

Includes interactive eBook with complete content

Merritt's Neurology

Thirteenth Edition

Elan D. Louis
Stephan A. Mayer
Lewis P. Rowland

 Wolters Kluwer

Edited by

Elan D. Louis MD, MS

*Professor of Neurology and Epidemiology
Chief, Division of Movement Disorders
Departments of Neurology and Chronic Disease Epidemiology
Yale School of Medicine and Yale School of Public Health
Yale University
New Haven, Connecticut*

Stephan A. Mayer MD, FCCM

*Professor of Neurology and Neurosurgery
Icahn School of Medicine at Mount Sinai
Director, Neurocritical Care
Mount Sinai Health System
New York, New York*

Lewis P. Rowland MD

*Professor of Neurology
Chairman of Neurology, Emeritus
Director of the Neurology Service, Emeritus
The Neurological Institute of New York
Columbia University Medical Center
New York, New York*

Section Editors

Neeraj Badjatia, MD

*Medical Director, Neurocritical Care
University of Maryland Medical Center
Baltimore, Maryland*

Carl W. Bazil, MD, PhD

*Caitlin Tynan Doyle Professor of Clinical Neurology
Director, Division of Comprehensive Epilepsy Center and
Sleep Center
Columbia University
New York, New York*

John C. M. Brust, MD

*Professor of Neurology
Columbia University College of Physicians and Surgeons
New York, New York*

Denise E. Chou, MD

*Assistant Professor
Department of Neurology*

*Columbia University Medical Center
Assistant Attending Neurologist
Department of Neurology
New York-Presbyterian Hospital
New York, New York*

Andrew B. Lassman, MD

*John Harris Associate Professor and Chief
Neuro-Oncology Division, Department of Neurology
Medical Director, Clinical Protocol & Data Management Office
Herbert Irving Comprehensive Cancer Center
Columbia University Medical Center
New York, New York*

Kiwon Lee, MD, FACP, FAHA

*Vice-chairman of Neurosurgery and Neurology for Critical Care
Associate Professor of Neurosurgery and Neurology
Chief, Division of Critical Care
Departments of Neurology and Neurosurgery
The University of Texas Health Science Center at Houston
Mischer Neuroscience Institute
Memorial Hermann-Texas Medical Center
Houston, Texas*

Laura Lennihan, MD

*Professor of Neurology
Vice-chair, Department of Neurology
Chief, Division of Critical Care and Hospitalist Neurology
Columbia University Medical Center
New York, New York*

Elan D. Louis, MD, MS

*Professor of Neurology and Epidemiology
Chief, Division of Movement Disorders
Departments of Neurology and Chronic Disease Epidemiology
Yale School of Medicine and Yale School of Public Health
Yale University
New Haven, Connecticut*

Karen S. Marder, MD, MPH

*Sally Kerlin Professor of Neurology
Gertrude H. Sergievsky Center
Department of Neurology
Columbia University Medical Center
New York, New York*

Stephan A. Mayer, MD, FCCM

*Professor of Neurology and Neurosurgery
Icahn School of Medicine at Mount Sinai
Director, Neurocritical Care
Mount Sinai Health System
New York, New York*

Paul C. McCormick, MD, MPH

*Herbert and Linda Gallen Professor of Neurological Surgery
Columbia University College of Physicians and Surgeons
New York, New York*

James M. Noble, MD, MS, CPH

*Assistant Professor of Neurology
Taub Institute for Research on Alzheimer's Disease and the Aging
Brain
Department of Neurology
Columbia University Medical Center
New York, New York*

Claire S. Riley, MD

*Assistant Professor of Neurology
Department of Neurology
Columbia University College of Physicians and Surgeons
Assistant Attending Neurologist
New York-Presbyterian Hospital
Columbia University Medical Center
New York, New York*

Fred Rincon, MD, MSc, MBE, FACP, FCCP, FCCM

*Assistant Professor of Neurology and Neurosurgery
Thomas Jefferson University
Philadelphia, Pennsylvania*

James J. Riviello Jr, MD

*Sergievsky Family Professor of Neurology and Pediatrics
Department of Neurology
Columbia University
New York, New York*

J. Kirk Roberts, MD

*Associate Professor of Neurology
College of Physicians and Surgeons
Columbia University Medical Center
New York-Presbyterian Hospital
New York, New York*

Karen L. Roos, MD

*John and Nancy Nelson Professor of Neurology
Department of Neurology
Indiana University School of Medicine
Indianapolis, Indiana*

Lewis P. Rowland, MD

*Professor of Neurology
Chairman of Neurology, Emeritus
Director of the Neurology Service, Emeritus
The Neurological Institute of New York
Columbia University Medical Center
New York, New York*

David H. Strauss, MD

*Associate Professor and Vice-chair
Research Administrator, Ethics and Policy
Director, Psychiatric Research
Department of Psychiatry
Columbia University
New York State Psychiatric Institute
New York, New York*

Louis H. Weimer, MD, FAAN, FANA

*Professor of Neurology
Director, EMG Laboratory
Department of Neurology
Columbia University Medical Center
New York, New York*

Contributors

Gary M. Abrams, MD

*Professor of Neurology
University of California, San Francisco
San Francisco, California*

Sachin Agarwal, MD, MPH

*Assistant Professor of Neurology
Neurocritical Care
Columbia University College of Physicians and Surgeons
New York-Presbyterian Hospital/Columbia Medical Center
New York, New York*

Teresa A. Allison, PharmD, BCPS

Clinical Pharmacist Specialist

*Program Director, PGY2 Critical Care Residency
Department of Pharmacy
Memorial Hermann-Texas Medical Center
Houston, Texas*

Tareq Saad H. Almaghrabi, MD

*Fellow, Division of Neurocritical Care
Department of Neurosurgery
The University of Texas Health Science Center at Houston
Houston, Texas*

Fawaz Al-Mufti, MD

*Neurocritical Care Fellow and Assistant Attending Neurologist
Division of Neurocritical Care
The Neurological Institute of New York
Columbia University Medical Center
New York, New York*

Peter D. Angevine, MD, MPH

*Assistant Professor
Department of Neurological Surgery
Columbia University College of Physicians and Surgeons
New York, New York*

John Ausiello, MD

*Assistant Professor of Medicine
Columbia University
New York-Presbyterian Hospital
New York, New York*

Neeraj Badjatia, MD

*Medical Director, Neurocritical Care
University of Maryland Medical Center
Baltimore, Maryland*

Kelly J. Baldwin, MD

*Department of Neurology
Geisinger Medical Center
Danville, Pennsylvania
Clinical Assistant Professor
Temple University School of Medicine
Philadelphia, Pennsylvania*

Jacob S. Ballon, MD, MPH

*Clinical Assistant Professor
Director, INSPIRE Clinic*

*Department of Psychiatry
Stanford University
Stanford, California*

Tracy T. Batchelor, MD, MPH

*Giovanni Armenise Harvard Professor of Neurology
Harvard Medical School
Executive Director, Stephen E. and Catherine Pappas Center for
Neuro-Oncology
Massachusetts General Hospital
Coleader, Brain Cancer Program
Dana-Farber/Harvard Cancer Center
Boston, Massachusetts*

Carl W. Bazil, MD, PhD

*Caitlin Tynan Doyle Professor of Clinical Neurology
Director, Division of Comprehensive Epilepsy Center and Sleep
Center
Columbia University
New York, New York*

Michelle Wilson Bell, MD

*Fellow in Clinical Neurophysiology (Epilepsy)
Department of Neurology
Columbia University
New York, New York*

Gary L. Bernardini, MD, PhD, FANA

*Professor of Neurology
Chair, Department of Neurology
New York Hospital Queens
Vice-Chair, Department of Neurology
Weill-Cornell Medical Center
New York, New York*

Thomas H. Brannagan III, MD

*Professor of Neurology
Director, Peripheral Neuropathy Center
Columbia University College of Physicians and Surgeons
New York, New York*

Susan B. Bressman, MD

*Chair and Professor
The Mirken Family Clinical Neuroscience Institute
Department of Neurology
Icahn School of Medicine at Mount Sinai*

New York, New York

Carolyn Barley Britton, MD, MS

Associate Professor of Clinical Neurology

Department of Neurology

Columbia University College of Physicians and Surgeons

New York, New York

Jeffrey N. Bruce, MD

Edgar M. Housepian Professor and Vice-chairman

Department of Neurological Surgery

Columbia University College of Physicians and Surgeons

New York, New York

Charles A. Bruno Jr, DO

Clinical Fellow, Interventional Neuroradiology

Department of Radiology

New York-Presbyterian Hospital

Columbia University Medical Center

New York, New York

John C. M. Brust, MD

Professor of Neurology

Columbia University College of Physicians and Surgeons

New York, New York

Robert E. Burke, MD

Departments of Neurology and Pathology and Cell Biology

Columbia University Medical Center

New York, New York

David Cachia, MD

Neurooncology Fellow

Department of Neuro-Oncology

The University of Texas MD Anderson Cancer Center

Houston, Texas

Joshua Cappell, MD, PhD

Assistant Professor of Pediatrics and Neurology

Columbia University Medical Center

Morgan Stanley Children's Hospital of New York-Presbyterian

New York, New York

Alejandro S. Cazzulino, BA

Research Assistant

Integrative Neuroscience

*Columbia University
New York, New York*

Tiffany R. Chang, MD

*Assistant Professor
Departments of Neurosurgery and Neurology
The University of Texas Medical School at Houston
Houston, Texas*

Claudia A. Chiriboga, MD, MPH

*Associate Professor of Neurology
Division of Pediatric Neurology
Department of Neurology
Columbia University Medical Center
New York, New York*

Enid Choi, MD, PhD

*Radiation Oncology
University of Maryland
Baltimore, Maryland*

Huimahn Alex Choi, MD, MS

*Assistant Professor of Neurology and Neurosurgery
The University of Texas Health Science Center at Houston
Houston, Texas*

Denise E. Chou, MD

*Assistant Professor
Department of Neurology
Columbia University Medical Center
Assistant Attending Neurologist
Department of Neurology
New York-Presbyterian Hospital
New York, New York*

Daniel S. Chow, MD

*Department of Radiology
Columbia University Medical Center
New York, New York*

Comana M. Cioroiu, MD

*Assistant Professor of Neurology
Columbia University College of Physicians and Surgeons
New York-Presbyterian Hospital
Columbia University Medical Center
New York, New York*

Jan Claassen, MD, PhD, FNCS

*Associate Professor of Neurology
Head of Neurocritical Care and Medical Director of the
Neurological Intensive Care Unit
Columbia University College of Physicians and Surgeons
New York, New York*

Gary D. Clark, MD

*The Blue Bird Circle Endowed Chair for the Chief of
Child Neurology
Section Chief, Section of Neurology and Developmental Neuroscience
Professor of Pediatrics, Neurology, and Neuroscience
Baylor College of Medicine
Chief, Neurology Service
Texas Children's Hospital
Houston, Texas*

Stephanie Cosentino, PhD

*Assistant Professor of Neuropsychology
Department of Neurology
Columbia University Medical Center
New York, New York*

John F. Crary, MD, PhD

*Department of Pathology, Fishberg Department of Neuroscience,
Friedman Brain Institute
Ronald M. Loeb Center for Alzheimer's Disease
Icahn School of Medicine at Mount Sinai
New York, New York*

Barry M. Czeisler, MD, MS

*Assistant Professor of Neurology
Division of Neurocritical Care
NYU Langone Medical Center
New York, New York*

Randy S. D'Amico, MD

*Department of Neurological Surgery
Columbia University Medical Center
New York, New York*

Jahannaz Dastgir, DO

*Assistant Professor of Neurology
Columbia University Medical Center
New York, New York*

Darryl C. De Vivo, MD

*Sidney Carter Professor of Neurology
Professor of Pediatrics
Associate Chairman (Neurology) for Pediatric Neurosciences
Director, Pediatric Neurology, Emeritus
Director, Colleen Giblin Research Laboratories
Director, Pediatric Neuromuscular Disease Center
Codirector, Center for Motor Neuron Biology and Disease
Columbia University College of Physicians and Surgeons
New York, New York*

Anna Lopatin Dickerman, MD

*Assistant Professor of Psychiatry
Weill Cornell Medical College
Assistant Attending Psychiatrist
Consultation-Liaison Service
New York-Presbyterian Hospital/Weill Cornell Medical Center
New York, New York*

Salvatore DiMauro, MD

*Lucy G. Moses Professor of Neurology
Department of Neurology
Columbia University Medical Center
New York, New York*

Nancy J. Edwards, MD

*Assistant Professor of Neurology and Neurosurgery
The University of Texas Health Science Center at Houston
Mischer Neuroscience Institute
Memorial Hermann-Texas Medical Center
Houston, Texas*

Mitchell S. V. Elkind, MD, MS, FAAN, FAHA

*Professor of Neurology and Epidemiology
Department of Neurology
College of Physicians and Surgeons
Department of Epidemiology
Mailman School of Public Health
Columbia University
New York, New York*

Charles C. Esenwa, MD

*Chief Resident and Clinical Instructor
Department of Neurology
Columbia University Medical Center*

New York, New York

Stanley Fahn, MD

*Movement Disorders Founding and Emeritus Director
H. Houston Merritt Professor of Neurology
Division of Movement Disorders
Department of Neurology
Columbia University Medical Center
New York, New York*

Charles L. Francoeur, MD, FRCPC

*Postdoctoral Clinical Fellow
Institute for Critical Care Medicine
Icahn School of Medicine at Mount Sinai
New York, New York*

Pamela U. Freda, MD

*Professor of Medicine
Department of Medicine
Columbia University College of Physicians and Surgeons
New York, New York*

Jennifer A. Frontera, MD, FNCS

*Associate Professor of Neurology
Cerebrovascular Center, Neurologic Institute
Cleveland Clinic
Cleveland, Ohio*

Steven J. Frucht, MD

*Professor of Neurology
Mount Sinai Medical Center
New York, New York*

Licinia Ganança, MD

*Division of Molecular Imaging and Neuropathology
New York State Psychiatric Institute
Columbia University
New York, New York*

James H. Garvin Jr, MD, PhD

*Professor of Pediatrics
Columbia University Medical Center
Attending Pediatrician
Morgan Stanley Children's Hospital of New York-Presbyterian
New York, New York*

Nicolas Gaspard, MD, PhD

Associate Professor

Department of Neurology

Université Libre de Bruxelles-Hôpital Erasme

Brussels, Belgium

Assistant Professor (Adjunct)

Department of Neurology

Yale University

New Haven, Connecticut

Michelle L. Ghobrial, MD

Assistant Professor

Department of Neurology

Division of Cerebrovascular and Neurocritical Care

Thomas Jefferson University Hospital

Philadelphia, Pennsylvania

Mark R. Gilbert, MD

Professor

Department of Neuro-Oncology

Division of Cancer Medicine

The University of Texas MD Anderson Cancer Center

Houston, Texas

Emily J. Gilmore, MD

Assistant Professor of Neurology

Staff Neurointensivist, Neuroscience Intensive Care Unit

Yale University School of Medicine

New Haven, Connecticut

Peter J. Goadsby, MD, PhD, DSc, FRACP, FRCP

Professor of Neurology

King's College London

Professor of Neurology

University of California

San Francisco, California

Jill S. Goldman, MS, MPhil, CGC

Taub Institute for Research on Alzheimer's Disease and the

Aging Brain

Columbia University Medical Center

New York, New York

Clifton L. Gooch, MD

Professor and Chair

Department of Neurology

*University of South Florida
Tampa, Florida*

Paul Greene, MD

*Department of Neurology
Icahn School of Medicine at Mount Sinai
New York, New York*

Noam Y. Harel, MD, PhD

*Assistant Professor
Departments of Neurology and Rehabilitation Medicine
Icahn School of Medicine at Mount Sinai
James J. Peters Veterans Affairs Medical Center
New York, New York*

Michio Hirano, MD

*Professor of Neurology
Department of Neurology
Columbia University Medical Center
New York, New York*

Lawrence S. Honig, MD, PhD, FAAN

*Professor of Neurology
Columbia University Medical Center
New York, New York*

Edward D. Huey, MD

*Herbert Irving Assistant Professor of Psychiatry and Neurology
Taub Institute for Research on Alzheimer's Disease and
the Aging Brain
Gertrude H. Sergievsky Center
Columbia University
New York, New York*

Christopher G. Hughes, MD

*Assistant Professor
Department of Anesthesiology and Critical Care Medicine
Vanderbilt University School of Medicine
Nashville, Tennessee*

Emitseilu K. Iluonakhamhe, MD

*Vivian L. Smith Department of Neurosurgery
The University of Texas Health Science Center at Houston
Houston, Texas*

Fabio M. Iwamoto, MD

*Deputy Director, Division of Neuro-Oncology
Department of Neurology
Columbia University
New York, New York*

Sarah C. Janicki, MD, MPH

*Assistant Professor in Neurology
Gertrude H. Sergievsky Center
Department of Neurology
Columbia University Medical Center
New York, New York*

Joseph Jankovic, MD

*Professor of Neurology
Distinguished Chair in Movement Disorders
Director, Parkinson's Disease Center and Movement
Disorders Clinic
Department of Neurology
Baylor College of Medicine
Houston, Texas*

Jasmin Jo, MD

*Neurooncology Fellow
Department of Neurology
Dana Farber Cancer Institute
Massachusetts General Hospital
Boston, Massachusetts*

Burk Jubelt, MD, FAAN

*Professor
Departments of Neurology, Microbiology/Immunology, and
Neuroscience
State University of New York Upstate Medical University
Syracuse, New York*

Michael G. Kaiser, MD

*Associate Professor of Clinical Neurological Surgery
Associate Director, Spine Center
Department of Neurosurgery
Columbia University Medical Center
New York, New York*

Thomas J. Kaley, MD

*Assistant Attending Neurologist
Department of Neurology
Memorial Sloan Kettering Cancer Center*

*Assistant Professor of Neurology
Department of Neurology
Weill Cornell Medical College
New York, New York*

Un Jung Kang, MD

*H. Houston Merritt Professor of Neurology
Chief, Division of Movement Disorders
Department of Neurology
Columbia University Medical Center
New York, New York*

Petra Kaufmann, MD, MSc

*Director, Division of Clinical Innovation
National Center for Advancing Translational Sciences
National Institutes of Health
Bethesda, Maryland
Adjunct Associate Professor of Neurology
Columbia University
New York, New York*

Steven G. Kernie, MD

*Associate Professor of Pediatrics, Pathology, and Cell Biology
Columbia University College of Physicians and Surgeons
New York, New York*

Alexander G. Khandji, MD, FACR

*Professor of Radiology
Departments of Neurological Surgery and Neurology
Columbia Presbyterian Medical Center
New York, New York*

Adam B. King, MD

*Assistant Professor
Department of Anesthesiology and Critical Care Medicine
Vanderbilt University Medical Center
Nashville, Tennessee*

Barbara S. Koppel, MD

*Professor of Clinical Neurology
New York Medical College
Valhalla, New York
Chief, Neurology Service
Metropolitan Hospital
New York, New York*

Andreas H. Kramer, MD, MSc, FRCPC

Clinical Associate Professor

Departments of Critical Care Medicine and Clinical Neurosciences

Hotchkiss Brain Institute

University of Calgary

Calgary, Alberta, Canada

William Charles Kreisl, MD

Assistant Professor of Neurology

Taub Institute for Research on Alzheimer's Disease and the Aging Brain

Division of Aging and Dementia, Department of Neurology

Columbia University Medical Center

Assistant Attending Neurologist

New York-Presbyterian Hospital

New York, New York

Shouri Lahiri, MD

Fellow, Neurocritical Care

New York-Presbyterian Hospital

Columbia University Medical Center

Weill Cornell Medical Center

New York, New York

Andrew B. Lassman, MD

John Harris Associate Professor and Chief

Neuro-Oncology Division, Department of Neurology

Medical Director, Clinical Protocol & Data Management Office

Herbert Irving Comprehensive Cancer Center

Columbia University Medical Center

New York, New York

Kiwon Lee, MD, FACP, FAHA

Vice-chairman of Neurosurgery and Neurology for Critical Care

Associate Professor of Neurosurgery and Neurology

Chief, Division of Critical Care

Departments of Neurology and Neurosurgery

The University of Texas Health Science Center at Houston

Mischer Neuroscience Institute

Memorial Hermann-Texas Medical Center

Houston, Texas

Laura Lennihan, MD

Professor of Neurology

Vice-chair, Department of Neurology

Chief, Division of Critical Care and Hospitalist Neurology

Columbia University Medical Center

New York, New York

Angela Lignelli, MD

*Department of Radiology
Columbia University Medical Center
New York, New York*

Elan D. Louis, MD, MS

*Professor of Neurology and Epidemiology
Chief, Division of Movement Disorders
Departments of Neurology and Chronic Disease Epidemiology
Yale School of Medicine and Yale School of Public Health
Yale University
New Haven, Connecticut*

Jennifer L. Lyons, MD

*Director, Division of Neurological Infections
Brigham and Women's Hospital
Instructor of Neurology
Department of Neurology
Harvard Medical School
Boston, Massachusetts*

Julia Mallory, BA, MS4

*Ophthalmology Research Fellow
Columbia University College of Physicians and Surgeons
New York, New York*

Hani R. Malone, MD

*Department of Neurological Surgery
Columbia University Medical Center
New York, New York*

Elliott L. Mancall, MD

*Emeritus Professor of Neurology
Jefferson Medical College
Thomas Jefferson University
Philadelphia, Pennsylvania*

Arthur M. Mandel, MD, PhD

*Assistant Professor of Clinical Neurology and Pediatrics
Department of Neurology
Columbia University
New York, New York*

Christopher E. Mandigo, MD

*Assistant Professor of Clinical Neurosurgery
Department of Neurosurgery
Columbia University Medical Center
New York, New York*

Karen S. Marder, MD, MPH

*Sally Kerlin Professor of Neurology
Gertrude H. Sergievsky Center
Department of Neurology
Columbia University Medical Center
New York, New York*

Randolph S. Marshall, MD, MS

*Elizabeth K. Harris Professor of Neurology
Columbia University College of Physicians and Surgeons
Director, Stroke Center
Attending Neurologist
New York-Presbyterian Hospital
Columbia University Medical Center
New York, New York*

Stephan A. Mayer, MD, FCCM

*Professor of Neurology and Neurosurgery
Icahn School of Medicine at Mount Sinai
Director, Neurocritical Care
Mount Sinai Health System
New York, New York*

Richard Mayeux, MD

*Sergievsky Professor and Chair
Department of Neurology
Director, Gertrude H. Sergievsky Center
Columbia University
New York, New York*

Paul C. McCormick, MD, MPH

*Herbert and Linda Gallen Professor of Neurological Surgery
Columbia University College of Physicians and Surgeons
New York, New York*

Minesh P. Mehta, MD, FASTRO

*Professor, Radiation Oncology
Medical Director, Maryland Proton Treatment Center
University of Maryland
Baltimore, Maryland*

Charles B. Mikell, MD

Resident

*Department of Neurological Surgery
Columbia University Medical Center
New York, New York*

Vesselin Zdravkov Miloushev, MD, PhD

Postdoctoral Clinical Fellow

*Department of Diagnostic Radiology
Columbia University
New York-Presbyterian Hospital
New York, New York*

Hiroshi Mitsumoto, MD, DSc

Professor of Neurology

*Department of Neurology
Columbia University
New York, New York*

J. P. Mohr, MD, MS

*Daniel Sciarra Professor of Neurology
Doris and Stanley Tananbaum Stroke Center
Department of Neurology
The Neurological Institute of New York
Columbia University Medical Center
New York, New York*

Shibani S. Mukerji, MD, PhD

*Department of Neurology
Massachusetts General Hospital
Brigham and Women's Hospital
Boston, Massachusetts*

Philip R. Muskin, MD

*Professor of Psychiatry
Columbia University Medical Center
Chief, Consultation-Liaison Psychiatry
New York-Presbyterian Hospital/Columbia Campus
Faculty
Columbia University Center for Psychoanalytic Training
and Research
Research Psychiatrist II
New York State Psychiatric Institute
New York, New York*

Barnett R. Nathan, MD

*Associate Professor
Department of Neurology
University of Virginia School of Medicine
Charlottesville, Virginia*

James M. Noble, MD, MS, CPH
*Assistant Professor of Neurology
Taub Institute for Research on Alzheimer's Disease and the
Aging Brain
Department of Neurology
Columbia University Medical Center
New York, New York*

Douglas R. Nordli Jr, MD
*Epilepsy Center
Ann & Robert H. Lurie Children's Hospital of Chicago
Northwestern University
Chicago, Illinois*

Jeffrey G. Odel, MD
*Professor of Ophthalmology
Columbia University Medical Center
Edward S. Harkness Eye Institute
New York, New York*

William G. Ondo, MD
*Professor of Neurology
The University of Texas Health Science Center at Houston
Houston, Texas*

Maria A. Oquendo, MD
*Professor and Vice-chair for Education
Department of Psychiatry
Columbia University and New York State Psychiatric Institute
New York, New York*

Natalie Organek, MD
*Neurology Resident
Department of Neurology
Cleveland Clinic
Cleveland, Ohio*

Edward (Mel) J. Otten, MD, FACMT, FAWM
*Professor of Emergency Medicine and Pediatrics
Director, Division of Toxicology
Department of Emergency Medicine*

*University of Cincinnati College of Medicine
Cincinnati, Ohio*

Alison M. Pack, MD, MPH

*Associate Professor of Neurology
Department of Neurology
Columbia University Medical Center
New York, New York*

Gunjan Y. Parikh, MD

*Assistant Professor
Division of Neurocritical Care
Department of Neurology
Program in Trauma
R Adams Cowley Shock Trauma Center
University of Maryland School of Medicine
Baltimore, Maryland*

Marc C. Patterson, MD, FRACP

*Chair, Division of Child and Adolescent Neurology
Professor of Neurology, Pediatrics, and Medical Genetics
Departments of Neurology, Pediatrics, and Medical Genetics
Mayo Clinic
Rochester, Minnesota*

Toni S. Pearson, MBBS

*Assistant Professor of Neurology
Icahn School of Medicine at Mount Sinai
New York, New York*

Timothy A. Pedley, MD

*Henry and Lucy Moses Professor of Neurology
Chairman, Department of Neurology
Columbia University College of Physicians and Surgeons
Neurologist-in-Chief
The Neurological Institute of New York
The New York-Presbyterian Hospital Columbia University
Medical Center
New York, New York*

Jonathan Perk, MD, PhD

*Assistant Professor of Neurology
Neurology Residency Program Director
SUNY Downstate Medical Center
Brooklyn, New York*

John Pile-Spellman, MD

Neuroradiologist

Department of Neurosurgery and Radiology

Winthrop University Hospital

Mineola, New York

Chiara Pisciotta, MD, PhD

Columbia University College of Physicians and Surgeons

New York, New York

Gustavo C. Román, MD, DrHC

*Jack S. Blanton Distinguished Endowed Chair
Houston Methodist Neurological Institute
Professor of Neurology
Weill Cornell Medical College
Houston, Texas*

Roger N. Rosenberg, MD

*Zale Distinguished Chair and Professor of Neurology
Director, Alzheimer's Disease Center
University of Texas Southwestern Medical Center at Dallas
Dallas, Texas*

Sara K. Rostanski, MD

*Department of Neurology
The Neurological Institute of New York
Columbia University Medical Center
New York, New York*

Lewis P. Rowland, MD

*Professor of Neurology
Chairman of Neurology, Emeritus
Director of the Neurology Service, Emeritus
The Neurological Institute of New York
Columbia University Medical Center
New York, New York*

Tatjana Rundek, MD, PhD

*Professor of Neurology and Public Health Sciences
Department of Neurology
University of Miami Miller School of Medicine
Miami, Florida*

Jennifer F. Russo, BA

*Department of Neurological Surgery
Columbia University Medical Center
New York, New York*

Ned Sacktor, MD

*Professor of Neurology
Johns Hopkins University School of Medicine
Johns Hopkins Bayview Medical Center
Baltimore, Maryland*

Daniel H. Sahlein, MD

*Departments of Radiology, Neurosurgery, and Neurology
Columbia University Medical Center
New York, New York*

Jacinda B. Sampson, MD, PhD
*Assistant Professor of Neurology
Gertrude H. Sergievsky Center
Columbia University Medical Center
New York, New York*

Sophie Samuel, PharmD, BCPS
*Department of Pharmacy
Memorial Hermann-Texas Medical Center
Houston, Texas*

Rachel Saunders-Pullman, MD, MPH
*Associate Professor of Neurology
Icahn School of Medicine at Mount Sinai
Mount Sinai Beth Israel
New York, New York*

Nikolaos Scarmeas, MD, MS, PhD
*Associate Professor of Neurology
Columbia University
New York, New York
National and Kapodistrian University of Athens
Athens, Greece*

Lauren R. Schaff, MD
*Resident Physician
Department of Neurology
New York-Presbyterian Hospital
Columbia University Medical Center
New York, New York*

Heidi Schambra, MD
*Assistant Professor of Neurology
Department of Rehabilitation and Regenerative Medicine
Columbia University
New York, New York*

David Schiff, MD
*Harrison Distinguished Teaching Professor of Neurology, Neurological
Surgery, and Medicine
Division of Neuro-Oncology, Department of Neurology
University of Virginia*

Charlottesville, Virginia

Hyman M. Schipper, MD, PhD, FRCP©

Professor

Department of Neurology and Neurosurgery

Department of Medicine (Geriatrics)

McGill University Faculty of Medicine

Montreal, Quebec, Canada

Franklin R. Schneier, MD

Special Lecturer

Department of Psychiatry

Columbia University Medical Center

Research Psychiatrist

Anxiety Disorders Clinic

New York State Psychiatric Institute

New York, New York

David B. Seder, MD, FCCP, FCCM

Director of Neurocritical Care

Maine Medical Center

Portland, Maine

Assistant Professor of Medicine

Tufts University School of Medicine

Boston, Massachusetts

Jennifer Sevush-Garcy, MD

Neurology Resident

College of Physicians and Surgeons

Columbia University

New York, New York

Tina Shih, MD

Associate Clinical Professor of Neurology

Department of Neurology

University of California at San Francisco

San Francisco, California

Michael E. Shy, MD

Professor of Neurology, Pediatrics, and Physiology/Biophysics

University of Iowa Carver College of Medicine

Iowa City, Iowa

Reet K. Sidhu, MD

Assistant Professor of Neurology

Department of Neurology, Division of Child Neurology

*Columbia University Medical Center
New York, New York*

Michael B. Sisti, MD, FACS

*James G. McMurtry III, MD, Associate Professor in Clinical
Neurological Surgery, Radiation Oncology, and Otolaryngology
Codirector, Center for Radiosurgery
Department of Neurosurgery
Columbia University Medical Center
The Neurological Institute of New York
New York-Presbyterian Hospital
New York, New York*

Scott A. Small, MD, PhD

*Boris and Rose Katz Professor of Neurology
Director, Alzheimer's Disease Research Center
Departments of Neurology, Radiology, and Psychiatry
Columbia University
New York, New York*

Robert A. Solomon, MD

*Byron Stookey Professor and Chairman
Department of Neurological Surgery
Columbia University College of Physicians and Surgeons
New York-Presbyterian Hospital
New York, New York*

Shraddha Srinivasan, MD

*Assistant Professor of Neurology
Columbia Comprehensive Epilepsy Center
The Neurological Institute of New York
New York, New York*

Yaakov Stern, PhD

*Professor of Neuropsychology
Departments of Neurology and Psychiatry
Taub Institute for Research on Alzheimer's Disease and the
Aging Brain

Preface

When H. Houston Merritt first published this *Textbook of Neurology* in 1955, he was the sole author. The book became popular, and he revised it himself through the fourth edition. The body of neurologic knowledge increased and, in the fifth edition, he finally accepted contributions from colleagues. Even then, he wrote most of the book himself, and he continued to do so for the sixth edition despite serious physical disability. He died in 1979, just as the sixth edition was released for distribution.

The seventh edition, published and edited in 1984 by Lewis P. Rowland, was prepared by 70 of Merritt's former students. Thirty of them headed neurology departments and others had become distinguished clinicians, teachers, and investigators. That edition documented the human legacy of a singular leader whose career had set models for clinical investigation (when it was just beginning), clinical practice, teaching, editing books and journals, administering departments and medical schools, and commitment to national professional and voluntary health organizations.

With the passage of 60 years, Merritt's has become one of the time-honored textbooks in the field of clinical neurology. We now provide the 13th edition, with Elan D. Louis, Stephan A. Mayer, and Lewis P. Rowland as coeditors.

As with any dynamic book, the list of authors has changed progressively. The editors have substantially broadened the authorship. With more than 180 authors, the editors have tapped into the best expertise across the country. Yet the ties to Merritt persist. Many of his personal students are still authors, as are their students as Merritt's intellectual grandchildren. Along the same lines, we have tried to maintain Merritt's literary style: direct, clear, and succinct writing; emphasis on facts rather than unsupported opinion; and ample use of illustrations and tables.

While maintaining ties with its tradition, this edition of Merritt's has undergone considerable reorganization. In short, our goal was to extensively revamp the book, with substantial consolidation and reduction in the number of chapters. While retaining its best elements and traditions, we aimed to create the essential modern neurology textbook with a global worldview. The main change in content is that the 13th edition emphasizes evidence-based medicine practice guidelines, diagnostic and treatment algorithms, management checklists, and practical pearls. Authors were encouraged to include more tables and figures as well as videos, when applicable. The book is designed for access from tablet, phone, and computer screens. The chief idea for our readers is to provide useful information at the bedside when they need it. The Internet is full of information, but it is difficult to sort through. Merritt's provides trusted and cohesive information from an expert.

The book has changed in other ways. The number of tables has expanded from 298 to 545 and the number of figures from 343 to 400. The figures themselves have been substantially updated and replaced. The book includes moving images for the first time, with more than 40 instructive videos, showing a broad range of involuntary movement disorders. Finally, the black and white text and photos of the 12th edition have now bloomed into full color text and illustrations.

We have also reordered the sections of the book, as the face of clinical neurology has changed. A new opening chapter reviews the global burden of neurologic disease, and the sections that follow cover neurologic diseases in order of their impact on international public health, starting with cerebrovascular disease, trauma, and dementia.

This edition of Merritt's also includes a new section in the front of the book, *Common Problems in Neurology*. These syndromebased chapters are designed to provide immediate expert access to clinicians on the front lines who confront common neurologic problems such as headache, dizziness, seizures, and stroke. These chapters provide a practical structured approach to managing undifferentiated neurologic syndromes in the office,

emergency department, or hospital. They focus on history, examination, localization, diagnosis, and initial management. This is where the classic neuroanatomy and description of clinical signs may be found. These chapters share a common structure that naturally flows with the course of evaluation and management.

For the first time, Merritt's specifically cites all level 1 standards for prevention, diagnosis, or treatment. The specific citation to back up a level 1 recommendation provides the single most authoritative trial, guideline, or meta-analysis.

A book of this clinical breadth and detail cannot be written by one or even a handful of authors. Moreover, the evolving complexity of subspecialty areas within neurology demands additional oversight of chapter content. With this edition of Merritt's, we have enlisted the careful assistance of 20 section editors. The content of each chapter has been reviewed both by a section editor and one of the three coeditors.

This edition includes comprehensive revisions demanded by the progress of research in every chapter listed in the table of contents. In addition, many new chapters have been added to reflect the evolution of clinical neurology, including neurocritical care monitoring, interventional neuroradiology, brain death, concussion, hypoxic-ischemic encephalopathy, autoimmune meningitis and encephalitis, vascular dementia, restless legs syndrome, and autonomic storming.

In the years since the last edition was published, the electronic world has expanded rapidly. To meet demands for easily accessible content, the 13th edition includes an interactive e-book, which offers tablet, smartphone, and online access to the complete content with enhanced navigation, search tools, and videos.

We thank all the authors for their devoted and skillful work. We also thank the many section editors for their thoughtful guidance and painstaking efforts.

This project would never have moved forward without the help of many people at Wolters Kluwer. Indeed, a full roster of people has been involved in the project, from its conception to completion. There are Julie Goolsby and Jamie Elfrank (acquisitions editors), Kristina Oberle and Andrea Vosburgh (product development editors), Brian Convery (editorial assistant), Joan Wendt (design coordinator), Marian Bellus (production project manager), and Stephanie Kindlick (marketing manager). Special

P.vi

thanks should go to Andrea Vosburgh, whose tireless efforts guided this book to completion.

We formally rededicate the book to H. Houston Merritt. Dr. Louis also dedicates this book to his late father, Dr. Sydney Louis, an academic neurologist who inspired his career in neurology—a role model as a humanist, an educator, a perceptive clinician with a keen eye for nuance and detail, and a patient-centered physician. Countless friends and colleagues with whom we have worked at The Neurological Institute of New York at Columbia University over the years deserve credit for inspiring us, most notably John Brust, E. Sander Connolly, Stanley Fahn, Matthew E. Fink, Laura Lennihan, Linda Lewis, Karen Marder, Richard Mayeux, J. P. Mohr, Timothy Pedley, and Robert A. Solomon. Finally, we would like to personally dedicate this book to the spouses and children of all the contributors and especially to our own families. The Louis family includes Elan Louis and Dr. Vinita Sehgal and children, Devin, Ravi, and Kiran. The Mayer family includes Dr. Elissa Fory and children, Philip, Catherine, and Chloe. The Rowland family comprises Esther E. Rowland; children, Andrew, Steven, and Joy; their spouses, Darryl and Kathleen; and grandchildren, Mikaela, Liam, Cameron Henry, Mariel, and Zuri.

Videos

The following videos can be found in the companion e-book edition.

Chapter 12

Video 12.1. Chorea in two twins with Huntington disease.

Video 12.2. Torticollis.

Video 12.3. Myoclonus involving the left arm.

Video 12.4. Facial tics.

Video 12.5. Kinetic tremor during spiral drawing in a patient with essential tremor.

Video 12.6. Akathitic movements in a patient exposed to antipsychotic drug therapy.

Video 12.7. Hemifacial spasm (left face).

Chapter 58

Video 58.1. Generalized tonic-clonic seizure. Abrupt vocalization with tonic posturing of both arms and legs followed by symmetric clonic jerking of all four extremities and face, followed by stertorous breathing in the postictal phase.

Video 58.2. Atonic seizure. Sudden loss of tone during activity causing head and arm drop.

Video 58.3. Automatisms in a right temporal lobe seizure. Ictal speech followed by right hand automatisms (sign of the cross with right hand, stereotyped stroking movements with right hand).

Video 58.4. Frontal lobe seizure with bizarre semiology. Bicycling movements of both legs occurring out of sleep, bizarre vocalizations, and facial grimacing followed by a very brief postictal state with rapid return to baseline mental status.

Video 58.5. Epilepsia partialis continua (EPC). Rhythmic twitching of the left face and mouth.

Video 58.6. Psychogenic nonepileptic seizure. Waxing and waning arrhythmic and asynchronous arm and leg movements with side-to-side head movements and pelvic thrusting.

Chapter 73

Video 73.1. Kinetic tremor with an intentional component is present during the finger-nose-finger maneuver (right arm).

Chapter 74

Video 74.1. Tics in a patient with Tourette syndrome. A patient with Tourette syndrome with simple motor tics of the face, trunk, and limbs; vocal tics (grunting); and complex motor tics.

Chapter 76

Video 76.1. Oppenheim (DYT1) dystonia. The boy developed twisting of his left ankle so severely that he walked on the top of his left foot. Within 2 years, he developed mild scoliosis of the trunk and dystonia of the right arm manifested during the action of writing. The left arm was not affected. At this stage, he has generalized dystonia.

Video 76.2. Cervical dystonia. This 48-year-old man developed twisting of his neck around age 30 years, which has persisted. The head tends to turn to the right, but the patient demonstrates certain “sensory tricks” that help alleviate the abnormal posture.

Video 76.3. Jaw-opening dystonia. This 69-year-old man developed blepharospasm 2.5 years ago. Two months later, he developed intermittent unpredictable jaw-opening spasms. Voluntary movements of his limbs or walking can bring on the jaw opening, but talking can overcome it. There was no history or exposure to a dopamine receptor antagonist medication, infection, or trauma.

Video 76.4. Writer's cramp. This 34-year-old right-handed woman developed twisting and tightness of the fingers on the right hand when she wrote. Placing the pen in certain positions in the hand alter the severity of the dystonia. When it becomes more severe, writer's cramp would also involve forearm and arm muscles.

Chapter 77

Video 77.1. Patient with hemifacial spasm. She has spasms of the orbicularis oculi, zygomaticus major, depressor anguli oris, and other muscles innervated by the facial nerve. Contractions in all muscles seem to be simultaneous. She has individual twitches, trains of twitches, and trains of twitches rapid enough to cause sustained partial eyelid closure and sustained pulling of the corner of the mouth. Contractions are triggered by looking up as well as many other actions controlled by the facial nerve not shown in this video. One may also see contractions of the platysma, depressors of the corner of the mouth, mentalis (contractions that cross the midline), and of the upper lip.

Chapter 78

Video 78.1. Myoclonus in Rasmussen encephalitis. This video demonstrates epilepsy partialis continua seen as myoclonic movements of the left orbicularis oculi with tonic contraction on the left lower face. These were much improved after intravenous immunoglobulin (IVIG) treatment.

Video 78.2. Posthypoxic myoclonus. The patient had generalized synchronous large-amplitude myoclonic jerks, more prominent with action than at rest. When standing, there was negative myoclonus of bilateral lower extremities, giving "a bouncing gait."

Video 78.3. Myoclonus-dystonia syndrome. The patient had myoclonic jerks, more prominent in proximal regions including neck, bilateral shoulders, and proximal upper extremities. Myoclonus was obvious with action including writing and pouring water from a cup but also occurred intermittently at rest.

Video 78.4. Hyperekplexia. This baby had severe exaggerated startle. Synchronous generalized myoclonic jerks of all extremities, upper greater than lower, were present even at rest and were also elicited by tapping the nose. Note that we do not recommend performing the repetitive nose tapping shown in this video. The latter part of the video shows hyperekplexia in Poll

P.xxvi

Hereford cattle. There were generalized myoclonic jerks with somesthetic stimuli.

Video 78.5. Propriospinal myoclonus. This video demonstrates reflex myoclonus, axial jerks shown as truncal flexion after being tapped with a reflex hammer. Note the relatively long latency between the taps and truncal flexion due to slow conduction via propriospinal pathways, in contrast to the short latency in cortical myoclonus due to conduction through corticospinal pathways.

Video 78.6. Hemifacial spasm. The first patient demonstrated clonic twitching of the left orbicularis oculi, especially in the lower portion, greater than left zygomaticus. There was synkinesis: When she puffed her cheek, there was also contraction of the left orbicularis oculi seen as left eye closure. The second patient demonstrated clonic and tonic twitching of the left facial muscles including orbicularis oculi and zygomaticus as well as left platysma. There was also synkinesis, similar to the first patient.

Chapter 79

Video 79.1. A 29-year-old woman with SCA2 exhibits a widebased, ataxic gait. (Courtesy of Sheng-Han Kuo, MD, Department of Neurology, Columbia University.)

Chapter 80

Video 80.1. Classic orobuccolingual dyskinesia and limb dyskinesia. The patient has typical orobuccal movements resembling chewing and swallowing as well as tongue popping and lip puckering. Oral movements cease when she talks and do not significantly interfere with speech. She also shows repetitive finger extension and flexion. The right thumb is in extended position, suggesting a dystonic component. She has similar flexion and extension movement of toes and wrist when standing up.

Video 80.2. Tardive dystonia. The patient shows excessive eye blinking and closure (blepharospasm) as well as lower facial grimacing movement. Her eyes open better when talking than listening to examiner.

Video 80.3. Tardive akathisia. The patient sits with crossing and uncrossing of his legs and arms, repeatedly touching his hat, and rocking his trunk back and forth. He jumps out of chair and paces around.

Chapter 81

Video 81.1. Sydenham disease. A 13-year-old boy with a 2-month history of left hemichorea and prior history of sore throat; serum antistreptolysin O (ASO) titer is greater than 600. The chorea completely resolved in 6 months.

Video 81.2. Kernicterus. An 11-year-old boy with a history of marked and prolonged neonatal jaundice, delayed developmental milestones, generalized choreoathetosis, vertical ophthalmoparesis, and deafness, typical of kernicterus.

Chapter 82

Video 82.1. Motor signs of Huntington disease.

Chapter 83

Video 83.1. Tremor. The patient has arm tremor at rest. The right arm tremor subsides for a second while he is moving his arm from the resting to outstretched position. Once his arm is in an outstretched position, the tremor reemerges. On the left, the tremor continues from rest to kinetic and to posture-holding positions. He has no kinetic tremor with finger-to-nose maneuvers on the right and slight intention tremor on the left. He also has jaw tremor at rest. The patient's rest tremor continues in both arms while walking.

Video 83.2. Bradykinesia and gait difficulty. The patient has mildly slurred speech. She has decreased facial expression with decreased blinking and partially open mouth. She has mild oral dyskinesia. Her rapid alternating movements are more impaired on the left side than the right side. Her finger tapping is slow, small in amplitude, and irregular, more severely affected in the left side. She stands up by pushing against the arm rest. Her posture is mildly stooped forward. She takes good strides, normal base, but without heel strike and with decreased arm swing on both sides. She takes five steps to turn 180 degrees. On pull test, she takes four steps of retropulsion before her fall was stopped by the examiner.

Video 83.3. Levodopa-induced dyskinesia. The patient has truncal, oral, and arm dyskinesia, with some dystonic posture of the left arm activated by voluntary movement of the right arm. She has excessive swinging of the left arm and oral dyskinesia while walking. She fails to regain her balance on pull test. With a few minutes, she turns "off" and shows left-sided rest tremor and akinesia. She continues to have oral dyskinesia, however.

Video 83.4. Freezing of gait. The patient freezes after reaching a destination and turning. He develops tremulous movements in the legs while attempting to take steps. After a few seconds, he is able to resume walking again.

Chapter 84

Video 84.1. Patient with mild signs and symptoms of progressive supranuclear palsy (PSP) for 2 years. Continuous, tiny square wave jerks are visible when he fixates. He has extremely limited upgaze and downgaze. He does not generate saccades when asked to look left or right. He is able to open his eyes after lid closure but there is a delay on the left. Tongue movements are mildly slow. He has marked axial bradykinesia (slowed shoulder shrug on the right) with mild slowing of rapid succession movements of the hands of feet. His blink rate is markedly reduced and he has a stare. He is able to rise from a chair with arms crossed, although slowly. He has a mildly broad based, slow gait with right > left arm abduction (“gunslinger’s walk”) and decreased arm swing.

Video 84.2. Patient with more severe PSP. She has the characteristic facial dystonia of PSP producing a troubled or angry look. She has poor balance, cannot rise from a chair safely with arms crossed, and falls in all directions. She also has a mildly broad-based stance and gait. When instructed to step backwards when pulled from behind, she falls backwards.

Video 84.3. Patient seen initially with mild signs and symptoms of cortical-basal ganglionic degeneration (CBGD). She has dystonic posturing of the right hand with twisting, slightly jerky movements of the right forearm, wrist, and fingers. Rapid succession movements of the upper extremities are mildly slowed on the left and markedly slowed on the right. She can rise slowly from a chair using her left hand. Her gait is slow, with mildly broad base, short stride on the left, dystonic posturing of both arm and leg on the right with even shorter stride, and no heel strike on either side. She turns en bloc, barely lifting the right foot. Two years later, she spends almost all her time in a wheelchair. She has severe dystonic posturing of the right

P.xxvii

arm and hand. She has overflow elevation of the right arm and left leg when she lifts the left. She has almost no function of the right hand or arm, requiring the left for simple actions like raising or lowering the arm. The left side is slow but significantly more functional than the right. She needs assistance to rise from a chair, and when she does, her right leg elevates and she can barely lower it to the ground and cannot support her weight with her legs alone.

Chapter 103

Video 103.1. Gross total resection of the thoracic meningioma seen in [Figure 103.6](#). After standard posterior thoracic laminectomy and midline opening of the dura mater is completed, microsurgical technique is used to dissect the arachnoid plane and separate the tumor from the spinal cord, nerve roots, and radiculomedullary artery and veins. Subsequently, the tumor capsule is incised, and a debulking followed by piecemeal resection is performed. After gross total resection is achieved, the dural insertion is cauterized to reduce risk of recurrence. We opted not to remove the dura given the anterior location and potential morbidity of a CSF leak.

Video 103.2. Gross total resection of an intramedullary ependymoma. After standard posterior thoracic laminectomy and midline opening of the dura mater is completed, microsurgical technique is used to perform a midline posterior myelotomy at the level of the posterior midline sulcus. The myelotomy is extended to allow complete exposure of the tumor. A plane of cleavage is developed and the dorsal and lateral border of the mass are gently separated from the surrounding spinal cord. Subsequently, the tumor is mobilized away from the ventral columns and all feeders from the anterior spinal artery are cauterized and cut allowing en bloc resection of the ependymoma.

Chapter 115

Video 115.1. Typical Takotsubo.

Video 115.2. Atypical Takotsubo.

Global Burden of Neurologic Disease

Jennifer Sevush-Garcy

Mitchell S. V. Elkind

INTRODUCTION

Neurologic disorders are globally among the most important causes of human illness and mortality. Quantifying the burden of neurologic disease and its impact on populations throughout the world is challenging for several reasons, however. First, neurologic disease includes disorders that primarily affect the brain as well as diseases that affect other body systems but have prominent neurologic manifestations. Second, neurologic diseases are notable for more frequently causing disability than death. Commonly used measures of disease impact, such as hospitalization or mortality rates, may not capture the impact of nonfatal neurologic problems such as migraine or epilepsy. Third, there are often disparities in neurologic disorders caused by socioeconomic and geographic factors. Assessment and diagnosis of neurologic disease may also depend on resources available for their measurement that are not available in all environments. Despite these limitations, present estimates of the burden of neurologic disorders suggest that they have an enormous impact on human health.

THE CLASSIFICATION OF DISEASE: WHAT IS A NEUROLOGIC DISORDER?

The classification of neurologic disorders can be broken down into two general categories: primary neurologic disorders affecting the nervous system only and secondary neurologic disorders, in which injury or dysfunction of the nervous system occurs as a result of a disease that primarily affects another organ system or in which dysfunction of the nervous system occurs along with dysfunction of several other organ systems. Examples of primary neurologic disorders include Alzheimer disease, migraine, and multiple sclerosis. Examples of secondary neurologic disorders include seizures secondary to infection with malaria, paraneoplastic syndromes associated with primary systemic cancer, and peripheral neuropathy occurring in the setting of nutritional deficiencies.

The distinction between primary and secondary neurologic disorders complicates the task of estimating global disease burden. For instance, do we classify diabetic neuropathy as a neurologic disorder or as a complication of an endocrinologic disorder? Should stroke be considered a neurologic disorder or a cardiovascular disease? Should head injury in the context of a motor vehicle accident be counted toward the burden of disease of neurologic disorders or of accidents? Various approaches have been taken to answer these questions, and in some instances, the definitions may shift depending on the purpose of the analysis. Although these distinctions may seem academic at first glance, they could have implications for public health campaigns and approaches to measuring, reporting, and acting on the relative burden of illness caused by different diseases.

ESTIMATING DISEASE BURDEN

There are several measures used to evaluate disease burden, including incidence, prevalence, morbidity, case fatality, mortality, disability, quality of life, pain, and cost. Incidence and prevalence are used to determine how common a disease is. The number of first cases of a disease over a defined time interval in a defined population determines its incidence. Prevalence measures the total number of cases, new and old, at a particular time in a defined population. Both indices depend on the accurate and complete enumeration of cases and adequate knowledge of the underlying population at risk. Case fatality refers to the proportion of patients with a disease who die from it. Mortality refers to the overall number of deaths due to the disease in a given time period.

Traditional approaches to estimating the impact of illness have focused on mortality because it is relatively easy

to measure. The impact of some neurologic disorders may be reasonably captured by reference to their case fatality or mortality. For example, malignant brain tumors, strokes, and head injuries are often severe and may lead to death. A metric focused exclusively on mortality, however, will fail to capture the impact of many neurologic disorders that are chronic and slowly progressive, or intermittent and disabling, but that do not cause their sufferers to die. For example, multiple sclerosis is a disease process that has low mortality but inflicts a rather high level of disability on its patients; however, it is relatively rare. Alternatively, migraine is a neurologic disorder that also has low mortality but has moderate disability and is extremely common. Clearly, attempts to measure this type of disease burden require a more versatile metric than mortality alone.

More recent attempts to measure disease burden have therefore aimed at capturing not only mortality but also morbidity, which captures the disability, handicap, and other physical costs associated with the disease. One common approach to measuring burden of disease is to consider a time-based metric that incorporates premature mortality (the number of years of life lost due to premature death, based on an expected life span) and disability (years of healthy life lost as a result of disability weighted by the severity of the disability). The combination of both of these measures yields disability-adjusted life years (DALYs). DALYs are a well-established metric of disease burden that measure the number of healthy years of life lost as a result of both death and disability caused by a particular disease. One DALY constitutes 1 year of healthy life lost in an ideal world in which everyone lives into old age free of any disease or disability. One advantage to using the DALY to measure disease burden is that it allows comparisons of impact across very different disease states, in effect serving as a common measure for acute severe illness (stroke, head injury, myocardial infarction) and less severe chronic illnesses (epilepsy, migraine). The DALY metric thus reflects the impact of disease on both early mortality and on

P.2

disability, both of which are particularly important for assessing the overall impact of neurologic disease.

FIGURE 1.1. Percentage of total DALYs for selected diseases and neurologic disorders.

Neurologic disorders account for the largest proportion of DALYs of any category of disease, more so than cancer, heart disease, or pulmonary disease (Fig. 1.1). Within the category of neurologic disorders, the greatest proportion of DALYs is due to cerebrovascular disease, which represents just over half of the DALYs due to all neurologic disorders. Alzheimer disease and other dementias, together with epilepsy and tetanus, comprise another quarter of the DALYs seen with neurologic disease. Perhaps surprisingly, migraine encompasses 8.3% of DALYs among neurologic disorders, which is double that encompassed by Parkinson disease and multiple sclerosis combined, although it contributes little to the occurrence of deaths. Likewise, although epilepsy contributes to almost 8% of DALYs, it is responsible for less than 2% of deaths. Stroke, on the other hand, which is also frequently fatal, is responsible for 85% of deaths when compared to other neurologic disorders (Figs. 1.2 and 1.3).

Among neurologic disorders, stroke carries the largest burden of disease. Estimates from the Global Burden of Diseases, Injuries, and Risk Factors Study, sponsored by the World Health Organization (WHO), ranked stroke as the second most common cause of death and the third most common cause of DALYs worldwide in 2010. These numbers may still underestimate the burden of disease, however, because they are limited to the clinical stroke syndromes that lead patients to seek medical attention. They generally do not include the subclinical disease burden from cerebrovascular disease, such as subclinical infarcts and white matter injury from ischemia, which may lead to cognitive impairment and functional decline.

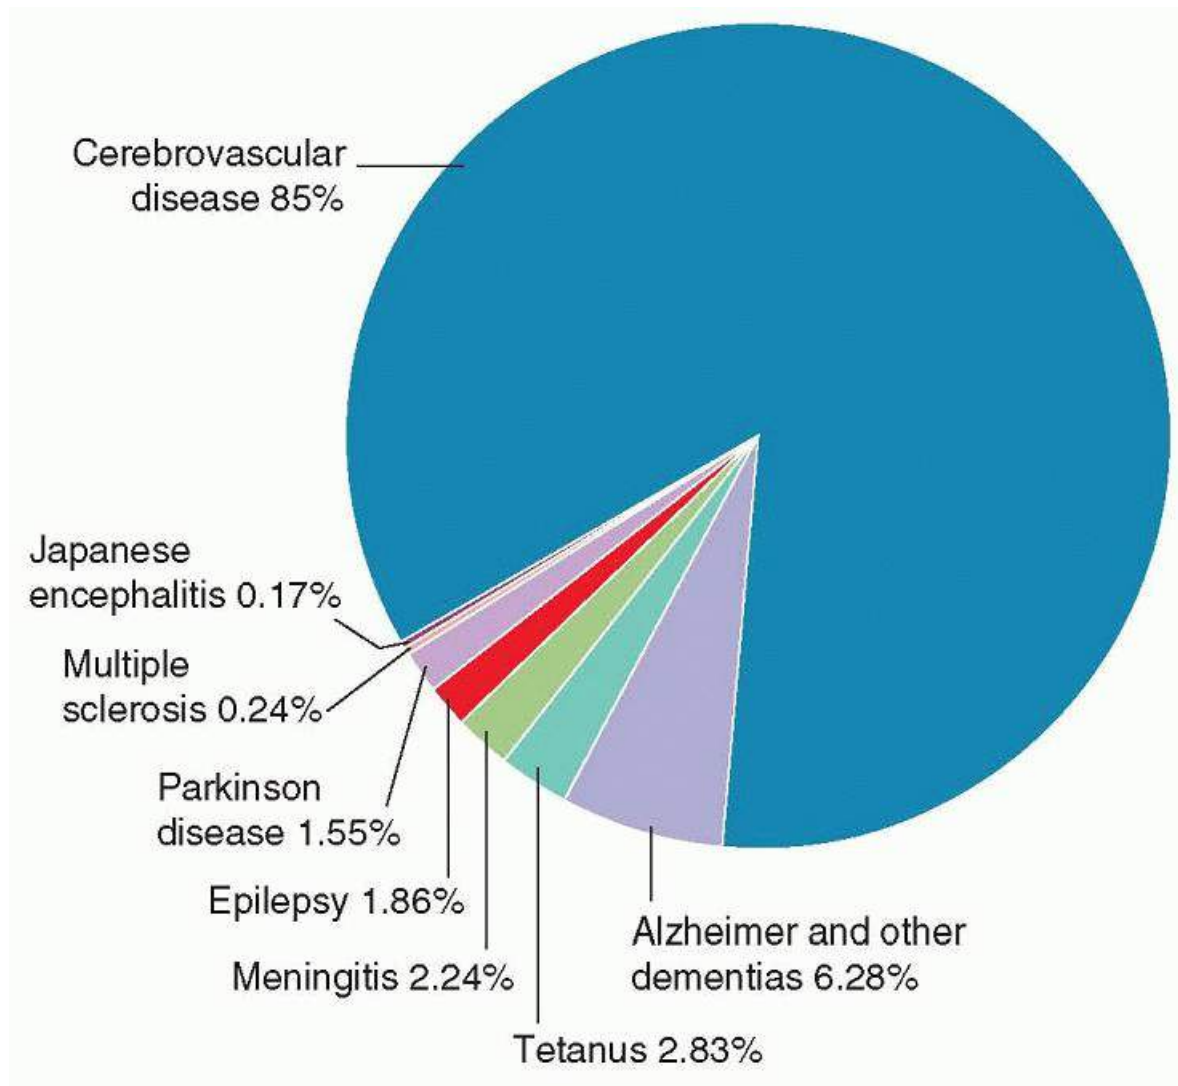

FIGURE 1.2. Deaths from selected neurologic disorders as percentage of total neurologic disorders. (From World Health Organization. *Neurological Disorders: Public Health Challenges*. Geneva, Switzerland: World Health Organization; 2006.)

THE SHIFTING CHARACTER OF NEUROLOGIC DISEASE OVER TIME

The relative importance of different neurologic disorders over time has changed not only as a consequence of changes in population demographics and risk factors but also as a consequence of world events and scientific knowledge. For example, tremendous advances in our understanding of peripheral nerve injuries, including phantom limb pain, occurred during the civil war, through the examination of amputees and injured soldiers by Silas Weir Mitchell and colleagues. Further advances in our understanding of head injuries occurred during the First World War. Early in the 20th century, neurologists also frequently

viral encephalitis. For example, the Spanish flu pandemic of 1918 to 1919 gave rise to many cases of postencephalitic parkinsonism, a disorder made familiar to many through Oliver Sacks' *Awakenings*. Later in the century, as life expectancy in developed countries increased, disorders of the elderly, including stroke and neurodegenerative disorders such as Parkinson disease and Alzheimer disease, were commonly encountered. Infectious neurologic disorders resurfaced again, however, in the 1980s in the form of the HIV/AIDS epidemic, with its well-known complications of toxoplasmosis and cerebral lymphoma. Rare and initially mystifying neurologic diseases have also captured the popular imagination and generated interest beyond what would be expected from the numbers of patients affected; the spongiform encephalopathies caused by prions, such as new variant Creutzfeldt-Jakob disease (or mad cow disease) had a tremendous impact in terms of teaching us about how diseases can jump from one species to another.

FIGURE 1.3. DALYs for individual neurologic disorders as percentage of total neurologic disorders. (From World Health Organization. *Neurological Disorders: Public Health Challenges*. Geneva, Switzerland: World Health Organization; 2006.)

THE EPIDEMIOLOGIC TRANSITION AND THE DOUBLE BURDEN OF DISEASE

The concept of the “epidemiologic transition” has been used to explain the shift in the types of diseases that often occur in countries as they pass through different stages of development. As nations industrialize and develop, the major causes of death and disability shift from a predominance of nutritional deficiencies and infectious diseases toward degenerative and chronic diseases, such as diabetes and cardiovascular disease. Investigators have described at least five stages of transition. The first stage (pestilence and famine) includes nutritional deficiencies and infection and characterizes regions such as sub-Saharan Africa and rural South Asia. In the second stage (receding pandemics), during which the pandemics of infectious disease and malnutrition recede, diseases related to hypertension, such as hemorrhagic stroke, become more common. China is an example of a region in this stage. During the third stage (degenerative and man-made diseases), life expectancy improves but high-fat diets, sedentary lifestyles, and cigarette smoking are introduced, allowing chronic, degenerative, and “man-made” diseases, including cardiovascular disease and ischemic stroke, to become more prominent. Urban India serves as an example of a country in this stage. As countries become more industrialized,

populations are also exposed to new environmental hazards. In a study conducted in Taipei, Taiwan, urban air pollution was associated with increased numbers of emergency admissions for cerebrovascular diseases. In the fourth stage (delayed degenerative disorders), there are increased efforts to prevent, diagnose, and treat these lifestyle-related diseases, which allows for a delay in their age of onset as well as the increase in degenerative diseases affecting the elderly. Western Europe and North America are considered to be in this fourth stage of the epidemiologic transition. Finally, a fifth stage may exist (social upheaval and social regression) in which social upheaval and war break down the existing health structures, leading to a resurgence of conditions seen in the first two stages as well as to the effects of violence and accidents. Post-Soviet Russia has been suggested as an example of this fifth stage.

As countries develop, they may also fall prey to the adverse consequences of a Western lifestyle (high-fat diet, sedentary lifestyle) before they fully emerge from the problems of underdevelopment. This phenomenon has been referred to as the *double burden* of disease and explains why countries in the middle levels of development have the highest rates of many illnesses. Developing and middle-income regions such as Latin America and urban India, for example, are experiencing an increased incidence of cardiovascular disease while simultaneously facing the lingering effects of infection and malnutrition.

Neurologic disorders are also subject to this epidemiologic staging. At any given time, different regions throughout the world may be in different stages of this transition. In particular, empirical evidence of the epidemiologic transition of stroke was nicely described in the Sino-MONICA-Beijing project. In this community-based surveillance study, investigators examined temporal trends in stroke incidence in Beijing over two decades from 1984 to 2004, a particularly rapid period of economic development in China. Four characteristics of the epidemiologic transition were observed: declining incidence of hemorrhagic stroke due to improved treatment of hypertension, reduced case fatality due to improved treatment after stroke, increased age of stroke onset, and an expanded proportion of ischemic heart disease deaths with a decreased proportion of stroke deaths in the study population. Additionally, an increase in the incidence of ischemic stroke was found, which was felt to be secondary to increased atherosclerotic risk factors.

DISPARITIES

Populations can be stratified by geography and income, and there are often disparities in neurologic disorders based on these factors. The WHO recognizes 6 geographic regions (Africa, Americas, Southeast Asia, Europe, Eastern Mediterranean, and Western Pacific) and 14 subregions, stratified according to child and adult mortality in those regions. The World Bank categorizes countries into four groups on the basis of gross national income per capita: low, lower middle, upper middle, and high-income. Varying types of neurologic disorders and degrees of disease burden occur in the different regions and income groups (Figs. 1.4 and 1.5). Low-income countries have a higher proportion of deaths from HIV, tuberculosis, and malaria infection, which can lead to infection within the nervous system, compared with high and middle-income countries. In the Southeast Asia region, tuberculosis, HIV, AIDS, and meningitis are four of the major causes of death in the region. WHO estimates that this region contributes 27% of the global burden of infectious and parasitic diseases and 35% of nutritional deficiencies. This is just one example of how countries in the WHO high mortality stratum or low-income category face major challenges from diseases associated with poverty, underdevelopment, and ineffective health care systems.

Worldwide, stroke accounts for approximately 10% of all deaths. The highest numbers of stroke deaths occur in Northern Asia, Eastern Europe, Central Africa, and the South Pacific. Systematic reviews of population-based studies from 28 countries showed that stroke incidence has increased in low-income and middle-income countries, whereas high-income countries have experienced a 42% decrease in incidence over the past four decades. According to a recent global analysis contained in the estimates from the Global Burden of Diseases,

Injuries, and Risk Factors Study, stroke mortality has decreased in the past two decades, whereas global stroke burden, rated in terms of yearly stroke survivorship, related deaths, and DALYs lost, has increased with the brunt of the burden in low-income and middle-income countries. Within high-income countries, improved health services and preventative stroke care may explain the reduction in stroke incidence, mortality, and DALYs lost and the converse for low-income and middle-income regions. In areas such as sub-Saharan Africa, there are high stroke mortality rates and low rates of reduction in DALYs lost.

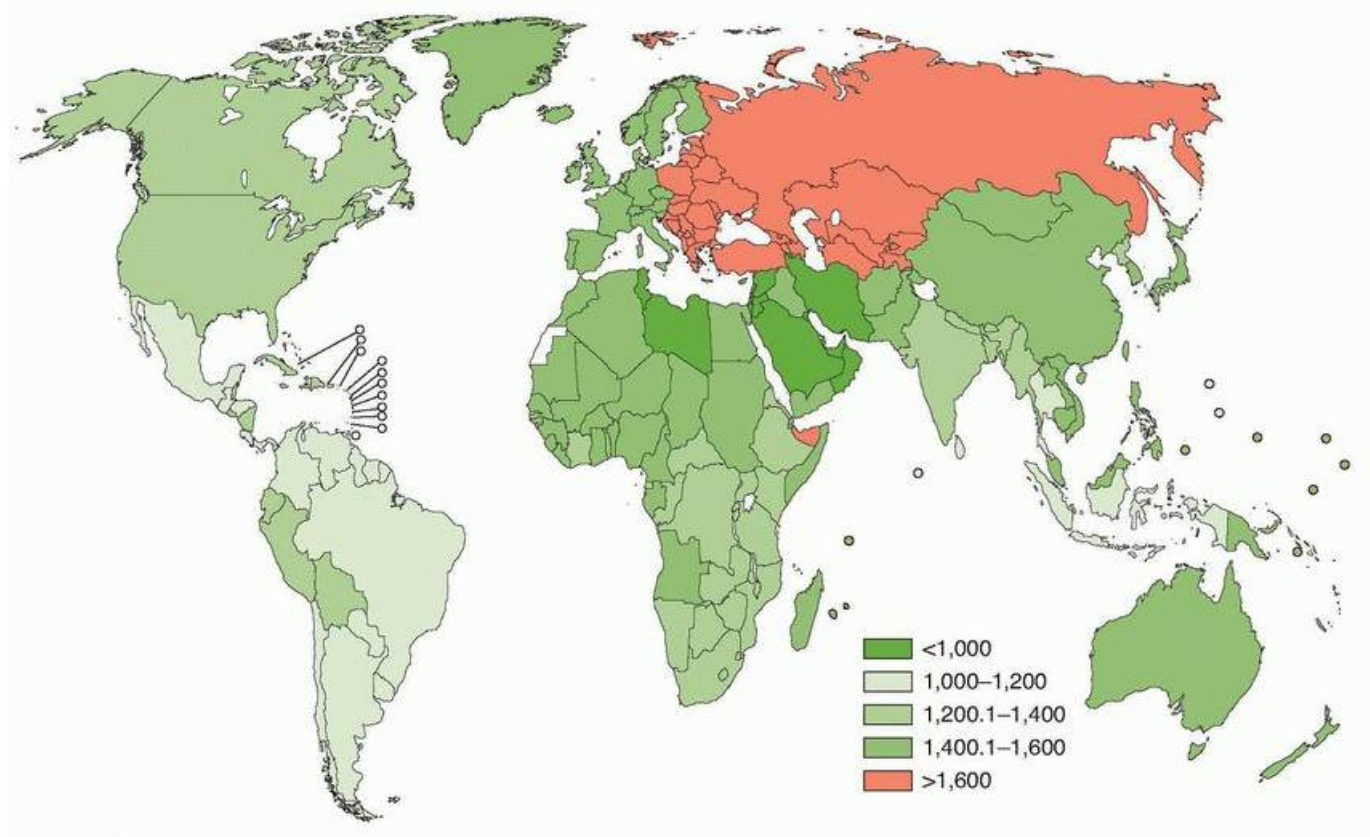

FIGURE 1.4. DALYs per 100,000 population associated with neurologic disorders by WHO region and mortality stratum. (From World Health Organization. *Neurological Disorders: Public Health Challenges*. Geneva, Switzerland: World Health Organization; 2006.)

Stroke disparities are not limited to the developing world; in fact, global disparities are reflected within nations. In the United States, racial minorities suffer increased stroke mortality and disability rates compared to non-Hispanic whites. African-Americans have the highest mortality rates due to stroke and Hispanics have a higher stroke incidence than whites. Within the United States, a geographic distribution in stroke incidence and mortality can be discerned. In the southeastern United States, within a region referred to as the *Stroke Belt*, stroke mortality and incidence rates are increased. The highest rates are found along the coast, in Georgia and the Carolinas, in a region nicknamed the *Stroke Buckle*. Variations in the race or ethnicity of people comprising the population do not appear to explain the disparities in stroke mortality and incidence that exist in the southeastern United States because African-Americans in that region seem to have increased stroke risks compared to African-Americans in other parts of the country. The difference may be attributable to socioeconomic factors limiting access to care, producing an increase in the prevalence of stroke risk factors. It has been noted that, at the age that Medicare becomes available to elderly Americans, African-Americans have no higher in-hospital mortality than do whites and no higher incidence in stroke rates or hypertension than do Hispanics. This provides indirect evidence that it is the lack of access to care that may be responsible for some of the racial and regional disparities.

FIGURE 1.5. Burden of neurologic diseases in lost DALYs per 1,000 person-years by World Bank national income level. (From Johnston SC, Hauser SL. Neurological disease on the global agenda. *Ann Neurol.* 2008;64:11-12.)

Global disparities in neurologic disease are not limited to stroke. In a population-based survey of residents older than age 65 years in seven countries with low and middle incomes (China, India, Cuba, Dominican Republic, Venezuela, Mexico, and Peru), dementia was overwhelmingly found to be the most important independent contributor to disability for elderly people in these countries. Chronic disease disability in countries with low and middle incomes is expected to increase by 224% in the least developed regions over the next four decades. Similarly, in a cross-sectional study of elderly Chinese people living in Hong Kong, dementia, stroke, and Parkinson disease were the chronic conditions most strongly associated with severe debility.

Limitations in neurologic resources and variability in resource allocation to neurologic problems contribute to the disparities in the global burden of neurologic disease. In a WHO/World Federation of Neurology survey of neurologic services, conducted from 2001 to 2003, there were marked disparities in availability of neurologists, neurosurgeons, subspecialized neurologic services, and methods of financing neurologic care across regions and income strata. The Americas and Southeast Asia had the highest regional availability of neurologic facilities at the primary health care level, whereas countries in the Western Pacific and Africa had limited emergency care or follow-up care for patients. Worldwide, the median number of neurologists per 100,000 people was 0.91. There was great variability, however: In Europe, the number of neurologists was four times higher, and in regions of Africa and Southeast Asia, the number of neurologists was substantially lower (Fig. 1.6). A similar regional pattern was identified regarding the availability of neurosurgeons and neurologic nurses around the world. Additionally, in 83% of countries from Africa, out-of-pocket payments represented the primary method of financing neurologic care, compared with 25.6% worldwide. Similarly, out-of-pocket payments represented the primary method of financing neurologic care in 84.2% of low-income countries. This survey illustrates the

existence of inadequate resources for neurologic disorders in most countries and highlights the inequalities in access to neurologic care particularly present in low-income countries.

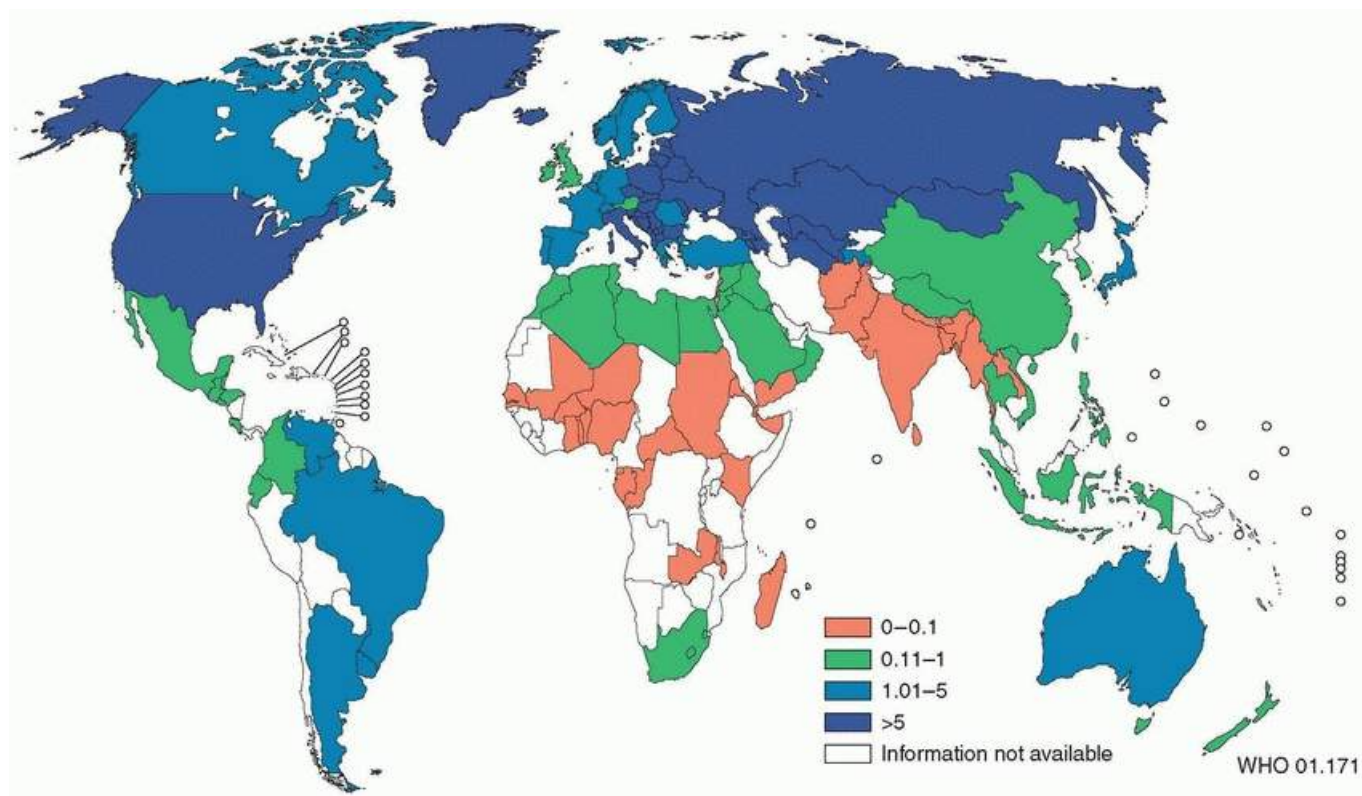

FIGURE 1.6. Global number of neurologists per 100,000 population. (From Janca A, Aarli JA, Prilipko L, et al. WHO/WFN survey of neurological services: a worldwide perspective. *J Neurol Sciences*. 2006;247:29-34.)

Variation in allocation of attention and research resources may contribute to the disparities seen in neurologic care worldwide. For example, of the 685 manuscripts published in the *Annals of Neurology* from 2005 through 2008, 91% had a corresponding author in either North America or Europe. Thus, 97% of manuscripts were produced in high-income countries where only 15% of the global population resides. Furthermore, the vast majority of clinical studies of neurologic disease describe people in high-income countries. A paradox has been observed within the pharmaceutical research realm where 90% of medical research funds are spent on 10% of the world's population. Apparently, research and development expenditures for diseases of poverty, including malaria, tropical diseases, and tuberculosis, are considered more likely to provide low returns and thus are considered high risk for failure and are not pursued.

SOCIOCULTURAL DIFFERENCES IN INTERPRETATION OF DISEASE

Cultural differences in disease screening, reporting, and management may contribute to the variation in identified global neurologic disease burden. A skew in the number of neurologic diagnoses identified in developing countries, as compared to high-income countries, might be a result of neurologically afflicted patients in developing countries not coming to medical attention. In one analysis of health systems constraints in Timor-Leste, one of the

P.6

poorest countries in Asia, it was found that poverty, strong beliefs in traditional medicine and healers, and low levels of education were barriers to people seeking care. Diagnostic equipment that is crucial for neurologic care, such as electroencephalography, electromyography, computed tomography, and magnetic resonance imaging, were absent. There were no manufacturers of medicine in the country, requiring importation of all necessary medicines.

In a study examining the reportable neurologic diseases in refugee camps in 19 countries within Africa, the Eastern Mediterranean, and Southeast Asia, a variety of diagnoses were revealed. Epilepsy represented more than 9 out of every 10 visits for neurologic disease in these refugee camps. The underlying causes of epilepsy in refugee camps, although unknown, were presumably similar to those for other inhabitants in the region, including perinatal injury, head trauma, cerebral malaria, and previous stroke. Within refugee camps throughout sub-Saharan Africa, the monitoring of meningitis and newer initiatives for vaccination were found to be crucial for preventing epidemic outbreaks, particularly those due to *Neisseria meningitidis*. However, there were limitations in accurate reporting in these regions, with many of the diagnoses not being verified by physicians and conditions such as meningitis being unlikely to have received cerebrospinal fluid confirmation. Regional and cultural differences in diagnosis and disease reporting can have an impact on the accurate assessment of the total global burden of neurologic disease.

Regional differences in the management of neurologic disease are also seen worldwide. Infectious disease, including meningitis, encephalitis, and cerebral malaria, is a major cause of critical neurologic illness in developing countries. Ischemic and hemorrhagic stroke, severe head injury, and epilepsy are major unaddressed causes of morbidity and mortality in many developing countries. In addition, neurologic manifestations of rabies, tetanus, eclampsia, and tuberculosis contribute to the burden of disease in these regions. The largest share of tuberculosis infection is seen in Africa and Asia where resource constraints hamper efforts to control new infections and prevent drug resistance. Infections of the nervous system by *Mycobacterium tuberculosis*, including meningitis, tuberculoma, tuberculous abscess, and nonosseous spinal tuberculoma, affect more than 10% of patients in the region. Tuberculosis is the leading cause of death in HIV-infected individuals in this population. Many low- and middle-income countries with high tuberculosis burdens have limited laboratory capacity to perform smear microscopy or run cultures for drug susceptibility testing. Unfortunately, in low-resource settings, patients often present late for medical care and are sometimes misdiagnosed and treated inappropriately, which can lead to a more severe clinical course. In some of even the least developed countries, governments fund hospitals that include intensive care unit-level care and, in addition, humanitarian efforts and military hospitals also contribute to offer some form of neurologic disease management, showing that neurocritical care can sometimes be practiced even in extremely resource-poor locations. There are, however, limitations in available resources. Many medications are not universally available. For example, although tissue plasminogen activator is a standard of care in high-income settings, developing countries still struggle with poor availability of this drug. Alternatives such as snake venom or urokinase may be employed instead. Finally, there remains a need for attention to neurologic recovery after the illness to allow for a seamless continuum between prevention, intervention, and rehabilitation from neurologic illness.

Cultural differences worldwide are an additional contributor to the differences seen in neurologic care around the world. For example, in many countries, patients with recurrent seizure may be considered to be possessed rather than as having epilepsy. In a cross-sectional study performed in Dar es Salaam, Tanzania, it was shown that of 100 traditional healers interviewed, 30% believed that epilepsy was caused by witchcraft, whereas 19% thought epilepsy had a genetic origin that could be inherited. The traditional healers treated epilepsy with up to 60 different plants, and some of these plants have demonstrated anticonvulsant activity. Among the Maasai population living throughout East Africa, who hold fast to their traditional and nomadic lifestyle, patients presenting with HIV/AIDS, epilepsy, and cerebral palsy are treated in remote sites using “bush medicine” within tents and working by sunlight with no electricity. In Maasai traditional medicine, herbs, roots, and bark are commonly boiled down into a soup. These examples serve as reminders that cultural differences in disease management and medication usage may vary greatly throughout the world.

