE

Although rare, parkinsonism induced by this toxin is important because it selectively destroys the dopamine nigrostriatal neurons, and the mechanism has been investigated intensively for possible clues to the etiology and pathogenesis of PD. 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is a protoxin, being converted to

MPP⁺ by the action of the enzyme monoamine oxidase type B.

MPP⁺ is taken up selectively by dopamine neurons and terminals via the dopamine transporter system. MPP⁺ inhibits complex I in the mitochondria, depletes ATP, and increases the content of superoxide ion radicals. Superoxide in turn can react with nitric oxide to form the oxyradical peroxynitrite. MPTP-induced parkinsonism has occurred in drug abusers who used it intravenously and possibly also in some laboratory workers exposed to the toxin. The clinical syndrome is indistinguishable from PD and responds to levodopa. PET indicates that a subclinical exposure to MPTP results in a reduction of fluorodopa uptake in the striatum, thereby making the person liable to future development of parkinsonism.

TABLE 84.4 Treatment of Progressive Supranuclear Palsy, Multiple System Atrophy, and Corticobasal Degeneration

Indication	Treatment	Potential Side Effects
Motor difficulty	Sinemet to tolerance	Orthostasis (esp. MSA), dystonia (esp. MSA), nausea, psychosis, others
Apraxia of eyelid opening (esp. PSP)	BTX injections	Ptosis, others
Depression	Antidepressants (except DRBA)	Lethargy, agitation, others
Drooling	Anticholinergics, BTX	Dry mouth, confusion (anticholinergics), dysphagia (esp. BTX)
Nocturnal incontinence	DDAVP	Hypertension
Constipation	As with PD	—
Painful muscle cramps	BTX	Excess muscle weakness
Aspiration	Gastric or duodenal tube	—

MSA, multiple system atrophy; PSP, progressive supranuclear palsy; BTX, botulinum toxin; DRBA, dopamine receptor-blocking agents; DDAVP, 1-deamino-8-D-arginine vasopressin; PD, Parkinson disease.

OTHER DRUGS BESIDES DOPAMINE RECEPTOR BLOCKERS AND MPTP

Many other medications are occasionally reported to cause reversible parkinsonism, including antidepressants, anticonvulsants, antihypertensive medications, antiarrhythmics, immunosuppressants and others. In some cases, parkinsonism is relatively common; in others, parkinsonism is reported only rarely. In the rare cases, other medications known to cause parkinsonism may have also played a role and some may be coincidental idiopathic

PD. For a partial list of drugs causing parkinsonism, see [Table 84.5](#).

LYTICO-BODIG (PARKINSON-DEMENTIA-AMYOTROPHIC LATERAL SCLEROSIS COMPLEX OF GUAM)

Although not definitely a drug-induced disorder, epidemiologic evidence supports a probable environmental cause for Lytico-Bodig, with exposure occurring during adolescence or early adult years. Lytico-Bodig was identified when Chamorro natives on Guam in the Western Pacific were found to have a surprising incidence of parkinsonism, dementia, and motor neuron disease. The incidence has declined gradually with modernization of the culture. One hypothesis is that environmental exposure to the neurotoxin found in the seed of the plant *Cycas circinalis* was responsible for the neuronal degeneration. Natives on Guam used this seed to make flour in World War II. However, this hypothesis has been refuted. Besides parkinsonism, dementia, and motor neuron disease in various combinations, supranuclear gaze defects also appear. A characteristic pathologic finding is the presence of NFTs in the degenerating neurons, including the substantia nigra. Lewy bodies and senile plaques are absent.

P.729

TABLE 84.5 Drugs Causing Drug-Induced Parkinsonism

Drugs/Indications	Mechanism of Action
High Risk of DIP	
First-generation antipsychotics: haloperidol, chlorpromazine, pimozide, thioxanthenes, trifluoperazine, others	Dopamine receptor blockade
Second-generation antipsychotics: risperidone, olanzapine, ziprasidone, aripiprazole	Dopamine receptor blockade
Dopamine depletors: tetrabenazine, reserpine	Dopamine depletion
Antiemetics: metoclopramide, prochlorperazine	Dopamine receptor blockade
Ca ⁺⁺ channel blockers: flunarizine, cinnarizine	Dopamine receptor blockade
MPTP	Destruction of dopamine-producing neurons
Intermediate Risk of DIP	
Atypical antipsychotics: quetiapine, clozapine	Dopamine receptor blockade
Ca ⁺⁺ channel blockers: diltiazem, verapamil	—

Antiepileptics: valproic acid, phenytoin, levetiracetam	—
Mood stabilizers: lithium	—
Low Risk of DIP	—
Antiarrhythmics: amiodarone	—
Immunosuppressants: cyclosporine	—
Antidepressants: SSRIs: fluoxetine, sertraline	—
MAO inhibitors: moclobemide, phenelzine	MAO inhibition
Antivirals: acyclovir, vidarabine, anti-HIV drugs	—
Statins: lovastatin	—
Antifungals: amphotericin B	—
Hormones: medroxyprogesterone, levothyroxine sodium	—
Cholinesterase inhibitors: donepezil, rivastigmine	—

Reports of parkinsonism in the low-risk category may be contaminated by coincidental idiopathic Parkinson disease or by polypharmacy.

DIP, drug-induced parkinsonism; MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine; SSRIs, selective serotonin reuptake inhibitors; MAO, monoamine oxidase.

Data from Lopez-Sendon J, Mena MA, de Yebenes JG. Drug-induced parkinsonism. *Expert Opin Drug Saf.* 2013;12:487-496.

HEMIPARKINSONISM-HEMIATROPHY SYNDROME

This relatively benign syndrome consists of hemiparkinsonism in association with ipsilateral body hemiatrophy and/or contralateral brain hemiatrophy. The parkinsonism usually begins in young adults and may remain as hemiparkinsonism, sometimes with hemidystonia, or progress to generalized parkinsonism. It tends to be nonprogressive or slowly progressive compared with PD. The disorder is thought to result from brain injury early in life, possibly even perinatally. It sometimes responds to medications.

NORMAL PRESSURE HYDROCEPHALUS

The gait disorder in normal pressure hydrocephalus (see [Chapter 106](#)) resembles that of parkinsonism, with shuffling short steps and loss of postural reflexes and sometimes freezing. Features of urinary incontinence and dementia occur later. Tremor is rare. The grossly enlarged ventricles lead to the correct diagnosis, with the symptoms often improving on removal or shunting of CSF. The gait disorder is in striking contrast to the lack of parkinsonism in the upper part of the body. The major differential diagnoses for lower body parkinsonism include

vascular parkinsonism and Parkinson-plus syndromes.

PARKINSON-DEMENTIA SYNDROMES

Although bradyphrenia is common in PD, dementia also occurs in over 30% of PD patients in clinics. The incidence of dementia increases with age, and those with dementia have a higher mortality rate. The two most common pathologic substrates for dementia in parkinsonism are pathologic changes typical of AD and the presence of Lewy bodies diffusely in the cerebral cortex. It is not known if the Alzheimer changes are coincidental because of the elderly population of affected individuals or whether AD and PD are somehow related. A clinical distinction has been made between patients who develop dementia before motor symptoms (or within a year of developing motor symptoms), labeled *DLBD* and those who develop dementia long after motor symptoms appear, labeled

P.730

Parkinson disease dementia (PDD). Because these conditions are similar in most other pathologic and clinical features, it is not known if these represent the spectrum of one disease or multiple separate diseases. Similarly, it is not known whether the spread of Lewy bodies into the cortex is a feature of progression of PD or a distinct entity.

POSTENCEPHALITIC PARKINSONISM

Although rarely encountered today, postencephalitic parkinsonism was common in the first half of the 20th century. Parkinsonism was the most prominent sequel of the pandemics of encephalitis lethargica (von Economo encephalitis) that occurred between 1919 and 1926. Although the causative agent was never established, it affected mainly the midbrain, thus destroying the substantia nigra. The pathology is distinctive because of the presence of NFTs in the remaining nigral neurons and absence of Lewy bodies. In addition to slowly progressive parkinsonism, with features similar to those of PD, oculogyric crises often occurred in which the eyes deviate to a fixed position for minutes to hours. Dystonia, tics, behavioral disorders, and ocular palsies may be present. Patients with postencephalitic parkinsonism are more sensitive to levodopa, with development of dyskinesias, mania, or hypersexuality at low dosages. Anticholinergics are tolerated and are effective against oculogyria.

VASCULAR PARKINSONISM

Vascular parkinsonism resulting from lacunar disease is not common but can be diagnosed by neuroimaging, with MRI evidence of hyperintense

T2-weighted signals compatible with small infarcts. Hypertension is usually required for the development of this disorder. The onset of symptoms, usually with a gait disorder, is insidious, and the course is progressive. A history of a major stroke preceding the onset of parkinsonism is rare, although a stepwise course is sometimes seen. Gait is profoundly affected (lower body parkinsonism) with freezing and loss of postural reflexes. Tremor is rare. Response to the typical antiparkinsonian agents is usually minimal or absent. Videos can be found in the companion e-book edition. For a full list of video legends, please see the front matter.

Amyotrophic Lateral Sclerosis and Motor Neuron Diseases

Rebecca Traub

Hiroshi Mitsumoto

INTRODUCTION

Several different diseases are characterized by progressive degeneration and loss of motor neurons in the spinal cord with or without similar lesions in the motor nuclei of the brain stem, the motor cortex, or both and by replacement of the lost cells by gliosis. All these can be considered *motor neuron diseases* (plural). The term *motor neuron disease* (singular), however, is used to describe an adult disease, *amyotrophic lateral sclerosis* (ALS), in which both upper and lower motor neurons are affected. (The terms *motor neuron disease* and *amyotrophic lateral sclerosis* have become equivalent in the United States.)

The term *spinal muscular atrophy* (SMA) refers to syndromes characterized solely by lower motor neuron signs. By conventional usage, the term *spinal muscular atrophy* is reserved for the child-hood form, which is heritable, as described in Chapter 141.

Other motor neuron disease variants include progressive muscular atrophy, in which patients show only lower motor neuron signs; primary lateral sclerosis, in which patients show only upper motor neuron signs; progressive bulbar palsy, with weakness limited to bulbar muscles; and monomelic amyotrophy, in which the usual lower motor neuron findings are restricted to a single limb. These motor neuron disease subtypes are described more in detail in the following sections ([Table 85.1](#)).

It should be noted that there is some clinical overlap between motor neuron diseases, pure motor neuropathies (particularly those that are hereditary), and the hereditary spastic paraplegias (HSP). Distinguishing and classifying clinical phenotypes that lie in the overlap between these diagnoses often clinically challenging at present because of lack of diagnostic biomarkers.

TABLE 85.1 Motor Neuron Disease Variants

Amyotrophic lateral sclerosis (ALS)	Upper and lower motor neuron degeneration
Progressive muscular atrophy (PMA)	Purely lower motor neuron involvement
Primary lateral sclerosis (PLS)	Purely upper motor neuron involvement
Progressive bulbar palsy	Bulbar symptoms only or bulbar-onset ALS
Monomelic muscular atrophy	Lower motor neuron predominant, one arm
Bibrachial amyotrophy	Lower motor neuron predominant, both arms

AMYOTROPHIC LATERAL SCLEROSIS

DEFINITION

ALS is a disease of unknown cause and pathogenesis. It is defined pathologically as one in which there is degeneration of both upper and lower motor neurons. Charcot made the key clinical and pathologic descriptions, and the disease is named for him in Europe. In the United States, the disease is colloquially called *Lou Gehrig disease* after the famous baseball player who had the disease. Clinically, ALS is defined by evidence of both lower motor neuron disease (weakness, wasting, and fasciculation) and upper motor neuron disease (spasticity, hyperactive tendon reflexes, Hoffmann signs, Babinski signs, or clonus) in the same limbs. The accuracy of clinical diagnosis is assumed to be more than 95%, but that figure has not been formally tested. Nevertheless, the reliability of clinical diagnosis suffices to make the findings in the history and examination part of the definition.

EPIDEMIOLOGY

ALS is found worldwide in roughly the same prevalence (about 50×10^{-6}), with the exception of a few geographic areas with high prevalence of ALS, parkinsonism, and dementia complex, most notably on the island of Guam in the past. Case-control studies have not identified consistent risk factors related to occupation, diet, or socioeconomic status. There appears to be an increased risk of ALS among certain professional athletes and some suggestion that repeated head trauma may increase the risk for the disease.

The disease is generally of middle and late life. Only 10% of cases begin before age 40 years; 5% begin before age 30 years, with a greater proportion of those younger cases attributed to hereditary motor neuron diseases. An increase in age-adjusted incidence is seen in succeeding decades, except for a decrease after age 80 years. In most series, men are affected one to two times more often than women. There is no known ethnic predilection except slightly higher incidence in Norway because of some concentration of genetic mutations.

GENETICS

Approximately 5% to 10% of ALS cases are familial. Most are autosomal dominant in inheritance, but autosomal recessive and X-linked mutations have also been described. Increasingly recognized are “sporadic” ALS cases, which can be linked to specific genetic mutations, sometimes as a result of de novo mutations or incomplete penetrance. New mutations accounting for familial ALS continue to be described, and at the time of publication of this book, new mutations are likely to have been found not included in this chapter.