There are a number of international organizations dedicated to neurologic care globally. Several member organizations within the United Nations, including the WHO, the World Bank, and the United Nations Children's

Fund have played roles in policy matters related to neurologic disease. Nongovernmental organizations provide care for people with neurologic disease in some of the least developed regions globally. Similarly, the World Federation of Neurology is an international organization of country-level neurologic societies composed of community-based and academic neurologists, who have successfully come together in the past to tackle international issues within neurologic disease.

SUMMARY

Neurologic disease has a tremendous impact on human illness and mortality globally. Despite the challenges in quantifying the burden of neurologic disease and assessing its impact on populations throughout the world, several points are clear. Neurologic diseases, whether they are primary or secondary, more frequently cause disability than death. This has been an obstacle to research employing common measures of disease impact. Additionally, disparities in incidence, diagnosis, disease management, and outcomes for patients in different geographic and socioeconomic sectors proffer a unique signature on the global burden of neurologic disease.

Signs and Symptoms in Neurologic Diagnosis: Approach to the Patient

Lewis P. Rowland

Timothy A. Pedley

INTRODUCTION

Accurate diagnosis is essential to making rational decisions about management and, increasingly in neurology, instituting effective treatment. Making a neurologic diagnosis requires a systematic approach to the patient. The history and physical examination provide essential but complementary data that form the cornerstone of diagnosis. Of course, laboratory tests are often necessary and are sometimes pathognomonic. They should, however, be ordered selectively, and students have to learn which tests are appropriate and when to order them. It is therefore necessary to know which diagnostic possibilities are reasonable considerations for a particular patient. Overreliance on laboratory tests and technology and analysis that is uninformed by clinical reasoning and appropriate differential diagnosis can lead to errors and delay suitable therapy.

The clinical data obtained by a careful history and physical examination are used to address three questions:

1. What anatomic structures of the nervous system are affected? Progressive weakness in the legs, for example, could be due to a myopathy, peripheral neuropathy, or myelopathy, but each of these possibilities can usually be distinguished by the presence or absence of characteristic symptoms and signs. It is usually not possible to make a specific etiologic diagnosis without knowing what parts of the nervous system are affected. In addition, knowing the probable anatomic substrate restricts the etiologic possibilities. Thus, making an accurate *anatomic diagnosis* should be the first step in analyzing a neurologic disorder. Clues to identifying the anatomic sites of neurologic disorders are discussed in the following section and later in this chapter.

2. What is the nature of the neurologic disorder? An individual patient's symptoms and signs usually cluster into broad syndromes or categories of disease: developmental disorder, peripheral neuropathy, acute encephalopathy, progressive dementia, parkinsonian syndrome, cerebrovascular syndrome, and so on. A syndromic diagnosis assists in clarifying the nature of the disease and further focuses on possible specific causes.

3. What are the most likely etiologies for the patient's illness? These derive from consideration of the anatomic and syndromic diagnoses in light of the tempo (rapid or slow) and course (fixed from onset, steadily progressive or stepwise) of the illness, relevant past history and family history, and whether there is evidence of systemic involvement. The possible etiologies listed in order of probability constitute the differential diagnosis, and this in turn determines which laboratory tests need to be ordered and the urgency with which the evaluation should proceed.

An experienced clinician is likely to deal with these three questions simultaneously or even reverse the order. To take an obvious example, if a patient suddenly becomes speechless or awakens with a hemiplegia, the diagnosis of stroke is presumed. The location is then deduced from findings made upon examination, and both site and

pathophysiologic process are ascertained by computed tomography (CT) or magnetic resonance imaging (MRI). If there are no surprises in the imaging study (e.g., demonstration of a tumor or vascular malformation), further laboratory tests might be considered to determine the precise cause of an ischemic infarct.

NEUROLOGIC HISTORY

A reliable and accurate history is essential. This should be obtained directly from the patient if at all possible, but it is often necessary to verify the patient's account or obtain additional information by speaking with relatives or close friends. This is particularly true if the illness has compromised the patient's mental function or use of language. Particular attention should be paid to the onset of symptoms, the circumstances in which they occurred, and their subsequent evolution. Have any of the symptoms resolved? Have similar or different neurologic symptoms occurred previously? To avoid errors, it is important that the physician avoids leading questions and clarifies what the patient means by ambiguous terms, such as *dizziness* or *weakness*. Discrepancies and inconsistencies in details obtained by different examiners are often the source of diagnostic confusion and must be resolved.

NEUROLOGIC EXAMINATION

Performing an accurate neurologic examination (Chapter 3) requires practice and skill. It begins with observations made as the patient enters the room and continues while his or her history is being obtained. Abnormalities of gait and balance may be readily apparent. The manner in which the patient tells the history may reveal confusion, aphasia, or memory loss. It is preferable to record exact observations (what the patient actually did or did not do) rather than interpretations that may introduce ambiguity. It is best to perform the examination in a standard sequence to avoid omissions, although it may be necessary to modify this based on the patient's condition and ability to cooperate. The usual order is mental status, cranial nerves, strength and coordination, sensation, and reflexes.

The specific nature of different symptoms and findings obtained from examination are reviewed in the following chapters. Other considerations that influence diagnosis are briefly described here.

IDENTIFYING THE SITE OF DISORDER

Aspects of the patient's history may suggest the nature of the disorder; specific symptoms and signs suggest the site of the disorder.

Cerebral disease is implied by seizures or by focal signs that may be attributed to a particular area of the brain; hemiplegia, aphasia, or hemianopia are examples. Generalized manifestations of cerebral disease are seizures, delirium, and dementia.

Brain stem disease is suggested by cranial nerve palsies, cerebellar signs of ataxia of gait or limbs, tremor, or dysarthria. Dysarthria may be the result of incoordination in disorders of the cerebellum itself or its brain stem connections. Cranial nerve palsies or the neuromuscular disorder of myasthenia gravis may also impair speech. Ocular signs have special localizing value. Involuntary movements suggest *basal ganglia disease*.

Spinal cord disease is suggested by spastic gait disorder and bilateral corticospinal signs, with or without bladder symptoms. If there is neck or back pain, a compressive lesion should be suspected; if there is no pain, multiple sclerosis is likely. The level of a spinal compressive lesion is more likely to be indicated by cutaneous sensory loss than by motor signs. The lesion that causes spastic paraparesis may be anywhere above the lumbar segments.

Peripheral nerve disease usually causes both motor and sensory symptoms (e.g., weakness and loss of sensation). The weakness is likely to be more severe distally, and the sensory loss may affect only position or vibration sense. A more specific indication of peripheral neuropathy is loss of cutaneous sensation in a glove-and-stocking distribution.

Neuromuscular disorders and diseases of muscle cause limb or cranial muscle weakness without sensory symptoms. If limb weakness and loss of tendon jerks are the only signs (with no sensory loss), electromyography and muscle biopsy are needed to determine whether the disorder is one of motor neurons, peripheral nerve, or muscle. The diseases that cause these symptoms and signs are described in later sections of this book.

AGE OF THE PATIENT

The symptoms and signs of a stroke may be virtually identical in a 10-year-old, a 25-year-old, and a 70-year-old patient, but the diagnostic implications are vastly different for each patient. Some brain tumors are more common in children, and others are more common in adults. Progressive paraparesis is more likely to be due to spinal cord tumor in a child, whereas in an adult, it is more likely to be due to multiple sclerosis. Focal seizures are less likely to be fixed in pattern and are less likely to indicate a specific structural brain lesion in a child than in an adult. Myopathic weakness of the legs in childhood is more likely to be caused by muscular dystrophy than polymyositis; the reverse is true in patients older than 25 years. Muscular dystrophy rarely begins after age 35 years. Multiple sclerosis rarely starts after age 55 years. Hysteria is not a likely diagnosis when neurologic symptoms start after age 50 years. These ages are somewhat arbitrary, but the point is that age is a consideration in some diagnoses.

GENDER SPECIFICITY

Only a few diseases are gender-specific. X-linked diseases (e.g., Duchenne muscular dystrophy) occur only in boys or, rarely, in girls with chromosome disorders. Among young adults, autoimmune diseases are more likely to affect women, especially systemic lupus erythematosus and myasthenia gravis, although young men are also affected in some cases. Women are exposed to the neurologic complications of pregnancy and may be at increased risk of stroke because of oral contraceptives. Men are more often exposed to the possibility of head injury.

ETHNICITY

Stating the race of the patient in every case history is an anachronism of modern medical education. In neurology, race is important only when sickle cell disease is considered. Malignant hypertension and sarcoidosis may be more prevalent in blacks, but whites are also susceptible. Other diseases are, however, more common in certain ethnic groups: Examples include Tay-Sachs disease, familial dysautonomia, and Gaucher disease in Ashkenazi Jews; familial inclusion body myopathy in Iranian Jews; familial Creutzfeldt-Jakob disease in Libyan Jews; thyrotoxic periodic paralysis in Japanese and perhaps other Asians; nasopharyngeal carcinoma in Chinese; sickle cell disease in people of African descent; Marchiafava-Bignami disease in Italian wine drinkers; and hemophilia in descendants of the Romanovs. Ethnicity is rarely important in diagnosis.

SOCIOECONOMIC CONSIDERATIONS

In general, social deprivation leads to increased mortality, and the reasons are not always clear. Ghetto dwellers, whatever their race, are prone to the ravages of alcoholism, drug addiction, and trauma. Impoverishment is also accompanied by malnutrition, infections, and the consequences of medical neglect. For most other neurologic disorders, however, race, ethnicity, sex, sexual orientation, and socioeconomic status do not affect the incidence.

Inequities of access affect prevention, early diagnosis, and treatment of neurologic conditions in the United States. Globally, poor countries suffer from tragedies of malnutrition, parasitic diseases, and AIDS. Embargos

have become popular political weapons but impose punishment on innocent civilian adults and children. It is not just poverty that impedes access; rural areas in any continent may have limited access to imaging or advanced therapeutic technology (a problem that has generated helicopter transfer and telemedicine). The many millions of U.S. citizens without health insurance have limited access.

TEMPO OF DISEASE

Seizures, strokes, and syncope are all abrupt in onset but differ in manifestation and duration. Syncope is the briefest. There are usually sensations that warn of the impending loss of consciousness. After fainting, the patient begins to recover consciousness in a minute or so. A seizure may or may not be preceded by warning symptoms. It may be brief or protracted and is manifested by alteration of consciousness or by repetitive movements, stereotypical behavior, or abnormal sensations. A stroke due to cerebral ischemia or hemorrhage strikes “out of the blue” and manifests as hemiparesis or other focal brain signs. The neurologic disorder that follows brain infarction may be permanent, or the patient may recover partially, or completely, in days or weeks. If the signs last less than 24 hours, the episode has traditionally been called a *transient ischemic attack* (TIA). Sometimes, it is difficult to differentiate a TIA from the postictal hemiparesis of a focal motor seizure, especially if imaging shows no lesion and the seizure was

P.10

not witnessed. Another syndrome of abrupt onset is subarachnoid hemorrhage, in which the patient is struck by a headache that is instantaneously severe and sometimes followed by loss of consciousness.

Symptoms of less than apoplectic onset may progress for hours (intoxication, infection, or subdural hematoma), days (Guillain-Barré syndrome), or longer (most tumors of the brain or spinal cord). The acute symptoms of increased intracranial pressure (ICP) or brain herniation are sometimes superimposed on the slower progression of a brain tumor. Progressive symptoms of brain tumor may be punctuated by seizures. Heritable or degenerative diseases tend to progress slowly, becoming most severe only after years of increasing disability (e.g., Parkinson disease, Alzheimer disease, essential tremor).

Remissions and exacerbations are characteristic of myasthenia gravis, multiple sclerosis, and some forms of peripheral neuropathy. Bouts of myasthenia tend to last for weeks at a time; episodes in multiple sclerosis may last only days in the first attacks and then tend to increase in duration and leave more permanent residual neurologic disability. These diseases sometimes become progressively worse without remissions.

The symptoms of myasthenia gravis vary in a way that differs from any other disease. The severity of myasthenic symptoms may vary from minute to minute. More often, however, there are differences in the course of a day (usually worse in the evening than in the morning but sometimes vice versa) or from day to day.

Some disorders characteristically occur in bouts that usually last minutes or hours but rarely longer. Periodic paralysis, migraine headache, cluster headaches, and narcolepsy are in this category. To recognize the significance of these differences in tempo, it is necessary to have some knowledge of the clinical features of the several disorders.

DURATION OF SYMPTOMS

It may be of diagnostic importance to ask patients how long they have been having similar symptoms. Long-standing headache is more apt to be a migraine, tension, or vascular headache, but headache of recent onset is likely to imply intracranial structural disease and should never be underestimated. Similarly, a seizure or drastic personality change for days or months implies the need for CT, MRI, and other studies to evaluate possible brain tumor or encephalopathy. If no such lesion is found or if seizures are uncontrolled for a long time, perhaps video-electroencephalographic monitoring should be carried out to determine the

best drug therapy or surgical approach.

MEDICAL HISTORY

It is always important to know whether there is any systemic disease in the patient's background. Common disorders, such as hypertensive vascular disease or diabetes mellitus, may be discovered for the first time when the patient is examined for neurologic symptoms. Because they are common, these two disorders may be merely coincidental, but, depending on the neurologic syndrome, either diabetes or hypertension may actually be involved in the pathogenesis of the neural signs. If the patient is known to have a carcinoma, metastatic disease is assumed to be the basis of neurologic symptoms until proven otherwise. If the patient is taking medication for any reason, the possibility of intoxication must be considered. Cutaneous signs may point to neurologic complications of von Recklinghausen disease or other phakomatoses or may suggest lupus erythematosus or some other systemic disease.

The Neurologic Examination

James M. Noble

INTRODUCTION

Of all the chapters presented in this book, the one most likely to remain nearly 100% relevant, if not also accurate, decades from now is that of the neurologic examination. Clearly new handheld and bedside examination tools continue to and will make implementation and interpretation of the exam different over time, but the general principles and approach have not substantially changed for decades and are unlikely to substantially differ over a trainee's career. This chapter should be used in close conjunction with the guidelines for developing the neurologic history that are presented in Chapter 2.

One must recognize that an exhaustively comprehensive neurologic examination cannot be defined within the scope of this chapter. Instead, this chapter provides a set of guiding principles on which the neurologic examination can be built to support, augment, or refute findings suggested by the neurologic history.

A thorough neurologic history and examination are designed to accurately localize neurologic dysfunction and develop a differential diagnosis of the most likely disease processes. The history and physical should be used in a complementary manner rather than as stand-alone devices. With the patient or family members as informants and physician as historian, the neurologic history should be a logical, linear story told such that the history leads sensibly into the examination, without many surprises to the examiner or another physician hearing about the encounter.

SETTING GOALS OF EXAMINATION VERSUS NEUROLOGIC TESTS

As is the case in many professions, there are likely as many ways to accomplish an examination as there are examiners performing the examination itself. However, some approaches may be far more efficient, understandable, and sensible than others. There are numerous neurologic examination techniques known, sufficient to comprise a substantial book, let alone a single chapter.

The approach presented here is intended to demystify the reasons and the methods by which a comprehensive neurologic examination is accomplished. It is well recognized that most trainees in neurology will not go on to become professionals or practitioners in advanced neurology. However, it must be the case that every graduate of any medical training program has a sufficient confidence, skill level, and knowledge base to begin to develop a proficient neurologic examination for each context it requires.

This chapter attempts to strike a balance between the comprehensive examination that neurologist can accomplish, with the base expectation of all practitioners being able to approach a neurologic patient without trepidation, concern, misdiagnosis, or more importantly, a missed urgent neurologic diagnosis. A comprehensive neurologic examination is one typically done in the context of a focused neurologic assessment. All physicians should be familiar with how to accomplish each of these tests in the appropriate context. However, it is likely good practice to perform a screening neurologic examination in any patient encounter seen in a general medical inpatient or outpatient assessment, as major neurologic diseases can likely be identified through such an approach or alternatively provide a good point of reference should the patient subsequently develop neurologic problems. Elements suggested to be included in comprehensive and screening neurologic examinations are provided in [Table 3.1](#). An in-depth review of the coma examination is provided in Chapter 18.

A TOP-DOWN APPROACH

The manner in which the neurologic examination should be presented follows a structured approach that facilitates a complete and comprehensive neurologic examination. Anatomically and generally speaking, this follows a “top-down” approach, which begins with the mental status examination and cranial nerve examination at the top with the head, followed by the body including motor and deep tendon reflex examinations, followed by sensory and coordination exams, and finally gait. The neurologic examination can be temptingly approached in an excitedly, symptom-focused manner, but this method introduces the risk of unintentionally forgoing an essential element of the neurologic examination. This approach is also designed to improve efficiency during the first pass assessment, to be followed by more focused and detailed examination based on relevant initial findings.

HELPING YOUR PATIENT THROUGH THE NEUROLOGIC EXAMINATION

There is a good chance that a neurologic examination performed on a patient may be perceived the most comprehensive medical examination the patient has experienced, with many elements even seemingly strange during the exam. Accordingly, some patients may unintentionally embellish the examination or even provide nonsensical physical exam responses, in an effort to impress their physician during demonstration of their neurologic system. In some cases, it may be helpful to tell the patient very specifically what is going to be done, as well as the expected outcome or finding, particularly when a normal examination is expected based on a benign relevant history. On the other hand, it may be more worthwhile to provide no instructions to patients with psychogenic disorders who are also prone to purposeful embellishment or feigned signs. It is certainly allowable for an unexpected neurologic examination finding to be repeated on a patient after coaching for expected findings has been given.

SOFT VERSUS HARD NEUROLOGIC EXAMINATION FINDINGS

In some cases, the examiner may be inclined to search unnecessarily for an abnormality on neurologic examination based on history provided or alternatively identify a subtle unexpected finding referred to as a “soft” neurologic sign. Commonly, faces may be asymmetric, strabismus persists into adulthood, memory may be imperfect, or

P.12

balance may be less than pristine especially with advancing age. Slight asymmetries, particularly in the face, are commonly found during neurologic examination in normal individuals and likely do not hold much clinical relevance. Some reviews have suggested that soft neurologic signs including poor motor coordination, sensory perception, and motor sequencing may occur in as much as half of all healthy individuals. Understanding when to strongly consider finding, simply record it, or to discard it altogether often takes a very skilled examiner cautiously interpreting each finding. However, this need not take a fully refined neurologist to make such decisions, particularly if one approaches the neurologic examination with a clear sense of the likely localization as suggested by a fully developed history. When findings are found in isolation, particularly without a clear connection to the history that has just been developed, it may be justifiable to recognize and record the finding but not necessarily dwell on it. A neurologist typically will take these findings into consideration and tailor, repeat, or perform additional elements of the neurologic examination to assure that the finding is simply an isolated finding (and perhaps even a normal variation) or a relevant new finding. In addition, it is certainly acceptable upon discovery of a subtle neurologic finding to reask a newly relevant history, which may not have otherwise been apparent despite a seemingly comprehensive initial history.

TABLE 3.1 The Neurologic Exam

Comprehensive	Screening
Mental Status	
Level of alertness	Level of alertness
Language function (fluency, comprehension, repetition, and naming)	Appropriateness of responses
Memory (short-term and long-term)	Orientation to date and place
Calculation	—
Visuospatial processing	—
Abstract reasoning	—
Cranial Nerves	
Vision (visual fields, visual acuity, and funduscopic examination)	Visual acuity
Pupillary light reflex	Pupillary light reflex
Eye movements	Eye movements
Facial sensation	—
Facial strength (muscles of facial expression and muscles of facial expression)	Facial strength (smile, eye closure)
Hearing	Hearing
Palatal movement	—
Speech	—
Neck movements (head rotation, shoulder elevation)	—
Tongue movement	—
Motor Function	
Gait (casual, on toes, on heels, and tandem gait)	Gait (casual, tandem)

Coordination (fine finger movements, rapid alternating movements, finger-to-nose, and heel-to-shin)	Coordination (fine finger movements, finger-to-nose)
Involuntary movements	—
Pronator drift	—
Tone (resistance to passive manipulation)	—
Bulk	—
Strength (shoulder abduction, elbow flexion/extension, wrist flexion/extension, finger flexion/extension/abduction, hip flexion/extension, knee flexion/extension, ankle dorsiflexion/plantar flexion)	Strength (shoulder abduction, elbow extension, wrist extension, finger abduction, hip flexion, knee flexion, ankle dorsiflexion)
Reflexes	
Deep tendon reflexes (biceps, triceps, brachioradialis, patellar, Achilles)	Deep tendon reflexes (biceps, patellar, Achilles)
Plantar responses	Plantar responses
Sensation	
Light touch	One modality at toes—can be light touch, pain/temperature, or proprioception
Pain or temperature	—
Proprioception	—
Vibration	—

DESCRIPTIONS VERSUS IMPRESSIONS

Whenever possible, a description of neurologic findings should be included in the examination rather than the synthesis of the findings themselves. Changes in the neurologic examination day to day can be remarkably subtle and only a descriptive neurologic examination may reveal such changes and sometimes only in retrospect. For example, a patient may be described on a series of examinations by different examiners to be lethargic, yet substantially different levels of stimulus are required to result in the same response from the patient, ranging from

light tactile to verbal stimuli to other more rigorous stimuli applied yet inadequately described. Such a failure to accurately describe patient, particularly in an era increasingly reliant on effective care transitions, can jeopardize true understanding of neurologic disease progression in both inpatient and outpatient practices.

POSITIONING THE PATIENT (AND EXAMINER)

Appropriately positioning the patient and examiner is an important first step in many aspects of the neurologic examination and is described in each of the relevant sections. Positioning of the patient and examiner is important throughout the patient encounter, including initial moments of a patient encounter when developing patient trust and rapport. At the bedside, correct position with each component of the neurologic examination is essential in both effective and efficient performance and interpretation of the neurologic examination. Positioning is most relevant not only to assessment of visual fields, funduscopy, strength, and deep tendon reflexes but also during times of potential injury during provocative or potentially risky elements of the exam, such as pull testing for assessing postural stability, or even when standing a patient affected by frailty or imbalance suggested in the history or during gross inspection.

REPEATED EXAMINATIONS ARE THE KEY TO IMPROVE SKILL

Skill and ability in any medical field, or in any field involving adult learners, likely relates to the prior volume of experience had in that field. A well-described cognitive heuristic suggests that adult learners transition from a hypothetical deductive approach in learning to a more automated approach through progressive experience.

A set of rich and deeply understood normative values can be determined for simple yet essential components of the neurologic examination, including determining the relatively normalcy of interpersonal interactions, conversations, or even walking. With this set of normal findings, an examiner can begin to dissect a subtly abnormal neurologic examination into its principal components. By the same measure, one cannot know how an abnormal funduscopy examination or tandem gait may appear until having seen normal findings in many patients. Although a specific diagnosis, particularly among patients with complicated history, may remain elusive even in the hands of an accomplished neurologist, an accomplished dissection of abnormal findings on the neurologic examination, used in conjunction with the history, can facilitate localization and diagnostic approach.

THE PATIENT EXAMINATION

GENERAL MEDICAL EXAMINATION

All neurologists participate in substantial training in internal medicine, whether in the adult or pediatric setting. Thus, it is expected that any patient with a neurologic disease should have a comprehensive general medical examination performed on them at least once in the course of their initial neurologic assessment. However, it is typically the case that a relatively brief overview of the general medical examination will be included in any neurologic case presentation with only the elements most germane to the neurologic diagnosis presented. For example, description of cardiac and carotid auscultation should be described for a patient presenting with stroke, and a rash should be described in a patient presenting with proximal myopathy.

However, each patient should have a complete and accurate description of the general impression—the essence of the strong first impression each patient may have provided to the examiner. Specific points to mention may include general appearing of wellness, nourishment, habitus, manner of dress, or other related elements. Some of these elements may be reinforced in the mental status examination.

MENTAL STATUS EXAMINATION

In contrast to other elements of the neurologic examination, the mental status examination is composed of a potentially variable set of tasks tailored to each patient. Rather than beginning with the prespecified set of neurologic examination tasks, a far preferable approach is one that aims to develop a description of the function of the cognitive domains based on a set of often interdependent tests. It is difficult, if not impossible, to find any single test that can comprise and completely describe an entire neuropsychological cognitive domain. Instead, many tests map to several cognitive domains and vice versa. In graphical or mathematical terms, the brain expresses its cognitive functions in a series of overlapping domains, conceptually representable as Venn diagrams (Fig. 3.1), which can broadly be broken down into domains of language, memory, attention and executive function, visuospatial function, and processing speed. Predicated on each of these is that the patient has a sufficient level of consciousness in order to participate in the examination.

The neurologic examination should include a standardized assessment of mental status for several reasons. First, any

P.14

standardized cognitive screening examination will often have been developed in the context of hundreds, if not thousands, of applications and multiple social economic and cultural contexts, making its interpretation more generalizable. Second, at the level of the examiner, use of the same examination repeatedly may give the examiner greater confidence in examination skill and interpretation based on a learned experience of typical or expected responses developed over the course of giving the same test in multiple clinical contexts. Third, most standardized mental status examinations allow for a hierarchical approach to understanding someone's cognitive abilities. For instance, for a task of delayed recall, it is important to understand not only what a patient can freely recall but also what the patient may recognize either through the contextual or categorical clue given for recognition tasks or subsequently through list of forced choices. Using a sequential, hierarchical approach to assessing memory abilities allows for determination of free word retrieval (presumably a harder response) versus recognition (by choices), which are thought to be independent of registration tasks. Finally, serial assessments of an individual patient may require adjustment of exam techniques to avoid the potential effects of learning or practice.

Many caveats apply to interpreting the mental status examination and thus require understanding and how it is devised for each patient, particularly how it is tailored to each cultural context. For instance, education and lifetime cognitive abilities play a strong role in one's ability to interpret both normal and abnormal mental status examination findings. Prior to each mental status examination, developed within social history must be a clear sense of someone's educational history, literacy, and thus likely expected performance on mental status testing. As a point of comparison, more formal neuropsychological testing will take into consideration two norms: the person's premorbid intellectual capacity as determined by intelligence quotient as well as comparison to normative values based on peer performance matched to age, education, and potentially primary language.

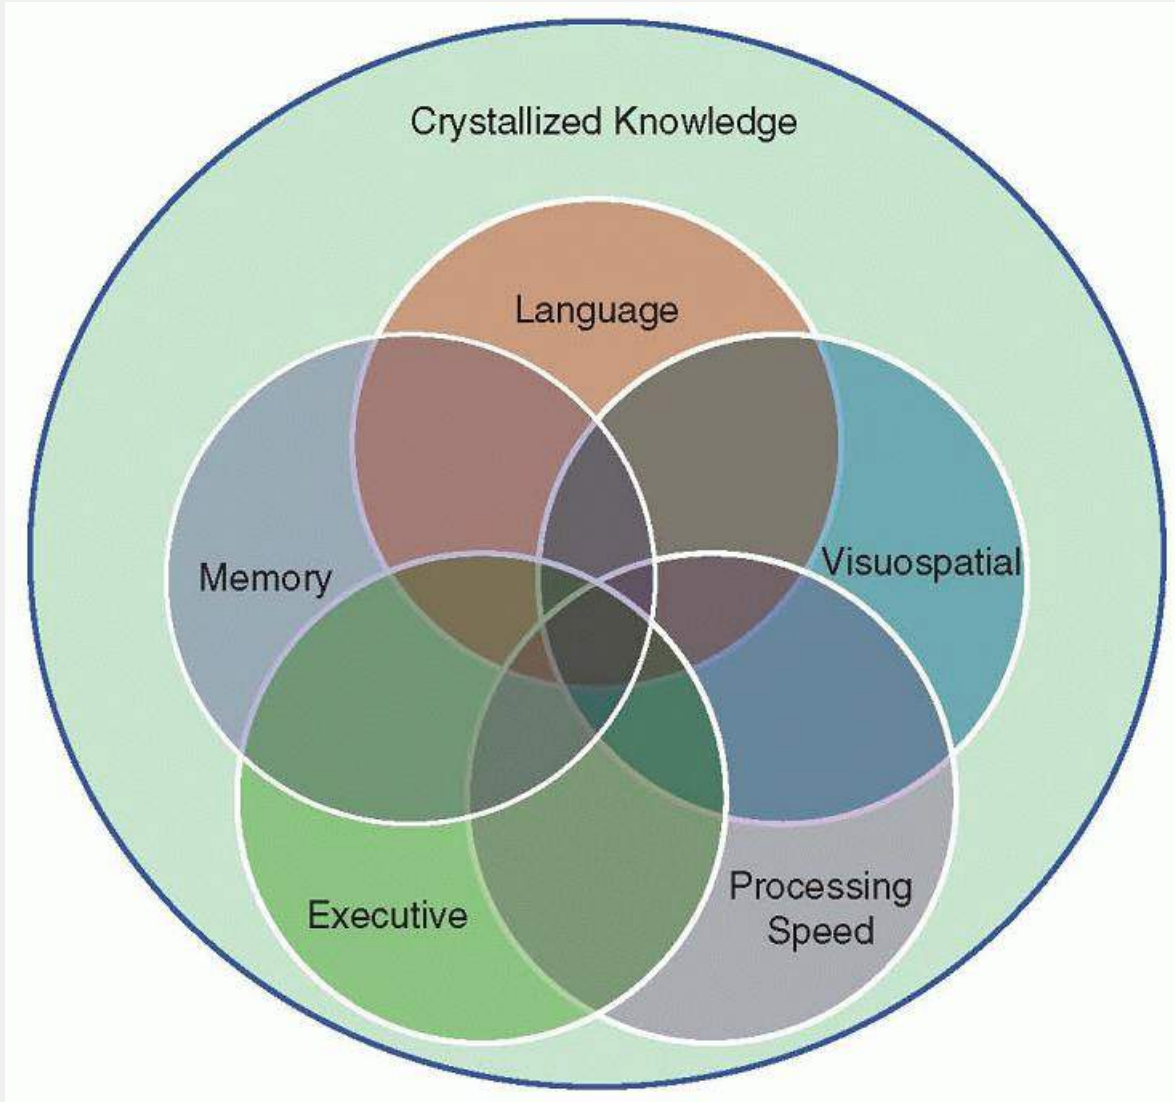

FIGURE 3.1 Conceptual framework for the mental status examination and interpretation. Each of the five principal cognitive domains (language, memory, visuospatial, processing speed, and executive function) are drawn from a series of tests comprising the mental status examination. Relative strengths and weaknesses in each domain may be inferred based on a series of related tests which map potentially to several domains but relatively consistently identify a domain of impairment. The interpretation of each abnormality must be considered within the context of each test, including normative information if known. The relative function of each domain is likely influenced by and superimposed on crystallized knowledge, which conceptually summarizes education, life experiences, and cognitive reserve.

It is important during the mental status examination not only to record whether or not the patient correctly answers the question but also the actual response itself. Much can be learned through some elements of the mental status examination which can, to some degree, be influenced by complex factors including mood. For instance, a patient may be considered to be disoriented to time and place through simple scoring, but when review of the actual answers suggest an exactly wrong response to every single question (including nonsensical dates, often in the future), it might suggest an element of feigned or embellished neurologic examination.

Determining Alertness

The entirety of the formal mental status testing is predicated on a patient being fully awake, alert, and able to engage the examiner. Presuming this is the case, neurologic examination as described in the following section is relevant in such patient. Determining a depressed level of alertness is described in

Chapter 18 as relates to the examination of coma and brain stem examination.

Tasks of Attention and Concentration

Typical tasks of attention and concentration relate to the ability of a patient to attend and focus any specific, often narrow set of tasks in real time. Typical bedside techniques in assessing concentration include serial subtraction, spelling a five-letter common word backward, or more simply involving stating the months of the year in reverse, days of the week in reverse, or counting from 20 down to 1, always beginning with the most difficult task first. Elements of these examinations are often appropriately interpreted in the context of related domains such as executive function. For instance, the ability of a patient to count down from 20 may reflect the ability to attend to the task, whereas subtracting a series of changing answers may suggest intact or impaired executive or calculation abilities. Other more practical tasks may involve simple addition and subtraction, presuming appropriate levels of literacy and numeracy. Tasks such as making monetary change may not only give one a sense of the patient's calculation abilities but also any degree of functional impairment should a clear impairment emerge. For a patient residing in a major metropolitan area, the ability to appropriately make change at a hypothetical street-side food vendor can be such an example.

Additional tasks of attention and concentration may be more conventionally thought of in conjunction with other cognitive tests, such having a patient register several words to be later recalled, following a three-step command, or drawing a complex figure. As detailed earlier, it is not the performance on a single test that draws concern but rather an overall pattern that may emerge across the sequence of several tests.

Memory Testing

Differing definitions of working, short-, and long-term memory exist, are often used inappropriately in colloquial examination and

P.15

presentations, and may have differing meanings depending on the person reviewing the examination described by others. A formal description of various forms of memory is provided in summary in [Table 30.2](#). Working memory is generally considered to be the online or in-the-moment memory, such as what may be used when repeating a series of unrelated words or number sequence. Short-term memory involves testing a set of ideas registered with the patient and specifically queried by the examiner after a delay of several minutes. Items not freely recalled but instead recognized from a list (recognition) can be additionally informative. Long-term memory can either represent a more prolonged delay in testing responses to the task of recollection, or in some other tasks may instead represent long-term general or autobiographical knowledge. It is important to document the content asked to be remembered and the duration of time until asking for retrieval of information. Recall is entirely predicated on the patient's ability to register several items to be recalled, and this begins with preparing patient for this task in a minimally distracting environment.

In its simplest form, memory testing involves having a patient remember several items in the context of an examination to be recalled several minutes later. Certainly, this is an important element of memory testing but is just one method of assessing memory among many. This manner of testing memory, in conjunction with several other tests, such as time and place orientation, may be highly specific in screening out major cognitive disorders, which may adversely affect health care such as medication compliance. However, it largely serves to only test verbal memory of three unrelated words, and does not take into account nondominant hippocampal function such as visuospatial memory or implicit memory associated with programmed motor tasks.

Ideally, a test of three to five unrelated words, or a brief contextually related phrase (name and address

of a fictional person), should be given to a patient to register and subsequently recall. It is most important for the examiner to use a series of words that have been rigorously studied to understand their cultural and socioeconomic norms, can be understandably and simply chosen from categorical clues, which may be given to help with recognition after-the-fact (e.g., “the first word was a color”), can be recognizable from a list of similar words, and is also easily memorable to the examiner who may be giving such an examination many times over the course today.

Verbal memory can also be tested through repetition and recall of a simple story. This can be particularly effective in identifying the patient with a confabulatory amnesic syndrome (i.e., Korsakoff syndrome) rather than anterograde amnesia (i.e., Alzheimer disease). For example, a patient may be given a brief story to recall such as “Johnny had a red tricycle. Billy liked Johnny's red tricycle and stole it one day. Billy broke Johnny's red tricycle after he took it. When Johnny found out Billy had stolen the tricycle, he got very upset.” A patient with a typical amnesic disorder may respond to this task by providing a few or a restricted set of elements germane to the story with the remainder unrecalled. In contrast, a patient with a confabulatory amnesic disorder may provide the initial basic elements of the story correctly but then provide an idiosyncratic thread far beyond the initial details provided in the story. Moreover, such a patient may begin with the same thread when testing the story on a follow-up examination, only to give a remarkably different yet linear story thereafter.

Nonverbal short-term memory is thought to be localizable to the nondominant hippocampus or most typically the right side in right-handed individuals. Testing visuospatial memory in the office can be somewhat difficult but can be accomplished. For instance, one can hide three objects within a room telling the examinee each time where each object is placed, to be registered and recounted several minutes later. A hospital corridor can be used as a visuospatial memory task by having a patient and examiner pass through a specific path, to be led by the patient immediately to demonstrate registration, and again several minutes later to demonstrate recollection.

Long-term memory likely engages separate circuits, widespread across the cerebrum, and is better categorized as public or autobiographical memory rather than a true function of working or recent memory. This memory type can also be easily conflated and is dependent on knowledge of worldly events and life experiences. Testing long-term memory can be approached by using a standardized set of questions which should be well known to the individual, such as sequential ordering of recent presidents. However, this can be easily tailored to a patient who may lack such conventional knowledge. For example, an elderly sports enthusiast can be tested for his knowledge of recent sports events important to him and hierarchically working back to biographical events which must be corroborated by an informant. A test of recent worldly events likely more reflects function of the same recent memory circuits being tested by recollecting three unrelated words, given the need to both register and recall worldly information gathered through the news.

Language

Language is composed of seven principal components: (1) fluency, (2) prosody, (3) repetition, (4) naming, (5) comprehension, (6) reading, and (7) writing. A language examination is not complete without each of the seven elements. The pattern of dysfunction related to these seven components allows the neurologist to diagnose and classify all types of aphasia ([Table 3.2](#)).

Fluency and prosody can often be determined through development of the neurologic history before turning to formal examination. Prosody is the musical component of language, the singsong nature, and cadence that allows one to understand the nature of a stated expression. For example, prosody allows one to discern when a declarative sentence is stated versus a question. In contrast to normal prosody, aprosodic patients may be identified among those with major neuropsychiatric disorders

including schizophrenia or in patients with advanced or untreated Parkinson disease. Fluency is a quality of speech pertaining to the ability of a patient to express him- or herself without hesitation or disruption spontaneously as well as during formal testing. Dysfluent speech may have hallmarks of patient frustration or an unexpected halting pattern, such as that seen in a suddenly acquired Broca area stroke, or progressively developed in a patient with progressive nonfluent aphasia form of frontotemporal dementia. Dysfluent speech is distinct from thought blocking, which is described within the elements of psychiatric examination.

Repetition may be assessed by asking a patient to repeat a simple, understandable phrase and further tested by a longer more complex sentence if the history and examination warrant further exploration. When such a phrase cannot be repeated, repetition of single words should be attempted.

Naming also should be approached in a hierarchical manner when testing knowledge of names of presented objects and virtual pictures. Standard images/figures comprise most neurologic screening examinations but differ among each exam. Objects to be named should be ubiquitous, well-known to the patient, and have elements that offer an opportunity to test parts and not just the sum of the object. This approach may reveal difficulty in describing

P.16

low-frequency relative to high-frequency words, as is often seen in disorders like Alzheimer disease. In addition, the naming examination may be tailored to the patient for objects well-known in the context of their life experience or profession, such as images of a set of carpenter's tools. A number of forms of specific categorical dysnomia are known to exist, such as color dysnomia, and should be tested in the appropriate clinical context.

TABLE 3.2 Types of Aphasia

Aphasia Subtype	Fluency	Comprehension	Repetition	Localization
Expressive (motor, Broca)	Effortful speech with paraphasic errors ^a and agrammatism ^b ; mutism in severe cases	Normal	Impaired ^c	Frontal opercular region of inferior frontal gyrus (Broca area) in the dominant hemisphere
Receptive (sensory, Wernicke)	Fluent speech, mostly nonsensical in content; frequent paraphasic errors	Impaired	Impaired ^c	Posterior-superior temporal region (Wernicke area) in the dominant hemisphere

Global aphasia (combination of expressive and receptive)	Effortful speech with paraphasic errors ^a and agrammatism ^b ; mutism in severe cases	Impaired	Impaired ^c	Both inferior frontal gyrus and posterior-superior temporal region in the dominant hemisphere
Conduction aphasia	Normal	Normal	Impaired	Due to lesions of the arcuate fasciculus connecting Broca and Wernicke areas in the dominant hemisphere

^a*Literal (phonemic) paraphasic error*: an error made by substituting a similar-sounding word for another (i.e., “pat” substituted for “cat”). *Verbal (semantic) paraphasic error*: an error made by substituting words with similar meaning (i.e., “cup” for “bottle”).

^b*Agrammatism or telegraphic speech*: Language content of spontaneously uttered sentences is condensed, missing many filler words, such as definite articles and sometimes verbs.

^cNormal repetition in the setting of expressive, receptive, or global aphasia denotes transcortical expressive, transcortical receptive, and transcortical mixed aphasia subtypes.

Comprehension is often tested as a three-step command. As with a memory task, the patient should be prompted to expect the task rather than occurring as a surprise. Numerous three-step commands have been published but should be easily understandable, contextually appropriate, and whenever possible use commonly available objects so that the same task can be repeated by a single examiner in multiple clinical contexts.

Reading testing begins with a patient reading a simple sentence aloud and offers an opportunity to test for comprehension by having the patient act on the sentence provided. Should a patient have difficulty reading a sentence (e.g., “Close your eyes.”), then the examiner should move on to simple phrase or a single word if the phrase cannot be read. In a similar approach, writing should begin with an instruction for the patient to write a complete sentence. If this cannot be accomplished, the patient should be asked to write a simple dictated sentence. If this is further not possible, the patient should be asked to write or sign his or her name, although this principally tests for praxis or dysgraphia. Such highly learned written tasks, and even a signature, likely localize to the nondominant frontal lobe as a programmed motor task, or “n-gram,” rather than a function of spontaneous written language.

Executive Function

Executive function can be demonstrated through several types of tasks highlighting the abilities or limitations of the frontal lobe or its principal subcortical circuits. Broadly speaking, these can be thought of as tasks which demonstrate the ability of a patient to both maintain and shift between specific tasks or concepts, as demonstrated by examinations of either language or physical/motor abilities.

Common tests of executive function involve repetition of a number series in the reverse order in which it was given, complex tasks of addition or subtraction, or sequential tasks performed by the patient in a specific order and manner. Examples of executive tasks involving the hands may be in a standard set of hand movements such as knocking (“fist”), chopping (“edge”), and slapping (“palm”) the hand on a table in sequence after being instructed to register the series, also known as the *Luria sequence*.

Tests of praxis may be considered to some degree to be tests of executive function, as a demonstration of ability or limitation in fine movement of the hands or limbs based on frontal lobe function. In contrast to weakness, praxis is the ability of a patient to coordinate and perform a simple or complex set of tasks based on instruction, independent of simple motor abilities. Simple, or ideo-motor, tests of praxis involve single motions with contextually independent movements such as the ability of a patient to open and close their hand either to simple instruction or to demonstration. In contrast, ideational tests of praxis instead involve a complex task often with multiple steps of a well-known or overlearned task used in daily life. Examples include demonstration of brushing one's hair, brushing teeth, or blowing out a match. More specific examples for common daily tasks include putting on a coat known as *dressing praxis*.

Visuospatial Function

Visuospatial function is often tested through tasks which require ability to perceive, plan, orient, and synthesize visual images. As is the case for other cognitive tests one might typically think of as specifically testing one domain, visuospatial abilities inevitably may have a basis in other domains including frontal executive function,

P.17

but are also reliant on memory (how one may be familiar with an object in daily life such as a clock or cube) or language (understanding the contextual basis for an image). The simplest of drawing tasks may limit the influence of frontal executive function on the ability of a patient to draw but must be taken in consideration relative to other nonvisuospatial tasks in order to fully interpret visuospatial test findings. Visuospatial tasks often involve drawing intersecting pentagons, a circle with a tangentially touching square, or cubes, among other figures. More complex figures used in common practice, such as a clock drawing, can be very helpful in demonstrating visuospatial function but may be also prone to a number of cognitive difficulties including planning, memory, as well as visual field deficits. As is the case with language, visuospatial function may be significantly impacted by a patient educational history, in particular simple literacy. Individuals who may not have held a writing implement for significant period of time in their life may have difficulty with relatively simple drawing tasks.

Higher Order Cognition

Higher order cognitive functions are often placed alongside executive functions but likely represent a separate set of cognitive abilities which are more often predicated on experiential knowledge and social norms. Tests of higher order function include interpretation of proverbs or common sayings and judgment as demonstrated by patient's response to simple hypothetical situations.

The neurologist should select a few proverbs for such tasks, which are culturally sensitive, relatively ubiquitously known, and interpretable by both the patients and the examiner in the response. Using a relatively narrow set of appropriate phrases will also give the examiner better experience in anticipating

a typical response from patients. Examples for proverb interpretation include “two heads are better than one,” “people in glass houses should not throw stones,” and “don't count your chickens before they hatch,” or one of many similar phrases. Examples of hypothetical situations to be provided for testing judgment may include asking for patient's response to discovering an unmailed fully addressed letter, or steps taken when facing a simple public emergency. As with any test, these must be interpreted with consideration of education and culturally based normative responses.

Key Psychiatric Examination Elements

The key elements of a conventional psychiatric examination will also be germane to many patients with neurologic disease, particularly those with an acquired cognitive disorder. The patient's reported symptoms of mood are recorded as mood, whereas the examiner's interpretation of the patient's mood is better characterized as affect. These can both be matched or unmatched in the context of examination and both are important distinctions to make for later interpretation.

Thought process is an important component of the psychiatric examination and is often discovered either during or in retrospect when the examiner reflects on a simple or challenging interview. Thought processes can be characterized using the following descriptors, which also have graphical corollaries to better conceptualize how conversation transpires (Fig. 3.2). These thought processes are linear, tangential, thought insertions, thought blocking, circumstantial (too many details, meandering but with spontaneous return), circumlocutions (talking around the subject with eventual arrival), and circumferential (talking around the subject without arrival). Thought content is considered the components and characteristics which make up thought processes and include psychotic and nonpsychotic phenomenology. Important psychotic phenomenology either identified during examination or history includes delusions (fixed false beliefs), hallucinations (idiosyncratic, spontaneously perceived visual, olfactory, gustatory, or auditory stimuli), or illusions (misperceived complex visual or auditory perceptions based on normal and present environmental cues). Other types of abnormal thought content include ideas of reference, sense of presence, or other thought idiosyncrasies.

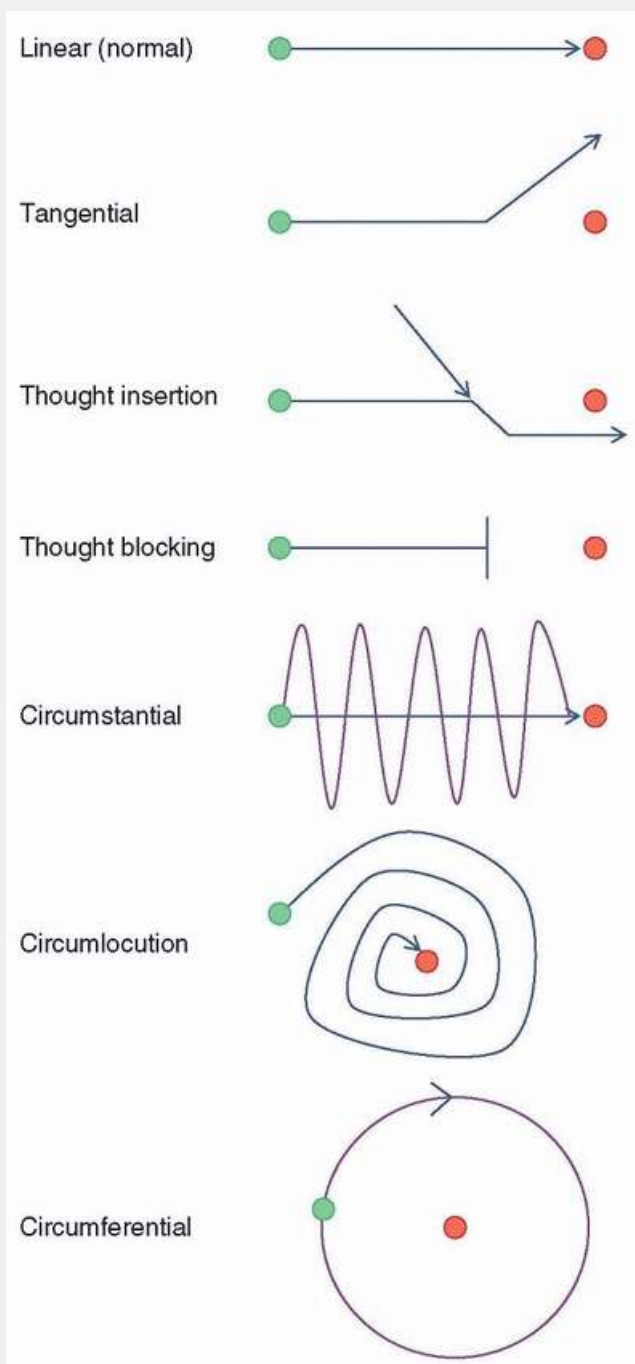

FIGURE 3.2 Graphical representations of thought processes. Starting points are indicated with a *green dot*, final points with a *red dot*. *Lines* represent direction of conversation. (Adapted with permission from Edward R. Norris, MD [personal communication].)

CRANIAL NERVE EXAMINATION

The cranial nerve examination is an essential component of the neurologic examination that requires skilled training and expertise to interpret appropriately. However, when approaching the examination methodically, based on its principal components, rapid interpretation of the individual and localizing findings can be accomplished.

As is the case with the remainder of the general medical and neurologic examinations, the cranial nerve examination should be

recorded. For instance, one may not assess olfaction in every neurologic examination, and it is unnecessary to state when it was not done. The examiner should demonstrate the findings again in a top-down approach beginning with findings identified in an ordinal manner, presenting the cranial nerves from lowest to highest number (begin with cranial nerve [CN] I and end with CN XII). CN function should be described in the context of the test performed rather than the nerves themselves (e.g., “eye movements fully intact” rather than “CNs III, IV, and VI intact”).

Cranial Nerve I (Olfactory Nerve)

Assessment of olfaction is important in certain neurologic diseases including frontal lobe tumor, head trauma, and degenerative disease, among others. Testing is comprised of commonly recognizable smells which are not caustic, toxic, or excessively potent in strength. Examples of commonly used, recognizable, and available smells include coffee, vanilla, and mint. These can be stored within a neurologist's equipment bag using plastic film canisters (although these are increasingly more difficult to find) or opaque contact lenses cases (so that the patient may not see the item to be smelled in advance). To test for smell, with the patient's eyes closed, have a patient fully close one of his or her nares and ask to take a deep breath with the item to be smelled placed immediately below the nares.

Cranial Nerve II (Optic Nerve)

Assessment of CN II includes tests of visual acuity, visual fields, funduscopy, and pupillary light reaction.

VISUAL ACUITY

Most standard physician examination kits include a Snellen card for testing visual acuity. One of the most important steps prior to doing a visual acuity examination is to know the exact distance at which the vision is to be tested. This is typically printed on the card and varies from 14 inches for near vision to 6 ft for far vision (as a surrogate for a standard 20-foot distance examination). Begin by instructing the patient to put the hypothenar eminence of his or her hand against the bridge of the nose such that the eyes completely obstructed by the palm of the hand. If the patient is simply instructed to cover his or her eye with hand, there is a tendency of using the fingers to cover the eye and therefore the possibility of peeking through these fingers in order to improve or embellish the examination findings. Related to this issue, the examiner should always hold a visual acuity card to avoid a patient's temptation to bring the card closer to the face and conflate the exam.

VISUAL FIELDS

This examination should begin with the examiner standing at an arm's distance from the patient. Testing visual fields at a farther distance may only test central vision rather than demonstrate any frank field deficits as is desired by this test. Using the instructions previously described for covering the eye, the examiner should close their ipsilateral eye when facing the patient (the examiner should close his or her own left eye while examining the patient's left eye). With arms held aloft, the examiner should attempt to assess monocular visual fields at the left and right of meridian as well as above and below the equator of each tested eye. Generally speaking, the bedside visual examination test should be used to discover quadrantanopsias, binocular visual field loss, or homonymous hemianopsias. Any smaller field deficits would be far more difficult to identify on bedside examination and may require formalized visual field testing as is done in an ophthalmologist office ([Fig. 3.3](#)).

FIGURE 3.3 Visual fields. (From Bickley L. *Bates' Guide to Physical Examination and History-Taking*. 11th ed. Philadelphia: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

Methods of testing visual field include counting fingers within each of these quadrants, identifying a statically held hand with a wiggling finger, or moving a hand into the field being tested. Despite their routine inclusion on examination, most bedside techniques are poorly sensitive but highly specific to identifying visual field deficits.

FUNDUSCOPY (VIA DIRECT OPHTHALMOSCOPY)

An essential element of the neurologic exam, and one which is marvelously distinguished as being the only visualized aspect of the neuraxis and can demonstrate both elements of chronic systemic disease and acute neurologic emergency, yet one which is far too frequently neglected out of examiner discomfort, lassitude, or disinterest, is funduscopy. The quality of the remainder of the exam and history as performed by a referring physician, in the eyes of a consulting neurologist, may be predicated on inclusion or at least attempt of this aspect of the exam for this reason, particularly when called for by the diagnosis. Two main barriers may persist and limit the interest of a physician on performing this exam: perceived difficulty of use of the equipment and simple availability. Two forms of direct ophthalmoscopes exist for the bedside exam: conventional and panoptic. The conventional heads have the benefit of bright light for magnification, portability, and relatively ubiquitous presence of these heads in many clinics, but are limited by perceived difficulty of use perhaps related to partial views of the optic disc even in optimal patients. The conventional heads are available in a normal size, as well as a smaller "micro" version, which offers even greater portability but faces the same limitations. The panoptic head offers the benefit of a wide field of view, but is limited by expense and lower light intensity.

The essential aspects to be identified in funduscopy include characteristics of the optic nerve head including the cup, margins, and vessels as well as the immediately visualizable

and relevant retinal components including the macula/fovea (Fig. 3.4). Visualizing the retina beyond the width of 2 or 3 optic disc diameters of most patients is particularly difficult by direct ophthalmoscopy.

FIGURE 3.4 Fundusoscopic view (right eye). (From Bickley L. *Bates' Guide to Physical Examination and History-Taking*. 11th ed. Philadelphia: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

Care should be taken to describe the color and shape of the disc as well as the cup-to-disc ratio if perceptible. A relative description of vessels can include the quantity and quality including relative diameter, or a suggestion of hypertensive change often described as “copper wiring,” or “AV nicking” when the vein appears compressed by a superimposed arteriole. Description of retinopathic changes including color variegations, vascularity, and plaques should be described. Having such an approach will leave more emergent and obvious abnormalities to the end of the focused examination and description.

PUPILLARY LIGHT RESPONSE

Two components of the pupillary response should be considered within each patient. These include the response of the ipsilateral and contralateral eyes to both direct and consensual light responses. While asking a patient to fixate on the examiner's face or another suitable target several feet away, using a light of sufficiently bright intensity, a narrowly focused beam is shown into a single eye with the examiner assessing for the ipsilateral and contralateral responses.

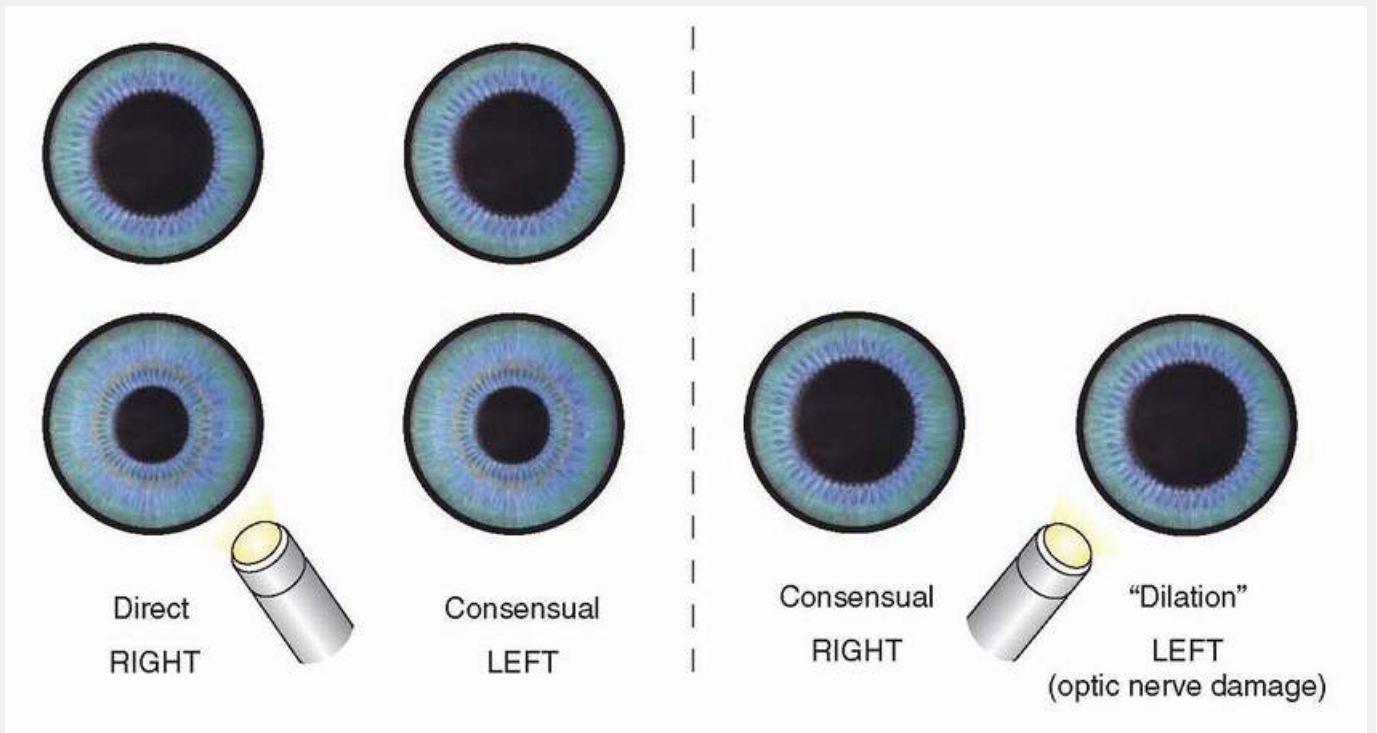

FIGURE 3.5 Swinging flashlight test. (From Bickley L. *Bates' Guide to Physical Examination and History-Taking*. 11th ed. Philadelphia: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

The swinging flashlight (Fig. 3.5) is another component of this test in which the initially examined eye is provided direct light followed by a rapid movement of light to be shown into the contralateral eye followed by a movement back to the initially tested eye. The object of this examination is to identify either a lack of direct response (in the case of severe optic neuropathy) or paradoxical dilatation to direct response (in less apparent cases, termed the relative afferent pupillary defect) as the swinging flashlight is shone back into an eye affected by an optic neuropathy.

In addition, pupillary asymmetries should be described and assessed in both a lit and a darkened environment with the use of tangential light (to assess pupillary size with minimal afferent stimulus).

Extraocular Movements (Cranial Nerves III [Oculomotor Nerve], IV [Trochlear Nerve], and VI [Abducens Nerve])

The elements of testing extraocular movements include demonstration of limitations of excursion of either individual or consensual gaze, rapidity of saccades, preservation of smooth pursuits, and the control of multiple types extraocular movements, both large and small excursions, as well as slow and fast movements.

Prior to any testing of eye movements, the patient should be carefully examined for any spontaneous eye movements when

focusing on a fixed near target placed several feet before the patient. Although this technique may demonstrate spontaneous eye movement abnormalities including so-called square wave jerks, finer perception of such movements may be identified during fundoscopic examination which magnifies subtle spontaneous eye movements otherwise missed during casual visual inspection.

FIGURE 3.6 Extraocular movements. (From Bickley L. *Bates' Guide to Physical Examination and History-Taking*. 11th ed. Philadelphia: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

To test for restriction of gaze, the patient (Fig. 3.6) should be asked to follow the finger or a similar near target at approximately an arm's length distance from the patient moving through a typical H pattern. Care should be taken not to move through these movements too quickly; otherwise, saccadization of pursuits may occur and potentially mislead the development of the oculomotor examination.

To test for rapidity of saccadic eye movements at a similarly near distance, the patient should be asked to fixate on the examiner's nose while both hands are placed in mid-position between the patient and examiner at about a shoulder width apart. With one hand wiggling (to indicate a target) and the patient staring at the examiner, the patient is instructed to look at the wiggling stimulus, followed by instructions to return to gaze back to the nose. After a series of repeated assessments, the rapidity of saccadizations as well as the ability to accurately fixate on the lateral and midline targets can be assessed using this technique. An alternating bright and dark cloth tape to stimulate optokinetic nystagmus can be an additionally helpful tool in potentially identifying lateralized saccadic eye movement deficit.

To further test for the accuracy of fixation and the ability to maintain fine, fixed, and accurate extraocular movements, the patient can be asked to additionally follow a moving target through an unpredictable series of movements in either the horizontal or vertical planes. A consistent need to provide a corrective saccade in all, or a single direction, provides a localizable deficit.

Cranial Nerve V (Trigeminal Nerve)

Principally, the trigeminal nerve serves to provide facial sensations including touch, temperature, and pinprick of the face and anterior elements of the mouth. Vibratory sensations applied to the face likely reflect neck vibratory sensory function, which is seldom if ever absent on examination and thus cannot be discerned from facial sensation. Joint position sense may only be evident in the jaw and rarely if ever demonstrably found.

As is the case for sensory testing within the torso and limbs, the goal of the sensory examination is to identify the modality of sensory deficit and thus the potential tracts and nerve fiber types involved against the pattern of sensory deficits identified on examination (Fig. 3.7). Patterns include laterality and segmentation in the face. Palpating the face (as well as within the mouth) can be useful in trying to identify trigger points in patients with suspected trigeminal neuralgia.

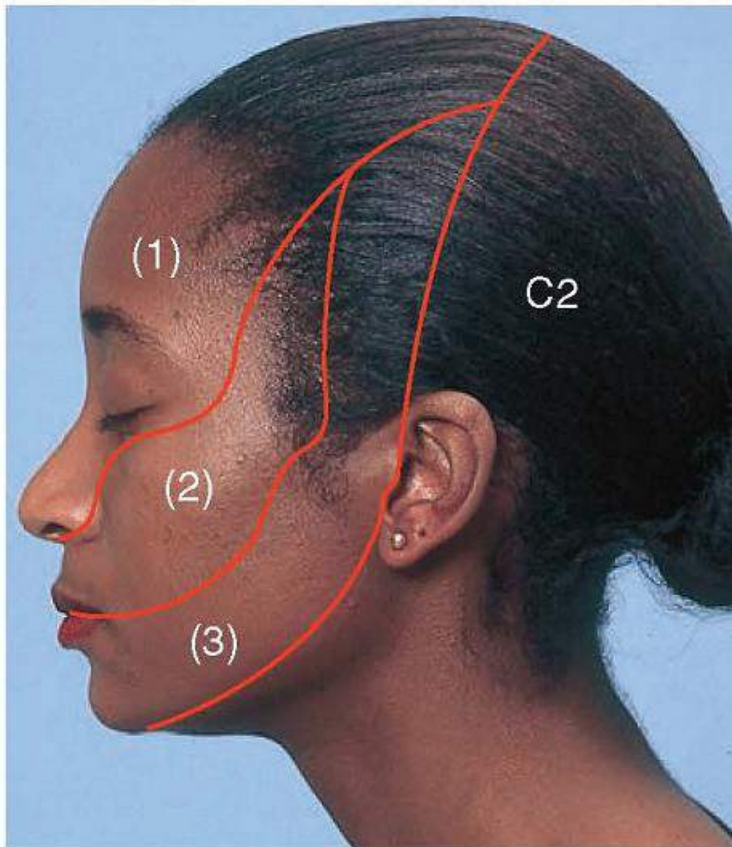

FIGURE 3.7 Dermatomes of the face and head. (1), (2), and (3) correspond to divisions of the trigeminal nerve. (From Bickley L. *Bates' Guide to Physical Examination and History-Taking*. 11th ed. Philadelphia: Wolters Kluwer Health Lippincott Williams & Wilkins; 2013.)

The fifth nerve also controls the muscles of mastication including the masseter and temporalis. Demonstrating weakness of these muscles may be identified through gross testing of the jaw opening and closure but rarely identified on exam outside of severe muscular weakness. Palpation of a tender temporomandibular joint or identifying crepitus may be useful in assessing a patient with headaches; this may be done by palpating the joint while the patient opens and closes the jaw.

Cranial Nerve VII (Facial Nerve)

The goal of testing the seventh nerve is to identify specific patterns of weakness which may be evident at rest, volitional action, or through unintentional means such as laughter. Although many examiners tend to jump to specific movements to demonstrate either segmental or unilateral weakness of the face, one of the most effective means of identifying facial weakness is through simple inspection, including critical appraisal during the interview. Flattened nasolabial folds will be extinguished by forced movements but may reveal low tone as a presenting sign in acute ischemic stroke or even Bell palsy. Specific facial movements that should be tested include brow raising, forced eye closure including assessment of “burying the eyelashes,” smiling, pursing the lips, and puffing the cheeks. Although patients may be able to demonstrate these functions on their own, assessment of force can be made by

the examiner by pulling on any of the muscles being tested one side against the other.

Testing for unilateral loss of taste perception may be helpful in assessing the localization of a Bell palsy. To test for taste, take a commonly perceived recognizable flavor, such as salt or sugar, which are also conveniently typically on hand in most physician office practices or hospital-based settings. Place a small amount of this into a small cup with water and stir with a cotton-tipped applicator. With

the patient's eyes closed and tongue protruded, attempt to paint the salty or sweet solution on the side of suspected facial paresis. The patient should be instructed not to draw his or her tongue into the mouth until asked whether or not he or she can taste the applied mixture. Upon demonstration or confirmation that no taste is perceived, the patient is then allowed to draw the tongue into the mouth and swirl around the fluid, and presumably, the taste will be perceived by the normal, contralateral side of the tongue unaffected by the facial paresis.

Cranial Nerve VIII (Vestibulocochlear Nerve)

The bedside examination of the CN VIII typically focuses on hearing but may include additional testing for the patient complaining of dizziness. Testing for hearing includes relatively crude screening measures to be done at the bedside beginning with perceptions of hearing grossly as simply assessed through the interview by the examiner's vocal volume required. Additional tests include using the 512 Hz (or similarly high tone) tuning fork for the Weber test for lateralized hearing loss (Fig. 3.8) and the Rinne test to identify the typical perception of air conduction being longer than bone conduction of sound (Fig. 3.9).

Additional tests include whispering a number into the patient's ear to be then repeated by the patient, or audible hand movements including lightly rubbing the fingertips, escalating to flicking the fingernail, and then snapping. Clearly, such testing cannot supplant more formal audiography. For the severely hearing impaired, history development and examination may be aided by placing the stethoscope earbuds into the patient's ears, with the examiner speaking into the diaphragm.

Vestibular testing in the dizzy patient should focus on attempting to identify central versus peripheral localizations of vertigo. Specific tests to apply to any such patient include the Dix-Hallpike maneuver, head impulse nystagmus test, and the Fukuda marching test, all of which will help to distinguish localization.

FIGURE 3.8 Weber hearing testing for lateralization of hearing. (From Bickley L. *Bates' Guide to Physical Examination and History-Taking*. 11th ed. Philadelphia: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

FIGURE 3.9 Rinne hearing testing for air > bone conduction. **A:** Bone conduction; once sound extinguishes. **B:** Air conduction is tested. (From Bickley L. *Bates' Guide to Physical Examination and History-Taking*. 11th ed. Philadelphia: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

The Lower Cranial Nerves Involved in Speech (IX [Glossopharyngeal Nerve], X [Vagus Nerve], and XII [Hypoglossal Nerve])

Speech, or the articulation of language, can be very helpful in localizing a neurologic disorder. [Table 3.3](#) reviews phonemes of speech and typical neurologic localization. The patient should be asked to speak each of these phonemes with particular attention paid to whether a singular or grossly abnormal speech pattern evident.

Additional testing includes asking the patient to open his or her mouth to assess symmetry in raising the palate ([Fig. 3.10](#)), assessment of phonation for vagal nerve abnormalities, and protrusion of the tongue in one direction or another to suggest hypoglossal dysfunction.

TABLE 3.3 Phonemes Tested for Patterns of Dysarthria

Phoneme	Neurologic Localization
Labial sounds: “ma,” “pa”	CN VII
Pharyngeal/guttural sounds: “ga” and “ka”	CN IX, X
Lingual sounds: “la,” “ta”	CN XII
Bland dysarthria (all sounds similarly involved)	Corticobulbar tracts to subcortical

Additional Speech Patterns

Scanning or “metronomic” speech	Cerebellar
Dysphonic (hoarse) voice	CN X

CN, cranial nerve.

Of note, a patient with a seventh nerve paresis may give the false impression of having an ipsilateral hypoglossal dysfunction simply because of the formation of the shape of the mouth. Thus, in patients with facial nerve weakness having tongue protrusion tested, the examiner should begin by forcibly opening the mouth in a symmetric fashion such that the tongue is allowed to exit the mouth in an unobstructed manner.

Cranial Nerve XI (Accessory Nerve)

The spinal accessory nerve has two principal functions including shoulder shrug by the trapezius muscle and head turning by the sternocleidomastoid muscles. Forcibly testing each of these movements may be of lower yield than simply observing shoulder shrug, which may demonstrate either low tone or slow or clumsy movement in a patient presenting with hemiparesis. Although frequently tested and included in neurologic examinations, head turning and shoulder shrug may only rarely be focally affected and thus infrequently provides additional information to the examination above and beyond the history and other findings on examination.

FIGURE 3.10 Examination of palate/uvula elevation to command. Weakness on the right leads to a deviation of the uvula to the left (unaffected side). (From Bickley L. *Bates' Guide to Physical Examination and History-Taking*. 11th ed. Philadelphia: Wolters Kluwer Health Lippincott Williams & Wilkins; 2013.)

MOTOR EXAMINATION

The motor examination has several principal components, including inspection, palpation, tone, power, and drift testing and other tests for identifying subtle lateralized motor deficit.

Inspection is an essential element of the neurologic examination particularly for a patient being assessed for the first time. Relatively straightforward diagnoses are often missed by failing to place the patient into a gown. Inspection may identify focal or global patterns of atrophy, fasciculations, or rashes which may be germane to muscular disorders. In determining the presence of fasciculations, it is often necessary to use a tangential light or observe subtle movements in the muscles affecting the overlying hair. Palpation of the muscles is indicated in a patient presenting with weakness or chronic pain, seeking to identify trigger points, but may be additionally helpful in other conditions, such as chronic low back pain in discerning musculoskeletal from neurogenic pain.

Tremor may also be identified to casual inspection or more formally during strength, tone, and coordination testing. Tremor should be described in each limb using the following features: its relative frequency (fast vs. slow), context in which it appears (with action [including specific actions if relevant], rest, posture, or multiple contexts), the consistency with which it appears during the examination (how frequently it is present), the severity of the movements (ranging from mild to disabling), and the quality of the movements themselves (ranging from sinusoidal and monotonous to irregular and chaotic or myoclonic).

Of all the components of the neurologic examination, muscle tone testing is one that requires particular attention to nuance and is learned principally through practice when working alongside a skilled examiner. Tone of the neck, arms, and legs should be assessed in all patients. Tone testing begins by moving a limb through several planes of motion simultaneously to prevent the patient from either contributing or diminishing tone in a volitional manner. To facilitate tone, the patient should be instructed to perform distracting tasks, such as contralateral movements, or even a complex arithmetic question, simply to further diminish the influence of volitional control of tone. Tone abnormalities may be static (rigidity), velocity-dependent with a sudden release at high speeds and extremes of joint flexion/extension (spasticity), or velocity-dependent without sudden changes (paratonia or *gegenhalten* — “holding against”).

Drift testing is an essential component of the motor examination because through its subtle nature, it may be one of the few highly reliable and easily identifiable findings in the early presentation of hemiparesis such as may be seen with stroke. Drift testing is accomplished by having a patient either sitting or lying in bed, with hands outstretched before the patient, palms facing upward. With eyes closed for approximately 10 seconds, the patient's hand position should remain static. Pronation may be demonstrable but so may be an altitudinal drift such that the hand does not pronate but moves in either an upward or downward or even a variable vertical direction. Drift testing in the foot involves bringing the leg off the bed and an approximate 30 degrees angle and with the patient's eyes closed instructing them to maintain that position for approximately 10 seconds. Any drift including a drop of the leg backed onto the bed suggests a positive finding. Other tests that can be used to detect or confirm the presence of a subtle lateralized motor deficit include the arm roll test (in which the unaffected arm tends to “orbit” the affected, less mobile arm), and the finger tap test (with velocity and amplitude of the finger or toe taps reduced on the affected side).

Strength Rating	Description
5	Full power to confrontational testing by the examiner (normal)
4	The examiner is able to overcome the strength of the patient but near full strength remains
3	Sufficient strength to overcome gravity only
2	Flexion possible when out of the plane of gravity
1	Demonstration of muscle contraction but without any demonstrable joint movement
0	No appreciable movement

Motor strength examination, or power testing, is often focally pursued by trainees while dropping other essential elements of the motor examination. In each patient, power testing must be considered in the context of other principal motor components. The score to evaluate all motor examination findings (0 to 5) has been modified over time and may be idiosyncratically applied by differing examiners. The scale often leaves the neurologist to adjust findings using subtleties in the scale such as +/- symbols rather than just relying on numbers as the scale suggests. The definitions of each strength value are listed in [Table 3.4](#).

Several essential elements of the motor examination include testing a single muscle side to side rather than testing an entire side of the patient compared with the other. A direct comparison of each muscle or joint side to side allows for a far more instructive examination and allows subtle asymmetries to be revealed. Correct positioning of the patient and examiner is essential in order to accurately interpret strength. Whenever possible, the examiner's body position should mimic the patient. Muscles being tested for strength should always be at mid position ([Fig. 3.11](#)), as at extremes of the joint position may convey inaccurate perception of superb strength or frank weakness. Other references are suggested as an additional guideline for testing each muscle group in a comprehensive manner, which is beyond the scope of this review.

FIGURE 3.11 Testing strength. The example of biceps brachialis strength testing is provided to demonstrate the importance of (1) isolation of the muscle being tested, (2) testing force at mid position, and (3) the examiner's own arm similarly positioned to the patient. (From Bickley L. *Bates' Guide to Physical Examination and History-Taking*. 11th ed. Philadelphia: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

Additional components of the strength examination may also include an assessment of fatigability as may be seen with myasthenia gravis, or facilitation as may be seen with the Lambert-Eaton myasthenic syndrome. Fatigability may be assessed by having a patient hold up his or her arms aloft for approximately 30 seconds and assess for fatigability when myasthenia is suspected. In contrast, facilitation may be elicited by having a patient's strength tested before and after sustained contraction (e.g. sustained biceps contraction).

Coordination

The coordination examination is used to principally identify abnormalities grossly associated with ataxia and cerebellar dysfunction. Cerebellar examination techniques include assessments of appendicular and axial functions. Appendicular coordination may be demonstrated by asking the patient to extend a pointed index finger to a target provided as far away from the patient as possible, followed by touching a near target such as the nose or chin (preferable for an obviously ataxic patient given the risk for eye injury). Axial coordination may be assessed using a heel-to-shin test, in which the patient places the heel of one foot against the shin of the opposite leg, with it moved vertically several times. Tests of coordination additionally include rapid movements such as finger taps (or more finely demonstrated as an index finger tapping on the thumb interphalangeal joint), rapid alternating movements (flipping the hand over, opening/closing the hand), and heel/toe tapping. These tasks are also essential in patients with suspected movement disorders. Additional coordination testing is comprised within the gait examination listed in the following section.

Gait, Station, and Body Movements

Observation of a patient's gait and station may be the first and importantly impressionistic examination done in the course of a visit as the patient enters from the waiting room, but also the last done as part of a formal examination. The assessment begins with watching casual gait, assessing for stride length and speed, and lateralizing findings such as a shoulder droop, asymmetric arm swing, or leg circumduction, followed by tandem gait, as well as assessments of balance on individual feet if indicated by the clinical context. Special attention should also be given to ability to stand, quality of turns (en bloc or with appropriate, distinct steps), and passage through

P.24

thresholds (doorways). Romberg testing and assessment of postural stability (pull testing) are additional essential exam elements. The Romberg test is performed by having the patient stand feet together, arms outstretched, followed by eye closure once the examiner is able to determine no postural sway, which could be due to other causes such as cerebellar disease. Once eyes are closed, a tendency to sway or fall is indicative of either a defect in vestibular or proprioceptive function. The pull test, which evaluates postural stability, is performed by having the examiner stand behind the patient pulling suddenly backward on the shoulders. In a normal response, the patient makes a quick corrective step to maintain balance. An abnormal response is characteristic of parkinsonism and other diseases that affect postural stability. Toe walking assesses gastrocnemius strength as much as it does test balance, although this may be distinguished when the examiner offers a steady hand.

Deep Tendon and Other Motor Reflexes

As is the case for motor examination, several essential elements allow for accurate interpretation of the deep tendon reflexes. These include correct positioning of the patient and assessing reflexes for subtle

asymmetry. Histories have been written about the various neurologic reflex hammers, and most neurologists have their favorite type. Trainees should identify and use a hammer of heavy mass which allows for consistent low-velocity strike to consistently test the deep tendon reflex, as opposed to a low-mass, high-velocity strike which may be more likely to injure the examiner than elicit the actual response intended.

As is the case for muscle testing, other resources are suggested to identify the optimal locations in which to strike the tendon of each respective deep tendon reflex, but several principal ones are provided in [Table 3.5](#).

TABLE 3.6 Deep Tendon Reflex Assessment Scale

4	Pathologic; with sustained clonus elicited and typically light percussion to elicit brisk reflexes
3	Usually pathologic; several beats of clonus or spread to adjacent ipsilateral muscle group or same group tested contralaterally are evident
2	Normal reflex; may have a brisk upstroke but without pathologic features
1	Hyporeflexic; contraction of the muscle as expected but insufficient force to move the joint
0	Hyporeflexic; no movement of the muscle or joint

Trainees are encouraged to test for biceps brachialis, brachioradialis, triceps, patellar, crossed adduction in the legs, and ankle jerks on all newly assessed patients. Finger flexion (Hoffman sign) and plantar scratch response (“Babinski sign” when positive) should be routinely assessed. Additional tests of the tendon reflex including jaw, shoulder, abdominal scratch, and deep abdominal reflexes may be relevant and pursued in the appropriate context ([Table 3.6](#)).

Frontal release signs, including snout, glabellar (Meyerson sign), and palmomental signs, are commonly included in neurologic examinations but are of questionable sensitivity and specificity. These are not true reflexes but are instead thought to represent loss of normal cortical circuitry which ordinarily inhibits these “primitive” adaptive responses and can be seen in a host of neurologic disorders including stroke, trauma, and degenerative disease.

SENSORY EXAMINATION

Similar to guidelines suggested in trigeminal nerve assessment, the approach of these sensory examination is intended to identify the nerve fiber type and tract involved, as based on the tested modality. Additionally, patterns of deficit are a principal goal of sensory examination, including laterality, dermatomal distribution (both radicular and peripheral dermatomal patterns), possible spinal level, and determination of a distal or proximal pattern of abnormality ([Fig. 3.12](#)). Each domain should be assessed with these in mind.

Essential components of the sensory examination include assessment of light touch (using a cotton-tipped applicator or fine gauze), pinprick (using disposable implement such as a safety pin or a broken wood handle of a cotton-tipped applicator), temperature (actually heat conduction of a metal damper on a low-frequency tuning fork), vibratory sensation, and joint position sense.

One of the great challenges of the sensory examination is determining objective measures within a largely subjective examination. Of all of the modalities included, only joint position sense is truly objective nature. Patients either do not perceive (totally anesthetic), occasionally misperceive (partially anesthetic patient), or exactly misperceive (somatoform presentation) the stimulus.

Light touch, pinprick, and temperature sensations are all assessed in a relatively similar manner by asking the patient whether or not they perceive the intended stimulus. An appropriate reference point may be to provide the stimulus to the cheek (for light touch, temperature, and pin prick sensation) or finger (for vibration) followed by the area being tested and asking the patient to assess whether they are equivalent. Although percentages of difference may be appropriate to determine the nature deficit, other analogies proportions may be more understandable such as considerations of money (\$1.00 v 10c in lieu of percentages).

Vibration sense is crudely assessed by using a 128-Hz tuning fork struck and then with its base applied to the distal most bony prominence available on a patient's limb, such as the interphalangeal joint of the great toe or the tip of the finger (Fig. 3.13). The patient is then asked to assess the presence and persistence of the vibratory stimulus until it is no longer perceived, at which time it may then be applied to the more proximal limb, such as moving from the toes to the finger and asking if the stimulus is still perceived. Two control conditions are established—one within the patient as well as the examiner presuming vibratory sensory function is normal in the examiner.

Joint position sense is performed by having the examiner touch the lateral aspects of the distal interphalangeal joint and asking the patient to close his or her eyes (Fig. 3.14). Using the smallest excursion possible, the patient is asked to perceive the movement (either up or down). The examiner should be careful to record the responses in a patient incorrectly identifying the position change, as consistently wrong answers may suggest a feigned response.

As is the case with vibratory sensory testing, assessment of the patient's sensation should begin with the most distal position and then moved proximally.