P.732

The two most common forms of autosomal dominant familial ALS are related to mutations in the C9ORF72 gene and the SOD1 gene. C9ORF72 repeat expansions are linked to both ALS, frontotemporal dementia (FTD), and often a combination of both clinical phenotypes. C9ORF72 mutations are currently the most common cause of familial ALS. Mutations in the SOD1 gene (ALS1) are the second most common cause of familial ALS. Many mutations in this gene have been described, and clinical phenotype is variable. Evidence suggests that mutant protein exerts its effects through accumulation of toxic protein. The SOD1 mutation has been used extensively in research as a model for studying pathology in ALS and identifying compounds for treatment trials.

TABLE 85.2 Familial Amyotrophic Lateral Sclerosis

Name	Site	Gene	Inheritance	Comment
FTD-	9p21	C9ORF72	AD	ALS and FTD

ALS				Hexanucleotide expansion Most common cause of familial ALS
ALS1	21q22.1	SOD1	AD	Adult 15%-20% of familial ALS
ALS2	2q33	Alsin	AR	Juvenile; may resemble PLS
ALS3	18q21	—	—	—
ALS4	9q34	Senataxin (SETX)	AD	Juvenile; slow progression; allelic to CMT2
ALS5	15q15.1-q21.1	SPG11	AR	Juvenile Most common AR ALS Also seen in HSP
ALS6	16p11.2	Fused in sarcoma (FUS)	AD	Adult
ALS7	20p13	—	AD	Adult
ALS8	20q13.33	VAPB	AD	Adult
ALS9	14q11.2	ANG	AD	—
ALS10	1p36.22	TARDBP	AD	Some with FTD
ALS11	6q21	FIG4	AD	Allelic to CMT 4J (AR)
ALS12	10p13	OPTN	AD/AR	—
ALS13	12q24.12	ATXN2	AD	CAG expansions and increased ALS risk Expansions also seen with SCA2
ALS14	9p13.3	VCP	AD	Mutations also seen with IBMPFD
ALS15	Xp11.21	UBQLN2	X-linked	Reduced penetrance in women
ALS16	9p13.3	SIGMAR1	AR	Juvenile
ALS17	3p11.2	CHMP2B	AD	May cause FTD
ALS18	17p13.2	PFN1	AD	—

ALS19	2q34	ERBB4	AD	—
ALS20	12q13.13	HNRNPA1	AD	May cause multisystem proteinopathy
ALS21	5q31.2	MATR3	AD	Formerly distal myopathy 2, VCPDM

Other genes described and implicated in familial ALS-DAO, NEFH, HNRNPA2B1, SQSTM1.

FTD, frontotemporal dementia; ALS, amyotrophic lateral sclerosis; AD, autosomal dominant; AR, autosomal recessive; PLS, primary lateral sclerosis; HSP, hereditary spastic paraplegia; CMT 2, Charcot-Marie-Tooth hereditary neuropathy type 2; CMT 4J, Charcot-Marie-Tooth neuropathy type 4J; CAG, cytosine-adenine-guanine; SCA 2, spinocerebellar ataxia type 2; IBMPFD, inclusion body myopathy with Paget disease and frontotemporal dementia; VCPDM, vocal cord and pharyngeal dysfunction with distal myopathy.

Other familial ALS gene mutations have provided insight into potential pathogenic mechanisms in sporadic disease. Mutations in the fused in sarcoma (FUS) gene (ALS6) and TAR DNA-binding protein 43 (TDP-43) gene (ALS10) suggest a possible mechanism of RNA regulation and metabolism underlying sporadic disease. The pathogenic expansion in C9ORF72 familial ALS may also exert effects through RNA toxicity.

A list of the currently identified mutations in familial ALS at the time of publication of this text are listed in [Table 85.2](#).

X-LINKED RECESSIVE SPINOBULBAR MUSCULAR ATROPHY (KENNEDY DISEASE)

Although not typically included among the list of familial ALS, X-linked recessive spinobulbar muscular atrophy (Kennedy disease) should be included as a hereditary motor neuron disease. The gene maps to Xq11-q12, the site of the androgen receptor. The mutation is an expansion of a cytosine-adenine-guanine (CAG) repeat. Symptoms usually begin after age 40 years, with dysarthria and dysphagia with prominent tongue and mentalis fasciculations and with a slow course and limb weakness delayed for years. Upper motor neuron signs are often absent. In contrast to ALS, there is often an associated large-fiber sensory peripheral neuropathy. Gynecomastia is present in most but not all patients. Diagnostic clues include the characteristic distribution of signs, lack of upper motor neuron signs, slow progression, and a family history suggesting X-linked inheritance.

PATHOBIOLOGY

The cause of sporadic ALS is not known. The only established risk factors are age and family history. Environmental factors have been suspected, likely in combination with genetic susceptibility, but no clear risk exposures have been identified. There is increasing interest in repetitive head trauma and a link to chronic traumatic encephalopathy, although this link has yet to be well established. Theories regarding the cause of ALS have included infectious causes, including retroviruses, effects of excitotoxic amino acids, mitochondrial dysregulation, oxidative stress, and autoimmune causes, but little evidence conclusively supports one of these causes. Increasing evidence points to abnormal RNA processing and metabolism underlying ALS, although the exact mechanisms and triggers have yet to be elucidated.

FIGURE 85.1 Pathologic findings in ALS. **A:** Axonal swelling and axonal spheroids (*arrow*) (Bodian silver stain, $\times 400$ magnification). **B:** Motor neuron degeneration (*arrows*) (hematoxylin and eosin stain, $\times 400$ magnification). **C:** Ubiquitinated skein-like inclusion (*arrow*) (ubiquitin immunoperoxidase stain, $\times 400$ magnification).

PATHOLOGY

The pathology of ALS implies selective vulnerability of motor neurons, which show several neuronal inclusions that include ubiquitinated skeins or Lewy-like formations and Bunina bodies (Fig. 85.1). These structures are found in most patients with sporadic ALS. In some familial forms, a different form is the “hyaline conglomerate,” which includes neurofilaments and does not contain ubiquitin. Authorities believe the cellular abnormalities identify a common basic mechanism for the syndromes of ALS, progressive muscular atrophy, primary lateral sclerosis, and amyotrophic lateral sclerosis-frontotemporal dementia (ALS-FTD).

The neuronal antigen in the inclusions recognized by anti-bodies to ubiquitin has been identified as TDP-43, and mutations in the TDP-43 gene are responsible for approximately 5% of familial ALS.

CLINICAL MANIFESTATIONS

Weakness may commence in the legs, hands, proximal arms, or bulbar muscles (with dysarthria and dysphagia). Often, the hands are affected first, usually asymmetrically, and with atrophy (Fig. 85.2). Progressive painless weakness is the typical primary clinical feature of ALS. Gait is impaired because leg muscles are weak, and footdrop is characteristic, although

proximal limb muscles are sometimes affected first. Alternatively, a spastic gait disorder may ensue. Slowly, the weakness becomes more severe, and more areas of the body are affected, leading to an increasing state of dependency. Muscle cramps (attributed to the hypersensitivity of denervated muscle) and weight loss (resulting from the combination of muscle wasting and dysphagia) are characteristic symptoms. Respiratory impairment is usually a late symptom but may, rarely, be an early or even the first manifestation; breathing is compromised by

diaphragm and paresis of intercostal muscles, and dysphagia may lead to aspiration and pneumonitis, both of which can be the terminal event. Sensation is not clinically affected unless a preexisting neuropathy is present; pain and persistent paresthesias are atypical for this diagnosis, unless there is a complicating disease (e.g., diabetic neuropathy). Typically, bladder function is spared. The eye muscles are affected only exceptionally. Pain is not an early symptom but may occur later when limbs are immobile due to severe spasticity and joint contracture.

FIGURE 85.2 Hand atrophy in ALS.

Lower motor neuron signs must be evident if the diagnosis is to be considered valid. Fasciculations may be seen in the tongue, even without dysarthria. If there is weakness and wasting of limb muscles, fasciculations are almost always seen. Tendon reflexes may be increased or decreased; the combination of overactive reflexes with Hoffmann signs in arms with weak, wasted, and fasciculating muscles is virtually pathognomonic of ALS. Unequivocal signs of upper motor neuron disorder are spasticity, Hoffmann or Babinski signs, and clonus. If a spastic gait disorder is seen without lower motor neuron signs in the legs, weakness in the legs may not be found, but incoordination is evident by clumsiness and slowness in the performance of alternating movements ([Table 85.3](#)).

The cranial nerve motor nuclei are implicated by dysarthria, lingual wasting and fasciculations, and impaired movement of the uvula ([Fig. 85.3](#)). Facial weakness and wasting can be discerned, especially in the mentalis muscle, but is usually not prominent. Dysarthria and dysphagia caused by upper motor neuron disease is made evident by movements of the uvula that are more vigorous on reflex innervation than on volition; that is, the uvula does not move well (or at all) on phonation, but a vigorous response is seen in the pharyngeal or gag reflex.

A common manifestation of pseudobulbar palsy is emotional lability with inappropriate laughing or, more often, crying, and that can be regarded erroneously as a reactive depression because of the diagnosis. Emotional lability is better regarded as a release phenomenon of the complex reflexes involved in emotional expression.

TABLE 85.3 Typical Clinical Findings in Amyotrophic Lateral Sclerosis

Upper Motor Neuron Symptoms and Signs

Spasticity

Hyperreflexia in deep tendon reflexes and/or clonus

Babinski sign/extensor plantar response

Hoffman sign

Increased jaw jerk

Spastic dysarthria

Pseudobulbar affect

Lower Motor Neuron Symptoms and Signs

Decreased muscle tone

Muscle atrophy

Fasciculations

Cramps

Hyporeflexia

Tongue atrophy and fasciculations

Facial weakness

Dysphagia

Dysarthria

Respiratory weakness

Neck weakness, head drop

The course is generally relentless and progressive without remissions, relapses, or even stable plateaus. Death results from respiratory failure, aspiration pneumonitis, or pulmonary embolism after prolonged immobility. The mean duration of symptoms is about 4 years; nearly 10% of patients live longer than 10 years. Once a tracheostomy has been placed, the patient may be kept alive for years, although totally paralyzed and unable to

move anything other than the eyes; this condition can be a locked-in state, and even eye muscles are paralyzed. Exceptional patients die in the first year or live longer than 25 years.

FIGURE 85.3 Tongue atrophy in ALS.

P.735

TABLE 85.4 Revised El Escorial Criteria for the Diagnosis of Amyotrophic Lateral Sclerosis

- Suspected ALS: a pure LMN syndrome in two or more regions

- Possible ALS: UMN and LMN signs present together in one region or UMN signs alone in two or more regions or LMN signs rostral to UMN signs

- Laboratory-supported ALS: UMN and LMN signs in one region or UMN signs alone in one region with LMN signs identified by EMG in two regions

- Probable ALS: UMN and LMN signs in more than two regions, and some UMN signs must be rostral to (above) LMN signs

- Definite ALS: UMN and LMN signs in three or more regions

All require absence of electrophysiologic or pathologic evidence of another disease process to explain clinical findings.

ALS, amyotrophic lateral sclerosis; LMN, lower motor neuron; UMN, upper motor neuron; EMG,

electromyogram.

AMYOTROPHIC LATERAL SCLEROSIS DIAGNOSTIC CRITERIA

A number of different diagnostic criteria have been proposed for the clinical and research diagnosis of ALS. The most commonly used criteria are the revised El Escorial criteria ([Table 85.4](#)), which requires, for the diagnosis of definite ALS, the combination of upper and lower motor neuron findings in three of four potential anatomic regions (cranial, cervical, thoracic, and lumbosacral). The Awaji ALS criteria were developed in 2008 with the intention of including a greater number of ALS patients earlier in their clinical course through some adjustments to the electrodiagnostic and clinical criteria required ([Table 85.5](#)). These criteria are primarily designed for research uses, and many patients are diagnosed with and treated for ALS before they meet the complete criteria.

AMYOTROPHIC LATERAL SCLEROSIS AND FRONTOTEMPORAL DEMENTIA

About 10% of patients with ALS have associated dementia. The most common pathology is that of FTD; some show postmortem changes of Alzheimer disease and some show nonspecific pathology. The most common form of familial ALS, secondary to expansions in the C9ORF72 gene, often include both ALS and FTD within the same patient or family. Abnormalities in TDP-43 protein are also seen in both ALS and FTD pathology, linking the disorders. Why certain patients express more cognitive involvement and other more motor neuron pathology is not well understood.

MOTOR NEURON DISEASE VARIANTS

PROGRESSIVE MUSCULAR ATROPHY

Progressive muscular atrophy (PMA) is the term used to describe the lower motor neuron only form of motor neuron disease. Clinical findings and course are similar to ALS but without the associated upper motor neuron signs, such as hyperreflexia, Babinski or Hoffman signs, or spasticity. Many patients will have lower motor neuron predominant ALS, but pathologically true PMA probably accounts for less than 8% of cases. These patients usually live longer than ALS on average of 12 months.