Higher order cognitive sensory testing should be included in patients with suspected cognitive impairment but can only be fully interpreted when performed in limbs/hand unaffected by primary sensory loss. These tests are myriad but commonly include assessment of graphesthesia (by drawing a number or letter on a patient's palm while eyes are closed; several training trials may be required), stereognosis (placing a single or similar objects within the palm of the patient such as paperclip/key or various familiar coins), and assessment of perception of simultaneously applied bilateral stimuli (by touching both hands after assessment of primary sensory function).

ADDITIONAL NEUROLOGIC TESTS FOR SPECIAL CONDITIONS

Dix-Hallpike Maneuver

The Dix-Hallpike maneuver is useful to apply to a patient with suspected benign paroxysmal positional vertigo (or a similar vertiginous syndrome) who is actively or very recently affected. Patients in a quiescent period will most likely be asymptomatic and have no demonstrable signs on examination. As demonstrated in the Figure 3.15, the patient begins seated with the head turned about 45 degrees in a single direction. The patient is then positioned supine with the head slightly extended (either hanging off the exam table or supported by the examiner's arm beneath the shoulder). With the patient's eyes open, looking at the

examiner's face, the expected positive test will reveal a 5- to 10-second delay in onset of rotatory nystagmus and recapitulation of symptoms. These should resolve after 10 to 30 seconds. A brief vertical nystagmus phase may occur upon sitting. In most cases, the finding should be unilateral and serves as the first step of the Epley maneuver.

The Head Impulse Test

One of the newest bedside diagnostic tests may be better at identifying some brain stem strokes than diffusion-weighted imaging. One component of the head impulse-nystagmus test of skew (HINTS) is the head impulse test. The test can only be applied and appropriately interpreted in a patient acutely symptomatic with

P.26

vertigo or a suspected related disorder (i.e., cerebellar dysfunction). As demonstrated in the [Figure 3.16](#), the examiner rotates the patient's head about 30 degrees off mid position. With the patient's gaze fixated on the examiner's face, the head is rapidly rotated to midposition. If a catch-up saccade is repeatedly identified, particularly unilaterally, a peripheral vestibular etiology is suggested but must be interpreted in the context of other neurologic examination findings, as ischemic vestibular mimics do occur.

FIGURE 3.12 Dermatome maps. (From Bickley L. *Bates' Guide to Physical Examination and History-Taking*. 11th ed. Philadelphia: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

Phalen and Tinel Signs

When considering the diagnosis of carpal tunnel syndrome, in addition to inspection of the hand and assessment of weakness of the opponens, two additional tests can be helpful. The Tinel sign (Fig. 3.17A) involves percussing the course of the median nerve across the wrist, whereas the Phalen sign (Fig. 3.17B) involves keeping a sustained position of flexed wrists. Both the Phalen and Tinel signs seek to recapitulate the patient's specific neurologic syndrome and not simply discomfort. A Tinel sign can also be identified anywhere a suspected focal neural compression may have occurred, such as across the olecranon or the fibular head.

Straight Leg Raise

The straight leg raise test is used in the context of diagnosing sciatica. As demonstrated in the Figure 3.18 with the patient lying down, the heel of the ipsilateral (affected) leg is raised straight off the bed by the examiner to about 30 to 45 degrees; at its conclusion, the toe may be passively dorsiflexed.

A contralateral (crossed) straight leg raise test may be applied to the opposite leg, only if the affected leg has a positive finding; the contralateral test seeks to recapitulate the affected leg symptoms, still on the affected side. To be considered a positive sign, the patient should report the specific pain (typically lancinating) syndrome which led to the patient to seek attention. The ipsilateral test is highly sensitive but weakly specific, whereas the contralateral test is highly specific but weakly sensitive.

P.27

FIGURE 3.13 Vibration sensation testing. (From Bickley L. *Bates' Guide to Physical Examination and History-Taking*. 11th ed. Philadelphia: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

Additional Spinal Reflexes (Male Patients Only)

THE CREMASTERIC REFLEX

The cremasteric reflex tests for the L1-L2 reflex arc and may be considered as a localizing test finding when considering a patient with a lower spinal cord neurologic disorder or as confirmatory reflex examination in patients exhibiting evidence of reflex abnormalities in ipsilateral limb muscle groups. The response will be

absent in both central and peripheral neurologic disorders. It is performed by lightly stroking a slightly noxious tactile stimulus proximally along the inner aspect of the thigh (suggest a disposable item such as tongue depressor or hard end of a wooden swab stick). The testicle will normally rise ipsilaterally in conjunction with the applied scratch.

BULBOCAVERNOSUS REFLEX

The bulbocavernosus should be applied specifically to individuals suspected of experiencing acute spinal cord injury. The test involves two potential stimuli: (1) squeezing on the glans penis or clitoris or (2) gently tugging on a Foley catheter while monitoring for anal sphincter contraction; this can be done electrophysiologically or manually. The response will be lost in acute spinal shock.

FIGURE 3.14 Joint position sense testing. (From Bickley L. *Bates' Guide to Physical Examination and History-Taking*. 11th ed. Philadelphia: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

FIGURE 3.15 Dix-Hallpike maneuver. 1 and 2 correspond to the first and second positions of the maneuver. (From Fife TD, Iverson DJ, Lempert T, et al. Practice parameter: therapies for benign paroxysmal positional vertigo [an evidence-based review]: report of the Quality Standards Subcommittee of the American Academy of Neurology. *Neurology*. 2008;70:2067-2074.)

As is the case with any potentially sensitive element of physical examination, but particularly with these tests, given their involvement of examination of genitalia, inclusion of an examination chaperone, particularly one of the same gender as the patient, should be included in all such examinations.

Tests of Malingering

Myriad tests have been proposed to potentially identify patients with embellished, feigned, or malingered signs. Of those which have been studied to identify their sensitivity and specificity, most are imperfect. However, as detailed earlier, when findings are identified in the context of others on the neurologic examination, some of these additional tests can be useful in the appropriate context. Whenever considering applying these tests, it is most important to do so tactfully, as both the act of applying and interpreting the findings takes a very skilled and advanced examiner to both appropriately perform and inform the patient about their findings with appropriate sensitivity and respect for the patient. Although some may consider these examination components potentially deceitful of the patient, they can be highly instructive, potentially avoid substantial evaluative cost and even morbidity (particularly when they may obviate invasive, unnecessary, or misleading diagnostic measures), and when appropriately disclosed, potentially highly therapeutic. The following are several techniques that can be particularly useful on examination.

P.28

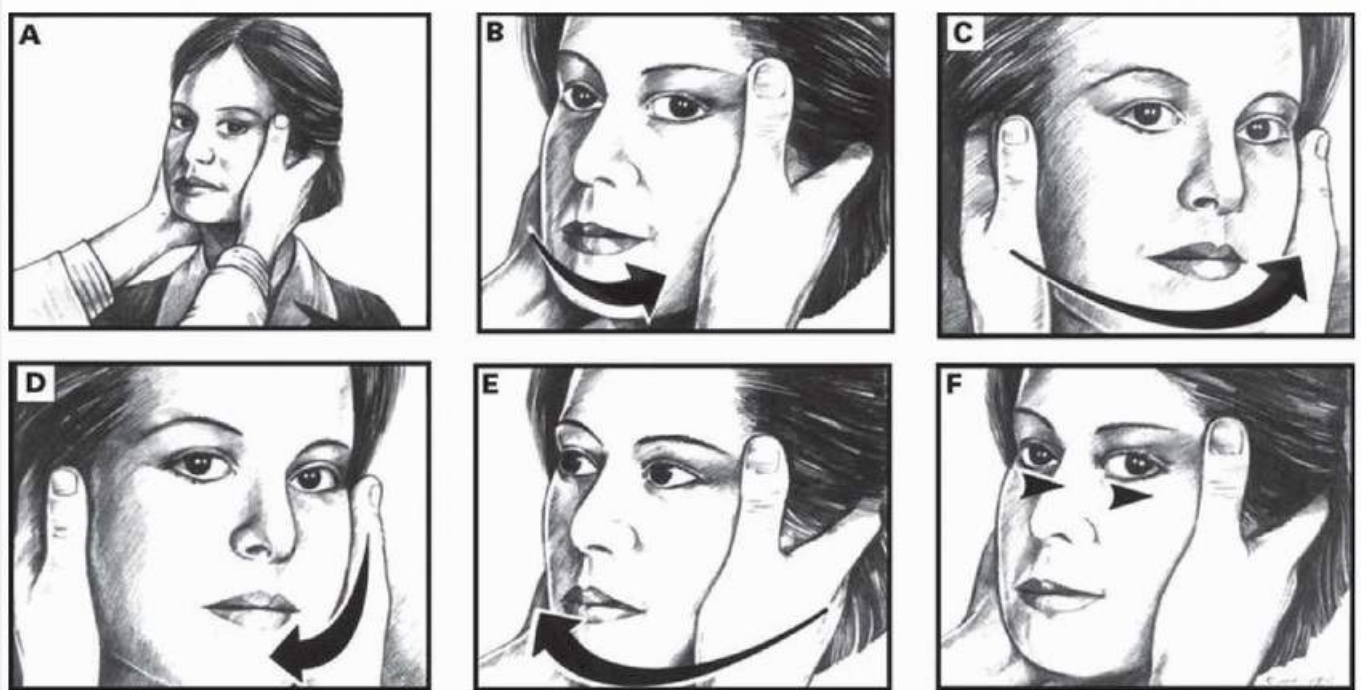

FIGURE 3.16 Head impulse test. With the patient fixated on a distant target, the examiner rapidly turns the head from 15 degrees to the right to 15 degrees to the left (**A-C**), with normally maintained fixation demonstrated. Testing in the opposite direction, **D-F** illustrate a right peripheral vestibular lesion with a severe loss of right lateral semicircular canal function and no vestibulo-ocular reflex as demonstrated by loss of fixation (**E**) followed by a voluntary corrective saccade (**F**). (From Halmagyi GM, Cremer PD. Assessment and treatment of dizziness. *J Neurol Neurosurg Psychiatry*. 2000;68:129-134.)

HOOVER SIGN

This test is used to identify feigned unilateral leg weakness. Following assessment of the normal leg, with

the patient lying down supine, the examiner places their hand beneath the heel of the normal leg and asks the patient to raise the left leg. Normally, a patient attempting to raise the affected leg should depress the normal leg toward the examination surface, with the force felt by the examiner. Caution in its interpretation should be raised in the patient with evidence of dyspraxia or delayed responses.

HEAD VIBRATORY HEMIANESTHESIA

Patients with psychogenic examinations may have hemianesthesia affecting the entire body including the face, often to all modalities

P.29

tested. Vibratory sensation in the head is likely principally or at least partially perceived by transmitted signal to the neck and to a lesser extent the head. Several methods to identify feigned from true facial hemianesthesia using vibratory sensation have been proposed. One approach involves, with the patient's eyes open, placing a 128-Hz tuning fork centrally above the brow, visible to the patient. While keeping the base position of the fork static, tilt the fork toward the affected (anesthetic) side followed by a tilt to the normal side. Record the patient's responses. Repeat the measure, out of sequence, with the eyes closed to discern an exam discrepancy.

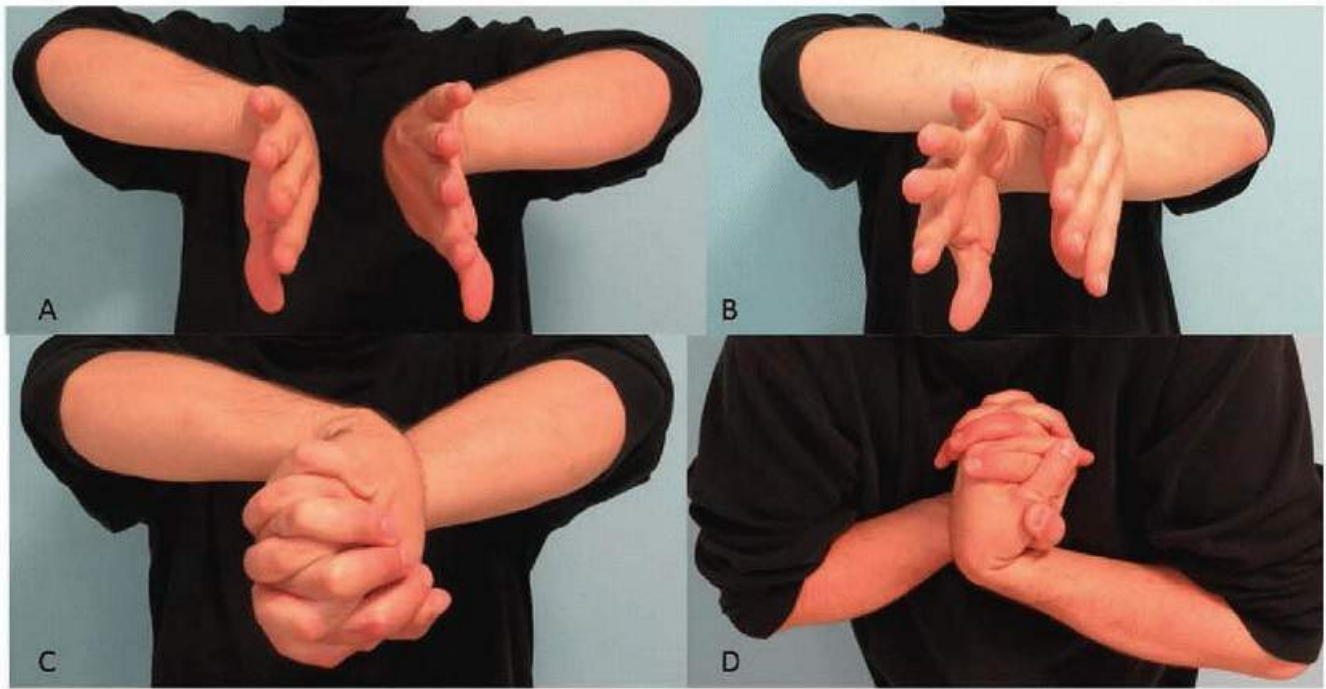

FIGURE 3.19 Bowlus and Currier test. Sequence of the Bowlus and Currier test, followed **A**, **B**, **C**, then **D**. Pinprick sensory testing is performed using a normal approach, comparing the left and right hand at baseline. When a nonphysiologic sensory examination is suspected, instruct the patient to position the hands in to that shown in **D**. Sensory testing is repeated quickly to identify discrepancies in examination. (Photos by James M. Noble, MD.)

BODY HEMIANESTHESIA

The Bowlus and Currier test (Fig. 3.19) can be a useful approach in distinguishing the patient with psychogenic hemianesthesia. As shown in the figures, the patient begins by pointing the thumbs down with the arms outstretched before them. Then the right wrist is crossed over the left and fingers are then interdigitated and flexed. Keeping the fingers locked together, the elbows are flexed, and the forearms supinated such that the hands are nearly at the patient's chin, thumbs pointing upward. Quickly thereafter, the examiner tests pinprick sensation on the knuckles of either hand, seeking not only for consistency but also for the rapidity with which the patient provides the answer. Substantial hesitation or inconsistency with primary sensory examination supports a feigned neurologic examination.

ACKNOWLEDGMENT

Dr. Noble would like to acknowledge the contributions of Drs. John Brust and Blair Ford in developing this approach to the neurologic examination.

Dizziness, Vertigo, and Hearing Loss

J. Kirk Roberts

INTRODUCTION

Dizziness is an imprecise term used to describe a variety of symptoms including but not limited to vertigo, light-headedness, faintness, giddiness, disequilibrium, confusion, etc. It affects nearly one quarter of the general population and is a common complaint in the emergency room and in the office of the neurologist, otolaryngologist, and internist. The causes of dizziness are varied, span across medical subspecialties, and range from the relatively benign to life threatening. The evaluation of dizziness is made more difficult by the fact that the symptom is difficult for the patient to describe. A first step is an attempt to categorize dizziness into vertigo, presyncope, disequilibrium, and other or nonspecific dizziness as noted in [Table 4.1](#).

Vertigo is an illusion of motion, either the environment or the self, most commonly rotatory but may be translational or tilting. *Presyncope* is the sensation encountered before loss of consciousness and is discussed in Chapter 5. *Dysequilibrium* is not a sensation of motion but a feeling of imbalance or unsteadiness and is discussed in Chapter 14. Other or nonspecific dizziness include those whose symptoms do not easily fit into one of the aforementioned categories or fall into more than one category. Rather than using the qualitative description of dizziness to categorize the subtype, it is often more helpful to use characteristics such as onset, duration, triggers, history of prior episodes, and associated symptoms in evaluating these patients.

TABLE 4.1 Dizziness Subtypes

	Vertigo	Presyncope	Disequilibrium	Nonspecific Dizziness
Symptom description	Illusion of motion, imbalance	Going to pass out, faint	Imbalance, unsteady, symptoms not in the head	Light-headed, foggy, floating
Onset	Usually sudden	Usually sudden	Sudden to slow	Poorly defined
Duration	Seconds to hours	Seconds to minutes	Acute to chronic	Subacute to chronic
Triggers	Head motion, position change	Orthostatic maneuvers, urination, cough, dehydration	Standing or walking, not when sitting or lying	Stress, situational, nonspecific
History	None or episodes	None or episodes	Chronic	Chronic

Associated symptoms	Nausea, ear symptoms (hearing loss, tinnitus), brain stem symptoms (diplopia, slurring, numbness, weakness, incoordination, ataxia)	Graying vision, warmth, diaphoresis, nausea, palpitations, chest pain	Slurring, incoordination	Many
----------------------------	---	---	--------------------------	------

VERTIGO

NEUROANATOMY

Vertigo primarily results from disorders of the vestibular system, which includes the vestibular labyrinth, vestibular nerve, vestibular nuclei in the brain stem, vestibular portions of the cerebellum, connections between these structures, and only rarely higher in the cerebrum. The vestibular labyrinth, located in the temporal bones, is composed of the three orthogonally oriented semicircular canals (anterior, posterior, and lateral) and the vestibule, which contains the otolith organs, the utricle and saccule, which are also angled at approximately 90 degrees to each other. The former responds to angular acceleration and the latter to linear acceleration including translation or tilt. When the head is rotated, endolymphatic fluid in the semicircular canals lags behind, leading to a deflection of the gelatinous cupula within the canal, which activates or inhibits the firing of hair cells. Activation on one side is paired with inhibition in the complementary canal on the other. The otolith organs, the utricle and saccule, contain hair cells on which calcium carbonate crystals, the otoconia, rest. Translational motion or tilt (via gravity) will activate or inhibit these cells. From the vestibular labyrinth, neurons travel centrally through the vestibular portion of the eighth cranial nerve into the brain stem to the vestibular nuclei and then project on to the cerebellum, ocular motor nuclei, spinal cord, and, via some less well understood pathways, to the

P.31

cerebrum. Integration of the combinations of activations and inhibitions of the various components of the vestibular system of both ears, along with visual input and proprioceptive input, detects motion, rotation, translation, and tilt and affects eye movements and posture.

TABLE 4.2 Peripheral versus Central Vertigo

	Peripheral	Central
Nausea/vomiting	Severe	Mild/moderate
Imbalance	Mild/moderate	Severe
Ear symptoms (hearing loss, tinnitus, pain)	Common	Rare
Other neurologic symptoms	Rare	Common

Vertigo can result from disorders of the peripheral vestibular system (labyrinth or nerve) or central vestibular system (brain stem, cerebellum, connections, and rarely, cerebrum) and this localization is the natural next step in the evaluation of vertigo. [Table 4.2](#) lists some differentiating features.

MANAGEMENT STRATEGY

In the patient with the acute first presentation of vertigo, the most significant concern is evaluating for stroke (ischemic or hemorrhagic) and differentiating from vestibular neuritis. A history of vascular risk factors and other neurologic symptoms, headache, and complaints related to the brain stem is particularly important. However, the lack of those symptoms does not exclude an ischemic etiology. Patients presenting with isolated vertigo have a threefold increased risk of stroke compared to the general population that increases with the presence of multiple vascular risk factors. In the patient presenting with recurrent attacks of vertigo, the major differential includes benign positional paroxysmal vertigo (BPPV), Ménière syndrome, and migraines. Vertebral artery compression from neck rotation is a very rare case of episodic dizziness or vertigo.

FOCUSED HISTORY

Loss of vestibular function affects eye movements and image stabilization, balance, and spatial orientation. In addition to vertigo, patients may feel tilted, the world jiggling while walking (oscillopsia), spatially disoriented, imbalanced, and rarely, suffer from drop attacks, where they may feel pulled or pushed to the ground. These drop attacks, known as *Tumarkin crises*, are most commonly seen in Ménière syndrome but also may occur in other vestibular conditions.

FOCUSED EXAMINATION

The examination of the patient with vertigo includes all components of the neurologic examination with special attention to certain aspects. The ear must be examined and hearing must be tested. Examination of the eyes is particularly important. Start by observing for nystagmus in primary gaze and with eye movements in all directions. Reobserve after removing the ability to fixate by the use of Frenzel lenses, goggles with magnifying lenses that allow you to see eye movements but does not allow the patient to fixate. If Frenzel lenses are unavailable, fixation can be eliminated during ophthalmoscopic examination of one eye by covering the eye not being examined with your free hand and observing for nystagmus of the optic disc. Remember that this movement is in the opposite direction of the movement of the front of the eye. Pay attention to the type of motion (horizontal, vertical, torsional, mixed), the effect of fixation, and the effect of gaze. Pendular nystagmus is sinusoidal, whereas jerk nystagmus, the more commonly observed nystagmus, is composed of slow drift in one direction and a rapid correction back. It is caused by an imbalance in vestibular input, either peripheral or central. Characteristics of peripheral versus central jerk nystagmus are listed in [Table 4.3](#). Jerk nystagmus is named for the direction of the fast phase and can be further categorized by its trajectory and the conditions under which it is seen. Some particular forms of nystagmus and their relevance are listed in [Table 4.4](#).

TABLE 4.3 Peripheral versus Central Nystagmus

	Peripheral	Central
Appearance	Combined torsional, horizontal, and vertical Nystagmus beats away from the affected side.	Often pure vertical, horizontal, or torsional; any trajectory
Fixation	Inhibits	No effect
Gaze	Obeys Alexander law (nystagmus increase when looking toward the side of the fast phase)	May change direction, does not obey Alexander law

In addition to nystagmus, unilateral peripheral vestibular dysfunction leads to a subtle skew deviation of vertical eye position with the ipsilateral eye lower in the orbit relative to the contralateral eye and conjugate torsion of the eyes to the ipsilateral side. In addition to the ocular motor findings, the patient usually has a small head roll or tilt to the affected side and a tendency to fall toward the same side. They may perceive vertical to be slightly tilted. Testing for past pointing will reveal deviation to the ipsilateral side. Tandem gait and Romberg will be impaired but are not specific. The Fukuda step test, marching in place with the eyes closed, will show deviation toward the side of the vestibular lesion.

Head Impulse Test

The head thrust or head impulse test evaluates for loss of vestibular input from either the vestibular labyrinth or vestibular nerve to the vestibulo-ocular reflex. It is performed (Fig. 4.1) by asking the patient to focus on a target in front of him or her. The head is then rapidly rotated a small amount (approximately 15 degrees). In normal circumstances, the eyes remain focused on the target. A vestibular lesion on the side to which the patient is being rotated will lead to a loss of fixation and the eyes will turn with the head and require a saccade to refixate. The input from the horizontal canal is most commonly tested by rotating the head in the horizontal plane. The other canals may also be tested by rotating the head along the plane of the canal in question. The head impulse test is generally normal in those with central causes of vertigo. In patients presenting with an acute vestibular syndrome, the use of the head impulse test along with the evaluation of nystagmus and the presence of skew can be used to distinguish an acute peripheral vestibular lesion from an acute central lesion such as cerebral infarct with more accuracy than magnetic resonance imaging (MRI). Dynamic visual acuity also

P.32

evaluates this reflex. It is performed by testing vision while stationary and then while shaking the head at approximately 2 Hz. Most can read no more than two to four lines worse on the eye chart with normal function of at least one labyrinth.

TABLE 4.4 Subtypes of Nystagmus

Jerk Nystagmus
Gaze-evoked: nystagmus at the extremes of gaze beating in the direction of gaze
Physiologic: fine nystagmus, usually fatigues
Drug/medication: often seen with sedatives and anticonvulsants
Brain stem/cerebellar lesions: may be sustained
Rebound nystagmus: After looking eccentrically for approximately 1 min on return to primary gaze, there is nystagmus beating in the other direction associated with brain stem or cerebellar lesions.
Bruns nystagmus: Slow, large-amplitude nystagmus in one direction and rapid, small-amplitude nystagmus in the other direction suggest a cerebellopontine angle lesion on the side of the slow, large-amplitude nystagmus.

Horizontal Nystagmus

Peripheral nystagmus: Nystagmus only beats in one direction, away from the affected side, obeys Alexander law, usually mixed with torsion, and inhibited by fixation.

Central nystagmus: Nystagmus may change directions, may be purely horizontal, does not obey Alexander law, and fixation does not inhibit.

Periodic alternating nystagmus: nystagmus alternating directions every 1-2 min associated with lesions at the cervicomedullary junction or in the cerebellum

Dissociated nystagmus: nystagmus differing between the eyes seen with internuclear ophthalmoplegia or mimicked by myasthenia gravis

Downbeat nystagmus: Nystagmus usually increases on down and lateral gaze seen with involvement of the dorsal medulla or the cerebellar flocculus or projections associated with lesions at the cervicomedullary junction, medications (lithium, carbamazepine, phenytoin), alcohol, hypomagnesemia, thiamine deficiency, paraneoplastic syndromes, cerebellar degenerations, and other.

Upbeat nystagmus: associated with brain stem and cerebellar lesions, most commonly the medulla

Congenital nystagmus: often a mixture of jerk and pendular nystagmus

Convergence-retraction nystagmus: part of Parinaud dorsal midbrain syndrome, convergence and retraction of the eyes

Positional nystagmus: seen with specific head motions and will be discussed more in the following text

Pendular Nystagmus

Acquired: seen with brain stem and cerebellar lesions

Congenital: often a mixture of jerk and pendular nystagmus

Spasmus nutans: infant onset; nystagmus is asymmetric and rapid, often associated with head nodding and head turning; usually resolves

Associated with visual loss

Seesaw nystagmus: opposite conjugate vertical and torsional movements associated with mesencephalic or parasellar lesions

Oculopalatal myoclonus: rhythmic 2-3-Hz movements seen late after lesion of Mollaret triangle

Oculomasticatory myorhythmia: rhythmic movements of eye convergence and contraction of masticatory or other muscles seen in 20% of patients with Whipple disease

Dix-Hallpike Maneuver

Positional maneuvers must also be performed to look for BPPV and this is discussed in more detail in Chapter 59. In this condition, vertigo is precipitated by characteristic head motions due to otolith debris loose in the semicircular canals, most commonly the posterior canal. To evaluate, the Dix-Hallpike maneuver (see [Fig. 3.15](#)) is performed by having the patient sit with the head turned 45 degrees to one side. The patient is then laid back into a supine position with the head extended 30 degrees and is observed for nystagmus for at least 30 seconds. A positive test will result in symptoms of vertigo after a few seconds, lasting up to a minute and the observer will see upbeating and rotatory nystagmus of the upper pole of the eye toward the ground. This response will fatigue with repeated maneuvers.

Less common horizontal canal BPPV might be revealed with horizontal nystagmus on Dix-Hallpike and is more reliably investigated with lateral head and body turns while supine. Anterior canal BPPV is quite rare. If the nystagmus is not characteristic for BPPV in terms of type, latency, and fatigability nystagmus, then a

P.33

central lesion must be considered. BPPV is best treated with repositioning maneuvers designed to “roll” the otolith debris out of the affected canal.

FIGURE 4.1 The head thrust test. (Modified from Barraclough K, Bronstein A. Vertigo. *BMJ*. 2009;339:b3493.)

Various causes along with characteristics of some of the causes of vertigo are listed in [Tables 4.5](#) (peripheral) and [4.6](#) (central). More details may be found in other chapters.

DIAGNOSIS

Diagnostic testing that is most useful in patients with vertigo includes comprehensive auditory examination to determine ear involvement especially with any complaints of hearing loss or tinnitus. Imaging is indicated when a central cause is under consideration and in other select cases. Computed tomography (CT) does not image the posterior fossa well and MRI is the imaging modality of choice. In the evaluation of superior canal dehiscence, CT better images the bony dehiscence that is the cause. Videonystagmography (VNG) or electronystagmography (ENG) is helpful if BBPV is considered, but nystagmus is not evident on clinical exam or if a unilateral vestibular lesion is suspected but not confirmed on clinical exam (see also [Chapter 28](#)). Rotational chair testing is also helpful in this circumstance and if bilateral vestibular dysfunction is suspected.

TREATMENT

The treatment of vertigo is primarily directed at the causes and is discussed in the appropriate chapters. Nonspecific treatments include antihistamines (meclizine, diphenhydramine, dimenhydrinate), anticholinergics (scopolamine, glycopyrrolate), and benzodiazepines (diazepam, lorazepam, alprazolam, clonazepam). Nausea and vomiting may also be treated with antiemetics. Vestibular rehabilitation is thought to benefit by promoting compensation, facilitating strategic substitution, limiting inactivity, and in the case of BPPV, repositioning otolith debris. There are some concerns that medications may interfere with rehabilitation.

TABLE 4.5 Causes of Peripheral Vertigo Causes of Peripheral Vertigo

Cause	Characteristics
BPPV	Brief, recurrent, positional nystagmus only in provoking position
Vestibular neuritis	Acute, single episode, viral prodrome
Ramsay Hunt syndrome (herpes zoster oticus)	Acute, single episode, vesicles in/near the ear, facial nerve palsy, deafness
Ménière syndrome	Recurrent, last minutes to hours, unilateral ear symptoms of fullness, hearing loss, tinnitus
Trauma	History of trauma
Perilymphatic fistula	Episodic, associated with Valsalva, loud sounds (Tullio phenomenon), history of trauma
Superior canal dehiscence	Episodic, associated with Valsalva, loud sounds
Cogan syndrome	Ménière-like syndrome with interstitial keratitis
Acoustic neuroma	Rare vertigo, more imbalance, unilateral hearing loss or tinnitus
Medications	Aminoglycoside exposure
Otitis	Evidence of otitis
Labyrinth ischemia	Presence of vascular risk factors, sudden vertigo, and hearing loss
Recurrent vestibulopathy	Recurrent attacks but without the ear symptoms to suggest Ménière

BPPV, benign positional paroxysmal vertigo.

TABLE 4.6 Causes of Central Vertigo Causes of Central Vertigo

Cause	Characteristics
Migraine-associated vertigo	Migraine history
Cerebral ischemia/hemorrhage	Vascular risk factors, other neurologic symptoms and signs, more prominent dysmetria or ataxia
Multiple sclerosis	History or presence of other neurologic symptoms or signs
Tumor	Presence of other neurologic symptoms or signs
Cranio cervical junction abnormalities (Arnold-Chiari, basilar impression, etc.)	Associated with headaches, neck pain, other lower cranial nerve involvement
Episodic ataxia type 2	Episodic vertigo and ataxia lasting hours to days
Cerebellar or spinocerebellar degenerations	More commonly ataxia and not vertigo
Mal de débarquement	After boat travel (or other), sensation of motion persists.

P.34

TABLE 4.7 Causes of Tinnitus

Pulsatile Tinnitus
Arteriovenous malformations/arteriovenous fistulas
Vascular stenosis/turbulence
Paragangliomas
Increased intracranial pressure
Jugular dehiscence

Tensor tympani or stapedius muscle spasm or myoclonus

Palatal spasm or myoclonus

Eustachian tube dysfunction

Nonpulsatile Tinnitus

Sensorineural hearing loss (age, toxicity, noise exposure, etc.)

Otosclerosis

Middle or inner ear trauma

Acoustic neuroma/cerebellopontine angle lesions

Temporomandibular joint dysfunction

Cranio cervical junction and cervical spine disorders

Medications

TINNITUS

Tinnitus is the perception of sound in the head when there is no external sound present. Disability may range from none to severe. Subjective tinnitus is heard only by the patient, whereas objective tinnitus is also heard by the examiner. Tinnitus can be classified into pulsatile and nonpulsatile tinnitus, with pulsatile tinnitus usually indicating a vascular etiology. [Table 4.7](#) lists various causes of tinnitus.

NEUROANATOMY

Most tinnitus is related to sensorineural hearing loss at the cochlear or cochlear nerve level and the tinnitus is thought to be generated in the central nervous system. Less commonly, tinnitus originates from structures in proximity to the ear, most commonly vascular structures.

FOCUSED HISTORY

One should inquire about the quality of the sound, whether it is episodic or constant, whether it is pulsatile or nonpulsatile, and precipitating and alleviating factors. Pay particular attention to a history of ear disease or trauma, hearing loss, noise exposure, headaches, and conditions that predispose to atherosclerosis such as hypertension, hypercholesterolemia, diabetes mellitus, and smoking. Tinnitus that is pulsatile or humming and changes with exercise or head motion raises more concern for a vascular etiology.

DIAGNOSIS

The ear and surrounding structures must be inspected; hearing must be tested; and one should listen for

bruits in the neck, over the skull, and over the eye. If a vascular etiology is suspected, further evaluation might include duplex Doppler, MRI without and with contrast, MR angiography, CT angiography, and in some cases, conventional angiography.

TREATMENT

The treatment of tinnitus from vascular abnormalities or from other nonaudiologic abnormalities are usually treated by treating the underlying condition. Patients with tinnitus thought to be related to disorders of the auditory systems should be referred for complete audiologic evaluation (CAE) and otolaryngology consultation. Unfortunately, the success of treatment of this type of tinnitus is marginal. Hearing aids may benefit patients with presbycusis. Behavioral therapies may help. The success of masking devices producing low-level sounds and electrical stimulation are unproven. Medication trials have largely been disappointing.

HEARING LOSS

Hearing loss is common. It is typically categorized as conductive, usually from a problem in the outer or middle ear, sensorineural, usually from a problem in the inner ear or the along the eighth cranial nerve, or mixed. It can be unilateral or bilateral.

FOCUSED HISTORY

The history should focus on the degree of hearing loss, time course, laterality, types of sounds affected, and precipitating factors, along with associated features such as tinnitus, vertigo, other cranial nerve abnormalities, headache, or other neurologic symptoms. Family history is important especially in those with onset at a younger age.

Outer and middle ear problems causing conductive hearing loss are listed in [Table 4.8](#), whereas inner ear and problems along the eighth cranial nerve causing sensorineural hearing loss are listed in [Table 4.9](#). Central nervous system causes of hearing loss are rare.

SUDDEN HEARING LOSS

The patient with sudden sensorineural hearing loss, usually unilateral, over 1 to 3 days is a particular subcategory of hearing loss.

P.35

The incidence is 5 to 20 per 100,000 people per year and is most common in the middle aged. The etiology in most cases is never identified. Autoimmune, inflammatory, infectious, and ischemic etiologies are postulated. Many report tinnitus and some report vertigo. Urgent evaluation is warranted. A repeated history suggests Ménière or a chronic autoimmune condition. Neck pain might suggest vertebral artery dissection. The internal auditory artery is a branch of the anterior inferior cerebellar artery (AICA). CAE and MRI should both usually be performed. The use of oral glucocorticoids is controversial but many treat with prednisone 60 mg daily for 2 weeks as long as given early. Intratympanic steroids have also been given, particularly to those who might not tolerate oral steroids or those who have not responded to oral steroids, again with a similar lack of evidence. Some, but not most, recommend antiviral therapy, similar to those who recommend it for Bell palsy. Prognosis is related to the severity of hearing loss at onset.

FOCUSED EXAMINATION

Examination must include visual inspection of the ear along with tests of hearing. Patients should be able to hear a finger rub or a whisper a few inches away from the ear. The Weber and Rinne tests provide additional information. The Weber test is performed by placing a 256-Hz tuning fork in the center of the forehead equidistant from both ears. A normal response is hearing the tuning fork similarly in both ears. A patient with a conductive hearing loss will hear the tuning fork louder in the affected ear and a patient with sensorineural hearing loss will hear the tuning fork louder in the unaffected ear. The Rinne test is performed by placing a 512-Hz tuning fork on the mastoid bone behind the ear and asking when the sound is no longer heard. It is then moved to 1 to 2 inches from the external auditory canal. In a patient with normal hearing or sensorineural hearing loss, the sound will still be heard, as air conduction is better than bone conduction. In a patient with conductive hearing loss, bone conduction is better than air conduction. Further hearing testing includes a CAE with pure tone audiometry, speech reception thresholds and discrimination, impedance testing, and acoustic reflexes. Imaging with MRI and/or CT will depend on the clinical situation.

TREATMENT

The treatment of hearing loss is directed at the cause along with hearing amplification and cochlear implantation.

Syncope and Spells

Tina Shih

INTRODUCTION

Sudden alteration of consciousness is a common presenting symptom in a variety of clinical contexts, from the emergency room to the outpatient clinic. The vast majority of events can be categorized as either seizure or syncope or the proverbial “fit” versus “faint.” This chapter aims to provide a practical framework to help the clinician distinguish between these two diagnoses. When evaluating a patient with a history of transient loss of consciousness, clinicians should spend the majority of their efforts on interviewing the patient and eyewitnesses, eliciting the symptoms and signs in a step-by-step fashion in order to understand the order and tempo of the events as they unfolded.

DIFFERENTIATING SYNCOPES FROM SEIZURES

Syncope is defined as a transient loss of consciousness due to insufficient blood flow to the brain. Epileptic *seizures* are defined as transient alteration in brain function due to abnormal electrocerebral activity. The most important clinical features distinguishing these two conditions are the following: (1) precipitating stimuli or situations, (2) prodromal symptoms before losing awareness, and (3) the postevent recovery ([Table 5.1](#)).

Although many patients and witnesses will use terms such as “passing out” or “fainting” to describe either condition, it is important to delve further and elicit a first-person narrative of the patient's actual experience, carefully parsing out what the patient means when using these words.

SYNCOPES

Syncope typically occurs when patients are upright (standing or sitting) and can be triggered by exercise, coughing, bearing down (Valsalva maneuver), venipuncture, prolonged standing, or pain. Presyncope begins with a sense of unwellness accompanied by light-headedness and nausea. Patients may feel weak and unsteady on their feet, followed by a decreased awareness or detachment from their environment. Immediately before losing consciousness, patients experience a “graying of the vision” and/or “muffling” of ambient sounds. Eyewitnesses will often note that the patients appear pale or ashen, diaphoretic, and tachypneic. Sometimes an attack can be aborted if the patients lie down quickly or lower the head below the level of the heart. Once patients lose consciousness, they will lose tone in the muscles of their trunk and legs and they will limply collapse to the floor. On the ground, the limbs are flaccid and patients continue to appear pale and sweaty. The period of unconsciousness is generally brief, lasting only seconds up to 1 to 2 minutes. If the degree of decreased cerebral perfusion is profound enough, patients may display a few jerking movements of the limbs (“convulsive syncope”) but this is also typically very brief (lasting only a few seconds). Generally, the pulse and blood pressure quickly return to normal with the patients in the recumbent position; and they rapidly regain consciousness and quickly become oriented and aware of their surroundings. Patients will often realize that they have fainted and remember details of the event up until the moment of losing consciousness. They might experience mild fatigue or brief disorientation after the event, but this should not last more than a few minutes.

SEIZURES

The clinical manifestations of seizures vary widely, depending on brain volume and neuroanatomic location of activation. Seizures can occur day or night, regardless of whether the patient is awake or asleep, and usually are not triggered by a precipitating stimuli or environment. Sometimes, a seizure may begin with the patients

reporting an “aura” or warning. These subjective experiences might be described as a sense of déjà vu (a sense of reliving a familiar experience), a noxious smell, sudden anxiety, or tingling over one side of the body. Eyewitnesses might find the patients unresponsive to their direct questions, staring into space, or stopping what they were previously doing (behavioral arrest). Some patients exhibit oral or manual automatisms (lip smacking, chewing, rubbing of their hands, picking at their clothes). If a focal seizure then secondarily generalizes (electrical activity starting off in one area of the brain but then spreading to both hemispheres of the brain), the patients’ head and eyes may suddenly and forcibly turn to one side, with stiffening of the limbs, frothing at the mouth, cyanosis of the lips, followed by rhythmic jerking of the limbs. Most secondarily generalized seizures last between 1 and 2 minutes in duration and rarely over 5 minutes in duration, but afterwards, the patients may be confused and disoriented for minutes to hours. Patients may report lateral tongue biting and urinary incontinence after some seizures.

CAUSES OF SYNCOPE

NEURALLY MEDIATED REFLEX SYNCOPE

The most common type of syncope, accounting for over half of cases, is reflex syncope, also known as *neurocardiogenic syncope*. In this form of syncope, an external factor or set of circumstances (apprehension of pain, cough, head turning etc....) leads to bradycardia, hypotension, or a mixture of both phenomena. Reflex syncope is divided into two main categories: vasovagal syncope and carotid sinus syncope (Table 5.2).

Vasovagal Syncope

Vasovagal syncope, the most common type of reflex syncope, is caused by a brief loss of neurally mediated circulatory control and is generally associated with a benign prognosis. Vasovagal syncope can be subdivided into three major categories: postural, central, and situational. In the postural form of vasovagal syncope, a common patient narrative might describe a young person attending a hot and crowded school assembly or concert, standing for a long period of time and having skipped a recent meal and ingested

P.37

some alcohol. In cases of centrally mediated vasovagal syncope, the trigger may involve sudden pain (commonly in the setting of venipuncture), apprehension of pain, or emotional shock immediately preceding the fainting episode. Less commonly, syncope occurs in specific situations or appears to be temporally related to specific triggers. Older men may report symptoms soon after arising from bed and emptying a distended bladder. Some young people describe recurrent syncope after exercise. Others describe syncope after coughing, laughing, or sneezing. It is not unusual for a history of vasovagal syncope to run in families. Surprisingly, despite the prevalence of this condition, the underlying pathophysiology of vasovagal syncope remains a mystery. Physiologists have yet to identify why an emotional state or coughing or prolonged standing can lead to a sudden decrease in blood pressure or why vasovagal syncope can recur frequently in some individuals, rarely in others.

TABLE 5.1 Clinical Features Distinguishing Syncope from Seizure

Feature	Syncope	Seizure
Before a Spell		
Trigger (change in position, prolonged standing, emotion,	Common	Rare

Valsalva, exercise)

Sweating, light-headedness, graying of vision, and/or nausea	Common	Rare
Occurring out of sleep	Rare	Occasional
Aura (déjà vu olfactory hallucination, unilateral symptoms)	Rare	Common
During a Spell		
Pallor	Common	Rare
Cyanosis	Rare	Common (generalized tonic-clonic seizures)
Duration of loss of consciousness	<20 s	>60 s
Movements	A few rhythmic jerking movements of the limbs, lasting <15 s	Prolonged stiffening of the limbs (tonic), transitioning to rhythmic jerking of the limbs (clonic), lasting ~1-2 min
Automatic behavior (lip smacking, picking, patting)	Occasional	Common (focal dyscognitive seizures)
Tongue biting (lateral)	Rare	Occasional
Frothing/hypersalivation/vomiting	Rare	Common
After a Spell		
Confusion/disorientation	Rare, <30 s	Common, several minutes or longer
Diffuse muscle pain	Rare, brief	Common, hours to days
Creatinine kinase (CK) elevation	Rare	Common (especially after 12-24 h)
Focal neurologic signs	Rare	Occasional
Incontinence	Rare	Occasional
Headache	Rare	Common

Amnesia for the event

Less common
(sometimes seen in
elderly)

Common

Carotid Sinus Syndrome

A more unusual type of reflex syncope is carotid sinus syndrome, which occurs when normal stimulation of an unusually sensitive carotid sinus leads to hypotension and/or bradycardia. This diagnosis should be suspected in older individuals who report unexplained falls or syncope with almost no prodromal symptoms; occasionally, a history of head turning, wearing a tight-collared shirt, or shaving preceding syncope is elicited, but in general, this diagnosis is often difficult to make and is considered after extensive diagnostic testing has been inconclusive or negative.

CARDIAC SYNCOPE

The most dangerous type of syncope is cardiac syncope, when a transient loss of consciousness is caused by either cardiac arrhythmia or structural heart disease. In a large population-based study of syncope, cardiac syncope was associated with a twofold increased risk of dying, regardless of etiology, as compared to individuals without a history of syncope.

Arrhythmias are the most common cause of cardiac syncope and both tachyarrhythmias and bradyarrhythmias have been implicated. The most common arrhythmia associated with syncope is sinus node dysfunction. Other arrhythmias include atrioventricular conduction system disease, supraventricular tachyarrhythmias, and ventricular tachyarrhythmias.

Mechanical or structural causes of cardiac syncope include prior myocardial infarction, cardiomyopathy, aortic stenosis,

P.38

mitral stenosis, pericardial tamponade, myxoma, aortic dissection, and pulmonary emboli.

TABLE 5.2 Causes of Syncope

Neurally Mediated Reflex Syncope

-

Antihypertensives, diuretics, antianginal, tricyclic antidepressants, levodopa, lithium, alcohol

- Hypovolemia
-

Anemia, failure to thrive, malnutrition

- Postural orthostatic hypotension syndrome (POTS)
-

Because of the high morbidity associated with cardiac syncope, it is imperative to consider this diagnosis when evaluating an individual with syncope. The clinical features most predictive of cardiac syncope include age older than 60 years, male gender, known structural heart disease, fewer events (less than three events by history), syncope while supine, and syncope during effort/exercise.

SYNCOPE DUE TO ORTHOSTATIC HYPOTENSION

Unlike individuals with vasovagal syncope (who have an intact autonomic nervous system at baseline), individuals with syncope due to orthostatic hypotension are believed to have underlying autonomic dysfunction involving sympathetic efferent pathways, preventing appropriate vasoconstriction upon standing. Therefore, when an individual with this condition rises from a supine position, he or she experiences an abnormal drop in systolic blood pressure. Patients who present with this form of syncope are usually elderly, and this condition rarely occurs in individuals younger than 40 years of age. The clinical history may reveal other symptoms upon standing, which include light-headedness/dizziness or presyncope, weakness/fatigue/lethargy, diaphoresis, vision disturbances (graying of vision, enhanced brightness, tunnel vision), muffled hearing, and/or pain in the shoulders (“coat hanger” distribution), invariably associated with an upright position.

Causes of orthostatic hypotension include neurodegenerative disorders such as multiple system atrophy, hereditary, toxic or paraneoplastic peripheral neuropathies, secondary neuropathies due to systemic diseases such as diabetes and amyloidosis, hypovolemia, and medications. A rare form of orthostatic hypotension with dizziness and near syncope is postural orthostatic hypotension syndrome (POTS), a poorly understood syndrome typically seen in young women with chronic fatigue syndrome. The syndrome consists of an increase in heart rate and unstable blood pressure upon standing.

SPELLS POTENTIALLY MISTAKEN FOR SYNCOPE

VERTEBROBASILAR TRANSIENT ISCHEMIC ATTACK

Transient ischemic attack (TIA) of the vertebrobasilar system is a rare cause of brief loss of consciousness. The underlying pathophysiology is believed to be due to temporary ischemia of the brain stem reticular activating system. Almost invariably, TIAs of the vertebrobasilar system are associated with focal neurologic symptoms due to ischemia of the brain stem, cerebellum, and/or occipital lobe. Therefore, patients and family members will typically describe associated dysarthria, diplopia, dysphagia, hemianopsia, ataxia, unilateral weakness, or numbness.

HYPOGLYCEMIA

Hypoglycemia may cause feelings of light-headedness or dizziness and rarely results in a brief loss of consciousness. A more typical presentation of hypoglycemia is a slow and insidious onset of delirium that may last minutes to hours and be associated with diaphoresis, hunger, tremulousness, anxiety, and palpitations. If severe enough, hypoglycemia can progress to coma and/or generalized tonic-clonic seizures.

BASILAR MIGRAINE

Basilar migraine may cause confusion but rarely leads to loss of consciousness. It is associated with headache, ataxia, and positive visual phenomenon developing over minutes to hours and therefore is unlikely to be confused with syncope.

SUBCLAVIAN STEAL SYNDROME

Subclavian steal syndrome is characterized by a reversal of blood flow in the vertebral artery, away from the brain, in order to supply blood flow to an ischemic arm. In this syndrome, exercising the affected arm leads to dizziness, vertigo, dysarthria, dysphagia, ataxia, unilateral weakness, and sometimes loss of consciousness.

FOCUSED EXAMINATION

If the clinician remains uncertain whether the diagnosis is syncope or seizure after taking the history, the physical examination is unlikely to be helpful. In cases of likely syncope, orthostatic blood pressure and auscultation of the neck and heart should be included as part of the routine physical examination and patients should have a routine 12-lead electrocardiogram (ECG).

Carotid sinus massage has been recommended in the evaluation of unexplained syncope in individuals older than age 45 years, but the procedure is generally not performed by neurologists. The generally accepted protocol for carotid sinus massage involves longitudinal massage at the region where the common carotid bifurcates, but the duration of massage should not last longer than 5 seconds and the force applied should not occlude the carotid

P.39

artery. The procedure should be performed in upright and supine positions with continuous ECG and noninvasive blood pressure monitoring. The procedure should not be performed in individuals with known carotid disease, history of TIA or stroke within the last 3 months, or carotid bruit.

The *active standing test* (having the patient move from lying position to standing position) with simultaneous intermittent manual blood pressure monitoring (sphygmomanometer) may be helpful in diagnosing orthostatic hypotension. A classic finding of orthostatic hypotension is defined as a greater than 20 mm Hg decrease in systolic blood pressure and greater than 10 mm Hg decrease in diastolic blood pressure with 3 minutes of standing. Initial orthostatic hypotension is defined as a blood pressure decrease immediately on standing of greater than 40 mm Hg, whereas delayed orthostatic hypotension is described as a slow, progressive decline in SBP while standing.

DIAGNOSIS

Once the syndrome of syncope has been established but the cause remains uncertain (unlikely reflex syncope or orthostatic hypotension), further laboratory studies to consider might include hemoglobin/hematocrit to look for anemia, chemistry panel to look for electrolyte disturbances, tilt table testing to try to reproduce neurally mediated reflex syncope, echocardiography to evaluate cardiac structure and function, and/or continuous electrocardiographic monitoring to investigate the possibility of a cardiac arrhythmia. The decision to pursue further cardiac testing (continuous ECG or echocardiography) should be strongly considered if there is any suspicion of a potential cardiac cause (Table 5.3). More systematic, protocol-based approaches attempting to stratify high-risk patients have failed to perform consistently when tested in varying patient populations, but expert consensus recommends prompt hospitalization and immediate evaluation for patients with abnormal 12-lead ECG findings, known severe cardiac disease, severe anemia, electrolyte disturbances, and/or clinical features concerning for cardiac syncope (Table 5.4).

TREATMENT

For patients with vasovagal syncope and orthostatic intolerance, nonpharmacologic management strategies are most effective. Patients benefit greatly from education about the condition, identification and then avoidance of potential triggers, and learning how to perform maneuvers to abort an episode (supine posture; physical counterpressure maneuvers consist of leg crossing, arm tensing, or hand grip).

TABLE 5.3 “Red Flags”: When to Consider a Diagnosis of Cardiac Syncope

Clinical features	<ul style="list-style-type: none">• Lack of clear trigger causing syncope• Absence of sweating/nausea before syncope• Syncope while supine• Palpitations at the time of syncope• Syncope with exercise/effort
Demographic features	<ul style="list-style-type: none">• Older age• Family history of sudden death• Personal history of structural heart disease• Fewer events (less than three syncopal events)

TABLE 5.4 “Red Flags”: When to Consider Prompt Hospitalization or Intensive Evaluation

Clinical features	<ul style="list-style-type: none">• Severe cardiac structural dysfunction or coronary artery disease• Family history of sudden cardiac death• Syncope during exercise or while supine• Palpitations at the time of syncope
-------------------	---

Comorbidities	<ul style="list-style-type: none"> • Severe anemia • Electrolyte disturbance
Abnormal ECG findings	<ul style="list-style-type: none"> • Bifascicular block or other intraventricular conduction block (QRS duration >120 ms) • Inadequate sinus bradycardia (<50 bpm) in absence of negative chronotropic medication or physical training • Prolonged or short QT interval • Right bundle branch block with ST elevation in leads V1-V3 (Brugada pattern) • ECG pattern suggestive of arrhythmogenic right ventricular cardiomyopathy

ECG, electrocardiogram.

If the events are recurrent and clear triggers have not been identified, patients should be counseled about high-risk activities such as driving, operating heavy machinery, and working at unrestricted heights, and in some states, mandatory reporting is required.

Seizures and Status Epilepticus

David Roh

Jan Claassen

INTRODUCTION

Seizures are frequently encountered in both the community and hospital setting. Epidemiologic studies in the United States have shown that 11% of the general population will have a seizure at some point in their life. Of these seizure patients, there is an estimated 1 million hospital visits due to seizures per year. The International League Against Epilepsy (ILAE) defines seizures as transient clinical events due to abnormally excessive or synchronous neuronal activity in the brain. These can manifest in a wide array of symptoms ranging from obvious convulsive activity to more subtle signs of twitching or altered mental status.

STATUS EPILEPTICUS

A failure to stop isolated seizures may lead to status epilepticus (SE). Its incidence has seen an increase in recent years with 5 to 30 cases per 100,000. SE is defined as convulsions lasting more than 5 minutes or two or more convulsions in a 5-minute interval without a return to preconvulsive neurologic baseline. Historically, SE had been defined as continuous convulsive seizure activity lasting greater than 30 minutes without complete recovery. However, the minimum time elapsed to qualify for SE was drastically shortened to 5 minutes based on the observation that convulsive seizures rarely last for more than a few minutes. Furthermore, seizures that are of longer duration typically do not stop spontaneously. Animal studies and human data have demonstrated irreversible brain injury can occur as early as 5 minutes of ongoing seizure activity. Delaying effective recognition and treatment of SE dramatically increases the patient's morbidity and mortality. Thus, SE constitutes a neurologic emergency requiring prompt and decisive intervention.

CAUSES OF SEIZURES

It is important to identify any underlying cause for seizures, as management will be tailored to reverse these factors if possible ([Table 6.1](#)). In adults without a history of prior seizures, stroke is the most frequent underlying etiology of seizures. The most common cause of SE is a history of epilepsy. Frequent precipitating factors in these patients include medication noncompliance, low antiepileptic drug (AED) levels, and recent changes in AEDs. Other seizures due to underlying metabolic derangements (hypoglycemia, hyponatremia) can be commonly seen but will be difficult to control with AED agents alone. Subsequently, timely investigation into the underlying cause of the seizure will need to be implemented in the management of acute seizures. Many of these provoking factors may be elicited from the patient's history or exam as discussed previously; however, laboratory and imaging workup can further elucidate these factors. See "[Initial Workup](#)" section for recommended testing.

TABLE 6.1 Etiology of Seizures

Acute

Stroke: ischemic or hemorrhagic

Metabolic derangement: hypoglycemia, electrolyte abnormalities, renal failure

Infection: CNS infection, sepsis

Head trauma

Drugs: AED noncompliance, withdrawal from alcohol, opiates, benzodiazepines, drug toxicity

Hypoxia/cardiac arrest

Hypertensive encephalopathy (PRES)

Chronic

Epilepsy with breakthrough seizures

Mass lesion: tumor, vascular malformations

Prior cortical CNS lesion: stroke, abscess, dysplasia

CNS, central nervous system; AED, antiepileptic drug; PRES, posterior reversible encephalopathy syndrome.

Adapted from Brophy GM, Bell R, Claassen J, et al. Guidelines for the evaluation and management of status epilepticus. *Neurocrit Care*. 2012;17(1):3-23.

DIAGNOSIS

The diagnosis of acute seizures can be made on clinical grounds depending on the patient's history and symptoms. Symptoms can range from obvious positive signs of rhythmic jerking and posturing to more subtle positive symptoms of twitching, nystagmus, automatisms, and eye deviation. Negative symptoms of seizures include staring, coma, lethargy, confusion, and aphasia. These negative symptoms may raise the suspicion of seizures in the appropriate context; however, the definite diagnosis requires an electroencephalogram (EEG). The differential diagnosis of seizures includes a wide variety of seizure mimics that produce sudden unexplained movements or alteration in level of consciousness ([Table 6.2](#)). If the patient is not exhibiting symptoms at the time of assessment, a focused history must be obtained from whoever witnessed the event.

FOCUSED HISTORY

Initial questions should be focused on what symptoms were seen, laterality of symptoms (hemibody or generalized), time of onset, length of activity, if the patient returned to baseline, seizure history, recent illness/fever, trauma, and relevant medications ([Table 6.3](#)). Medication history should include antiepileptics or agents that would lower seizure threshold ([Table 6.4](#)). These questions may allow the examiner to rapidly differentiate seizure versus SE, direct an initial diagnosis for the underlying etiology, and guide the diagnostic workup.

TABLE 6.2 Common Seizure Mimics

Movement disorders

Limb-shaking transient ischemic attacks

Convulsive syncope

Motor posturing (in coma)

Sleep disorders

Transient global amnesia

Complicated migraine

Psychiatric nonelectrographic seizure activity

FOCUSED EXAM

A focused general physical exam should rapidly screen the patient's stability and identify life-threatening etiologies of seizures. These may include meningitis, hemorrhage, ischemic stroke, or mass effect (Table 6.5). Vital signs should be monitored with particular attention to hemodynamic stability and respiratory status. Focus should be paid to the presence of fever, nuchal rigidity, and rash. These findings, if present, should raise suspicion for central nervous system (CNS) infection, prompting further laboratory investigation and empiric treatment.

Observation and neurologic examination may detect obvious positive symptoms of seizures supporting the diagnosis. However, absence of obvious symptoms should not preclude the possibility of seizures. Nearly half of patients with generalized tonic-clonic SE will continue to have electrographic seizures after clinical symptoms disappear. This can result in continued subtle signs such as eye deviation, nystagmus, and facial twitching. Some of these subtle positive findings may have localizing value (Table 6.6). *Comatose patients who have subtle lateralized facial or extremity twitching, nystagmus, or eye deviation should be considered to be in nonconvulsive SE until proven otherwise by EEG.*

TREATMENT STRATEGY

Emergency EEG is indicated for patients who present with SE who fail to awaken after cessation of convulsive seizures. Nonconvulsive seizures occur in up to 40% of patients who fail to awaken after convulsive seizures. This can cause further depression of level of consciousness and increase resistance to antiepileptic therapy if not controlled. Affected patients will not exhibit obvious physical signs of seizures, but electrographic seizure activity will be detected on EEG. As a result, the clinician must be wary of the possibility of nonconvulsive status epilepticus (NCSE) if the patient does not awaken after cessation of seizure activity or displays subtle symptoms of continuing seizures. Please see Chapter 58 for further details on seizure semiology, localizing signs, and seizure syndromes.

TABLE 6.3 Focused History: Questions to Ask in the Patient with Seizure

Recent illness or fever

Preceding trauma

Prior medical history (e.g., stroke, brain tumor, brain infection)

TABLE 6.4 Drugs that Lower the Seizure Threshold

Analgesics: narcotics (tramadol, fentanyl, meperidine)

Antibiotics: penicillins, imipenem, cephalosporins, isoniazid, metronidazole

Anticholinesterases

Antidepressants: bupropion, tricyclics

Antihistamines: diphenhydramine

Antipsychotics: clozapine, phenothiazine

Chemotherapy: etoposide, cisplatin

EMERGENT TREATMENT OF STATUS EPILEPTICUS

PREHOSPITAL TREATMENT

The most important factor in the treatment of acute seizures is the amount of time it takes to administer the initial treatment. This requires a timely recognition of seizures by bystanders and notification of emergency medical services (EMS). Prehospital EMS care with patient stabilization and medication administration is

vital in early treatment of acute seizures and has been associated with improved patient outcomes. Stabilization includes initial assessment of secure airway, stable breathing, and circulation. Once stabilized, prehospital care also involves attempts at obtaining intravenous (IV) access and assessing for reversible causes of seizures such as hypoglycemia.

Following initial assessment, treatment for convulsive seizures can be given by EMS. Benzodiazepines have been the AED of choice in the field (Table 6.7). IV agents have traditionally been used with lorazepam (4 mg) or diazepam (10 mg). In appropriate, targeted dosing, seizure patients that receive IV benzodiazepines have lower instances of respiratory depression/intubation than patients that have prolonged seizures without treatment. Subsequently, the efficacy and safety of IV benzodiazepine use, particularly IV

P.43

lorazepam, has been an important finding in the early prehospital treatment of convulsive seizures [Level 1].¹

TABLE 6.5 Red Flags for Life-Threatening Causes of Seizures

Findings	Etiology
Nuchal rigidity	Meningitis
Fever	
Rash	
Anisocoria	Transtentorial herniation
Gaze deviation	Hemispheric mass lesion
Hemibody weakness	Contralateral stroke
Periorbital ecchymosis	Trauma

TABLE 6.6 Localizing Symptoms of Seizures

Signs	Localization
Positive Symptoms	
Hemibody convulsion	Contralateral hemisphere
Generalized convulsion	Generalized cerebral activity
Lateralized facial twitching	Contralateral hemisphere

Eye deviation	Contralateral frontal eye field
Directional nystagmus	Contralateral hemisphere
Echolalia	Temporal or frontal lobe
Automatism	Nonlocalizable
Negative Symptoms	
Aphasia	Dominant hemisphere
Coma	Bilateral hemispheres

The ability of EMS to establish venous access to appropriately provide IV benzodiazepines along with the storage of IV lorazepam in ambulances have provided limitations to its use. As a result, intramuscular (IM) midazolam (10 mg) has been used increasingly in the prehospital setting. Its study has revealed efficacy and efficiency as an alternative treatment to IV lorazepam [Level 1].²

HOSPITAL TREATMENT

Once the patient arrives to the hospital, they should once again be assessed for stable airway, breathing, and circulation (Table 6.8). Supplemental oxygen can be provided. Hemodynamic monitoring should be implemented with particular attention to blood pressure, cardiac monitoring, and oxygenation. IV access, if not already established, should be obtained along with fluid resuscitation to maintain euvolemia. Physicians should reassess glycemic status, and if there is evidence of hypoglycemia, it is important to promptly treat with D50W 50 mL IV with concurrent thiamine 100 mg IV. Handoff between EMS and physicians should establish what treatments were given in the field, including benzodiazepine doses.

TABLE 6.7 Emergent First-line Therapy Benzodiazepine Agents and Dosing

Benzodiazepine	Route	Dosing
Lorazepam	IV	0.1 mg/kg IV (max 4 mg per dose) and can repeat at 5-10 min
Diazepam	IV	0.15 mg/kg IV (max 10 mg per dose) and can repeat in 5 min
	PR	0.2 mg/kg PR for >12 yr 0.3 mg/kg PR for 6-11 yr 0.5 mg/kg PR for 2-5 yr
Midazolam	IM	0.2 mg/kg IM (max 10 mg)

Intranasal 0.2 mg/kg intranasal

Buccal 0.5 mg/kg buccal

IV, intravenous; PR, per rectum; IM, intramuscular.

TABLE 6.8 Status Epilepticus Algorithm Status Epilepticus Algorithm

Emergent Management

- Recognition and diagnosis of prolonged seizures
-
- Stabilize patient: ABCs (airway, breathing, circulation). Place IV, supplemental O₂, and hemodynamic monitoring.
-
- Thiamine 100 mg and D50W 50 mL IV (if hypoglycemia)
-
- Lorazepam 4 mg over 2 min IV; can repeat after 5 min if still seizing; diazepam 10 mg IM or 20 mg per rectum if no IV route available
-
- Monitor BP and respiratory status during treatment. If no return to baseline:
-

Second-Line Therapy/Urgent Control Therapy

- Fosphenytoin 20 mg/kg IV at 150 mg/min or valproic acid 40 mg/kg IV over 10 min
-
- Can consider levetiracetam 1-3 g IV over 2-5 mg/kg/min
-
- Start maintenance dose of loaded AEDs and order AED levels post loading.
-
- Order cEEG unless patient is clearly back to baseline.
-
- Can consider giving additional fosphenytoin 5-10 mg/kg IV ×1 vs. valproic acid 20 mg/kg IV ×1 if no improvement or continued seizure activity. However, do not perform this at the expense of delaying more aggressive RSE treatment measures.
-
- Monitor BP and respiratory status during treatment. Consider intubation if sedation or seizure compromises airway. If no improvement:

Refractory Status Epilepticus

- Intubate patient and admit to the ICU.
- cEEG should be in place.
- RSE cIV anesthetic agents to goal of burst suppression: See table for RSE medications.
- Monitor hemodynamic stability and add vasopressors if needed.
- Monitor cEEG for 24-48 h for seizure suppression and optimize maintenance AED.

IV, intravenous; O₂, oxygen; IM, intramuscular; BP, blood pressure; AED, antiepileptic drug; cEEG, continuous electroencephalography; RSE, refractory status epilepticus; ICU, intensive care unit; cIV, continuous intravenous.

Benzodiazepine initial therapy is frequently underdosed due to the seizure treatment dosing being higher than most indications seen by EMS or the emergency department (ED). Attention should be made to provide full appropriate benzodiazepine treatment via additional doses if not given initially. Lorazepam IV has been shown to be the preferred initial agent. A recommended total dose of 0.1 mg/kg (4 mg per dose) can be given [**Level 1**].³ A repeat dose of 4 mg can be given after 5 to 10 minutes if needed (for a maximum total of 8 mg). Lorazepam should be administered at a rate up to 2 mg/min. Close attention should be taken to cardiopulmonary status during

P.44

benzodiazepine administration to avoid uncontrolled hypotension or respiratory depression. Similar to the prehospital management, if there is no IV access readily available, benzodiazepines can be administered via IM, rectal, nasal, or buccal routes. Midazolam is the preferred agent for IM administration. This can be administered at 0.2 mg/kg IM for a total dose of 10 mg (see [Table 6.4](#)).

INITIAL WORKUP

Although emergent management is underway, concurrent workup needs to be carried out to establish the underlying cause of seizures as discussed earlier ([Table 6.9](#)). All patients should receive basic serum lab evaluation including complete blood count, basic metabolic panel, liver function tests, AED levels, and drug toxicology to evaluate for any metabolic etiologies for seizures. A noncontrast computed tomography (CT) of the brain should be performed for most patients on admission to screen for any obvious structural etiologies of seizures.

The extended workup to be chosen on a case-by-case basis includes a lumbar puncture, magnetic resonance imaging (MRI), and further miscellaneous laboratory tests. If the patient has clear inciting factors (i.e., epilepsy with AED noncompliance or hypoglycemia), a lumbar puncture (LP) may not be necessary. Conversely, in febrile patients, those with an elevated white blood cell count and nuchal rigidity, suspicion should be raised for a CNS infection and an LP is warranted. In addition, if basic metabolic serum workup and CT neuroimaging fail to reveal an obvious etiology of seizures, an MRI of the brain should be performed along with an LP. If infection is

suspected, these tests should be pursued without delaying empiric antibiotic treatment. Aggressive measures should be taken to treat life-threatening causes of seizures or SE.

TABLE 6.9 Diagnostic Seizure Evaluation

Perform immediately if possible and concurrently with emergent management and treatment.

All Patients

- Glucose fingerstick
-
- Hemodynamic monitoring and vital signs (blood pressure, cardiac monitoring, O₂ saturation, heart rate)
-
- Neuro checks
-
- IV access
-
- O₂ administration (if needed)
-
- Head CT scan
-
- Serum lab tests: complete blood count, basic metabolic panel, blood glucose, liver function tests, calcium (total and ionized), magnesium, troponin, antiepileptic drug levels, toxicology screen (cocaine and urine), pregnancy test (if female)
-
- EEG
-

Consider Depending on Presentation

- Brain MRI
-
- Lumbar puncture
-
- Comprehensive toxicology panel: toxins that can cause seizures (isoniazid, tricyclic antidepressants, theophylline, sympathomimetics, organophosphates, cyclosporine)
-
- Serum blood work: type and hold, coagulation studies, arterial blood gas, inborn errors of metabolism

O₂, oxygen; IV, intravenous; CT, computed tomography; EEG, electroencephalography; MRI, magnetic resonance imaging.

INDICATIONS FOR HOSPITAL ADMISSION

ED policy states that patients with a normal neurologic examination following a seizure can be discharged from the ED with outpatient follow-up. However, if the patient fails to return to baseline in 10 minutes, SE should be suspected and admission is warranted. Failure to control convulsive seizures or persistent unexplained altered mental status requires further evaluation with a continuous EEG (cEEG). These patients with suspected SE require admission to an intensive care unit for further EEG directed treatment and hemodynamic monitoring. cEEG monitoring should be established within 1 hour of SE and should be placed for at least 48 hours in comatose patients to detect nonconvulsive seizures.

TREATMENT ALGORITHM FOR STATUS EPILEPTICUS

In patients with SE, the timely administration of second-line therapy is vital. Second-line therapy administration should ideally occur concomitantly with first-line benzodiazepine therapy. Benzodiazepine therapy alone has a short duration of treatment effect and will not be effective in preventing prolonged seizures or SE. There is no need to delay the administration of second-line therapy to assess if the patient responds to first-line benzodiazepine therapy. The goal of second-line/urgent control therapy is to establish rapid therapeutic levels.

Frequently used second-line agents include phenytoin/fosphenytoin, valproic acid, phenobarbital, and levetiracetam. Prospective studies have not revealed a superior second-line AED agent. However, fosphenytoin/phenytoin is commonly used as the second-line therapy of choice. A 20-mg/kg IV can be given with either formulation. Fosphenytoin can be given at rate of 150 mg/min and phenytoin at 50 mg/min. Care must be taken to avoid rapid infusion, as this may cause hypotension or arrhythmias. Despite preference for phenytoin use, IV valproic acid may be of equal efficacy without the caveats of phenytoin's side effects. A 20- to 40-mg/kg IV can be given over 10 minutes with an option of giving an additional 20 mg/kg over 5 minutes if seizure activity continues. Levetiracetam IV has also been used for second-line therapy for SE. Doses of 1,000 to 3,000 mg IV can be given with administration rate of 2 to 5 mg/kg/min IV.

After second-line or urgent control therapy is administered, AED maintenance therapy is required even if SE is controlled. This requires giving maintenance doses of the AED that was administered IV. Many experts advocate for more aggressive treatment of SE. Rather than treating with second-line AEDs, waiting for a clinical response, and reloading with these agents, the idea of proceeding directly to continuous IV agents while concomitantly using second-line AEDs have been proposed. Studies have shown suboptimal cessation of seizure activity with the sole use of classic second-line agents such as phenytoin. Consequently, when possible, the aggressive escalation of treatment straight to continuous IV AEDs such as midazolam can be considered.

REFRACTORY STATUS EPILEPTICUS

If there is failure to control SE after the use of a benzodiazepine and second-line AED, the patient is considered to be in refractory SE (RSE). RSE occurs in approximately 30% of patients with SE and is

associated with increased morbidity and mortality compared to SE counterparts. The pathophysiology of propagation to RSE involves the internalization of γ -aminobutyric acid receptors and upregulation of excitatory *N*-methyl-D-aspartate receptors. Consequently, management of RSE requires rapid and aggressive escalation of care with intubation (if not already performed) and induction of coma with continuous IV (cIV) anesthetic agents with therapeutic targets at these two receptors. It is unclear of the treatment target endpoints as some evidence

suggests that RSE outcome is based on the underlying cause of RSE rather than the aggressiveness of treatment. Despite this, many experts agree that aggressive treatment tailored to EEG suppression rather than clinical seizure activity is ideal in the escalation of care. Consequently, cEEG is vital at this point in both evaluating for seizure activity and response to therapy. Attempts to advance therapy should not be delayed with repeat treatments with second-line agents.

TABLE 6.10 Continuous Intravenous Anesthetic Agents for Refractory Status Epilepticus

Drug	Bolus Dose	Maintenance Dose	Side Effects
Pentobarbital	5-15 mg/kg (up to 50 mg/min) Repeat bolus of 5 mg/kg until seizures stop.	1-10 mg/kg/h	<ul style="list-style-type: none"> • Hypotension • Ileus • Respiratory/cardiac depression
Propofol	1-2 mg/kg over 3-5 min Repeat bolus every 3-5 min until seizures stop (maximum 10 mg/kg).	30-100 µg/kg/min	<ul style="list-style-type: none"> • Hypotension • Propofol infusion syndrome (particularly at >80 µg/kg/min for >48 h)
Midazolam	0.2 mg/kg (rate of 2 mg/min) Repeat bolus of 0.2-0.4 mg/kg every 5 min until seizures stop (maximum of 2 mg/kg).	0.05-2.9 mg/kg/h	<ul style="list-style-type: none"> • Respiratory depression • Hypotension (less than propofol and pentobarbital) • Tachyphylaxis

Although there is no uniform consensus on optimal RSE therapy, frequently used agents include midazolam, propofol, and pentobarbital (Table 6.10). When intubation is not possible, valproic acid can be used as a viable alternative. There remains a paucity of prospective comparative studies for these agents. However, retrospective analysis and limited prospective studies have given some guidance for future studies and selection of preferred RSE treatments.

Pentobarbital has been seen to have higher treatment efficacy compared to propofol and midazolam. However, longer rates of mechanical ventilation have been seen with barbiturate use due to its long half-life along with increased risk of cardiac side effects. Pentobarbital infusion is preceded by a loading dose of 5 to 15 mg/kg (up to 50 mg/min) with repeated boluses of 5 mg/kg until seizures stop. Maintenance infusion can be started at 1 mg/kg/h with titration up to 10 mg/kg/h for goal of EEG burst suppression.

Propofol is also an effective agent but it requires careful hemodynamic monitoring. It has the caveat of hypotension along with propofol infusion syndrome (circulatory collapse, lactic acidosis, hypertriglyceridemia, rhabdomyolysis). Propofol requires a 1- to 2-mg/kg loading dose over 3 to 5 minutes. Repeat boluses can be given every 3 to 5 minutes until seizures stop (maximum loading dose of 10 mg/kg). Maintenance propofol dosing should be titrated to EEG burst suppression at 30 to 100 µg/kg/min. Doses of greater than 80 µg/kg/min for

extended periods of time (>48 hours) may place the patient at risk for propofol infusion syndrome.

Midazolam appears to have less of an effect on blood pressure in comparison to propofol or pentobarbital. However, its use is particularly prone to tachyphylaxis and its mechanism of action is hindered by not having any effect on NMDA receptor sites. Midazolam requires a loading dose of 0.2 mg/kg at a rate of 2 mg/min. Repeat boluses of 0.2 to 0.4 mg/kg boluses every 5 minutes can be given until seizures stop with a maximum loading dose of 2 mg/kg. Maintenance infusion can be titrated for goal of EEG burst suppression at 0.05 to 2 mg/kg/h. However, maintenance infusion rates of as high as 2.9 mg/kg/h can be used safely with lower rates of withdrawal seizures and lower discharge mortality rates.

There is no clear support for the length of treatment and seizure suppression with cIV anesthetic agents before weaning attempts are made. However, general consensus states that patients should remain seizure free for 24 to 48 hours on cEEG monitoring. While waiting for this to occur, the patient's maintenance AED agents should be optimized from a therapeutic level standpoint. Levels can be allowed to be supratherapeutic and should be dictated based on seizure control and side effect profile. Gradual attempts can then be made to wean off of these agents.

KEY POINTS

- Distinguishing between isolated seizures and SE is paramount for effective treatment.
- Focused history/exam should characterize seizure activity, presumed duration of seizures, and pertinent history (i.e., seizures in the past).
- Treatment begins with assessment of airway, breathing, and circulation.
- Prehospital treatment with benzodiazepines should be initiated as soon as possible and may be given by a number of routes (i.e., IV, IM, buccal, rectal).
- Concurrent workup and tests should occur while the patient is being stabilized and treated.
- Treat early with initial line of therapy with benzodiazepines; agent of choice is lorazepam IV.
- Continue therapy with second-line urgent control therapy with phenytoin/fosphenytoin or valproic acid; alternatives include levetiracetam or phenobarbital.
- Start maintenance AED therapy after second-line urgent control therapy.

P.46

- If the patient does not return to baseline within 20 minutes after convulsions stop, suspect nonconvulsive seizures or SE.
- cEEG must be ordered to further drive therapeutic management if concerns for SE.
- If evidence of prolonged seizures, intubate and escalate to cIV anesthetic AED agents.
- Do not delay treatment.

Headache and Facial Pain

Julio R. Vieira

Denise E. Chou

INTRODUCTION

Headache is one of the most frequent reasons for which patients seek medical attention and accounts for more disability on a global scale than any other neurologic problem when including direct and indirect costs. The appropriate management of headache disorders relies on a careful diagnostic approach that is based on an understanding of the physiologic mechanisms of head pain and different characteristics of both primary and secondary headache syndromes.

GENERAL PRINCIPLES

A classification system for headache disorders has been established by the International Headache Society (IHS). The most recent version, *International Classification of Headache Disorders*, 3rd edition, beta version (ICHD-3 beta) divides headache disorders into *primary syndromes* (in which the headache and associated features constitute the disorder itself) and *secondary disorders* (in which the headache results from exogenous causes).

The most common primary headache syndrome is tension headache comprising 69% of all primary headaches; however, such headaches are rarely debilitating and are generally self-treated with over-the-counter medications. The second most common primary headache disorder is migraine, with a 1-year prevalence of 12% (17% among women and 6% among men peaking around the fourth decade of life). Recurrent and disabling headaches in a primary care setting are most often migraines. Life-threatening headache is infrequent; however, caution and adequate surveillance are needed to properly diagnose and manage these cases.

DIAGNOSIS

The key to the proper diagnosis of headache is obtaining a comprehensive and precise history. Important components of the headache history include the following:

- **Onset:** abrupt versus insidious; context in which headache began (e.g., recent head trauma, including head/neck surgeries, viral illness, pregnancy/postpartum)
- **Timing:** chronicity, duration, and frequency of headache attacks; time to maximal intensity; diurnal versus nocturnal
- **Quality:** for example, sharp, dull, pressure, throbbing, stabbing, lancinating, burning
- **Laterality:** unilateral versus bilateral; side-locked versus alternating
- **Location:** for example, retroorbital, frontal, temporal, occipital
- **Severity:** including disability and interference with work/normal activities
- **Change:** different pattern from prior headaches
- **Associated symptoms:** sensory hypersensitivity (e.g., to light, noise, sound, smell, movement); nausea/vomiting; visual changes; numbness/tingling of the face or extremities; focal motor weakness; impairment of speech; light-headedness/vertigo; cognitive dysfunction
- **Cranial autonomic features:** lacrimation, conjunctival injection, periorbital or facial edema, ptosis,

pupillary changes; nasal congestion or rhinorrhea; aural fullness or tinnitus

- **Premonitory features:** symptoms that are experienced days to hours prior to headache attacks (such as yawning, sleepiness, increased thirst, changes in bowel/bladder pattern, neck stiffness)
- **Triggers:** for example, menstrual cycle; skipping meals; lack of sleep or oversleeping; stress or relaxation from stress; altitude or barometric changes; position (lying down vs. standing up); Valsalva maneuvers or physical exertion; bright lights, noise, or smells; alcohol; caffeine; and certain foods (such as those containing nitrates or monosodium glutamate)
- **Family history** of headache disorders

Past medical history, review of systems, social history, concomitant medications, prior imaging, and labwork should also be reviewed in detail, as these may reveal an underlying cause for the headache.

The physical examination should include a comprehensive systemic and neurologic examination with particular attention to the following: bruits of the head or neck, temporal artery tenderness and pulsations, occipital nerve tenderness, pupillary size and symmetry, funduscopic examination (for evaluation of papilledema and retinal venous pulsations), visual field testing and extraocular movements, facial sensation (including corneal responses), and motor function.

The first goal of diagnosis is to differentiate between a benign headache disorder (usually a primary syndrome) and a serious underlying condition (secondary headache). There are a few tools available to help identify a potential life-threatening headache (using so-called red flags); conversely, the presence of “white or green flags” can suggest a more benign scenario.

RED FLAGS

Symptoms that may point to a serious underlying disorder can be evaluated by the mnemonic “SNOOP” (Table 7.1). Despite the use of SNOOP, the neurologic examination remains the best predictor of structural intracranial pathology. The evaluation of a patient with headache in the emergency room is shown in Figure 7.1.

Alarming causes of secondary headaches that require urgent evaluation include meningitis, intracranial hemorrhage, acute ischemic event, tumor or obstructive lesion, glaucoma, purulent sinusitis, cortical vein/cranial sinus thrombosis, carotid/vertebral artery dissection, pituitary apoplexy, posterior reversible encephalopathy

P.48

syndrome (PRES), and reversible cerebral vasoconstriction syndrome (RCVS). Patients who had a recent ischemic infarct and develop new-onset headache should also undergo immediate head computed tomography (CT) to rule out hemorrhage, particularly those patients who received thrombolysis. Thyroid disorders (most commonly hypothyroidism) are also frequently associated with headache.

TABLE 7.1 “Red Flags” When Evaluating Headache Symptoms

Systemic	Systemic signs/symptoms: stiff neck, vomiting preceding the headache, fever, night sweats, rash, myalgia, weight loss; also headache during pregnancy or postpartum and comorbid systemic disease (e.g., HIV, malignancy)
Neurologic symptoms	Change in mental status or level of consciousness; papilledema, diplopia; loss of sensation; weakness; ataxia; local tenderness (region of temporal artery); headache induced by Valsalva maneuvers (bending, lifting, cough, sneezing); pain that disturbs sleep or presents immediately upon awakening; history of

seizure/collapse/loss of consciousness

Older	Onset after age 50 years
Onset	Onset sudden and/or first ever; severe or “worst” headache of life; “thunderclap” headache (pain reaches maximal intensity in an instant)
Pattern change	Change in frequency, severity, or clinical features of the attack; subacute worsening over days/weeks or accelerating pattern, continuous or persistent headache; pain triggered by sexual activity, Valsalva maneuver, or sleep; worsening with change in position

Adapted from Silberstein SD, Lipton RB, Dodick D, et al. *Wolff's Headache and Other Head Pain*. 8th ed. New York: Oxford University Press; 2008.

FIGURE 7.1 Evaluation of a patient with headache in the emergency room. CT, computed tomography; SAH, subarachnoid hemorrhage; ICH, intracerebral hemorrhage; SDH, subdural hemorrhage; EDH, extradural hemorrhage; LP, lumbar puncture; MRI, magnetic resonance imaging; MRV, magnetic resonance venography; CTA, computed tomography angiography; CTV, computed tomography venography; ESR, erythrocyte sedimentation rate; CRP, C-reactive protein; ICP, intracranial pressure; RBC, red blood cell; WBC, white blood cell. (Adapted from Gordon DL. Approach to the patient with acute headache. In: Biller J, ed. *Practical Neurology*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2012:194-206.)

TABLE 7.2 POUND Mnemonic for Identifying Migraine Headache

Pulsatile quality of headache

One-day duration (4-72 h)

Unilateral location

Nausea or vomiting

Disabling intensity

GREEN FLAGS

Certain clinical features support a benign primary headache disorder. Simple tools that can help identify migraine include *ID Migraine*, a set of three questions regarding photophobia, nausea, and disability simplified as “PIN” (photophobia, inability to function, and nausea). If two out of the three features are present, a diagnosis of migraine is likely (with sensitivity of 81% and specificity of 75%). If all three are present, there is a 93% probability of meeting IHS diagnostic criteria for migraine. Another tool is the *POUND mnemonic* (Table 7.2), in which the presence of four out of five features can accurately predict a diagnosis of migraine.

Despite present guideline recommendations, many clinicians overorder imaging in benign scenarios. The American Headache Society (AHS) created the “Choosing Wisely” recommendations to address the need for neuroimaging as follows:

- No need for imaging in patients with stable headache that meet migraine criteria
- No CT for headache when magnetic resonance imaging (MRI) is available except in emergency settings.

SECONDARY CAUSES OF HEADACHE

MENINGITIS

Presence of fever, stiff neck, and Kernig and Brudzinski signs (poor sensitivity but good specificity) warrant further workup with imaging (CT/MRI) followed by lumbar puncture for cerebrospinal fluid (CSF) analysis to rule out an infectious or inflammatory meningitis. If suspecting meningitis, cover with empiric antibiotics while awaiting CSF results.

SUBARACHNOID HEMORRHAGE

History of a “thunderclap headache” or “worst headache of life” can be suggestive of subarachnoid hemorrhage. In addition, focal neurologic deficits can be present on examination. A third nerve palsy suggests a possible posterior communicating (PComm) artery aneurysm, whereas a sixth nerve palsy can suggest a posterior fossa lesion or increased intracranial pressure, as can nystagmus or ataxia. Bilateral leg weakness or abulia may signify an anterior communicating (AComm) artery aneurysm; aphasia, hemiparesis, or neglect can suggest a middle cerebral artery (MCA) aneurysm. Patients with these presenting symptoms should undergo immediate noncontrast head CT imaging; if this is negative and subarachnoid hemorrhage is still suspected, lumbar puncture should be performed (checking for the presence of red blood cells or xanthochromia). Note that patients

presenting with headache for more than 2 weeks with a negative CT and clear CSF may still have subarachnoid hemorrhage requiring further workup with MRI and vessel imaging with computed tomography angiogram (CTA), magnetic resonance angiogram (MRA), or conventional angiogram.

BRAIN TUMOR

Approximately 30% of patients diagnosed with a brain tumor report headache at presentation; however, only 1% present with headache as the *only* clinical symptom. Apart from focal neurologic deficits, clues that may suggest an intracranial lesion include sudden change in pattern of a preexisting headache disorder, worsening of headache with Valsalva maneuvers and exertion, or headache that awakens one up from sleep. However, these characteristics are also commonly seen in primary headache disorders, such as migraine and cluster headache.

SUBDURAL HEMATOMA

Headache is reported in 80% of cases and is more insidious in onset than subarachnoid hemorrhage. Otherwise, headache characteristics may resemble those of a brain tumor (due to mass effect). Mental status changes and gait instability are common in the elderly who are prone to acute-on-chronic subdural bleeding (often from nonwitnessed or nonreported falls).

CERVICAL ARTERY DISSECTION

Headache with carotid artery dissection is typically unilateral and may be associated with ipsilateral neck pain or Horner syndrome. Headache from vertebral artery dissection is posterolateral and may be accompanied by meningismus when subarachnoid hemorrhage has resulted from dissection of blood through the vessel wall of the intracranial segment.

CEREBRAL VENOUS THROMBOSIS

Approximately 90% of cases present with headache (most common feature but not specific); other signs include seizures, altered mental status, papilledema, and focal neurologic deficits. This condition is most common among young adult women.

REVERSIBLE CEREBRAL VASOCONSTRICTION SYNDROME

This condition often presents with thunderclap headache resembling subarachnoid hemorrhage. The diagnosis is established by demonstrating the absence of blood in the CSF, the presence of diffuse cerebral arterial vasospasm, and a relatively benign clinical course with resolution of the syndrome over a period of weeks.

P.50

GIANT CELL ARTERITIS

New-onset headache at age 50 years or older, with associated temporal artery tenderness or decreased temporal artery pulse, should raise suspicion for giant cell arteritis (temporal arteritis). Other associated symptoms include jaw claudication, unanticipated weight loss, fatigue, and/or myalgias. An elevated erythrocyte sedimentation rate (ESR) and/or C-reactive protein (CRP) should be checked in such cases; if these are normal but clinical suspicion remains high, a temporal artery biopsy should be pursued. Headache typically resolves or greatly improves within 3 days of starting high-dose corticosteroids.

SPONTANEOUS INTRACRANIAL HYPOTENSION

Headache is exquisitely orthostatic in nature, occurring in the upright position and resolving or notably improving upon lying supine. Pain may also be worsened by Valsalva maneuvers and especially in the Trendelenburg position. Stiff neck and nausea are prevalent. If intracranial hypotension is suspected, an MRI brain with and without contrast should be performed, which may reveal subdural fluid collections, pachymeningeal

enhancement, engorgement of venous structures, pituitary hyperemia, and/or sagging of the brain with cerebellar tonsil displacement. If there is no clear precipitating event (such as a recent lumbar puncture), spinal MRI with T2 weighting and CT/magnetic resonance (MR) myelography should be considered to identify potential sites of CSF leakage. Treatment options include bedrest, intravenous fluids and caffeine, and blood patch (if the site of leak is identified). In patients with intractable pain, oral theophylline is a useful alternative.

IDIOPATHIC INTRACRANIAL HYPERTENSION

Idiopathic intracranial hypertension (IIH), formerly called *pseudotumor cerebri*, is a syndrome of elevated intracranial pressure associated with normal brain imaging and CSF findings that occurs primarily in young women. Headache may share features as seen with brain tumors, such as worsening with Valsalva maneuvers, wakening from sleep, and/or intractable nausea or vomiting. Other symptoms include transient visual obscuration, photopsia, and pulsatile tinnitus. Persistently raised intracranial pressure can also trigger migraine symptoms such as photophobia or phonophobia. Abnormal findings on examination include papilledema or cessation of venous pulsations (suggesting elevated intracranial pressure) or diplopia from sixth nerve palsy. IIH is most commonly associated with obesity and women of childbearing age; however, the disorder can also manifest at any age, in men, and in patients who are not overweight. Certain medications may increase the risk for developing IIH, such as estrogen-containing oral contraceptives, excessive intake of vitamin A or retinoic acid derivatives, and lithium. Brain MRI and magnetic resonance venogram (MRV) should be obtained if there is concern; imaging may reveal an empty sella, flattening of the posterior globes, protruding of optic nerve heads, and vertical tortuosity of optic nerves. An elevated opening pressure on lumbar puncture and improvement in headache following removal of CSF is diagnostic. Initial treatment is with acetazolamide 250 to 500 mg twice a day (b.i.d.); topiramate is the next treatment of choice. Severely disabled patients who do not respond to medical treatment require intracranial pressure monitoring and may require ventriculoperitoneal shunting.

EMERGENCY EVALUATION OF HEADACHE

Upon presentation to the emergency department (ED), it is necessary to evaluate for the presence of red flags—if any are present, the algorithm in [Figure 7.1](#) should be followed for further workup. Useful lab work for the evaluation of headache in the emergency room include the following:

- Comprehensive metabolic panel
- Complete blood count
- Coagulation panel, β -human chorionic gonadotropin (β -HCG) (pregnancy test)
- Thyroid studies
- ESR and CRP (if concern for temporal arteritis)

If there is concern for intracranial hemorrhage or space-occupying lesion, a noncontrast head CT should be obtained first; a follow-up MRI brain may be later obtained for further characterization. Vascular imaging (such as with MRA/CTA, MRV/computed tomography venography [CTV], or conventional angiography) may be considered in the circumstances described earlier. In other conditions, lumbar puncture may be required, unless a benign etiology can be otherwise established.

The exclusion of underlying secondary causes suggests a non-life-threatening headache disorder; likewise, the presence of white or green flags provides reassurance of a primary headache syndrome, most commonly migraine. The primary headache syndromes are further covered in Chapter 54.

FACIAL PAIN AND CRANIAL NEURALGIAS

The analysis of facial pain requires a different approach. *Neuralgias* are characterized by paroxysmal, fleeting,

and often electric shock-like episodes in the distribution of a particular nerve usually without a background of chronic pain. Such disorders are generally caused by ectatic vascular loops compressing the associated nerve (e.g., trigeminal or glossopharyngeal) at the nerve root entry zone, activating a pain-generating mechanism in the brain stem. Other causes, including demyelinating lesions at the central portions of the nerve root entry zones, are more commonly seen in younger patients who are less likely to have ectatic vascular loops. However, the most common cause of facial pain is dental pathology or irritation; provocation by hot or cold foods is typical. Application of a cold stimulus repeatedly induces dental pain, whereas in neuralgic disorders, a refractory period usually occurs after the initial response, so that pain cannot be induced repeatedly. The presence of refractory periods nearly always may be elicited in the history, thereby saving the patient from a painful testing experience.

Trigger maneuvers characteristically provoke paroxysms of pain. Activation of the pain by chewing points to trigeminal neuralgia, temporomandibular joint dysfunction (TMD), giant cell arteritis, or occasionally angina (jaw claudication), whereas the combination of swallowing *and* taste provocation points to glossopharyngeal neuralgia. Pain on swallowing is common

P.51

among patients with *carotidynia* (facial migraine) because the inflamed, tender carotid artery abuts the esophagus during deglutition.

As with other painful conditions, many patients with facial pain do not describe stereotypic syndromes and are frequently given a diagnosis of “atypical facial pain.” Vague, poorly localized, continuous facial pain can be seen in conditions such as nasopharyngeal carcinoma and other somatic diseases; a burning, painful element often supervenes as deafferentation occurs and evidence of cranial neuropathy appears. Occasionally, the underlying cause may not be promptly uncovered, thus necessitating periodic follow-up examinations until further clues appear. Facial pain syndromes and the cranial neuralgias are further covered in Chapter 55.

TREATMENT

The core principles of effective headache treatment are reassurance, adequate hydration, and the appropriate control of pain and associated symptoms (such as nausea). Treatment goals include accurate diagnosis of the headache syndrome, reduction of disability, and rapid return to normal functioning, as well as avoidance of medication overuse and prevention of recurrent emergency room visits.

Despite evidence against the use of opioids for headache treatment in the emergency setting, administration of such medications has been increasing over recent years. Indeed, opioids are the most commonly prescribed medications for migraine in the emergency room, whereas migraine-specific therapies (such as triptans and dihydroergotamine) are scarcely used in the ED setting.

The Choosing Wisely campaign from the American Board of Internal Medicine (ABIM) recommends avoiding opioids and butalbital-containing medications as first-line treatment for recurrent headache.

Butalbital is associated with a high frequency of medication overuse (“rebound”) headache and has been banned in some countries. Opioids are not as effective for acute migraine treatment as phenothiazines (e.g., chlorpromazine, prochlorperazine, and promethazine), dihydroergotamine, ketorolac, and butyrophenones and have more side effects. In addition, opioids may decrease the effectiveness of migraine-specific abortive therapies (such as triptans and ketorolac), increase relapse with recurrent ED visits and medication overuse, and accelerate progression to chronic migraine due to a “pain memory state.”

HEADACHE TREATMENT IN THE EMERGENCY DEPARTMENT

As previously mentioned, the majority of headache cases presenting to the ED are migraine. For mild headache without nausea, oral nonsteroidal anti-inflammatory drugs (NSAIDs) and/or triptans are recommended as first-line treatments (see [Table 54.3](#) for detailed dosage information). More severe

headache with or without nausea can be treated with intravenous fluids along with a single dose of a dopamine receptor antagonist such as chlorpromazine 25 to 50 mg, prochlorperazine 10 to 25 mg, promethazine 25 to 50 mg, or metoclopramide 5 to 10 mg, which have both antiemetic and antinociceptive properties. Patients should be monitored for the development of akathisia or other extrapyramidal side effects (particularly with use of prochlorperazine and metoclopramide), which can be treated or prevented with concomitant administration of intravenous diphenhydramine.

Intravenous valproic acid 10-15 mg/kg can also be considered for treatment of severe migraine; however, one study showed lower efficacy than metoclopramide or ketorolac alone. Use of valproic acid should be avoided in pregnant women and cautiously used in women of childbearing age, as well as those with liver disease or urea cycle disorders.

The addition of intravenous dexamethasone 4 to 10 mg has been shown to decrease headache recurrence with a number needed to treat (NNT) of 10 when used prior to ED discharge.

For refractory pain, dihydroergotamine (DHE) 1 mg intravenous/intramuscular (IM)/subcutaneous (SC) can be useful; repetitive dosing over a 3- to 5-day course is generally more effective than a single infusion. Contraindications include pregnancy, uncontrolled hypertension, history of coronary artery disease, cerebrovascular disease or severe peripheral vascular disease, acute porphyria, Raynaud disease, and use of any triptan or ergot in the preceding 24 hours. Alternatively, a continuous infusion of intravenous lidocaine (1 to 4 mg/min) over a 7- to 10-day course under cardiac monitoring can be considered in patients with refractory headache who are unable to receive DHE for these reasons.

Headache recurrence after ED discharge is remarkably frequent, occurring in approximately 75% of patients within 48 hours of discharge; thus, close outpatient follow-up is necessary. Oral naproxen (Naprosyn) 500 mg and/or sumatriptan 100 mg at headache onset as abortive therapy are useful options upon discharge to avoid recurrent migraine.

Special conditions include the trigeminal autonomic cephalalgias (TACs), which are further covered in Chapter 54. The acute treatment of cluster headache includes 100% oxygen inhaled via a nonrebreather mask at a rate of 10 to 12 L/min for 15 to 20 minutes and/or sumatriptan 6 mg SC. Alternative options include intranasal sumatriptan 20 mg or zolmitriptan 5 mg or DHE 1 mg administered IM or intravenously. Paroxysmal hemicrania (PH) and hemicrania continua (HC) respond exquisitely to oral indomethacin, which can be started at a dose of 25 mg three times a day (t.i.d.) for 5 to 7 days, if no response then increased to 50 mg t.i.d. for an additional 5 to 7 days and further if needed to 75 mg t.i.d. A single intramuscular dose of indomethacin 100 mg ("Indotest") can be useful to confirm a diagnosis of PH or HC; however, this formulation is currently not available in the United States. SUNCT (**s**hort-lasting **u**nilateral **n**euralgiform headache with **c**onjunctival **t**earing and injection) or SUNA (**s**hort-lasting **u**nilateral **n**euralgiform headache with cranial **a**utonomic symptoms) that is not responsive to oral therapies (such as lamotrigine) may require a short course of intravenous lidocaine 1 to 4 mg/min under cardiac monitoring.

One of the challenges in standardizing headache treatment in the ED is that about half of such cases do not fit IHS criteria, which raises concerns about the external validity of ED studies. The schematic in [Figure 7.2](#) is a suggested general approach to the management of the migraine patient presenting to the ED. However, treatment ultimately should be tailored to the patient's individual headache characteristics, associated features, and medical comorbidities.

Pain, Numbness, and Paresthesias

Comana M. Cioroiu

INTRODUCTION

For the general neurologist, the evaluation of a patient with complaints of numbness can be a daunting one. Being the most subjective of neurologic complaints, numbness is often a difficult sensation for the patient to explain and often all the more difficult for the clinician to appreciate on examination.

MANAGEMENT STRATEGY

As with all complaints in medicine, the first step is to obtain a detailed history. The first question should be one aimed at best characterizing the sensation (or lack thereof) described by the patient. It is important to differentiate between numbness as a *loss of sensation* as opposed to the *presence of an abnormal sensation*. At times, patients may also use the term *numbness* to describe muscle weakness, and this is important to keep in mind during one's examination.

TYPES OF SENSORY SYMPTOMS

Numbness can occur as a result of pathology at several different parts of the neuraxis, including the cortex, brain stem, spinal cord, and peripheral nerves. *Paresthesias*, spontaneous and abnormal sensations often described as “tingling” or “pins and needles,” may imply a different neurologic localization than a complete lack of sensation alone. They also may occur following a period of absent sensation as nerves begin to slowly regenerate.

FIGURE 8.1 Sites of origin of pain within the nociceptive pathway. NSAIDs, nonsteroidal anti-inflammatory drugs. (Adapted from Marshall R, Mayer S. *On Call Neurology*. 3rd ed. Philadelphia: Saunders; 2007.)

NEUROPATHIC PAIN

Neuropathic pain (see [Chapter 57](#)) is a category of pain specific to that caused by nerve injury and is often described as painful paresthesias, associated with a sensation of burning or radiating pain as can be seen in cases of peripheral neuropathy or radiculopathy ([Fig. 8.1](#)). In such cases, patients may exhibit altered sensation or abnormally increased sensations—*hyperesthesia* refers to increased sensation, whereas *dysesthesia* refers to an evoked unpleasant or painful sensation.

An exaggerated response to stimuli that normally evoke pain is known as *hyperalgesia*, whereas an exaggerated response to stimuli that should not normally invoke pain is referred to as *allodynia*. These abnormal sensations can be seen with various nerve injuries, both at the central and peripheral level. Conversely, *hypoesthesia* refers to the diminished perception of pain, *anesthesia* to the inability to perceive pain, and *analgesia* to the inability to feel pain.

Neuropathic pain must be differentiated from somatic pain caused by pathology in bones, ligaments, muscles, and other soft tissues.

Complex regional pain syndrome (CRPS; also known as *reflex sympathetic dystrophy*) is a chronic disease characterized by severe neuropathic pain, skin changes, and swelling in one limb. It may occur in the absence of a known nerve injury (type 1) or in the

P.55

setting of known nerve injury (type 2). Diagnosis and treatment of CRPS is further discussed in Chapter 56.

TABLE 8.1 Patterns of Sensory Loss

Localization	Sensory Pattern	Associated Findings
Cortical	<ul style="list-style-type: none"> • Contralateral sensory loss 	<ul style="list-style-type: none"> • Cortical sensory loss (i.e., neglect, astereognosis, agraphesthesia) • Visuospatial deficits
Brain stem	<ul style="list-style-type: none"> • Contralateral sensory loss of arm and leg with ipsilateral loss in face 	<ul style="list-style-type: none"> • Cranial neuropathies (i.e., ophthalmoparesis, facial weakness) • Ataxia • Contralateral weakness • Hyperreflexia
Spinal cord	<ul style="list-style-type: none"> • Complete transverse lesion: loss of all sensory modalities below the level of the lesion • Central cord lesion (i.e., syrinx): loss of pain and temperature below the level of the lesion • Anterior cord lesion: contralateral loss of pain and temperature sensation below level of the lesion • Cord hemisection (Brown-Séquard syndrome): ipsilateral loss of vibration and joint position below the level of the 	<ul style="list-style-type: none"> • Contralateral or complete paralysis below the level of the lesion • Change in bladder or bowel control • Areflexia/hyporeflexia at the level of the

	<p>lesion and contralateral loss of pain and temperature two or three segments below the level of the lesion</p> <ul style="list-style-type: none"> • Cauda equina syndrome or conus medullaris syndrome: saddle anesthesia 	<p>lesion with hyperreflexia below the lesion</p> <ul style="list-style-type: none"> • Dissociation between sensory modalities
Brachial plexus	<ul style="list-style-type: none"> • Ipsilateral sensory loss in the distribution of more than one peripheral nerve or nerve root 	<ul style="list-style-type: none"> • Weakness in the distribution of the involved peripheral nerves or nerve roots • Areflexia • Neuropathic pain
Dorsal root ganglion	<ul style="list-style-type: none"> • Complete loss of sensation of all modalities in the affected dermatome 	<ul style="list-style-type: none"> • Neuropathic pain • No weakness
Nerve root	<ul style="list-style-type: none"> • Loss or diminution of all sensory modalities in the affected dermatome 	<ul style="list-style-type: none"> • Radicular pain • Weakness in the corresponding myotome • Areflexia or hyporeflexia
Peripheral nerve (also see Fig. 8.1)	<ul style="list-style-type: none"> • Mononeuropathy: loss or diminution of all sensory modalities in the distribution of the nerve • Polyneuropathy: distal and symmetric loss of sensation (vibration and joint position in cases of large-fiber neuropathy and pain and temperature in cases of small-fiber neuropathy) • Mononeuritis multiplex: loss of sensation in various peripheral nerves in an asymmetric fashion 	<ul style="list-style-type: none"> • Weakness involving muscles of the corresponding peripheral nerve • Distal and symmetric weakness in cases of large fiber polyneuropathy • Autonomic findings • Neuropathic pain • Areflexia or hyporeflexia

NEUROANATOMY AND LOCALIZATION

The pattern and distribution of sensory complaints provides important clues regarding the localization of the pathology (Table 8.1). Sensory syndromes that relate to injury at different levels of the neuraxis are discussed in the following section.

CENTRAL SENSORY SYNDROMES

Cortex

Numbness and paresthesias can result from both lesions in the central or peripheral nervous system. Higher

cortical sensory functions are localized to the parietal cortex, with the primary sensory cortex being the postcentral gyrus of the parietal lobe. Lesions of the parietal lobe such as tumors or vascular insults (i.e., stroke, vascular malformation, hemorrhage) may cause sensory loss and numbness and are often associated with other impaired parietal lobe functions clinically manifested by poor visuospatial skills and hemineglect. Subcortical lesions in the parietal lobe may also manifest with loss of sensation as can be seen with demyelinating plaques of multiple sclerosis.

Brain Stem

Brain stem lesions involving the trigeminal nucleus, medial lemniscus, or spinothalamic tract may also present with facial or limb numbness but are frequently associated with other brain stem findings such as ophthalmoparesis, weakness, or ataxia. Numbness resulting from spinal cord injury may correspond to a particular dermatome but may also lead to a sensory level, in which the entire body below the lesion is affected (see [Chapter 13](#)). Examples

P.56

of this include cases of transverse myelitis, in which patients may present with a sensory level with complaints of numbness extending down from a particular dermatomal level.

Spinal Cord

The two main central sensory pathways in the spinal cord are the *dorsal columns* also known as the *medial lemniscus* and the *spinothalamic tract* (see [Fig. 16.1](#)). Neurons carrying information related to vibration sense and proprioception travel up the cuneate and gracile fasciculus (which form the dorsal columns) in the spinal cord and synapse in their respective nuclei in the medulla, after which they decussate and form the medial lemniscus which carries these fibers to the ventral posterolateral (VPL) nucleus of the thalamus.

Fibers carrying pain and temperature sensation form the lateral spinothalamic tract in the spinal cord and typically ascend two spinal levels in Lissauer tract in the ipsilateral cord before synapsing with a second-order sensory neuron. From there, they decussate (cross over) in the anterior white commissure to the contralateral cord, and the tract then travels up the remainder of the spinal cord and brain stem and synapses again in the thalamus. Pathology of the posterior limb of the internal capsule or VPL nucleus of the thalamus may also cause numbness, and sudden-onset isolated numbness of a limb in a patient with vascular risk factors should raise concern for a possible vascular event in these regions. Similarly, sudden-onset numbness of the face may result from a lesion in the ventral posteromedial (VPM) nucleus of the thalamus.

Numbness resulting from spinal cord injury may also be accompanied by weakness and changes in bowel or bladder function. Depending on which segment of the cord is injured, patients may have preferential involvement of one tract or another and may have only certain sensory modalities affected; one classic example of this is the *Brown-Séquard syndrome*, where a spinal cord hemisection leads to ipsilateral weakness and loss of vibration and joint position sense below the level of the lesion and contralateral loss of cold and temperature sensation two or three segments below the level of the lesion.

PERIPHERAL SENSORY SYNDROMES

Dorsal Root Ganglia

The dorsal root ganglion is a group of nerve cell bodies distal to the spinal cord carrying somatic afferents to the cord. A *sensory ganglionopathy* refers to the selective destruction or involvement of the dorsal root ganglion and clinically typically manifests as a sensory ataxia with profound deficits in proprioception, at times also with marked neuropathic pain and paresthesias. A ganglionopathy of this type may be autoimmune, paraneoplastic (specifically related to anti-Hu antibodies), toxic, or associated with a paraproteinemia or with Sjögren syndrome.

Injury to the nerve root just distal to the spinal cord may cause numbness and pain in the setting of a radiculopathy —patient may complain of radiating pain of an electric quality, at times associated with muscle soreness.

Nerve Roots and Plexuses

Sensory loss in a specific dermatomal distribution may be seen on exam (see [Fig. 3.12](#)). Processes affecting the brachial or lumbosacral plexus often present with pain as well as numbness and weakness in one limb in the distribution of more than one peripheral nerve or nerve root. *Brachial plexopathy* is the most common of these and can result from trauma, tumor infiltration, a postinfectious autoimmune process, or can often be idiopathic.

Peripheral Nerves

Neuropathic pain and numbness is a classic complaint in diseases of the peripheral nerves, such as in *polyneuropathy* (see [Chapter 87](#)). These patients will often complain of numbness and neuropathic pain that is distal and symmetric, typically starting in the feet. Neuropathy may preferentially affect large myelinated nerve fibers (group A fibers) carrying information related to vibration and joint position sense or small unmyelinated nerve fibers (group C fibers) transmitting pain and temperature sensation (see [Fig. 8.1](#)). Polyneuropathy can be either primarily axonal (with a predominant loss of axonal integrity) or demyelinating (due to destruction of the myelin sheath and often autoimmune in origin). Diseases of the neuromuscular junction and muscle do not present with sensory complaints, although some patients may complain of proximal muscle pain (as with the inflammatory myopathies).

FOCUSED HISTORY

A detailed history is the best tool a clinician has in the initial evaluation of a patient with sensory complaints. First, one must try to characterize the nature of the complaint. It is helpful to determine the nature of the pain or numbness and whether the patient is referring to a complete lack of sensation or the presence of an abnormal sensation (i.e., paresthesias). One must inquire as to the nature of symptom onset, as an acute or sudden onset of numbness may point more toward a vascular lesion (i.e., stroke) than towards a progressive process, and requires more urgent evaluation. *Red flags suggesting a more serious structural problem in a patient with primary sensory complaints include the presence of fever, weakness, and bowel or bladder changes.*

NUMBNESS AND PARESTHESIAS

When evaluating complaints of numbness or paresthesias, the anatomic distribution is important to determine, as this will help with localization and differential diagnosis: For instance, numbness or paresthesias localized to a specific dermatome will have different implications than numbness involving an entire limb. One must ask about symmetry, duration of symptoms, and any alleviating or exacerbating factors. For instance, neuropathic pain often worsens at night while patients are in bed, and radicular pain/paresthesias may be elicited with specific movements of the neck or back. In order to help formulate a differential diagnosis, it is crucial to ask about various associated symptoms. Numbness associated with changes in bowel or bladder habits may point towards a spinal cord lesion. A recent history of viral infection associated with ascending numbness should alert one to the possibility of Guillain-Barré syndrome. Asking about any recent trauma or injury may also help differentiate between an acute as opposed to a chronic nerve injury. Questions regarding gait are pertinent, as patients with polyneuropathy may complain of imbalance early in the disease course.

PAIN

Acute pain is often managed very different from chronic pain, as the former may respond well to a brief course of a particular kind of analgesic, whereas the latter may require a complex regimen of medications. *Back pain* (see [Chapter 109](#)) is one of the most common complaints in neurology, and one must differentiate between benign

causes of low back pain and other causes of pain, which may be indicative of a more serious diagnosis. An acute disk

herniation is characterized by an abrupt onset often incited by lifting, Valsalva maneuver, or a sudden positional change. Lying down typically relieves this pain, whereas it is exacerbated by movement. It may be associated with radicular pain down the distribution of a particular dermatome. Chronic back pain is often challenging to treat and may require a complex therapeutic approach including medications, physical therapy, pain management, and sometimes surgical intervention.

PAST MEDICAL HISTORY

The patient's past medical history is important as well, as certain systemic illnesses may point toward an underlying etiology of the patient's symptoms. For instance, there are several conditions that may be associated with peripheral neuropathy, such as diabetes mellitus, rheumatologic diseases, or a history of cancer. A prior history of stroke of the thalamus or lateral medulla may contribute to a chronic pain syndrome (*Dejerine-Roussy syndrome*). A comprehensive list of current medications is also important to gather, as paresthesias can at times be a known side effect of certain medications (i.e., paresthesias of the hands with use of topiramate). When obtaining the family history, one must be careful to inquire as to any possible neurologic diseases or any family members with a history of known neuropathy or foot deformities that may, for instance, point toward Charcot-Marie-Tooth disease. Exposure to certain substances such as heavy metals, pesticides, or chemotherapeutic agents may be implicated in those with neuropathy (some of which can be quite painful), and thus, one should ask about these possibilities when no other clear etiology can be found.

FOCUSED EXAM

The examination of a patient complaining of numbness is often challenging, as the sensory exam is the most subjective part of the neurologic exam. See [Chapter 3](#) for a complete description of the neurologic exam.

GENERAL MEDICAL EXAMINATION

As with all other patients, one should begin with a thorough general medical examination to look for any hints of a possible systemic disease or other findings that may be associated with the patient's complaints. For a patient with numbness or neuropathic pain, this should include an examination of the skin, assessing for rashes, hair loss, or trophic skin changes as can be seen in patients with neuropathy. Although often difficult, looking directly at the skin of the affected region may be very telling—for instance, in a patient with neuropathic pain confined to a particular dermatome, patchy erythema with grouped vesicles may be diagnostic of herpes zoster (although zoster may present without a rash, as in zoster sine herpete, or the rash may present after the onset of pain). Any patient with acute onset of numbness in which a vascular event is suspected should have a thorough cardiac evaluation including examination of the carotid arteries.

Examination of the extremities should also involve an assessment of both active and passive range of motion of affected limbs, including a *straight leg raise test* (when indicated) which may be positive in cases of lumbosacral radiculopathy (see [Fig. 3.16](#)). A straight leg raise is performed while having the patient lie supine as the examiner raises each leg up vertically. If the test is positive, the patient's radicular symptoms are reproduced with passive lifting of the leg (particularly the contralateral leg), as the nerve roots are stretched. *Lhermitte sign* can at times be elicited with passive flexion of the neck and is positive when the patient reports a feeling of paresthesias radiating down the arms or legs. This is caused by pressure over the posterior columns and suggests a lesion in the posterior cervical cord as can be seen in patients with multiple sclerosis. *Tinel* and *Phalen* signs can elicit signs of median nerve compression from carpal tunnel syndrome in patients with unilateral or bilateral hand numbness (see [Fig. 3.15](#)).

NEUROLOGIC EXAMINATION

Mental Status

The majority of patients with complaints of paresthesias or neuropathic pain should have an entirely normal mental status. An abnormal finding in the patient's mental status examination points toward a cortical lesion. Higher cortical sensory function can be assessed by testing for *graphesthesia* (the ability to identify a number or letter written on the skin) and *stereognosis* (the ability to recognize an object placed in one's hand without visual or auditory stimuli). Testing for hemispatial neglect or extinction may also help identify a parietal lobe lesion.

Cranial Nerves

Similarly, a comprehensive examination of the cranial nerves can help to further localize a brain stem problem. A cranial neuropathy of any kind also suggests a central lesion as can be seen with a brain stem process or an intracranial lesion. Facial pain and neuropathies of the trigeminal nerve are discussed in detail in Chapters 55 and 86.

Motor Examination

A thorough motor examination is crucial to the evaluation of a patient with numbness and pain. In cases of chronic peripheral nerve injury, one may see atrophy of muscles in the distribution of the affected nerve. When pain is severe, a reliable determination of strength is often difficult to make. Similarly, when numbness is profound (particularly when proprioception is markedly affected), one may mistake joint position impairment for weakness. Weakness in the same distribution as numbness may point to a central lesion in the brain or spinal cord or a peripheral process in the nerve root or peripheral nerve. Distal and symmetric weakness is often most suggestive of a large-fiber polyneuropathy. Ataxia noted on finger-to-nose tests or heel-knee-shin tests may help localize a lesion to the brain stem; however, one may also find a marked sensory ataxia on coordination testing if joint position is markedly impaired.

Sensory Examination

The sensory examination is the most subjective part of the neurologic examination and often the most challenging. Several modalities can be tested and which ones are tested and how is dictated by the clinical presentation. Paresthesias that are transient and sporadic are infrequently associated with a clear loss of sensation on exam.

TABLE 8.2 Basic Principles of Sensory Examination

- Is the sensory loss symmetric?
-

- Does it follow a distal pattern?
-

- Does it correspond to a particular territory (i.e., of one dermatome or one peripheral nerve)?

When examining sensation, it is helpful to keep in mind *three basic principles* (Table 8.2). Taking the time to map out a specific distribution of numbness is often diagnostic and of localizing value. For instance, in suspected spinal cord lesions, one should assess for a sensory level, which may suggest the location of the cord pathology. One can begin with an assessment of light touch sensation, for example, using the tip of a cotton swab. Pinprick sensation and temperature sensation evaluate the integrity of the spinothalamic tract and small unmyelinated nerve fibers, whereas a selective loss of vibration or joint position implies injury to the posterior columns or to the large myelinated nerve fibers as seen in polyneuropathy.

Vibration sense is determined using a 128-Hz tuning fork placed over a bony prominence, most commonly the big toe and medial malleolus of the ankle (see Fig. 3.11). Interpretation of the vibratory exam must take into account the patient's age, as vibration sense diminishes with age over time, and can be absent in those older than 80 years old. Joint position is tested by moving the most distal joint passively up or down and asking the patient the direction of movement. Typically, the most subtle of movements should be detected, and if a problem is found in the most distal joint, one should move more proximally to determine the full extent of impairment. In those with severe joint position sense abnormalities, involuntary movements of the fingers may be observed with arms outstretched (*pseudoathetosis*).

Reflexes

Deep tendon reflexes are important to elicit, as they may be pathologically brisk or hyperreflexic in cases of central lesions—for instance, in spinal cord injury, reflexes may be diminished or absent at the level of the lesion but increased below the level of the lesion. In cases of peripheral neuropathies, reflexes are typically diminished or absent.

Gait and Station

A careful assessment of gait, including stance, toe walking, heel walking, and tandem gait are also of importance, for example, as loss of balance is often a key complaint in cases of polyneuropathy. A positive Romberg test suggests impaired proprioception as can be seen with disorders of the posterior columns or with advanced large-fiber polyneuropathy.

DIAGNOSTIC EVALUATION

Following a comprehensive history and exam, one should consider appropriate diagnostic studies based on the differential diagnosis and most likely localization.

SEROLOGIC TESTS

Various tests are available to us in working up patients with neuropathic pain and numbness. Serum studies are routinely done early on in the workup and in cases of sensory loss should include electrolyte and vitamin levels (particularly B₁₂, B₆, B₁) as well as a hemoglobin A1c level, as vitamin deficiencies and diabetes are common systemic illnesses that often contribute to nerve damage. Depending on the clinical scenario and index of suspicion, serum testing can be expanded to include testing for HIV, thyroid function, hematologic malignancies, rheumatologic diseases, and various other illnesses. In those patients with a history of specific environmental exposures, testing can be done to evaluate for the presence of specific toxic agents such as heavy metals. Genetic causes of numbness and paresthesias exist (i.e., Charcot-Marie-Tooth disease, hereditary neuropathy

with liability to pressure palsies), and genetic testing should be pursued in those with a family history and the appropriate clinical phenotype.

NEUROIMAGING

If a central lesion is suspected, imaging studies are typically done early to evaluate for a structural lesion. Magnetic resonance imaging (MRI) (see [Chapter 21](#)) has the highest sensitivity and is the preferred imaging modality; however, a computed tomography (CT) scan can be done in patients unable to tolerate or undergo MRI testing. Spine imaging in particular can be instructive when considering a lesion at the level of the cord or the nerve root. In those patients in whom MRI is not feasible, CT myelography can be used to assess for structural lesions of the spine and nerve roots. More distally, imaging of the brachial plexus is at times instructive in providing a more clear etiology in cases of plexopathy and can be used to evaluate for hemorrhage, inflammation, or infiltrative lesions.

LUMBAR PUNCTURE

Lumbar puncture (LP) (see [Chapter 31](#)) should be performed in cases of suspected inflammatory, infectious, or neoplastic processes. It is particularly helpful in cases of suspected autoimmune demyelinating neuropathies, which will show a characteristic albuminocytologic dissociation with elevated protein in the setting of a normal cell count.

ELECTRODIAGNOSTIC AND QUANTITATIVE SENSORY TESTING

Nerve conduction studies and electromyography (EMG) are important in helping to diagnose conditions of the peripheral nervous system and can help localize a complaint of numbness or neuropathic pain to the nerve root, plexus, or peripheral nerve (see [Chapter 25](#)). These tests have long been the standard practice in the diagnosis of neuropathy involving large nerve fibers and can characterize the severity of injury as well as distinguish between generalized and focal forms of either purely axonal or demyelinating forms of neuropathy (such as acute or chronic inflammatory demyelinating neuropathy). Nerve conduction study techniques are not sensitive in the assessment of small nerve fibers and are normal in cases of small-fiber neuropathy. More extensive quantitative sensory testing (QST) can be done in certain patients to more sensitively assess sensory dysfunction. QST uses noninvasive methods to determine the sensory threshold to various modalities including vibration, temperature, and pain and compare it to standardized normal values.

SKIN AND NERVE BIOPSY

Given the inability of routine electrodiagnostic tests to assess for involvement of small unmyelinated cutaneous nerve fibers, a diagnosis of small-fiber neuropathy is typically made via skin biopsy. *Nerve biopsy*, a more invasive test, is typically best reserved for cases in which the diagnosis is in question and there is no known etiology (see [Chapter 32](#)). The diagnostic yield and use of nerve biopsy is best seen in cases of inflammatory, demyelinating, or infiltrative etiologies of neuropathy, with the most informative being those done on a nerve with abnormalities demonstrated on nerve conduction studies.

P.59

INITIAL MANAGEMENT

IDENTIFY POTENTIALLY SERIOUS CONDITIONS

Most patients with complaints of pain or paresthesias can be safely evaluated on an outpatient basis; however, exceptions certainly do exist. *Acute conditions that may lead to rapid deterioration must be identified promptly and treated as such.* For instance, a patient presenting with acute-onset lateralized numbness with vascular risk factors should be directed to the emergency room for stroke evaluation. Similarly, a patient with suspected

Guillain-Barré syndrome or transverse myelitis should be evaluated rapidly and admitted to the hospital, as a delay in treatment could result in rapid deterioration and possible respiratory compromise. Inpatient hospitalization for treatment with steroids, intravenous immunoglobulin (IVIg), plasmapheresis, or other immunomodulatory agents is at times necessary for these patients depending on the clinical situation.

SYMPTOMATIC TREATMENT

Once all diagnostic tests are completed, treatment of pain and paresthesias is twofold. The first approach is to treat the underlying etiology of the symptoms—for instance, if a structural lesion is found, surgical intervention may be appropriate, or if an autoimmune condition is diagnosed, treatment with immunomodulatory therapy is indicated. Patient with diabetes should be counseled regarding glycemic control and diet modification, those with vitamin deficiencies should be repleted, and so forth. Second, symptomatic therapy should be initiated to help with bothersome symptoms. *The treatment of neuropathic pain and paresthesias is vast and is discussed in detail in Chapter 57.* Symptomatic treatment should be multidisciplinary and include a combination of pharmacologic measures, physical therapy, and behavioral modifications. Chronic pain is often markedly challenging to treat and can be frustrating to both patients and practitioners alike.

KEY POINTS

- Characterize the nature of the complaint—what does the patient mean by “numbness”? How can you characterize the pain?
- Obtain a detailed history and examination to help localize the patient's complaints of numbness/paresthesias to a location in either the central or peripheral nervous system.
- When examining a patient with sensory loss, look for asymmetry, a distal versus proximal gradient, and try to identify a pattern of sensory loss to guide your diagnostic impression.
- Look out for red flags that suggest an urgent problem that needs to be addressed and treated rapidly.
- Let your differential diagnosis guide your diagnostic testing.
- Treatment of chronic pain and paresthesias can be complex and often requires a multidisciplinary approach.

Visual Disturbances

Jeffrey G. Odel

Julia Mallory

INTRODUCTION

No symptom may be as disturbing or dramatic to a patient as acute visual loss. Although acute ocular diseases such as glaucoma, uveitis, and retinal detachment may require urgent evaluation by an ophthalmologist, a high percentage of visual disturbances fall within the province of the neurologist. Neurologic visual symptoms may be reported as blurriness, focal obscurations, or positive visual phenomena. Because the visual pathway from the retina to the calcarine cortex is constant from individual to individual, anatomic localization can be made with a high degree of accuracy on physical examination. The progression, associated symptoms and signs, and clinical setting will help you make the correct diagnosis and suggest the proper acute management.

NEUROANATOMY

The optical system of the eyes focuses images onto the outer retina where the light energy is converted into nervous impulses by rods and cones. These impulses are then conveyed by the axons of the retinal ganglion cells on a path centripetally through the inner retina, converging on the optic nerve head. The impulses then travel along the optic nerve and through the optic chiasm where fibers from the nasal retina (temporal visual field) decussate to join temporal retinal fibers (nasal visual field) from the other eye in the contralateral optic tract. The retinal ganglion cell axons pass from the optic tract into the geniculate body where they synapse. The nervous impulse is conveyed by the geniculocalcarine pathway, composed of the axons from the geniculate body cells that pass through the temporal and parietal lobes, to synapse in the calcarine cortex in the occipital lobe which relays the impulses for higher cortical analyses such as reading and recognition.

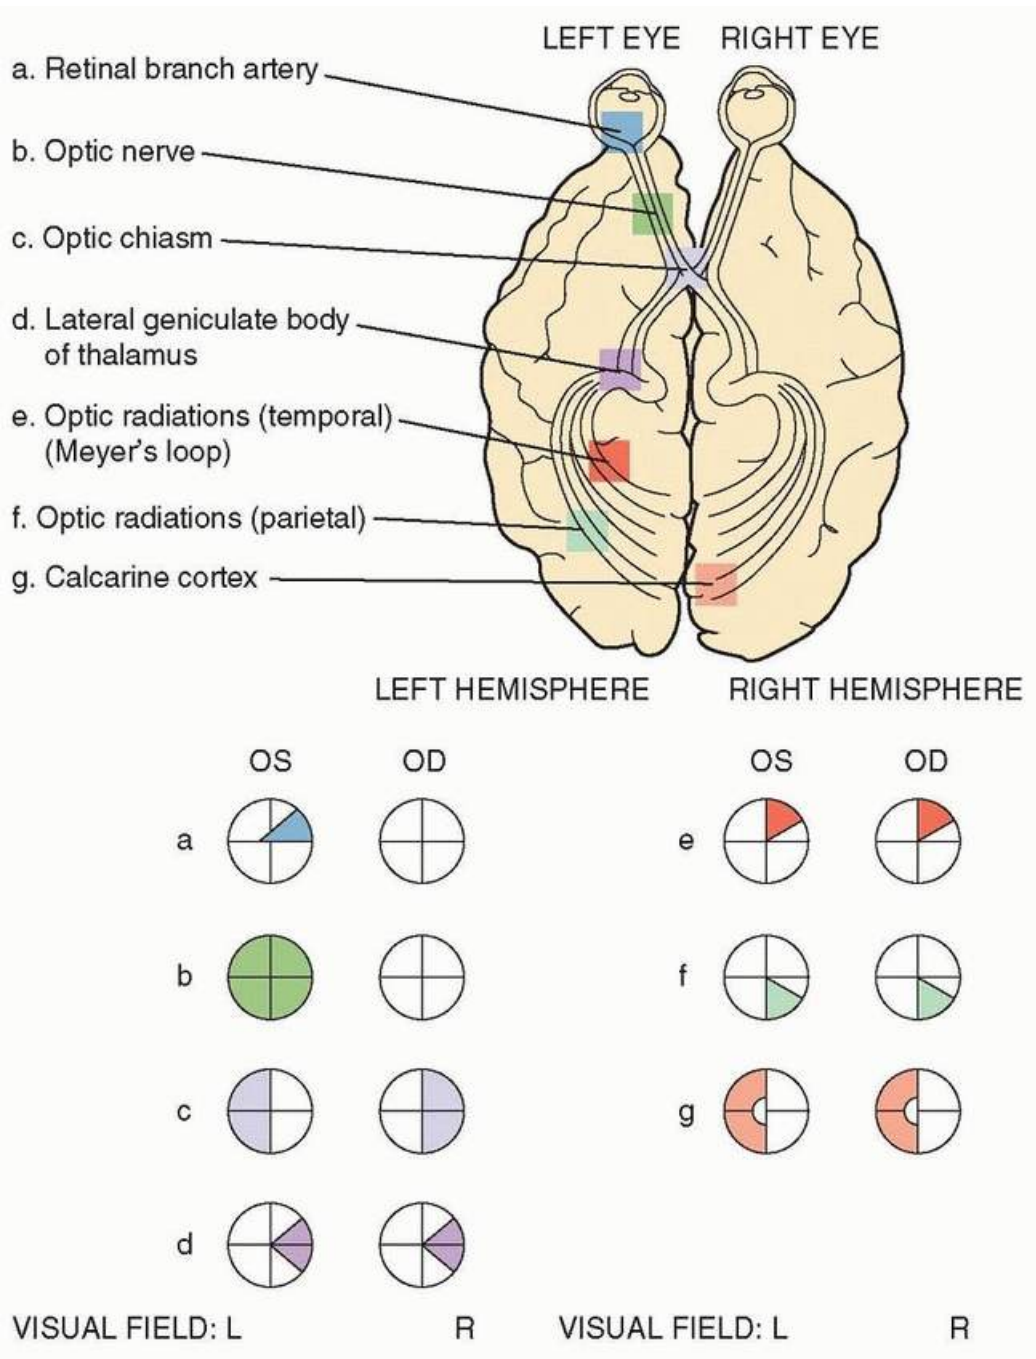

FIGURE 9.1 Visual field cuts produced by lesions at different points along the visual pathway. (a) Monocular segment anopia produced by a retinal artery branch occlusion in the left eye. (b) Monocular blindness produced by a lesion in the left optic nerve. (c) Bitemporal hemianopia produced by a mass lesion at the optic chiasm. (d) Right segment anopia produced by a lesion in the lateral geniculate body of the left thalamus. (e) Right upper quadrantanopia produced by a lesion in the left temporal optic radiation (Meyer loop). (f) Right lower quadrantanopia produced by a lesion in the left parietal optic radiation. (g) Left homonymous hemianopia produced by a lesion in the calcarine cortex of the right occipital lobe. Note that macular vision is sometimes spared because of middle cerebral artery collateral blood flow to the occipital pole. OS, oculus sinister; OD, oculus dexter. (Adapted from Marshall R, Mayer S. *On Call Neurology*. 3rd ed. Philadelphia: Saunders; 2007.)

COMMON PROBLEMS

Visual loss may be due to abnormalities of the ocular media, the retina, the anterior visual pathway (the optic nerves, chiasm, and optic tracts), or the geniculocalcarine pathway (Fig. 9.1 and Table 9.1).

It may also result from a lesion in the oculomotor or vestibular systems from diplopia or oscillopsia. Patients with

alexia or agnosia may also complain of visual loss, although their acuity may test normally.

TABLE 9.1 Signs and Symptoms that Suggest Location in the Visual Pathway

Location of Lesion along Visual Pathway	Signs and Symptoms
Anterior segment of the eye	<ul style="list-style-type: none"> • Blurred vision • Glare or halos • Foreign body sense in eye • Correction with squinting, pinhole, or ophthalmoscope • Response to blinking • Visible opacities on exam
Retina	<ul style="list-style-type: none"> • Metamorphopsia • Macropsia or micropsia • Positive scotoma • Geographic scotoma • Central scotoma unconnected to blind spot • Prolonged photostress recovery time • Flashes or floaters • Nyctalopia or hemeralopia • Purple, yellow, or green vision
Optic nerve	<ul style="list-style-type: none"> • Negative scotoma • Decreased brightness and/or color sense • Cecocentral, arcuate, or altitudinal visual field defect or horizontal step in visual field • Relative afferent pupillary defect • Optic disc swelling or atrophy • Nerve fiber layer dropout • Optic nerve head cupping
Chiasm	<ul style="list-style-type: none"> • Bitemporal hemianopia • Band atrophy of optic disc • Postfixation blindness • Hemifield slide phenomena
Optic tract	<ul style="list-style-type: none"> • Homonymous hemianopia with optic atrophy and relative afferent pupillary defect in contralateral eye
Geniculate body	<ul style="list-style-type: none"> • Congruent horizontal homonymous sectoranopsia • Congruent upper and lower sectoranopsias • Incongruent homonymous hemianopia • Optic atrophy

Geniculocalcarine pathway	<ul style="list-style-type: none"> • Homonymous hemianopia • “Pie-in-the-sky” hemianopia, temporal lobe • “Pie-on-the-floor” hemianopia, parietal lobe • Optokinetic defect ipsilateral to parietal lobe lesion • Scotomatous hemianopia—occipital lobe • Preserved temporal crescent of field—occipital lobe • Hemiparesis, aphasia, alexia, agnosia, somatosensory disturbance
Oculomotor/vestibular system	<ul style="list-style-type: none"> • Oscillopsia • Diplopia

BLURRED VISION

Refractive errors, as in myopia, hyperopia, and astigmatism, cause blurred vision. This blurring may be corrected by having the patient focus through an ophthalmoscope by turning the lens wheel either at distance or with a reading card held at 14 inches. If the ophthalmoscope fails or is not available, having the patient view through a pinhole (with an optimum diameter of 2 mm) corrects most refractive errors. Cataract and corneal edema or opacity may cause glare, halos, or light beams from lights. Tear film disturbance, or dry eye, responds to blinking or artificial tears. Opacities of the ocular media, as in cataract, corneal scar, or aqueous or vitreous hemorrhage, may be visualized during examination using an ophthalmoscope while focusing on the red reflex in the pupil. Opacities anterior to the center of the eye in the cornea, anterior chamber, and lens rise when the patient looks up slightly, whereas those in the posterior half of eye (vitreous) descend.

VISUAL DISTORTIONS

Retinal pathology that distorts the retina may cause straight lines to appear bent, broken, or curved (*metamorphopsia*) or objects to appear small (*micropsia*) or large (*macropsia*). This is caused by distortion of the outer retina by detachment, edema, fibrosis, neovascularization, or hemorrhage. Vitreous traction on the retina will cause photopsias if the vitreous detaches from the retina or vitreous traction tears or pulls a hole in the retina; *floaters* may be seen.

Retinal detachment will occur if fluid accumulates under the retina because of a hole or tear and would be appreciated as a shadow or curtain over the eye. With disease of the rods, as in retinitis pigmentosa or vitamin A deficiency, the patient experiences night blindness (*nyctalopia*) and prolonged dark adaptation. Impaired vision in daylight (*hemeralopia*) suggests cone dysfunction as in cone dystrophy but may be seen with central visual field defects of optic nerve origin. Central scotomas (areas of depressed visual sensitivity surrounded by areas of higher sensitivity) so small as to be unconnected to the blind spot are almost only seen in retinal conditions (Fig. 9.2A). Central ring scotomas are also a strong indicator of a retinal process (Fig. 9.2B).

Impaired visual recovery following bright light exposure suggests a retinal process. Purple vision suggests poor oxygenation to the outer retina from ipsilateral high-grade carotid stenosis or poor choroidal perfusion from giant cell arteritis; this can also be seen in central serous chorioretinopathy. Yellow, green, or snowy vision suggests retinal toxicity from digitalis toxicity. A dark blotch, positive scotoma, suggests a retinal process particularly if associated with photopsia. With visual loss of ocular origin, there may be associated local symptoms or signs, such as pain, photophobia, redness, or soft-tissue swelling.

FIGURE 9.2 Examples of visual field loss. Areas in *red* denote the physiologic blind spot created by the optic disc. Areas in *blue* denote pathologic visual loss. **A:** Bilateral small central scotomas at the fovea indicating a retinal condition. **B:** Bilateral central ring scotoma also strongly indicative of a retinal condition. **C:** Bilateral cecentral scotomas, as in optic neuropathy. **D:** Left eye: paracentral defect. Right eye: paracentral defects that have coalesced to an arcuate defect. **E:** Left eye: nasal horizontal step field defect. **F:** Left eye: junctional scotoma of Traquair. **G:** Left eye: cecentral defect ipsilateral to the affected left optic nerve. Right eye: junctional temporal defect in the contralateral (*right*) eye. **H:** Variation of BTH as in pituitary adenoma or meningioma attacking the chiasm from above.

VISUAL FIELD DEFECTS

Retinal Nerve Fiber Bundle Defects

The retinal nerve fiber bundle path is determined by the fovea, which is the center of the macula; the optic disc, which is centered about 15 degrees nasal to the fovea slightly above the horizontal; and the horizontal retinal raphe. Fibers coming from the retina temporal and superior to the foveal center arc above the macula, entering

the superior optic disc; those temporal and inferior to the center of the fovea arc below the macula and enter the optic disc inferiorly (Fig. 9.3).

This divergent pathway of the superior and inferior axons in the temporal retina around the macula creates the horizontal retinal raphe in the temporal retina and is the anatomic correlate of the nasal horizontal step field defect (Fig. 9.2E). These defects are more marked in the nasal visual field typically closer to fixation nasally and show respect for the horizontal meridian. Axonal damage may occur in the retina, disc, or retrobulbar optic nerve, as the nerve bundles stay together anterior to the chiasm. The axons from

P.63

the nasal fovea and axons originating between the fovea and the disc course directly into the temporal disc, and damage to these axons results in a cecocentral scotoma (Fig. 9.2C). This bundle then occupies the center of the optic nerve anterior to the chiasm. Damage to fibers coming from the retina nasal to the disc leads to temporal sectoral defect with an apex at the blind spot.

FIGURE 9.3 Retinal nerve fiber anatomy of a right eye as seen on ophthalmoscopy, with the optic disc nasal to the fovea, which is the center of the macula. PM is the papillomacular bundle of fibers that carry visual impulses nasally directly from the macula to the optic disc. HR is the horizontal retinal raphe. Nerve fibers arising from the retina temporal to the fovea arch above and below the macula and PM, and insert into the superior and inferior poles of the optic disc respectively. These arcuate paths of fibers from the temporal retina (nasal visual field) are responsible for the characteristic visual field defects of optic nerve disease, including peripheral horizontal nasal steps, arcuate defects, and cecocentral scotomas.

Symptoms and Signs of Optic Nerve Defects

The hallmarks of optic nerve dysfunction are visual field defects, loss of brightness and color sense, decreased pupillary reaction to light, optic nerve head swelling or optic atrophy, and nerve fiber layer dropout. Optic neuropathy causes cecocentral visual field defects (see Fig. 9.2C), paracentral defects (see Fig. 9.2D left eye), arcuate visual field defects (see Fig. 9.2D right eye), nasal step defects (see Fig. 9.2E left eye), and altitudinal defects (see Fig. 9.2E right eye).

In optic neuropathy, the shape of visual field defects corresponds to the path of the arcuate and macular-

papillary nerve fiber bundles. Paracentral defects, the smallest defects in the arcuate region may coalesce to form arcuate defects (Fig. 9.2D) as in glaucoma.

Injury of nasal optic nerve fibers anywhere from the back of the eye to just anterior to the chiasm will produce an ipsilateral relative temporal visual field defect that does not respect the vertical meridian. A small lesion right at the nasal junction of the optic nerve and chiasm may result in an ipsilateral central temporal defect that respects the vertical meridian, the monocular junctional scotoma of Traquair (Fig. 9.2F). Injury of temporal fibers of the optic nerve between the optic canal and the chiasm will produce a relative ipsilateral nasal defect that does not respect the vertical. More marked junctional involvement of the optic nerve and chiasm may produce a cecocentral defect ipsilateral to the involved optic nerve and an upper temporal defect in the contralateral eye (Fig. 9.2G). *Thus with loss of vision in one eye, it is critical to check the other eye to look for an unsuspected temporal visual field defect, as this is frequently caused by a mass lesion such as a pituitary adenoma or meningioma.*

Chiasmal Defects

Chiasmal involvement leads to variations of bitemporal hemianopsia (BTH) due to damage to crossing fibers from the nasal retinas, which carry information from the temporal visual fields. Tumors that compress the chiasm from below produce BTH that is greatest superiorly (Fig. 9.2H). Lesions attacking the chiasm from above, such as craniopharyngiomas, produce BTH that starts inferiorly (Fig. 9.4A). The visual field defect of lateral chiasmal compression (typically due to an aneurysm) spares the ipsilateral superior temporal visual field, causing visual loss in the other three ipsilateral quadrants and in the contralateral superior temporal quadrant (Fig. 9.4B).

Optic Tract Defects

Lesions of the optic tract (the continuation of the optic nerve relaying signals from the optic chiasm to the ipsilateral lateral geniculate nucleus) produce *contralateral incongruent homonymous hemianopsias*. These may have elements of chiasmal involvement and are accompanied by optic atrophy. The eye with more visual field loss, typically the contralateral eye, may exhibit a relative afferent pupillary defect. The pattern of optic atrophy is band or bow tie shaped in the eye with the temporal field defect; it is more generalized in the eye with the nasal defect. Some examiners have found congruous homonymous hemianopsias in tract lesions.

Geniculate Body Defects

Geniculate body lesions may cause incongruous or congruous visual field defects. Tumors of the geniculate body produce incongruous homonymous hemianopsias. There are two syndromes of geniculate infarction that result in striking congruous defects. Lateral posterior choroidal artery infarction results in a *congruous horizontal homonymous sectoranopia*, (Fig. 9.4C), a wedge-shaped hemianopia along the horizontal with the apex pointing to fixation and the wedge spreading out to the contralateral periphery. Anterior choroidal artery occlusion results in *upper and lower homonymous sectoranopias* that spare the horizontal and are complementary in shape to the horizontal homonymous sectoranopia (Fig. 9.4D). Because the optic tract synapses in the geniculate body, optic atrophy may be observed several weeks after a geniculate lesion.

Hemispheric Defects

Homonymous hemianopias are caused by lesions of the geniculocalcarine pathway in the temporal, parietal, or occipital lobes. Traditionally, the more posterior the site of a lesion, the more congruous it was thought to be, with occipital lesions being highly congruous. Recently, however, the rule of congruity has been questioned due to radiographic verification that shows congruous hemianopias at all retrochiasmal locations, even in the optic tract. "Pie-in-the-sky" upper quadrantanopias that do not respect the horizontal suggest a temporal lobe location (Fig. 9.4E), whereas hemianopias that are greatest inferiorly suggest a parietal localization (Fig. 9.4F). This is

especially true when accompanied by a defect in optokinetic nystagmus with targets following to the side of the lesion. The *extinction phenomenon* is an apparent hemianopsia in a seeing area of the visual field that occurs during simultaneous stimulation to right and left hemifields. Extinction can be confirmed by finding a similar defect to tactile simultaneous stimulation that is not present on single-sided stimulation.

Homonymous hemianopic scotomas suggest occipital lesions but are not specific for that location (Fig. 9.4G). Involvement of the calcarine cortex (or primary visual cortex, V1, Brodmann area 17),

P.64

anterior in the occipital lobe, where peripheral vision is represented, results in a *monocular temporal crescent visual field defect*. After a retinal detachment has been ruled out, this is specific for an occipital lobe lesion contralateral to the field defect and is usually caused by a tumor. Sparing of the anterior calcarine cortex is common in infarcts of the posterior cerebral artery and results in a preservation of the temporal crescent contralateral to the lesion. It is highly suggestive of occipital localization. A homonymous hemianopia with sparing of the central visual field is referred to as *macular-sparing hemianopsia* (Fig. 9.4H) and is suggestive of occipital involvement but macular sparing has been reported as anterior as the optic tract. Preservation of motion vision in a hemianopic defect, termed the *Riddoch phenomenon*, is also suggestive of occipital involvement, although it has also been seen as far anteriorly as the optic tract as well. *Anton syndrome*, denial of blindness in the setting of bilateral hemianopsias, represents bilateral calcarine

P.65

involvement plus an association area infarction. Quadrantic visual field defects precisely respecting the horizontal meridian in each eye have been reported in extrastriatal occipital cortex lesions involving areas V2/V3.

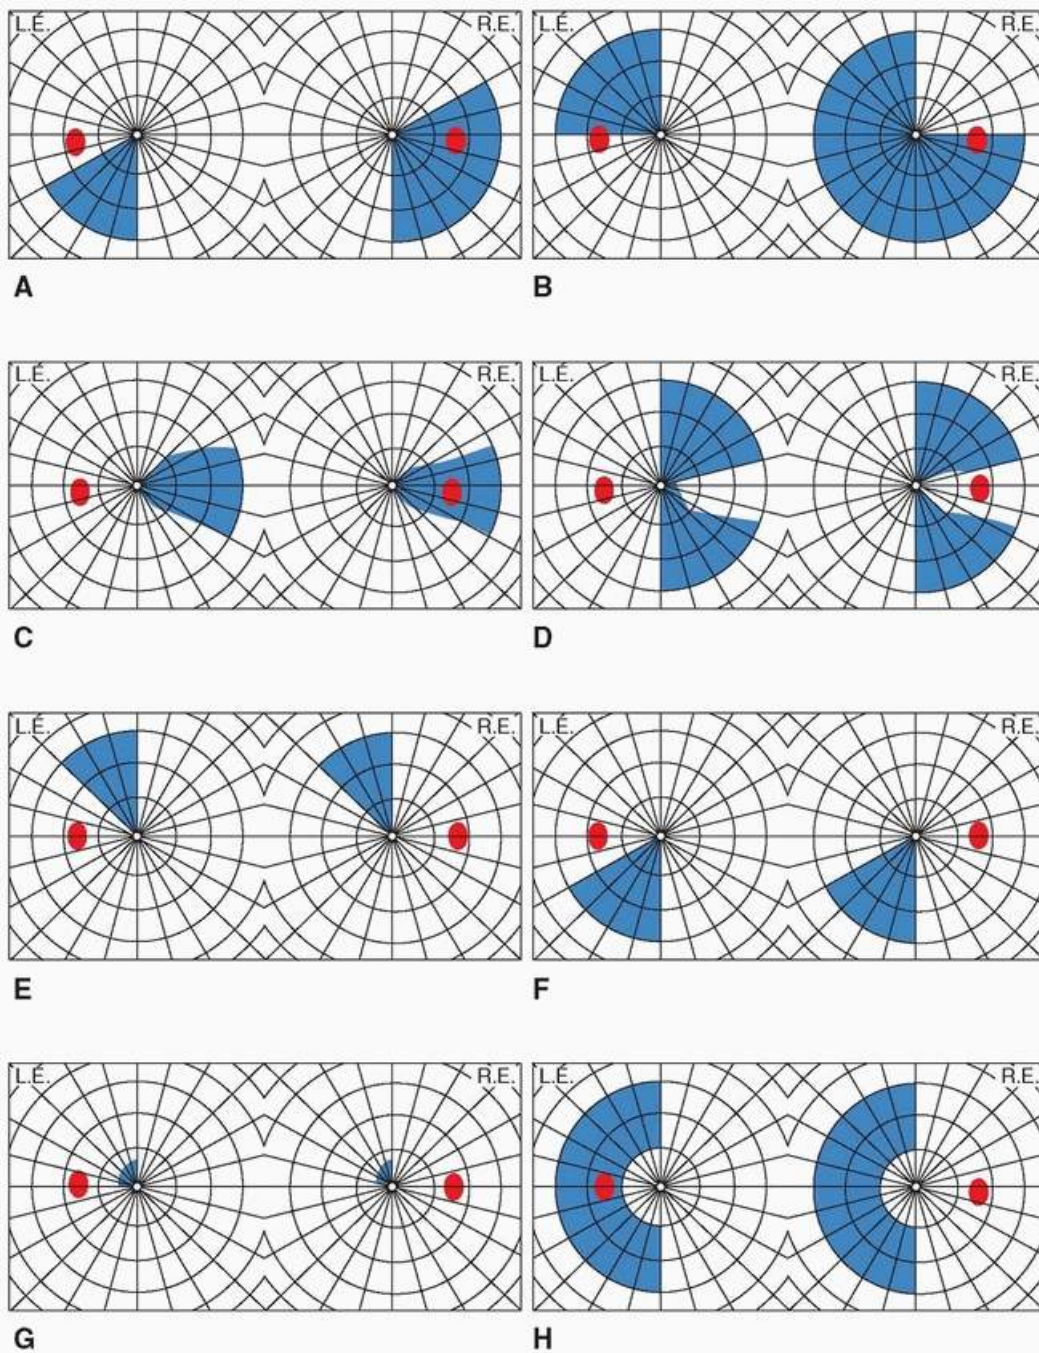

FIGURE 9.4 Examples of visual field loss. Areas in *red* denote the physiologic blind spot created by the optic disc. Areas in *blue* denote pathologic visual loss. **A:** Variable bitemporal inferior quadrantanopsia attacking the chiasm from below. **B:** Variable bilateral visual field defects from a right lateral chiasmal compression from an aneurysm. **C:** Bilateral congruous horizontal homonymous sectoranopia resulting from lateral posterior choroidal artery infarction. **D:** Upper and lower homonymous sectoranopias that spare the horizontal as in anterior choroidal artery occlusion. **E:** Bilateral pie-in-the-sky upper quadranopias from a temporal lobe lesion. **F:** Hemianopia greater inferiorly from a parietal lesion. **G:** Homonymous hemianopic scotoma suggesting but not specific for occipital lesion. **H:** Macular-sparing hemianopsia suggesting but not specific for occipital lesion.

DIPLOPIA

Disturbances of eye movement and ocular alignment result in diplopia. This can result from ocular muscle problems, neuromuscular transmission defects, cranial neuropathies, and ocular motor nuclear and internuclear ophthalmoplegias and cause double vision, which the patient may report as blurry vision. Damage to the central vertical and horizontal gaze pathways and vestibular systems may result in gaze palsies or nystagmus that the patient may report as visual difficulty.

CAUSES OF VISUAL LOSS

Visual loss may be fleeting (unilaterally or bilaterally), acute and slowly remitting, slowly progressive, acute and nonremitting, or acute with ophthalmoplegia. The tempo of visual loss provides important clues regarding etiology.

TRANSIENT MONOCULAR BLINDNESS

Also known as *Amaurosis fugax* (AF), transient monocular blindness (TMB) may be complete or partial and lasts from seconds to 20 minutes with recovery. The most frequent cause is thromboembolism of the retinal artery, but many other conditions can cause the syndrome as well ([Table 9.2](#)).

Embolic Transient Monocular Blindness

TMB from *embolism* is frequently described as a descending curtain that covers all or half of the field of vision or may start with quadrant involvement. Less frequently, it is reported as an ascending curtain and rarely, as a sideways moving blind. It may appear as a ground glass, a gray-out, a cloud, or complete blackness. Swirling sparks of light, signifying emboli that are entoptically stimulating the retina as they course through the retinal vessels, may occur. TMB may clear like a clearing fog or regress like a curtain that goes up or down, altitudinally or quadrantly. This pattern of AF suggests embolic origin most frequently from an ulcerative plaque of the carotid bifurcation or originating from the ascending aorta or heart. These cases require emergent evaluation.

TABLE 9.2 Causes of Transient Unilateral Visual Loss

- Optic nerve head drusen

- Congenital optic nerve anomalies (coloboma, morning glory disc)

- Orbital masses (causes gaze-evoked monocular visual loss)

- Uthoff phenomenon

-
- Asymmetric light adaptation

Hypotensive Transient Monocular Blindness

Hypotensive TMB usually occurs in the setting of extensive arterial occlusive disease. Hypotensive AF may range from being very brief to lasting longer than embolic AF. The episodes may present with monocular concentric constriction, or blotchy vision, or bright objects appearing brighter, loss of contrast, or photographic negative vision. Bright light may provoke hypotensive TMB, and there may be prolonged photostress recovery of vision. It may be associated with ocular ache and mild signs of cerebral ischemia such as poor concentration, sudden fatigue, or feeling faint. Hypotensive TMB may be precipitated by arterial hypotension, arrhythmias, or venous hypertension. Bending over, standing up, exercising, bright light, and overheating may also precipitate attacks. Giant cell arteritis, Takayasu disease, and other occlusive disorders of the aortic arch or carotid arteries may also be present.

During an attack of hypotensive TMB, the retinal vessels on ophthalmoscopy may be narrow and the disc blanched; just following an attack, the vessels dilate with irregularity of the veins and hyperemia of the disc. Between attacks, the retina may have midperipheral and peripheral retina dot and blot hemorrhage at the end of vessels, venous tortuosity, and microaneurysms. This is referred to as *venous stasis retinopathy* and can be differentiated from vein occlusion by the presence of arterial pulsations spontaneously or with light pressure on the globe.

Arterial Spasm

Arterial spasm in the ophthalmic, retinal, or choroidal circulation may result in TMB in the adolescent or young adult who is otherwise healthy. The description of the visual loss is varied but does not involve a curtain falling over the vision. It more closely mimics the description of hypotensive TMB with blotchy visual loss of several minutes' duration. Previously, it was referred to as *retinal migraine*; however, its relation to migraine is now less certain.

Ocular Erosions

Other ocular abnormalities may cause transient visual blurring. For instance, recurrent erosions of the superficial corneal epithelium, usually seen in the setting of corneal epithelial basement membrane dystrophy, may present with foreign body sensation and generalized hazy vision that may be unilateral or bilateral. These symptoms start upon opening the eyes after sleep, last from minutes to hours, and respond to blinking.

Angle-closure Glaucoma

Angle-closure glaucoma can cause transient visual loss. The episodes of visual loss are unilateral, recurrent, and can be painful or painless. Patients may report seeing halos around lights. During an attack, the eye may exhibit perilimbal injection, a vertically oval pupil, a cloudy cornea, and high intraocular pressure that may normalize if the attack breaks. Angle closure occurs in patients who are middle aged or older and can be precipitated by watching a movie in darkness, exercise, sexual activity, and drugs that dilate the pupil, for example, atropinic drugs used during anesthesia or sulfur drugs that enlarge the ciliary body, for example, topiramate. The neurologist should arrange for slit lamp examination, intraocular pressure check, gonioscopy of the angle, and fundus examination

with an ophthalmologist. Release of pigment from the posterior leaf of the iris may cause acute elevations of

intraocular pressure called *pigmentary glaucoma*. This form of glaucoma causes transient monocular visual loss after vigorous exercise or in situations that dilate the pupil and again requires ophthalmic consultation.

Ocular Hemorrhage

Hyphema is blood in the anterior chamber of the eye between the cornea and iris. It may trigger hazy vision if it is dispersed as when the patient bends over. *Vitreous hemorrhage* may do the same. *Uveitis-glaucoma-hyphema (UGH) syndrome*, as the name suggests, is characterized by uveitis, glaucoma, and hyphema and caused by repeated anterior chamber hemorrhages following intraocular lens surgery. It too may be responsible for repeated bouts of hazy vision.

Drusen

Hyaline bodies in the anterior optic nerve, called *optic nerve head drusen* (ONHD), can cause monocular or binocular transient obscurations of several seconds' duration. ONHD buried within the disc in childhood grow, calcify, and extrude through to the disc surface with age. They are sometimes mistaken for papilledema, particularly before they extrude, but ultrasound and CT scan reveal their calcification. Optic discs with ONHD are small, have no cup, and display early bifurcation of the retinal blood vessels. Visible drusen are usually multiple and may resemble mulberries. Blood vessels can be followed coursing from the disc to the retina unlike those in real disc edema, which are obscured by axoplasmic transport backup in the nerve fiber layer. The adjacent peripapillary retina may have small areas of retinal pigment hypertrophy and scarring from old subretinal hemorrhage. When seen acutely, this appears as a flat, crescent-shaped area adjacent to the disc.

Congenital Optic Disc Anomalies

Congenital optic disc anomalies such as *coloboma* and *morning glory disc* may be associated with transient visual obscurations. Acquired disc elevations, particularly *papilledema* and *central retinal vein occlusion*, may also be associated with transient visual obscurations. These are described as gray or blackouts associated with postural change, can be unilateral or bilateral, and last for seconds.

Others

Acquired disc edema from compression or infiltration of the optic nerve by tumors, for example, meningioma or hemangioma, can be associated with transient visual obscurations. *Gaze-evoked monocular visual loss* occurring on eccentric gaze suggests an orbital tumor with vascular compromise. *Uhthoff phenomenon* of crescendo-decrescendo visual loss over 20 to 30 minutes with exercise, overheating, hot baths, or showers suggests demyelination of the optic nerve; it can also be seen in nerve compression.

Finally, asymmetric light adaptation occurs situationally when one eye is dark adapted compared to the other. This presents when a patient is reading next to a bedside lamp. When the light is turned off, the eye further from the lamp is relatively dark adapted, whereas the eye closer to the light is unable to see in the darkness for several minutes.

FLEETING BILATERAL VISUAL LOSS

Migraine

Migraine is the most frequent cause of bilateral simultaneous transient visual loss (Table 9.3). The migrainous aura typically precedes the headache beginning as a tiny paracentral scintillating scotoma or negative scotoma. The scotoma is experienced homonomously and congruently usually in the shape of a C in the left hemifield or a backward C in the right hemifield. Over 20 minutes, it expands and migrates centrifugally, leaving in its wake an area of transiently depressed field disappearing into the periphery of the involved field. It is variously described as zigzagged, saw-toothed, or lightning-like or if viewing a face imparting a *Picasso effect*. A headache

contralateral to the involved field typically begins within minutes of the scotoma's disappearance. Rarely, a structural lesion of the occipital lobe can trigger a migrainous march in which case the aura never switches sides. Occipital epilepsy does not have the characteristic 20-minute expansion and migration and may persist for hours or days.

TABLE 9.3 Causes of Fleeting Bilateral Visual Loss

- Migraine

- Vertebrobasilar insufficiency

- Papilledema

- Blepharospasm

- Dry eye

Vertebrobasilar Insufficiency and Others

Patients with *vertebrobasilar insufficiency* (VBI) may experience bilateral blurry vision as if looking through water. It may be hemianopic or bihemianopic and typically lasts minutes, typically without photopsia, migration, or expansion. It may be accompanied by other symptoms of VBI. A patient with papilledema has transient obscurations of vision that can be bilateral or unilateral. They are typically brief, exacerbated by postural change, and accompanied by optic disc swelling. Clearly, blepharospasm, with its random intermittent closures of the eyelid, leads to interruptions in vision. This cause, however, may not be apparent to the patient who merely complains of unclear vision. Finally, dry eye may cause generalized visual blurring of either or both eyes, which is made worse by wind and relieved by blinking and artificial tears.

ACUTE, SLOWLY REMITTING VISUAL LOSS

Optic Neuritis

Optic neuritis (ON) is the most common cause of acute optic neuropathy in patients younger than age 50 years (see also [Chapter 69](#)). ON is characterized by painful, monocular visual loss that typically does not worsen beyond 2 weeks and recovers dramatically in the ensuing months (although persistent pain beyond this timeline may occur). It is usually a manifestation of multiple sclerosis (MS). In 95% of cases, patients experience either pain on motion of the globe, ocular tenderness, or ocular ache. Patients with painless ON typically show magnetic resonance imaging (MRI) involvement limited to the optic canal or intracranial optic nerve. Color vision, as measured by color plates or subjective comparison with the other eye, is more markedly impaired than acuity. The visual field defect is typically a cecocentral scotoma (see [Fig. 9.2C](#)) that has sloping borders. Nerve fiber bundle (arcuate) defects may also be seen (see [Fig. 9.2D](#)).

Acutely, the majority of adult patients have normal-appearing optic discs indicating retrobulbar ON. Papillitis, or optic disc

swelling, however, is present in 40% of adults at the time of presentation. In childhood, papillitis is present in the

majority as is simultaneous or sequential bilaterality. Occasionally, one may have demyelination of the chiasm or of the optic tract. Peripapillary hemorrhage is a rarity in demyelinating papillitis. If a patient with papillitis develops macular exudates in the form of a star or hemistar 2 weeks after onset, it is referred to as *neuroretinitis*, which is not related to MS. Neuroretinitis is caused by catscratch fever, syphilis, Lyme disease, tuberculosis, viral and nematode infections, sarcoidosis, and Behçet disease.

The vast majority of cases of typical monocular painful ON in the 20- to 50-year age group will be found to be from MS or to be isolated ON, probably monosymptomatic MS. However, other processes can cause ON such as neuromyelitis optica, leukodystrophies, syphilis, viral infections, postviral reactions, reactions to vaccines, fungal infections, sinusitis, Lyme disease, nematodes, and sarcoidosis. Several poorly characterized variants of ON exist such as relapsing ON, autoimmune ON, and chronic relapsing inflammatory optic neuropathy (CRION). Relapsing ON is a form of isolated ON that occurs and recovers spontaneously multiple times. Autoimmune ON may be of several forms that are identified by the presence of antibodies such as antinuclear antibody (ANA) or aquaporin-4 antibodies. These disorders and CRION may be identified by their steroid dependence or their tendency toward progressive worsening.

Central Serous Chorioretinopathy

Central serous chorioretinopathy occurs in patients 25 to 55 years of age, mostly male, who have “type A” personalities, or take corticosteroids. It presents as painless visual loss with metamorphopsia, prolonged ipsilateral photostress recovery time, and no or a minimal relative afferent pupillary defect. With careful ophthalmoscopy, a yellow oval elevation can be seen in the macula representing a serous detachment of the retina. Most resolve spontaneously within 3 to 4 months but some may require laser or vascular endothelial growth factor inhibitor injections.

SLOWLY PROGRESSIVE VISUAL LOSS

Primary Open-angle Glaucoma

The most common optic neuropathy is *glaucoma* (Table 9.4). The most common form is *primary open-angle glaucoma*. It is painless and causes bilateral, asymmetric, slowly progressive visual field constriction, typically nasally, while sparing central acuity until its late stage. Visual field loss in glaucoma is characterized by steps along the horizontal meridian in the nasal visual field as well as paracentral defects in the arcuate region closer to fixation in the nasal visual field. Glaucoma may be suspected on ophthalmoscopy over time by an increasing diameter of the optic disc cup (and thereby an increase in the cup-to-disc ratio).

Glaucoma may be suspected when the cup-to-disc ratio exceeds 30% or when one eye's ratio is 20% larger than that in the fellow eye. The rim around the cup represents healthy nerve fibers. Typically, the inferior (I) rim is widest, followed by the superior (S) rim, then the nasal (N) rim, and lastly, the temporal (T) rim. This progression has been called the *ISNT rule*. If the *ISNT rule* is broken, glaucoma should be suspected. Optical coherence tomography is used to measure the thickness of the nerve fiber layer and the ganglion cell layer complex (ganglion cells plus the inner plexiform layer) in the diagnosis and management of glaucoma and other optic neuropathies. In glaucoma, the intraocular pressure is typically elevated above 22 mm Hg; however, a single intraocular pressure measurement is not sensitive for detecting glaucoma and in fact, many glaucoma patients do not have elevated intraocular pressure (low-tension glaucoma).