TABLE 85.5 Awaji Criteria for the Diagnosis of Amyotrophic Lateral Sclerosis

The diagnosis of amyotrophic lateral sclerosis (ALS) requires the presence of the following:

- Evidence of lower motor neuron (LMN) degeneration by clinical, electrophysiologic, or neuropathologic examination
- Evidence of upper motor neuron (UMN) degeneration by clinical examination
- Progressive spread of symptoms or signs within a region or to other regions, as determined by history, physical examination, or electrophysiologic tests

The absence of the following:

- Electrophysiologic or pathologic evidence of other disease processes that might explain the signs of LMN and/or UMN degeneration

-
- Neuroimaging evidence of other disease processes that might explain the observed clinical and electrophysiologic signs
-

Diagnostic Categories

- Clinically definite ALS is defined by clinical or electrophysiologic evidence by the presence of LMN as well as UMN signs in the bulbar region and at least two spinal regions or the presence of LMN and UMN signs in three spinal regions.
-
- Clinically probable ALS is defined on clinical or electrophysiologic evidence by LMN and UMN signs in at least two regions with some UMN signs necessarily rostral to (above) the LMN signs.
-
- Clinically possible ALS is defined when clinical or electrophysiologic signs of UMN and LMN dysfunction are found in only one region, or UMN signs are found alone in two or more regions, or LMN signs are found rostral.
-

The diagnosis of PMA should always be made with caution, as it raises the question of a potentially treatable motor neuropathy, such as multifocal motor neuropathy. Diagnostic testing should include electrodiagnostic testing (electromyography and nerve conducting studies) with proximal stimulation on nerve conduction studies to exclude areas of conduction block and demyelinating findings, lab testing to evaluate for antibodies often seen in motor neuropathies, and consideration for spinal fluid testing to look for elevated protein. Magnetic resonance imaging (MRI) of the brain and transcranial magnetic stimulation can be used to look for subclinical upper motor neuron involvement.

PRIMARY LATERAL SCLEROSIS

Primary lateral sclerosis (PLS) refers to the clinical syndrome of progressive motor neuron disease affecting only upper motor neurons. As with PMA, there are often patients with upper motor neuron-dominant ALS, and true isolated upper motor neuron disease is uncommon, less than 5% of cases in autopsy series. The clinical symptoms and signs in PLS include spasticity and associated gait dysfunction, spastic dysarthria, and associated pathologic reflexes. Testing must include neuroimaging to exclude structural causes of upper motor neuron injury, lab testing to evaluate for metabolic disorders mimicking the clinical picture, and consideration for spinal fluid testing for infectious and inflammatory causes. Electrodiagnostic testing is critical for evaluating for lower motor neuron involvement, even in patients without clinical atrophy or fasciculations, and may need repeating over months to years to confirm the absence of denervation. It is generally agreed among experts that the diagnosis

P.736

of PLS requires at least 4 years' observation. When spasticity and upper motor neuron findings are restricted to the legs or spare bulbar muscles, the clinician must consider the alternative diagnosis of HSP.

PROGRESSIVE BULBAR PALSY

The term *progressive bulbar palsy* has been used to describe motor neuron disease selectively affecting the bulbar muscles, causing dysarthria and dysphagia. This term is falling out of favor, as most of these patients do have at least some limb involvement, sometimes subclinical, at the time that bulbar symptoms begin. The term *bulbar-onset ALS* is more appropriate to describe those patients presenting with early or prominent bulbar

symptoms.

MONOMELIC MUSCULAR ATROPHY

Monomelic muscular atrophy is a focal motor neuron disease restricted to one limb, usually an arm and a hand rather than a leg. Other names for the syndrome include *monomelic amyotrophy*, *benign focal amyotrophy*, *SMA of the unilateral upper extremity*, and *Hirayama syndrome*.

Monomelic muscular atrophy affects men 10 times more often than women and starts at about age 20 years, in contrast to typical sporadic ALS, which has a much older age of onset. The disease is most commonly seen in southeastern Asia, particularly Japan and India, although cases have been reported in Western countries. The weakness typically involves the hand and forearm, involving C7-T1 innervated muscles. Tendon reflexes are generally reduced in the affected arm. Upper motor neuron signs in other limbs are not seen. The condition progresses for 1 or 2 years and then seems to become arrested in most cases, although some have continued slow progression for many years. The origin of the disorder is not known, but most believe it is a focal motor neuron disorder or repetitive flexion-extension injury to the cervical spinal cord.

The differential diagnosis for monomelic muscular atrophy should include the initial onset of a more generalized ALS, multi-focal motor neuropathy, or polio-like infectious syndromes, as in those seen with West Nile virus.

BIBRACHIAL AMYOTROPHY

A few percent of patients develop a lower motor neuron syndrome restricted to both arms. As in monomelic amyotrophy, it is more common in men than women, with a ratio of 8 to 9:1. It usually presents with proximal arm and shoulder muscle weakness. The progression is much slower than typical ALS. Arm posture is typically pronated and arms are dangling; sometimes it is called a *man-in-a-barrel*. Usually, lower motor neuron findings predominate, but sometimes upper motor neuron signs are present.

DIAGNOSTIC TESTING

ALS is primarily a clinical diagnosis, and electrodiagnostic, radiographic, and lab test results must be combined with the clinical picture to form the diagnosis. Ultimately, a clinical history and an attentive physical and neurologic exam are the most important diagnostic tools in ALS evaluation. The combination of typical upper and lower motor neuron findings in multiple limbs and affecting bulbar muscles has little differential diagnosis.

ELECTRODIAGNOSTIC TESTING

Electrodiagnostic testing including nerve conduction studies (NCS) and electromyography (EMG) are critical to confirming the lower motor neuron involvement in ALS and excluding motor neuropathy mimics. NCS may show low motor amplitudes but may also be normal, particularly early in the course. NCS primarily are done to exclude findings suggestive of motor neuropathy, with conduction block or other demyelinating findings. Abnormal sensory responses should not be seen in ALS unless related to a pre-existing condition (e.g., diabetic neuropathy). Needle EMG should demonstrate evidence of active denervation (fibrillation and fasciculation potentials) and chronic denervation in three body segments (cranial, cervical, thoracic, and lumbosacral) to meet Awaji or El Escorial criteria. It should be noted that the electrodiagnostic findings must be combined with radiographic and clinical exam, as a severe polyradiculopathy or motor neuropathy might demonstrate similar EMG abnormalities.

Transcranial magnetic stimulation (TMS) is an electrodiagnostic method used to assess for upper motor neuron abnormalities in ALS, most useful when the predominant clinical picture is of lower motor neuron dysfunction. Stimulation over the motor cortex, cervical spine, and lumbar spine is performed with recording of a compound motor action potential (CMAP), assessing for delayed latency and central conduction. Unfortunately, it is done only at a few medical centers.

NEUROIMAGING

Imaging of the brain and spine, with MRI when possible, is typically recommended to exclude structural processes, most notably spinal stenosis, that might mimic ALS. Brain imaging occasionally demonstrates abnormalities in the corticospinal tracts that support the clinical findings of upper motor neuron disease or atrophy suggestive of an associated FTD. In most cases of ALS, neuroimaging is normal or demonstrates mild incidental abnormalities.

LAB TESTING

Spinal fluid studies are not required in the assessment of a patient with suspected ALS but should be considered in atypical cases, lower motor neuron (PMA) or upper motor neuron variants (PLS), or when there is concern for a motor neuropathy mimic, looking for elevation in protein, white blood cells, abnormal cytology, or elevated IgG synthesis.

Blood tests are recommended to evaluate for metabolic, endocrine, or inflammatory conditions that might mimic ALS. Testing for monoclonal gammopathy, antiganglioside antibodies, angiotensin-converting enzyme (ACE) levels, parathyroid hormone, and paraneoplastic markers rarely result in alternative diagnosis. Creatine kinase (CK) levels are often modestly elevated in ALS and are not inconsistent with the diagnosis. Genetic testing for familial ALS can be considered in cases in which there is a suggestive family history but is best performed with the help of a genetic counselor or physician experienced in genetic testing.

MUSCLE BIOPSY

Muscle biopsy is not routinely recommended in the evaluation of ALS and associated motor neuron disorders and typically demonstrates findings consistent with active and chronic denervation. The primary indication for muscle biopsy when considering a diagnosis of ALS is if there are clinical findings suggestive of inclusion body myositis, which may have some overlap in clinical presentation.

DIFFERENTIAL DIAGNOSES

Although the typical clinical picture of ALS is difficult to confuse with other neurologic disorders, cases occur which sometimes raise the question of other neuromuscular disorders with similar clinical

P.737

phenotypes. Given that there is currently no disease-modifying treatment for ALS, the focus of testing when this diagnosis is considered is on excluding these other potentially treatable disorders ([Table 85.6](#)).

MULTIFOCAL MOTOR NEUROPATHY

Multifocal motor neuropathy (MMN) or multifocal motor neuropathy with conduction block (MMNCB) is a clinical syndrome of pure motor neuropathy, with conduction block in more than one nerve and not at sites of entrapment neuropathy. Anti-GM1 or other ganglioside antibodies are often associated. Symptoms often begin or predominate in the upper extremities. Although frank upper motor neuron findings should not be present, deep tendon reflexes are sometimes relatively preserved and muscle atrophy is often minimal given the degree of weakness. MMN is a potentially treatable autoimmune condition, treated with intravenous immunoglobulin (IVIg) or other immunosuppressing drugs, so the focus of NCS is often on assessing for this treatable diagnosis.

TABLE 85.6 Differential Diagnosis of Motor Neuron Diseases

Multifocal motor neuropathy

- Primarily lower motor neuron syndrome but may have preserved reflexes

- Conduction block on nerve conduction studies
- Lab testing for GM1 antibodies

Chronic inflammatory demyelinating polyneuropathy

- Typically sensorimotor involvement clinically
- Demyelinating findings on nerve conduction studies
- Elevated CSF protein

Myasthenia gravis

- Typically more ocular symptoms, fluctuation, and fatigability
- Decrement on repetitive stimulation with nerve conduction studies and no denervation on needle EMG
- Acetylcholine receptor and musclespecific kinase antibodies if clinically appropriate

Spinal stenosis

- Typically more pain and sensory symptoms
- MRI or other imaging demonstrates structural abnormalities
- No bulbar or facial involvement

Inclusion body myositis

- Typically affects quadriceps and finger flexors more severely
- Needle EMG shows myopathic findings
- Greater elevations in CK levels
- Muscle biopsy to confirm diagnosis if clinical suspicion

Postpolio syndrome

- History of polio with later life decline in strength

Hereditary spastic paraparesis

- Upper motor neuron syndrome affecting primarily the legs
- Family history may be useful
- Genetic testing when clinically appropriate

Benign fasciculation syndrome/cramp fasciculation syndrome

- Absence of weakness, muscle wasting
- Electrodiagnostics may show fasciculations but no other abnormalities

Paraneoplastic syndromes

- Paraneoplastic panel/antibody testing

Other systemic disorders

- Diabetes, sarcoidosis, parathyroid disease, hexosaminidase A deficiency

CSF, cerebrospinal fluid; EMG, electromyogram; MRI, magnetic resonance imaging; CK, creatinine kinase.

MYASTHENIA GRAVIS

Myasthenia gravis (MG) is a common cause of dysarthria and dysphagia in people who are in the age range of those afflicted with ALS and may be considered in the differential diagnosis when bulbar symptoms predominate. If there is concomitant ptosis or ophthalmoparesis, if diurnal fluctuation in severity is marked, or if remissions

have occurred, MG is more likely. If there is suspicion for this diagnosis, testing should include blood testing of antibodies to acetylcholine receptor and muscle-specific tyrosine kinase (MuSK) and repetitive stimulation with NCS.

SPINAL STENOSIS

Although spinal disease should not cause bulbar symptoms, in patients with pure limb symptoms, cervical and lumbosacral polyradiculopathy due to spinal stenosis can cause a combination of upper and lower motor neuron symptoms and exam findings, which may be difficult to distinguish from limb-onset ALS. Spine imaging with MRI is thus recommended for all patients in whom the diagnosis of ALS is being considered.

MYOPATHY

Myopathy, most notably inclusion body myositis (IBM), may present with a clinical syndrome similar to ALS, with prominent arm weakness (typically affecting finger flexors and quadriceps disproportionately) and bulbar symptoms. Needle EMG testing is usually suggestive of a myopathic disorder, but sometimes neurogenic findings are seen. CK levels should be higher in IBM than in ALS. Fasciculations and upper motor neuron findings should not be seen in muscle disorders. Muscle biopsy is recommended when inflammatory myopathies are considered.

POSTPOLIO SYNDROME

Postpolio syndrome is a clinical worsening of weakness years after full or partial recovery from viral poliomyelitis. The consensus is that this syndrome is a residual effect in previously paralyzed muscles and that it is not a new motor neuron disease. Progression is slow and is limited to previously paralyzed muscles.

BENIGN FASCICULATIONS

Fasciculations, with or with muscle cramps, in the absence of weakness or upper motor neuron findings is nearly always a benign finding. There is no increased risk for future motor neuron disease in these patients. Electrodiagnostic testing may be useful to demonstrate no evidence of active or chronic denervation and reassure the patient regarding the diagnosis.

TREATMENT

Sadly, there is no effective drug therapy for disease modification in ALS. Therapeutic trials have shown no benefit from immunosuppression, immunoenhancement, plasmapheresis, lymph node irradiation, glutamate antagonists, nerve growth factors, antiviral agents, and numerous other categories of drugs.

P.738

Riluzole, a glutamate inhibitor, is the only drug approved by the U.S. Food and Drug Administration (FDA) for the treatment of ALS. In two randomized controlled trials, it was shown to improve 12- and 18-month survival, although the benefits were small [**Level 1**].^{1,2} The usual dose is 50 mg twice daily. The most common side effects are nausea and dizziness, and hepatic function monitoring is recommended.

Treatment is therefore primarily symptomatic (Table 85.7), and emotional support is vitally important; management may be carried out most efficiently in a multidisciplinary ALS center, which is one of the few interventions shown to improve survival and quality of life [**Level 1**].³ Early in the course, patients should try to continue to perform routine activities as long as they can. There is difference of opinion about exercising weak muscles, but physical therapy can help maintain function as long as possible. Drooling of saliva (sialorrhea) may be helped by atropine sulfate, glycopyrrolate, amitriptyline, or botulinum toxin injections into the salivary glands. Antispasticity agents have not been helpful in the spastic gait disorder, but intrathecal administration of baclofen might be considered in some patients, particularly those with PLS.

Dysphagia leads to percutaneous gastrostomy to maintain nutrition; it does not prevent aspiration. Communication devices can ameliorate severe dysarthria. Noninvasive positive pressure ventilation has been used with increasing frequency to improve nocturnal dyspnea, insomnia, and overall respiratory discomfort, and it is likely not only to prolong life but also improve quality of life [**Level 1**].⁴ Medications may also help with pseudobulbar symptoms, including the use of the combination drug dextromethorphan-quinidine [**Level 1**].⁵

TABLE 85.7 Treatment for Amyotrophic Lateral Sclerosis and Motor Neuron Disorders

Disease Modifying

- Riluzole: only FDA-approved disease-modifying therapy for ALS
-

Improving Quality of Life and/or Survival

- Multidisciplinary ALS center care
-
- Noninvasive positive pressure ventilation/cough assist machine
-
- Physical therapy and rehabilitation
-
- Durable medical equipment and assistive devices to prevent falls and improve mobility
-
- Nutritional/calorie maintenance and percutaneous gastrostomy tube
-
- Tracheostomy and mechanical ventilation
-

Symptomatic Therapies

- Treatment of sialorrhea—atropine, glycopyrrolate, amitriptyline, botulinum toxin injections
-
- Treatment of spasticity—baclofen, cyclobenzaprine, benzodiazepines, intrathecal baclofen
-
- Communication devices
-
- Pseudobulbar symptom management—dextromethorphanquinidine, selective serotonin reuptake inhibitors (SSRIs)
-
- Treatment of depression and associated mood disorders—SSRI, SNRI, tricyclic antidepressants
-
- Treatment of fatigue—modafinil, pyridostigmine
-

- Emotional support for patient and family caregivers

Comfort Measures, Pain Control, Palliative Care, and Hospice

FDA, U.S. Food and Drug Administration; ALS, amyotrophic lateral sclerosis; SNRI, serotonin-norepinephrine reuptake inhibitors.

The long-term care of patients with ALS has been addressed by evidence-based medicine recommendations made by a committee of the American Academy of Neurology. It is important for patients to be followed by one of the multidisciplinary ALS clinics because evidence shows that patients will have better symptomatic treatment, improved quality of life, and prolonged survival. The major decision concerns the use of tracheostomy and chronic mechanical ventilation, which can be done at home. In making the decision, patients should be informed fully about the long-term consequences of life without movement; they must decide whether they want to be kept alive or made as comfortable as possible—two choices that are not identical. Palliative care (relief of symptoms but not prolonging life) is becoming a standard option.

Bell Palsy and Cranial Neuropathies

Comana M. Cioroiu

Thomas H. Brannagan III

Isolated cranial neuropathies are not uncommon, the most frequently encountered of which is Bell palsy. These syndromes can be seen in both the inpatient and outpatient settings, and all have a very varied differential diagnosis. The cranial nerve examination is a crucial component of a complete neurologic exam. Cranial nerve injury can be implicated in various diseases with widespread neurologic involvement such as stroke, multiple sclerosis, and demyelinating neuropathies, particularly when other pathways and neuroanatomic regions are involved as well. Cranial neuropathies can occur together (with involvement of more than one nerve) or in isolation (with involvement of only one nerve). Multiple cranial neuropathies are most often caused by cancer, infarct, and trauma, and these etiologies must be considered and carefully excluded when evaluating these patients, with particular attention paid to the brain stem where several cranial nerves localize together. However, occasionally, there may be abnormal findings limited to one cranial nerve in isolation. In these instances of isolated cranial neuropathies, the differential diagnosis depends on the nerve involved and the clinical picture as a whole. This chapter will address common cranial mononeuropathies and their evaluation and management. Several of these are addressed in other chapters of this text and are referred to when appropriate.

THE OLFACTORY NERVE (CRANIAL NERVE I)

The ability to smell is a special quality relegated to the olfactory cells in the nasal mucosa. The molecular biology of smell is uncertain, but transcription-activating factors, such as Olf-1, found exclusively in neurons with olfactory receptors, probably direct cellular differentiation. Smell may be impaired after injury of the nasal mucosa, the olfactory bulb or its filaments, or central nervous system (CNS) connections. Nerve injury causes diminution or loss of the sense of smell. The most common complaint of patients with olfactory nerve injury, however, is not loss of smell but diminished taste; olfaction plays a key role in taste perception because of the volatile substances in many food and beverages. A loss of sense of smell may be congenital or acquired and occurs in various conditions (Table 86.1). The sense of smell is most commonly impaired, transiently, because of allergic nasal congestion or the common cold. The most common traumatic olfactory nerve injury occurs in head injury, usually of the acceleration-deceleration variety, including motor vehicle accidents. The delicate olfactory nerve filaments are sheared by the perforations of the cribriform plate. The olfactory bulb can also be contused or lacerated in head injuries. Leigh and Zee (2006) reported altered olfactory sense in 7.2% of patients with head injuries at a military hospital, with complete loss in 4.1% and partial loss in 3.1%. Recovery of smell occurred in only 6 of 72 patients. In a study of head injuries in civilians, Friedman and Merritt (1944) found that the olfactory nerve was damaged in 11 (2.6%) of 430 patients. In all patients, anosmia was bilateral. In three, the loss was transient and disappeared within 2 weeks of injury. *Parosmia* (i.e., perversion of sense of smell) was present in 12 patients.

Inflammatory or neuritic lesions of the bulb or tract are uncommon, but these structures are sometimes affected in meningitis or in mononeuritis multiplex. Rarely, patients with diabetes mellitus have impaired smell, sometimes stemming from olfactory nerve infarction. Hyposmia or anosmia is also common early in Refsum disease (an autosomal recessive disease leading to an overaccumulation of phytanic acid). Kallmann syndrome is an X-linked inherited disorder causing hypogonadism and anosmia due to olfactory tract hypoplasia. The olfactory bulb or tract may be compressed by meningiomas (particularly at the olfactory groove or sphenoidal ridge), metastatic tumors, or aneurysms in the anterior fossa or by infiltrating tumors of the frontal lobe. The Foster-

Kennedy syndrome is a classic syndrome caused by a tumor invading the orbitofrontal region, leading to unilateral and ipsilateral optic atrophy, contralateral papilledema, and anosmia. Neurodegenerative diseases at times may be heralded by a loss of smell, and this is seen particularly with Parkinson disease, where loss of smell may be a presenting sign. Certain drugs are often implicated in a loss of smell, particularly cocaine when used intranasally, although other toxins such as cadmium and chemotherapeutic agents have been implicated as well.

Parosmia is not accompanied by impairment of olfactory acuity and is most commonly caused by lesions of the temporal lobe, although it has been reported with injury to the olfactory bulb or tract.

P.741

Olfactory hallucinations may occur in psychosis or as a seizure aura that involves the hippocampal or uncinate gyrus; perceptions are described as strange, unpleasant, and ill-defined odors. Increased sensitivity to olfactory stimuli is generally rare, although it may occur in migraineurs and in patients with reactive airways disease, perhaps because of prior sensitization to olfactory triggers. Cases in which the sense of smell is so acute that it is a source of continuous discomfort, however, may be psychogenic.

Disorders of the visual system are described in Chapter 9.

THE TRIGEMINAL NERVE (CRANIAL NERVE V)

The fifth cranial nerve, or the trigeminal nerve, has both a large sensory component as well as a smaller motor component. The nerve has three major branches—the ophthalmic division (V1), the maxillary division (V2), and the mandibular division (V3). These three branches carry sensory information from distinct dermatomes of the face, head, and mucous membranes and converge on the trigeminal or gasserian ganglion located in Meckel's cave (which serves as the dorsal root ganglion). Sensory fibers from all three divisions ascend in the pons to terminate in the three parts of the trigeminal nucleus. The spinal trigeminal nucleus receives afferent fibers related to facial pain and temperature sensation, the principal sensory nucleus receives fibers related to light touch and mechanoreception, whereas the mesencephalic nucleus contains cell bodies with fibers carrying information regarding jaw proprioception. Motor branches originate in the motor nucleus of the trigeminal nerve and are distributed in the mandibular division to innervate the muscles of mastication.

Injury to the fifth cranial nerve causes loss of soft-tactile, thermal, and pain sensation in the face; loss of the corneal and sneezing (i.e., sternutatory) reflexes; and paralysis of the muscles of mastication. Lesions of the trigeminal pathways in the pons usually affect the motor and chief sensory nuclei causing paralysis of the muscles of mastication and loss of light touch perception in the face; lesions in the medulla affect only the descending tract and cause loss of facial light touch sensation. Brain magnetic resonance imaging (MRI) with contrast is often useful to search for mass lesions, ischemia, and inflammation, whereas electrophysiologic testing (e.g., blink reflex testing) may help quantitate both the afferent (i.e., trigeminal nerve) and efferent (i.e., facial nerve) components of the corneal reflex. The fifth nerve may be injured by trauma, neoplasm, aneurysm, or meningeal infection. Infarcts and other vascular lesions, as well as intramedullary tumors, may damage the sensory and motor nuclei in the pons and medulla. Isolated lesions of the descending tract may occur in syringobulbia or in multiple sclerosis. Common causes of trigeminal nerve injury with facial numbness include dental or cranial trauma, herpes zoster, head and neck tumors, intracranial tumors, and idiopathic trigeminal neuropathy. Less common causes include multiple sclerosis, systemic sclerosis, mixed connective tissue diseases, amyloidosis, and sarcoidosis. Isolated facial numbness may also occur without a clearly identifiable cause (i.e., *idiopathic trigeminal neuropathy*), but these patients must be carefully evaluated to ensure an occult process is not overlooked. Although restricted loss of sensation over the chin (i.e., the *numb chin syndrome*) usually is caused by dental trauma, dental or surgical procedures, or even poorly fitting dentures, this syndrome is a recognized initial feature of a systemic malignancy such as lymphoma, metastatic breast carcinoma, melanoma, or prostate cancer. MRI of the mandible may help separate these disorders. Painful facial numbness may herald nasopharyngeal or metastatic carcinoma. Isolated weakness of the trigeminal innervated muscles of mastication may be seen in motor neuron disease where patients often develop jaw weakness and dysphagia. This can also be seen with diseases of the neuromuscular junction, that is, myasthenia gravis.

TRIGEMINAL NEURALGIA

Epidemiology and Pathobiology

Trigeminal neuralgia, also commonly known as *tic douloureux*, is a syndrome of extremely severe facial pain without numbness or objective findings in the fifth nerve distribution (see also [Chapter 55](#)). This disorder of the trigeminal nerve is characterized by recurrent paroxysms of sharp, stabbing pains in the distribution of one or more nerve branches. Unlike herpes zoster, the second and third divisions of the trigeminal nerve are the most commonly involved and the first is primarily affected in only less than 5% of patients. Onset is usually in middle or late life but may occur at any age. Typical trigeminal neuralgia occasionally affects children but rarely occurs before age 35 years—presentation at that age should prompt an investigation for demyelinating disease. The incidence of trigeminal neuralgia is slightly greater in women than in men and found to be about 12.6 per

100,000 people in some studies.

The cause remains unknown. In most cases, no organic disease of the fifth nerve or the CNS is identified. Degenerative or fibrotic changes in the gasserian ganglion have been described but are too variable to be considered causal. Trigeminal nerve compression related to an anomalous blood vessel, usually in the vicinity of the ganglion, is a long-standing but controversial etiology of the disorder. Most commonly, this is thought to be compression by a loop of either the anterior inferior cerebellar or superior cerebellar artery. Painful symptoms typical of trigeminal neuralgia occasionally occur with demyelinating brain stem lesions including those produced by multiple sclerosis, as well as vascular ischemia affecting the descending root of the fifth nerve. When trigeminal neuralgia has a known structural cause, it is categorized as symptomatic, as opposed to the idiopathic form that has no known etiology. Although trigeminal neuralgia usually follows other symptoms of multiple sclerosis rather than precedes them, up to 10% of patients may have facial pain as part of their initial presentation. Tumors invading the gasserian ganglion or the cerebellopontine angle may also cause symptoms of trigeminal neuralgia, although usually in the setting of an abnormal neurologic examination. The paroxysmal attacks of facial pain in trigeminal neuralgia may be related to excessive discharge within the descending nucleus of the nerve triggered by an influx of impulses. Relief of symptoms by section of the greater auricular or occipital nerves in some patients suggests a role for peripheral excitation, and interruption of an episode by intravenous phenytoin, as well as a general therapeutic response to antiepileptic agents, suggests aberrant neuronal discharge may also play an important part in the pathophysiology of this disorder. Trigeminal neuralgia is the most common of all neuralgias.

Clinical Manifestations and Diagnosis

The pain is extremely severe, is described by many patients as among the worst pain imaginable, and in severe and refractory cases,

P.742

the risk of suicide is increased. The pain appears in paroxysms and typically lasts seconds, although episodes of up to 15 minutes can occur. Between episodes, the patient is free of symptoms, except for fear of an impending attack. The pain is searing or burning, coming in lightning-like jabs. The frequency of attacks varies from many times a day to a few times a month. The patient ceases to talk when the pain strikes and may rub or pinch the face; movements of the face and jaw may accompany the pain.