Dominant Optic Atrophy

Several recessive neurologic disorders with associated optic neuropathies frequently present with blindness in infancy. For example, *Wolfram syndrome*, also known as *DIDMOAD* (diabetes insipidus, diabetes mellitus, optic atrophy, and deafness), presents in childhood and is recessively inherited.

Dominant optic atrophy (DOA), the most common hereditary optic neuropathy, presents in adolescence with symmetric mild to moderately decreased acuity (20/25 to 20/200), tritanopic axis (blue-yellow) color vision loss, cecentral scotomas, and temporal optic disc pallor. It is a progressive neuropathy, but visual loss rarely continues past the third decade of life. DOA has variable penetrance. Some families with DOA have an associated mutation (OPA1). Some patients present with large cups and have “dominant pseudoglaucoma.”

Compression

Expansile or proliferative lesions can damage the anterior visual pathway (optic nerves, chiasm, and tract) by compression, infiltration, a combination of infiltration with exophytic compression, leaking of toxic cystic content, apoplectic hemorrhage or infarction, interference with blood supply, meningeal spread, or provocation of a paraneoplastic reaction. The location (intracranial, intracanalicular, orbital, or disc), relation to adjacent structures (meninges, skull and orbital bone, gland, cavernous sinus, nasal sinuses, and blood supply), and nature of the lesion (cyst, solid tumor, aneurysmal, inflammatory, infectious, hemopoietic, lymphoproliferative, or

paraneoplastic) determine the presentation.

Pituitary tumors are the most frequent cause of chiasmal compression and BTH. Meningiomas may also present with gradually PPLOV. The pattern of visual field loss and additional signs reflect the location of the mass. Intracranial meningiomas of the medial sphenoid may cause hyperostosis with proptosis and orbital dystopia and orbital venous congestion with upper lid edema after recumbency. They may compress the optic nerves, chiasm, or tract.

P.68

With extension into the cavernous sinus, cranial nerve palsies ensue. Meningiomas of the optic canal are often silent, other than their visual loss, and may be bilateral. An optic nerve sheath meningioma (ONSM) produces axial proptosis and optic disc swelling with pallor. If it blocks retinal venous outflow, optociliary shunt vessels develop on the disc. With pressure on the back of the globe, chorioretinal folds and a hyperopic shift occur. With PPLOV, optociliary shunt vessels, and blurred disc pallor in adult, an ONSM is likely. Meningiomas may spread from the orbit to the intracranial space or vice versa along the optic nerve.

Craniopharyngiomas are cystic suprasellar tumors that attack the anterior visual pathway from above, tending to produce inferior visual field defects. Cystic tumors may produce conduction block along the anterior visual pathways prior to axonal death. As a result, acuity and field loss present prior to optic atrophy and may mislead the examiner to suspect functional visual loss, especially in children.

The *gyrus rectus syndrome* occurs when hemorrhage or swelling in the frontal lobe herniates the gyrus rectus downward onto the ipsilateral optic nerve causing an acute compressive optic neuropathy. *Aneurysms* of the ophthalmic, anterior communicating or carotid arteries can produce optic neuropathy by compression of the optic nerves or chiasm.

Optic gliomas are most frequently pilocytic astrocytomas that appear in the first decade of life and are often associated with neurofibromatosis type 1. They may originate in the orbital or intracranial optic nerve, chiasm, or tract. Orbital gliomas present with visual loss, strabismus, proptosis, and optic disc edema that gives way to optic atrophy. The glioma infiltrates the normal structure resulting in fusiform enlargement of the nerve. Infiltration of the anterior visual pathway causes enlargement, and an exophytic component may even cause compression of the adjacent visual pathway. Chiasmal gliomas are more common than optic nerve gliomas and present with bilateral visual loss, strabismus, nystagmus, optic atrophy, papilledema, hydrocephalus, and endocrine problems. Optic gliomas of childhood have limited growth potential, but because of their location, even limited growth may cause serious disability. *Malignant optic gliomas of adulthood* are rare, high-grade gliomas of middle age. They present with painful loss of vision, which progresses to total bilateral blindness over 3 to 4 months and to death in a year. The tumor infiltrates the anterior pathway rapidly, causing vascular occlusions from compression of the central retinal vessels, papilledema, and marked retinal hemorrhages. Proptosis may occur and the patient ultimately develops signs of a hemispheric glioma.

Hereditary, Nutritional, and Toxic Optic Neuropathies

These neuropathies present with bilateral color and acuity loss, cecocentral scotomas, and temporal pallor of the optic discs (see also [Chapter 123](#)). Some toxins, such as methanol, cause disc edema when acutely ingested (see also [Chapter 128](#)).

Nutritional amblyopia, formally called *tobacco-alcohol amblyopia*, is frequently seen in middle-aged men who avoid vegetables and get their caloric intake through ethanol, although it can also be seen in nonalcoholics and children with poor nutrition. It can be accompanied by hearing loss and peripheral neuropathy and has been seen epidemically in prisoners of war and in Cuba during a food shortage at the time of the collapse of the former Union of Soviet Socialist Republics (USSR). Isolated optic neuropathy from ethanol is not seen in the setting of good nutrition, and isolated tobacco amblyopia is excessively rare. B₁₂ deficiency can present with decreased

vision prior to the recognition of combined degeneration of the spinal cord. Complex vitamin B deficiencies and deficiencies of folate and copper are also reported to cause visual loss.

The administration of ethambutol, isoniazid, chloramphenicol, linezolid, and disulfiram can result in a bilateral toxic optic neuropathy. If not recognized, this will progress to optic atrophy, but stopping the drug usually results in slow recovery. Exposure to heavy metals, methanol, and toluene can also result in optic atrophy. A newly recognized syndrome caused by cobalt and chromium metallosis results in optic neuropathy, retinopathy, hearing loss, cardiomyopathy, hypothyroidism, and pseudotumors. It occurs following total hip replacement with a cobalt-chromium metal-on-metal (MoM) implant that follow a failed ceramic total hip replacement where ceramic debris remains in the joint at the time of the MoM hip placement. In these cases, the ceramic debris grinds against the metal ball over time, sending dangerous amounts of cobalt and chromium into the bloodstream. The toxicity is treated by surgical removal of the metal implant and washing out the metal debris.

ACUTE, NONREMITTING VISUAL LOSS

Nonarteritic Anterior Ischemic Optic Neuropathy

Nonarteritic anterior ischemic optic neuropathy (NAION) is the most common acute optic neuropathy in the population older than age 50 years (Table 9.5). It is typically painless, although some ache is present in 10% to 15% of cases. Pain on motion of the globe, present in less than 1% of NAION patients, should make one suspect ON. NAION is usually noted upon awakening as an inferior altitudinal clouding with decreased acuity. Superior and cecocentral loss may also occur. The visual loss is typically stable, although it may progress while the disc is swollen. Some improvement in acuity is noted in a minority of NAION patients, but in contrast to ON, there is little improvement in the visual field. Color vision, as measured by color plate testing, is lost in proportion to acuity loss, which helps differentiate it from ON, where dyschromatopsia is marked. A relative afferent pupillary defect will be present if the process is unilateral and the other eye is normal. The optic disc is swollen, either segmentally or diffusely, and funduscopic exam shows arterial narrowing and splinter hemorrhages at the disc margin. Early in the course, the swelling is hyperemic and later, it becomes pallid. Usually, in 1.5 to 3 months, the disc becomes atrophic and the hemorrhages resorb.

NAION occurs in optic nerves with small cup-to-disc ratios, the so-called disc at risk. Risk factors associated with NAION include hypertension, diabetes, smoking, hyperlipidemia, anemia, obstructive sleep apnea, and nocturnal hypotension. NAION occurs

P.69

in patients with ONHD, following cataract extraction, following an attack of migraine, and following hypotensive anesthesia of long duration with blood loss and crystalloid replacement. Amiodarone, PDE-5 inhibitors, and interferon- α may be related to the attacks of NAION. No treatment has proven effective in NAION.

TABLE 9.5 Causes of Acute, Nonremitting Visual Loss

- Nonarteritic anterior ischemic optic neuropathy (NAION)

- Arteritic anterior ischemic optic neuropathy

- Retinal artery occlusion

- Leber optic neuropathy

- Subacute loss of vision
- Pituitary apoplexy

Diabetic papillopathy, a variant of ischemic optic neuropathy, occurs in long-standing insulin-dependent and non-insulin-dependent diabetics. It may be unilateral, sequential, or bilateral with disc swelling and a proliferation of radially oriented telangiectatic capillaries on the disc surface. There is often mild arcuate or altitudinal visual field loss and mild acuity loss. Typically, the patients have no or minimal diabetic retinopathy. The swelling and vessel changes resolve over months, leaving mild visual impairment. Diabetic papillopathy occurs in patients with small cups as does NAION. Interestingly, it often follows when patients achieve rapid glycemic control.

Arteritic Anterior Ischemic Optic Neuropathy

NAION must be distinguished from arteritic anterior ischemic optic neuropathy (AAION) that is caused by giant cell arteritis and rarely by other causes of vasculitis (see also [Chapter 42](#)). Giant cell arteritis occurs over age 50 years and may be accompanied by polymyalgia rheumatica, jaw claudication, temporal tenderness, loss of appetite, weight loss, and fever. Acutely, the optic nerve appears pale, even chalk white, and swollen. If suspected, the patient should have an erythrocyte sedimentation rate (ESR), a C-reactive protein (CRP), and a complete blood count performed stat and started on at least 80 mg prednisone by mouth daily until the blood tests return. If blood testing is supportive with elevated ESR, CRP, and platelets, temporal artery biopsy should be performed immediately to secure the diagnosis.

Retinal Artery Occlusion

Retinal artery occlusions are acute and painless causes of visual loss. On early examination, the inner retina is cloudy representing ganglion cell layer and nerve fiber layer ischemic damage and the retinal arteries may exhibit interrupted circulation. In a branch retinal artery occlusion (BRAO), there is edema in the wedge-shaped area of distribution of the vessel. BRAO are nearly always embolic, although they may rarely be angiopathic as in *Susac syndrome*, a microangiopathy characterized by BRAOs, deafness, and encephalopathy (see also [Chapter 43](#)). In central retinal artery occlusion (CRAO), cloudy swelling of the inner retina is again seen. However, because there are no ganglion cells or nerve fiber layer in the fovea, the cloudy swelling of the ganglion cells does not extend there. This results in a cherry-red spot (CRS) in the fovea. The CRS represents the normal choroid unobstructed by edema. After 4 to 6 weeks, the CRS and edema dissipate. CRAO does not result in complete blindness, as small vessels coming from the optic disc usually result in a small area of nasal retinal perfusion and thus some remaining temporal vision. Like BRAO, CRAO is frequently embolic (50% of the time; however, CRAO may also be caused by giant cell arteritis). A cilioretinal artery is present in about 17% of the population. It is supplied directly by the choroidal circulation and frequently supplies the macula; occlusion therefore may lead to central vision loss. Conversely, in CRAO, a cilioretinal artery if present may preserve central vision.

In retinal artery occlusions, an embolism may be made up of calcium, cholesterol (Hollenhorst plaque), or a mix of platelets and fibrin. Calcific emboli tend to lodge on or near the disc and are white globs appearing larger than the occluded vessel; they never dissolve. They typically originate from the aortic or mitral valves. Hollenhorst plaques lodge at retinal arterial bifurcations, are reflective yellow shards, and can be made to move slightly with light ocular pressure. They ultimately break up and disappear. They originate from ulcerative plaques at the carotid bifurcation or in the proximal aorta. Finally, platelet fibrin emboli are cream-colored, non-shiny and break up quickly; they may be seen snaking through the vessels and again, originate from ulcerative plaques.

Patients with retinal artery occlusions require emergent ophthalmologic referral for possible paracentesis, ocular

digital massage, acetazolamide, carbogen breathing, and consideration of tissue plasminogen activator (TPA) to reestablish circulation. If the retinal circulation has already been reestablished when the patient is examined, these treatments are unnecessary. In general, once cloudy swelling of the ganglion cells is present, visual prognosis is guarded. Both embolic and thrombotic risk factors should be assessed in all retinal artery occlusions.

Ophthalmic artery occlusion results in complete, ipsilateral, painless blindness and marked retinal cloudy swelling frequently without a CRS, as the choroid is ischemic as well. In the elderly, giant cell arteritis should be suspected.

Leber Hereditary Optic Atrophy

Leber hereditary optic atrophy, a disorder of mitochondrial DNA substitution mutations, typically presents in young males but may present in females and patients of all ages. It typically presents with acute to subacute painless monocular loss of vision. If examined acutely, the peripapillary nerve fiber layer may appear swollen, and the small arterioles coming off the major retinal arteries near the disc may appear telangiectatic (microangiopathy). On fluorescein angiography, no staining is seen of the disc or vessels. The nerve fiber swelling and telangiectasias may be seen in the presymptomatic phase and also just after the visual loss. Over several weeks, the nerve fiber layer swelling and telangiectasias are replaced by optic atrophy. Simultaneous eye involvement occurs in 25% of cases. Bilateral involvement may be present without relative afferent papillary defect (RAPD) and be less obvious especially if the nerve fiber layer swelling and the microangiopathy are not seen; these patients may be dismissed as having functional vision loss. There are three common substitutions at the 3460, 14484, and 11778 positions in the mitochondrial DNA genome that account for 95% of cases. Late spontaneous improvement in vision may occur in a minority of patients, most commonly in those with the 14484 mutations and least commonly in those with the 11778 mutation. Some patients have an associated cardiac preexcitation disorder, whereas others have an MS-like presentation.

Finally, there is a rare malignant type of optic glioma occurring in adulthood, which follows an acute, nonremitting course.

ACUTE VISUAL LOSS WITH PAINFUL OPHTHALMOPLEGIA

Pituitary apoplexy may be acute or subacute. It is due to either a hemorrhage or infarction with swelling of a sella or suprasellar tumor into the chiasm, one or both cavernous sinuses, the brain stem, or the subarachnoid space. It may cause a combination of visual loss, severe headache referred to the forehead, meningitis, seizures, adrenal failure, cerebrospinal fluid (CSF) rhinorrhea, and loss of consciousness depending on the direction the hemorrhage or swelling takes. The third nerve is the most medially placed and is therefore closest to the pituitary body and most prone to compression. Pituitary apoplexy should be suspected if band or bow tie atrophy of the optic discs is found in a patient with a history

P.70

of headache followed by loss of consciousness. Recovery from the ophthalmoplegia of pituitary apoplexy is better than the recovery of the visual loss, although aberrant regeneration may occur.

PAINFUL OPHTHALMOPLEGIA WITHOUT VISUAL LOSS

Cerebral Aneurysms

Several life-threatening syndromes can present with painful ophthalmoplegia; these must be distinguished from self-limited conditions. *Aneurysms* of the junction between the posterior communicating artery and internal carotid artery commonly cause acute, isolated, painful third nerve palsies in adults due to enlargement or bleeding. This presents with a pupil involving third nerve palsy. Patients may complain of a generalized headache, ipsilateral orbital pain, forehead pain, or even signs of meningismus. Any acute third nerve palsy in an

adult must be evaluated to rule out posterior communicating artery aneurysms unless the palsy is complete and the pupil is entirely spared (i.e., equal in size and reactivity to the other eye). Partial external third nerve palsies with complete pupillary sparing and complete external third nerve palsies with relative pupil sparing require aneurysm rule out. An isolated, dilated, or nonreactive pupil with or without headache is not from an aneurysm and is instead the result of *Adie tonic pupil*, atropinic exposure, or an intrinsic iris anomaly.

After several months, recovery from aneurysmal ophthalmoplegia may occur and the patient typically develops *aberrant regeneration of the third nerve*. Aberrant regeneration is caused by misdirection of the recovering third nerve axons to all third nerve innervated ocular muscles following traumatic or compressive lesions in the peripheral third nerve. For instance, the levator muscle receives regenerated fibers that were originally innervating the inferior and medial recti. As a result, when the inferior or medial recti receive stimulation for downgaze or adduction, the levator simultaneously fires, and the eyelid retracts. Similarly, on downgaze and adduction, the levator and pupillary sphincter are innervated causing lid retraction and miosis.

Diabetic Ophthalmoplegia

Isolated, acute, painful third, fourth, and sixth nerve palsies, and rarely, combinations of the three may be caused by diabetic ophthalmoplegia (DO). In fact, DO is occasionally the presenting symptom of diabetes mellitus. The pain may be severe and may precede, accompany, or follow the ophthalmoplegia. Pain is not helpful in distinguishing from aneurysm and may last from days to 3 weeks. Recovery from DO occurs within 3 to 4 months. A thorough workup is necessary in adults if recovery does not take place in 3 to 4 months. Rarely, DO presents in children; when it does, a full workup is necessary. Patients can have several bouts of DO involving any combination of cranial nerves III, IV, and VI. When DO involves the third nerve, it must be distinguished from an aneurysmal cause. Although DO tends to spare the pupil, the only sparing that is of diagnostic importance is complete pupillary sparing in the setting of complete third nerve palsy. Aberrant regeneration of the third nerve never follows DO.

Internal Carotid Artery Dissection

Dissection of the internal carotid artery may be accompanied by neck, throat, ear, eye, and forehead pain, bruit, dysgeusia, postganglionic oculosympathetic palsy, retinal artery occlusion; and stroke. If the dissection extends into the cavernous sinus, ophthalmoplegia may result from compression of cranial nerves.

Cavernous Sinus Abnormalities

Aneurysms of the cavernous sinus may present with acute, chronic or episodic pain in the trigeminal distribution. They may also present with sixth or third nerve palsies or postganglionic oculosympathetic paresis. *Carotid-cavernous fistulas* that drain posteriorly, white-eyed shunts, can present with painful third, fourth, or sixth nerve palsies and will not exhibit the scleral, dilated blood vessels typical of other carotid-cavernous fistulae. In white-eyed shunts, the pain may precede the palsy by months.

The cavernous sinus and orbit may also be invaded by nasopharyngeal carcinomas, other sinus and skull-based malignancies, lymphomas, leukemia, Langerhans cell disorders, and inflammatory disease.

Cavernous sinus compressive lesions of the third nerve may spare the fibers to the pupillary sphincter resulting in a pupil-sparing third nerve palsy.

Temporal Arteritis

Temporal arteritis can cause diplopia from cranial nerve or extraocular muscle ischemia, brain stem transient ischemic attack (TIA), or stroke. Pain can come from tenderness of the temporal artery, scalp ischemia, jaw claudication, or ocular ischemia. In any patient older than the age of 50 years presenting with headache, loss of vision, or double vision, temporal arteritis must be excluded. Other vasculitides, namely Granulomatosis with

polyangiitis (formerly known as *Wegener granulomatosis*) and polyarteritis nodosa, may present with painful ophthalmoplegia as well.

Infection

Rhinocerebral mucormycosis, seen in diabetics with ketoacidosis and in the immunosuppressed, is a fungal infection that spreads from the nasal sinuses into the orbit, cavernous sinus, and brain. It can spread via blood vessels and results in necrosis of the orbital contents and lids, causing blindness, pain, proptosis, and ophthalmoplegia. A black, necrotic patch may be seen inside the nose. Additionally, syphilis, Lyme disease, tuberculosis, and chronic fungal meningitis can cause painful ophthalmoplegia.

Following or with an attack of trigeminal herpes zoster, patients may present with a painful third, fourth, or sixth nerve palsy. This may be accompanied by postherpetic neuralgia and if the third nerve is involved, aberrant regeneration.

Transneural Tumor Growth

These tumors form along the sensory nerves of the face and results in chronic, unrelenting facial pain; formication; and dysesthesias. This may occur following excision of squamous cell carcinomas and occasionally, basal cell carcinomas and melanomas. With spread to the cavernous sinus, motor cranial nerve palsies and ophthalmoplegia ensue.

Tolosa-Hunt Syndrome

The painful ophthalmologic syndrome known as *Tolosa-Hunt syndrome* (THS) is an idiopathic, presumed granulomatous inflammation of the cavernous sinus, and is a diagnosis of exclusion. It presents with a boring pain, numbness, and paresthesias in the trigeminal distribution with ipsilateral paresis of one or more of the ocular motor nerves. It has a relapsing and remitting course that, together with its dramatic remission in response to high-dose oral steroids, was felt to be diagnostic. Subsequently, however, both masses and infiltrations were found to have the exact same presentation. On MRI, the cavernous sinus in THS is enlarged in about half the cases. Extensive systemic workup to exclude

P.71

lymphomas, primary and secondary tumors of cavernous sinus, IgG4-related disease, syphilis, tuberculosis, and infiltrations, such as sarcoid, should be performed.

TABLE 9.6 Key Questions When Evaluating Visual Disturbances

- Is the visual loss unilateral or bilateral?
-

- What is the time course?
-

- Is it painful or painless? If so, where and when?
-

- What's the tempo of any recovery of symptoms?
-

- Are the symptoms situational?
-

- Is there any metamorphopsia?

-
- Is there any red eye or foreign body sensation?
-
- Was the episode preceded by floaters or flashing lights?
-
- Are there any symptoms of polymyalgia rheumatica or giant cell arteritis?
-
- Are there any endocrine symptoms?
-
- What is the patient's nutritional status?
-
- Is there any family history of eye disease?
-
- Are the symptoms more pronounced during the day or night?
-
- What medications is the patient taking?

FOCUSED HISTORY

Visual disturbances loss can occur due to problems anywhere along the visual system. To determine the cause of the vision loss, break the history down to determine whether it is transient or progressive. The key questions to ask are shown in [Table 9.6](#). Then use physical exam to localize the pathology and further narrow the diagnosis.

EXAMINATION

[Table 9.7](#) shows the essential components of a complete neuroophthalmologic examination.

VISUAL ACUITY

If vision is not improved with refraction or pinhole during visual acuity assessment with a Snellen chart or card, an *Amsler grid* should be used to assess for maculopathy. In this test, the patient uses near correction to look at a piece of graph paper for the straightness of its lines while focusing on the paper's central fixation dot. Each Amsler grid graph box represents one degree when viewing at 14 inches. If the lines appear bent, curved, or broken (metamorphopsia), the patient has maculopathy. Rotate the grid 180 degrees around the fixation point and the grid is now a map of where to look at the macula relative to the foveal center for pathology; for scale, the horizontal diameter of the disc is about 5 degrees. Missing areas of the grid suggest neural damage. Maculopathy is suggested by prolonged photostress recovery measured by the time it takes to read one line less than best acuity following a minute of staring into a light; a difference of 30 seconds between eyes is significant.

COLOR

Relative color saturation and brightness sense are useful in unilateral visual loss to distinguish optic neuropathy from maculopathy; they are preserved in retinal disorders and decreased in optic neuropathy. The common forms of hereditary color blindness spare color saturation. Compressive and inflammatory optic neuropathies decrease overall brightness and color sense. Color desaturation can be explained to

patients by asking, “What happens to the color of blue jeans after several washings?” Brightness and color saturation may appear equal between eyes in unilateral ischemic optic neuropathy, as it tends to affect the optic nerve focally as in an inferior altitudinal visual field defect; however, the color sense and brightness will be depressed in the area of the visual field defect. In hemianopsias, color and brightness sense will be depressed in the affected hemifield, as it will be inside a cecocentral scotoma from ON. Color vision as measured by color plates as in the American Optical Hardy-Rand-Rittler (AO-HRR) plates is helpful in separating optic neuropathy from maculopathies. Maculopathies spare color vision except for the rare cone dystrophies and hereditary color vision defects, whereas optic neuropathies lose color vision in advance of visual acuity.

TABLE 9.7 Components of Neuroophthalmologic Examination

Visual acuity	<ul style="list-style-type: none"> • Snellen visual acuity chart • Amsler grid to detect metamorphopsia (distortion of straight lines), which suggests retinal disease
Color	<ul style="list-style-type: none"> • AO/HRR plates • Color comparison • Look for asymmetry in color perception or color desaturation (red). • Desaturation suggests optic nerve cause.
Confrontation visual fields	<ul style="list-style-type: none"> • Perform for each eye separately
Pupils	<ul style="list-style-type: none"> • Record size in dark and in light. • Record response to light. • Perform swinging flashlight test to look for relative afferent pupillary defect (RAPD).
External exam	<ul style="list-style-type: none"> • Look for ptosis and proptosis. • Look for injection of conjunctiva. • Examine for bruits. • Examine for temporal artery tenderness.
Motility	<ul style="list-style-type: none"> • Look for restrictions in extraocular movement, presence of phorias or tropias, abnormal saccades, abnormal pursuit, nystagmus, optokinetic nystagmus (OKN).
Funduscopy exam (ophthalmoscopy)	<ul style="list-style-type: none"> • Examine the fundus for optic nerve and retinal pathology.

VISUAL FIELDS

Visual fields can be performed by confrontation. With one eye covered, the patient fixes on the examiner's

nose at a distance of 1 to 2 m and is asked to describe what is seen or missing (Fig. 9.5). The examiners can wink an eye, protrude their tongue, raise their brow, smile, or frown; in this way, subtle central defects may be explored. With the patient fixed on the examiner's nose, the examiner then checks finger counting in the quadrants by placing fingers diagonally in the quadrants about 12 to 18 inches from

P.72

fixation. If the fingers are not seen, the examiner brings the finger toward the vertical midline checking for a vertical step as seen in hemianopsia. After checking for vertical steps, horizontal steps can be sought. Colored objects can be compared across the horizontal and vertical. Double simultaneous presentation can be used to pick up subtle defects. A laser pointer and a fixation dot on a piece of tape can be used to do an improvised tangent screen visual field exam that can be used on the ceiling in bed-bound patients. In children or adults who have trouble fixating, the head is held and the fingers placed in the temporal field to check for hemianopias.

FIGURE 9.5 Visual field technique: Sit 1 to 2 m from the patient and have the patient cover one eye completely while looking at the examiner's nose. In quick succession, flash one, two, or five fingers in all four quadrants. Then switch eyes. (Adapted from Marshall R, Mayer S. *On Call Neurology*. 3rd ed. Philadelphia: Saunders; 2007.)

PUPILS

The size and shape of the pupils are noted while the patient is fixing at distance in a dark room and in the light. The briskness of the pupillary reactions to light and near is recorded and the swinging flashlight test is performed. If the pupil is distorted, an inspection with a slit lamp or magnifier may reveal iris adhesions to the lens, damage to the iris sphincter, or iris stromal damage. A penlight applied to the lid inferotemporally while the eye is open in a dark room transilluminates the globe and reveals a pupillary red reflex. In traumatic, surgical, or inflammatory damage, the iris itself may transilluminate revealing sites of damage.

The RAPD results from an optic nerve lesion in one eye or asymmetric bilateral optic neuropathy; the sign is

best shown by the swinging flashlight test. This pupillary sign is not seen if the problem is media opacity, a moderate retinopathy, or a nonorganic visual loss. It may be present to a mild degree in simple amblyopia. In the test, a bright flashlight is swung from one eye to the other, just below the visual axis, while the subject stares at a distant object in a dark room. Constriction of the pupils should be the same when either eye is illuminated. However, if an eye with optic nerve dysfunction is illuminated, the pupil constricts less briskly, less completely, and less persistently in response to the light than when the normal fellow eye is illuminated. If the pupil dilates or if the initial constriction is less brisk than that of the fellow eye, the test is positive. The RAPD may be quantified by placing increasing amounts of neutral density filter before the good eye until the reaction of the pupils is equal. Both pupils are equal in size at all times in purely afferent defects because there is hemidecussation of all afferent light input to the midbrain with equal efferent stimulation through both third cranial nerves. Therefore, if one pupil is fixed to light because of an efferent defect, the other one may be observed throughout the performance of this test.

EXTERNAL EXAM

A clear understanding of visual disturbances is aided by an examination of the palpebral fissures, lids, and brows. In the normal adult, the upper lid covers 1 to 2 mm of the corneal limbus and the lower lid just kisses the lower limbus. The brows sit symmetrically at the supraorbital ridge. With unilateral or asymmetric facial weakness, the side of the weaker orbicularis oculi will have a wider palpebral fissure. When a patient's brow is below the supraorbital ridge along with an ipsilateral, narrow fissure, there is a blepharospastic disorder. This indicates either diplopia avoidance, aberrant regeneration of the facial nerve, hemifacial spasm, or facial myokymia. If the brow is raised on the side of the narrower fissure, the brow is purposefully being raised to compensate for ptosis.

The height of the palpebral fissure is recorded with a millimeter rule. With the patient looking at a light, the distance from the upper lid to the corneal light reflex is recorded which is the *marginal reflex distance 1* (MRD 1); normal is about 4.5 mm. The distance from the light reflex to the lower lid is the MRD 2 and normal is about 5.5 mm. The MRD 1 and MRD 2 are equal to the palpebral fissure height that in normals is about 10 mm. The MRD measurements were introduced to clarify the effects of congenital and acquired lower lid anomalies on palpebral fissure height and focus in on levator dysfunction. In levator weakness, if the upper lid covers the corneal light reflex, the MRD 1 is recorded in negative numbers. In lid retraction and proptosis as in Graves disease or orbital tumors, the MRDs are increased; with enophthalmos, the MRDs are decreased. In oculosympathetic palsy with Mueller muscle weakness, the MRD 1 and 2 are both smaller, as there is Mueller muscle in both upper and lower lids. To measure levator function, press the eyebrow to the supraorbital ridge with your thumb and measure the excursion of the upper lid from down- to upgaze. Normal levator function is 15 mm. Decreased levator function implies levator weakness as seen in third nerve palsy, myasthenia gravis, mitochondrial myopathies, and congenital ptosis. Levator aponeurosis dehiscence is the most common cause of acquired ptosis in adults and has normal levator function.

Relative prominence of the globes can be observed by having the patient recline in a chair as the examiner looks directly down over the patient's nose for relative proptosis or enophthalmos. Using a ruler placed horizontally through the corneal light reflex of one eye as the patient stares straight ahead will detect anomalies of vertical globe alignment as seen in blowout fracture of the orbital floor or the silent sinus syndrome where the roof of the maxillary sinus descends.

OCULAR MOTILITY

The examination of eye movements starts with ocular alignment as measured by the cover test. While the patient is comfortably seated and fixing on a distance target straight ahead, the examiner covers one of the patient's eyes with an occluder and watches the other eye for a *refixation movement*. If a refixation movement is seen, a manifest deviation of the eyes is present called a *tropia*. If the eye being watched

moves toward the nose, it means that it was deviated out relative to fixation and the term *exotropia* (wall-eyed) applies.

P.73

If the watched eye moves away from the nose, it was deviated in and it is termed *esotropia* (cross-eyed). If the eye moves down, it was hypertropic and if it moves up, hypotropic. If the watched eye does not move, it means it was aligned and fixating on the distance target. The next step is to switch and now cover the previously watched eye and observe the other eye for a tropia. The test can be performed in right gaze, left gaze, up gaze, down gaze as well as up and right, up and left, down and right, and down and left to reveal deficits of movement. For instance, a patient who complains of new-onset diplopia and has an esotropia in primary position that increases in right gaze and decreases or is gone in left gaze has a right lateral rectus weakness and may have a right sixth nerve palsy.

The second step is to look for latent disorders of ocular alignment, called *phorias*, with the alternate cover test. With the patient fixating at distance, the examiner covers one eye and then alternates the cover back and forth several times rapidly from one eye to the other eye, looking for movements of the uncovered eye. If the uncovered eye moves toward the nose, the patient has an exophoria and the other eye will act the same. If the eyes move away from the nose, esophoria is present. Phorias can be overcome by the patient's fusion mechanism but may break down into tropias with fatigue, alcohol, medication, or age. The normal patient may have a small exophoria at distance and near. An esophoria for distance or near, however, is always a sign of either congenital tendency to strabismus or neural or muscular dysfunction. Phorias and tropias that are about the same in the different positions of gaze and with either eye fixing are called *comitant deviations*. Comitant horizontal tropias usually occur in patients who had childhood strabismus. Deviations that vary in different directions are deemed incomitant and are a sign of muscular or neural dysfunction. Incomitant phorias may precede tropias as a pathologic process evolves. For example, an early right sixth nerve palsy may have an esophoria in right gaze before a manifest tropia with diplopia develops. A consequence of Herring law of equal innervation of agonist extraocular muscles is that the deviation is greatest with the paretic eye fixing, so in a paretic deviation, the refixation movement will be biggest when the paretic eye fixes.

Next in the eye movement exam is to have the patient follow into the eight different gaze positions looking for lag of movement. Movements with both eyes open are versions; if one eye is checked at a time, they are called *ductions*. Ductions produce larger movements than versions. Notation of the extent of the movements can be recorded using a millimeter ruler or the lag of ductions can be estimated on a scale of 1 to 4, with 4 being no movement at all. The pattern of lag of ductions can be inspected for a neurogenic pattern as in sixth or third nerve palsy; internuclear ophthalmoplegia; or a myogenic pattern with relatively symmetric, bilateral, and reduced movements in all directions with ptosis and pupil sparing as in mitochondrial myopathy or autosomal dominant French-Canadian muscular dystrophy. In isolation, an inability to look up in abduction, mimicking weakness of the superior rectus muscle, is likely Graves disease that has caused fibrosis of the ipsilateral inferior rectus muscle restricting the superior rectus. In isolated inferior rectus weakness, myasthenia gravis is the most likely diagnosis. In inferior rectus weakness seen in the setting of other neurologic signs or acute neurologic dysfunction, a stroke or mass of the midbrain involving the rostral portion of the third nerve nucleus in the inferior rectus subnucleus must be suspected. An eye that cannot elevate in adduction due to an apparent deficit of the inferior oblique muscle is seen in Brown tendon sheath syndrome. This is a congenital malformation of the superior oblique sheath that prevents free movement of the superior oblique tendon through the trochlea and is unaccompanied by diplopia. An acquired version of Brown syndrome occurs in rheumatoid arthritis and is accompanied by diplopia. Duane retraction syndrome is a congenital anomaly more common in women that is unaccompanied by diplopia. It demonstrates decreased abduction, typically on the left, with globe retraction on adduction, which is

recognized by narrowing of the palpebral fissure.

Eye movements should next be examined for fast eye movements or saccades. If eye movements are incomplete, saccades should be inspected for slowing. Saccadic slowing suggests neural involvement anywhere from the peripheral cranial nerve, brain stem nuclei, internuclear connections, and supranuclear pathways. Saccadic slowing can be checked for with repetitive, voluntary saccades into the area of interest, or the saccades can be generated using an optokinetic nystagmus flag or drum. Restrictive problems, as in Graves disease, orbital myositis, and orbital blowout fractures, do not slow saccades enough to be recognized by the unaided eye. Slowing of saccades of horizontal and vertical versions may be a result of the lesions of the frontal pontine pathways for gaze, the paramedian pontine reticular formation, the rostral interstitial nucleus of the medial longitudinal fasciculus, or their connections. Saccades should also be checked for dysmetria by having the patient refixate from 30 degrees to the right of center, then from 30 degrees to the left of center.

Finally, examination of the fundus in each eye is critical to a complete assessment with observations of the disc for swelling or atrophy, the nerve fiber layer for dropout, the vessels for diameter, emboli, or occlusion, and the macula for hemorrhages, exudates, or detachments.

Delirium

Adam B. King

Christopher G. Hughes

INTRODUCTION

Delirium is a clinical syndrome characterized by fluctuations in mental status caused by acute cerebral dysfunction. Patients may present with inattention, disorganized thinking, disorientation, and/or altered levels of consciousness. Other symptoms associated with delirium include sleep disturbances, abnormal psychomotor activity, hallucinations, and emotional disturbances such as fear, depression, or anxiety. Patients may experience symptomatology that is hyperactive or hypoactive or fluctuate between both (mixed delirium). Although hyperactive delirium is more dramatic, hypoactive delirium is more common and much more underdiagnosed.

Development of delirium while in the intensive care unit (ICU) has been associated with increased cost, ICU length of stay, hospital length of stay, and long-term cognitive dysfunction. This risk is independent of preexisting comorbid conditions, severity of concurrent illness, and age. Additionally, duration of delirium has been shown to increase the relative risk of death by 10% per day of delirium.

Delirium is common among hospitalized patients. Upon admission, approximately 11% to 25% of elderly patients are delirious, and an additional 30% or so will go on to develop delirium. Delirium is even more frequent among critically ill patients; it is estimated that up to 80% of patients in the ICU experience an episode of delirium. Given the implications of an episode of delirium on patient outcomes, prevention and treatment is of utmost importance.

MANAGEMENT STRATEGY

- Rule out life-threatening causes of mental status change such as hypoxia, hypercarbia, drug ingestion/withdrawal, or seizures.
- Perform focused history and physical exam including assessment of arousal level and delirium with tools such as the confusion assessment method (CAM) or confusion assessment method for the intensive care unit (CAM-ICU).
- Focus on appropriate and early removal of catheters/restraints, promote sleep, perform early mobilization, provide glasses and hearing aids, and eliminate unnecessary alarms and auditory stimuli (e.g., television).
- Establish a calm, reassuring environment, and promote human contact, especially with loved ones.
- Ensure patient and staff safety. Pharmacologic management may be required in patients whose agitation puts them at risk for harming themselves or others.

CAUSES OF DELIRIUM

The underlying mechanism of delirium or acute brain dysfunction has many proposed mechanisms. Systemic inflammation, cholinergic deficiency, and disturbances in other neurotransmitters such as serotonin and norepinephrine have been implicated in the development of delirium.

Risk factors for delirium can be characterized into patient factors, current illness factors, and iatrogenic causes, as outlined in [Table 10.1](#). Baseline patient factors that have been associated with development of delirium include preexisting dementia, history of hypertension, alcoholism, and a high severity of illness upon admission. Additionally, age has been shown to be an independent risk factor for development of delirium outside of the

ICU; however, within the ICU, there is discordance about it as a risk factor.

Clinicians are able to modify several risk factors for delirium by improving sleep hygiene and sedative regimens and avoiding medications that might trigger delirium. For instance, lorazepam administration is an independent risk factor for development of delirium in ICU patients undergoing mechanical ventilation. In addition, midazolam administration has been associated with worse delirium outcomes in mixed ICU patients.

Analgesic regimens, specifically opiates, do not have a clearly defined relationship with development of delirium. In fact, inadequate pain control is a risk factor for development of delirium. In a prospective study that enrolled patients with hip fractures without preexisting delirium, patients who received less than 10 mg of morphine equivalents per day were at increased risk of development of delirium. However, other studies have associated morphine and meperidine administration with the development of delirium. It appears that adequate pain control might be beneficial in protection against delirium, but use of opiates for sedation might place patients at risk for development of delirium.

NEUROANATOMY

Neuroanatomic changes that include brain atrophy and white matter changes have been witnessed in patients with delirium. White matter changes continue to persist even after hospital discharge and may be the cause of long-term cognitive impairment in these patients. In addition, patients have dysregulation of acetylcholine, dopamine, and γ -aminobutyric acid.

TABLE 10.1 Clinical Risk Factors for Delirium

Patient Factors	Acute Illness	Iatrogenic Causes
Baseline cognitive impairment	Electrolyte disturbances	Sedative medications
Age	Hypoxemia	Sleep disturbances
Baseline comorbidity	Global severity of disease	Anticholinergic medications
Frailty	Sepsis	Analgesic medications

FOCUSED HISTORY

Evaluation of the patient with suspected delirium should start with a history and physical exam. Causes of delirium such as drug ingestion, alcohol or drug withdrawal, metabolic derangements, and infection should be sought. Because features of delirium such as confusion or inattention may be present, history may be difficult to obtain from the patient. Assistance from staff or family members may be necessary. In addition, baseline functional status of the patient should be obtained, as this can help differentiate between dementia and delirium.

FOCUSED EXAM

Physical exam should look for possible sources of infection (e.g., pneumonia or urinary tract infection) as the cause of the patient's acute change in mental status. In addition, physical exam findings suggestive of drug exposure may be useful. For example, anticholinergic exposure would reveal increased temperature, flushed dry skin, tachycardia, and pupillary dilation on exam. Focal neurologic findings that could point to seizure activity or

stroke should also be sought.

The development of validated instruments now allows for assessment of patient's level of arousal and content of consciousness even when a patient is mechanically ventilated. The Richmond Agitation-Sedation Scale (RASS) (Table 10.2) and the Riker Sedation-Agitation Scale (SAS) are commonly used tools that can be used to assess level of arousal. Assessment for delirium cannot occur if the patient is deemed unresponsive by the sedation scales (RASS -4 to -5 or SAS of 1 to 2). If the patient is responsive to verbal stimuli, then delirium can be assessed using tools such as the CAM, the CAM-ICU, or the Intensive Care Delirium Screening Checklist (ICDSC). Further information about these tools used for diagnosis of delirium can be found in the "Diagnosis" section.

Delirium is a syndrome of brain dysfunction and rarely presents as a single clinical entity. Pure hyperactive delirium is less common despite being the foremost perception of delirium to most clinicians. Patients with hyperactive delirium display prominent agitated motor behaviors such as pulling at lines/catheters and physically or verbally assaulting staff. In contrast, most patients are either hypoactive or have a mixed subtype. Hypoactive delirium is characterized by slow patient movements, decreased speed of cognition, and decreased alertness. It might be associated with worse outcomes; however, patients are often overlooked because they are not displaying disruptive behavior.

TABLE 10.2 Richmond Agitation-Sedation Scale Richmond Agitation-Sedation Scale

Score	Term	Description
+4	Combative	Overly combative, violent, immediate danger to staff
+3	Very agitated	Pulls or removes tube(s) or catheter(s); aggressive
+2	Agitated	Frequent or nonpurposeful movements, fights ventilator
+1	Restless	Anxious but movements not aggressive/vigorous
0	Alert and calm	
-1	Drowsy	Not fully alert but has sustained awakening (eye opening/eye contact) to voice >10 s
-2	Light sedation	Briefly awakens with eye contact to voice (<10 s)
-3	Moderate sedation	Movement or eye opening to voice (but no eye contact)
-4	Deep sedation	No response to voice but movement or eye opening to physical stimulation
-5	Unarousable	No response to voice or physical stimulation

DIAGNOSIS

In addition to a history and physical exam, other causes of changes in mental status should be sought. An electrolyte panel, blood count, and liver and thyroid function tests should be obtained. Additionally, infectious causes should be ruled out with appropriate testing such as chest radiograph, urinalysis, and culture data. Hypoxemia and hypercarbia should also be excluded as causes of confusion, which may require arterial blood gas analysis.

After a thorough history and physical exam, the next step is determining the patient's level of arousal through the use of a sedation scale such as the RASS, as described in the physical exam section. If the patient is determined to be unresponsive, RASS -4 or -5, then they are in a coma and cannot be assessed for delirium. There are several validated tools through which delirium diagnosis and screening can be performed.

TOOLS FOR SCREENING AND DIAGNOSIS

Diagnosis of delirium relies on determination from the history and physical that the condition is an acute change in the patients' status. In patients who are not mechanically ventilated, the CAM (Table 10.3) can be used for diagnosis. The CAM assesses the patient for the key features of delirium such as an acute onset, fluctuating course, and inattention. It then assesses the patient for other symptomatology of delirium such as disorganized thinking or altered level of consciousness.

In critically ill or mechanically ventilated patients, the CAM-ICU (Table 10.4) and ICDSC (Table 10.5) have been validated. The CAM-ICU assesses the same four features as the CAM in an abbreviated manner more applicable to patients with critical illness: acute change or fluctuation in mental status, inattention, disorganized thinking, and an altered level of consciousness. The ICDSC uses eight diagnostic features; the diagnosis of delirium requires four or more features to be present.

DIAGNOSIS OF DELIRIUM AFTER STROKE

The incidence of poststroke delirium varies from 10% to 48%. Diagnosis of delirium in this patient population requires the ability to differentiate

P.77

delirium from mental status changes from the underlying disease process. The CAM-ICU has been validated in stroke patients by comparing it to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (*DSM-IV*), criteria for delirium. The CAM-ICU proved to be 76% sensitive and 98% specific for the diagnosis of delirium after stroke. The positive predictive value was 91%.

TABLE 10.3 Confusion Assessment Method

Diagnosis of delirium requires the presence of BOTH features A and B and the presence of EITHER feature C or D.

A. Acute onset or fluctuating course

Is there evidence of an acute change in mental status from baseline?

Does the abnormal behavior:

- Fluctuate over time?
- Come and go?

- Increase/decrease in severity?

B. Inattention	<p>Does the patient:</p> <ul style="list-style-type: none"> • Have difficulty focusing? • Become easily distracted? • Have difficulty keeping track of what is said?
C. Disorganized thinking	<p>Is the patient's thinking:</p> <ul style="list-style-type: none"> • Disorganized? • Incoherent?
D. Altered level of consciousness	<p>Is the patient:</p> <ul style="list-style-type: none"> • Alert (normal)? • Vigilant (hyperalert)? • Lethargic (drowsy but arousable)? • Stuporous (difficult to arouse)? • Comatose (unarousable)?

TABLE 10.4 Confusion Assessment Method for the Intensive Care Unit

Feature A plus B and either C or D present = CAM-ICU positive

A. Acute onset or fluctuating course	<ul style="list-style-type: none"> • Is the patient different than his or her baseline? <p>OR</p> <ul style="list-style-type: none"> • Has the patient had any fluctuation in mental status in the past 24 h?
B. Inattention	<ul style="list-style-type: none"> • Letters attention test: <p>Say to the patient, "I am going to read to you a series of 10 letters. Whenever you hear the letter 'A,' indicate by squeezing my hand."</p> <p>SAVEAHAART or CASABLANCA or ABADABADAAY</p> <p>Errors are counted when patient fails to squeeze on the letter "A" and when patient squeezes on any letter other than "A."</p> <p>If greater than two errors, patient has inattention.</p>
C. Altered level of consciousness	<ul style="list-style-type: none"> • Present if the RASS score is anything other than alert and calm or RASS 0.
D. Disorganized thinking	<ul style="list-style-type: none"> • Ask patient yes/no questions: <ol style="list-style-type: none"> 1. Will a stone float on water? 2. Are there fish in the sea? 3. Does 1 lb weigh more than 2 lb? <p>Errors are counted when the patient incorrectly answers a question.</p> <ul style="list-style-type: none"> • Have the patient follow commands: <p>Say to patient "Hold this many fingers up" (show two fingers to patient). Have</p>

him or her repeat with the other hand using a different number of fingers. An error is counted if patient is unable to complete the entire command. If patient makes greater than one error, then he or she is positive for this feature.

CAM-ICU, confusion assessment method for the intensive care unit; RASS, Richmond Agitation-Sedation Scale.

DELIRIUM VERSUS DEMENTIA: A DIAGNOSTIC CHALLENGE

It is estimated that 4.5 million elderly Americans have Alzheimer disease (AD). As the population continues to age, this number will continue to increase. The prevalence of delirium in hospitalized patients with coexisting AD is estimated at 60% to 89% of patients, and delirium in patients with preexisting dementia has been associated with long-term cognitive decline that persists for at least 5 years after discharge from the hospital. Diagnosis of delirium in patients with underlying dementia can be difficult; symptoms of delirium can be attributed to the underlying cognitive dysfunction and overlooked as new symptomatology. Trials for validating delirium assessment tools have either excluded or included few patients with underlying dementia; however, based on the available evidence, the CAM and CAM-ICU are currently considered the best available tools.

ELECTROENCEPHALOGRAM FINDINGS IN DELIRIUM

The fluctuating state of awareness in delirium is accompanied by changes in the electroencephalogram (EEG). Changes in level of attention parallel the slowing of background EEG rhythms. There may be deceleration or complete loss of posterior background

P.78

rhythm, global slowing, and intermittent rhythmic delta activity especially in the frontal regions. Triphasic waves may be present when metabolic encephalopathy is a contributing factor.

TABLE 10.5 Intensive Care Delirium Screening Checklist

1.	Altered level of consciousness	
A.	Exaggerated response to normal stimulation	RASS +1 to +4
B.	Normal wakefulness	RASS 0
C.	Response to mild/moderate stimulation	RASS -1 to -3
D.	Response only to intense stimulation	RASS -4
E.	No response	RASS -5

Assessment is terminated if patient is a RASS -4 or RASS -5.

2. Inattention

- A. Difficulty in following commands
- B. Easily distracted by external stimuli
- C. Difficulty in shifting focus

One point if any are present

3. Disorientation

Patient not oriented to person, place, or time

One point if any are present

4. Hallucinations or delusions

- A. Equivocal evidence of hallucinations or behavior due to hallucinations
- B. Delusions

One point if any are present

5. Psychomotor agitation or retardation

- A. Hyperactivity requiring the use of additional sedatives or restraints
- B. Hypoactivity or psychomotor slowing

One point if any are present

6. Inappropriate speech or mood

- A. Inappropriate, disorganized, or incoherent speech
- B. Inappropriate mood

One point if any are present

7. Sleep/wake cycle disturbance

- A. Sleeping <4 h per night
- B. Waking frequently at night
- C. Sleeping >4 h during the day

One point if any are present

8. Symptom fluctuation

Fluctuation of any of the above items over the previous 24 h

Total score is based on adding items up from 1 to 8. A score >4 is concerning for delirium.

RASS, Richmond Agitation-Sedation Scale.

MANAGEMENT

Delirium is an urgent medical condition and prompt review of possible causes or inciting factors should be performed. Underlying causes such as pain, metabolic derangements, infection, and hypoxemia should be sought and treated.

Treatment consists of two broad categories: *pharmacologic symptom management* and *environmental optimization*. The initial step in management is to ensure patient and staff safety. If the patient is exhibiting signs of hyperactive delirium and is trying to remove medically necessary devices, pharmacologic management is likely needed. If pain is an inciting cause, analgesic therapy with opioids or NSAIDs should be used as the first line of therapy. Symptomatic treatment is usually with dexmedetomidine or an antipsychotic medication such as haloperidol, olanzapine, or quetiapine (Table 10.6). Benzodiazepines can often exacerbate delirium symptoms and should be avoided unless the cause is alcohol withdrawal or if there is a component of severe anxiety. Despite common use among clinicians, there is a lack of large randomized controlled trials of medications for the treatment of delirium, and current evidence is limited to small cohort studies.

PHARMACOLOGIC THERAPY

First-line pharmacologic therapy for delirium prevention and treatment after pain control consists of dexmedetomidine and antipsychotic medications. The Maximizing Efficacy of Targeted Sedation and Reducing Neurological Dysfunction (MENDS) trial compared lorazepam and dexmedetomidine for sedation in critically ill patients, and patients who received dexmedetomidine for sedation had more days free of delirium [Level 1].¹ The Safety and Efficacy of Dexmedetomidine Compared with Midazolam (SEDCOM) trial showed that patients sedated with dexmedetomidine achieved adequate levels of sedation while experiencing less episodes of delirium and shorter time to extubation [Level 1].² A small, open-label trial comparing haloperidol versus dexmedetomidine in delirious, agitated, mechanically ventilated patients showed earlier time to extubation and shorter ICU length of stay in the dexmedetomidine group. Together, these studies support the use of dexmedetomidine as a first-line therapy to prevent and treat delirium in mechanically ventilated ICU patients.

There are several small randomized controlled trials examining the efficacy of antipsychotics for treatment or prevention of delirium. The Modifying the Incidence of Delirium (MIND) study compared ziprasidone (an atypical antipsychotic) with haloperidol (a typical antipsychotic) versus placebo and found no difference in outcomes between groups. Quetiapine was compared to placebo in a small trial of critically ill patients with delirium. Patients in both groups received haloperidol as rescue medication. Quetiapine was shown to decrease the number of hours until resolution of delirium symptoms and reduce rescue medication but was not effective in preventing recurrence of symptoms. Another randomized

controlled trial showed that single dose of risperidone given sublingually after cardiac surgery was more effective than placebo in prevention of delirium. A pre/post trial in the Netherlands found haloperidol prophylaxis decrease the incidence of delirium from 75% to 65% in this group of patients who were at high risk for development of delirium. The HOPE-ICU trial, however, found that intravenous haloperidol given to patients with delirium or coma did not improve outcomes versus placebo. At the present time, there is insufficient data to recommend routine prophylactic therapy with antipsychotic agents to prevent delirium in high-risk patients.

TABLE 10.6 Medications Used to Control Delirium Symptoms

Drug	Dose
Dexmedetomidine (Precedex)	0.7-1.4 µg/kg/min IV infusion
Haloperidol (Haldol)	1-10 mg q4-6h
Lorazepam (Ativan)	0.5-4 mg IV q4h
Olanzapine (Zyprexa)	5-10 mg PO q8h
Quetiapine (Seroquel)	25-50 mg q8-12h

IV, intravenous; PO, by mouth.

TABLE 10.7 Key Points for Managing Delirium

- Delirium is common among hospitalized patients; occurring in up to 80% of patients with critical illness.
- Development of delirium increases the patients' hospital length of stay and is associated with long-term cognitive impairment and mortality.
- Treatment is focused on correcting any possible underlying causes of delirium and improving environmental factors. Pharmacologic therapy may be undertaken for symptom management.
- Medications should be used judiciously due to uncertainty about their efficacy and their potential effect on patient's sensorium.
- Improvement in the patient's sleep/wake cycle, early mobility, removal of unnecessary lines/catheters, and frequent stimulating activities may provide some delirium prevention.

ENVIRONMENTAL OPTIMIZATION

Nonpharmacologic interventions have been shown to be beneficial in patients with delirium, and improving the environmental factors remains the first-line intervention for delirium prevention and treatment. These treatments include sleep hygiene and patient reorientation. A study in medical patients reduced the incidence of delirium by 40% by focusing on regulation of environmental factors [Level 1].³ These factors included appropriate and early removal of catheters/restraints, nonpharmacologic sleep protocols, early mobilization, providing regular stimulating activities, and attention to hydration. In a randomized trial of early physical and occupational therapy in critically ill patients, patients in the early mobilization group had greater return to functional status at hospital discharge and shorter duration of delirium [Level 1].⁴ In addition to early physical therapy, sedation protocols have also been shown to reduce delirium. The Awakening and Breathing Coordination, Delirium Monitoring/Management, and Early Exercise/Mobility trial (ABCDE) showed that sedation protocols combined with early mobilization can reduce the incidence of delirium and length of mechanical ventilation in critically ill patients.

CONCLUSION

Delirium commonly occurs in hospitalized patients and is independently associated with worse outcomes (Table 10.7). Early recognition of delirium may be achieved through active use of screening tools such as the CAM or CAM-ICU. Treatment should focus on nonpharmacologic therapy such as improvement in the patient's sleep/wake cycle, early mobility, removal of unnecessary lines/catheters, and frequent stimulating activities. Pharmacologic therapy should be used when patient behavior places themselves or staff at risk. These therapies should be used judiciously, as they have unproven efficacy and alter patient sensorium.

Dementia and Memory Loss

Lawrence S. Honig

INTRODUCTION

Dementia is characterized by intellectual deterioration, with concomitant decline in independence and daily social or occupational functions.

With different dementia disorders, various cognitive domains may be dominantly affected including memory, orientation, abstraction, learning ability, visuospatial perception, language functions, constructional praxis, and higher executive functions such as planning, organizing, and sequencing activities. By past convention, now loosened, dementia was not typically diagnosed in the presence of impairment of only a single domain, requiring significant involvement of at least two domains.

In the *Diagnostic and Statistical Manual of Mental Disorders (DSM)* versions I through IV-TR, there was a requirement that at least one of the affected cognitive domains be memory. This requirement, designed originally for Alzheimer disease (see [Chapter 50](#)), has been dropped in the most recent *DSM-5* with recognition of various dementias that do not initially or primarily involve memory, for example, frontotemporal dementia (see [Chapter 51](#)).

Dementia is diagnosed only when there is some significant decline in ability to function at home or at work. Dementia may be distinguished from mild cognitive impairment (MCI; see [Chapter 49](#)) in the requirement of significant impairment of independence in everyday activities such as occupational, social, or self-maintenance activities. The patient with MCI may have cognitive impairment in one or more domains, but this dysfunction is insufficient to cause functional impairment. For this reason, detailed analysis of the patient's need for help from others for simple activities of daily living (e.g., toileting, food preparation, shopping, housework) is crucial.

TERMINOLOGY AND CLASSIFICATION

In the most recent *DSM-5*, the American Psychiatric Association has eliminated the term *dementia* in favor of Major Neurocognitive Disorder. However, the distinction between dementia and MCI remains, as it pertains to functional status. The *DSM-5* formulation is of “major” and “minor” neurocognitive disorders, depending on the degree of functional impairment. The major neurocognitive disorders are what were termed dementias, and the minor neurocognitive disorders represent types of MCI that may be precursors to dementias (see [Chapter 49](#)). The new *DSM-5* criteria permit both major and minor neurocognitive disorders to involve impairment with even a single domain but keep the distinction as to presence or absence of functional impairment. Despite the revised terminology of the *DSM-5*, the use of the terms dementia and MCI are likely to persist in both neurologic and lay parlances.

Dementia can be classified in various ways. The oldest system was to classify dementias as presenile (i.e., young at onset) or senile (i.e., old at onset). This is not of any present use because each of the dementing disorders can have first symptoms arise over a wide range of age at onset. Older texts also referred to treatable versus untreatable dementias, with the treatable group including conditions such as hypothyroidism or B₁₂ deficiency and the untreatable group including Alzheimer disease and other degenerative conditions. Such a classification is not presently useful because treatment is being developed for dementing disorders previously deemed untreatable. For example, as of 2015, five different drugs are approved in the United States, per U.S. Food and Drug Administration labeling, specifically for treatment of Alzheimer disease (see [Chapter 50](#)). Another dichotomous categorization of dementia proposed separating disorders into those of genetic origin and others of

“sporadic” nature. However, this also has proven to be of minimal use because most dementia disorders may occur in either inherited (familial) forms or sporadic varieties. Dividing dementias into those with principally cortical or subcortical features, or into those with or without motor signs, has not proven useful for diagnosis, prognosis, or treatment and management. Thus, the most useful categorization of dementias is now based on the pathoetiologic basis of disease (Table 11.1). With clinicopathologic correlation, it is now usually possible to provide a specific diagnosis during life with 75% to 85% accuracy. It is important to recognize that even with an excellent clinical history and examination and auxiliary testing, clinical diagnosis of the dementia pathoetiology will not have perfect sensitivity or specificity.

Some patients have subjective complaints of cognitive disturbance, which is objectively verifiable but insufficient in either severity or functional disturbance or activities of daily life to meet criteria for dementia. In these cases, a diagnosis of MCI may be made, with specification of the involved cognitive domains (memory, language, visuospatial, executive, or attention). A large proportion of persons with MCI will develop some form of dementia within 5 to 7 years, with an annual rate of conversion of MCI to dementia as high as 10% to 15%.

CAUSES OF DEMENTIA

Dementing disorders are best etiologically classified as endocrine, metabolic, cerebrovascular, inflammatory, infectious, structural, or neurodegenerative (see Table 11.1). The last category is characterized by absence of the prior-listed etiologies.

NEURODEGENERATIVE DEMENTIAS

In the United States, the most common causes of dementia of the elderly are neurodegenerative. These include Alzheimer disease, Lewy body dementia, frontotemporal dementia, and Creutzfeldt-Jakob disease (CJD).

Alzheimer Disease

Alzheimer disease (see Chapter 50), with prominent memory and language impairment, is the most frequent form of dementia, accounting in the elderly for about 80% of the total number of patients in autopsy, clinical, or population-based series (Table 11.2). Structurally, it is marked by temporal and parietal degeneration.

P.82

Molecularly, it is characterized as an “amyloidopathy” because the most specific hallmark is abnormal deposits of β -amyloid in plaques, in addition to the less specific hyperphosphorylated tau protein evident in neurofibrillary tangles.

TABLE 11.1 Dementias Categorized by Pathoetiologic Basis

Primary Neurodegenerative Disorders

Alzheimer disease (AD)

Lewy body disorders

Dementia with Lewy bodies (DLB)

Parkinson disease dementia (PDD)

Frontotemporal dementias (FTD)

Behavioral variant frontotemporal dementia (bvFTD)

Progressive nonfluent aphasia (PNFA)

Frontotemporal dementia with motor neuron disease (FTD-ALS, FTD-MND)

Progressive supranuclear palsy (PSP)

Corticobasal degeneration (CBD)

Huntington disease (HD)

Wilson disease (WD)

Creutzfeldt-Jakob disease (CJD) and other prion diseases

Hippocampal sclerosis

Others: British familial dementia, HDLS, others

Vascular dementias: multi-infarct dementia, Binswanger disease, CADASIL

Immune-mediated encephalitides: NMDARAE, VGKCAE, others

Demyelinating dementias: multiple sclerosis, adreno- and metachromatic leukodystrophies

Inflammatory dementias: CNS vasculitides, Behçet syndrome, systemic lupus

Infectious dementias: neurosyphilis, neuroborreliosis, HIV dementia, others

Neoplastic dementias: tumors, carcinomatous meningitis, paraneoplastic syndromes

Metabolic or endocrine dementias: B₁₂ or rarer vitamin deficiencies, hypothyroidism

Structural dementias: hydrocephalus, brain trauma

FTD-ALS, frontotemporal dementia with amyotrophic lateral sclerosis; HDLS, hereditary diffuse leukoencephalopathy with spheroids; CADASIL, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; NMDARAE, *N*-methyl-D-aspartate receptor antibody encephalitis; VGKCAE, voltage-gated potassium channel antibody encephalitis; CNS, central nervous system.

Lewy Body Dementia

Lewy body dementia is the second most frequent cause of dementia in the elderly (see [Chapter 52](#)), characterized clinically by parkinsonism, hallucinations, and fluctuations in level of consciousness. Pathologically, the presence of Lewy bodies with molecular composition principally alpha-synuclein has led to the term *synucleinopathy*.

Frontotemporal Dementias

Frontotemporal dementias represent a molecularly heterogeneous group of degenerative disorders marked by frontal and temporal degeneration (see [Chapter 51](#)). Frontotemporal degeneration often presents with onset of symptoms at younger ages, in the 50s, and accounts for 5% to 10% of cases. Manifestations typically consist of either frontal-type behavioral disturbances (e.g., disinhibition, apathy, social impropriety, obsessions) or language disturbances. The molecular pathologies of this group of disorders can be broadly divided into those involving tau and those involving TDP-43 protein (TAR DNA-binding protein 43), with less common involvement of FUS, CHMP3, or VCP proteins. Pathologic entities including Pick disease, progressive supranuclear palsy, corticobasal degeneration, tangle dominant dementia, and argyrophilic grain disease are marked by prominent tau abnormalities and all now termed *tauopathies*. Motor neuron disease with dementia (amyotrophic lateral sclerosis dementia), some progressive aphasic disorders, and some behavioral variant frontotemporal dementias are TDP-43 proteinopathies.

TABLE 11.2 Prevalence of Dementing Disorders in the Elderly

Alzheimer disease[*]	65%-85%
Lewy body disorders[†]	15%-30%
Frontotemporal dementias	5%-10%
Vascular dementias[‡]	2%-10%
Other dementias	5%-10%

^{*}Note that Lewy bodies may also be present in 20%-40% of cases.

[†]Note that concomitant Alzheimer disease is present in 65%-90% of cases.

[‡]Note that infarcts are noted in ~35% of cases of dementia.

Less Common Neurodegenerative Dementias

Other degenerative dementias include Wilson disease (see [Chapter 134](#)), a genetic disorder marked by copper deposition in the basal ganglia, dementia, and tremor, and Huntington disease (see [Chapter 82](#)), a genetic disorder marked by bicaudate atrophy, clinical dementia, chorea, and gait disorder. Even less frequent neurodegenerative dementing disorders include CJD (see [Chapter 68](#)), British familial dementia, neuroaxonal dystrophy, certain spinocerebellar ataxias, fragile X tremor ataxia syndrome, and others.

VASCULAR DEMENTIA

Cerebrovascular disease was once considered to be a major cause of dementia of the elderly but is now

recognized to be the principle cause of dementia in less than 5% of cases in the United States. Syndromes of strategic infarct dementia, multiple infarct dementia, severe ischemic white matter disease (Binswanger disease or subcortical arteriosclerotic dementia), and hemorrhagic brain disease may all cause dementia (see [Chapter 53](#)). Acute stroke is a common cause of cognitive impairment but does not present as a gradually progressive dementing illness; instead, cognitive deficits follow in the aftermath of acute focal neurologic deficits or may take a stepwise course with discrete episodes of impairment and disability.

STRUCTURAL CAUSES OF DEMENTIA

The most common structural causes of dementia are chronic subdural hematoma (see [Chapter 46](#)) and hydrocephalus (see [Chapter 106](#)). Both diagnoses are established, in part, by neuroimaging, such as computerized tomography or magnetic resonance imaging, although imaging itself is not sufficient to determine the role of hydrocephalus in dementia. Subdural hematoma

P.83

typically presents as progressive deterioration in cognition and gait over days to weeks. Headache and lateralized focal deficits may or may not be present. Hydrocephalus represents a relative increase in cerebrospinal fluid in the cranial vault, causing compressive dysfunction of descending cortical pathways and cortex itself. The symptoms classically involve gait disorder, urinary incontinence, and dementia. Risk factors for hydrocephalus include prior history of intracranial hemorrhage, head injury, or meningitis, although these may not be known. Radiologically, distinguishing ventricular enlargement due to hydrocephalus from ventricular enlargement due to brain atrophy can be challenging.

METABOLIC CAUSES OF DEMENTIA

Metabolic causes of dementia include cobalamin (vitamin B12) deficiency, hypothyroidism, hypercalcemic disorders, and rarer vitamin or endocrine deficiencies. Toxic disorders can include inhalant, mercury, or manganese poisoning. Inherited metabolic disorders that may lead to dementia in adults include Wilson disease, the adult form of ceroid lipofuscinosis (Kufs disease), cerebrotendinous xanthomatosis, metachromatic leukodystrophy, adrenoleukodystrophy, mitochondrial disorders such as MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes). Transient reversible memory loss may occur from acute medical illness, drug intoxications (most notably benzodiazepines), or from the poorly understood syndrome of *transient global amnesia* (Chapter 60). This disorder typically occurs in older persons and consists of an acute circumscribed period of time in which no new memories are acquired, with complete anterograde amnesia. Patients typically repetitively ask questions about their current situation.

INFECTIOUS CAUSES OF DEMENTIA

Infectious causes of dementia are less common in the developed world and mostly more frequent in the younger population. CJD, which results from prion protein infiltration of the brain resulting in a spongiform encephalopathy (see [Chapter 68](#)), is the most notorious potentially infectious cause of dementia, although it can only be transmitted by direct exposure to diseased nervous system tissue. Viral disorders include HIV-associated dementia or herpesvirus family disorders (herpes simplex virus, varicella-zoster virus, cytomegalovirus, Epstein-Barr virus, human herpesvirus 6). Bacterial disorders include spirochetal disorders neurosyphilis and neuroborreliosis (Lyme disease) and atypical bacterial infections (tuberculosis). Fungal infections include meningitides owing to infection with *Cryptococcus*, *Coccidioides*, histoplasmosis, or others.

DEMENTIA FROM ENDOCRINE DYSFUNCTION

Undiagnosed hypothyroidism is the most common endocrine abnormality that can present as dementia. Other endocrine disturbances that can cause dementia include Addison or Cushing disease, repeated episodes of hypoglycemia in diabetics, hyperparathyroidism associated with hypercalcemia, and hyperthyroidism (see

[Chapter 117](#)). Hashimoto encephalopathy is a rare autoimmune encephalitis that occurs in conjunction with autoantibodies to thyroid proteins (see [Chapter 71](#)).

INFLAMMATORY CAUSES OF DEMENTIA

Rapidly progressive dementia can be caused by the immune-mediated encephalitides (see [Chapter 71](#)), some of which are paraneoplastic disorders.

EPIDEMIOLOGY

Dementia increases in prevalence with age. Although uncommon in younger persons, with a prevalence of 1% by age 60 years, dementia becomes dramatically more common thereafter, with a prevalence of 50% or greater at age 90 years and older. In autopsy studies of individuals with dementia, about 70% to 80% of brains show pathologically definite Alzheimer disease (see [Table 11.2](#)). About half of these have concomitant pathology, with evidence of Lewy body involvement or cerebrovascular infarctions. Thus, only one-third of autopsy brains have “pure” Alzheimer disease.

FOCUSED HISTORY AND DIFFERENTIAL DIAGNOSIS

The first symptoms of dementia often include occasional forgetfulness, misplacing objects, and word-finding difficulties ([Table 11.3](#)). With aging, a decline in memory may be observed, and thus sometimes the distinction between cognitive decline in old age and early dementia may be difficult. By definition, dementia is associated with progressive decline in functioning and thus is distinguished from a static encephalopathy such as mental retardation or congenital syndromes. Important exclusionary criteria for dementia include syndromes that are better explained by delirium (see [Chapter 10](#)) or by a primary psychiatric disorder such as major affective disorder or schizophrenia.

QUESTIONS TO ASK

Evaluation of complaints of cognitive dysfunction, whether self-tendered or enunciated by a family member or caregiver, are first elicited by obtaining a thorough history. Particular attention should be paid as to which symptoms predominated at onset. Symptoms of loss of memory (whether short term or long term), language usage (word-finding problems or decreased fluency, comprehension, or naming), praxis (dressing, use of utensils, or use of mechanical devices such as telephone or remote electronic controls), executive function (disorganization), insight (such as failure to recognize symptoms), dyscalculia, or behavioral dysfunction (agitation, disinhibition, depression, obsessions, delusions, or hallucinations) should be elicited. Symptoms of motor or gait impairment, adventitious movements, autonomic involvement (hypotension, urinary or bowel dysfunction), or sleep disturbance should also be elicited.

TABLE 11.3 Ten Warning Signs of Alzheimer Disease

- | | |
|----|--------------------------------------|
| 1. | Memory loss that affects job skills |
| 2. | Difficulty performing familiar tasks |
| 3. | Problems with language |
| 4. | Disorientation to time and place |

5. Poor or decreased judgment

6. Problems with abstract thinking

7. Misplacing things

8. Changes in mood or personality

9. Problems with directions or spatial relations

10. Loss of initiative

DEMENTIA VERSUS MILD COGNITIVE IMPAIRMENT

Attempts have been made to better define cognitive changes associated with aging, and varying sets of criteria have produced multiple terms, including such terms as age-associated memory impairment (AAMI), age-related cognitive change (ARCD), and questionable dementia (QD), among others. The most widely used term for cognitive change insufficient to meet criteria for dementia is *mild cognitive impairment* or, in the most recent psychiatric lexicon (*DSM-5*), *minor neurocognitive disorder* (Chapter 49). Criteria for MCI include subjective cognitive complaints and objective cognitive dysfunction but preserved general cognitive function and activities of daily living, with pursuant absence of dementia diagnosis. Follow-up examinations of individuals with MCI indicate that some, but not all, develop dementia over time.

DEMENTIA VERSUS DELIRIUM

Delirium presents acutely or subacutely and is a state of mental confusion that, unlike dementia, is primarily characterized by inattention to the immediate environment. Dementia is insidious in onset, evolves over months to years with normal consciousness and progressively worsens, whereas delirium is acute in onset, evolving in days to weeks, with fluctuations in consciousness. Both dementia and delirium may involve anxiety, hallucinations, illusions, delusions, and dysautonomia. Delirium is often a consequence of diffuse systemic or cerebral insults, including pain, infections, intoxications, or withdrawal from medications or drugs of abuse, metabolic disorders including hepatic or renal dysfunction, hypoxemia, or other medical or neurologic diseases. It is not possible to diagnose dementia with certainty in the presence of delirium. Delirium in elderly hospitalized patients very often has an underlying substrate of a baseline dementing illness that becomes apparent once the delirium has resolved.

Several features help differentiate dementia from delirium. Attention is not usually impaired in patients with dementia, although it is almost always altered in delirium. Increased or decreased motor activity is inherent in delirium but absent usually in dementia. If the cause is identified, delirium itself can be reversed (although not necessarily an underlying dementia process), although most forms of dementia progressively worsen.

DEMENTIA VERSUS DEPRESSION

Differentiating dementia from depression can sometimes be difficult. Depression (see [Chapter 149](#)) may be an early manifestation of Alzheimer disease. In depression, memory loss typically declines as the mood worsens. The onset of memory problems may be more abrupt than usually occurs in dementia and is mild,

fluctuating, and nonprogressive. Neuropsychological test results may reflect variability in performance and greater difficulties with learning, concentration, and attention, rather than true memory deficits such as seen with Alzheimer disease.

FOCUSED EXAMINATION

MENTAL STATUS EXAMINATION

The mental status evaluation is an essential part of every neurologic examination but particularly so in the evaluation of patients with cognitive symptoms. Much of the evaluation is predicated upon an attentive and communicative patient. Thus, the evaluation starts with determination of level of consciousness, alertness, and attention and proceeds to basic ascertainment of expressive and receptive language. If these are not intact, the evaluation is necessarily difficult and limited. General assessments include the following:

- Awareness and consciousness
- Verbal behavior including appropriateness
- Motor behavior including agitation or picking movements
- Mood and emotional state

More specific cognitive assessments include the following:

- Orientation to time (hour, day, date, month, year, season) and place (institution, address, floor, city, state)
- Concentration (e.g., spelling a five-letter word in reverse, counting backwards by serial 7s, reciting the months of the year in reverse)
- Detailed language testing (expressive speech, aural and reading comprehension of one-, two, or three-step commands, naming of solid objects or drawings, repetition of easy or difficult [prepositional] phrases, reading comprehension, ability to write a sentence)
- Registration or immediate recall (of three or five objects or words)
- Short-term memory or delayed recall after 3 to 10 minutes of three or five objects or words
- Long-term memory or fund of knowledge (names of current and prior elected officials, birthdates of family members, items of history)
- Visuospatial constructive abilities (copying simple shapes)
- Arithmetic calculations (mentally summing the values of coins, simple one- or two-digit additions or subtractions)
- Abstract reasoning (defining similarities, interpreting proverbs)
- Motor sequencing and praxis (sequential movements and motor commands)

BEDSIDE STANDARDIZED COGNITIVE TESTING

Two widely used brief standardized cognitive assessments are the Mini-Mental State Examination (MMSE) and the Montreal Cognitive Assessment (MoCA). These tests were introduced as standard measures of cognitive function for both research and clinical purposes. They are short, requiring less than 10 minutes, relatively easy to administer, and result in scores of 0 point (failing all items) to 30 points (perfect score).

It is important to emphasize that the MMSE and MoCA, like all brief mental status exams, are not perfectly

sensitive or specific for dementia. These tests are sensitive to cultural and language factors and level of education. Well-educated patients may suffer from dementia and nonetheless score a “perfect” 30 points on these 30-point scales, whereas poorly educated patients may score much lower and yet be nondemented. Therefore, the MMSE or MoCA should be used as screening instruments, but they do not replace a detailed history and examination or full neuropsychological testing (see [Chapter 30](#)).

GENERAL NEUROLOGIC EXAMINATION

The general neurologic examination is useful in the evaluation of the patient with dementia because certain signs ([Table 11.4](#)) may make a diagnosis of Alzheimer unlikely and may point to another causative etiology. For example, focal findings of hemiparesis may suggest a vascular component or, in cases of hemineglect, the degenerative disorder corticobasal degeneration. Prominent visual dysfunction may suggest posterior cortical atrophy, usually a variant of Alzheimer disease, or cerebral amyloid angiopathy. Paralysis of supranuclear gaze with preserved brain stem reflexes may suggest progressive supranuclear palsy or corticobasal degeneration.

P.85

Lower motor neuron signs, such as fasciculations and atrophy, may suggest frontotemporal dementia with motor neuron disease.

TABLE 11.4 Neurologic Signs and Symptoms Atypical for Alzheimer Disease

Sign or Symptom	Possible Significance
Dominant nonmemory Sx (e.g., language, praxis, visuospatial dysfunction)	Frontotemporal degenerations, posterior cortical atrophy
Prominent behavioral, personality, psychotic symptoms	Frontotemporal degenerations, Lewy body dementia
Early parkinsonism (e.g., resting tremor, bradykinesia, cogwheeling)	Lewy body dementia, progressive supranuclear palsy (no rest tremor), corticobasal degeneration, hydrocephalus
Urinary incontinence	Hydrocephalus
REM sleep behavior disorder	Parkinson disease dementia, Lewy body dementia
Seizures	Immune-mediated or infectious encephalitides
Myoclonus	Creutzfeldt-Jakob disease
Frequent falls	Progressive supranuclear palsy
Early unexplained gait abnormalities	Lewy body dementia, progressive supranuclear palsy, corticobasal degeneration, hydrocephalus

Early prominence of bulbar/brain stem signs	Progressive supranuclear palsy
Unexplained motor or reflex asymmetries	Vascular dementia, corticobasal degeneration
Unexplained (early) UMN signs (e.g., Babinski sign)	Frontotemporal degeneration with motor neuron disease
Unexplained LMN signs (e.g., fasciculations)	Frontotemporal degeneration with motor neuron disease

Sx, symptoms; REM, rapid eye movement; UMN, upper motor neuron; LMN, lower motor neuron.

DIAGNOSTIC TESTING

The American Academy of Neurology in 2001 developed the evidence-based practice parameters for evaluation of the diagnosis and cause of dementia. These parameters have been entirely revolutionized by the development of modern neuroimaging, biomarkers, and genetic tests. A workgroup formed by the National Institute on Aging in conjunction with the Alzheimer's Association published in 2011, revised recommendations on diagnostic criteria, which are included in [Table 11.5](#).

NEUROPSYCHOLOGICAL TESTING

Detailed neuropsychological testing (see [Chapter 30](#)) may be performed to augment the clinical mental status examination by assessing severity and regional pattern of cognitive impairment through use of standardized tests with normative values. This can be very helpful not only in differential diagnosis but also in monitoring disease progression.

TABLE 11.5 Practice Parameters for Diagnosis of Dementia

Clinical Evaluation

History from patient and an informant

Cognitive assessment - mental status examination

Neuropsychological testing (when above is insufficient for confident diagnosis)

Routine Testing

Complete blood cell count

Serum chemistry - electrolytes, glucose

Serum BUN, creatinine, liver function tests

Serum thyroid function tests (TSH) and B12 level

Serologic tests for syphilis and HIV (optional - depending on risk)

Biomarkers

Measures of cerebrovascular disease

Brain MRI

Measures of neuronal injury

CSF tau measurement

FDG-PET

MRI hippocampal volume

Measures of beta-amyloid

CSF beta-amyloid measurement

PET amyloid imaging

Measure of dopaminergic dysfunction

loflupane SPECT scan

Genetic tests (depending on age, family history and clinical presentation)

AD mutations: PS1, PS2, APP

FTD mutations: tau, C9orf, progranulin

Prion protein mutations

Other mutations

BUN, blood urea nitrogen; MRI, magnetic resonance imaging; AD, Alzheimer disease; PET, positron emission tomography; SPECT, single photon computed tomography; CSF, cerebrospinal fluid; FTD, frontotemporal dementia.

This table is based on first practice guidelines published by American Academy of Neurology (2001), more recent National Institute on Aging-Alzheimer's Association Workgroup recommendations (2011), and other practice guidelines.

Memory impairment can be parsed into immediate or working memory, short-term memory, and remote memory. Working memory is typically unaffected in early Alzheimer disease but often significantly affected in depression and subcortical dementias such as Parkinson disease dementia. In contradistinction, short-term recall is severely and early affected in Alzheimer disease and its precursor, amnesic MCI. Remote or long-term memory is affected later in the disease course of Alzheimer disease but may be relatively preserved even late in the course of some of the other dementias.

Language impairments can be assessed. Naming difficulties, common in Alzheimer disease, are less common in subcortical dementias. Verbal fluency for categories (semantic verbal fluency) is

P.86

much more severely affected in disorders of the temporal lobes, such as Alzheimer disease, compared to verbal fluency for letters (phonemic verbal fluency) which is more affected in disorders of the frontal lobes, such as frontotemporal dementia.

Visuospatial impairments can be assessed. Typically, visuosper-ceptive impairment is marked in Alzheimer disease, whereas disorganization is more prominent in frontotemporal dementias. Micropraxia (drawing very small shapes) is common in the Lewy body disorders.

LABORATORY BLOOD TESTING

Recommendations for auxiliary testing generally include basic laboratory tests (blood chemistry and cell counts) and, more specifically, laboratory testing for vitamin B₁₂ deficiency (with homocysteine and methylmalonate ordered if B₁₂ is borderline or low) and thyroid deficiency (thyroid-stimulating hormone [TSH], with free T4 ordered if TSH is out of normal range). The American Academy of Neurology guidelines specify B₁₂, TSH, and structural imaging (generally magnetic resonance imaging [MRI]) to exclude contributory disorders to cognitive symptoms, which might be otherwise unrecognized **[Level 1].1** Serologic tests for exposure to syphilis (Venereal Disease Research Laboratory and fluorescent treponemal antibody-absorption test), Lyme disease (screening enzyme immunoassay, with confirmatory Western blots), or HIV (HIV-1/2 antibody and antigen) may be of value.