Sometimes, ipsilateral lacrimation is prominent. No objective loss of cutaneous sensation is found during or after the paroxysms, but the patient may complain of facial hyperesthesia.

A characteristic feature in the presentation is the *trigger zone*, stimulation of which sets off a typical paroxysm of pain. This zone is a small area on the cheek, lip, or nose that may be stimulated by facial movement, chewing, brushing teeth, or touch. The patient may avoid making facial expressions during conversation, may go without eating for days, or may avoid the slightest breeze to prevent an attack. The pain is limited strictly to one or more branches of the fifth nerve and does not spread beyond the distribution of that nerve. The second division is involved more frequently than the third. Pain may spread to one or both of the other divisions. In cases of long duration, all three divisions are affected in 15% of patients. The pain is occasionally bilateral (5%) for some but rarely occurs at the same time. Bilateral trigeminal neuralgia is encountered most often in patients with multiple sclerosis. A new classification scheme differentiates classic trigeminal neuralgia with paroxysms of pain from a different form, in which the paroxysms are associated with a concomitant dull, constant facial pain.

The diagnosis of trigeminal neuralgia is usually made from the history. Neurologic examination in patients with trigeminal neuralgia is usually normal, although some patients may also have concurrent hemifacial spasm, and patients whose attacks are provoked by eating may appear thin or cachectic. The results of

serum studies and other diagnostic evaluations are also normal. Characteristically, patients avoid touching the area of origin when asked to point it out, instead holding the tip of the index finger a short distance from the face. On examination, patients will show no clinical sensory or motor deficits in the trigeminal nerve distribution, although the affected area is often very sensitive. Computed tomography (CT) or MRI of the brain is reasonable to exclude structural causes and at times may demonstrate an aberrant vessel causing compression. However, the sensitivity and specificity of MRI for identifying neurovascular compression is variable and thus its role for this purpose is controversial. In 2008, the American Academy of Neurology put forth a practice parameter concerning the diagnosis and treatment of trigeminal neuralgia, which stated that electrodiagnostic evaluation of the trigeminal reflex is a reasonable first step in excluding symptomatic trigeminal neuralgia and can be considered before imaging.

Trigeminal neuralgia must be differentiated from other types of facial pain or headache, especially infections of the teeth and nasal sinuses. These pains are usually steady instead of episodic, are often throbbing, and persist for many hours. However, it is not uncommon for patients with trigeminal neuralgia to undergo surgical treatment of the sinuses and/or tooth extractions before the diagnosis is established. Conversely, patients with diseased teeth may be referred to neurology with a diagnosis of trigeminal neuralgia, although careful dental examination usually identifies the teeth as the source of pain in these patients.

Temporomandibular joint disease may also mimic trigeminal neuralgia, but the pain is not paroxysmal and, although exacerbated by eating, no trigger point may be identified and symptoms are usually less severe between meals. Cluster headaches are another consideration but occur in protracted clusters rather than as brief events and are accompanied by ipsilateral nasal congestion, ipsilateral conjunctival injection and lacrimation, and an ipsilateral Horner syndrome. Atypical facial pain may have a trigeminal distribution but the individual paroxysms always last longer than a few seconds (usually minutes or hours). The pain itself is dull, aching, crushing, or burning. Surgical treatment is not effective in atypical facial pain and its etiology remains obscure, although it may be associated with depression.

A more detailed discussion of headache and facial pain syndromes can be found in Chapter 7.

Treatment and Outcome

Although surgical options now exist, medical therapy remains first line as far as treatment options. Trigeminal neuralgia is most effectively treated with carbamazepine at 800 mg/day to a maximum dose of 1,500 mg/day in four divided doses. A Cochrane Database review found carbamazepine to be consistently effective, with a number needed to treat of 1.8. However, dosing should be titrated to effect, and doses producing serum levels above the therapeutic range for seizure control may be needed as long as potentially dose-limiting side effects are tolerated. Overdosage is manifested by drowsiness, dizziness, ataxia, unsteady gait, and nausea. Hepatotoxicity may occur but is usually reversible with discontinuation. Another more rare but serious complication is aplastic anemia, and both periodic liver function testing and monitoring of the blood count are needed. In some patients, tolerance may develop over time. Baclofen is also effective in many cases in doses of 40 to 80 mg/day; phenytoin is less effective but may be used as adjunctive therapy. Some of the newer antiepileptic agents may also provide some relief, and oxcarbazepine, a derivative of carbamazepine, in doses of 400 to 1,200 mg/day is thought to be as effective as carbamazepine. Other medications which have been shown to be effective in some cases (although no controlled trials exist) include lamotrigine, gabapentin, pregabalin, sumatriptan, and topiramate. More recently, both intravenous lidocaine and onabotulinum toxin A have been found to be successful in treating acute episodes of trigeminal neuralgia, although more rigorous trials are needed. Surgical procedures used to treat this condition include microvascular decompression, radiofrequency ablation, balloon microcompression, and chemical gangliolysis and rhizotomy. More recently, stereotactic radiosurgery using

Gamma Knife has been used with noted improvements in pain scores. Of these methods, radiofrequency ablation has met with the greatest success in initial treatment, although recurrence rates have not been studied carefully. As compression of the trigeminal nerve by arterial loops may play a role in some cases, posterior fossa exploration with decompression has sometimes been used for refractory cases. Other chronic masses, such as arteriovenous malformation, aneurysm, and cholesteatoma, may also cause compression of the ganglion and may be more amenable to surgical correction.

THE FACIAL NERVE (CRANIAL NERVE VII)

The seventh cranial nerve (facial nerve), although predominantly motor, also serves an important parasympathetic and sensory function (Fig. 86.1). On exiting the brain stem ventrally via the internal acoustic meatus in the petrous part of the temporal bone near the pontomedullary junction, the facial nerve forms two divisions: the nervus intermedius and the motor root. The motor root is

P.743

composed of nerve fibers arising from the facial motor nucleus, and after exiting the nucleus, these axons travel dorsomedially in the pons to circle the abducens nucleus (thus forming the facial colliculus) and travel down to meet the nervus intermedius to form the facial nerve. The nervus intermedius arises from superior salivatory and lacrimal nuclei (eventually sending parasympathetic innervation to the salivary glands, specifically the submaxillary and sphenopalatine ganglia), the nucleus solitarius (fibers of which ultimately relays afferent taste sensation from the anterior two-thirds of the tongue), and the spinal trigeminal nucleus (carrying somatosensory afferent fibers to parts of the face and ear). The fibers of the seventh cranial nerve arising from the spinal trigeminal nucleus may also relay proprioceptive impulses from the facial muscles and cutaneous sensation from the posteromedial surface of the pinna and the external auditory canal. The fibers arising from the nucleus solitarius and spinal trigeminal nucleus together synapse in the geniculate ganglion in close proximity to the brain stem. Distal to the geniculate ganglion, the facial nerve forms several branches. Axons from the superior lacrimal nucleus form the greater petrosal nerve, which synapses in the sphenopalatine ganglion prior to innervating the lacrimal glands. Fibers originating from the nucleus solitarius and the superior salivatory and nuclei travel further distally in the facial nerve prior to forming the chorda tympani, a branch of the nerve which crosses the middle ear and exits the skull to join the lingual nerve. Just prior to the chorda tympani, the facial nerve also gives off a motor branch to the stapedius muscle. Distal to the chorda tympani, the motor root of the facial nerve runs through the facial canal and exits the skull via the stylomastoid foramen. At this point, it gives rise to the posterior auricular nerve innervating the scalp and ear, as well as a motor branch to the stylohyoid muscle and digastric muscle. The nerve then continues on into the parotid gland, where it divides into its five major branches—temporal, zygomatic, buccal, marginal mandibular, and cervical.

FIGURE 86.1 Anatomy of the facial nerve. (From Campbell WW. *DeJong's The Neurologic Examination*. 6th ed. Philadelphia: Lippincott Williams and Wilkins; 2005.)

Lesions near the origin of the nerve, or in the vicinity of the geniculate ganglion, are accompanied by loss of motor, gustatory,

P.744

and autonomic functions. Lesions between the geniculate ganglion and the origin of the chorda tympani typically spare lacrimation, whereas lesions near the stylomastoid foramen spare taste and lacrimation, causing only ipsilateral facial paralysis of the upper and lower face. Lesions of the facial nerve nucleus in the brain stem also cause ipsilateral paralysis of all facial muscles, both upper and lower.

The pattern of peripheral or nuclear injury (the peripheral seventh nerve lesion) must be distinguished from that associated with central motor pathway lesions above the level of the nucleus, which cause weakness and paralysis in the lower half of the face while sparing forehead wrinkling because of redundancy of central pathways subserving upper face muscles (central facial weakness; supranuclear palsy). In supranuclear lesions, voluntary contractions of the face differ, being more or less intense, from those occurring during spontaneous emotional expression, particularly when accompanied by laughing or crying. Depending on the precise site and

extent of associated injury within the CNS, other neurologic signs may also appear.

Owing to this anatomic organization, the signs of peripheral facial nerve injury are somewhat variable (Table 86.2). More severe injury produces obvious facial paralysis at rest with sagging of the muscles of the lower ipsilateral face. The normal folds and lines around the lips, nose, and forehead are attenuated; the palpebral fissure is wider than normal; and voluntary movement of the facial and platysmal muscles is absent. Smiling highlights the weakness by contrasting the normal and unaffected orbicularis oris with the droop of the affected side. Although weakness of both the upper and lower halves of the face is seen, occasionally, the lower muscles may be weaker than the upper, or more rarely, the upper muscles may be weaker than the lower, with partial nerve injury. Saliva may seep from the paralyzed side of the mouth at rest, and food or fluids may leak out when eating. Closure of the eyelid is incomplete, and the upward and inward deviation of the eye may be seen during examination when eye closure is attempted (Bell phenomenon). This common complication assumes great importance because early patching and lubrication of the affected eye after seventh nerve injury is critical to prevent corneal desiccation and potentially permanent scarring. Tear production is diminished only if the lesion is proximal to the geniculate ganglion. With lesions peripheral to the ganglion, lacrimation is spared but tears may still be sequestered in the conjunctival sac because incomplete eyelid closure no longer moves them effectively through the lacrimal duct. The corneal reflex is also impaired by paralysis of the upper lid, although preservation of corneal sensation and the afferent portion of the reflex is confirmed by consensual blinking of the contralateral eyelid during corneal reflex testing. Decreased salivation and loss of taste in the anterior two-thirds of the tongue are present when the chorda tympani is affected. Loss of somatic sensation to the external auditory canal, however, is less common. The seventh nerve also supplies the stapedius muscle, and patients may develop increased sensitivity to loud sounds (i.e., hyperacusis) when the small muscle is paralyzed and its dampening effect on the tympanic membrane is lost. Recovery from facial paralysis depends on the severity of the lesion and the specific cause. If the nerve is completely crushed or severed, the chances of even partial recovery are remote, especially if the intraneural scaffolding necessary to guide axonal regeneration is lost. In contrast, in purely demyelinating lesions without axonal injury, excellent and often complete recovery is expected. When the facial nerve attempts to regenerate through proximal axonal growth across an injured segment, axonal extension sometimes results in aberrant reinnervation. This faulty circuit results in the movement of previously unrelated facial muscles when the patient attempts isolated activation of a separate muscle, a process known as *synkinesis*. In such patients, for example, lip movement may occur with each eye blink. Aberrant reinnervation may also cause excessive lacrimation during activation of the facial muscles or when the salivary glands are activated during eating (e.g., producing “crocodile tears”). In addition, some patients develop paroxysmal clonic contractions of the hemifacial muscles (i.e., hemifacial spasm) that may simulate focal seizures.

TABLE 86.2 Clinical Manifestations of Lesions of the Facial Nerve

Location of Lesion	Motor Function	Gustatory Sensation	Lacrimation
At facial nerve nucleus in pons	Impaired	Impaired	Impaired
Origin of nerve/geniculate ganglion	Impaired	Impaired	Impaired
Between geniculate ganglion and chorda tympani	Impaired	Impaired	Spared

BELL PALSY

Epidemiology and Pathobiology

Bell palsy, named after the Scottish anatomist Charles Bell, is a common clinical syndrome of uncertain etiology in which acute, unilateral paresis or paralysis of muscles innervated by the facial nerve appears spontaneously, over hours to days, and is the most common cause of facial nerve injury and acute mononeuropathy. It occurs at all ages but is slightly more common in the third to fifth decades and is equally likely to affect the right or left sides. Bell palsy is the common cause of facial nerve paralysis and in one study accounted for 65% of cases of peripheral facial paralysis in a pediatric population (excluding congenital causes). Recurrence, either on the same or on the opposite side, is rare and raises the question of a more generalized disorder. Familial Bell palsy is reported but is also rare. Risk factors are not well defined, although some patients report exposure of the affected side to a steady breeze or fan for several hours just prior to onset. It has also found to be associated with diabetes mellitus, pregnancy, and hypertension. Some postulate that it may be caused by reactivation of a latent herpes simplex virus or varicella-zoster, and possibly human herpesvirus 6 (HHV-6). Lyme disease is also often implicated particularly in cases of bilateral facial palsy.