LABORATORY CEREBROSPINAL FLUID TESTING

Analysis of cerebrospinal fluid (CSF) obtained through lumbar puncture (see [Chapter 31](#)) is increasingly used in diagnosis of cognitive dysfunction. CSF provides information in two broad categories: (1) In an exclusionary fashion, it may be used to be certain that various infectious or inflammatory etiologies of dementia discussed earlier are not present, and (2) in an inclusionary fashion, it may provide information with regard to neurodegenerative diseases, such as Alzheimer disease or CJD, through use of protein biomarkers (see [Chapter 31](#)). Presence of abnormal numbers of leukocytes, taking into account any blood contamination, is typically indicative of an inflammatory or infectious process. Biomarkers including β -amyloid-42, total tau, phosphotau, and 14-3-3 protein are established as of use in the diagnosis of Alzheimer disease and CJD. In Alzheimer disease, typically β -amyloid-42 is lower than normal, total tau is higher than normal, and phosphotau is higher than normal. These changes are often the earliest biomarker of Alzheimer disease and may be evident prior to clinical symptoms and prior to structural and functional neuroimaging changes seen by MRI or positron emission tomography (PET) scans. Currently, these biomarkers are being increasingly utilized not only for their diagnostic value, but also to potentially provide surrogate indices of dementia severity and progress. For CJD, typically both

total tau and 14-3-3 are highly elevated. CSF biomarkers not only may yield improvements in the differential diagnostic process but also allow better assessment of change during investigational therapies designed to affect disease symptoms or modify the disease process (Table 11.6).

NEUROPHYSIOLOGIC TESTING

Electroencephalogram (EEG) testing can be useful in two fashions: (1) It may assist in the assessment of the possibility of subclinical paroxysmal disorders being responsible for abnormal mental status and (2) it may be of use in cases where it is less clear whether a primary psychiatric or neurologic diagnosis is operative. Epileptiform activity may be particularly prominent in the immune-mediated encephalitides or other rapidly progressive dementias such as rabies or herpes simplex encephalitis. In disorders that are purely psychiatric, frequently background EEG rhythm may be normal, whereas conversely neurologic disorders may be accompanied by focal or generalized background slowing.

TABLE 11.6 Dementias Categorized by Protein Pathologies

β-Amyloidopathy	Alzheimer disease
β-Synucleinopathy	Lewy body disorders (DLB), PDD
Tauopathy	Frontotemporal dementia: Pick disease, PSP, CBD (Note that AD has secondary tau pathology.)
TDP-43 proteinopathy	Frontotemporal dementia (FTD-U), ALS with dementia
Prionopathy	Creutzfeldt-Jakob disease, sporadic/familial fatal insomnia, GSS, vCJD

DLB, dementia with Lewy bodies; PDD, Parkinson disease dementia; PSP, progressive supranuclear palsy; CBD, corticobasal degeneration; AD, Alzheimer disease; ALS, amyotrophic lateral sclerosis; GSS, Gerstmann-Sträussler-Scheinker disease; vCJD, variant Creutzfeldt-Jakob disease.

Electromyography provides an assessment of the lower motor neurons which can be helpful in ascertaining the presence of frontotemporal dementia with motor neuron disease. Sensory nerve studies may be helpful in rarer disorders such as metachromatic leukodystrophy.

NEUROIMAGING

Conventional Computed Tomography and Magnetic Resonance

Structural neuroimaging can be useful in both exclusionary and inclusionary fashions with respect to neurodegenerative dementias. Discovery of significant vascular injury, inflammatory lesions, contrast-enhancing processes, or tumors may be decisive in ruling out degenerative processes and indicating some infectious, inflammatory, or neoplastic process. However, even in cases of “radiologically normal” scans, structural features such as parietal atrophy or temporal atrophy may be indicative of an Alzheimer process. Specialized imaging such as gradient echo sequences can reveal microhemorrhages, which when multiple may be suggestive of amyloid angiopathy, cerebral autosomal dominant arteriopathy with subcortical infarcts and

leukoencephalopathy, or less frequently hypertensive cerebrovascular injury. Other specialized sequences such as diffusion-weighted imaging may show strong evidence of prion disease. CJD typically results in diffusion-weighted hyperintensities in cortical regions confined to the gray matter cortical ribbon and also to the deep gray nuclei, including thalami, caudate, and lenticular nuclei.

Biomarker Imaging

Nuclear medicine imaging provides useful information in cases of suspected dementia. Single-photon emission computed tomography (SPECT) imaging (see [Chapter 22](#)) using ^{99m}Tc -hexamethyl propylene amine oxime (HMPAO) or ^{99m}Tc -ethyl cysteine dimer (ECD) allows imaging of brain perfusion. These tests, as well as ^{18}O -PET which also images brain blood perfusion, and more frequently used ^{18}F -fluorodeoxyglucose (FDG) PET imaging

P.87

(see [Chapter 22](#)) which images the closely linked feature of brain glucose metabolism, can be of value in displaying topographic patterns of brain dysfunction. These patterns can be relatively disease specific. Typically, Alzheimer disease shows a pattern of biparietal and bitemporal hypoperfusion, or hypometabolism, that may be more or less asymmetric. There is sparing of the primary cortices including sensory, motor, and visual regions, as well as the deep gray nuclei. Lewy body disease shows a similar pattern but often with less prominent temporal involvement and much more parietal and occipital involvement, often involving the visual cortices. Frontotemporal dementias typically involve frontal and/or anterior temporal regions, sometimes quite asymmetrically, with preservation of parietal and other posterior regions. Most recently, the expanding field of molecular imaging has provided more specific imaging biomarker tools for neurodegenerative disorders. Assistance with diagnosis of Lewy body disorders may be provided, albeit with less than excellent sensitivity or specificity, through dopamine transporter imaging, such as ^{123}I -ioflupane SPECT. Most recently, use of amyloid imaging, including ^{18}F -florbetapir, ^{18}F -florbetaben, and ^{18}F -flutemetamol, has allowed in vivo assessment in humans of fibrillar β -amyloid, indicating an Alzheimer process. Currently, this testing has high sensitivity but low specificity because many clinically unaffected individuals older than age 65 years may show evidence of amyloid deposition as determined by binding of these radiopharmaceutical tracers imaged using PET. However, additional investigational molecular imaging tools such as tracers believed to be specific for the tau protein aggregated in neurofibrillary tangles may also prove to be of diagnostic assistance.

Involuntary Movements

Elan D. Louis

INTRODUCTION

Abnormal involuntary movements, often called *dyskinesias*, are uncontrollable movements that are usually evident when a patient is at rest and, with rare exceptions (e.g., palatal myoclonus), these movements disappear during sleep. These movements are continual or easily evoked, although some are intermittent or paroxysmal, such as the *tics*, *paroxysmal dyskinesias*, or *episodic ataxias*. Although convulsions, fasciculations, and reflex clonus are involuntary movements, they are not classified with the types of abnormal involuntary movements that are described in this chapter.

The various dyskinesias are distinguished from one another based primarily on the visual inspection of the patient. Hence, the neurologic examination is of central importance when assigning a diagnosis.

The visual opposite of the hyperkinesias are the hypokinesias. Hypokinesia refers to reduced amplitude of movement or a paucity of movement that is not due to weakness or paralysis, but the term is commonly used synonymously with bradykinesia (slow movement), and the two features typically occur together in the parkinsonian states. Furthermore, hesitation and freezing phenomena (i.e., delays and interruptions of movement) are frequent features of parkinsonian states.

TYPES OF DYSKINESIAS

There are a large number of dyskinesias ([Table 12.1](#)), and each of these will be described further in the following text.

CHOREA

Chorea refers to brief, irregular contractions that, although rapid, are not as lightning-like as myoclonic jerks. In classic choreic disorders, such as Huntington disease (see [Chapter 82](#)) and Sydenham chorea (see [Chapter 81](#)), the movements affect individual muscles as random events that seem to flow from one muscle or muscle group to another ([Video 12.1](#)). The movements are neither repetitive nor rhythmic. *Ballism* is a form of chorea in which the movements are more jerk-like and are of large amplitude, producing flinging movements of the affected limbs.

DYSTONIA

Dystonia (see [Chapter 76](#)) is a syndrome of sustained muscle contraction that frequently causes twisting and repetitive movements or abnormal postures. The spasms may affect the neck muscles (*torticollis*) ([Video 12.2](#)), periocular muscles (*blepharospasm*), facial muscles (*Meige syndrome*), or limb muscles (e.g., *writer's cramp*). Dystonia is represented by the following phenomena: (1) sustained contractions of both agonist and antagonist muscles simultaneously (cocontraction) and persisting in the same muscle groups repeatedly (“patterning”), in contrast to the flowing of choreic movements; (2) an increase of these involuntary contractions when voluntary movement in other body parts is attempted (“overflow”); (3) rhythmic interruptions of these involuntary, sustained contractions (*dystonic tremor*); (4) inappropriate or opposing contractions during specific voluntary motor actions (*action dystonia*); and (5) torsion spasms that may be as rapid as chorea but differ because the movements are continual, patterned, and of a twisting nature, in contrast to the random and seemingly flowing movements of chorea. The speed of dystonic movements varies considerably from slow (athetotic dystonia) to shock-like (myoclonic dystonia). One of the characteristic features of dystonic movements is that they can often be

diminished by tactile or proprioceptive “sensory tricks” (geste antagoniste). Thus, touching the involved body part or an adjacent body part can often reduce the muscle contractions (e.g., patients with torticollis may touch their chin to lessen the spasms).

Inexperienced clinicians might assume that this sign indicates that the abnormal movements are psychogenic; however, the presence of sensory tricks strongly suggests an organic etiology.

TABLE 12.1 List of Involuntary Movements List of Involuntary Movements

Hyperkinesias

Akathitic movements

Asynergia

Athetosis

Ballism

Chorea

Dysmetria

Dystonia

Episodic ataxia

Hemifacial spasm

Hyperkplexia and jumping disorders

Hypnogenic dyskinesias

Jumpy stumps

Myoclonus

Myorhythmia

Painful legs-moving toes

Paroxysmal movement disorders (paroxysmal dyskinesias, episodic ataxias, paroxysmal hypnogenic dyskinesias, transient dyskinesias of infants)

Restless legs syndrome

Stereotypy

Tics

Tremor

Hypokinesias

Akinesia/bradykinesia (parkinsonism)

Hesitation and freezing phenomenon

MYOCLONUS

Myoclonus (see [Chapter 78](#)) refers to an ultrabrief, shock-like movement that may arise from sudden muscle contractions (Video 12.3) or sudden interruption of ongoing muscle contractions with resultant postural lapses (i.e., negative myoclonus). The most common form of negative myoclonus is asterixis, which frequently accompanies various metabolic encephalopathies. In asterixis, the brief flapping of the outstretched limbs is due to transient inhibition of the muscles that maintain posture of those extremities.

Myoclonus can appear when the affected body part is at rest but it may also occur when it is performing a voluntary motor act (i.e., “action myoclonus”). Myoclonic jerks are usually irregular (arrhythmic) but can also be rhythmical (such as in *palatal myoclonus*, *ocular myoclonus*, or *limb myorhythmia*, with a rate of approximately 2 Hz).

TICS

Tics may be simple jerks or complex sequences of coordinated movements that appear suddenly and intermittently (Video 12.4). When simple, the movements may resemble a myoclonic jerk. Complex tics often include head shaking, eye blinking, sniffing, shoulder shrugging, facial distortions, arm waving, touching parts of the body, jumping movements, or making obscene gestures (*copropraxia*). Tics are usually rapid and brief, but occasionally, they may involve sustained muscle contractions (i.e., dystonic). In addition to motor tics, phonic tics involve sounds through the nose (e.g., sniffing) or throat (throat clearing) as well as other vocalizations. These range from sounds, such as barking or squealing, to verbalizations, including the utterance of obscenities (*coprolalia*) and the repetitions of sounds, words, or phrases (*palilalia* and *echolalia*). Motor and phonic tics are the essential features of the Tourette syndrome (see [Chapter 74](#)). One feature of tics is the compelling urge felt by the patient to make the motor or phonic tic, with the result that the tic movement brings relief from unpleasant sensations that develop in the involved body part. Tics may be voluntarily controlled for brief intervals, but such a conscious effort at suppression is usually followed by more intense and frequent contractions. The spectrum of severity and persistence of tics is wide; the milder the tic disorder is, the more control the patient may exert over the tics.

STEREOTYPIES

Stereotypic movements (*stereotypies*) occur as repetitive, sometimes rhythmic movements (e.g., hand flapping, head nodding, body rocking), and they may resemble tics; these are encountered in persons with mental retardation, autism, or schizophrenia, although they also occur in normal developing children. Stereotypic

movements are also encountered in the syndrome of drug-induced tardive dyskinesia (see [Chapter 80](#)) and refer to repetitive movements that most often affect the mouth; in *orobuccolingual dyskinesia*, there are constant chewing movements of the jaw, writhing and protrusion movements of the tongue, and puckering movements of the lips.

TREMOR

Tremors are rhythmic oscillatory movements. They result either from alternating contractions of opposing muscle groups or from simultaneous contractions of agonist and antagonist muscles. A useful way to differentiate various tremors clinically is to determine whether the tremor is present during different conditions: when the affected body part is at rest, as in parkinsonian disorders; when posture is maintained (e.g., with arms outstretched in front of the body or with elbows flexed with arms in a winged position), as in Wilson disease and essential tremor (see [Chapter 73](#)); when action is undertaken (e.g., writing or pouring water from a cup) (Video 12.5), as in essential tremor; or when intention is present (e.g., during finger-to-nose maneuver), as in diseases involving the cerebellum such as ataxias and essential tremor (see [Chapters 73](#) and [79](#)).

ATHETOSIS

Athetosis is a slow, continuous, writhing movement of the limbs, trunk, head, face, or tongue. When these movements are brief, they merge with chorea (*choreoathetosis*). When the movements are sustained at the peak of the contractions, they merge with dystonia, and the term *athetotic dystonia* may be applied.

AKATHISIA

Akathitic movements commonly accompany the subjective symptom of *akathisia*, an inner feeling of motor restlessness or the need to move (Video 12.6). Today, akathisia is most commonly seen as a side effect of antipsychotic drug therapy, either as acute akathisia or tardive akathisia, which often accompanies tardive dyskinesia. In addition to that induced by antipsychotic drugs, pathologic akathisia may be seen in the encephalopathies of confusional states, in some dementias, and in Parkinson disease. Picking at the bedclothes (i.e., carphology) is a manifestation of akathitic movements in patients who are bedridden. Akathitic movements (e.g., crossing and uncrossing the legs, squirming and/or attempting to rise from a chair, pacing the floor) may also be a reaction to stress, anxiety, boredom, or impatience; these may then be termed *physiologic* akathisia.

RESTLESS LEGS SYNDROME

One other neurologic condition in which there are subjective feelings of the need to move is *restless legs syndrome*. This is characterized by formication in the legs, particularly in the evening when the patient is relaxing and sitting or lying down and attempting to fall asleep. These sensations of ants crawling under the skin disappear when the patient gets up and walks around.

PAROXYSMAL MOVEMENT DISORDERS

Paroxysmal movement disorders are syndromes in which the abnormal involuntary movements appear for brief periods out of a background of normal movement patterns. They may be divided into four distinct groups: (1) the *paroxysmal dyskinesias* (either induced by movement or not), (2) *episodic ataxias*, (3) *paroxysmal hypnogenic dyskinesias* (intermittent dystonia and chorea that begins during sleep), and (4) *transient dyskinesias of infants* (e.g., torticollis, body tilt).

HYPEREKPLEXIA

Hyperekplexia (startle disease) consists of dramatic, complex motor responses to sudden tactile or auditory stimuli. It may be hereditary or sporadic. The reaction can consist of a blink; facial contortion; abduction of the arms; and flexion of the neck, trunk, and arm. Sometimes instead of movements, the body becomes stiff and

curtailed because a sudden attack may lead to injury from falling. Hyperekplexia, however, is probably distinct from jumping disorders, which are often described with local names, such as jumping Frenchmen of Maine, myriachit (in Siberia), latah (in Malaysia), and ragin' Cajun (in Louisiana); these jumpers may react to a sudden visual threat and may also respond to sudden verbal commands, such as "jump" or "throw." They may incorporate echolalia and echopraxia (repetition or imitation of another person's actions).

OTHER DYSKINESIAS AND MOVEMENT DISORDERS

Continued muscle stiffness due to continuous muscle firing may be seen in patients with neuromyotonia, encephalomyelitis with rigidity, the stiff limb syndrome, and the stiff person syndrome, which tends to involve axial and proximal limb muscles (see [Chapter 94](#)).

Cerebellar diseases (see [Chapter 79](#)) or lesions involving the pathways to or from the cerebellum result in a variety of abnormalities of movement. *Asynergia* or *dyssynergia* refers to the decomposition of movement due to breakdown of normal coordinated execution of a voluntary movement. Instead of a smooth, continuous movement, the limb moves off its trajectory in attempting to reach a target, with corrective maneuvers that resemble oscillations of the limb. The limb often misses the target (*dysmetria*); the asynergia worsens when the limb approaches the target. Common tests for asynergia and dysmetria are the finger-nose-finger and the heel-knee-shin maneuvers. Limb asynergia is also manifested by *dysdiadochokinesia*, which refers to the breakup and irregularity that occurs when the limb is attempting to carry out rapid alternating movements. The dysmetria in cerebellar disease is due to overshooting (*hypermetria*) and undershooting (*hypometria*) the target. There may be an associated *intention* (or terminal) *tremor*. Asynergia is usually associated with hypotonia, loss of check (when a fast voluntary movement is unable to stop precisely on target as the limb reaches its destination), and rebound (when sudden displacement of a limb results in excessive overcorrection to return to the baseline position). *Ataxia* of gait is typified by unsteadiness on walking with a wide base, the body swaying, and a difficulty with tandem walking (heel-to-toe walking).

TABLE 12.2 Red Flags for Psychogenic Movements

Finding	Explanation
Inconsistency	Movements that change quality (e.g., change in direction or frequency)
Combination of several hyperkinesias that do not ordinarily occur together	Unusual combinations of movements that do not typically co-occur in organic disease
Fixed postures	Postures that are sustained for prolonged periods of time
Deliberate slowness	Practiced slowness that resolves when the patient is unaware that they are still being observed
Suggestibility	The movement is reproduced when the examiner performs a maneuver that he or she suggests will acutely bring on the movement.

Distractibility	The movement stops when the examiner draws the patient's attention away from the affected body part to perform a task that requires considerable effort and concentration.
Entrainment (in tremor disorders)	Tremor frequency changes to match the frequency of tapping with the opposite limb.
Give-way weakness	During strength testing, the patient initially provides resistance against the examiner's force but then suddenly "gives way" and provides no further muscular resistance.
Nonanatomic sensory impairment	Sensory deficits that do not follow anatomic patterns/boundaries
Marked fatigue and exhaustion	By history, the amount of fatigue is out of proportion to the severity of the movements.

Although most of the involuntary movements described are the result of lesions in the central nervous system, some dyskinesias are attributed to peripheral disorders, and these include hemifacial spasm (Video 12.7) (see [Chapter 77](#)), painful legs-moving toes, jumpy stumps, and the sustained muscle contractions seen in reflex sympathetic dystrophy (complex regional pain syndrome) (see [Chapter 56](#)).

Psychogenic movement disorders may manifest with a variety of movements but particularly shaking, fixed postures, bizarre gaits, or paroxysmal disorders ([Table 12.2](#)). Careful evaluation of the phenomenology for inconsistency, incongruity, prolonged fixed postures, deliberate slowness, suggestibility, distractibility, entrainment, false (give-way) weakness, nonanatomic sensory impairment, and marked fatigue and exhaustion from the "involuntary" movements suggest the diagnosis.

NEUROANATOMY

Most of the involuntary movements are the result of central nervous system disorders and more specifically, lesions involving the basal ganglia and cerebellum. For example, the motor features of Parkinson disease are related to a lesion in the substantia nigra pars compacta, chorea is related to disorders of the caudate nucleus but sometimes involving other structures, and ballism is more often related to lesions of the subthalamic nucleus. Ataxia and intention tremor are related to lesions of the cerebellum.

The neural site of origin of myoclonus is more widespread, including the cerebral cortex (cortical myoclonus), brain stem (reticular reflex myoclonus), and spinal cord (proprio-spinal myoclonus). Rhythmic myoclonias are typically due to structural lesions of the brain stem or spinal cord (therefore also called *segmental myoclonus*).

Dyskinesias attributed to peripheral disorders are hemifacial spasm, painful legs-moving toes, jumpy stumps, and the sustained muscle contractions seen in reflex sympathetic dystrophy.

FOCUSED EXAMINATION

The neurologic examination is the most important tool for the diagnosis of involuntary movements. To begin with, it is important to spend time observing the patient and visualizing the movements. Tell the patient that you are going to watch their movements, and then sit in front of them and observe. Patients may sometimes

be self-conscious and may try to inhibit their involuntary movements, particularly if these movements are embarrassing. If this is the case, then ask the patient to just let their body “do what it wants to do ... don't try to stop it.” After the observation, it is important to ask the patient to perform certain maneuvers designed to bring out the movement (e.g., writing may bring out a tremor, heel-knee-shin maneuver may bring out asynergia, and walking may bring out a dystonic foot movement). Some movements may be quite elaborate, and the examiner may need to observe for quite some time before being able to detect a consistent pattern or before being able to fully encapsulate and describe the phenomenology.

FOCUSED HISTORY

The neurologic history is also an important step in arriving at the correct diagnosis (Table 12.3). It is important to ask the patient about the location of the movements. Some patients with tremor may feel the movements in body parts that are not visibly shaking. Other features, including the periodicity of the movements and the items that exacerbate and/or relieve the movements, are important to assess. The conditions during which the movements occur (e.g., at rest or with movement) is also of importance in tremor classification, and accompanying feelings of restlessness, urges to move, and relief after the movement are important historical features to consider when diagnosing tics, akathisia, and restless legs syndrome. Family history information is also important, and it may be instructive to examine additional family members. It is important to obtain a list of current medications (as these may be producing, exacerbating, or partially suppressing movements) as well as medication exposures in the past (especially neuroleptics).

TABLE 12.3 Questions to Ask the Patient Who Presents with Involuntary Movements

Question	Relevant Involuntary Movement
Where (i.e., in what body regions) are the movements?	All
Do movements occur at rest or with action?	All
Does anything (e.g., movement, startle) trigger the movements?	Paroxysmal movement disorders, hyperekplexia
Are there accompanying vocalizations?	Tics, Tourette syndrome
Does the movement produce a feeling of relief?	Tics
Is there an urge to move?	Akathisia, tics, restless legs syndrome
Is the patient feeling restless?	Akathisia, restless legs syndrome
Is the patient able to suppress the movements?	Tics, chorea (briefly)
Is there pain/discomfort in the region where the movements are occurring?	Dystonia (esp. torticollis)

Is there a pulling feeling in the muscles?	Dystonia (esp. torticollis)
Is there a sensory trick (a place they can touch to lessen the movement)?	Dystonia
What are the current medications?	Tremor, parkinsonism, chorea
What were the past medications (e.g., neuroleptics)?	Tardive movements

DIAGNOSIS

The first step in diagnosing a movement disorder is to recognize the movement phenomenology itself, and this is based primarily on keen and unhurried observation. Once the specific movement or movement types are identified, one may consider the various etiologies that can result in that/those type(s) of movements. In some instances, electromyogram may be helpful by determining the rate, rhythmicity, and synchrony of involuntary movements, as well as the duration of individual contractions. The duration of an individual contraction may distinguish specific types of dyskinesias; for instance, differentiating an organic myoclonic jerk from a psychogenic one. Motor control physiology laboratories typically perform this service. Additional blood work as well as brain imaging may aid in the diagnosis, although these should not be used as a substitute for clinical observation. Psychogenic movements due to somatoform disorders (conversion, hysteria) are subconscious and thus involuntary, in contrast to malingering. A common mistake is to label an abnormal movement not previously encountered by the physician as psychogenic. Experience of seeing a large number of movement disorders brings knowledge that helps in distinguishing psychogenic versus organic movements. It is important to look for positive signs such as give-way weakness, nonanatomic sensory impairment, and a combination of several hyperkinesias that do not ordinarily occur together; distraction; and entrainment (in tremor disorders) to help establish the diagnosis of a psychogenic movement disorder.

TREATMENT

The initial management of involuntary movements is the triaging into those that require acute treatment versus those that do not. There are a small number of movement disorders that must be dealt with acutely, including acute dystonic reactions and the paralytic form of Sydenham chorea. A number of emergent situations may arise in the treatment of patients with involuntary movements, including acute psychosis in patients with Parkinson

P.92

disease, neuroleptic malignant syndrome, dystonic storm, and oculogyric crisis (Table 12.4). The initial management of the remaining patients depends very much on the stage and severity of the disease; in many instances, a realistic goal of therapy is to lessen the frequency, severity, and functional impact of movements rather than to aim for complete cessation. Dosages of drugs used in movement disorder emergencies are shown in Table 12.5.

TABLE 12.4 Emergent Situations in the Treatment of Patients with Involuntary Movements

Entity	Comments	Acute Management
Dystonic storm	Continuous dystonic spasms	<ul style="list-style-type: none"> • Admission to ICU • Monitor fluids and electrolytes. • Treat rhabdomyolysis. • Treat with anticholinergic agents (diphenhydramine), baclofen, and benzodiazepines (lorazepam). • Sedation, airway protection, and paralysis may be necessary.
Hemiballismus	Continuous violent flailing, lateralized arm and leg movements seen with injury to the subthalamic nucleus	<ul style="list-style-type: none"> • May require intubation, sedation, and paralysis in the most severe cases
Acute psychosis in patients with Parkinson disease	Generally due to medication effects	<ul style="list-style-type: none"> • Acute hospitalization may be necessary. • Reduce and/or withdraw medication. • Treat with antipsychotic agents.
Parkinsonian hyperpyrexia	May occur in a variety of settings	<ul style="list-style-type: none"> • Admission to ICU • Monitor fluids and electrolytes. • Carbidopa/levodopa, dantrolene, or steroids may be beneficial.
Stridor in patients with multiple system atrophy	More often at night and may result in respiratory arrest	<ul style="list-style-type: none"> • Nasal continuous positive airway pressure mask • Botulinum toxin injections to the thyroarytenoid muscles • Tracheostomy
Neuroleptic malignant syndrome	Due to drugs with dopamine-blocking activity	<ul style="list-style-type: none"> • Admission to ICU • Withdrawal of offending medication • Treat with bromocriptine, amantadine, dantrolene, or lorazepam.
Acute dystonic reaction	Due to drugs with dopamine-blocking activity	<ul style="list-style-type: none"> • Withdraw offending drug. • Treat with IV diphenhydramine.
Oculogyric crisis	Due to drugs with dopamine-blocking activity	<ul style="list-style-type: none"> • Withdraw or lower dose of offending drug.

- Treat with IV diphenhydramine.

Paralytic form of Sydenham chorea

A severe hypotonic state with paralysis

- Treatment with IV steroids

ICU, intensive care unit; IV, intravenous.

TABLE 12.5 Medications Used in Movement Disorder Emergencies

Amantadine (Symmetrel)	100 mg PO t.i.d.
Baclofen (Lioresal)	10-20 mg PO t.i.d.
Bromocriptine (Parlodel)	5-10 mg PO q8h
Carbidopa-levodopa	25/100 mg PO
Dantrolene sodium (Dantrium)	2.5 mg/kg IV loading dose, 0.25 mg/kg/h IV infusion
Diphenhydramine (Benadryl)	25-50 mg IV q4-8h
Lorazepam (Ativan)	2-4 mg IV q4-6h

PO, by mouth; IV, intravenous.

Videos can be found in the companion e-book edition. For a full list of video legends, please see the front matter.

INTRODUCTION

Weakness is one of the most common complaints in all of neurology; hence, both the scope of the term and its differential diagnosis is broad. A patient may have weakness due to a lesion anywhere in the central or peripheral nervous system from the motor cortex to the muscle itself. Often, patients will use the term *weakness* to describe various functionally limiting symptoms unrelated to loss of strength as with the bradykinesia seen in parkinsonism or the clumsiness experienced with cerebellar ataxia. The concept of weakness is particularly challenging to differentiate from an overall sense of fatigue or asthenia, which is a common complaint in patients with psychiatric (i.e., depression) or systemic diseases such as cancer. It is not at all uncommon for patients to present to the neurologist with a feeling of poorly described generalized weakness, which can be attributed to various nonneurologic or a specific neurologic cause. The charge of the neurologist in this situation is to focus on the backbone of our specialty: Obtain a comprehensive history and perform a detailed neurologic examination to determine if the patient's complaints are caused by a problem within the nervous system.

MANAGEMENT STRATEGY

Asking the patient about the specific functional consequences of his or her weakness (i.e., trouble climbing stairs, buttoning buttons, opening jars) may help distinguish generalized weakness due to fatigue from weakness with an underlying localizable neurologic cause. Both the history and examination should help the clinician localize the problem to a specific region of the central or peripheral nervous system and give clues to possible etiologies. Symptoms concurrent and associated with the weakness are helpful in formulating a diagnostic impression. Complaints of muscle pain, cramping, or stiffness may invoke a myopathy, whereas numbness or tingling suggests a peripheral neuropathy or central nervous system lesion.

Specific "red flags" in the history or examination may provide important clues and prompt one to institute more acute treatment (Table 13.1). Once a comprehensive differential diagnosis is made, testing is done to confirm or exclude a specific disorder and may include but not be limited to serum studies, imaging, and electrodiagnostic testing. Many weak patients are encountered in the office setting; however, acute weakness may present in the hospital as well and often warrants a more prompt evaluation and rapid institution of therapy (Table 13.2).

NEUROANATOMY AND LOCALIZATION OF WEAKNESS

Weakness can be localized to various regions within the neuraxis, from the cortex to the muscle itself, and can be thought of as originating within either the central or peripheral nervous system.

TABLE 13.1 Red Flags in the Evaluation of Weakness

- Weakness that becomes severe over a few days or less

- Dyspnea

- Inability to raise the head against gravity

- Bulbar symptoms (e.g., difficulty chewing, talking, and swallowing)

- Loss of ambulation

- Changes in bowel or bladder function

The central, or pyramidal, motor system is composed of the motor cortex, corticospinal tract, and the various other tracts that modify and interact with it (i.e., the rubrospinal and tectospinal tracts). Weakness related to a central process affecting the corticospinal tract or pyramidal system is typically thought to produce a clinical syndrome of upper motor neuron weakness manifested by spastic tone, hyperreflexia, and pathologic reflexes (i.e., Babinski response).

Weakness due to pathology in the peripheral nervous system characteristically produces a pattern of peripheral lower motor neuron weakness consisting of hyporeflexia, muscle atrophy and wasting, reduced tone, and in some cases, spontaneous muscle activity such as fasciculations. The peripheral motor system is typically considered to include the motor neuron within the anterior horn of the spinal cord (or brain stem for cranial nerves), the peripheral nerve, neuromuscular junction, and muscle distal to it. Both the history and neurologic exam will help localize the problem to a particular part of the neuraxis and thus guide one's differential diagnosis and treatment plan.

TABLE 13.2 Key Steps in the Diagnosis and Management of Weakness

- Characterize the weakness in terms of tempo, variability, distribution, and associated symptoms.

- Perform a detailed neurologic examination to help localize the weakness within the neuraxis.

- Determine if there are predominantly upper or lower motor neuron findings.

- Look out for red flags (see Table 13.1).

- Order appropriate tests depending on most likely localization and differential diagnosis.

- Beware of diagnoses or signs prompting acute intervention (i.e., Guillain-Barré syndrome, mononeuritis multiplex, or myasthenia gravis).

CENTRAL (UPPER MOTOR NEURON) WEAKNESS

The corticospinal tract or pyramidal system can be damaged anywhere along its tract from the cortex through the corona radiata to the posterior limb of the internal capsule and down to the brain stem via the cerebral peduncles of the midbrain to the medulla and spinal cord. The highest possible lesion is in the primary motor cortex of the brain, where the largest of the pyramidal cells (Betz cells) lie in layer 5 of the cortex. Responsibility for planning and preparation of movement lies within the supplementary and premotor cortices, which regulate the motor action. The actions of the corticospinal tract are further modulated by the cerebellum as well as the basal ganglia and its tracts, which is also known as the *extrapyramidal system*. Pathology within this system can lead to either a paucity or exaggeration of movement, and the functional impairment experienced by the patient can be frequently described as weakness.

The neurologic examination and history can point toward a diagnosis localized within either the cerebellar or extrapyramidal system (such as Parkinson disease) and can include such findings as ataxia, bradykinesia (paucity and slowness of movement), tremor, and postural instability. In many cases, the key to localization is “pattern-matching”—actively looking for a pattern or constellation of findings that point to a specific cause of weakness (Table 13.3).

Cortical Lesions

A variety of diseases can affect the corticospinal tract from large strokes or hemorrhages to tumors and infections. Cortical lesions cause a characteristic pattern of weakness, where one limb is typically preferentially affected due to the distribution of motor representation in the homunculus of the primary motor cortex. For instance, infarcts affecting the middle cerebral artery territory will preferentially affect the arm and face more so than the leg. Often, there are other associated cortical signs such as aphasia or neglect, and patients may also present with headaches or seizures. Cortical weakness can also result from etiologies such as atypical migraine or postictal Todd paralysis; these diagnoses should be considered in the appropriate clinical setting.

Subcortical Lesions

Subcortical lesions, such as those in the internal capsule, will present with more complete unilateral weakness that may or may not spare the face. Demyelinating diseases such as multiple sclerosis (MS) are often implicated in subcortical weakness, although various other etiologies such as infarct or tumor are possible as well. Weakness attributed to a brain stem lesion can present with unilateral weakness of an arm and leg, and the face may be involved as well. There are usually associated symptoms attributable to cranial nerve dysfunction such as diplopia and facial numbness or hemiataxia due to involvement of cerebellar tracts within the brain stem.

TABLE 13.3 Common Etiologies of Weakness Depending on Time Course

Acute (Seconds to Minutes)	Subacute (Minutes to Hours)	Chronic (Months to Years)
• Infarction	• Demyelinating CNS disease (i.e., MS)	• Neoplasm
• Hemorrhage	• Toxic ingestion	• Neuromuscular junction disorder
• Periodic paralysis	• Plexopathy	• Axonal polyneuropathy
• Complicated migraine	• Acute demyelinating neuropathy (Guillain-Barré syndrome)	• Structural lesion (i.e., herniated disk)
• Trauma	• Metabolic disturbances	• Motor neuron disease
• Postictal Todd paralysis	• Neuromuscular junction disease	• Myopathy
• Conversion disorder	• Infection	
	• Mononeuritis multiplex	

CNS, central nervous system; MS, multiple sclerosis.

Spinal Cord Lesions

After decussating in the pyramids of the medulla, the lateral corticospinal tract is formed within the spinal cord where it travels ipsilateral to the innervated side of the body, lying anterior to the posterior columns and medial to the posterior spinocerebellar tract. Of note, about 10% of fibers in the corticospinal tract do not decussate and travel down into the cord to form the anterior or ventral corticospinal tract. Patients with weakness related to spinal cord pathology will typically present with both motor and sensory complaints, which can be bilateral or localized to one limb. Pain may be present or absent, and its description will vary depending on the cause of weakness. For instance, it may be described as stiffness related to myelopathy, Lhermitte sign (shock-like sensations with back flexion), or diffuse back pain. There may be disturbances in bowel or bladder function requiring prompt evaluation for cord compression.

PERIPHERAL (LOWER MOTOR NEURON) WEAKNESS

Upper motor neurons that form the corticospinal tracts synapse with both interneurons and lower motor neurons within the anterior horn of the spinal cord. The motor unit is defined as one alpha motor neuron within the anterior horn (or brain stem when related to cranial nerves) and all of the muscle fibers it innervates. Pathology within the anterior horn itself may present with a combination of both upper and lower motor neuron signs as seen in amyotrophic lateral sclerosis (ALS) and often includes concomitant bulbar weakness. Patients with weakness localized to the anterior horn will often present with asymmetric weakness, which begins in the bulbar region or within one limb and then progresses segmentally over time. Pain related to muscle cramps and stiffness is a common complaint.

The lower motor neuron exits the spinal cord to form the ventral motor portion of the spinal nerve root, after which it meets the dorsal sensory nerve root past the dorsal root

ganglion to form the peripheral nerve. At this location, the dorsal nerve root is commonly susceptible to compression by vertebral disk herniation, and patients may present with radiating pain or sensory loss corresponding to a particular *dermatome*. A *myotome* is defined as the group of muscles innervated by one single nerve root. Most muscles are supplied by two or more nerve roots and thus, a single root lesion rarely causes marked weakness due to this overlap within myotomes.

Brachial Plexus

Prior to separating into specific peripheral nerves, the motor and sensory fibers together form a network called a *plexus*, of which there are two (brachial and lumbosacral). The brachial plexus consists of nerve roots from C5 to T1, whereas the lumbosacral plexus consists of those from L1 to S3. The brachial plexus is composed of three trunks (upper, middle, lower) dividing into two divisions (anterior and posterior), which then form three cords (medial, lateral, posterior) ultimately subdividing and ending in terminal peripheral nerves (Fig. 13.1). Different peripheral nerves come off the brachial plexus at different levels; some, such as the phrenic nerve, exit immediately off the nerve roots, whereas others form the terminal branches of the plexus. These terminal nerves may be pure motor, pure sensory, or mixed.

Lumbosacral Plexus

The lumbosacral plexus is arranged somewhat differently, with various nerve roots coming together to form large nerves that then continue to differentiate into terminal branches or peripheral nerves. For instance, nerve roots from L4 to S3 come together to form the sciatic nerve, which later then subdivides into the fibular and tibial nerves. Weakness localized to the plexus typically presents with acute or subacute pain in one limb and is most commonly traumatic but can also result from other various etiologies such as infectious, structural, and inflammatory causes. Weakness is localized to one limb, often in the distribution of various nerves. There may be associated sensory complaints but the sensory examination is frequently normal.

FIGURE 13.1 Brachial plexus. (Adapted from Marshall R, Mayer S. *On Call Neurology*. 3rd ed. Philadelphia: Saunders; 2007.)

Peripheral Nerves

Terminal or peripheral nerves may be affected in isolation (mononeuropathy) or together in a uniform or multifocal pattern. Mononeuropathies are most commonly due to compression, and symptoms and exam findings are restricted to the distribution of one nerve distal to the injury. Polyneuropathies have a broad differential and can be subdivided into those caused by demyelination and those with predominant axonal involvement.

Demyelinating neuropathies typically also involve the nerve roots and can be referred to as *radiculoneuropathies*. They tend to have a motor greater than sensory predominance, present with more generalized or multifocal rather than length-dependent weakness, and areflexia is typical on examination. Cranial nerves may be affected as well.

Axonal polyneuropathies are usually length-dependent, affect sensory greater than motor function, and spare cranial nerves. The differential for such a polyneuropathy is vast and includes metabolic, infectious, and systemic causes among others. Diabetic neuropathy is by far the most common etiology of length-dependent axonal polyneuropathy.

At times, different peripheral nerves can be affected in an asymmetric and patchy fashion (Fig. 13.2). Such a syndrome of multiple mononeuropathies (also frequently referred to as *mononeuritis multiplex*) is often the result of ischemic injury to different peripheral nerves and present with acute and painful weakness and sensory loss. In these instances, it is crucial to rule out an underlying vasculitis, as management must be prompt to avoid further irreversible injury.

Neuromuscular Junction

Each peripheral nerve ultimately terminates at the motor endplate of the muscle it supplies, where it forms the neuromuscular

junction. At this point, calcium influx into the terminal portion of the neuron leads to binding of acetylcholine-containing vesicles to the neuronal membrane and release of Ach into the postsynaptic space. The Ach-release site is known as the *active zone* and is the location of both calcium influx via voltage-gated calcium channels and acetylcholine release. Binding of acetylcholine to its corresponding postsynaptic receptors at the motor endplate leads to opening of sodium channels and consequent depolarization of the muscle membrane and an endplate potential (EPP). The summation of several EPPs is ultimately what leads to a discrete muscle fiber potential and subsequent muscle contraction.

FIGURE 13.2 Patterns of sensory loss in patients with neuropathy. **A:** Polyneuropathy: diffuse stocking-glove pattern. **B:** Mononeuropathy: focal involvement corresponding to a single peripheral nerve. **C:** Mononeuritis multiplex: pattern of multiple, asymmetric regions of sensory loss corresponding to multiple peripheral nerves. (Adapted from Marshall R, Mayer S. *On Call Neurology*. 3rd ed. Philadelphia: Saunders; 2007.)

Weakness localized to the neuromuscular junction (see [Chapter 89](#)) often presents with proximal and bulbar weakness, which fluctuates with activity and time of day. Autoantibodies may be directed toward components of the presynaptic membrane (i.e., toward the voltage-gated calcium channel in Lambert-Eaton myasthenic syndrome) or the postsynaptic membrane (i.e., myasthenia gravis, where antibodies are formed against acetylcholine receptors). The muscle fiber action potential causes depolarization of the internal portion of the muscle fiber and leads to activation of calcium channels in the sarcoplasmic reticulum of the myocyte leading to calcium release. Calcium then binds to troponin C on the actin filaments of the myofibril, thereby unbinding tropomyosin from the filament, allowing the binding of myosin. The binding of adenosine triphosphate (ATP) to myosin then allows unbinding and release of actin, thereby leading to muscle relaxation.

Myopathy

Muscle weakness due to pathology within the muscle itself is frequently proximal, symmetric, and progressive. There can be associated facial weakness and weakness of eye movements (such as in mitochondrial myopathies). Myalgias are common, and the sensory examination should be normal. Etiologies are variable and can include inflammatory, congenital, and metabolic causes.

FOCUSED HISTORY DEMOGRAPHICS AND PAST MEDICAL HISTORY

Knowledge of the patient's age and prior medical history is crucial, as various etiologies are more or less likely depending on the age of the patient. A left hemiparesis presenting in a young woman is more likely to be attributable to an MS flare than a stroke, and the opposite is true in an 87-year-old man with hypertension.

One must be careful to obtain a complete list of medications the patient is taking, as certain exposures may provide diagnostic clues (i.e., statin myopathy). The social history is important to obtain, particularly with respect to toxic exposures and travel, as both toxic ingestion (i.e., alcohol, lead) and various infectious agents may lead to weakness of either central or peripheral origin. A detailed family history is required in cases of suspected hereditary disorders and a pedigree is often helpful. Thus, the age and complete medical, social, and family history of a patient will help formulate an appropriate differential diagnosis based on likelihood and help dictate management.

TEMPO OF WEAKNESS

One of the key questions one must ask is the time of onset and whether the weakness is acute, subacute, or chronically progressive (see [Table 13.3](#)). Focal weakness that begins abruptly (i.e., over seconds to minutes) is most concerning for a vascular event such as a hemorrhage or infarct and these patients must be emergently assessed and evaluated. Subacute onset of weakness has a broader differential and may be due to demyelinating disease such as MS, a mass lesion, or an acute demyelinating neuropathy, among others. Weakness that evolves chronically over months to years is suggestive of a neurodegenerative disease such as motor neuron disease, peripheral neuropathy, myopathy, or a slowly progressive structural lesion. *The tempo of the course of symptoms dictates the urgency with which the patient should be evaluated and managed.*

VARIABILITY OF WEAKNESS

Another crucial component of a detailed neurologic history includes asking about the nature of the weakness and whether it is transient, fluctuating, or permanent. Transient weakness that fluctuates with the time of day or with exertion may point toward a neuromuscular junction disorder, MS flare, or a channelopathy (i.e., periodic paralysis).

DISTRIBUTION OF WEAKNESS

The distribution and symmetry of weakness is equally important to characterize when formulating a plan for localization and likely etiology. Weakness affecting one arm and leg on the same side is referred to as *hemiparesis*. If the arm and leg are affected on opposite sides, this is known as *crossed hemiparesis*. If the weakness involves only one limb, this is called *monoparesis*, whereas weakness of both legs is known as *paraparesis*. The term *plegia* in the same context refers to complete paralysis.

Certain patterns of weakness give clues regarding localization. Predominantly upper motor neuron weakness of one limb, with or without facial involvement, suggests a cortical lesion in the central nervous system such as a stroke or MS. Given the distribution of the motor homunculus, incomplete upper motor neuron weakness in one limb suggests a lesion in the cortex, whereas complete hemiplegia involving the face is more likely to be localized to subcortical

structures or the brain stem. If certain muscles within one limb (corresponding to a particular myotome or peripheral nerve) are preferentially affected, this may indicate a problem in the peripheral nervous system such as a radiculopathy or mononeuropathy. Generalized weakness can involve all four limbs and be related to a process within the spinal cord (i.e., cervical myelopathy), peripheral nerve (i.e., polyneuropathy), neuromuscular junction, or muscle.

Further characterizing the pattern as being *distal* or *proximal* is also helpful. For instance, generalized weakness that is symmetric and distal is commonly related to a

polyneuropathy, whereas proximal weakness is more likely referable to a problem in the neuromuscular junction or muscle.

SENSORY SYMPTOMS

Asking about associated symptoms is crucial to determining not only proper localization but also in assisting with thinking of possible etiologies (Table 13.4). One must ask about associated sensory symptoms, as this could point toward a neuropathy, plexopathy, or spinal cord lesion. Sensory disturbances can have a positive quality (tingling, paresthesias, pain), or a negative quality (numbness or loss of sensation). A specific sensory level is indicative of pathology within the spinal cord and should be looked for in the appropriate setting.

Cognitive complaints or language symptoms will always be most suspicious of a cortical process, and weakness in this instance may involve the face and typically affect one limb more than another.

PAIN

Pain can be encountered in the setting of neuromuscular weakness but must be differentiated from the diffuse myalgias that can be related to an underlying systemic medical illness or psychiatric disease. Often, this distinction is difficult to make, as complaints can be nearly identical. Patients with neuropathy often present with burning pain, which is distal and symmetric, and those with radiculopathy or plexopathy may complain of radiating neck, arm, or shoulder pain. Hand pain is a common manifestation of carpal tunnel syndrome, which may eventually progress to hand weakness and clumsiness. Mononeuritis multiplex due to nerve infarcts in the setting of vasculitis can present with acute pain in a variable distribution. Plexopathy is often heralded by acute to subacute pain in the affected limb prior to weakness or sensory complaints. Weakness in the setting of a slowly progressive brain or spinal cord mass may present associated with headaches or back pain.

STIFFNESS AND CRAMPS

Muscle stiffness is commonly encountered in upper motor neuron lesions causing spasticity and can be seen in both weakness due to cortical, subcortical, and brain stem lesions as well as with myelopathy in spinal cord syndromes. *Cramps* (a localized muscle spasm or persistent contraction) are more of a lower motor neuron/muscle phenomenon and are encountered frequently in various peripheral syndromes. It is seen as a frequent manifestation of motor neuron disease, where patients may complain of frequent cramps and intermittent debilitating muscle spasms. Those with polyneuropathy may often also have cramping or stiffness that is more constant and less paroxysmal.

Various primary muscle diseases include cramps as a primary symptom, and often, the distinction must be made between cramps and more diffuse myalgias. Myopathies characterized by *myotonia* (prolonged muscle contraction after voluntary contraction or percussion) such as myotonic dystrophy and certain channelopathies commonly present with cramps as an initial symptom. Metabolic and certain mitochondrial myopathies often also may present with intermittent cramps. *Stiff person syndrome* (see Chapter 94) is an autoimmune disorder characterized by painful muscle spasms caused by diffuse or localized body stiffness usually in the absence of weakness.

VISUAL AND SPEECH DISTURBANCES

If visual complaints are present, it is necessary to characterize them well. A visual field cut or gaze preference may point to a cortical problem, whereas ptosis or diplopia could be a manifestation of a neuromuscular junction disorder or a myopathy.

Trouble with speech in the form of dysarthria must first be differentiated from a language disturbance. The presence of dysarthria may point toward bulbar weakness of various etiologies. A cortical, subcortical, or brain stem lesion may affect tongue fibers; motor neuron disease may present with or lead to bulbar involvement; and similarly, a neuromuscular junction or muscle disorder may involve trouble with speech and swallowing. A complaint of dysarthria should always prompt one to inquire about swallowing difficulties, as this may have important management and prognostic implications.

RESPIRATORY SYMPTOMS

Asking about respiratory involvement is also essential in patients presenting with weakness whether localized or general. Large cortical and brain stem lesions may rapidly lead to respiratory failure when acute. Disorders of the motor neuron, neuromuscular junction, and muscle may often be complicated by respiratory insufficiency, which may present as shortness of breath, early morning headaches, or daytime fatigue. Acute demyelinating inflammatory polyneuropathy at times may lead to diaphragmatic weakness and subsequent respiratory failure, and thus, respiratory function must be carefully monitored in these patients.

AUTONOMIC DISTURBANCES

Urinary complaints (most often incontinence or frequency) are most commonly seen with upper motor neuron lesions, such as those involving the paracentral frontal lobe or spinal cord. A complaint of dark-colored urine may indicate the presence of myoglobinuria indicative of muscle breakdown suggesting a primary muscle disease such as McArdle disease. One should ask about autonomic involvement as well (i.e., symptoms of orthostasis, dry mouth or eyes), as this may play an important role in certain neuropathies. Finally, symptoms suggesting cardiac involvement such as syncope, chest pain, and shortness of breath with activity may be worrisome for a concurrent cardiomyopathy as can be seen with certain myopathies (i.e., Duchenne or Becker muscular dystrophy).

FOCUSED EXAM

A focused and goal-directed neurologic exam is critical to the evaluation of a patient with weakness. Ideally, this should be done with the patient undressed and in a gown. Acquisition of both sitting and standing heart rate and blood pressure, when appropriate, is useful to assess for orthostatic changes suggestive of autonomic nervous system involvement.

MENTAL STATUS

Testing of mental status is important, particularly in cases of weakness due to cortical and subcortical processes (i.e., stroke, neoplasm), as this may further assist in localization. Weakness due to a peripheral nervous system disorder should preserve cognitive and language function.

TABLE 13.4 Symptoms Associated with Various Weakness Syndromes

	Cortex	Brain Stem	Spinal Cord	Motor Neuron	Nerve Root or Plexus	Peripheral Nerve	Neuromuscular Junction	Muscle
Sensory loss	May be in the same distribution of weakness	May be in the same distribution of weakness	Corresponds to level of weakness, usually with	<i>Absent</i>	Can be in a dermatomal or peripheral	May be in the distribution of one nerve or many nerves (i.e., distal	<i>Absent</i>	<i>Absent</i>

	(i.e., stroke, MS plaque)		sensory level		nerve distribution	stocking-glove distribution)		
Cognitive or language deficits	Present	<i>Absent</i>	<i>Absent</i>	<i>Absent</i> (advanced ALS can be associated with cognitive deficits)	<i>Absent</i>	<i>Absent</i>	<i>Absent</i>	<i>Absent</i>
Pain	Headache may be present.	Headache may be present.	Localized or diffuse back pain	<i>Absent</i>	Radicular pain or diffuse pain with plexopathy in the affected limb	Burning or paresthesias (i.e., poly neuropathy), acute pain (i.e., mononeuritis multiplex)	<i>Absent</i>	Myalgias, proximal greater than distal
Cramps or stiffness	Spasticity	Spasticity	Spasticity	Both cramps and stiffness are common.	<i>Absent</i>	Both cramps and stiffness with both polyneuropathy and certain mononeuropathies	<i>Absent</i>	Cramps common in <ul style="list-style-type: none"> • Myotonic dystrophy • Channelopathies • Metabolic myopathies • Mitochondrial myopathies • Stiff person syndrome
Visual changes	Involvement of frontal eye fields or hemianopsia	Diplopia or nystagmus	<i>Absent</i>	<i>Absent</i>	<i>Absent</i>	Ophthalmoparesis or diplopia can be seen in GBS or Miller-Fisher syndrome	Diplopia or ptosis occurs with myasthenia gravis.	Diplopia as can be seen in mitochondrial myopathies, among others
Speech or swallowing difficulties	Due to tongue/facial weakness	Due to tongue/facial weakness	<i>Absent</i>	Bulbar involvement in motor neuron disease	<i>Absent</i>	Can be seen in demyelinating neuropathies with cranial nerve involvement	Nasal speech, dysphagia in myasthenia gravis	Due to both pharyngeal and tongue weakness
Respiratory compromise	Occurs with large infarcts or hemorrhages	Occurs with infarcts or hemorrhages	Can be present with high cervical lesions	Bulbar involvement in motor neuron disease	Phrenic involvement in plexopathies	Can be seen in demyelinating neuropathies with bulbar and phrenic nerve involvement	Bulbar involvement in both pre- and postsynaptic neuromuscular junction disorders	Can be present in certain myopathies (i.e., amyloid, distal myopathy with early respiratory failure)
Cardiac symptoms	<i>Absent</i>	<i>Absent</i>	<i>Absent</i>	<i>Absent</i>	<i>Absent</i>	<i>Absent</i>	<i>Absent</i>	Cardiomyopathy can be associated with various myopathies (i.e., myotonic dystrophy, Duchenne or Becker myopathy).
Urinary disturbances	Incontinence with paracentral frontal lesions	<i>Absent</i>	Urinary incontinence with cord compression	<i>Absent</i>	<i>Absent</i>	<i>Absent</i>	<i>Absent</i>	Myoglobinuria with certain myopathies (i.e., McArdle disease)

MS, multiple sclerosis; ALS, amyotrophic lateral sclerosis; GBS, Guillain-Barré syndrome.

CRANIAL NERVES

In testing cranial nerves, particular attention should be paid to examination of the eyes starting with their appearance at rest. One should make note of the presence or absence of ptosis, skew, or other asymmetry at rest. Both central and peripheral processes may lead to pupillary involvement with or without ophthalmoparesis.

A careful assessment of extraocular movements is essential, as they can be abnormal in states affecting supranuclear, nuclear, and peripheral cranial nerve function (i.e., brain stem processes) as well as in diseases of the neuromuscular junction (i.e., myasthenia gravis) and muscle (i.e., mitochondrial myopathies).

Facial strength is examined both by assessment of asymmetry at rest (i.e., a flattened nasolabial fold), as well as by having the patient activate various muscles. Ask the patient to forcefully close his or her eyes and subsequently try to pry them open to assess strength of eye closure. Patients with facial weakness are typically unable to bury their eyelashes with forced eye closure, and eyes are easily pried open. To assess strength in the lower face, ask the patient to purse his or her lips together or whistle. Asymmetric facial weakness sparing the forehead implicates an upper motor neuron facial nerve lesion, whereas facial weakness involving the entire half of the face suggests a peripheral seventh cranial nerve lesion. Symmetric weakness of the facial muscles most typically implies a lesion of the neuromuscular junction or muscle but can rarely also be seen in certain demyelinating neuropathies and in motor neuron disease with bulbar involvement.

Tongue weakness can be evaluated by looking for deviation with tongue protrusion and by having the patient push the tongue against the inner cheek with the examiner's resistance. The tongue should also be carefully inspected for the presence of atrophy and fasciculations as can be seen with motor neuron disease. Pharyngeal weakness should also be assessed by having the patient make guttural sounds and checking for the presence of an intact gag reflex.

MOTOR EXAMINATION

Inspection

The motor examination should always begin with inspection and observation. It is in this part of the examination that one makes the distinction between weakness due to upper motor neuron dysfunction (most commonly related to a process localized to the corticospinal tract) versus lower motor neuron disease localized to the peripheral nervous system. One should look for muscle atrophy and wasting, both in large proximal muscles as well as in the smaller distal muscles such as the intrinsic hand muscles (i.e., first dorsal interosseus) in which subtle atrophy can often be more frequently appreciated.

Adventitious Movements

Abnormal movements such as *fasciculations*, *myokymia*, and *tremor* should be sought in various muscles. The presence of atrophy and fasciculations are indicative of lower motor neuron dysfunction as can be seen with motor neuron disease or chronic mono- or polyneuropathies. Myokymia can be seen in limb muscles but also in the face, where it typically is suggestive of a brain stem lesion such as an MS plaque. The back should also be inspected for both atrophy (i.e., scapular winging) as well as fasciculations. Assessment of tone is also helpful in distinguishing an upper motor neuron from lower motor neuron problem.

Tone

Increased tone in the arms can manifest as either rigidity (resistance that is consistent and present throughout the full range of motion) related to basal ganglia dysfunction or spasticity (resistance that is velocity dependent) related to corticospinal tract disease and upper motor neuron dysfunction. When testing tone in the arms, it is often helpful to have the patient open and close the opposite hand, which may accentuate mildly increased tone. Examining tone in the legs is often best done in the supine position where the knees are grasped and quickly pulled up. An unintentional lifting of the heels off the bed is indicative of increased tone in the legs, whereas the heels will naturally slide up the bed in the setting of normal tone.

The motor exam is also an appropriate time to check for the presence or absence of *myotonia* when clinically suspected. One approach is to test for grip myotonia by having the patient squeeze the examiner's hand for 10 seconds, then asking the patient to quickly let go. In the presence of myotonia, the patient will be unable to relax the grip. Similarly, one can check for percussion myotonia by tapping on a muscle—those with myotonia will demonstrate subsequent prolonged muscle contraction (typically, the abductor pollicis brevis is used, but the tongue can be checked as well).

Power

Assessment of strength can be done both by objectively examining different muscle groups and by observation. The first step in examination of strength is often testing of *pronator drift* where the arms are outstretched with the palms up and the patient's eyes closed. Those with subtle or overt hemiparesis due to an upper motor neuron lesion will exhibit pronation and a downward drift. Testing of *rapid finger taps* and *arm rolling* may also demonstrate subtle weakness in the setting of a mild hemiparesis. Particularly in cases of suspected peripheral causes of weakness, a detailed examination of various muscle groups is necessary. One must remember to test strength of neck flexion and extension, as this may have important implications particularly in motor neuron disease, neuromuscular junction disorders, and myopathies. Strength of neck flexion is often correlated with respiratory insufficiency due to respiratory muscle weakness and is important to check in all cases of motor neuron disease, neuromuscular junction disease, myopathy, and acute inflammatory demyelinating polyneuropathy.

Objective testing of muscle power is traditionally based on the Medical Research Council (MRC) scale from 0 to 5, with 5 representing full strength and 0 being complete absence of muscle movement. A score of 1 implies a discernible muscle twitch without movement of a full muscle. A score of 2 indicates movement in the same plane of gravity, whereas movement against gravity but not resistance is a score of 3. A score of 4 represents active movement against resistance and can be further assigned a "+" or a "-" when appropriate to make a more subtle distinction between variations in resistance.

When testing power, each muscle should be tested in a position in which it is at its maximal mechanical advantage—for instance, finger abduction should be tested with the wrist in the neutral position and not flexed. At times, weakness may be too subtle to detect with formal testing of power. It is helpful at times to ask the patient to perform certain functional movements, which may be impaired in cases of subtle weakness. For instance, someone with full strength on testing of power may have trouble standing up from a squatted position or hopping on one foot. A recognition and identification of a specific pattern of weakness is important, as

P.102

different diseases will manifest with different patterns of weakness. For instance, weakness in one limb following a specific myotome may point toward a root or plexus problem, whereas symmetric proximal weakness may suggest either a neuromuscular junction or muscle disorder. Knowledge of the innervation and action of various muscle groups is essential in localization of weakness due to a peripheral cause, as the pattern of muscle involvement may point one toward a particular localization and diagnosis (Table 13.5).

SENSORY EXAMINATION

Evaluation of sensory loss is often challenging, as it is the most subjective and thus least reliable portion of the neurologic exam. The best approach is to use the sensory exam to confirm what is clinically suspected. Look for particular patterns of sensory loss to complement the clinical picture, such as sensory loss in a dermatomal pattern consistent with a mononeuropathy or in a distal and symmetric pattern consistent with a polyneuropathy. Testing of different modalities is often helpful in discerning specific spinal cord syndromes (i.e., Brown-Séquard) and in distinguishing a large- from a small-fiber neuropathy.

REFLEXES

The absence of reflexes or hypoactive reflexes point toward a lower motor neuron lesion in the peripheral nervous system, whereas pathologically hyperactive reflexes, particularly when in the presence of a Babinski sign or Hoffmann sign, are indicative of an upper motor neuron lesion and corticospinal tract localization. Examination of reflexes may be an important diagnostic clue; for instance, complete loss of reflexes in the setting of subacute weakness should prompt one to quickly consider a diagnosis of acute inflammatory demyelinating neuropathy.

COORDINATION

Tests of coordination such as finger-to-nose testing are often impaired in the setting of weakness, and the distinction should be made accordingly to avoid confusing subtle weakness for cerebellar or sensory ataxia.

GAIT

Examination of gait is often critical, as the scissoring, spastic gait of myelopathy will look appreciably different from the waddling gait of myopathy with proximal leg weakness. When assessing gait, one can also notice subtle steppage related to a footdrop or circumduction in the setting of a hemiparesis. It is important to differentiate gait disturbance due to weakness from that related to basal ganglia dysfunction as seen with a shuffling, stooped parkinsonian gait or cerebellar disease where a wide-based ataxic gait is the predominant manifestation. More subtle gait testing involving heel, toe, and tandem gait is often sometimes necessary to further complement the rest of the examination and help elucidate the problem.

DIAGNOSIS AND INITIAL TREATMENT

Once one has formed a differential diagnosis based on likelihood of a particular diagnosis (Table 13.6), various tests can be ordered to further confirm or refute one's diagnostic impression. The urgency of certain tests will depend on the clinical context and circumstances. Patients seen in an emergency room or inpatient setting with acute complaints will often require a more prompt evaluation, and tests can be performed on a more urgent basis. Most patients in the office can be managed with tests ordered on an outpatient basis. However, at times, patients can be seen in the outpatient setting that need urgent evaluation, and it is crucial for the clinician to make this distinction following a detailed history and examination.

RECOGNITION OF EMERGENT SITUATIONS

A patient presenting to the office with subacute ascending weakness and areflexia should be promptly admitted to the hospital for evaluation and treatment of probable Guillain-Barré syndrome. Similarly, those with chronic weakness and known diagnoses may present with progressive symptoms requiring hospitalization and more urgent management. For instance, a myasthenic presenting with new-onset shortness of breath and dysphagia needs hospitalization for respiratory monitoring and treatment for likely crisis. It is important to identify patients in need of prompt evaluation where the most important tests to be ordered often include pulmonary function tests and a formal swallowing evaluation.

LABORATORY TESTING

Various tests are available in the evaluation of muscle weakness. Serum studies are important to exclude various metabolic, infectious, inflammatory, or autoimmune conditions. The extent of testing depends on the differential diagnosis. For instance, the workup for causes of axonal polyneuropathy is very broad and can include tests from vitamin levels to heavy metal testing. In cases of suspected neuromuscular junction disease, appropriate antibody testing is necessary, and a creatine kinase should be checked in patients with suspected myopathy.

Genetic tests are now available for those with a family history or other evidence to suggest a congenital or genetic etiology. Imaging is often first line for patients with central causes of weakness.

IMAGING STUDIES

For patients with predominantly upper motor neuron signs and cortical involvement, a computed tomography (CT) scan (see Chapter 20) or magnetic resonance imaging (MRI) (see Chapter 21) of the brain is indicated. Brain imaging is indicated for anyone with a history and exam that localizes to the cortex, subcortex, or brain stem.

In cases of suspected spinal cord pathology, an MRI of the spinal cord is indicated. The exam will guide which particular part of the cord to image, as it can be either cervical, thoracic, or lumbosacral. In some instances, all three may be necessary. Imaging can also be done of the brachial or lumbosacral plexus, and this is often instructive in cases of plexopathy where trauma, structural lesions, or neoplastic infiltration are suspected. A contrast MRI of the plexus can at times be abnormal in cases of idiopathic brachial neuritis. In patients who cannot tolerate MRI, a CT scan can be helpful to exclude structural and neoplastic processes. CT myelography is still performed at times in those who cannot undergo MRI and can provide more detailed imaging of the nerve roots than a CT scan alone.

LUMBAR PUNCTURE

A lumbar puncture (see Chapter 31) is important to consider in various cases of both central and peripheral weakness. For instance, a patient with a suspected inflammatory, autoimmune, infectious, or neoplastic etiology will typically warrant examination of the cerebrospinal fluid looking for cells, abnormal protein, and the presence of various other antibodies and cells which may be diagnostic. It is particularly useful in the diagnosis of Guillain-Barré syndrome where one typically sees a cytoalbuminologic dissociation with elevated protein in the absence of cells.

TABLE 13.5 Common Muscle Groups, Actions, and Innervation

Muscle	Peripheral Nerve	Nerve Root	Action
A. Muscles of the Back, Shoulder, and Neck			
Sternocleidomastoid	Spinal accessory	CN XI, C2, C3	Contralateral rotation of the head
Trapezius	Spinal accessory	CN XI, C3, C4	Shoulder elevation
Diaphragm	Phrenic	C3, C4, C5	Inspiration
Serratus anterior	Long thoracic	C5, C6, C7	Protraction and stabilization of scapula
Rhomboid	Dorsal scapular	C4, C5	Abduction and elevation of scapula
Levator scapulae	Dorsal scapular	C4, C5	Elevation of scapula
Supraspinatus	Suprascapular	C5, C6	Abduction of arm to 90 degrees

Infraspinatus	Suprascapular	C5, C6	Lateral arm rotation
Deltoid	Axillary	C5, C6	Abduction of arm past 30 degrees
Teres minor	Axillary	C4, C5	Medial arm rotation
Teres major	Subscapular	C5, C6, C7	Medial rotation and adduction of arm
Latissimus dorsi	Thoracodorsal	C6, C7, C8	Adduction of arm
B. Muscles of the Arm and Hand			
Biceps brachii	Musculocutaneous	C5, C6	Forearm flexion with arm supinated
Brachialis	Musculocutaneous	C5, C6	Forearm flexion with arm pronated
Triceps brachii	Radial	C6, C7, C8	Forearm extension
Brachioradialis	Radial	C6, C7	Forearm flexion with arm supinated to 90 degrees
Extensor carpi radialis	Radial	C6, C7	Hand extension
Supinator	Radial	C6, C7	Forearm supination
Extensor digitorum	Radial (posterior interosseus nerve [PIN])	C7, C8	Extension of hand and digits two to five
Extensor carpi ulnaris	Radial (PIN)	C7, C8	Hand extension toward ulna
Abductor pollicis longus	Radial (PIN)	C7, C8	Thumb abduction
Extensor pollicis longus and brevis	Radial (PIN)	C7, C8	Thumb extension
Extensor indicis	Radial (PIN)	C7, C8	Index finger extension
Flexor carpi ulnaris	Ulnar	C7, C8, T1	Ulnar hand flexion
Flexor digitorum profundus	Ulnar	C8, T1	Flexion of distal phalanx of digits four and five
Adductor pollicis	Ulnar	C8, T1	Thumb adduction
Abductor digiti minimi	Ulnar	C8, T1	Abduction of fifth digit
Interossei	Ulnar	C8, T1	Finger abduction or adduction
Lumbricals three and four	Ulnar	C8	Flexion of proximal phalanx and extension of distal phalanx of digits four and five
Flexor carpi radialis	Median	C6, C7	Radial hand flexion
Pronator teres	Median	C6, C7	Forearm pronation
B. Muscles of the Arm and Hand			
Flexor digitorum superficialis	Median	C7, C8, T1	Flexion of the middle phalanx of digits two to five
Abductor pollicis brevis	Median	C8, T1	Abduction of thumb at the metacarpal joint
Flexor pollicis brevis	Median	C8, T1	Flexion of thumb at the metacarpal joint
Opponens pollicis	Median	C8, T1	Thumb opposition
Lumbricals one and two	Median	C8, T1	Flexion of proximal phalanx and extension of distal phalanx of digits two and three
Flexor digitorum profundus	Median (anterior interosseous nerve [AIN])	C7, C8	Flexion of distal phalanx of digits two and three
Flexor pollicis longus	Median (AIN)	C7, C8	Flexion of distal phalanx of the thumb

Pronator quadratus	Median (AIN)	C8, T1	Forearm pronation
C. Muscles of the Hip, Leg, and Foot			
Iliopsoas	Femoral and nerve roots	L1, L2, L3	Hip flexion
Sartorius	Femoral	L2, L3	Hip flexion and lateral thigh rotation
Quadriceps femoris	Femoral	L2, L3, L4	Knee extension
Adductor longus, brevis, magnus	Obturator	L2, L3, L4	Thigh adduction
Gracilis	Obturator	L2, L3, L4	Thigh adduction
Obturator externus	Obturator	L3, L4	Thigh adduction and lateral rotation
Gluteus medius and minimus	Superior gluteal	L4, L5, S1	Thigh abduction and medial rotation
Tensor fasciae latae	Superior gluteal	L4, L5	Thigh abduction
Gluteus maximus	Inferior gluteal	L5, S1, S2	Hip extension
Biceps femoris (long head)	Sciatic	L5, S1, S2	Knee flexion
Biceps femoris (short head)	Sciatic (fibular)	L5, S1, S2	Knee flexion
Semitendinosus	Sciatic	L5, S1, S2	Knee flexion
Semimembranosus	Sciatic	L5, S1, S2	Knee flexion
Tibialis anterior	Fibular	L4, L5	Foot dorsiflexion
Extensor digitorum longus	Fibular	L5, S1	Extension of toes two to five
Extensor hallucis longus	Fibular	L5, S1	Great toe extension
Extensor digitorum brevis	Fibular	L5, S1	Toe extension
Fibularis longus and brevis	Fibular	L5, S1	Foot eversion
Tibialis posterior	Tibial	L5, S1	Foot inversion and plantarflexion
Flexor digitorum longus	Tibial	S2, S3	Flexion of toes two to four
Flexor hallucis longus	Tibial	S1, S2	Flexion of great toe
Gastrocnemius	Tibial	S1, S2	Foot plantarflexion
Soleus	Tibial	S1	Foot plantarflexion
Muscles of perineum	Pudendal	S2, S3, S4	Contraction of pelvic floor muscles

The nerve roots in boldface are the dominant roots involved in that particular muscle's innervation.

TABLE 13.6 Common Causes of Weakness

Cortical, Subcortical, or Brain Stem

- Tumor
- Demyelinating disease (e.g., transverse myelitis or NMO)
- Infection (e.g., zoster, HIV, HTLV-1)
- Vascular malformation
- Nutritional (e.g., B₁₂ deficiency)
- Spinal cord infarction
- Inflammatory (e.g., lupus, sarcoid)
- Toxic (e.g., nitrous oxide)

Motor Neuron/Anterior Horn

- Amyotrophic lateral sclerosis
- Primary lateral sclerosis
- Progressive muscular atrophy
- Monomelic amyotrophy
- Spinal muscular atrophy
- Poliomyelitis
- Kennedy disease

Nerve Root

- Structural
 - Herniated disk
 - Spondylosis

- Infection

- CMV polyradiculopathy

- Lyme

- Malignancy

- Tumor invasion

- Leptomeningeal metastasis

- Infarction

- Inflammatory

- Sarcoidosis

Plexus

- Trauma

- Structural

- Thoracic outlet syndrome

- Idiopathic brachial neuritis (Parsonage-Turner syndrome)

- Radiation plexopathy

- Tumor infiltration

- Diabetic amyotrophy

Peripheral Nerve

- Mononeuropathy

- Entrapment

- Carpal tunnel syndrome

- Ulnar nerve entrapment at the elbow

- Fibular nerve entrapment at the fibular head

- Mononeuritis multiplex

- Vasculitis

- Polyneuropathy

- Demyelinating

- Acquired

- AIDP (Guillain-Barré syndrome)

- CIDP

- Congenital

- CMT

- Axonal

- Associated with systemic disease (diabetes, monoclonal gammopathy, amyloid)
- Infectious (HIV, Lyme)
- Nutritious (vitamin deficiency such as B₁₂, B₆, B₁)
- Toxic (chemotherapy, alcohol, nitrous oxide, arsenic)
- Autoimmune (anti-MAG, anti-sulfatide)
- Hereditary (CMT2)

Neuromuscular Junction

- Myasthenia gravis
- Lambert-Eaton myasthenic syndrome
- Botulism
- Congenital myasthenia

Muscle

- Electrolyte imbalance
 - Hyper-/hypokalemia
 - Hypophosphatemia
 - Hypercalcemia
- Metabolic myopathies
 - Glycogen storage diseases
 - Disorders of lipid metabolism
- Muscular dystrophies
 - Dystrophinopathy (e.g., Duchenne/Becker)
 - Limb girdle muscular dystrophy
 - Myotonic dystrophy
 - Myotonic dystrophy
- Congenital myopathies
- Endocrine myopathies
 - Hyper- or hypothyroidism
 - Diabetes
- Mitochondrial myopathies

- MELAS

- Leigh disease

- Progressive external ophthalmoplegia

- Toxic myopathies

- Statin

- Steroid

- Inflammatory myopathies

- Dermatomyositis

- Polymyositis

- Inclusion body myositis

- Infectious myositis (e.g., trichinosis)

- Periodic paralysis

- Amyloid myopathy

- Critical illness myopathy

MS, multiple sclerosis; ADEM, acute disseminated encephalomyelitis; PML, progressive multifocal leukoencephalopathy; NMO, neuromyelitis optica; HTLV-1, human T-lymphotropic virus 1; CMV, cytomegalovirus; AIDP, acute inflammatory demyelinating polyneuropathy; CIDP, chronic inflammatory demyelinating polyneuropathy; CMT, Charcot-Marie-Tooth; MAG, myelin-associated glycoprotein; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes.

ELECTRODIAGNOSTIC TESTING

Electrodiagnostic testing (see [Chapter 26](#)) is important in the evaluation of weakness due to a peripheral cause. Classically, electrodiagnostic testing consisting of nerve conduction studies and electromyography (EMG) have been the standard practice in the diagnosis of several diseases of the peripheral nervous system. These studies are useful for several reasons. First, they can help to localize the problem to the peripheral nerve and exclude other etiologies such as a primary muscle disease, a plexopathy, or a mononeuropathy. Second, it is of crucial importance in helping to distinguish between generalized and focal forms of either purely axonal or demyelinating forms of neuropathy (such as acute or chronic inflammatory demyelinating neuropathy), which may show evidence of markedly slowed conduction velocity or conduction block. Nerve conduction studies and EMG also help assess the severity of the nerve injury partially in demonstrating whether there is resultant denervation of muscle.

Repetitive stimulation testing can be done to evaluate for neuromuscular junction diseases, which may show evidence of electrodecrement or increment. Single-fiber EMG can be done in certain instances, as it is the most sensitive (although not specific) test for neuromuscular junction disorders. In cases of motor neuron disease, EMG is necessary to demonstrate diffuse active and chronic denervation of several muscles in various distributions. EMG is often abnormal in primary muscle diseases and may show evidence of myopathic changes with or without muscle inflammation.

MUSCLE OR NERVE BIOPSY

In situations where testing is inconclusive, biopsies can be performed on most tissues in an attempt to make a definitive diagnosis (see [Chapter 32](#)). This may include biopsy of brain tissue, the meninges, muscle, or nerve. Given the invasive nature of biopsy, this is typically not performed unless there is a clear need and the benefits of the procedure outweigh the risks.

14

Gait Disorders

Ashwini K. Rao

INTRODUCTION

The evolution of locomotion has been very important for humans, as it enabled us to travel greater distances and interact with novel and complex environments. Bipedal locomotion also facilitated the evolution of complex manipulation skills. The capacity for independent gait is crucial for function: For instance, the loss of independent ambulation is a predictor of the need for long-term care in a number of age-related neurologic disorders. In addition to independent gait, achieving a requisite speed is also important for independent mobility in the community. For example, in people who have suffered a stroke, speed of 0.85 m/s is predictive of the ability to independently ambulate in the community.

Gait impairments are very common sequelae of aging and neurologic disorders. At the age of 60 years, about 15% people have gait impairments. Among people older than the age of 85 years, approximately 80% report gait impairments. Even among middle-aged individuals, approximately 40% report mild difficulties with mobility functions. Gait impairments can have devastating consequences, such as falls and injury. Approximately one-third of community-dwelling individuals older than the age of 65 years fall and fall-related injuries increase with age. An unfortunate consequence of gait impairments is that individuals often reduce their mobility in order to prevent falls and related incidents. However, reduced mobility further increases risk for falls by reducing muscle strength and worsening balance.

The purpose of this chapter is to briefly describe the gait cycle, the neural pathways underlying gait, the most commonly seen disorders of gait, and methods for clinical assessment of gait. Finally, we present the risk factors and assessment of falls in the elderly.

FIGURE 14.1 The gait cycle. The position of the right leg (*shaded red*) shows major events within the gait cycle during stance and swing phases.

INTRODUCTION TO THE GAIT CYCLE

The gait cycle consists of repetitive sequential movements of the limbs that help propel the body forward along a predetermined line of progression. The gait cycle is defined by foot contact with the ground and extends from the

heel strike of one lower limb to the subsequent heel strike of the same limb (Fig. 14.1). We define two phases within each gait cycle: a stance phase, which consists of approximately 60% of the gait cycle and a swing phase, which consists of approximately 40% of the gait cycle. Stance phase begins with heel strike and ends with toe off and consists of three events—foot flat, midstance, and heel off. The function of the stance phase is to accept the weight of the body on to the supporting (stance) limb. At the beginning of stance (from heel strike to foot flat on the right side) and at the end of stance (from heel off to toe off on the right), both feet are on the ground simultaneously. The period of double support comprises approximately 20% of the gait cycle. During midstance, body weight is supported by one limb (single limb support). During a typical gait cycle, the lower limbs move in a symmetric alternating movement with a phase lag of 0.5 (indicating that when one limb initiates swing, the opposite limb is in the middle of stance phase).

The swing phase of a limb begins with toe off and ends with heel strike. The events within the swing phase (foot clearance and midswing) serve to allow the foot to clear the floor as it propels the body forward in preparation for the subsequent step. The events within the gait cycle described earlier pertain to walking at a comfortable preferred speed. As speed of gait increases, the percentage of time spent in double support decreases. During running, there is no double support phase. Gait can be described quantitatively

P.108

with respect to its spatial and temporal features. Gait measures that can be assessed in the clinical setting are described in Table 14.1 and Figure 14.2.

TABLE 14.1 Definition of Clinical Gait Measures

Gait Variable	Definition
Speed	Distance covered in unit time (e.g., meters per second)
Cadence	Step frequency—number of steps in a given time (steps per minute)
Step length	Distance (measured in meters along the line of progression) between successive heel strikes of the lower limbs
Stride length	Distance (measured in meters along the line of progression) between successive heel strikes of the same limb
Step width	Distance (measured in meters perpendicular to the line of progression) between successive heel strikes of the lower limbs
Step height	Vertical clearance of the foot from the floor during swing
Step symmetry	Ratio of step length on the right and left sides
Step continuity	Ratio of step time on the right and left sides

Foot angle	Angle formed by the long axis of the foot with the line of progression
Walking path	Direction of the line of progression

NEURAL CONTROL OF GAIT

Gait is a complex task that requires the coordinated activity of several brain circuits. Even walking in an uncluttered environment at a preferred speed (considered an easy task) elicits activity in higher cortical regions. The following description briefly discusses the role of different circuits in controlling gait. Readers interested in additional details are referred to excellent recent reviews in the suggested readings list. In order to successfully initiate and control gait, the nervous system needs to perform the following tasks:

- Maintain balance against the force of gravity under static (e.g., during stance) and dynamic conditions (e.g., during walking). Maintenance of balance under dynamic conditions includes predictive and reactive control of destabilizing forces that are either generated internally (e.g., destabilizing forces generated by movement of the arms) or externally (e.g., destabilizing forces generated by bumping into another person).
- Coordinate movements of the lower limbs to propel the body forward.
- Help navigate complex environments, which may include stationary obstacles (e.g., furniture) and moving obstacles (e.g., people walking).
- Perform concurrent tasks with walking, such as talking, listening, or manipulating objects (e.g., mobile phone).

FIGURE 14.2 Spatial characteristics of gait. Spatial gait variables defined by foot placement along the line of progression.

Most of the experimental work in understanding the neural control of gait has come from experiments with quadruped and biped animals. These experiments suggest that distinct neural circuits perform specific functions. Cortical circuits (including premotor and motor areas, parietal and occipital areas) are involved with *activation* and *guidance*. Reciprocal circuits between the cortex-basal ganglia and cortex-cerebellum are involved with *regulation* of gait (including postural tone, balance, and coordination of limb movement). Finally, brain stem and spinal cord circuits are involved with the *execution* of gait (including gait initiation, step frequency, reciprocal movements of the lower limbs). A simplified diagram of the neural structures involved in control of gait is presented in [Figure 14.3](#) and functions of brain structures are summarized in [Table 14.2](#).

ACTIVATION AND VISUAL GUIDANCE OF GAIT

Gait can be activated either by a volitional process under the control of cerebral cortical circuits or by emotional cues (fight or flight reaction) under the control of limbic circuits. Volitional guidance of gait requires precise visual information about the environment, which is processed in the visual areas of the occipital cortex. The posterior parietal cortex (PPC) receives information from the visual cortex and project to the motor areas in the frontal cortex. An important function of the PPC is to construct maps of space, which are very important for visual guidance of locomotion. The premotor areas, in particular the supplementary motor area (SMA), are important for postural control during gait. The motor cortex projects to interneurons and motor neurons in the spinal cord and is important in the control of limb movements during gait.

REGULATION OF GAIT

The basal ganglia and cerebellum have a major influence on motor output even though they do not directly project to the spinal cord. The basal ganglia input nuclei, in particular the putamen, receive inputs from the premotor and motor cortex. The output nuclei of the basal ganglia (*globus pallidus internal segment and substantia nigra pars reticulata*) project back to the premotor and motor cortex via the thalamus. These projections are thought to be important for regulating movement amplitude and speed. In addition, the basal ganglia send inhibitory projections to the midbrain locomotor region (MLR) and the pedunculopontine nucleus (PPN). The projection from the basal ganglia to the MLR is responsible for

P.109

regulating the rhythmic aspects of gait. When there is damage to these projections, as seen in Parkinson disease and Huntington disease, rhythmic control of gait is impaired. The projection from the basal ganglia to the PPN is responsible for regulating muscle tone. Damage to these projections lead to disorders of postural muscle tone, as seen in Parkinson disease.

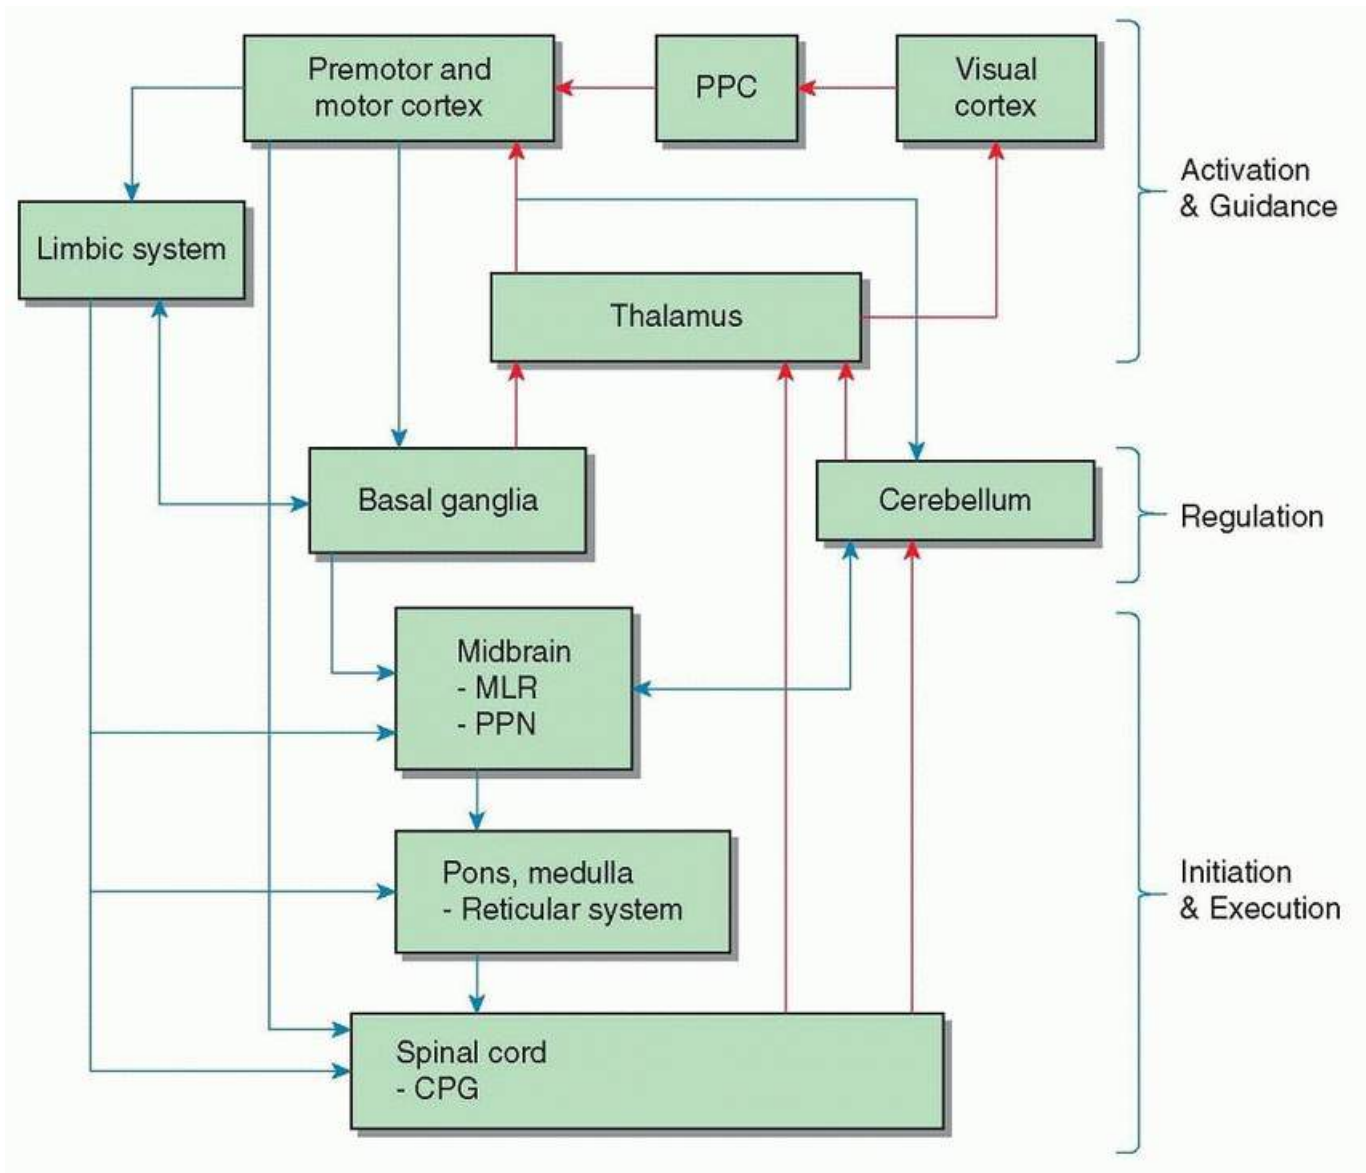

FIGURE 14.3 Neural control of gait. Schematic illustration of neural structures involved in the control of gait. Efferent connections are shown in *blue arrows* and afferent connections in *red arrows*. PPC, posterior parietal cortex; MLR, midbrain locomotor region; PPN, pedunculopontine nucleus; CPG, central pattern generator.

The cerebellum receives a tremendous amount of afferent information from the limbs and vestibular apparatus. In addition, projections from the cerebral cortex to the cerebellum provide information regarding the upcoming movement. The output of the cerebellum is directed to the motor areas of the cerebral cortex, midbrain (MLR and PPN), and brain stem (vestibular and reticular nuclei). A major function of the cerebellum is to evaluate disparities between intended movement and actual movement (based on feedback). The cerebellum is important for regulating balance and limb coordination during gait and for providing adaptability to novel conditions based on trial and error learning.

TABLE 14.2 Neural Control of Gait

Region	Area	Function
Cortex	Motor areas	Volitional activation Visual guidance

	Limbic system	Emotional activation
Subcortical	Basal ganglia	Inhibition of postural tone Regulate rhythmic aspects of gait
	Cerebellum	Balance Limb coordination Adaptation
Brain stem	MLR	Initiation of locomotor pattern
	PPN	Postural muscle tone
Spinal cord	Interneurons	Control locomotor pattern

MLR, midbrain locomotor region; PPN, pedunculopontine nucleus.

EXECUTION OF GAIT

Two areas in the brain stem are important for initiating and executing locomotion—the MLR and the PPN. The MLR receives inputs from the cerebral cortex, limbic system, basal ganglia, and cerebellum. A primary function of the MLR is activation of spinal cord circuitry to initiate gait. Inputs from the motor areas and the limbic system to MLR provide the neural substrate for activation of gait based on volitional (motor areas) and emotional (limbic system) cues. The PPN also receives inputs from the motor areas of the cerebral cortex, limbic system, basal ganglia, and cerebellum. The PPN inhibits spinal interneurons and motor neurons. A major function of the PPN is to modulate muscle tone during stance and gait. The spinal cord circuitry includes networks of interneurons (central pattern generators) and motor neurons that innervate skeletal muscles. There are two sets of interneurons, termed *half centers*, that project to flexor and extensor motor neurons. The half centers mutually inhibit each other and are responsible for producing the basic locomotor pattern. Although the half centers do not require sensory input to generate the basic locomotor pattern, their activity can be modulated by sensory input from the limbs. For example, signals from proprioceptors of the hip flexors may be used to signal the end of stance phase. In addition, skin afferents from the limbs are important for adjusting stepping movements in the presence of obstacles. Thus, the function of the spinal cord is to execute the rhythmic movement pattern of gait.

P.110

DISORDERS OF GAIT

In neurologic disorders, gait performance is classified as disordered based on comparison with healthy subjects, for whom normative values through the course of aging are available. However, given the large variability of what is considered “normal” gait, caution must be used in order to describe gait patterns as impaired. [Table 14.3](#) highlights gait impairments that are clinically evident in neurologic disorders. Several classifications have been proposed for gait disorders including anatomic, hierarchical (e.g., low, mid, and high level), etiologic (e.g., degenerative) or phenomenologic (e.g., atalgic gait). Anatomic classification describes gait disorders based on brain pathology (e.g., cerebellar gait). Hierarchical classification differentiates gait disorders into three categories based on the level of pathology (e.g., low level, midlevel, and high level). Gait disorders due to peripheral sensory (e.g., sensory ataxic) or motor disorders (e.g., spinal muscular atrophy) are classified as low-level disorders. Disorders that occur as a result of pathology in the motor system, including motor cortical areas, basal ganglia, and cerebellum, are classified as midlevel disorders. Finally, gait disorders that result from the

interaction of cognitive (frontal cortex) and motor systems (e.g., Alzheimer disease) are classified as high-level disorders. Finally, classification of gait disorders by phenomenology takes into account etiology and clinical features. In this chapter, gait disorders are classified by hierarchy and pathophysiology, which more closely reflects clinical practice. The table also separates phenomena that may be observed throughout gait observation (continuous) from those that are unpredictable (episodic). According to this classification, continuous phenomena reflect the underlying pathology and compensatory mechanisms, whereas episodic phenomena are those that the patient cannot adapt to because of their unpredictability.

FALLS IN THE ELDERLY

Falls are defined as “unexpected events in which a person comes to rest on the floor, ground, or supporting surface.” Falls are considered an inevitable consequence of aging and may result in serious adverse events in older adults. Approximately one-third of community-dwelling people older than the age of 65 years fall each year. The number of falls is much higher for older people living in nursing homes: approximately 1.5 falls per bed per year. The high incidence of falls coupled with the susceptibility to injury (because of comorbidities and age-related physiologic changes) leads to adverse events in the elderly. Falls may result in injuries such as abrasions, bruising, lacerations, and sprains. It is important to note that falls resulting in minor injuries may be underreported by patients. A careful ascertainment of history of falls is very important in clinical practice. About 10% of falls result in fractures, the type of fracture depending on the nature of the fall. Forward or backward falls on outstretched hands result in wrist fractures, falls to the side result in hip fractures, and falls resulting in impact to the head may result in head injury and loss of consciousness. Backward falls on the buttocks result in lower rates of fractures, although fractures of the vertebrae can occur.

Falls account for two-thirds of accidental deaths. The other negative consequences of falls include increased fear of falls and reduced mobility. This results in a negative spiral: Reduced mobility leads to reduction in muscle strength, flexibility and postural stability, and gait impairments, all of which, in turn, increase the risk for additional falls. Falls have a significant negative impact on the quality of life of elders.

Risk factors for falls can be classified as intrinsic or extrinsic. Intrinsic factors include age, muscle strength, gait and balance impairments, and neurologic or cognitive disorder. Extrinsic factors include medications, environmental hazards, and type of activity (based on hazard). The greatest risk factors for falls are previous history of falls, muscle weakness, gait and balance impairments, use of walking aids, vertigo, Parkinson disease, and medication use. It is important to note that a number of these factors, such as weakness, gait and balance impairments, use of walking aids, and medications are modifiable factors. Often, patients report near falls, defined as a “loss of balance that would have resulted in a fall if sufficient recovery mechanisms (movement of the trunk or arms, change in stride length or velocity) were not activated.” Near falls often precede falls and are more frequent than falls. Clinical assessment of falls should include information on near fall events. More information on fall assessment appears in the following section. Physical exercise (under the supervision of a physical or occupational therapist) is effective in reducing the frequency of falls and preventing future falls. In addition, home hazard assessment and reduction (under the supervision of occupational therapists) reduces the frequency of fallers and the number of falls. Clinicians should consult physical and occupational therapists, as needed.

CLINICAL ASSESSMENT OF STANCE, GAIT, AND FALLS

Assessment should include a detailed medical history and clinical exam, which consists of two parts: clinical observation and standardized assessment. A summary of the clinical assessment procedures is provided in [Table 14.4](#).

HISTORY

It is important to document the history of acute and chronic medical problems, history of near falls and falls, history of problems with balance and gait, and level of physical activity. Ask the patient about the most recent fall and ascertain the circumstances around the fall, including what the patient was doing, what caused the fall, where the fall occurred, environmental hazards that may have caused the fall, and the consequence of the fall.

MEDICATIONS

Note the list of prescribed medications and if any medications and/or dosages have been recently modified.

FOCUSED EXAMINATION

Physical examination should include an assessment of musculoskeletal function and footwear. Neurologic examination should include tests of cognitive function (using an assessment such as the Montreal Cognitive Assessment), muscle strength, reflexes, sensation, coordination, and presence of involuntary movements.

BALANCE AND GAIT ASSESSMENT

The examination begins with observation of a patient in a quiet stance. Clinicians should observe the patient from the front, back, and side. Determine if head is flexed, translated forward or backward, or tilted to one side. It is important to note if the shoulders are level or positioned asymmetrically. Examine if shoulders are hunched (rotated) forward. Note the position of the trunk to determine if it is kyphotic (rounded) as seen in disorders of aging or lordotic (hyperextended). Examine if trunk is tilted to one side, as this may be an indication of pain, diminished sensory feedback, or impaired vestibular system.

P.111

TABLE 14.3 Disorders of Gait

Disorder	Continuous Phenomena (Speed, Support Base, Arm Swing, Symmetry, Path)	Episodic Phenomena (Freezing of Gait, Gait Initiation, Falls)
High-Level Gait Disorders		
Alzheimer disease Gait disorder occurs late in the disease.	Slow gait speed Short step length Lower cadence Increased percentage of time in double support Increased variability, particularly when performing cognitive dual task	Increased risk for falls
Mild cognitive impairment (MCI)	Slow gait speed Short step or stride length Increased percentage of time in double support Gait variability is higher in amnesic MCI but not in nonamnesic MCI Poor limb coordination (foot tapping) compared	Increased risk for falls and fear of falls

with controls

Vascular dementia Gait disorder occurs early in the disease.	Slow gait speed Short step length Wide support base Rigidity	Freezing of gait Imbalance and falls seen
Normal pressure hydrocephalus Gait disorder seen early in the disease in conjunction with cognitive impairment and urinary incontinence.	Slow gait speed Short step length Wide support base and outward rotation of foot (may be compensation for poor balance) Asymmetric steps Low step height (shuffling steps)	Increased risk for falls
Dementia with Lewy bodies Gait impairments seen in conjunction with visual hallucinations.	Slow gait speed Reduced arm swing Flexed trunk posture Rigidity	Increased risk for falls
Frontotemporal dementia Gait impairments seen in the presence of behavioral disturbances (impulsivity, disinhibition).	Slow gait speed Involuntary trunk movements Postural instability	Increased risk for falls
Psychogenic gait disorder Gait impairments seen in the presence of psychiatric disorders such as anxiety, depression, or personality disorder.	Gait impairments are not consistent from one session to the next, may have sudden onset, very severe impairments at onset, and spontaneous remissions. Astasia-abasia Knee buckling during stance Wide support base and short step length (waddling) Excessive retropulsion	Tremor and dystonia seen although may not be observed when the patient is distracted
Hemiparesis	Slow gait speed Asymmetric stepping During swing Impaired lower limb moves in circumduction; hip hiking seen (Trendelenburg sign) Ankle may be maintained in plantar flexion and inversion leading to loss of heel strike at the beginning of stance. During stance, knee joint may hyperextend.	Increased risk for falls

	<p>Reduced arm swing on impaired side and reduced trunk rotation</p> <p>During dual-task gait, impairments worsen.</p>	
<p>Paraparesis</p>	<p>Slow gait speed</p> <p>Low cadence</p> <p>Low step height</p> <p>Circumduction may be seen.</p> <p>Decreased support base (scissoring gait) seen in patients with spasticity</p>	<p>Increased risk for falls due to weakness and imbalance</p>
<p>Parkinson disease</p> <p>Gait impairments seen in the presence of tremor, rigidity, and postural instability.</p>	<p>Slow gait speed</p> <p>Very short step length</p> <p>Poor foot clearance during swing (which leads to shuffling gait)</p> <p>Increased temporal variability</p> <p>Postural instability and impaired balance seen (missteps during tandem gait)</p> <p>During dual-task gait, Parkinson disease patients pay greater attention to secondary cognitive task as opposed to gait leading to greater gait impairments (posture second strategy).</p>	<p>Freezing of gait</p> <p>Difficulty initiating gait</p> <p>Increased fear of falls and increased risk for falls as disease progresses</p>
<p>Multiple system atrophy</p> <p>Gait impairments seen in the presence of autonomic dysfunction and urinary incontinence.</p>	<p>May present like Parkinson disease (slow speed, short step length)</p> <p>May present like cerebellar ataxia (gait ataxia—increased support base, path deviation, postural instability, impaired balance—missteps during tandem gait)</p>	<p>Increased risk for falls as disease progresses</p>
<p>Progressive supranuclear palsy</p>	<p>Postural instability</p> <p>Wide support base</p> <p>Rigid support base</p> <p>Slow gait speed</p> <p>Difficulty turning (turn en bloc)</p>	<p>High risk for falls, increased fear of falls</p>
<p>Huntington disease</p>	<p>Slow gait speed</p> <p>Decreased step/stride length</p> <p>Decreased cadence</p> <p>Increased time in double support</p> <p>Asymmetric step length</p> <p>Inconsistent step time</p> <p>Increased temporal variability</p> <p>Gait impairments worsen during secondary dual task</p> <p>Chorea of limbs or trunk may increase instability.</p>	<p>Increased fear of falls and greater number of falls as disease progresses</p>

Essential tremor	<p>Slow gait speed Decreased cadence Increased time in double support Asymmetric step length Wide support base Increased temporal variability Prominent balance impairment (missteps during tandem gait)</p>	<p>Increased fear of falls and greater number of falls</p>
-------------------------	--	--

Cerebellar ataxia	<p>Inconsistent step time Asymmetric step length Short step length and low step height Wide support base Increased temporal variability Increased postural sway Greater missteps during tandem gait</p>	<p>High risk for falls, increased fear of falls</p>
--------------------------	---	---

Low-Level Gait Disorders

1. Peripheral sensory disorders (peripheral neuropathy, posterior *column* disorder, vestibular and visual deficit)

Sensory ataxic gait	<p>Wide support base Postural instability increased when standing with eyes closed Increased step height (steppage gait) Short step length Foot slap evident at the beginning of stance phase Patients tend to look at their feet while walking.</p>	<p>Increased risk for falls when not using vision</p>
----------------------------	---	---

2. Peripheral *motor* disorders

Antalgic gait	<p>Decreased weight bearing on painful limb leading to shorter stance phase Short stride length Reduced range of motion in affected joint(s) Trendelenburg sign may be seen due to pain at the hip joint.</p>	
----------------------	--	--

Spinal muscular atrophy	<p>Slow gait speed Decreased step/stride length Decreased cadence Wide support base Trendelenburg sign Impairments (particularly speed and cadence) worsen with fatigue during continuous walking.</p>	<p>Increased risk for falls</p>
--------------------------------	---	---------------------------------

Duchenne muscular dystrophy	<p>Lordotic posture and anterior pelvic tilt</p> <p>Waddling gait (short step length, wide support base)</p> <p>Knee hyperextension during stance</p> <p>Ankle plantar flexion during swing</p> <p>Gait pattern does not change with continuous walking.</p>	Increased risk for falls
------------------------------------	--	--------------------------

TABLE 14.4 Clinical Assessment Clinical Assessment

History	<p>Falls and near falls</p> <p>Level of physical activity</p> <p>Complaints of gait and balance</p>
Medications	<p>Prescribed medications</p> <p>Change in medication or dosage</p>
Most recent fall incident	<ol style="list-style-type: none"> 1. What was the patient doing? (Standing, walking, turning, bending, reaching for objects, transfers, climbing on step-stool or ladder, recreational activity) 2. What caused the fall? (Dizziness, loss of balance, weakness, dual-task performance, slip/trip, fatigue, bumped into object) 3. Where did the fall occur? (Indoor level surface, indoor uneven surface, outdoor level surface, outdoor uneven surface) 4. Did environmental hazard cause fall? (Icy or wet surface, clutter, rugs/carpet, darkness, moving objects) 5. What was the result of the fall? (Minor injury, major injury)
Physical examination	<p>Cognitive function (e.g., Montreal Cognitive Assessment [MoCA])</p> <p>Musculoskeletal examination (Range of motion, joint pain, swelling)</p> <p>Footwear (Sandals, flip-flops, sneakers)</p>
Neurologic examination	<p>Muscle strength</p> <p>Reflexes</p> <p>Sensation</p> <p>Presence of involuntary movements</p> <p>Coordination</p>

Balance and gait assessment

Clinical observation and standardized assessments. Please see [Table 14.5](#).

Environmental assessment

Presence of safety grab bars
Clutter and presence of area rugs or carpets
Adequacy of lighting
Height of chairs
Surfaces (uneven, incline, stairs)
Use of walking aids (cane, walker)

Upper Extremities

Healthy people tend to maintain their arms next to the trunk with slight internal rotation at the shoulder and extension at the elbows. Observe if the arm is maintained in a flexed and internally rotated posture (as is often the case in people with stroke) and if involuntary movements are present (such as writhing choreic movements in Huntington disease or resting hand tremor seen in Parkinson disease). Also note if the hand is maintained in a fixed posture, as this may be a sign of dystonia.

Lower Extremities

Healthy people stand with the pelvis in a neutral position and lower limbs extended with the feet pointing straight ahead. Note if the hip and knee joints are maintained in flexion, as is sometimes seen in people with muscle tightness or weakness.

Ensure that there is adequate space (length of 7 to 10 m) to conduct a comprehensive gait assessment. Observe the patient from the front, back, and sides. Note the position of the head and trunk during gait, presence or absence of arm swing, and instability during walking and turning.

- *Standard walk*: Ask the patient to walk at their comfortable pace. Observe position of the head and trunk, walking path, and length and symmetry of steps. Note presence of instability during gait.
- *Turns*: Ask the patient to turn and observe the number of steps taken to turn. Note presence of instability during turns.

P.115

- *Narrow doorway*: Ask the patient to walk through a narrow doorway. This test is provocative for freezing of gait. Note presence of freezing.
- *Tandem walk*: Ask the patient to walk heel to toe for 10 steps. Note whether the patient can perform the task without support and the number of steps taken away from a straight line.
- *Dual-task walk*: Ask the patient to walk at his or her comfortable speed while performing a secondary motor or cognitive task. Typical secondary motor tasks include carrying a cup of water or carrying a tray with a cup on it. Several secondary cognitive tasks have been employed and include the following:
 - *Count backwards*: Give the patient a number and ask him or her to count backwards by 3 (serial 3) or by 7 (serial 7). Note that performance on the serial 7 task is dependent on level of education and may be too difficult for several patients.
 - *Verbal fluency*: Ask the patient to generate words that begin with a certain letter (such as “d”) or words that belong to a category (e.g., animals).

- Walking while talking: Ask the patient a question (such as “What did you have for breakfast today?”)

TABLE 14.5 Standardized Assessments of Mobility, Balance, and Fall Risk

Assessment	Details	Clinical Indication
Timed up and go	Time taken to get up from a seated position, walk 3 m, turn around, walk back, and take a seat	Increased fall risk in the following: a. Community-dwelling elderly: >13.5 s b. Parkinson disease: >11.5 s c. Stroke: >14 s
Tinetti performance-oriented mobility assessment	Balance scale consists of nine items that assess balance in sitting, standing, transitions, and turning.	Total score is 28. Score >25 indicates low fall risk, score between 19 and 24 indicates medium fall risk, and scores <19 indicate high fall risk.
Berg Balance Scale	Measures performance on 14 functional tests of sitting and standing balance, transfers, turning, etc.	Total score is 56. Scores <45 indicative of increased fall risk.
Dynamic Gait Index	Measures ability to walk a distance of 6.1 m (20 ft) under external demands (such as head turns)	Total score is 24. Score <19 indicative of fall risk.
Walking while talking	Examines whether patients are able to walk while reciting the alphabet (simple) or every alternate alphabet (complex)	Community-dwelling elderly: >20 s for simple task; >30 s for complex task indicative of falls.
10-m walk	Patient is asked to walk a distance of 10 m at either a self-selected comfortable speed or fast speed. Time taken to cover middle 6-m distance is measured to eliminate the effect of acceleration and deceleration.	Household ambulator = speed <0.4 m/s; Limited community ambulator = speed between 0.4 and 0.8 m/s; Community ambulator = speed >0.8 m/s
Tandem walk	Measures ability to walk 10 steps tandem (heel to toe) walk	<2 completed steps indicative of fall risk
6-min walk test	Measures the distance walked in a period of 6 min along a 30-m long walkway	Distance <400 m indicates lack of aerobic capacity.

In addition to clinical observation, several standardized assessments of mobility, balance, and fall risk are available, summarized in [Table 14.5](#).

Acute Stroke: The First Hour

Barry M. Czeisler

Stephan A. Mayer

INTRODUCTION

Sudden focal neurologic deficits can result from a variety of causes, the most frequent and concerning of which is acute stroke. The two most common forms of stroke that cause sudden onset of focal neurologic deficits without antecedent symptoms are acute ischemic stroke (AIS) and intracerebral hemorrhage (ICH). Both conditions are neurologic emergencies. The symptoms of AIS and ICH ([Table 15.1](#)) have significant overlap necessitating imaging studies to distinguish the two conditions.

The greatest opportunity to positively impact on the ultimate outcome of the patient with stroke occurs within the first hour of diagnosis and within 4 hours of the onset of symptoms. Emergency management of AIS is focused on attaining vascular reperfusion as soon as possible, most commonly with the administration of intravenous tissue plasminogen activator (IV tPA) for thrombolysis. In most cases, the outer limit of the time window for effective intervention is 4.5 hours after symptom onset. It has been estimated that every 15-minute reduction in onset-to-treatment time translates into a meaningful reduction in the risk of long-term disability at 3 months. In the case of ICH, emergency care is focused on blood pressure control, reversal of anticoagulation, and management of intracranial pressure (ICP).

This chapter focuses on the emergency management of the patient presenting with an acute focal neurologic deficit. Subsequent management after the first hour is discussed in Chapter 35 for AIS and in Chapter 38 for ICH.

PHASE 1: INITIAL MANAGEMENT AND IMAGING

Due to the importance of early intervention in stroke, the emphasis of emergency department (ED) management should not be on identifying subtle, unusual, or interesting neurologic signs but on the following five simple priorities. These tasks are ideally performed in parallel by four different personnel immediately upon patient arrival (e.g., the ED attending, resident, nurse, and stroke neurologist):

1. Assess level of consciousness and ensure adequate airway, breathing, and circulation.
2. Obtain the history with precise attention to the specific time of onset (or discovery) of symptoms along with a list of current medications.
3. Establish large-bore (preferably 18 gauge) intravenous access, and obtain admission labs.
4. Perform a National Institutes of Health (NIH) Stroke Scale examination.
5. Obtain head computed tomography (CT) imaging as soon as possible.

TABLE 15.1 Symptoms of Acute Stroke Symptoms of Acute Stroke

Facial asymmetry

Lateralized limb weakness or clumsiness

Lateralized numbness or paresthesias

Slurred or confused speech

Visual disturbances (diplopia or difficulty seeing)

Dizziness or vertigo

Gait instability

Headache

Alterations in level of consciousness

Modern emergency stroke management is evolving toward a paradigm that resembles trauma resuscitation. The initial goal is to minimize door-to-CT time because subsequent management is entirely dependent on the results of the scan. For AIS, the conventional goal is to obtain CT within 20 minutes and to start tPA infusion within 60 minutes of arrival to the ED (Figure 15.1). Currently, most hospitals struggle to have half of their AIS patients meet these targets.

New acute stroke care delivery models emphasizing parallel processing and lean management principles that exclude unnecessary steps have been shown to significantly reduce door-to-needle time for AIS. In the Helsinki model, physicians have proven the feasibility of safely administering IV tPA within 20 minutes of hospital arrival. In this paradigm, prehospital notification by ambulance triggers the stroke code, which then leads to the following:

1. Notification of the stroke team and ED staff, which assembles to meet the patient at the CT scanner
2. Transmitting the mobile phone number of any first responders or eyewitnesses to the stroke team to facilitate obtaining the history
3. Establishing a medical record number and hospital chart prior to arrival
4. Preordering the CT scan
5. Notification of pharmacy so that tPA or an anticoagulation reversing agent can be provided as soon as possible after CT

Given the complexity of coordinated personnel, resources, preparation, and teamwork that is required, most municipalities triage acute stroke patients directly to hospitals that are designated as primary stroke centers. After the initial resuscitation is completed, if the patient is unusually complex or critically ill, consideration should be given to transferring the patient to the nearest comprehensive stroke center.

INITIAL SURVEY AND VITAL SIGNS PRIOR TO COMPUTED TOMOGRAPHY

Level of Consciousness

ICH with mass effect as well as ischemic strokes of the brain stem, thalami, or large cortical regions can cause impairment in

mental status. Depressed level of consciousness may in turn lead to aspiration of oropharyngeal contents or

ineffective respirations due to upper airway obstruction, either of which may necessitate endotracheal intubation prior to further evaluation and management.

FIGURE 15.1 NINDS timeline targets for attaining an IV tPA door-to-needle time of 60 minutes or less. ED, emergency department; MD, doctor of medicine; NIHSS, National Institutes of Health Stroke Scale; CT, computed tomography; ASPECTS, Alberta Stroke Program Early CT Score; tPA, tissue plasminogen activator.

Blood Pressure

Hypertension occurs commonly as a nonspecific response to cerebral injury and can be present in both AIS and ICH. Elevated blood pressure (BP) is a strong indicator that the patient is actually having a stroke as opposed to a stroke mimic. Early BP elevation may be advantageous in AIS, allowing for increased cerebral perfusion to the *ischemic penumbra*, areas of marginally perfused brain. Aggressive BP reduction within the first few hours of AIS onset can lead to worsening of the neurologic deficit and therefore should be avoided.

BP should only be lowered prior to noncontrast CT if the systolic BP is higher than 220 mm Hg, diastolic BP is higher than 120 mm Hg [**Level 1**],¹ or it is suspected that hypertension is leading to acute end-organ damage (e.g., acute myocardial infarction, aortic dissection, or cardiogenic pulmonary edema). If BP is lowered, a systolic BP of 180 mm Hg is the preferred target. The preferred agents and their dosages for emergency BP control in acute stroke are shown in [Table 38.3](#). BP goals are reevaluated after CT imaging has established the etiology of the symptoms and, for AIS, once decisions are made regarding reperfusion therapy.

Heart Rate

Atrial fibrillation (AF) with rapid ventricular response (RVR) or other tachyarrhythmias can occur on presentation and may necessitate stabilization prior to obtaining CT. Diltiazem 10 mg IV or metoprolol 5 mg IV are commonly used initial therapies for AF with RVR in this setting. A cardiac monitor should be placed if there is any concern about heart rate or if the patient reports chest pain or palpitations. Routine electrocardiography should be obtained in acute stroke patients but is only required prior to CT if there is significant dysrhythmia or if an acute coronary syndrome is suspected.

Respirations and Breathing

Obvious respiratory distress should trigger placement of an oxygen saturation monitor and oxygen via nasal cannula. A decision whether to proceed directly to CT or to defer until adequate airway and ventilation can be assured then needs to be made. Patients with severe dyspnea or significantly impaired level of consciousness

(stupor or coma) should be intubated prior to CT scan, as failure to control the airway can lead to respiratory arrest or severe aspiration.

Temperature

In general, it is not necessary to measure body temperature prior to CT in a patient with acute stroke unless meningitis is suspected.

INITIAL HISTORY

If eyewitnesses are available, obtain a collateral history from them to corroborate the patient's account. Whenever possible, confirm the patient's history with emergency medical system (EMS) personnel, and ask prehospital providers to provide mobile phone numbers of eyewitnesses who might not be immediately present in the ED. Be sure to inquire about the following points.

1. Exactly when did the stroke symptoms first begin?

If the onset of symptoms cannot be reported by the patient and were not witnessed, ask when the patient was last known well. For those who present on waking from sleep, the physician must determine whether the symptoms were present immediately upon awakening or shortly thereafter after a brief period of normalcy. If they truly awoke with the symptoms, the last known well time may be the time when they went to sleep the prior evening but often will be a time that they awoke transiently in the middle of the night.

2. What were the initial symptoms?

A maximal deficit at onset in a fully alert patient supports cerebral infarction and suggests embolism in particular. Ask specifically if the patient's deficits have worsened or fluctuated since onset. Early headache, vomiting, or change in level of consciousness supports

P.120

ICH. Inquire specifically about lateralized weakness, numbness, or other classic symptoms of acute stroke (see [Table 15.1](#)).

3. Was any seizure activity observed?

Postictal deficits from seizures can mimic stroke. Seizures manifesting as focal motor convulsions or generalized tonic-clonic activity can also occur at the onset of ICH or AIS, but this is unusual.

4. What is the patient's medical history and neurologic baseline?

Assess for stroke risk factors such as hypertension, diabetes mellitus, dyslipidemia, cigarette smoking, AF, carotid stenosis, and prior transient ischemic attacks (TIAs) or strokes. A patient presenting with worsening of an existing or previously resolved neurologic deficit may have the "peeling-the-onion" syndrome ([Table 15.2](#)), with their symptoms resulting from unmasking of their prior deficit due to systemic derangements such as fever, hypoglycemia, or hypoxia.

5. What medications is the patient taking?

Ask particularly about anticoagulants or antiplatelet agents. Use of these agents not only predisposes to ICH but can also limit therapeutic options in the setting of ischemic stroke.

ESTABLISH INTRAVENOUS ACCESS AND DRAW ADMISSION LABS

Ideally, two peripheral IVs should be placed, at least one of which ideally should be 18 gauge to facilitate advanced imaging studies (i.e., CT angiography) if necessary. Labs should be drawn for complete blood count, serum chemistries, prothrombin time (PT)/partial thromboplastin time (PTT)/international normalized ratio (INR), troponin I, and other tests as indicated (e.g., liver function tests, toxicology screen, etc.). Point-of-care finger stick

blood glucose level should also be obtained.

NATIONAL INSTITUTES OF HEALTH STROKE SCALE EXAMINATION

The National Institutes of Health Stroke Scale (NIHSS, [Table 15.3](#)) is a simple algorithm for quantifying the severity of neurologic deficits in patients with acute hemispheric or cerebellar syndromes. Eleven items are tested, and a score is generated on a scale ranging from 0 (no deficit) to 42 (comatose and quadriplegic). In expert hands, the test takes only several minutes to administer. When obtained within 6 hours of symptom onset, an NIHSS score greater than or equal to 7 indicates a nearly 85% chance of detecting a large-vessel intracranial occlusion by CT angiography. In hospitals that offer intra-arterial (IA) endovascular intervention for AIS, this cut point can be used to select patients for immediate CT angiography after the noncontrast CT has excluded blood in order to expedite endovascular therapies. Scores higher than 20 in patients with AIS imply a high risk of large territory infarction and a very poor prognosis if reperfusion is not attained. Once the history and examination are completed, the lesion should be able to be localized clinically.

PERFORM NONCONTRAST COMPUTED TOMOGRAPHY IMAGING

Noncontrast CT is by far the most readily available test for differentiation of AIS and ICH and the only one that must absolutely be obtained prior to administering thrombolytic therapy for AIS. The ability to obtain timely CT scans is greatly improved by having the CT scanner located within the ED. To minimize any delays in treatment, the patient should ideally be taken directly from the ambulance to the CT scanner with coordinated evaluation and intervention performed just outside the CT suite or on the CT table.

Studies show that obtaining CT imaging is the rate-limiting step in acute stroke management, so optimization of door-to-CT times should be of high priority. *The main differential diagnosis in acute stroke is infarction versus hemorrhage.* All further management decisions will depend on making this distinction.

Analysis for Hemorrhage

Blood is hyperdense (bright) and easily identifiable on noncontrast helical computed tomography (NCHCT) ([Fig. 15.2A](#)). ICH appears as a discrete focus of blood that displaces the surrounding brain parenchyma. ICH volume, a strong predictor of 30-day mortality and functional outcome, can be quickly measured using the ABC/2 method (see [Fig. 38.3](#)). Two diameters (A + B), measured at right angles on the slice that corresponds to the epicenter of the hemorrhage, are measured in centimeters. The third diameter perpendicular to that plane (C) is measured by multiplying the number of slices on which the bleed is apparent by each slice thickness (usually 5 mm, expressed 0.5 cm). The product of these three diameters is divided by two as a simplification of the equation for the volume of an ellipsoid. Patients with ICH volumes of less than 30 mL have potential for a good prognosis and have a small risk of early deterioration, whereas those with ICH volumes between 30 and 70 mL are at higher risk for early deterioration due to mass effect. Patients with hemorrhages greater than 70 mL were traditionally considered to be uniformly lethal, although survival with reasonable recovery can be attained in this group with emergency surgery, most often hemicraniectomy.

Whenever ICH is present, be sure to check for the following radiographic findings:

- *Subarachnoid hemorrhage* ([Fig. 15.2B](#)) in association with intraparenchymal hemorrhage suggests a ruptured aneurysm and requires angiography.
- *Intraventricular hemorrhage* ([Fig. 15.2C](#)) in association with ventricular enlargement requires neurosurgical evaluation for possible emergent ventriculostomy.
- *Fluid/fluid levels* within a hematoma ([Fig. 15.2D](#)) result from separation of red blood cells and plasma and are

indicative of a coagulopathy.

- *Edema, mass effect, and midline shift* usually lead to delayed neurologic deterioration when associated with a large hemorrhage (> 30 mL). Perihematomal edema takes several hours to develop after ICH and is therefore not usually seen on initial head CT. An abnormally large or an irregular amount of edema associated with hemorrhage on initial presentation suggests (1) hemorrhagic conversion of infarcted tissue, (2) bleeding associated with neoplasm, or (3) venous infarction from dural sinus thrombosis.

Analysis for Ischemic Stroke

Infarction does not cause consistent changes on CT within 6 hours of stroke onset. *Infarction is suspected when a patient presenting with sudden onset of neurologic deficits has a normal CT scan.* Over a period of approximately 6 hours, regions of ischemia will gradually develop into an area of hypodensity as the tissue infarcts. The presence of a large hypodensity on NCHCT in an AIS patient should prompt reevaluation and careful scrutiny of the reported time of onset.

TABLE 15.2 Differential Diagnosis of Acute Neurologic Deficits

Diagnosis	Clinical Characteristics
Stroke	
Ischemic stroke	<ul style="list-style-type: none"> • Deficits that are maximal at onset suggest embolism • Sometimes preceded by transient ischemic attacks • Headache is uncommon • BP often elevated
Intracerebral hemorrhage	<ul style="list-style-type: none"> • Often presents with headache and/or nausea and vomiting • Deficit commonly worsens over minutes to hours as hemorrhage expands • Loss of consciousness at onset is rare • BP often extremely elevated
Subarachnoid hemorrhage	<ul style="list-style-type: none"> • Typically presents with sudden “thunderclap headache” • Often associated with transient loss of consciousness • Focal symptoms are unusual
Stroke Mimics	
Seizure with postictal deficit	<ul style="list-style-type: none"> • Occurs in aftermath of focal motor activity or an unwitnessed seizure • Deficits gradually improve and resolve over minutes to hours after onset • Can be differentiated from ischemic stroke with diffusion-weighted (DWI) MRI • EEG may show corresponding epileptiform activity

Migraine with aura	<ul style="list-style-type: none"> • Typical patient has a history of migraine and prior similar events • Can present with weakness, aphasia, neglect, visual changes, and/or sensory loss • Symptoms may precede, be concurrent with, or follow a typical migraine headache • Typically occurs in younger women with no stroke risk factors
Unmasking of a prior focal deficit (i.e., “peeling-the-onion” phenomenon)	<ul style="list-style-type: none"> • Sudden worsening of old stroke symptoms (does not cause new symptoms) • Triggered by fever, hypoxia, hypoglycemia, hyponatremia, or other metabolic disturbances • Focal deficits are typically accompanied by features of encephalopathy
Subdural hematoma	<ul style="list-style-type: none"> • May not have a clear history of recent trauma in elderly patients with acute-on-chronic bleeding • Typically presents with focal deficits or subacute confusion and gait disturbance in an elderly patient • Headache is common but not universal
Brain tumor or abscess	<ul style="list-style-type: none"> • Usually has a subacute to chronic presentation but can suddenly worsen due to associated seizure or bleeding into the tumor • Often with symptoms of headache, especially when recumbent
Multiple sclerosis or other demyelinating disease	<ul style="list-style-type: none"> • Usually has a more subacute presentation but can mimic acute stroke at times • Often has history of prior deficits in varying locations • Can be differentiated from ischemic stroke with DWI MRI • Affects younger patients with no stroke risk factors
Peripheral (labyrinthine) vertigo	<ul style="list-style-type: none"> • Can mimic an infarct in the brain stem or cerebellum causing acute vertigo • Can be differentiated from ischemic stroke with careful examination (horizontal head impulse test, characterization of nystagmus, and cover-uncover test^a) in most but not all cases • Definitive exclusion of ischemic stroke requires DWI MRI, although DWI can also miss small brain stem infarcts
Hypertensive encephalopathy (posterior reversible encephalopathy syndrome)	<ul style="list-style-type: none"> • Most commonly presents with altered mental status, headache, vision changes, or seizures • Usually does not cause unilateral symptoms • BP usually elevated • Can occur in younger patients with no stroke risk factors
Conversion disorder	<ul style="list-style-type: none"> • A diagnosis of exclusion

- Detailed neurologic exam sometimes reveals inconsistencies suggesting a nonphysiologic cause of symptoms
- Positive signs of misdirected effort may be elicited (e.g., Hoover sign)

BP, blood pressure; MRI, magnetic resonance imaging; EEG, electroencephalogram.

^aSee [Chapter 4](#) for details of the Head Impulse Nystagmus Test of Skew (HINTS) examination for differentiating central from peripheral vertigo.

TABLE 15.3 The National Institutes of Health Stroke Scale

1a. Level of consciousness (LOC):

0	Alert; keenly responsive
=	
1	Not alert but arousable by minor stimulation to obey, answer, or respond
=	
2	Not alert; requires repeated stimulation to attend or is obtunded and requires strong or painful stimulation to make movements (not stereotyped)
=	
3	Responds only with reflex motor or autonomic effects or totally unresponsive, flaccid, and areflexic
=	

1b. LOC questions: The patient is asked the month and his or her age.

0	Answers both questions correctly
=	
1	Answers one question correctly
=	
2	Answers neither question correctly
=	

1c. LOC commands: The patient is asked to open and close the eyes and then to grip and release the nonparetic hand.

0	Performs both tasks correctly
=	

1 Performs one task correctly
=

2 Performs neither task correctly
=

2. Best gaze: horizontal eye movements

0 Normal
=

1 Partial gaze palsy; gaze is abnormal in one or both eyes.
=

2 Forced deviation or total gaze paresis not overcome by the oculoccephalic maneuver
=

3. Visual loss:

0 No visual loss
=

1 Partial hemianopia
=

2 Complete hemianopia
=

3 Bilateral hemianopia (blind including cortical blindness)
=

4. Facial palsy:

0 Normal symmetric movements
=

1 Minor paralysis (flattened nasolabial fold, asymmetry on smiling)
=

2 Partial paralysis (total or near-total paralysis of lower face)
=

3 Complete paralysis of one or both sides (absence of facial movement in the upper and lower face)
=

5. Motor arm: The limb is elevated for 10 s, scored separately for left and right.

0 No drift; limb holds 90 (or 45) degrees for full 10 s.

=

1 Drift; limb holds 90 (or 45) degrees but drifts down before full 10 s; does not hit bed or other support

=

2 Some effort against gravity; limb cannot get to or maintain (if cued) 90 (or 45) degrees, drifts down to bed, but has some effort against gravity.

=

3 No effort against gravity; limb falls.

=

4 No movement

=

6. Motor leg: The limb is elevated for 5 s, scored separately for left and right.

0 No drift; leg holds 30-degree position for full 5 s.

=

1 Drift; leg falls by the end of the 5-s period but does not hit bed.

=

2 Some effort against gravity; leg falls to bed by 5 s but has some effort against gravity.

=

3 No effort against gravity; leg falls to bed immediately.

=

4 No movement

=

7. Limb ataxia:

0 Absent

=

1 Present in one limb

=

2 Present in two limbs

=

8. Sensory:

0 Normal; no sensory loss

=

1 Mild to moderate sensory loss; patient feels pinprick is less sharp or is dull on the affected side; or there is a loss of superficial pain with pinprick, but patient is aware of being touched.

2 Severe to total sensory loss; patient is not aware of being touched in the face, arm, and leg.

9. Best language:

0 No aphasia; normal

=

1 Mild to moderate aphasia

=

2 Severe aphasia; all communication is through fragmentary expression.

=

3 Mute, global aphasia; no usable speech or auditory comprehension

=

10. Dysarthria:

0 Normal

=

1 Mild to moderate dysarthria; patient slurs at least some words and, at worst, can be understood with some difficulty.

2 Severe dysarthria; patient's speech is so slurred as to be unintelligible in the absence of or out of proportion to aphasia.

11. Extinction and inattention:

0 No abnormality

=

1 Visual, tactile, auditory, spatial, or personal inattention or extinction to bilateral simultaneous stimulation in one of the sensory modalities

2 Profound hemi-inattention or extinction to more than one modality; does not recognize own hand or orients to only one side of space

Total score ranges from 0 (normal) to 42 (comatose and quadriplegic). For informational purpose only. Accurate and reliable scoring of the NIHSS requires strict adherence to a standardized testing protocol.

FIGURE 15.2 CT scans of brain hemorrhage. **A:** Intracerebral hemorrhage. **B:** Subarachnoid hemorrhage. **C:** Intraventricular hemorrhage. **D:** Acute hemorrhage with fluid/fluid level indicative of a coagulopathy.

The Alberta Stroke Programme Early CT Score (ASPECTS) was developed to quantify the extent of infarction on initial CT imaging (Fig. 15.3). Loss of differentiation between gray and white in the cortex and deep structures such as the caudate, putamen, or globus pallidus results from early ischemic injury and portends eventual progression to irreversible infarction (Fig. 15.4). The score is composed of seven cortical regions and three subcortical regions of the middle cerebral artery (MCA) territory totaling 10 points for a normal study from which 1 point is subtracted for each area of visualized infarct. This score has high interrater reliability and serves to quantify infarction, predict outcome, and stratify patients regarding the use of reperfusion therapies. The risk of hemorrhagic conversion after thrombolysis is increased in patients with ASPECTS lower than 7.

Acute thrombus in a proximal vessel such as the MCA (“dense MCA sign”) or basilar artery can create a hyperdense appearance to the vessel on NCHCT. The presence of a hyperdense vessel may have clinical use in the acute setting, as it helps to confirm the diagnosis of large-vessel occlusion (LVO) and may lead clinicians to mobilize neurointerventional teams for clot extraction.

PHASE 2: POST-COMPUTED TOMOGRAPHY EMERGENCY MANAGEMENT

INTRACEREBRAL HEMORRHAGE

The following management guidelines apply specifically to spontaneous intraparenchymal ICH. Refer to Chapter 39 for management of *subarachnoid hemorrhage* and Chapter 46 for management of *traumatic brain injury*.

Diagnose and Reverse Coagulopathy and Platelet Dysfunction

The presence of blood on CT mandates that a PT/INR, PTT, and platelet count are sent as STAT tests to confirm normal values as soon as possible. Next, confirm whether or not the patient is taking any anticoagulants that do not significantly affect these values (e.g., dabigatran, rivaroxaban, apixaban, low molecular weight heparins). Also inquire about antiplatelet agents (e.g., aspirin, clopidogrel, dipyridamole, prasugrel). A basic metabolic panel is also useful to show evidence of uremia, which can cause a qualitative platelet defect.

P.124

FIGURE 15.3 Anatomic regions evaluated in the ASPECTS. A score of 10 indicates no evidence of early ischemic change from which 1 point is subtracted for each region of infarction. Patients with scores below 7 are at high risk for hemorrhagic transformation if given IV tPA. C, caudate; I, insula; L, lentiform nucleus; IC, internal capsule; M, middle cerebral artery territories 1 through 6.

Suggested protocols for the reversal of different forms of anticoagulation or platelet dysfunction are shown in [Table 15.4](#). *If there is a clear history of current use, steps to reverse anticoagulation or restore platelet function should not be delayed by waiting for coagulation testing or a platelet count [Level 1].*² In patients with oral anticoagulant-associated ICH, successful reversal of the INR to <1.3 and reduction of systolic BP to <160 mm Hg is associated with a reduced risk of hematoma enlargement.

Control Severe Hypertension

In contrast to the AIS patient, continued hypertension can harm the ICH patient by causing expansion of the hemorrhage and worsened perihematomal edema. Older guidelines suggest lowering the systolic BP to lower than 180 mm Hg, whereas a more recent randomized trial (Intensive Blood Pressure Reduction in Acute Cerebral Hemorrhage Trial [INTERACT]) showed that lowering to systolic BP lower than 140 mm Hg is safe and may be of clinical benefit [Level 1].³ Nicardipine or clevidipine infusion is preferable because of their reliable dose-response characteristics and quick onset and offset times. If these short-acting agents are unavailable, labetalol can be administered initially as IV pushes followed by an infusion (see [Table 38.3](#)). Nitrates such as sodium nitroprusside should be avoided due to their potential to cause cerebral vasodilation and elevated ICP.

Treat Suspected Elevated Intracranial Pressure or Symptomatic Mass Effect

If the NCHCT shows significant mass effect (midline shift, effacement of the basal cisterns, or both) and the patient has depressed level of consciousness, empiric treatment of ICP should be initiated. Hyperventilation causes vasoconstriction that will lower cerebral blood volume and thus lower ICP. It should be used transiently as a bridge to further intervention in intubated patients who show signs of transtentorial herniation (i.e., dilated pupil). In general, a partial pressure of carbon dioxide (PCO₂) level of 30 is targeted. If the patient is intubated and agitated or coughing, sedation should be considered. Bolus osmotherapy with mannitol 1 to 1.5 g/kg IV can be easily administered through a peripheral IV. Alternatively, 30 mL of 23.4% hypertonic saline can be given, but this requires central venous access. Steroids should not be administered, as they have been shown to be ineffective for management of cerebral edema after ICH [Level 1]⁴ and may increase the risk of infectious complications (see also [Chapter 107](#)).

Consider External Ventricular Drain Placement or Placement of an Intracranial Pressure Monitor

Obstructive hydrocephalus typically develops in ICH patients who also have a significant amount of intraventricular hemorrhage in the third or fourth ventricles. Any new enlargement of the temporal horns of the lateral ventricles on NCHCT in a patient with altered level of consciousness should prompt consideration of external ventricular drain placement for management of hydrocephalus and control of ICP. Without diversion of cerebrospinal fluid, patients with hydrocephalus can deteriorate rapidly. If significant mass effect is present in a patient who is ineligible for surgical evacuation, a parenchymal ICP monitor may be considered to allow for optimization of ICP management (see [Chapter 33](#)).

FIGURE 15.4 Early cerebral infarction with loss of gray-white definition and sulcal effacement. (Arrows indicate anterior and posterior borders of the involved territory of the MCA.)

Consider Emergent Surgical Hematoma Evacuation

For cerebellar hemorrhage greater than 3 cm in diameter, suboccipital surgical decompression with or without hematoma evacuation is recommended if the patient shows decreased level of consciousness and CT shows evidence of mass effect [Level 1].² For supratentorial hemorrhage, however, there is far less consensus. The Surgical Trial in Intracerebral Hemorrhage (STICH) was unable to show definitive benefit for craniotomy with evacuation of supratentorial ICH within 72 hours of onset compared with best medical therapy [Level 1].^{5,6} Most likely, the incision in cerebral cortex required to surgically evacuate deeper hemorrhage leads to further neurologic injury that negates any benefit. Despite these results, there is some suggestion that younger patients with active deterioration due to mass effect may still benefit from surgical evacuation, as these patients were not randomized into the trials.

Consider Anticonvulsant Therapy

Hemorrhage can cause cortical irritation and the development of seizure activity. If seizures occur, patients

should be given an IV antiepileptic medication (commonly used agents are levetiracetam 1 to 2 g IV, fosphenytoin 20 mg/kg IV, or phenytoin 20 mg/kg IV) [Level 1].² Prophylactic treatment with anticonvulsants for 7 days after onset can be considered in unstable patients with cortical hemorrhage, as these patients are at higher risk for seizures.

Consider Advanced Imaging

ICH is most commonly due to hypertension when it occurs in the putamen, globus pallidus, caudate, thalamus, pons, or cerebellum. Cortical ICH occurs more frequently in the elderly and usually results from *amyloid angiopathy*, the deposition of amyloid into the arterial wall. However, ICH may also be caused by aneurysms (if adjacent to the subarachnoid space), arteriovenous malformations (AVMs), cavernous malformations, tumors, or other less common etiologies. Young patients, those with atypical CT findings, and those without a history of hypertension or anticoagulant use should undergo further imaging studies to evaluate for an underlying lesion. Imaging options include CT angiography, magnetic resonance imaging/magnetic resonance angiography (MRI/MRA), or catheter angiography. CT angiography can be performed on the CT table immediately after NCHCT identifies ICH, provided the patient remains stable and does not urgently require any additional treatments.

Disposition

Due to high risks of neurologic deterioration and development of medical complications, all patients with acute ICH should ideally be admitted to an intensive care unit for further evaluation and management.

ACUTE ISCHEMIC STROKE

For patients presenting with an acute neurologic deficit who show no signs of hemorrhage on noncontrast CT, the presumptive diagnosis is ischemic stroke and the primary goal is to provide eligible patients with reperfusion therapy as soon as possible. Thrombolysis with IV tPA loses its efficacy rapidly as acute ischemia progresses to infarction. Optimization of each step of acute stroke management is required to ensure timely therapies. When done successfully, thrombolysis with IV tPA can be administered within 20 minutes after ED arrival.

Indications for Intravenous Tissue Plasminogen Activator

With the completion of the National Institute of Neurological Disorders and Stroke (NINDS) trial in 1995, administration of IV tPA has become the standard of care for acute reperfusion therapy in AIS within 3 hours of symptom onset [Level 1].⁷ Thrombolysis with tPA increases the chances of a good recovery at 3 months after infarction from approximately 26% to 39% corresponding to a number needed to treat of 8 with no effect on mortality. Unfortunately, tPA also carries a 6% risk of symptomatic hemorrhagic conversion, most commonly in patients given tPA at later time points relative to symptom onset or in those with extensive signs of early ischemic change as evidenced by an ASPECTS lower than 7.

More recently, the European Cooperative Acute Stroke Study III (ECASS III) trial confirmed the safety and efficacy of IV tPA up to 4.5 hours after symptom onset in a subgroup of patients who were younger than 80 years of age. The benefit of tPA in this subset is less than those treated within 3 hours. Patients given tPA within the 3.0- to 4.5-hour window also have increased rates of hemorrhagic conversion and worsened mortality compared with patients given tPA within 3 hours of onset [Level 1].⁸ Speed of attaining reperfusion is by far the most important determinant of the efficacy of tPA. The number needed to treat to achieve one functionally independent patient after ischemic stroke increases from as little as 5 for patients treated within 90 minutes of onset to 15 when tPA is given within the 3.0- to 4.5-hour window. For patients who present beyond 4.5 hours from onset, IV tPA is not of proven benefit and may cause harm, as the risk of hemorrhagic conversion increases significantly [Level 1].⁹

TABLE 15.4 Strategies for Reversal of Anticoagulation or Platelet Dysfunction in Acute Intracerebral Hemorrhage

Agent	Treatment Strategy	Comments
Warfarin (vitamin K antagonist that results in reduced synthesis of factors II, VII, IX, and X)	Administer vitamin K 10 mg IV over 30 min. <i>and</i> Four-factor prothrombin complex concentrate (PCC) 25-50 U/kg IV <i>or</i> Fresh frozen plasma (FFP) 2-4 200 mL units IV	If available, PCC is preferable, as it results in a substantially quicker time to INR reversal than FFP using a much smaller volume of infusion. The goal should be to lower the INR to <1.5.
Dabigatran (direct thrombin inhibitor)	Give activated charcoal if the medication was ingested within the past 2 h. <i>and</i> Consider emergency hemodialysis.	There is limited data to support other therapies, but four-factor PCC or factor VIIa can be considered.
Rivaroxaban, apixaban, edoxaban (Xa inhibitors)	Consider a four-factor PCC 25-50 U/kg IV.	In one study, PCC was shown to be superior to FFP for normalizing the INR in normal subjects treated with rivaroxaban. These drugs are heavily bound to plasma protein, so plasma exchange can be considered, but there is limited experience with its use.
Unfractionated heparin (UFH)	For IV bolus UFH given <1 h ago, administer 1 mg of protamine sulfate for every 100 units of UFH. If UFH was given 1-2 h ago, give 1 mg of protamine sulfate for every 200 units of UFH. If UFH was given >2 h ago, give 1 mg of protamine sulfate for every 400 units of UFH.	For patients receiving an IV infusion of UFH, administer protamine sulfate 1 mg for every 100 units given in the past 2 h.
Enoxaparin, dalteparin (low molecular weight heparin [LMWH])	If LMWH was given <8 h ago, give 1 mg of protamine sulfate per 100 anti-Xa units	Enoxaparin has 100 anti-Xa U/mg, whereas dalteparin has 156 anti-Xa U/mg.

of LMWH.
 If LMWH was given 8-24 h ago, give 1 mg of protamine sulfate per 200 anti-Xa units of LMWH.
 If bleeding continues, an additional dose of 0.5 mg per 100 anti-Xa units can be administered.

Antiplatelet agents, platelet abnormalities (i.e., uremia), or thrombocytopenia

Give DDAVP 0.3 µg/kg IV over 30 min *and/or* 1 unit of single-donor platelets (or 6 units of pooled platelets)

Limited data is available to support these interventions.
 For thrombocytopenia, transfuse platelets to goal of >50,000/cm³.

INR, international normalized ratio; IV, intravenous; DDAVP, desmopressin acetate.

Contraindications to Tissue Plasminogen Activator Administration

The 1995 NINDS trial used strict exclusion criteria derived from expert opinion at the time, which were subsequently translated into contraindications for tPA administration. However, these rigorous contraindications may not necessarily define the full population of patients who might benefit from tPA. [Table 15.5](#) shows the relative strength of various contraindications to tPA therapy. These updated recommendations largely reflect case series, cohort studies, and 20 years of clinical experience since the original approval of tPA. It is crucial to use sound clinical judgment when giving tPA in the setting of a relative contraindication and to fully explain how this may alter the risks of therapy relative to the expected benefit. The most commonly encountered exclusions are discussed in the following sections.

EARLY INFARCT SIGNS

Early ischemic changes on imaging are clearly associated with higher rates of hemorrhagic conversion. Early ischemic changes should not exclude patients from thrombolysis if the extent of these changes is small (ASPECTS of 7 to 9).

IMPROVING OR MILD SYMPTOMS

Although as many as 30% of AIS patients are not administered tPA due to rapidly improving or minor stroke syndromes, 25% of these patients still have poor functional outcomes or death after stroke. AIS patients with minor or resolving deficits may still benefit from thrombolysis and should be considered on a case-by-case basis.

BLOOD PRESSURE HIGHER THAN OR EQUAL TO 185/110 MM HG

Severe hypertension is thought to increase the risk of hemorrhagic transformation after thrombolysis, although good evidence of cause and effect is scant. It is reasonable to rapidly control BP to lower than 185/110 mm Hg and start tPA while continued efforts are made to attain target BP with a continuous infusion agent such as nicardipine or clevidipine ([Table 38.3](#)).

TABLE 15.5 Strength of Evidence for Contraindications to Tissue Plasminogen Activator Therapy

Clinical Scenario	Strength of Contraindication
CT evidence of hemorrhage	Absolute
Early infarct signs involving >1/3 of the MCA territory	Absolute
Time of symptom onset unknown	Absolute
History of coagulopathy or anticoagulant use or documented elevation of INR (>1.7) or aPTT (>1.5 × control)	Relative, strong
Thrombocytopenia (platelet count <100,000)	Relative, strong
SBP >185 mm Hg or DBP >110 mm Hg ^a	Relative, moderate
Major surgery or serious trauma within preceding 14 days	Relative, moderate
Glucose <50 or >400 mg/dL ^a	Relative, moderate
Pregnancy	Relative, moderate
Stroke or serious head trauma within preceding 3 mo	Relative, weak
Seizure at onset of stroke	Relative, weak
Rapidly improving or minor symptoms (e.g., pure sensory, minimal weakness)	Relative, weak
Gastrointestinal, urinary tract, or other significant bleeding within preceding 21 days	Relative, weak
Significant MI within past 4 wk or symptoms of post-MI pericarditis	Relative, weak
Arterial puncture at a noncompressible site within preceding 7 days	Relative, weak
Lumbar puncture within preceding 7 days	Relative, weak

This information is intended to serve only as a guideline. Successful and safe use of IV tPA has been reported despite the presence of one or more of these complications. Decisions regarding the risks and benefits of tPA should be individualized.

^aBlood pressure and glucose can be urgently corrected and then tPA can be administered.

CT, computed tomography; MCA, middle cerebral artery; INR, international normalized ratio; aPTT, activated partial thromboplastin time; SBP, systolic blood pressure; DBP, diastolic blood pressure; MI, myocardial infarction.

SEIZURE AT ONSET

Seizures at onset are unusual in AIS and raise the strong possibility that the patient may have a postictal rather than ischemic deficit. Nevertheless, tPA is safe in patients with seizures at onset, and it is reasonable to give tPA if the index of suspicion for AIS is very high, especially in the setting of an LVO seen on imaging.

WARFARIN WITH INTERNATIONAL NORMALIZED RATIO GREATER THAN 1.7

A history of warfarin use in patients with AIS mandates a STAT INR. Otherwise, there is no need to check coagulation routinely prior to giving tPA. There is conflicting evidence as to whether tPA is associated with an increased risk of hemorrhagic transformation when the INR is either below or mildly above 1.7 among patients taking warfarin.

ABNORMAL BLOOD GLUCOSE

Elevated blood glucose has been associated with a decreased likelihood of neurologic improvement, decreased rates of recanalization, and a higher risk of hemorrhagic conversion after thrombolysis for AIS. Treatment of hyperglycemia has not yet been shown to modify outcome, but it nevertheless is prudent to control blood glucose within a tight normal range when administering tPA. Both hyper- and hypoglycemia raises the possibility of a stroke mimic due to “unmasking” of a prior focal deficit.

OLD AGE

Although those older than age 80 years do not benefit as much from thrombolysis, patients given tPA still show improved outcomes compared with those in whom tPA is withheld. Thrombolysis with IV tPA should not be withheld from elderly patients without other contraindications.

Tissue Plasminogen Activator and Stroke Mimics

The prevalence of potential AIS that prove to be stroke mimics is as high as 20% to 25% in some regions, most of which represent seizure, complicated migraine, or conversion disorder. MRI, which can more definitively differentiate stroke from mimics, leads to delays that reduce the efficacy of tPA in improving neurologic outcomes. Fortunately, several studies show that tPA administration to stroke mimics is not associated with ICH or other complications. A rate of treating stroke mimics with thrombolysis of up to 15% is considered acceptable in most active stroke centers.

Dosage of Intravenous Tissue Plasminogen Activator

tPA is supplied in powder form and must be reconstituted with sterile water prior to administration. For eligible patients, 0.9 mg/kg of IV tPA is administered up to a maximum dose of 90 mg with the initial 10% given as an IV push and the remainder infused over 1 hour.

Post-Tissue Plasminogen Activator Blood Pressure Management

BP should be strictly maintained at lower than 180/105 mm Hg for at least 24 hours after tPA is administered to minimize the risk of hemorrhagic conversion. Because the half-life of tPA is extremely short, a radial arterial line

can be safely placed for BP monitoring 1 hour after discontinuation of the infusion, as direct pressure can be effectively applied if bleeding occurs at this location. Intravenous short-acting drip antihypertensive agents that can be easily titrated are optimal to definitively achieve this goal and to avoid large swings in BP.

Aspirin

Patients who do not receive IV tPA should be given aspirin 81 to 325 mg as soon as possible. For those who receive IV tPA, aspirin administration should be delayed for 24 hours after tPA infusion to prevent hemorrhagic conversion and then started thereafter. Early aspirin administration after AIS has been shown to decrease the risk of early recurrent stroke, death, and dependency [Level 1].^{10,11}

Role of Interventional Therapy

An important limitation of tPA is that it fails to recanalize the occluded vessel in 40% of cases. When larger clots occlude the major large intracranial vessels—the proximal MCA, internal

P.128

carotid artery (ICA) terminus, or basilar artery—recanalization rates are even worse and outcomes remain poor despite IV tPA administration. Interventional bridging therapy is the strategy of proceeding immediately to endovascular intervention while tPA is infusing. If a persistent LVO is detected, endovascular intervention to extract the clot from the vessel using a suction, corkscrew, or retrievable stent device can then be attempted (see Chapter 35 for details).

In 2013, the Interventional Management of Stroke III trial (IMS III), Systemic Thrombolysis for Acute Ischemic Stroke (SYNTHESIS) trial, and Mechanical Retrieval and Recanalization of Stroke Clots Using Embolectomy (MR RESCUE) trials all failed to show benefit of endovascular intervention in the setting of AIS. These trials used less effective devices than are available today and most patients were recanalized many hours after the onset of symptoms. More recent clinical trials reported in 2015, including Multicentre Randomised Clinical Trial of Endovascular Treatment for Acute Ischemic Stroke in the Netherlands (MR CLEAN) [Level 1],¹² Endovascular Treatment for Small Core and Anterior Circulation Proximal Occlusion with Emphasis on Minimizing CT to Recanalization Times (ESCAPE) [Level 1],¹³ and five additional trials (Table 35.5), used modern retrievable stent technology, achieved better recanalization rates, and showed that urgent intra-arterial intervention combined with IV tPA can improve outcome. Interventional therapy can also be considered in patients with certain contraindications to IV tPA, such as patients already on anticoagulation or those with recent major surgery.

In the absence of widely accepted practice guidelines, clinical practice at this level varies widely. Many primary stroke centers in the United States do not offer endovascular intervention, although most comprehensive stroke centers do. To be successful, rapid evaluation and mobilization of the interventional team requires preparation and interdisciplinary teamwork.

Emergency Computed Tomography Angiography for Detecting Large-Vessel Occlusion

Increasingly, major stroke centers are incorporating CT angiography into their acute stroke algorithms with the goal of detecting a treatable LVO (Fig. 15.5) during tPA therapy or in patients who present acutely but have a contraindication to its use. A high NIHSS score very early in the course of stroke implies a high probability of a LVO. One study showed that among AIS patients who present within 6 hours with a baseline NIHSS higher than or equal to 7, CT angiography demonstrates a potentially treatable LVO in nearly 85% of patients. By contrast, in the MR CLEAN Trial mechanical thrombectomy within 6 hours of onset improved outcome in AIS patients with documented LVO and NIHSS scores as low as 2. Many stroke centers have established protocols in which tPA therapy is initiated in the CT scanner immediately after the noncontrast CT is obtained. This allows the team to proceed directly with a CT angiogram without delaying tPA administration. In these protocols routine

documentation of a normal serum creatinine level is waived owing to the urgency of the situation and the low risk of serious contrast-induced nephropathy (<1%). Demonstration of LVO then triggers an interventional “secondary page” that mobilizes the interventional team with the goal of beating a 60-minute “picture-to-puncture” time interval.

Even if mechanical thrombectomy is not being pursued, vessel and perfusion imaging may clarify or confirm sites of cervical vessel occlusion, guide BP management, affect disposition, and establish prognosis. For patients with severe or fluctuating stroke syndromes presenting beyond 4.5 hours who are therefore not eligible for IV tPA, CT angiography/CT perfusion or MRA/MR perfusion can be considered at the time of initial imaging to allow for the possibility of pursuing endovascular intervention.

FIGURE 15.5 CT angiogram maximum intensity projection (MIP) image (coronal view) demonstrating total occlusion of the left M1 segment of the middle cerebral artery.

Disposition

Ischemic stroke patients should be transferred to a stroke unit or a neuro-ICU whenever possible depending on the clinical scenario, including active comorbidities and the immediate risk of neurologic deterioration.

Acute Spinal Cord Syndromes

Natalie R. Weathered

Noam Y. Harel

INTRODUCTION

Patients presenting with acute spinal cord syndromes represent true neurologic emergencies. Pathologic damage to the cord is usually incomplete. Therefore, there is opportunity to salvage (and peril of losing) vital cord tissue and function over the ensuing minutes and hours after presentation. As with other neurologic presentations, clinicians must first localize and then differentiate the type of damage in order to initiate the most effective interventions.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for an acute cord syndrome ranges from mechanical to vascular, infectious, inflammatory, neoplastic, and toxic etiologies (Tables 16.1 and 16.2). A careful history regarding remote or recent trauma, other systemic symptoms, or toxic habits may help narrow your differential. Determining the rate of symptom progression proves critical, as patients whose symptoms reach maximal involvement within minutes are more likely to have a mechanical or vascular cause rather than an infectious, inflammatory, or neoplastic cause.

SPINAL CORD ANATOMY

To aid with localization, recall that the caudal spinal cord segments do not align with the vertebrae bearing the same names. The spinal cord ends around L1, with the roots of the cauda equina below that vertebral level. Additionally, within the cervical cord, the spinal roots exit the spinal canal above the associated vertebral level except for root C8, which exits between C7 and T1. Thereafter, each spinal root exits below the corresponding vertebral body.

MOTOR SYSTEM

The majority of the corticospinal tract, mediating a large proportion of our volitional limb movements, decussates in the medulla before descending in the contralateral lateral corticospinal tract. The minority of motor axons that do not decussate within the medulla form the anterior corticospinal tract. The lower motor neurons, receiving input from corticospinal fibers as well as segmental interneurons, reside within the ventral horn (Fig. 16.1).

SENSORY SYSTEM

Afferent sensory fibers from the dorsal root ganglia enter the spinal cord at the dorsal horn. From there, their course depends on the type of modality being transmitted.

Pain and Temperature

These fibers travel rostrally within Lissauer tract for one or two spinal segments before synapsing within the dorsal horn and crossing to the contralateral anterolateral system. The anterolateral system is composed of the anterior spinothalamic tract, which carries crude touch sensory fibers, and the lateral spinothalamic tract, which carries pain and temperature fibers.

TABLE 16.2 Classic Spinal Cord Syndromes

Syndrome

Typical Causes

Clinical Characteristics

Central cord syndrome (syringomyelia)	Underlying cervical spondylosis with hyperextension injury; damage relatively greater to gray than white matter	Weakness in upper extremities > in lower extremities; may have neurogenic bladder dysfunction and varying degrees of sensory loss at or below the lesion (often in a “cape-like” distribution).
Brown-Séquard syndrome	Penetrating trauma (many nonpenetrating injuries show partial asymmetric syndromes)	Ipsilateral motor and vibration/proprioception loss below the lesion, contralateral pain/temperature loss two levels below the lesion
Anterior cord syndrome	Hypotensive event leading to infarct within the midthoracic region, or hyperflexion injury leading to compression of the anterior spinal artery	Bilateral loss of motor, pain/temperature sensation below the lesion with preservation of vibration/proprioception/two-point discrimination
Posterior cord syndrome	B ₁₂ deficiency, MS, vascular malformations, atlantoaxial subluxation	Bilateral loss of vibration/proprioception/two-point discrimination with preservation of motor, pain/temperature sensation below the lesion
Cauda equina syndrome	Disk herniation, tumor	Asymmetric lower extremity weakness, patchy impaired sensation to all modalities, loss of deep tendon reflexes as well as bulbocavernosus reflex and anal wink, often with low back and radicular pain
Conus medullaris syndrome	Disk herniation, trauma, tumor	Symmetric sacral > lumbar weakness (may have normal leg strength), saddle anesthesia, bowel/bladder dysfunction

MS, multiple sclerosis.

Vibration, Proprioception, and Two-Point Discrimination

These fibers travel within the ipsilateral dorsal columns to the gracilis and cuneatus nuclei of the lower medulla. Axons from the legs (fasciculus gracilis) are pushed medially by entering axons from the arms (fasciculus cuneatus) (see [Fig. 16.1](#)).

AUTONOMIC SYSTEM

Sympathetic

Sympathetic preganglionic neurons are located within the inter-mediolateral nucleus of the thoracic and upper lumbar (L1-L2) spinal cord. Their axons exit via the ventral roots and synapse on the postganglionic sympathetic neurons in the paravertebral ganglia (the “sympathetic chain ganglia”) or the prevertebral ganglia.

FIGURE 16.1 Anatomy of the spinal cord (cross-section). Tract lamination: S, sacral segments; L, lumbar segments; Th, thoracic segments; C, cervical segments. (From Brazis PW, Masdeu JC, Biller J. *Localization in Clinical Neurology*. 5th ed. Philadelphia: Lippincott Williams and Wilkins; 2007.)

Parasympathetic

Parasympathetic preganglionic neurons are found within four brain stem nuclei (cranial nerve [CN] III, VII, IX, X) of which only the vagus nerve contributes to autonomic control below the head. Additionally, parasympathetic preganglionic axons originating in cord segments S2-S4 exit via the sacral ventral roots. The vagus innervates the heart, bronchi, pancreas, kidney, and

P.132

the upper portion of the gastrointestinal tract, whereas sacral parasympathetics innervate the sexual organs, bladder, descending colon, and rectum.

Cardiovascular Innervation

The vagus nerve tonically reduces heart rate through effects on the sinoatrial node. Sympathetics arising from the upper thoracic levels (T1-T5) increase heart rate and contractility, whereas sympathetics from T5 to T12 increase vasoconstriction in the splanchnic bed and lower extremities. Splanchnic vasoconstriction can increase systemic blood pressure to dangerous, even lethal levels, in the phenomenon of autonomic dysreflexia, which is seen in some individuals with severe injuries at or above the T6 level.

Pulmonary Innervation

The phrenic nerve, which innervates the diaphragm, arises from C3 to C5. Although preservation of the phrenic nerve allows independent respiration, more subtle impairment of respiratory function may still be seen in those with lower injuries as a result of weakness in the intercostal or abdominal musculature.

VASCULAR ANATOMY OF THE SPINAL CORD

Three primary arteries run longitudinally along the spinal cord: the anterior spinal artery and two posterior spinal arteries. Branches of the single anterior spinal artery are responsible for two-thirds of the cord's cross-sectional

area, whereas branches of the two posterior arteries serve a combined one-third of the cord's area. Therefore, the anterior portion of the cord is more susceptible to ischemia (Fig. 16.2).

The spinal arteries are fed by segmental radicular arteries, which are notoriously variable between individuals. The artery of Adamkiewicz is one of the largest radicular arteries that most commonly arises from the 9th to 12th intercostal arteries on the left. The artery of Adamkiewicz serves a critical role in supplying the anterior spinal artery's distribution over the lower third of the spinal cord including the conus medullaris. This artery is vulnerable to occlusion by aortic aneurysms and aortic repair procedures, resulting in a high rate of catastrophic cord ischemia and paraplegia. Rostral to the artery of Adamkiewicz, there is a relative paucity of collateral blood flow, making the midthoracic region particularly susceptible to ischemia from systemic hypotension.

FIGURE 16.2 The vascular supply of the spinal cord. (From Brazis PW, Masdeu JC, Biller J. *Localization in Clinical Neurology*. 5th ed. Philadelphia: Lippincott Williams and Wilkins; 2007.)

FOCUSED HISTORY: KEY QUESTIONS

Depending on the level of injury, patients with spinal cord lesions are at risk for catastrophic acute cardiac and respiratory complications. Therefore, before taking the history, one must quickly assess airway, breathing, and circulation.

LOCALIZATION

- Does the patient have any *weakness*, and if so, what is its distribution? Does it involve only the lower extremities or the upper extremities or both?
- Does the patient have any *numbness* or *paresthesias*, and if so, what is its distribution?
- Is there any *pain* present? Is it local to the back or does it follow a radicular distribution?
- Is there any evidence of *bowel* or *bladder dysfunction*? In acute presentations without prior symptoms, the bladder may be prone to retention and overflow incontinence. In cases presenting with acute exacerbation of subacutely or chronically progressing lesions, the bladder may be spastic, with a history of increasing frequency, nocturia, and urge incontinence over the preceding weeks to months.

Conversely, lesions affecting the lumbosacral cord segments may cause bladder hypotonia, leading to retention and frequent urinary tract infection.

DIFFERENTIAL DIAGNOSIS

- Is there a history of *trauma* or falls?
- Did the patient recently have *surgery* that may have led to hypotension or local cord ischemia?
- Does the patient have a known history of *cancer* or recent unexplained weight loss?
- Has the patient had any recent *infectious symptoms* such as fevers, chills, or cough?
- Has the patient had a *rash*?

P.133

- Is the patient *immunocompromised* due to medications, cancer, or HIV? This may predispose to infection or medication-induced myelopathy.
- Is there a history of *vision loss* in either eye that later resolved partially or completely?
- Is there a history of *substance abuse* or *workplace/environmental exposures*?

FOCUSED EXAM

GENERAL EXAM

Recall that with cervical lesions, the *respiratory* and *cardiovascular* systems may be compromised (Table 16.3).

Respiratory

Shortness of breath or frank respiratory failure may occur. Careful observation must be paid to assess not only for hypoxia but also for hypercapnic respiratory failure and increased work of breathing using accessory muscles.

Cardiovascular

Lesions at or above T6 place the patient at risk of unbalanced sympathetic-parasympathetic drive. These patients may present with neurogenic shock: hypotension (resting and orthostatic), bradycardia, or other cardiac arrhythmias including asystole. At later time points, affected patients are also at risk for autonomic dysreflexia: episodes of extreme hypertension (due to excessive sympathetic vasoconstriction of the splanchnic vessel bed) with corresponding autonomic signs or symptoms such as diaphoresis, piloerection, facial flushing, and bradycardia (due to parasympathetic-mediated vasodilation above the lesion), and headache. These episodes most often have an identifiable trigger such as bladder or bowel irritation.

Autonomic

Effects on bowel and bladder function are not as straightforward as often perceived. During acute spinal shock, tone is decreased, leading to urinary retention, decreased rectal tone, and loss of bulbocavernosus reflex. Therefore, the rectal exam and checking the postvoid residual are required.

TABLE 16.3 Summary of Exam Findings

System	Exam Signs/Symptoms
--------	---------------------

Respiratory	Tachypnea, shallow breathing, complaints of shortness of breath
Cardiovascular	Hypotension, bradycardia, arrhythmia
Dermatologic	Presence of a rash may aid in narrowing the differential
Motor	Weakness below lesion; decreased tone initially, transitioning to increased tone/spasticity
Sensory	Sensory level at lesion
Reflexes	May be depressed initially then below lesion then transition to hyperreflexia
Autonomic	Evaluate for decreased rectal tone (heart rate, etc.)

Dermatologic

A cutaneous rash, if present, helps narrow the differential diagnosis to a stronger consideration of infectious or autoimmune mechanism.