Clinical Features and Diagnosis

Pain is not typical except in the Ramsay Hunt syndrome (see the following section), which is caused by herpes zoster and is usually accompanied by vesicular eruption in the sensory distribution of the seventh nerve in the ipsilateral ear. Patients typically present with unilateral facial weakness or complete paralysis, which can be scored from 1 to 6 on the House-Brackmann scale which is determined by measurements of eyebrow and mouth movements. Facial weakness is associated with diminished lacrimation, impaired taste

P.745

in the anterior two-thirds of the tongue on the affected side, and a weakened or absent blink reflex. Given the innervation of the stapedius muscle, there may be an increased sensitivity to noise on the affected side. There should not, however, be any impairment of eye movements, change in vision, or other bulbar symptoms such as dysphagia or facial numbness. When present, any of those signs or symptoms should prompt one to look for an alternative diagnosis. In 2013, the American Academy of Otolaryngology-Head and Neck Surgery Foundation (AAO-HNSF) published a new clinical practice guideline on the diagnosis and treatment of Bell palsy. Regarding appropriate diagnostic workup, it was concluded that in the appropriate clinical scenario following a complete history and examination, there is no role for laboratory investigation, diagnostic imaging, or electrodiagnostic testing (unless there is complete facial paralysis). Patients should, however, be referred to a specialist in cases of new or worsening findings, ocular symptoms, or incomplete recovery 3 months after onset. Nevertheless, nerve conduction studies (NCS) of the extracranial portion of the facial nerve are at times performed (particularly in cases of complete paralysis) along with needle recordings from its myotomes (e.g., facial muscle electromyography [EMG]) to help determine the nature and degree of injury. Injury to the intracranial portion may be detected by blink reflex testing.

Treatment and Outcome

Although permanent deficits may occur in severe cases, the vast majority of patients with Bell palsy experience full, functional recovery with minimal to no residual signs. Long-term prognosis is typically very

favorable, although there is some recent limited evidence that these patients may be at a slightly higher risk for developing cancer (particularly oral cancer) and a slightly higher risk of stroke. Inflammation, herpes simplex virus infection, and swelling with compression may be involved in the pathogenesis of Bell palsy, so steroids, antiviral medication (acyclovir), and surgical decompression have been advocated as acute therapy. A large, randomized controlled study showed that 94% receiving prednisolone 25 mg b.i.d. for 10 days had a good recovery at 9 months compared with 82% who did not receive steroids. The same study showed no benefit for the antiviral agent acyclovir at doses of 400 mg five times per day for 10 days, although another large study showed benefit for valacyclovir at 1 g/day for 5 days. Surgical intervention has been looked at as well, and a recent Cochrane Database review found insufficient evidence to decide whether it is beneficial or harmful but given the generally good prognosis and spontaneous recovery is often not recommended. Early physical therapy may be beneficial particularly in cases of very severe paresis or complete paralysis. The 2013 AAO-HNSF practice guidelines recommend offering antiviral therapy in addition to oral steroids with 72 hours of symptom onset although made no recommendation regarding the use of physical therapy, acupuncture, or surgical referral. The American Academy of Neurology published an update regarding recommendations on steroids and antiviral therapy which stated that steroids should be offered to those with new-onset palsy and that antiviral may be offered although are likely to be of modest benefit at best. It is important that affected patients patch the weak eye overnight, as weakness of eye closure may lead to dry eyes and corneal abrasions. Eye drops such as artificial tears and lubricating ointments should be given as well. The prognosis of facial nerve injury after Bell palsy has also been the focus of much discussion. In general, preservation of motor amplitudes on NCS after 7 to 10 days supports retained axonal integrity and suggests a favorable prognosis for recovery. In contrast, rapid loss of motor amplitudes suggests prominent axonal involvement, wallerian degeneration, and poorer chance for functional improvement. Needle EMG examination may also aid in detecting denervation change, further supporting axonal injury. Electroneurography (ENoG) has recently been looked at with regard to its prognostic value, and ENoG value was found to be positively correlated with a higher chance of recovery in both Bell palsy and Ramsay Hunt syndrome, although it is not commonly used in practice. In the long term, patients may develop synkinesis as described earlier.

RAMSAY HUNT SYNDROME

Ramsay Hunt syndrome, also known as *herpes zoster oticus*, is another cause of facial mononeuropathy although much less common than Bell palsy and tends to affect younger patients. Mean incidence is thought to be about five cases per 100,000 person-years. It is caused by a reactivation of a latent varicella-zoster virus infection affecting the geniculate ganglion leading to inflammation of the facial nerve and therefore is seen commonly in immunocompromised conditions (i.e., posttransplant, in the setting of malignancy). Typically, in addition to facial weakness, as in Bell palsy, there is associated hyperacusis, diminished taste, and impaired salivation and lacrimation. The degree of weakness in these patients is often more severe than in those with Bell palsy, and pain is a distinguishing factor. Pain is very common and can be in deep to the face; in the ear; or in the orbit, tongue, or palate (particularly if sensory fibers are involved). Most commonly, there is pain behind the ear on the affected side. On examination, one may see herpetic vesicles in the external auditory canal or behind the ear and at times may also be found on the neck and palate. However, a rash is not always seen (or may erupt after the onset of weakness) and one must have a high index of clinical suspicion based on the patient's history and presentation in order to consider this diagnosis rather than Bell palsy. Herpetic infection can spread to the eighth cranial nerve leading to complaints of nausea, tinnitus, and vertigo and infrequently to other cranial nerves as well.

Both steroids and antivirals have been used to treat Ramsay Hunt syndrome with varying degrees of success.

Although there have been no randomized controlled trials, several studies have noted that early administration of steroids and antivirals (within 3 to 5 days) leads to improved facial and vestibulocochlear nerve recovery. Some suggest using intravenous methylprednisolone in those patients not improving or with poor prognostic factors. Overall, patients with Ramsay Hunt syndrome have an overall poorer prognosis than those with Bell palsy and often have an incomplete recovery.

OTHER CAUSES OF FACIAL NERVE INJURY

Many other processes may significantly damage the facial nerve. Intracranially, it may be injured by tumors, aneurysms, meningeal infections, leukemia, osteomyelitis, herpes zoster, Paget disease, sarcomas, and bony tumors, among others. It may also be damaged by leprosy polyneuritis, Guillain-Barré syndrome, and diphtheritic polyneuropathy. Diabetic seventh nerve lesions may also occur but are less common than other cranial mononeuropathies in that disorder. The peripheral segment of the nerve may be compressed by tumors of the parotid gland, sarcoidosis, and more rarely, mumps. Bilateral facial palsy also may be caused by many of the same conditions producing unilateral paralysis but is most often seen in sarcoidosis, Guillain-Barré syndrome, leprosy, leukemia, and meningococcal meningitis. Sarcoid, in fact, can be implicated in most cranial neuropathies and a full discussion of neurosarcoidosis

P.746

can be found in Chapter 72. *Melkersson-Rosenthal syndrome* is a syndrome presenting in childhood characterized by a constellation of clinical symptoms and signs including facial and lip edema, a furrowed and fissured tongue (*lingua plicata*), and recurrent attacks of facial weakness. Although there is no known etiology, it is thought to be familial in some instances. Other congenital causes of facial palsy include Möbius syndrome, in which facial weakness is associated with impaired lateral eye movement due to poor development of both the seventh and sixth cranial nerves. The facial nucleus, itself, may be damaged by vascular lesions, multiple sclerosis, intraparenchymal tumors, inflammatory lesions, and acute poliomyelitis, among others. The relatively superficial peripheral branches of the seventh nerve are vulnerable to stab and gunshot wounds, cuts, and in neonates, birth trauma. Occasionally, the nerve is also injured in surgeries involving the mastoid and parotid glands, acoustic neuroma resection, and trigeminal ganglion decompression, as well as in fractures of the temporal bone.

Cases of facial nerve injury with a specific, identifiable cause may require aggressive intervention. Microsurgical anastomosis may be performed in some cases of transection of the extracranial nerve or its branches. However, when the nerve is damaged proximal to the stylomastoid foramen, operative anastomosis becomes more difficult. Surgery may still be indicated, however, if a mass lesion is found before excessive damage is done. In cases of partial or inaccessible intracranial facial nerve injury, compensatory surgical reinnervation may be provided by suturing the distal portion of the 7th nerve to the central portion of either the 11th nerve or the 12th nerve. With rehabilitative training, these patients may learn to reroute impulses formerly destined for the sternocleidomastoid muscle, or half of the tongue, to the newly rewired facial musculature. However, use of the 11th nerve for this procedure causes permanent paralysis of the sternocleidomastoid and upper fibers of the trapezius muscle, whereas use of the 12th nerve causes atrophy and paralysis of one-half of the tongue. Anastomosis of the facial nerve with either the 11th or the 12th nerve should be performed as soon as possible following acute injury, such as with surgical misadventure by surgery of the mastoid or removal of an acoustic neuroma, for instance. In other situations, surgery may need to be delayed for up to 6 months or more to determine whether spontaneous regeneration occurs.

Hemifacial spasm is a disorder involving involuntary muscle contractions of facial muscles on one side of the face and is covered in detail in Chapter 77.

THE ACOUSTIC NERVE (CRANIAL NERVE VIII)

Eighth nerve disorders are described in Chapter 59.

THE GLOSSOPHARYNGEAL NERVE (CRANIAL NERVE IX)

The ninth cranial nerve contains both motor and sensory (general as well as taste) fibers. The motor fibers originating in the nucleus ambiguus supply the stylopharyngeus muscle and the constrictors of the pharynx, whereas other efferent fibers innervate secretory glands in the pharyngeal mucosa. The sensory fibers carry general sensation from the upper part of the pharynx (as well as the tonsil, tympanic membrane, and external ear) and the special sensation of taste from the posterior one-third of the tongue. The glossopharyngeal nerve also conveys sensory afferent fibers from the carotid sinus and body by way of the nucleus solitarius and provides parasympathetic innervation to the parotid gland via the otic ganglion through the lesser petrosal nerve. Isolated lesions of the nerve, or its nuclei, are rare and are not accompanied by perceptible disability. Taste is lost on the posterior one-third of the tongue, and the gag reflex is absent on the side of the lesion. Injuries of the ninth nerve by infections or tumors are rarely isolated and are usually accompanied by signs of injury to nearby cranial nerves. As the 9th, 10th, and 11th nerves exit the jugular foramen together, tumors at that point produce multiple cranial nerve palsies (i.e., *jugular foramen syndrome*). Within the brain stem, the tractus solitarius receives taste fibers from both the seventh and the ninth nerves and is commonly injured by vascular or neoplastic lesions in the brain stem.

GLOSSOPHARYNGEAL NEURALGIA

Glossopharyngeal neuralgia (GN), also known as *tic douloureux* of the ninth nerve, is characterized by paroxysms of excruciating pain in the region of the tonsils, posterior pharynx, and back of the tongue with radiation to the middle ear. The cause of GN is unknown, and no significant pathologic changes occur in most cases. Idiopathic GN must be differentiated from pain in the distribution of the nerve following its injury in the neck by tumors. GN is rare, with a frequency of approximately 5% that of trigeminal neuralgia. Unlike trigeminal neuralgia, men and women are affected equally and GN is more likely to be bilateral than trigeminal neuralgia. The paroxysms consist of burning or stabbing pain and may occur spontaneously but are often precipitated by swallowing, talking, or touching the tonsils or posterior pharynx. The attacks usually last only a few seconds but sometimes may last several minutes, and they may occur many times daily or once every few weeks. Patients may become emaciated because of the fear that chewing each morsel of food will precipitate a pain paroxysm; general quality of life may be seriously affected, especially in severe cases. On occasion, attacks may lead to syncope, arrhythmia, or convulsions due to stimulation of the carotid sinus reflex.

The diagnosis of GN is best made by history and may be confirmed by provocative testing (e.g., precipitation by stimulation of the tonsils, posterior pharynx, or base of the tongue) or by transient relief of pain following the application of topical anesthetic to the ninth nerve dermatome. Following this procedure, the pain is no longer precipitated by stimulation, and the patient may swallow food and talk without discomfort until the anesthetic wears off. The differential diagnosis is limited but includes neuralgia of the mandibular branch of the fifth nerve. There may be long remissions, during which pain is no longer triggered. The pains usually recur, however, unless prevented by medical therapy or surgical resection of the nerve. Medications used to treat trigeminal neuralgia are equally effective with GN, and carbamazepine alone or in combination with phenytoin often provides effective control and induces a pharmacologic remission. Duloxetine as well as certain newer antiepileptic drugs such as pregabalin, gabapentin, topiramate, and lamotrigine might also be effective.

If medical therapy is unsuccessful and the pain is intractable, surgical interventions have been shown to be effective, including microvascular decompression, radiofrequency ablation, and Gamma Knife ablation. Intracranial transection of the nerve may also provide relief. Following this procedure, the mucous membrane supplied by the ninth nerve is permanently anesthetized, with ipsilateral loss of the gag reflex and ipsilateral loss of taste on

the posterior one-third of the tongue. Motor symptoms, such as dysphagia or dysarthria, are not typical unless the 10th nerve is injured during surgery.

THE VAGUS NERVE (CRANIAL NERVE X)

Efferent fibers of the vagus nerve arise from both the nucleus ambiguus and the dorsal motor nucleus. Fibers from the nucleus ambiguus ultimately innervate the somatic muscles of the pharynx and larynx through the pharyngeal, superior laryngeal, and recurrent laryngeal nerves, whereas those from the dorsal motor nucleus supply autonomic innervation to the heart, lungs, esophagus, and stomach. The vagus nerve also relays sensory fibers from the mucosa in the oropharynx and upper part of the gastrointestinal tract to the spinal nucleus of the trigeminal nucleus and relays sensory fibers from the thoracic and abdominal organs to the tractus solitarius. Central lesions of the above nuclei in the brain stem cause a number of symptoms. Unilateral lesions of the nucleus ambiguus result in dysarthria and dysphagia, although rarely is the condition severe. However, because the nucleus has a considerable longitudinal extent in the medulla, such lesions may produce dysarthria without dysphagia or vice versa (i.e., caudal nuclear lesions cause dysphagia, whereas rostral lesions produce dysarthria). Hoarseness may also occur, but speech is usually intelligible. Dysphagia is usually slight, although occasionally, a more severe transient aphagia necessitates the use of a feeding tube for days to weeks. On examination, contraction of the palatal muscles is absent on the affected side during gag reflex testing. The palate on the affected side is lax at rest, and the uvula deviates to the opposite side on phonation, drawn away from the paralyzed muscles by normal, contralateral, palatal contraction (i.e., contralateral uvular deviation).

In contrast to the mild deficits typically seen with unilateral lesions, bilateral lesions of the nucleus ambiguus cause complete aphonia and aphagia. Focused bilateral injury of this type is rare but may be seen in advanced amyotrophic lateral sclerosis (ALS) in the setting of pseudobulbar palsy. Selective destruction of portions of the nucleus ambiguus may be produced by syringobulbia, intramedullary tumors, or ischemia and may cause a clinical syndrome of vocal cord paralysis during adduction. The patient may talk and swallow without difficulty, but inspiratory stridor and dyspnea may appear and progress sufficiently to require tracheotomy. Unilateral lesions of the dorsal motor nucleus are not accompanied by any significant symptoms, but bilateral lesions may produce life-threatening autonomic instability. The dorsal nucleus may be damaged by infection (e.g., acute poliomyelitis), intramedullary tumor, ischemia, and polyneuropathy, especially that associated with diphtheria and Guillain-Barré syndrome.

Individual branches of the vagus nerve are most amenable to injury in the neck, thorax, and, less commonly, the abdomen. Injury to the pharyngeal branches of the vagus nerve causes dysphagia, whereas lesions of the superior laryngeal nerve produce anesthesia of the upper part of the larynx and paralysis of the cricothyroid muscle. In these cases, the voice is weak and easily fatigable. Injury to a single, recurrent laryngeal nerve (i.e., frequently seen with aneurysms of the aorta, tumors or trauma of the neck, and occasionally after operations in the neck) causes unilateral paralysis of the vocal cords with hoarseness and dysphonia; bilateral injury causes complete vocal cord paralysis with aphonia and inspiratory stridor. Partial bilateral paralysis may produce a paralysis of both abductors, with severe dyspnea and inspiratory stridor, but does not usually cause any alteration in the voice. Bilateral lesions of the vagus nerve invariably lead to death via cardiac arrhythmias, irregular respirations, gastrointestinal atonia, and complete paralysis of the pharynx and larynx.

THE SPINAL ACCESSORY NERVE (CRANIAL NERVE XI)

The spinal accessory nerve is composed of two primary branches—the first is a small accessory cranial branch contributing visceral efferent fibers to the vagus nerve, which emerges from the jugular foramen to blend with the vagus as it descends (primarily in the recurrent laryngeal nerve). The majority of the accessory nerve, the spinal portion, innervates the sternocleidomastoid and part or all of the trapezius muscles. Its fibers originate in the

upper cervical spinal cord (C2, C3, and C4), enter the skull via the foramen magnum, and travel through the jugular foramen along the carotid artery to innervate the sternocleidomastoid (SCM) muscle. Another branch emerges in the mid-SCM at its posterior border and crosses the posterior triangle of the neck to innervate the upper trapezius. It is important to note that supranuclear efferents to the SCM are primarily ipsilateral, whereas inputs to the trapezius cross contralaterally from the motor cortex. Therefore, on examination, a lesion of the ipsilateral hemisphere or accessory spinal nerve will result in an inability to turn the head contralaterally (as the SCM turns the head in the opposite direction). Fibers of the spinal accessory nerve also travel in the medial longitudinal fasciculus, where they make connections with the oculomotor, trochlear, abducens, and vestibular nuclei and help coordinate eye movements with head motion in response to external stimuli.

Lesions of the spinal portion of the 11th nerve produce weakness and atrophy of the trapezius muscle and SCM, impairing rotary movements of the neck and chin to the opposite side, and weakness of shrugging movements of the shoulder. Weakness of the upper portion of the trapezius results in winging of the scapula, which must be differentiated from that produced by weakness of the serratus anterior. Scapular winging from weakness of the trapezius is present at rest (e.g., arms at side) and becomes worse on abduction of the shoulder. Scapular winging from weakness of the serratus anterior is negligible at rest and worsens during flexion of the shoulder (holding or pushing the arm forward). Bilateral paralysis of the trapezius may present with “dropped head syndrome” due to weakness of head extension. With unilateral SCM weakness, there is typically little head tilt, as there are contributions from several other muscles to head rotation, although the patient will have difficulty turning the head to the contralateral side. The accessory or cranial portion of the nerve originates in the nucleus ambiguus and passes through the jugular foramen with the 10th nerve, traveling with the spinal fibers (see earlier), eventually innervating the larynx, and functionally is considered by some to be a part of the vagus nerve complex.

The nucleus of the 11th nerve may be destroyed by infections and degenerative disorders in the medulla, such as syringobulbia or ALS. The nerve itself may be injured by polyneuropathy, meningeal infection, extramedullary tumor (e.g., meningioma and neurinoma), trauma (i.e., basilar skull fracture), or by destructive processes in the occipital bone. It is particularly vulnerable to damage along its course in the posterior triangle of the neck, for instance, during lymph node biopsy, radiation, cannulation of the internal jugular vein, or carotid endarterectomy. The SCM and trapezius are also often involved in cases of extrapyramidal dysfunction (discussed in later chapters), such as torticollis due to

P.748

cervical dystonia. Idiopathic focal mononeuropathies of the spinal accessory nerve exist although are rare, and the nerve at times may be involved in cases of Parsonage-Turner syndrome. Primary diseases of muscle and the neuromuscular junction also commonly involve the muscles innervated by the 11th cranial nerve, such as in fascioscapulohumeral dystrophy, myotonic dystrophy, and myasthenia gravis. Diagnosis of a spinal accessory nerve palsy is made clinically but can be supported with imaging and electrodiagnostic testing. Recent reports point to a potential role for ultrasound in diagnosis and in determining etiology.

THE HYPOGLOSSAL NERVE (CRANIAL NERVE XII)

The hypoglossal nerve (a pure motor nerve) emerges from the medulla between the ventrolateral sulcus, between the olive and the pyramids, as a number of rootlets that converge into the hypoglossal nerve. The nerve then exits the cranium through the hypoglossal foramen in the posterior cranial fossa traveling close to cranial nerves IX, X, and XI and passing downward near the inferior ganglion of the vagus to lie between the internal carotid artery and internal jugular vein. It then crosses laterally to the bifurcation of the common carotid artery and loops above the hyoid bone before moving ventrally to supply the genioglossus (which has crossed supranuclear innervation) and other muscles of the tongue with the exception of the palatoglossus (innervated by the vagus nerve). The 12th nerve and its nucleus may be injured by most of the same processes that damage

the 10th and 11th nuclei. Occlusions of the short branches of the basilar artery supplying the paramedian medulla cause paralysis of the tongue on one side and paralysis of the arm and leg on the opposite side (i.e., alternating hemiplegia). Unilateral injury to the nucleus results in atrophy and paralysis of the muscles of one-half of the tongue causing deviation toward the paralyzed side with protrusion.

Fibrillation of the muscles is seen with chronic injury to the hypoglossal nerve or its nucleus in syringobulbia or ALS and may be observed as miniscule twitching of the surface of the tongue on visual inspection. Bilateral paralysis of the nucleus or nerve produces atrophy of both sides of the tongue and paralysis of all movements with severe dysarthria and difficulty manipulating food in the mouth. The tongue is only rarely affected by supranuclear lesions within the CNS; unilateral weakness may accompany severe hemiplegia with slight deviation of the tongue to the paralyzed side when protruded. Moderate weakness of the tongue may accompany pseudobulbar palsy but is never as severe as that caused by destruction of both medullary nuclei. The hypoglossal nerve is susceptible to injury anywhere along its course (both intra and extramedullary) and can be involved in cases of meningitis, neoplastic infiltration, trauma, lymphadenopathy, radiation, and processes involving the skull base. Occasionally, muscle diseases may involve the tongue, such as in myotonic dystrophy where percussion of the tongue may cause a temporary contraction along the line of percussion.

Acquired Peripheral Neuropathies

Thomas H. Brannagan III

Kurenai Tanji

APPROACH TO PERIPHERAL NERVE DISORDERS

The peripheral nervous system is composed of multiple cell types and elements that subserve diverse motor, sensory, and autonomic functions. The clinical manifestations of neuropathies depend on the severity, distribution, and functions affected. *Peripheral neuropathy* and *polyneuropathy* are terms that describe syndromes resulting from diffuse lesions of peripheral nerves, usually manifested by weakness, sensory loss, pain, and autonomic dysfunction. *Mononeuropathy* indicates a disorder of a single nerve often resulting from local trauma, compression, or entrapment. *Mononeuropathy multiplex* signifies focal involvement of two or more nerves, usually as a result of a generalized disorder such as diabetes mellitus or vasculitis. This chapter discusses an approach to peripheral nerve disorders, mononeuropathies, including plexus disorders, and specific acquired polyneuropathies. Inherited neuropathies are discussed in Chapter 88.

EPIDEMIOLOGY

Peripheral neuropathy which includes polyneuropathies of various causes and mononeuropathies are common disorders. One mononeuropathy, carpal tunnel syndrome, is estimated to occur in 3% to 5.8% and is three times more common in women than men. A prevalence of 2% to 7% of symmetric polyneuropathy has been found in studies conducted around the world. Currently, the most common cause of peripheral neuropathy worldwide is diabetes, although prior to 1994, the most common cause of peripheral neuropathy worldwide was leprosy. The prevalence of peripheral neuropathy increases with age, affecting 15% of the population older than the age of 40 years and 24% older than the age of 70 years.

CLINICAL FEATURES

Polyneuropathy may occur at any age, although particular syndromes are more likely to occur in certain age groups. Charcot-Marie-Tooth (CMT) disease, for example, often begins in childhood or adolescence, whereas neuropathy associated with paraproteinemia is seen more frequently with increasing age. The onset and progression differ; the Guillain-Barré syndrome (GBS), tick paralysis, and porphyria begin acutely and may remit. Others, such as vitamin B₁₂ deficiency or carcinomatous neuropathy, begin insidiously and progress slowly. Still others, such as chronic inflammatory demyelinating polyneuropathy, may begin acutely or insidiously and then progress with remissions and relapses.

The myelin sheaths or the motor or sensory axons or neurons themselves may be predominantly affected, or the neuropathy may be mixed, axonal, or demyelinating. Most polyneuropathies, especially those with primary demyelination, affect both motor and sensory functions. A predominantly motor polyneuropathy is seen in lead toxicity, dapsone or *n*-hexane intoxication, tick paralysis, porphyria, some cases of GBS, and multifocal motor neuropathy. Sensory neuropathy is divided into loss of large-diameter and small-diameter nerve fibers, although a combination of fiber types is most typical. Predominantly small-fiber neuropathy, often with concomitant autonomic dysfunction, is seen in diabetes mellitus, amyloidosis, Fabry disease, and lepromatous leprosy. Less prevalent, predominant large-fiber neuropathy occurs with thallium poisoning, paraneoplastic ganglioneuritis, Sjögren disease, pyridoxine (vitamin B₆) toxicity, and syphilis. Predominant involvement of the autonomic system can be seen in acute or chronic autonomic neuropathy or in amyloidosis.

Symptoms of polyneuropathy include distal pain, paresthesias, weakness, and sensory loss. Pain may be spontaneous or elicited by stimulation of the skin and may be sharp or burning. Paresthesias are usually described as numbness (a dead sensation), tingling, buzzing, stinging, burning, or a feeling of constriction. Lack of pain perception may result in repeated traumatic injuries with degeneration of joints (*arthropathy* or *Charcot joints*) and in chronic ulcerations.

Weakness is greatest in distal limb muscles in most neuropathies; there may be paralysis of the intrinsic foot and hand muscles with footdrop or wrist-drop. Tendon reflexes are often lost, especially in demyelinating neuropathy. In severe polyneuropathy, the patient may become quadriplegic and respirator dependent. The cranial nerves may be affected, particularly in GBS and diphtheritic neuropathy. Cutaneous sensory loss appears in a stocking-and-glove distribution. All modes of sensation may be affected, or there may be selective impairment of "large" myelinated fiber functions (position and vibratory sense) or "small" unmyelinated fiber functions (pain and temperature perception). Often, detection of painful stimuli is impaired with a delayed and greater than normal reaction. Inappropriate pain perception is often paradoxically present despite loss of pain fibers.

Involvement of autonomic nerves may cause miosis (small pupil), Adie pupils, anhidrosis (impaired sweating), orthostatic hypotension, sphincter disturbance, gastrointestinal dysmotility, impotence, and vasomotor abnormalities; these may occur without other evidence of neuropathy but are more commonly seen in association with symmetric distal polyneuropathy. Diabetes mellitus is the most common cause. Amyloidosis causes notably severe autonomic neuropathy. The majority of neuropathy types produce distal impairment of sweating, vasomotor reflexes, and local influences that help produce the typical trophic signs in the feet of neuropathy patients. Distal loss of sweating may induce symptomatic excessive sweating proximally as a compensatory response.

In *mononeuropathy* or *mononeuropathy multiplex*, focal motor, sensory, and reflex changes are restricted to areas innervated by specific nerves. When multiple distal nerves are affected in mononeuropathy multiplex, the pattern may coalesce into more symmetric involvement suggesting polyneuropathy. The most frequent causes of mononeuropathy multiplex are vasculitic neuropathy, diabetes mellitus, rheumatoid arthritis, brachial neuropathy,

P.751

leprosy, or sarcoidosis. Asymmetric neuropathy is also seen in multifocal motor neuropathy with conduction block, sometimes with increased anti-GM1 antibody titers, multifocal demyelinating sensory and motor neuropathy (Lewis-Sumner syndrome), and brachial neuritis.

Processes that affect nerve roots are termed *radiculopathies* and affect a single or multiple myotomes or dermatomes. Focal compression is most common, but other processes also target nerves at these proximal sites. Electric-like pain radiating down a specific segment is most characteristic; loss of sensation or strength in a specific territory occurs with more severe involvement. *Plexopathy* occurs with compromise of the brachial or lumbosacral plexus and often displays a pattern of multiple contiguous nerves or nerve root impairment.

Superficial cutaneous nerves may be thickened and visibly enlarged secondary to Schwann cell proliferation and collagen deposition from repeated episodes of segmental demyelination and remyelination or from amyloid or polysaccharide deposition in the nerves. Hypertrophic nerves may be observed or palpated in the demyelinating form of CMT disease (type I), Dejerine-Sottas neuropathy, Refsum disease, von Recklinghausen disease (neurofibromatosis), and various other disorders.

Fasciculations, or spontaneous contractions of individual motor units, are visible twitches of limb or cranial muscles. They are characteristic of anterior horn cell diseases but also occasionally occur in other chronic neuropathic conditions. *Fibrillation* potentials are discharges of denervated single muscle fibers and are not visible on the skin but are recordable during electromyography (EMG). *Myokymia* is worm-like muscle activity seen in limb muscles in a small number of disorders including radiation plexopathy, episodic ataxia type 1, and

certain autoimmune channelopathies. Potassium channel antibodies or defects are implicated in some entities; facial myokymia is more common and less specific.

ETIOLOGY AND DIAGNOSIS

Peripheral nerve disorders may be divided into hereditary and acquired forms. The most common hereditary disorder is CMT type 1A (peroneal muscular atrophy), which is associated with duplication of the peripheral myelin protein 22 (*PMP22*) gene. Deletion of the same region produces hereditary neuropathy with liability to pressure palsies. The most commonly acquired neuropathies in the United States are associated with diabetes mellitus; selected other causes of polyneuropathy are listed in [Table 87.1](#). Trauma, compression, and entrapment are considered in the differential diagnosis of mononeuropathies, especially median neuropathy at the wrist, ulnar nerve at the elbow, or fibular nerve across the fibular head. Patients with any form of polyneuropathy are more vulnerable to mechanical and toxic nerve injury; cachectic or immobile patients may develop focal neuropathy from pressure or trauma.

In the evaluation of a patient with peripheral neuropathy, a detailed family, social, and medical and medication history; neurologic examination; and electrodiagnostic and laboratory testing are usually necessary for diagnosis. The American Academy of Neurology has made recommendations for evaluation of distal symmetric polyneuropathy ([Table 87.2](#)). Well over 200 individual causes are known, many of which are evident from initial screening measures. Skin or nerve biopsy studies are indicated in some cases. Despite these efforts, the cause of a significant minority remains idiopathic after a comprehensive evaluation. A classification of the most common acquired and hereditary polyneuropathies and their laboratory evaluation are presented in [Table 87.1](#).

TREATMENT

Treatment of patients with peripheral nerve disorders can be divided into two phases: removal or treatment of the inciting condition and symptomatic therapy. Specific treatments are considered in discussions of individual disorders.

Symptomatic treatment of polyneuropathy consists of general supportive measures, amelioration of pain, and physiotherapy. Tracheal intubation and respiratory support may be needed in GBS. The corneas are protected if significant eye closure weakness is present. The bed is kept clean and the sheets are kept smooth to prevent injury to the anesthetic skin; a special mattress can be used to prevent pressure sores. Chronic compression of vulnerable nerves (ulnar at the elbow and common fibular at the knee) is avoided. Paralyzed limbs are splinted to prevent contractures. Physical therapy includes massage and passive joint movement. In chronic polyneuropathy with footdrop, a foot orthosis often improves gait. Treatment of neuropathic pain (see [Chapter 57](#)) and autonomic failure (see [Chapter 112](#)) are discussed elsewhere in the book.

OUTCOME

Polyneuropathy may be progressive or remitting, and the prognosis is affected by the extent of nerve degeneration. With removal or treatment of the inciting cause, recovery is more rapid if macroscopic continuity of the nerves is maintained. Conversely, recovery may be delayed for many months or remain incomplete if significant wallerian degeneration occurs. Axonal regeneration proceeds at a rate of 1 to 2 mm/day and may be further delayed where the axons must penetrate scar tissue, injured nerve segments, or other barriers. Aberrant growth of axonal sprouts may lead to formation of persistent neuromas. After

severe wallerian degeneration, there may be permanent weakness, muscular wasting, diminution of reflexes, and sensory loss. In demyelinating neuropathies, recovery is sometimes more rapid and complete because of remyelination or resolution of conduction block.

MONONEUROPATHIES AND COMPRESSION NEUROPATHIES

THE SPINAL ROOTS AND BRACHIAL PLEXUS

At each cervical spinal level, numerous rootlets containing both motor and sensory fibers join after leaving the spinal cord to form the spinal roots that exit the spinal canal through the intervertebral foramen of the spinal column, immediately branching into anterior and posterior rami. The nerve roots are commonly injured by degenerative joint disease and disk herniation at the cervical and lumbosacral levels. Importantly, the dorsal root ganglia (i.e., the cell bodies of the sensory nerves) are located outside the foramen and are spared in foraminal compression, meaning the remainder of the sensory nerve will remain viable and will appear normal on nerve conduction studies, even though it is disconnected from the central nervous system (CNS) and the patient reports numbness and pain. Before forming the brachial plexus, the C5 nerve root gives off a proximal branch, the *dorsal scapular nerve* (to the rhomboid muscles), whereas the C5, C6, and C7 roots give proximal branches that join to form the *long thoracic nerve*, supplying the serratus anterior muscle. The C5 and C6 roots then join to form the *upper trunk* of the brachial plexus, whereas the C7 root forms the *middle trunk*, and the C8 and T1

P.752

P.753

roots form the *lower trunk*. The upper trunk gives off a small branch, the *suprascapular nerve*, which supplies the supra- and infraspinatus muscles. All trunks pass through the supraclavicular fossa under the cervical and scalene muscles. Each trunk then forms two branches and these branches regroup to form new divisions, the cords, as they course through the *thoracic outlet*, between the first rib and the clavicle, along with the subclavian artery. The lateral branches of the upper and middle trunks contribute to the *lateral cord* (i.e., C5, C6, C7), whereas the medial branches join with the lateral branch of the lower trunk and move dorsally to form the *posterior cord* (i.e., C5, C6, C7, C8). Finally, the lower trunk gives rise to the *medial cord* (i.e., C8, T1). The *lateral and medial pectoral nerves* branch off near the juncture of the trunks and the lateral and medial cords, respectively, supplying the pectoralis major muscle.

TABLE 87.1 Neuropathy Diagnosis and Laboratory Tests

Cause or Diagnosis	Manifestations	Laboratory Tests
Vitamin deficiency/excess	S, SM, SYM	Vitamins B ₁₂ , pyridoxine (B ₆), B ₁ , folate, vitamin E, methylmalonic acid
Infectious		
Lyme disease	S, SM, SYM, MF, CN	Serology, PCR
HIV-1	S, SM, SYM, MF, CN	Serology, PCR

Hepatitis C	S, SM, SYM, MF, CN	Serology, PCR
Herpes zoster	S, radicular	Serology, PCR
CMV	SM, M, SYM, MF	Serology, PCR, culture
Immune mediated		
Guillain-Barré and variants	SM, S, M, SYM, MF, CN	IgG antiganglioside antibodies (GM1, GD1a, GQ1b, GD1b), urine porphyrins
IgM antibody associated	M, MF	IgM anti-GM1, GD1a
	S, SM, SYM	IgM anti-MAG, sulfatide, GD1b, GQ1b
Monoclonal gammopathy	M, S, SM, SYM, MF	Serum immunofixation electrophoresis, quantitative immunoglobulins
Autonomic neuropathy	Autonomic dysfunction	Antinicotinic acetylcholine receptor antibodies, anti-Hu
Vasculitis	SM, S, MF, SYM	ESR, cryoglobulins, hepatitis C serology, or PCR
Sarcoidosis	SM, S, MF, SYM	ACE, chest radiograph
Celiac disease	S, SM, MF, SYM	Antigliadin, endomysial, transglutaminase antibodies
Rheumatologic diseases	SM, S, MF, SYM	SSA-Ro, SSB-La antibodies
Sjögren syndrome	—	ANA, ANCA (PR3, myeloperoxidase), dsDNA, Ab, RNP, rheumatoid factor
Lupus	—	—
Wegener granulomatosis Rheumatoid arthritis	—	—
Paraneoplastic		
Lung cancer	S, SYM	Anti-Hu Ab, chest radiograph/CT
Waldenström syndrome	SM, S, M, SYM, MF	Serum immunofixation electrophoresis

Myeloma	SM, M, SYM, MF	Serum and urine immunofixation electrophoresis, skeletal survey
Hereditary		
CMT-1	Demyelinating, SM, SYM, MF	DNA tests for PMP-22, MPZ, EGR2, Cx32, others
CMT-2	Axonal, SM, SYM	DNA tests for NF-L, Cx32, MPZ, others
Mitochondrial	NARP, SM, MF	Serum lactate, thymidine phosphorylase, DNA testing
Other	Axonal, S, SM, amyloid, porphyria	DNA tests for transthyretin, periaxin, urine porphyrins
Metabolic/toxic		
Diabetes	S, SM, SYM, MF, CN	Fasting glucose, HgbA1c, glucose tolerance test
Renal failure	S, SM, SYM	Chem 7
Thyroid disease	S, SM, SYM, MF	TSH, T4
Heavy metal toxicity	S, SM, SYM, MF	Urine lead, mercury, arsenic, thallium

S, sensory; SM, sensorimotor; SYM, symmetric; MF, multifocal; CN, cranial nerves; PCR, polymerase chain reaction; CMV, cytomegalovirus; GM1, GD1a, ganglioside components of myelin; M, motor; MAG, myelin-associated glycoprotein; ESR, erythrocyte sedimentation rate; ACE, angiotensin-converting enzyme; SSA, SSB, antigens for Sjögren syndrome severe antibodies; ANA, antinuclear antibody; ANCA, antineutrophil cytoplasmic antibodies; RNP, ribonucleoprotein; CT, computed tomography; PMP, peripheral myelin protein; MPZ, myelin protein zero; NARP, neuropathy, ataxia, and retinitis pigmentosa; EGR, early growth response protein; Cx32, connexin; NF-L, neurofilament light chain; HgbA1c, hemoglobin A1c; TSH, thyroid-stimulating hormone.

TABLE 87.2 American Academy of Neurology Recommendations for Testing for Distal Symmetric Polyneuropathy

Basic Laboratory Evaluation for Distal Symmetric Neuropathy

CBC, ESR, or CRP

Vitamin B₁₂^a and if B₁₂ is low normal, metabolites, including methylmalonic acid and/or homocysteine.^a

Comprehensive metabolic panel, including fasting blood glucose^a, glucose tolerance test^a if indicated to look for impaired glucose tolerance

Serum protein immunofixation electrophoresis^a

Urine analysis, urine electrophoresis

Inquire about drugs and toxins

Other Laboratory Testing that May Be Performed in Selected Patients

ANA, rheumatoid factor, anti-Ro/SSA, anti-LA/SSB, antineutrophil cytoplasmic antigen (ANCA) antibodies, cryoglobulins

Campylobacter jejuni, cytomegalovirus (CMV), hepatitis panel (B and C), HIV, Lyme antibodies, herpesviruses tests, West Nile virus tests, cerebrospinal fluid (CSF) analysis

Antigliadin; IgA transglutaminase antibodies; endomysial antibodies; vitamins E, B₁, and B₆

Serum angiotensin-converting enzyme (ACE), CSF analysis with CSF ACE

Arsenic, lead, mercury, thallium

Antiganglioside antibodies (GM1, GD1a, GD1b, GD3, GQ1b, GT1b), anti-MAG, paraneoplastic antibodies (anti-Hu, anti-CV2), CSF oligoclonal bands

Molecular tests for Charcot-Marie-Tooth, Hereditary neuropathy with tendency to pressure palsy (HNPP), familial amyloidosis

Skeletal survey; computed tomography or MRI of chest, abdomen, or pelvis; ultrasound of abdomen and pelvis; positron emission tomography (PET), CSF cytology

^aTests with highest yield.