NEUROLOGIC EXAM

Strength and Reflexes

Involvement of the lateral corticospinal tract results in upper motor neuron weakness: Below the lesion, one observes increased tone in velocity-dependent fashion (spasticity), as well as hyperreflexia (often but not always including an extensor response to noxious plantar stimulation). Ventral horn involvement results in lower motor neuron weakness *at* the lesion levels with decreased or flaccid tone as well as hyporeflexia. Atrophy takes weeks or longer to develop. Note that cervical injuries often demonstrate *both* types of weakness—lower motor neuron weakness at the cervical level (due to damage of the ventral horn) and upper motor neuron weakness below the lesion (due to damage of the passing corticospinal tracts).

A period of *spinal shock* lasting up to several days may result in the patient presenting with flaccid tone and diffuse hyporeflexia regardless of upper or lower motor neuron involvement. On examining any patient with an injury not involving the sacrum, spinal shock is confirmed by absence of the bulbocavernosus reflex. Key muscle groups useful for localizing spinal levels include elbow flexors (C5), wrist extensors (C6), elbow extensors (C7), intrinsic hand muscles (C8-T1), hip flexors (L2), knee extensors (L3), ankle dorsiflexors (L4), and ankle plantarflexors (S1).

Sensory

A sensory “level,” with sharply demarcated decreased or absent sensation below the level of the lesion, may be seen. Depending on the distribution of the lesion in the anteroposterior and mediolateral axes, different combinations of bilateral, ipsilateral, and contralateral sensory loss may be observed, such as loss of vibration and proprioception (dorsal columns) and/or loss of pain and temperature (anterolateral system). Useful dermatomal landmarks include the nipple line (T4) and navel line (T10).

DIAGNOSTIC TESTING

IMAGING

To visualize the cord parenchyma, intervertebral disks, and surrounding soft tissues, magnetic resonance imaging (MRI) with T2-weighted imaging is the gold standard (see also [Chapter 21](#)). If an infectious, inflammatory, or neoplastic process is suspected, post-intravenous gadolinium contrast sequences should be performed as well, unless the patient's renal function is compromised. If an ischemic process is suspected, then diffusion-weighted and apparent diffusion coefficient sequences warrant special attention, with consideration of magnetic resonance angiography. In general, MRI should focus on the cord region suspected to harbor the lesion. For example, the clinician should avoid the common mistake of imaging the lumbosacral cord in a patient presenting with bilateral leg weakness, leg hypertonia, and hyperreflexia. This upper motor neuron presentation strongly argues for a thoracic, not a lumbosacral lesion. It should be noted that a total spinal cord survey may be warranted in many situations, such as to assess for multiple lesions or diffuse meningeal involvement.

LABORATORY TESTING

A lumbar puncture should be performed as part of the diagnostic evaluation in patients with suspected infectious, inflammatory, or image-negative etiology. A list of tests to consider are listed in [Table 16.4](#).

INITIAL MANAGEMENT

SPINAL STABILIZATION

As part of the “ABCs” (airway, breathing, circulation) of emergency medicine, any acute traumatic spinal cord presentation should be immediately stabilized with a rigid cervical collar in the emergency department (ED) if not already applied in the field ([Table 16.5](#)). Please see [Chapter 47](#) for more on the management of acute spinal trauma.

INTENSIVE CARE UNIT ADMISSION

Intensive care, within a neurologic intensive care unit (ICU) if available, is preferred in any patient who has cardiovascular or pulmonary symptoms associated with the lesion or who has rapid progression of neurologic symptoms. The ICU setting allows for the frequent neurologic examination and urgent pulmonary and cardiovascular care that is often necessary to prevent further deterioration in the setting of acute cord pathology.

TABLE 16.5 Acute Spinal Cord Management Checklist

1. Stabilize cervical spine in all patients with traumatic or suspected traumatic etiology.

2. Assess need for ICU admission.

3. Consider neurosurgical consultation.

4. Pulmonary management: pulse oximetry, ABG, bedside pulmonary function tests

5. Cardiovascular management: telemetry, frequent or continuous blood pressure monitoring

6. Bowel care: neurogenic bowel protocol

7. Bladder care: frequent bladder scans with catheterization as appropriate

8. Skin care: aggressive monitoring and early treatment to prevent pressure ulcers

9. DVT prophylaxis: early initiation of chemoprophylaxis and mechanical devices

ICU, intensive care unit; ABG, arterial blood gas; DVT, deep vein thrombosis.

NEUROSURGICAL CONSULTATION

If the etiology of the patient's presentation is compressive, neurosurgical consultation is emergently required.

PULMONARY MANAGEMENT

Patients with high cervical or elongated multilevel cervical or thoracic lesions should be monitored for respiratory compromise even if intubation is not immediately needed. Not all patients will decompensate immediately. Hypercarbia often precedes hypoxia, so abnormalities are often present on arterial blood gas (ABG) before they become evident on pulse oximetry.

Regardless of lesion location, all patients with spinal cord compromise are at high risk of developing pulmonary complications such as atelectasis, pneumonia, and embolism. Incentive spirometry, chest physiotherapy, and early mobilization can mitigate these risks.

CARDIOVASCULAR MANAGEMENT

During the acute period, spinal shock may result in decreased sympathetic outflow leading to neurogenic hypotension, bradycardia, and arrhythmia. Therefore, patients should be closely followed using telemetry and frequent or continuous blood pressure monitoring. To prevent exacerbation of cord dysfunction from systemic hypoperfusion, a mean arterial pressure of at least 85 mm Hg for the first 7 days is recommended using fluid resuscitation and vasopressors as necessary.

BLADDER CARE

Urinary retention during the acute period places the patient at increased risk for urinary tract infection and renal complications. If the patient is still able to void, bladder scanning or catheterization for postvoid residuals is required every 6 hours. If the patient is unable to void acutely, a Foley catheter should be placed

initially, with the goal of transitioning to intermittent catheterization as soon as feasible to avoid complications in

the postacute period.

BOWEL CARE

Clinicians often assume that spinal cord injury simply causes bowel incontinence. However, the far more common bowel sequela is severe constipation or even an utter inability to defecate. Bowel retention can trigger episodes of life-threatening autonomic dysreflexia. In addition to an aggressive bowel protocol consisting of stool softeners, fiber, hyperosmotic agents, and intermittent colonic irritants, digital stimulation is often needed to trigger the rectocolic reflex. Patients with hand function should be trained by nurses experienced in spinal cord injury bowel care to self-perform digital stimulation on a fixed daily or every-other-day schedule.

SKIN CARE

Patients with cord dysfunction may lack the sensorimotor feedback required to make subtle adjustments in body position to relieve pressure on bony prominences. Hence, pressure ulcers are a critical concern during both the acute and chronic periods. Vigilant monitoring and aggressive treatment at the first sign of skin breakdown (erythema) are required. Frequent rotation by nursing or a rotating bed will aid in ulcer prevention.

DEEP VEIN THROMBOSIS PROPHYLAXIS

Patients with spinal cord lesions are at highly increased risk of developing deep vein thromboses (DVTs) and pulmonary emboli. Consequentially, multimodal DVT prophylaxis with both medication and sequential compression devices is warranted. Routine placement of prophylactic vena cava filters is not recommended.

STEROIDS

The extremely high-dose methylprednisolone protocol previously recommended during the first 24 to 48 hours after acute traumatic injury has fallen out of favor (see [Chapter 47](#)). However, the role of lower or moderate-dose glucocorticoids (decadron 4–10 mg IV q6H) in reducing inflammation and vasogenic edema from tumor or epidural abscess still warrants their use in many situations.

NEXT-GENERATION SPINAL CORD TREATMENTS

Clinicians caring for patients with acute spinal cord syndromes would be well served to treat their patients with the same mindset as they do for patients with acute brain injury—viable tissue can be saved through quick intervention and development of “next-generation” treatments. In the following section are some promising avenues for improving care and outcomes in acute spinal cord syndromes. Although these treatments are not evidence-based, the poor prognosis for recovery associated with acute spinal cord injury encourages many practitioners and teams to offer these interventions.

LIMITING SECONDARY DAMAGE

Therapeutic Hypothermia

In parallel to its use in ischemic cardiac and brain settings, the goal of mild to moderate hypothermia is to reduce cellular metabolic demand during the acute stages of spinal cord compression and ischemia. To date, only nonrandomized, noncontrolled cohorts have been reported using this modality in patients with spinal injury.

Antiexcitotoxic Agents

Many putative neuroprotective drugs have been trialed for efficacy in the setting of stroke and neurodegenerative disease. To date, all have failed. However, several neuroprotectants that have shown early promise in spinal cord injury are currently undergoing efficacy trials: riluzole (sodium channel and glutamate antagonist), magnesium (*N*-methyl-D -aspartate [NMDA] antagonist), and minocycline (anti-

inflammatory and antiapoptosis).

Perfusion Pressure Support

Maintenance of a mean arterial perfusion pressure above 85 mm Hg with the use of fluid resuscitation and vasopressors has been cited as a method for reducing secondary ischemic injury after acute spinal cord injury.

Intrathecal Pressure Relief

Decompression of vertebral or neoplastic tissue is a basic approach in situations involving trauma or metastatic encroachment. Necrosis, edema, and inflammation may cause ongoing increased intradural pressure and resultant hypoperfusion of the cord parenchyma. For this reason, work in animals as well as preliminarily in humans has begun to focus on the potential of performing durotomy or even myelotomy in the acute setting to improve local perfusion.

IMPROVING NEURAL PLASTICITY AND RECOVERY

Spared neural tissue persists even after clinically severe spinal cord syndromes. Therapies that increase activity and sprouting of residual neural circuitry show great promise in animal models. Multiple human trials on agents listed below are either underway or in planning stages. Importantly, these approaches are not mutually exclusive—optimal treatment will require combinations of drugs, electrical, and cellular approaches with intense physical rehabilitation.

Intrinsic Neural Reactivators

These drugs stimulate intrinsic neuronal second-messenger pathways: rolipram (cyclic adenosine monophosphate [AMP] agonist), SUN13837 (basic fibroblast growth factor agonist), dalfampridine (potassium channel antagonist), and lithium (glycogen synthase kinase 3 inhibitor).

Extrinsic Inhibitor Antagonists

These drugs block the inhibitory role played by myelin proteins and chondroitin sulfate proteoglycans in limiting neural regeneration: ATI 355 (anti-Nogo-A antibodies), chondroitinase ABC, and BA-210 (Rho antagonist).

Neural Reactivating Devices

Exoskeletal robotic devices for improving arm and leg function are rapidly evolving. But implanted epidural stimulation represents the most promising device-based approach to truly reactivating spared neural circuits. Early human results show that when implanted over the lower cord, these devices, already U.S. Food and

P.136

Drug Association (FDA) approved as spine stimulators for patients with chronic pain, can amplify endogenous signals from residual circuitry to result in voluntary leg movement in patients that previously had complete motor paraplegia.

Stem Cells

Long heralded as the cure for most ills, stem cells continue to make slow progress toward practical clinical application. In spinal injury, implantation of predifferentiated stem cells may improve recovery through release of neurotrophic growth factors as well as through improved remyelination of residual axons.

Focal Mass Lesions

Michelle Wilson Bell

Alexander G. Khandji

Fabio M. Iwamoto

INTRODUCTION

The differential diagnosis of an undifferentiated focal brain mass lesion is broad and the clinical presentation quite variable. This chapter will discuss the major etiologic categories of focal brain mass lesions—namely tumors, abscesses, and other inflammatory lesions—and present an algorithm for implementing empiric management in stable patients while a definitive diagnosis is pursued.

EMERGENT MANAGEMENT OF SYMPTOMATIC INTRACRANIAL MASS EFFECT

The first step in management of a focal mass lesion is to assess for increased intracranial pressure (ICP) and signs of herniation in patients with radiographic signs of mass effect and midline shift.

Common symptoms and signs of increased ICP include headache, vomiting, depressed level of consciousness, papilledema, abducens nerve palsies, and hypertension with or without bradycardia (Cushing reflex). As mass effect worsens, in addition to the expected contralateral hemiparesis, patients develop motor signs *ipsilateral* to the lesion as a result of lateral and rotation displacement of both corticospinal tracts. Common signs include stiffening, hyperreflexia, and extensor plantar responses. With further brain tissue displacement, transtentorial herniation leads to ipsilateral third nerve palsy (“blown pupil”).

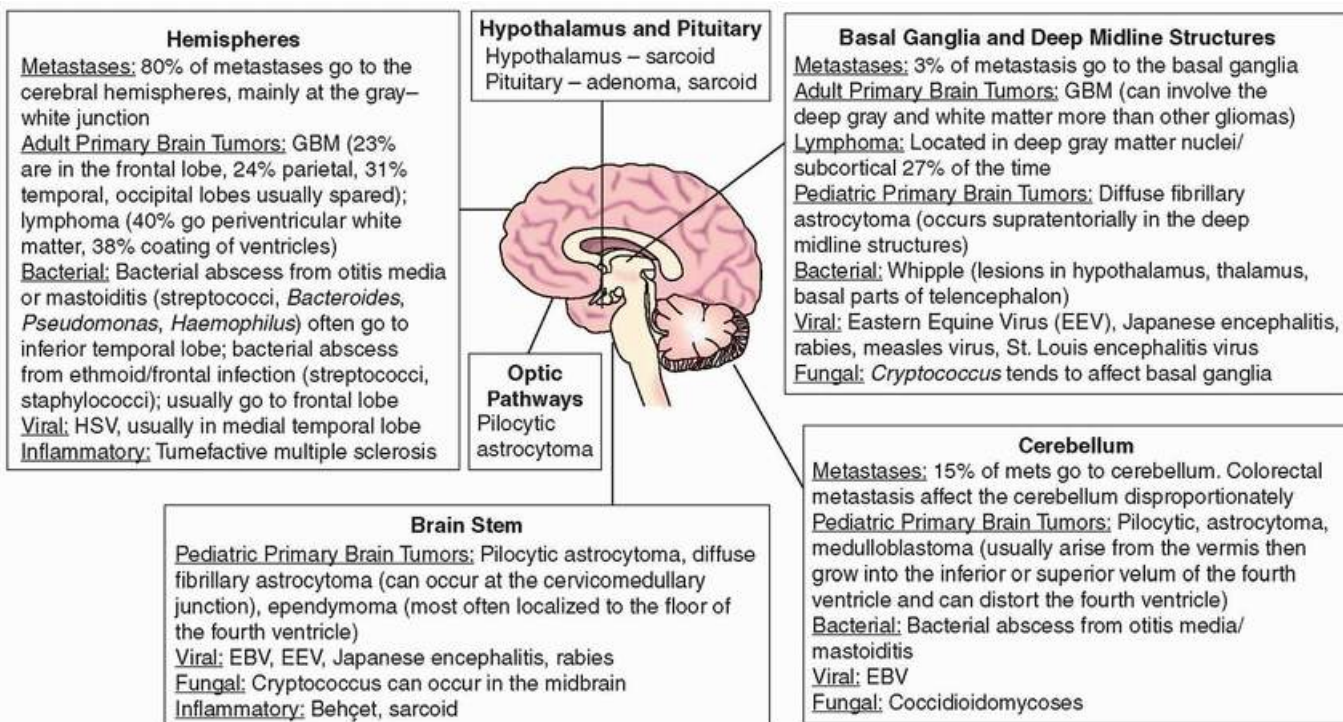

FIGURE 17.1 Common causes of focal lesions in the brain based on location. GBM, glioblastoma; HSV, herpes simplex virus; EBV, Epstein-Barr virus.

If the clinical assessment is concerning for elevated ICP, it is imperative to take immediate measures to reduce it.

First-line interventions include head elevation to 30 degrees and bolus osmotherapy with either 20% mannitol 1 g/kg intravenously (IV) or 30 mL of 23.4% hypertonic saline if there is central venous access. If level of consciousness is depressed with inability to maintain and protect the airway, the patient should be intubated and hyperventilated to PaCO₂ of 30 mm Hg while awaiting definitive treatment (see [Chapter 107](#) for further details).

If there is no evidence of increased ICP, further management should be determined by the clinician's assessment of the most likely underlying cause of the mass lesion. This chapter will discuss the diagnostic evaluation of undifferentiated mass lesions and the initial steps in management depending on the suspected diagnosis.

CAUSES OF FOCAL BRAIN LESIONS

[Figure 17.1](#) shows common causes of focal lesions of the brain not consistent with stroke or trauma based on location.

P.138

BRAIN TUMORS

Tumors account for the majority of focal brain mass lesions. In adults, *metastatic tumors* account for approximately 50% of symptomatic brain tumors ([Fig. 17.2](#)). The most common primary tumor to metastasize to the brain is lung cancer. Approximately 50% to 60% of brain metastasis originate from lung cancer, with 25% to 40% being of non-small cell lung cancer (NSCLC) origin and 5% to 15% being of small cell lung cancer (SCLC) origin. About 20% of lung cancer brain metastases are found at the time of initial diagnosis. The next most common sources of brain metastases are breast cancers (15% to 30%), melanoma (10%), renal cancer (5%), and gastrointestinal cancers (5%) (see [Chapter 97](#)).

FIGURE 17.2 Metastatic small cell lung cancer. T1 MRI of the brain shows multiple small enhancing metastatic nodules.

FIGURE 17.3 Large parasagittal olfactory groove meningioma strongly enhancing after contrast. Note the small cleft of CSF noted along the left margin of the lesion (coronal image, panel A).

FIGURE 17.4 Glioblastoma multiforme. T1 MRI shows central necrosis and ring enhancement with a nodular component extending into the center of the lesion.

Approximately 70,000 primary brain tumors are diagnosed each year. The most common form of primary brain tumor found in adults are *meningiomas* (35%). These dural-based masses enhance densely with gadolinium on magnetic resonance imaging (MRI) (Fig. 17.3) and are easy to identify prior to surgery due to their highly characteristic appearance (see Chapter 98). *Gliomas* are the second most common form of primary tumor accounting for 30% of all brain tumors (see Chapter 97). Glioblastoma multiforme is the most common form of glioma and account for 80% of all malignant brain tumors (Fig. 17.4). Anaplastic astrocytoma and oligodendrogliomas (Fig. 17.5) are lower grade tumors that show less prominent enhancement and no necrosis. Less common

P.139

adult primary brain tumors, in order of frequency, are pituitary adenomas (Fig. 17.6 and Chapter 100), nerve sheath tumors such as acoustic neuromas (see Chapter 102), and primary central nervous system (CNS) lymphomas (Fig. 17.7 and Chapter 99). Table 17.1 outlines typical clinical features, imaging findings, and suggested ancillary testing in adult patients with suspected brain neoplasm.

A

B

FIGURE 17.5 FLAIR (A) and T1 gadolinium enhanced (B) MR of a right frontal oligodendroglioma showing very little contrast enhancement and very little surrounding edema.

A

B

FIGURE 17.6 Pituitary macroadenoma. A: Hypointense on T1. B: Enhancing postcontrast.

In children, the most common primary brain tumors are gliomas (40%) including pilocytic astrocytoma (Fig. 17.8), embryonal tumors (15%) including medulloblastoma (Fig. 17.9), and ependymoma (~5%). Table 17.2 outlines typical clinical features, imaging findings, and suggested ancillary testing in children with suspected brain neoplasm (see also Chapter 145).

FIGURE 17.7 Primary CNS lymphoma. **A:** MRI restricted diffusion of DWI. **B:** Reduced apparent diffusion coefficient (ADC) appears as a dark core. **C:** T1 hypointense. **D:** T2 hyperintense peripherally due to edema tracking through the white matter. **E:** Avid contrast enhancement with gadolinium on T1 imaging.

TABLE 17.1 Common Adult Brain Tumors

	Clinical Pearls	Imaging Features	CSF Studies and Systemic Workup
Metastatic tumors (in order of decreasing)	Lung <ul style="list-style-type: none"> • Small cell lung cancer eventually metastasized to the 	<ul style="list-style-type: none"> • 80% of brain metastases occur in the cerebral hemispheres, 15% in the cerebellum, and 5% in the basal ganglia. 	More than 60% of patients with brain metastases will have a mass

<p>frequency)</p> <p>Breast</p> <ul style="list-style-type: none"> • HER2+/ER- receptor status portends a higher likelihood of metastasis to the brain. <p>Melanoma</p> <ul style="list-style-type: none"> • Head, neck, and primary oral lesions have a higher rate of metastasis. <p>Renal</p> <ul style="list-style-type: none"> • In up to 10% of patients, a new metastasis later develops in patients who were thought to have been cured of their primary tumor. <p>Colorectal</p> <ul style="list-style-type: none"> • Left-sided cancers are more likely to metastasize to the lung and brain, whereas right-sided tumors usually go to liver. 	<p>brain in up to 50% of cases.</p>	<ul style="list-style-type: none"> • Metastases tend to localize to the gray-white junction location and the border zone between two major arterial distributions. • Brain metastases are multiple, approximately 50% of cases. • FLAIR imaging tends to reveal a large amount of associated vasogenic edema. • MR spectroscopy shows low <i>N</i>-acetylaspartate (NAA) and creatine levels and elevated choline levels reflecting cell membrane and myelin turnover. • Gradient echo or SWI may demonstrate hemosiderin deposits in cancers that tend to hemorrhage (e.g., melanoma, choriocarcinoma, renal cell, and thyroid cancer). Melanoma tends to be hyperdense on CT scan even in the absence of hemorrhage. On MRI, melanoma is hyperintense on T1 and hypointense on T2. • Colorectal metastases involve the cerebellum disproportionately. 	<p>demonstrated on chest imaging that is either due to a primary lung cancer or lung metastases from a primary tumor elsewhere. Tests to consider when brain metastases are suspected:</p> <ul style="list-style-type: none"> • Mammogram • Skin exam • Whole-body CT • Whole-body FDG-PET
---	-------------------------------------	---	--

--	---	-------------	-------------

Gliomas

- 30% of all primary brain tumors
- Average age of diagnosis:
 - Glioblastoma: 65 yr
 - Anaplastic astrocytoma: 50 yr
 - Oligodendroglioma: 40 yr
 - Anaplastic astrocytoma usually evolves from a lower grade astrocytoma.

Glioblastoma (GBM)

- Causes extensive edema in the deep white matter
- Enhances with gadolinium
- Central areas of necrosis restrict on DWI (bright)
- May have satellite lesions
- Tumor often crosses the corpus callosum and anterior commissure.
- MR spectroscopy: Cho/NAA ratio >2.2 is thought to be high grade.

Anaplastic astrocytoma

- Some contrast enhancement but no necrosis

Oligodendroglioma

- 40%-80% rate of calcification
- Enhances in 50%-70%
- Hemorrhage or cyst formation occurs in 20%.
- Usually, there is little edema.

Order lower extremity Doppler in patients with GBM. Ultimately, up to 25% of these patients suffer from venous thromboembolism during the first year of diagnosis.

Pituitary adenoma

10% of all primary brain tumors

Classified as secretory (75%) and nonsecretory (25%)

Prolactinoma

- Amenorrhea
- Galactorrhea
- Gynecomastia
- Erectile dysfunction or impotence
- Infertility
- Decrease in body hair

Growth-hormone-producing tumor:

- Gigantism
- Acromegaly

Adrenocorticotrophic hormone (ACTH)-producing tumors

- Cushing syndrome

Thyroid-stimulating hormone (TSH)-producing tumors:

- Primary

- Tends to be hypodense on CT
- Microadenomas are generally hypointense on T1 and variable intensity on T2.
- Adenomas do not enhance as much, and enhance later, than normal pituitary tissue. Dynamic contrast-enhanced MRI scans are best of delineate adenomas.
- Macroadenoma are adenomas >10 mm. They have a propensity for hemorrhage and infarction (pituitary apoplexy).
- Differential diagnosis:
 - Rathke cyst: hyperintense on T1 and does not enhance
 - Craniopharyngioma: has cystic lesions and calcifications

Pituitary hormone panel

- Prolactin
- FSH
- LH

Serum and 24-h urine cortisol levels
TSH and T3/T4 levels

Growth hormone
Formal visual field testing and ophthalmologic evaluation are critical.

Serum prolactin >200 µg/L with an adenoma >10 mm in size is diagnostic of a prolactinoma.

Primary central nervous system lymphoma (PCNSL)

- Causes <5% of all primary brain tumors
- Immunocompromised state (e.g., HIV, transplant) is a major risk factor.
- Among immunocompetent patients, the mean age of onset is 60 yr and there is a slight male predominance.

Tends to be hypodense on CT
MRI features

- T1 hypointense and T2 hyperintense
- DWI shows diffusion restriction (bright)

Anatomic predilection

- Periventricular white matter in 40%
- Coating of ventricles in 40%
- Deep gray matter nuclei/subcortical in 30%
- Unusual multifocal distribution of tumor can occur.

Diffusely enhancing in the immunocompetent patients; necrotic center can occur in immunocompromised patients.

Spread across corpus callosum is suggestive of PCNSL.

Masses tend to be <2 cm in patients with AIDS and >2 cm in non-AIDS patients.

Slit lamp examination reveals intraocular involvement in 15% of patients.

CSF, cerebrospinal fluid; FLAIR, fluid-attenuated inversion recovery; MR, magnetic resonance; SWI, susceptibility-weighted imaging; CT, computed tomography; MRI, magnetic resonance imaging; FDG-PET, ¹⁸F-fluorodeoxyglucose positron emission tomography; DWI, diffusion-weighted imaging; FSH, follicle-stimulating hormone; LH, luteinizing hormone.

FIGURE 17.8 Pilocytic astrocytoma with high signal intensity on FLAIR imaging invading the midbrain.

FIGURE 17.9 Medulloblastoma with distortion of the fourth ventricle and secondary hydrocephalus. **A and B:** Hypointense on T1. **C:** Moderate partial gadolinium enhancement.

P.144

CEREBRITIS AND ABSCESSSES

Approximately 1,500 cases of brain abscess occur annually in the United States with an incidence of 0.3 to 1.3 cases per 100,000 of the population annually. Brain abscess (see [Chapter 62](#)) is most commonly caused by bacterial infection ([Fig. 17.10](#)), most commonly streptococci and staphylococci. Focal brain infection resulting in cerebritis or abscess can also be caused by *fungi* ([Table 17.3](#)). Among fungal infections, aspergillosis ([Fig. 17.11](#)), cryptococcosis ([Fig. 17.12](#)), candida, mucormycosis, and nocardia are most common in immunosuppressed patients. *Blastomyces*, *Histoplasmosis*, and

P.145

P.146

P.147

Coccidioides are most common in immunocompetent patients. The most common *parasitic* organisms that causes brain abscess are by far toxoplasmosis ([Fig. 17.13](#)) and cysticercosis ([Fig. 17.14](#)), although *Strongyloides* and *Entamoeba histolytica* are also common causes (see [Chapter 65](#)). *Tuberculosis* forms solid tuberculomas; after the caseous core liquefies, the tuberculoma becomes a tuberculous abscess (see [Chapter](#)

64). *Syphilis* can form gummas, cysticercosis can cause an inflammatory mass lesion when the cyst degenerates and dies, and viruses such as *herpes simplex 1* (see [Chapter 66](#)) can cause encephalitis complicated by acute swelling and inflammation of the affected temporal lobes ([Fig. 17.15](#)).

TABLE 17.2 Common Pediatric Brain Tumors

	Clinical Pearls	Imaging Features	CSF Studies and Systemic Workup
Gliomas <ul style="list-style-type: none"> Grade 1: pilocytic astrocytoma (see Fig. 17.7) Grade 2: diffuse fibrillary astrocytoma 	Two main types in children: <ul style="list-style-type: none"> Pilocytic astrocytoma Diffuse fibrillary astrocytoma 	<ul style="list-style-type: none"> Pilocytic astrocytoma is predominately located in the cerebellum, optic pathways, and the dorsal brain stem. Well circumscribed with a cystic component and an enhancing mural nodule Diffuse fibrillary astrocytoma occurs more often supratentorially in deep midline structures and at the cervicomedullary junction. Hypointense on T1 and hyperintense on T2 with varying degrees of enhancement 	None
Medulloblastoma	Peak incidence is approximately between 5 and 10 yr of age Occurs in boys twice as often as girls	<ul style="list-style-type: none"> Accounts for 50% of cerebellar tumors in children Usually arise from the vermis then grow into the inferior or superior velum of the fourth ventricle As opposed to ependymoma, medulloblastoma distorts the fourth ventricle. Well circumscribed and hyperdense on CT. Up to 20% have calcification or cystic changes. MRI often has diffusion restriction on DWI. Medulloblastoma tends to enhance to a moderate degree. 	None

Ependymoma

Among pediatric patients, peak incidence among infants, toddlers, and preschoolers. Another peak of incidence occurs in adults.

- Intracranial in 90% of pediatric patients (more often spinal in adults); most often localized to the floor of the fourth ventricle
- Hypodense to isodense on CT
- Calcification in up to 50%, cystic changes in 15%. Mild enhancement is the rule.

Spinal MRI is mandatory if cranial ependymoma is suspected. Spinal drop metastasis occurs in 5% of cases.

CSF, cerebrospinal fluid; CT, computed tomography; MRI, magnetic resonance imaging; DWI, diffusion-weighted imaging.

FIGURE 17.10 Left basal ganglia abscess. **A and B:** Bright on DWI (**A**) with restricted ADC. (*continued*)

FIGURE 17.10 (continued) Left basal ganglia abscess. **C and D:** T2 images show hyperintense core and a hypointense ring (**C**) and postcontrast T1 image shows sharply demarcated thin rim enhancement post contrast.

FIGURE 17.11 Focal *Aspergillus* infection with little edema or mass effect. **A:** Bright on DWI with restriction. **B:** Dark on ADC suggesting necrosis. **C:** Heterogeneous coarse irregular enhancement on T1 with gadolinium.

FIGURE 17.12 Cryptococcal meningitis with hydrocephalus and small punctate areas of enhancement in the midbrain (A) and basal ganglia (B) on T1-enhanced imaging.

TABLE 17.3 Common Infectious Etiologies of Mass Lesions

	Clinical Pearls	Imaging Features	CSF Studies and Systemic Workup
Bacterial abscess	Most abscesses in immunocompetent individuals are bacterial. Only 50% of patients have fever on initial presentation.	<ul style="list-style-type: none"> • Characterized on T2 imaging as hyperintense core and hypointense ring, both of which restrict on DWI. • Ring enhancement with contrast imaging • MRS features: <ul style="list-style-type: none"> ◦ Pyogenic aerobic abscess: Amino acids, lactate, and lipid are elevated. ◦ Pyogenic anaerobic abscess: Succinate and acetate are elevated. ◦ Tuberculosis (TB): Only lipid is elevated. 	<ul style="list-style-type: none"> • Blood cultures • Transesophageal echocardiography to detect a valvular vegetation • LP may reveal concurrent meningitis.
Tuberculoma	When the caseous core	CT appearance	Tuberculin skin test

of the tuberculoma liquefies, a tuberculous abscess results.

- Solid-enhancing, ring-enhancing, or mixed lesions
- Occasionally, there is the “target sign,” which is pathognomonic of TB: central calcification surrounded by a hypodense area with peripheral ring enhancement.

is positive in up to 85% of patients. Chest CT suggests pulmonary TB in 50%-80% of patients.

MRI appearance

- DWI: no abnormalities or can be bright with restriction like a bacterial abscess
- T1: isointense in gray matter with a hyperintense ring
- T2: noncaseating: hyperintense with nodular enhancement; caseating: iso-/hypointense with ring enhancement

<p>Gummatous neurosyphilis</p>	<p>Histology reveals that the central portion of the mass is necrotic material, and the peripheral region is infiltrated with plasma cells.</p>	<ul style="list-style-type: none"> • CNS gummas can arise from the meningeal surfaces and extend directly into the brain or may arise directly from the parenchyma. • Presents as a ring-enhancing mass lesion 	<p>Serum RPR and FTA-ABS CSF VDRL</p>
<p>Viral encephalitis</p>	<p>HSV-1 only rarely causes a typical vesicular skin eruption in the setting of meningitis.</p>	<ul style="list-style-type: none"> • DWI sequences on MRI are most sensitive for detecting tissue injury from encephalitis. • Herpes encephalitis can cause significant swelling and mass effect of the temporal lobes, mimicking tumor. 	<p>CSF shows lymphocytic pleocytosis with normal or decreased glucose but can be normal.</p>
<p>Fungal</p>	<p>Immunocompromised</p> <ul style="list-style-type: none"> • Aspergillosis • Cryptococcosis • Candida • Mucormycosis • Nocardia <p>Immunocompetent</p> <ul style="list-style-type: none"> • <i>Blastomyces</i> • <i>Histoplasma</i> 	<ul style="list-style-type: none"> • DWI shows restricted diffusion in the wall of a fungal abscess. Typically, the core does not show restriction (unlike in a bacterial abscess). • MRS can show increased trehalose, amino acids, and lactate. 	<p>CSF shows lymphocytic predominance, although neutrophils may predominate early in the course. <i>Histoplasmosis</i> causes CSF mononuclear</p>

- *Coccidioides*
 - Anatomic predilections
 - *Cryptococcus*: predominately in midbrain and basal ganglia
 - Coccidioidomycosis: predilection for the cerebellum
 - Mucormycosis: rim of soft-tissue thickness along the walls of the paranasal sinus. In some cases, bony destruction is present.
 - Nocardial: enhancing capsule containing multiple loculations
 - Aspergillosis: Aggressive forms manifest as meningoencephalitis; less aggressive forms manifest as solitary abscess or isolated granulomas.
- pleocytosis. *Coccidioides* may cause CSF eosinophilia.

<p>Helminthic infection</p>	<p>Travel history</p> <ul style="list-style-type: none"> • Coenurosis cerebrealis: sheep-raising areas North America/Europe/South America/Africa • Cysticercosis: endemic in Latin America, sub-Saharan Africa, and some regions of Asia • <i>Echinococcus granulosus</i>: reported in the Americas as well as Mediterranean countries • <i>Ascaris</i>: endemic in North America. Host are raccoons. • <i>Paragonimus</i>: Asia and South Pacific Islands • <i>Schistosoma japonicum</i>: Southeast Asia • <i>Spirometra</i>: Southeast Asia and 	<p>Cyst-forming</p> <ul style="list-style-type: none"> • Coenurosis • Cysticercosis • <i>Echinococcus granulosus</i> <p>Granuloma-forming</p> <ul style="list-style-type: none"> • <i>Ascaris</i> • <i>Paragonimus</i> • <i>Schistosoma japonicum</i> • <i>Spirometra</i> • <i>Toxocara</i> • <i>Trichinella</i> <p>Abscess</p> <ul style="list-style-type: none"> • <i>Strongyloides</i> 	<p>CSF shows lymphocytic predominance except: <i>Trichinella</i>, which demonstrates eosinophilic pleocytosis. <i>Strongyloides</i>, which demonstrates a neutrophilic pleocytosis.</p>
------------------------------------	--	---	---

the Americas

- *Toxocara*: worldwide
- *Trichinella*: worldwide
- *Strongyloides*: Latin America, Caribbean, Africa, Asia

Protozoal infections

Immunosuppressed

- *Acanthamoeba*: transmitted via swimming in freshwater pools
- Toxoplasmosis: transmitted via food or congenitally
- *Entamoeba histolytica* is associated with liver abscess.

Granulomatous encephalitis

- *Acanthamoeba*
 - Toxoplasmosis
- Brain abscess
- *Entamoeba histolytica*

- *Acanthamoeba*
- CSF protein and glucose usually normal
- Toxoplasmosis
- The presence of IgG antibodies indicates prior exposure to the parasites and potential for reactivation

CSF, cerebrospinal fluid; DWI, diffusion-weighted imaging; MRS, magnetic resonance spectroscopy; LP, lumbar puncture; MRI, magnetic resonance imaging; CT, computed tomography; CNS, central nervous system; RPR, rapid plasma reagin; FTA-ABS, fluorescent treponemal antibody absorption; VDRL, Venereal Disease Research Laboratory; HSV-1, herpes simplex virus 1; IgG, immunoglobulin G.

OTHER INFLAMMATORY LESIONS

Occasionally, noninfectious inflammatory processes can also cause mass lesions (Table 17.4). Most notoriously, *multiple sclerosis* (see Chapter 69) can form a large demyelinating mass lesion known as *Marburg variant* or *tumefactive multiple sclerosis* (Fig. 17.16). *Sarcoidosis* (see Chapter 72) can also present as an inflammatory intraparenchymal mass lesion. *Radiation necrosis* can present as a space-occupying mass lesion months to decades after prior radiation treatment (see Chapter 105).

FOCUSED HISTORY

DEMOGRAPHICS

Age is an important factor for narrowing the differential diagnosis particularly for brain tumors. Children develop a very different set of brain tumors than do adults. Ependymoma affects the youngest children (high incidence among infants, toddlers, and preschoolers), followed by medulloblastoma and pilocytic astrocytoma (peak incidence between 5 and 10 years of age), oligodendroglioma (incidence peak at 40 years of age), anaplastic astrocytoma (incidence peak at 50 years of age), and glioblastoma (incidence peak at 65 years of age). The average age at diagnosis for pituitary adenomas and meningiomas straddle several decades, with pituitary adenomas primarily being diagnosed between age 20 and 50 years and meningiomas between age 40 and 60 years. Pituitary adenoma and meningiomas occur more commonly in women.

TIME COURSE

Symptoms associated with abscesses tend to develop acutely to subacutely (with bacterial infections presenting more acutely and

fungal infections more subacutely), whereas tumors present more subacutely to chronically based on their grade (for instance, glioblastoma tends to have a more subacute presentation as compared to meningiomas which tend to have a more chronic presentations).

TABLE 17.4 Select Inflammatory Causes of Focal Brain Lesions

	Clinical Pearls	Imaging Features	CSF Studies and Systemic Workup
Sarcoidosis	<ul style="list-style-type: none"> • Sarcoidosis primarily occurs in the third and fourth decade. • Five percent of cases of systemic sarcoid have neurologic involvement. 	<ul style="list-style-type: none"> • Intraparenchymal sarcoid masses may or may not enhance. • Nodules may be calcified, have an increased density, or be isodense and can occur throughout the brain parenchyma. • Nodular meningeal enhancement is common. • The nodules are not usually associated with edema. • Sarcoid nodules do not cavitate as frequently as tuberculosis. 	<ul style="list-style-type: none"> • Chest CT • Gallium scan • Lacrimal gland biopsy • CSF and serum ACE activity

Whipple disease

- Mean age of onset is around 50 yr.
 - Men are more commonly affected (80%).
 - In about 5% of the cases, the presentation is solely neurologic. In other cases, the small bowel is involved.
 - Granuloma formation is a delayed hypersensitivity to Whipple disease.
- The lesions are in the gray matter, in the basal part of the telencephalon, the hypothalamus, and the thalamus.
- *Tropheryma whippelii* PCR
 - Small bowel biopsy

Behçet disease

- Most common in the countries around the eastern shores of the Mediterranean, the Middle East, and Eastern Asia
 - Mean age of onset of neurologic symptoms is about 30 yr of age.
 - Triad of recurrent genital ulcerations, skin or eye lesions, and meningitis
- Predilection for brain stem
 - Enhancement may occur as a ring or nodule.
- May also present as cortical vein thrombosis or isolated increased intracranial pressure

Tumefactive multiple sclerosis

- Mean age of onset is approximately 35 yr of age.
 - The female-to-male prevalence is 1.2:1.
 - May have had previous neurologic symptoms isolated in space and time supportive of multiple sclerosis as a diagnosis
- Demyelinating lesion ≥ 2 cm in size
 - Incomplete ring enhancement open on the gray matter side of the lesion
 - Does not restrict on DWI
 - MR perfusion normal
- C-spine MRI

CSF, cerebrospinal fluid; CT, computed tomography; ACE, angiotensin-converting enzyme; PCR, polymerase chain reaction; DWI, diffusion-weighted imaging; MR, magnetic resonance; MRI, magnetic resonance imaging.

PAST MEDICAL HISTORY

It is essential to learn whether there was a past history of cancer and/or a history of immunosuppression. In patients with a history of systemic cancer, certain details are helpful in determining the likelihood that brain mass is a metastatic tumor. SCLC metastasizes to the brain in about 50% of instances as opposed to 7% in cases of NSCLC. In patients with prior breast cancer, HER2+/ER- status portends a higher likelihood of metastasis to the brain. The same applies for melanoma patients with head/neck/oral lesions and colorectal cancer patients with

left-sided cancers. Regarding immunosuppression, a history of HIV is a major risk factor for primary central nervous system lymphoma (PCNSL) and toxoplasma infection (see [Chapter 67](#)), whereas neutropenia and steroid use is a major risk factor for aspergillosis, candida, mucormycosis, and nocardia infections. Other important history elements include the following:

- A prior distant (usually 5 to 30 years prior) history of irradiation, which increases the long-term risk of meningiomas and malignant glioma
- A recent history of radiation treatment, which can lead to radiation necrosis
- A history of systemic sarcoidosis, which increases the likelihood that a brain mass is due to neurosarcoidosis
- Prior diagnoses of amenorrhea, galactorrhea, erectile dysfunction, infertility, or hyperthyroidism, which can be seen in pituitary adenomas

P.150

FIGURE 17.16 Tumefactive multiple sclerosis with a large high-intensity focal mass lesion in the right parietal lobe on FLAIR imaging. Note the periventricular lesions.

SOCIAL HISTORY

The social history portion of the interview may reveal HIV risk factors and/or risk factors for systemic cancers such as smoking history. Additionally, the patient's travel history may be helpful, particularly for identifying potential fungal and helminthic infections (see [Table 17.1](#)).

REVIEW OF SYSTEMS

In the neurologic review of systems, a history of episodic changes in neurologic status may indicate either an epileptic seizure or an ICP plateau wave. Plateau waves are thought to be the result of a sudden increase in cerebral blood volume because of a sudden decrease in cerebral vascular resistance. Patients who have diminished blood flow absorption, either from an intracranial mass or leptomeningeal disease, are more likely to develop plateau waves than patients with normal cerebrospinal fluid (CSF) absorption.

Another important point of query should focus on prior episodes of focal neurologic deficits lasting days in distributions characteristic of multiple sclerosis attacks, such as unilateral vision loss, bilateral leg paresthesias, unilateral arm weakness/paresthesia, or double vision. This can point to tumefactive multiple sclerosis as the causative etiology.

Symptoms of subacute to chronic weight loss can point to an occult malignancy and when combined with fever and night sweats may indicate either a CNS lymphoma or tuberculosis, given the clinical context. History of galactorrhea or gynecomastia can raise concern for pituitary adenoma (see [Chapter 100](#)).

FOCUSED EXAM

In patients with focal mass lesions of the brain, the most important role of the exam is to assess for increased ICP and herniation. A pale optic disc, red desaturation, partial internuclear ophthalmoplegia, and increased leg reflexes with normal arm reflexes can all be indications of prior multiple sclerosis demyelinating episodes.

The next most important elements of the exam are found in the general exam. Patients with undetermined focal mass lesions require a careful lung, breast, skin, and gastrointestinal exam to assess for lumps or masses suggestive of malignancy.

The breast exam is also helpful to assess for gynecomastia, which can occur with pituitary adenoma. Skin examination may also be helpful to look for herpes simplex rashes, melanoma, Kaposi sarcoma, or peripheral manifestations of bacterial endocarditis such as Janeway lesions (nontender, small erythematous macular lesions on the palms or soles only a few millimeters in diameter that are indicative of infective endocarditis).

DIAGNOSIS

The diagnostic cornerstones for brain masses are imaging, lumbar puncture, and biopsy.

IMAGING

Usually, a computed tomography (CT) scan (see [Chapter 20](#)) is the first radiographic study performed when a patient presents with a new neurologic symptom. Most focal brain lesions from tumor or abscess tend to be hypodense on CT. Admixture of heterogeneous hyperdense signal usually represents hemorrhage into a tumor (typically glioblastoma multiforme) or less commonly an abscess. A homogenous hyperdense pattern can result from melanoma, medulloblastoma, or meningioma. Calcification, usually punctate, occurs in 40% of ependymomas, 20% of meningiomas, and 10% of medulloblastomas. Tuberculomas have a pathognomonic “target sign” resulting from central calcification surrounded by a hypodense area with peripheral ring enhancement with IV contrast.

Although the CT scan can sometimes be helpful, an MRI (see [Chapter 21](#)) is always recommended unless there is a contraindication (e.g., pacemaker). The important MRI sequences are diffusion-weighted imaging (DWI), fluid-attenuated inversion recovery (FLAIR), susceptibility-weighted imaging (SWI), T1 precontrast, and T1 postcontrast. Important imaging features are reviewed in [Table 17.1](#).

Magnetic resonance (MR) spectroscopy is sometimes pursued, although its use is limited. Primary brain tumors are classically thought of as having an increased choline/*N*-acetylaspartate (NAA) ratio (with ratio >2 suggestive of a high-grade tumor). In high-grade brain tumors, the surrounding FLAIR hyperintensity is thought to represent infiltrative tumor and also has an elevated choline/NAA ratio, whereas in metastatic

tumor, this surrounding FLAIR hyperintensity is thought to represent vasogenic edema and therefore has a low choline level. Additionally, lactate is thought to be very elevated in infections, although it can also be elevated in necrotic tumors, making the distinction somewhat difficult.

Brain positron emission tomography (PET) scans (see [Chapter 22](#)) can be helpful in distinguishing between radiation necrosis and recurrent tumor in that radiation necrosis is hypometabolic and recurrent tumor is hypermetabolic. The PET scan would also demonstrate increased metabolism in a high-grade tumor as opposed to a lowgrade tumor. PET scans, however, have poor spatial resolution and are not useful for lesions smaller than 1 cm.

Whole-body CT scanning should be pursued whenever metastatic disease is being entertained.

LUMBAR PUNCTURE AND BIOPSY

Lumbar puncture (see [Chapter 31](#)) is an essential part of the neurologic examination in patients with intracranial mass lesions. CSF examination can reveal an infectious organism or the presence

P.151

of malignant cells by cytology when CNS lymphoma, germ cell tumors, or carcinomatous meningitis is suspected.

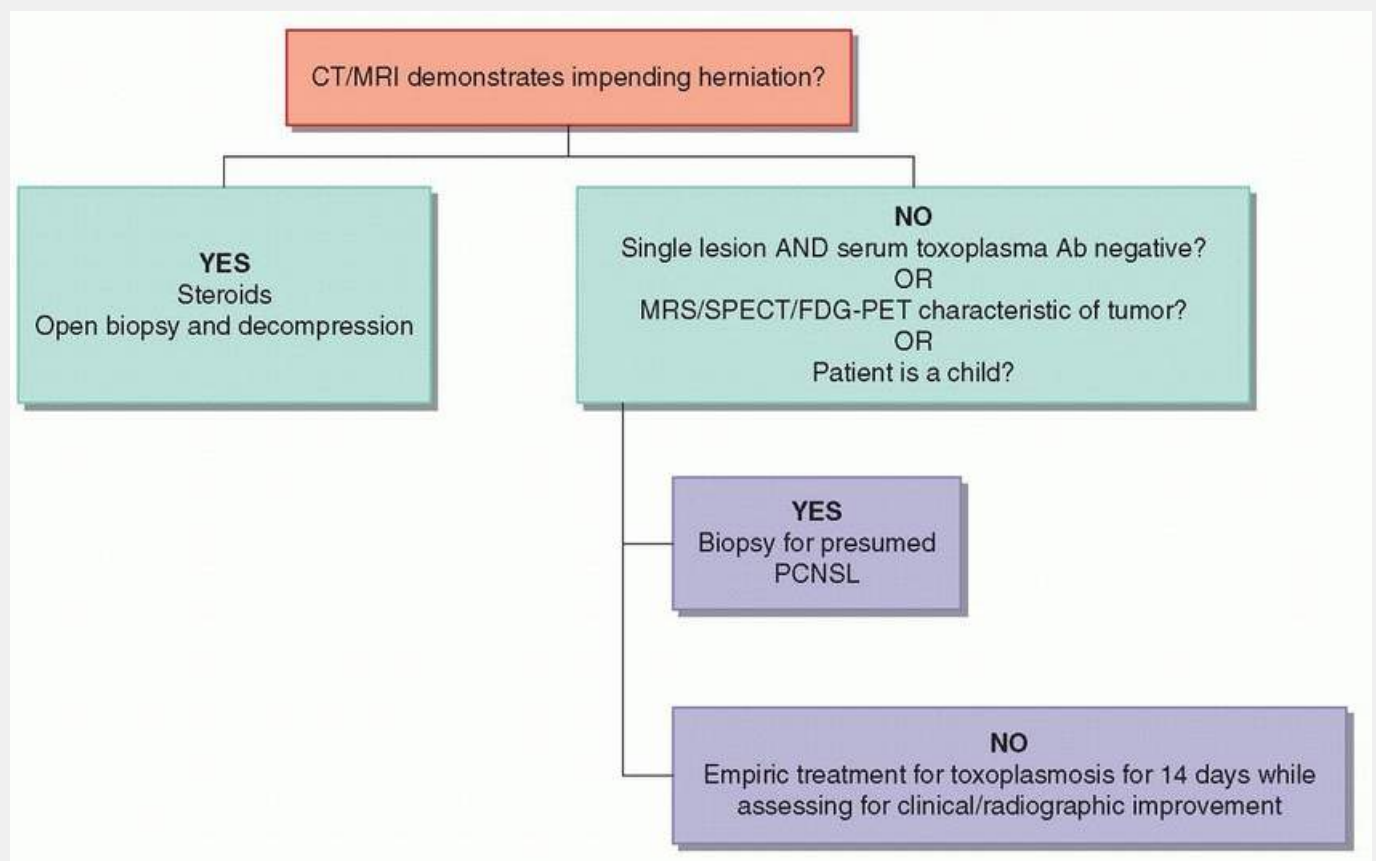

FIGURE 17.17 Algorithm for diagnosis and management of enhancing mass lesions in an AIDS patient. CT, computed tomography; MRI, magnetic resonance imaging; MRS, magnetic resonance spectroscopy; SPECT, single-photon emission computed tomography; FDG-PET, 18F-fluorodeoxyglucose positron emission tomography; PCNSL, primary central nervous system lymphoma.

For most primary brain tumors, however, lumbar puncture is not diagnostic and when there is evidence of impending herniation, it is also not safe. CSF in the setting of cerebral abscess formation is often nondiagnostic. An important exception is in patients with HIV/AIDS who often can be infected with multiple opportunistic infections. In the case of encephalitis, whether viral, parasitic, or fungal, lumbar puncture is essential for establishing the diagnosis. Lumbar puncture is also routinely performed for the diagnosis of inflammatory masses resulting from sarcoidosis or multiple sclerosis.

The diagnostic method of choice for suspected malignancy or abscess is tissue biopsy or CT-guided drainage and culture, respectively (see [Chapter 32](#)). Eventually, the majority of patients with suspected brain tumor are diagnosed by pathologic examination of surgically resected tissue as the result of a diagnostic biopsy or as part of a partial debulking or gross total resection of the lesion.

INITIAL MANAGEMENT

If imaging reveals significant vasogenic edema, corticosteroids can be used to prevent further neurologic injury in the case of impending herniation or for symptomatic relief if the cause is felt to be tumor or abscess. Most often, the corticosteroid regimen is dexamethasone 10 mg IV as an initial dose followed by 4 to 6 mg every 6 hours. Use of steroids should be avoided when PCNSL is a main consideration, as steroids can significantly lead to loss of the main histologic findings if the lesion is biopsied.

One situation in which lymphoma should be seriously considered is the case of the AIDS patient ($CD4 < 100/\mu L$). In this case, the two most common etiologies of enhancing focal mass lesions are toxoplasmosis and PCNSL. [Figure 17.17](#) outlines an algorithm for managing to diagnosis, and [Table 17.5](#) outlines the imaging differences between lymphoma and toxoplasmosis. The standard approach is to withhold steroids unless absolutely necessary and proceed directly to biopsy in patients at high risk for PCNSL and otherwise to proceed with empiric therapy for toxoplasmosis. Therapy for toxoplasma encephalitis is oral pyrimethamine (adults: an initial loading dose of 50 to 200 mg followed by 25 to 50 mg/day; children: 2 mg/kg/day administered in divided doses every 12 hours for 1 to 3 days, then 1 mg/kg daily or as divided doses every 12 hours to a maximum of 25 mg/day) and sulfadiazine (adults: 6 to 8 g/day divided into four equal doses; children: 120 mg/kg/day in divided doses every 6 hours in doses not to exceed

P.152

the adult dose). Individuals allergic to sulfadiazine may be desensitized to sulfadiazine or alternatively treated with clindamycin 2,400 mg/day in three equal doses. Other treatment alternatives include atovaquone or azithromycin. In conjunction with the antitoxoplasmosis agents, folinic acid (5 to 10 mg/day) is concurrently administered to diminish bone marrow suppression. Regression of the lesion on follow-up MR or CT confirms the diagnosis of toxoplasmosis. The total duration of therapy is at least 6 weeks and longer if the clinical response is incomplete at that time.

TABLE 17.5 Imaging Differences between Lymphoma and Toxoplasmosis

Lymphoma	Toxoplasmosis
Periventricular propensity	Basal ganglia propensity
Hypodense on T2/FLAIR	Hyperdense on T2/FLAIR
Single or multiple lesions	Lesions more numerous and smaller than lymphoma lesions
Does not tend to bleed except after steroids	May bleed pretreatment
Thallium spectroscopy and MR perfusion demonstrate increased uptake.	Thallium spectroscopy and MR perfusion demonstrate decreased uptake.

MR spectroscopy shows moderately elevated lactate and lipid and markedly elevated choline.

MR spectroscopy shows markedly elevated lactate and lipid.

FLAIR, fluid-attenuated inversion recovery; MR, magnetic resonance.

Another question that frequently arises in patients with new-onset mass lesions is whether to initiate antiepileptic treatment. Generally, unless the patient has had a seizure, antiepileptic treatment is not recommended. If the patient has significant increase in ICP with impending herniation, it is reasonable to initiate antiepileptic treatment even without a clinical history of a seizure. The thought in this circumstance is that by causing an increased cerebral metabolic demand, a seizure can lead to further increase in ICP and herniation.

Stupor and Coma

Jan Claassen

Stephan A. Mayer

John C. M. Brust

INTRODUCTION

“Normal human consciousness consists of a serially, time-ordered, organized, restricted, and reflective awareness of self and the environment. Moreover, it is an experience of graded complexity and quantity.” Schiff and Plum, J Clin Neurophys, 2000.

Philosophical and religious frameworks may influence definitions of consciousness. Consciousness is classically defined as awareness of self and the environment and requires both arousal (i.e., wakefulness) and cognitive content (i.e., thoughts and perceptions).

Coma is a state of unconsciousness that differs from sleep in that it represents a neurologic deficit and is not readily reversed. Cerebral oxygen uptake (cerebral metabolic rate of oxygen [CMRO₂]) is normal in sleep, and brain electrical activity progresses through organized stages of synchronized activity on electroencephalography (EEG). In coma, CMRO₂ is abnormally reduced and EEG activity progressively slows and becomes attenuated, with loss of normal reactivity to sensory stimuli.

DEFINITIONS

Coma is clinically defined by the neurologic examination, especially responses to external stimuli. Terms such as *lethargy*, *obtundation*, *stupor*, and *coma* usually depend on the patient's response to normal verbal stimuli, shouting, shaking, or pain. These terms are not rigidly defined, and it is useful to record both the response and the stimulus that elicited it. Occasionally, the true level of consciousness may be difficult or impossible to determine due to coexisting behavioral disturbances (i.e., catatonia in severe depression) or neurologic deficits (i.e., akinesia plus aphasia) that blunt responses to stimuli.

The chronicity of the impaired mental status differentiates acute disorders of consciousness such as stupor and coma from their long-term correlates: the chronic disorders of consciousness known as unresponsive wakefulness (UW) or persistent vegetative state (PVS) and minimally conscious state (MCS). UW/PVS is characterized by eyes-open unresponsiveness, purely reflexive behavior, and lack of the ability to follow verbal commands. MCS differs from PVS in that the patient is able to follow simple commands, albeit sometimes inconsistently, consistent with partial preservation of conscious awareness.

Induced states of altered consciousness such as those seen during general anesthesia or with sedation in the intensive care unit (ICU) share some similarities with coma induced by brain injury and may confound the assessment of comatose patients. Sedatives are frequently required in critically ill patients to facilitate ventilator management or to manage pain or agitation. *Accurate neurologic assessment of level of consciousness in the ICU can only be performed when sedatives have been stopped or interrupted.* For this reason, short-acting continuous infusion agents such as propofol, midazolam, or fentanyl are preferred in the setting of acute brain injury.

NEUROANATOMY

Confusional state and *delirium* are terms that refer to a state of inattentiveness, altered cognitive content, and sometimes hyperactivity, rather than to a decreased level of arousal; these conditions may presage or alternate with obtundation, stupor, or coma.

The anatomic substrate of consciousness lies within the reticular activating system, thalamus, and cerebral cortex. Location for classic structural brain lesions associated with stupor and coma have been derived from lesion studies and more recently confirmed and expanded based on structural and functional brain imaging studies such as diffusion tensor and resting state magnetic resonance imaging (MRI) (Fig. 18.1).

FIGURE 18.1 Anatomy of coma. Classic brain lesions that cause coma include those located diffuse bihemispheric (A), diencephalic (B), paramedian caudal midbrain and caudal diencephalic (C), high pontine and lower midbrain paramedian tegmental regions (D), and pontine (E). (From Posner JB, Saper CB, Schiff ND, et al. *Plum and Posner's Diagnosis of Stupor and Coma*. 4th ed. New York: Oxford University Press; 2007 by permission of Oxford University Press, USA.)

MANAGEMENT STRATEGY

A suggested algorithm for the initial management of new-onset coma is shown in [Figure 18.2](#).

INITIAL RESUSCITATION

Initial management of the comatose patient should always focus on the ABCs: airway, breathing, and circulation. Assuring a patent airway, securing adequate ventilation, and restoring or maintaining circulation should take precedence, as it does with any critically ill patient. Vascular access needs to be obtained as soon as possible and may include central venous access and large bore peripheral access. Detection and treatment of immediately life-threatening systemic conditions may include stopping a hemorrhage; supporting the circulation by administration of fluids, blood products, or pressors; intubation when necessary (e.g., to prevent aspiration in a patient who is vomiting); and obtaining an electrocardiogram to detect dangerous arrhythmias. Fingerstick glucose should be obtained immediately and if in doubt, 50% dextrose should be given intravenously with parenteral thiamine. (Administering glucose alone to a thiamine-deficient patient can precipitate Wernicke-Korsakoff syndrome.) When opiate overdose is a possibility, naloxone hydrochloride (Narcan) 0.4 mg IV is given. If trauma is suspected, damage to internal organs and cervical fracture should be assumed until radiographs determine otherwise and emergency ultrasound scanning (i.e., focused assessment with sonography for trauma [FAST]) or other imaging has ruled out major internal bleeding or organ injury.

HISTORY AND GENERAL PHYSICAL EXAMINATION

The next step is to localize and identify the underlying cause of coma. A history is obtained from whoever accompanies the patient, including emergency medical service providers. [Table 18.2](#) lists a number of practical pearls to look for that can aid in the diagnosis of nontraumatic coma. Order an emergent EEG to evaluate for nonconvulsive seizures or status epilepticus if even minor involuntary facial or extremity twitching is observed.

TABLE 18.1 Glasgow Coma Scale

Eye opening	Spontaneous	4
	To voice	3
	To pain	2
	None	1
Best motor response	Obeys commands	6
	Localizes to pain	5
	Withdraws to pain	4
	Flexor posturing	3
	Extensor posturing	2

	None	1
Best verbal response	Conversant and oriented	5
	Conversant and disoriented	4
	Inappropriate words	3
	Incomprehensible sounds	2
	None	1
Total score		3-15

Although a total score can be calculated, proper notation of the Glasgow Coma Scale involves delimitation of the three subscores. For instance, e3 m5 v3 applies to a patient who opens eyes to voice, localizes to pain, and is capable of uttering words but not sentences.

From Teasdale G, Jennett B. Assessment of coma and impaired consciousness. A practical scale. *Lancet*. 1974;2(7872):81-84.

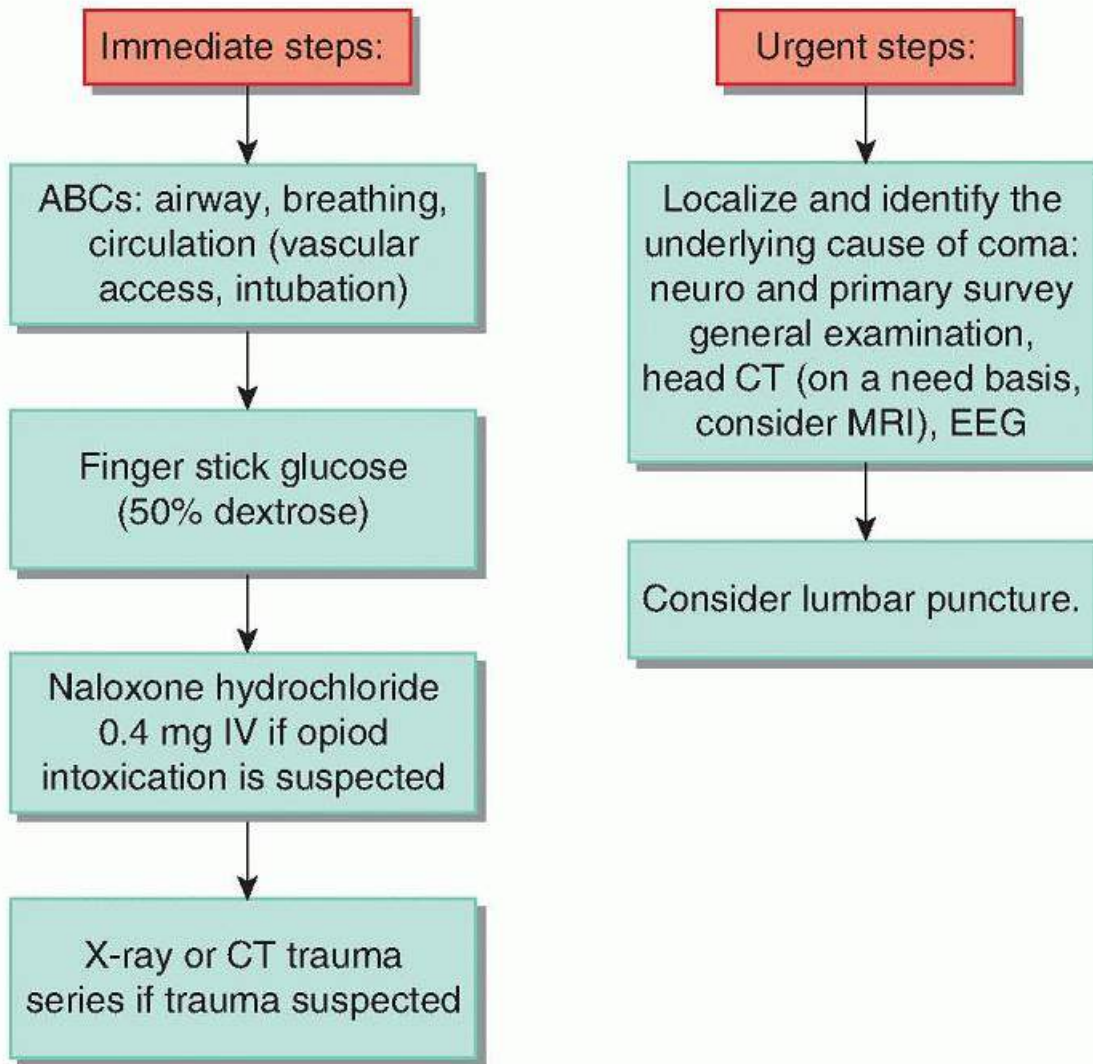

FIGURE 18.2 Management algorithm for new-onset coma. IV, intravenous; CT, computed tomography; MRI, magnetic resonance imaging; EEG, electroencephalography.

FOCUSED NEUROLOGIC EXAMINATION

In their classic monograph, Plum and Posner divided the causes of coma into supra- and infratentorial structural lesions and diffuse or metabolic diseases. By concentrating on motor responses to stimuli, respiratory patterns, pupils, and eye movements, the clinician can usually localize the cause and identify the category of coma. However, immediate computed tomography (CT) imaging should not be delayed after stabilization of the vital signs.

Motor Responses

The patient is observed to assess respiration, limb position, and spontaneous movements. Myoclonus or seizures may be subtle (e.g., twitching of one or two fingers or the corner of the mouth). More florid movements, such as facial grimacing, jaw gyrations, tongue protrusion, or complex repetitive limb movements, may defy ready interpretation. Asymmetric movements or postures may signify either focal seizures or hemiparesis.

Assessment of motor tone is crucial in the examination of coma. Asymmetry of muscle tone suggests a structural lesion, but it is not always clear which side is abnormal. *Gegenhalten*, or *paratonia*, is variable resistance to passive movement that often increases with the velocity of the movement; it is attributed to diffuse forebrain dysfunction and is often accompanied by a grasp reflex. *Rigidity* is present throughout the

entire range of movement, is often seen in combination with cogwheeling, and usually indicates basal ganglia dysfunction (e.g., parkinsonism) or symptomatic hydrocephalus. *Spasticity* has a characteristic “catch” midway through passive movement and indicates corticospinal pathway dysfunction. Acute transtentorial herniation often produces exaggerated lower extremity spasticity and clonus.

TABLE 18.2 Practical Pearls in the Physical Examination of the Comatose Patient

System	Positive Finding
Body temperature	<ul style="list-style-type: none"> • Fever (implies infection or heatstroke) • Hypothermia (cold exposure, sepsis, cardiac arrest, hypothyroidism, hypoglycemia)
Peripheral pulses	<ul style="list-style-type: none"> • Asymmetry of pulses suggests dissecting aortic aneurysm.
Head and scalp	<ul style="list-style-type: none"> • External signs of trauma (e.g., mastoid ecchymoses consistent with Battle sign) • Ears and nose are examined for blood or CSF.
Skin, nails, and mucous membranes	<ul style="list-style-type: none"> • Pallor • Cherry redness (carbon monoxide poisoning) • Cyanosis • Jaundice • Sweating • Uremic frost • Myxedema (dry, flaky, cool skin) • Petechiae • Dehydration • Decubiti • Signs of trauma
Breath	<ul style="list-style-type: none"> • Acetone • Alcohol • Feter hepaticus
Optic fundi	<ul style="list-style-type: none"> • Papilledema (suggests elevated ICP), hypertensive or diabetic retinopathy, retinal ischemia • Roth spots (suggests endocarditis) • Subhyaloid hemorrhages (suggests subarachnoid hemorrhage)
Neck	<ul style="list-style-type: none"> • Resistance to passive neck flexion but not to turning suggests meningitis, subarachnoid hemorrhage, or foramen magnum herniation. • Resistance to manipulation in all directions suggests bone or joint disease, including fracture.

Urinary or fecal incontinence

- May signify an unwitnessed seizure, especially in patients who subsequently awaken

CSF, cerebrospinal fluid; ICP, increased cranial pressure.

Motor responses to stimuli may be appropriate, inappropriate, or absent. Even when patients are not fully awake, they may be roused to follow simple commands. Some patients who respond only to noxious stimuli (e.g., pressure on the sternum or supraorbital bone; pinching the neck or limbs; or squeezing muscle, tendon, or nail beds) may make voluntary avoidance responses. The terms *decorticate* and *decerebrate* posturing are physiologic misnomers but refer to stereotyped hypertonic flexion or extension in response to noxious stimuli (Fig. 18.3). In *decorticate rigidity*, the arms are flexed, adducted, and internally rotated, and the legs are extended; in *decerebrate rigidity*, the arms and legs are all extended. These postures are most often associated with cerebral hemisphere disease, including hypoxic-ischemic or metabolic encephalopathy, but may follow upper brain stem lesions or

P.156

transtentorial herniation as well (see later section for a discussion of herniation syndromes). Flexor posturing generally implies a more rostral lesion and has a better prognosis than extensor posturing, but the pattern of response may vary with different stimuli, or there may be flexion of one arm and extension of the other. When these postures seem to occur spontaneously, there may be an unrecognized stimulus (e.g., airway obstruction or bladder distention). With continuing rostrocaudal deterioration, there may be extension of the arms and flexion of the legs until, with lower brain stem destruction, there is flaccid unresponsiveness. However, lack of motor response to any stimulus should always raise the possibility of limb paralysis caused by cervical trauma, Guillain-Barré neuropathy, or the locked-in state.

FIGURE 18.3 Decerebrate or extensor posturing (A) and decorticate or flexor posturing (B).

Respiration

In Cheyne-Stokes respiration (CSR), periods of hyperventilation and apnea alternate in a crescendo-decrescendo fashion. The hyperpneic phase is usually longer than the apneic, so arterial gases tend to show respiratory alkalosis. CSR occurs with bilateral cerebral disease or metabolic encephalopathy. It usually signifies that the patient is not in imminent danger. Long-cycle CSR, with brief periods of apnea occurring every 1 to 2 minutes, is a stable breathing pattern and does not imply impending respiratory

arrest. Conversely, “short-cycle CSR” (*cluster breathing*) with less smooth waxing and waning is often an ominous sign of a posterior fossa lesion or dangerously elevated ICP.

Sustained hyperventilation is usually due to metabolic acidosis, pulmonary congestion, hepatic encephalopathy, or during acute herniation (see Fig. 18.3). Rarely, it is the result of a lesion in the rostral brain stem. *Apneustic breathing*, consisting of long inspiratory pauses, is seen with pontine lesions, especially infarction; it occurs infrequently with metabolic coma or transtentorial herniation.

Respiration having a variably irregular rate and amplitude (*ataxic breathing*) indicates medullary damage and may progress to apnea, which also occurs abruptly in acute posterior fossa lesions. Loss of automatic respiration with preserved voluntary breathing (*Ondine curse*) occurs with medullary lesions; as the patient becomes less alert, apnea may be fatal. Other ominous respiratory signs are end-expiratory pushing (e.g., coughing) and “fish-mouthing” (i.e., lower jaw depression with inspiration). Stertorous breathing (i.e., inspiratory noise) is a sign of airway obstruction.

Pupils

Pupillary abnormalities in coma may reflect an imbalance between input from the parasympathetic and sympathetic nervous systems or lesions of both. Although many people have slight pupillary inequality, anisocoria should be considered pathologic in a comatose patient. Retinal or optic nerve damage does not cause anisocoria, even though there is an afferent pupillary defect. Parasympathetic lesions (e.g., oculomotor nerve compression in uncal herniation or after rupture of an internal carotid artery aneurysm) cause pupillary enlargement and, ultimately, full dilation with loss of reactivity to light. Sympathetic lesions, either intraparenchymal (e.g., hypothalamic injury or lateral medullary infarction) or extraparenchymal (e.g., invasion of the superior cervical ganglion by lung cancer), cause Horner syndrome with miosis. With involvement of both systems (e.g., midbrain destruction), one or both pupils are in mid position and are unreactive. Small but reactive pupils following pontine hemorrhage are the result of damage to descending intra-axial sympathetic pathways.

With few exceptions, metabolic disease does not cause unequal or unreactive pupils. Fixed, dilated pupils after diffuse anoxia-ischemia denote a bad prognosis. Anticholinergic drugs, including glutethimide, amitriptyline, and antiparkinsonian agents, abolish pupillary reactivity. Hypothermia and severe barbiturate intoxication may cause not only fixed pupils but also a reversible picture that mimics brain death. Bilateral or unilateral pupillary dilation and nonreactivity may accompany (or briefly follow) a seizure. In opiate overdose, miosis may be so severe that a very bright light and a magnifying glass are necessary to detect reactivity. Some pupillary abnormalities are local in origin (e.g., trauma or synechiae).

Eyelids and Eye Movements

Spontaneous blinking may occur with or without purposeful limb movements. Eyes that are conjugately deviated away from hemiparetic limbs indicate a destructive cerebral lesion on the side toward which the eyes are directed. Eyes turned toward paretic limbs may indicate a pontine lesion, an adverse seizure, or the wrong-way gaze paresis of thalamic hemorrhage. Eyes that are dysconjugate while at rest may indicate paresis of individual muscles, internuclear ophthalmoplegia, or preexisting tropia or phoria.

When the brain stem is intact, the eyes may rove irregularly from side to side with a slow, smooth velocity; jerky movements suggest saccades and relative wakefulness. Repetitive smooth excursions of the eyes first to one side and then to the other, with 2- to 3-second pauses in each direction (*periodic alternating or*

ping-pong gaze), may follow bilateral cerebral infarction or cerebellar hemorrhage with an intact brain stem.

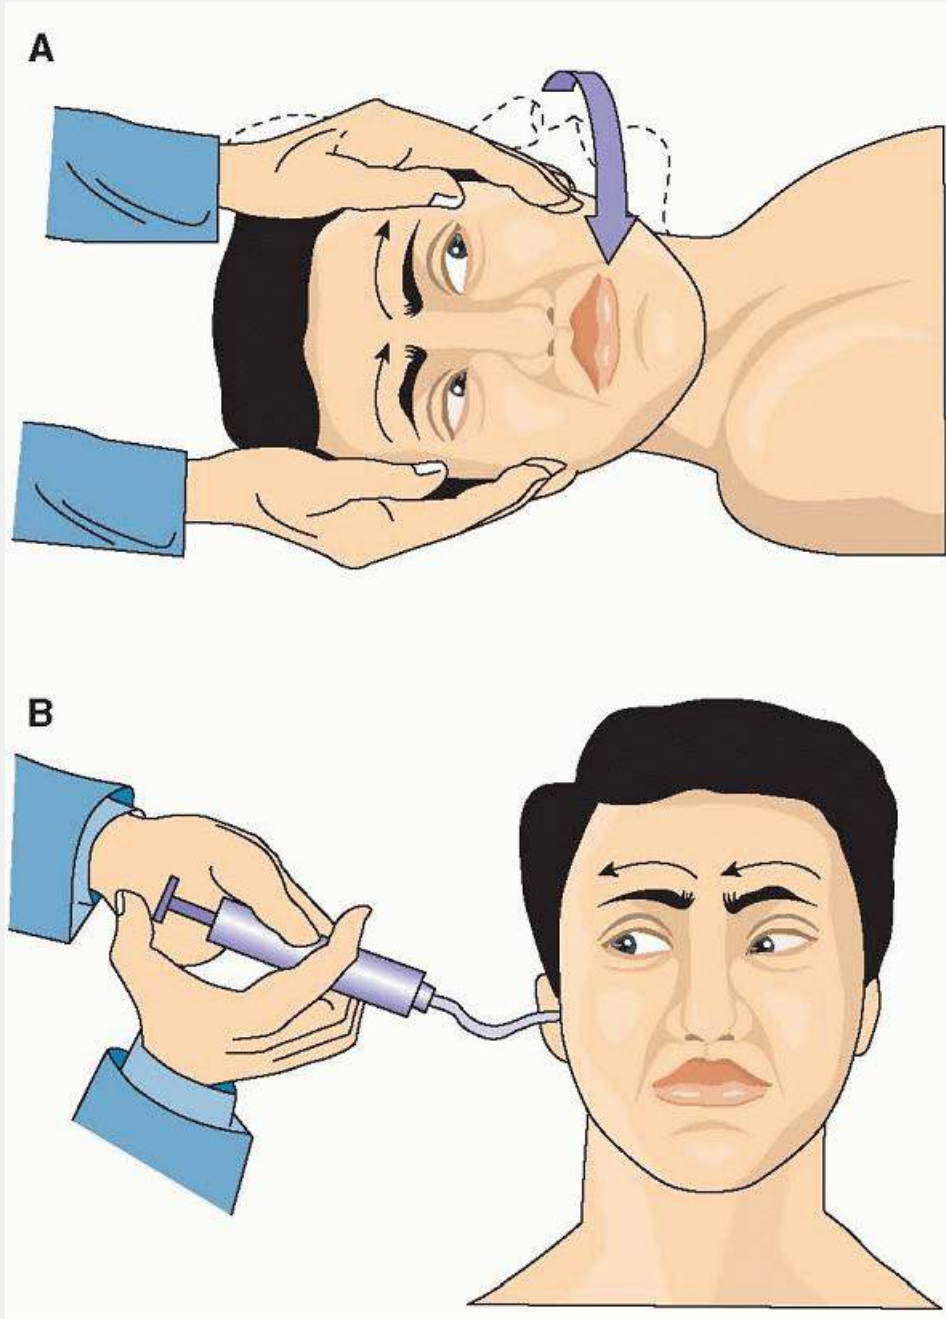

FIGURE 18.4 A: Doll's eye maneuver (oculocephalic reflex): With intact brain stem (cranial nerves III through VIII), the eyes remain relatively stationary and move opposite to the direction of head turning. **B:** Cold caloric test (oculovestibular reflex): With intact brain stem, cold water in the auditory canal results in tonic conjugate eye deviation toward the cold ear.

If cervical injury has been ruled out, oculocephalic testing (the *doll's eyes maneuver*) is performed by passively turning the head from side to side; with an intact reflex arc (vestibular system → brain stem → eye muscles), the eyes move conjugately in the opposite direction (Fig. 18.4). A more vigorous stimulus is produced by irrigating each ear with 30 to 60 mL of ice water. A normal, awake person with head elevated at 30 degrees has nystagmus with the fast component in the direction opposite the ear stimulated, but a comatose patient with an intact reflex arc has deviation of the eyes toward the stimulus, usually for several minutes. Simultaneous bilateral irrigation causes vertical deviation, upward after warm water and downward after cold water.

Oculocephalic or caloric testing may reveal intact eye movements, gaze palsy, individual muscle paresis, internuclear ophthalmoplegia, or no response. Cerebral gaze paresis may often be overcome by these maneuvers, but brain stem gaze palsies are usually fixed. Complete ophthalmoplegia may follow either

extensive brain stem damage or metabolic coma, but except for barbiturate or phenytoin poisoning, eye movements are preserved early in metabolic encephalopathy. Unexplained disconjugate eyes indicate a brain stem or cranial nerve lesion (including abducens palsy due to increased ICP).

Downward deviation of the eyes occurs with lesions in the thalamus or midbrain pretectum and may be accompanied by pupils that do not react to light (*Parinaud syndrome*). Downward eye deviation also occurs in metabolic coma, especially in barbiturate poisoning and after a seizure. Skew deviation, or vertical divergence, follows lesions of the cerebellum or brain stem, especially the pontine tegmentum.

Retraction and convergence nystagmus may be seen with midbrain lesions, but spontaneous nystagmus is rare in coma. *Ocular bobbing* (i.e., conjugate brisk downward movements from the primary position) usually follows destructive lesions of the pontine tegmentum (when lateral eye movements are lost). Preservation of voluntary vertical eye movements with loss of lateral eye movements and quadriplegia is consistent with *locked-in syndrome*. Unilateral bobbing (i.e., nystagmoid jerking) signifies pontine disease.

DIAGNOSTIC TESTS

CT or MRI should be promptly performed whenever coma is unexplained. Unless meningitis is suspected, imaging should precede lumbar puncture. If imaging is not readily available, a spinal tap is cautiously performed with a 20- or 22-gauge needle. If imaging reveals frank, transtentorial, or foramen magnum herniation, the comparative risks of performing a lumbar puncture or of treating for meningitis without CSF confirmation must be weighed individually for each patient.

Other emergency laboratory studies include serum levels of glucose, sodium, calcium, and BUN or creatinine; determination of arterial pH and partial pressures of oxygen (PO₂) and carbon dioxide (PCO₂); and blood or urine toxicology testing (including testing serum levels of sedative drugs and ethanol). Blood and CSF should be cultured and liver function studies and other serum electrolyte levels determined. The use of coagulation studies and other metabolic tests is based on the index of suspicion.

The EEG may distinguish coma from psychic unresponsiveness or locked-in state, although alpha-like activity in coma after brain stem infarction or cardiopulmonary arrest may make the distinction difficult. In metabolic coma, the EEG is always abnormal, and early in the course, it may be a more sensitive indicator of abnormality than the clinical state of the patient. The EEG may also reveal asymmetries or evidence of clinically unsuspected seizure activity. Infrequently, patients without clinical seizures demonstrate repetitive electrographic seizures or continuous spike-and-wave activity; conversely, patients with subtle motor manifestations of seizures sometimes display only diffuse electrographic slowing. Distinguishing true status epilepticus from myoclonus (common after anoxic-ischemic brain damage) is often difficult, both clinically and electrographically; if any doubt exists, anticonvulsant therapy should be instituted.

COMA PRESENTATIONS AND TREATMENT

Many structural and nonstructural pathologies can result in impaired consciousness, necessitating a structured diagnostic approach with a broad differential. For rapid efficient communication between providers, generalizable scales such as the Full Outline of UnResponsiveness (FOUR) score may be helpful (Fig. 18.5). A more commonly used alternative is the Glasgow Coma Scale (see Table 18.1).

COMA FROM SUPRATENTORIAL HERNIATION SYNDROMES

Coma may result from bilateral cerebral damage or from sudden large unilateral lesions that functionally disrupt the contralateral hemisphere (*diaschisis*). Herniation syndromes result from mass lesions that shift the brain out of its normal position. CT studies indicate that with acute hemisphere masses, early

depression of consciousness correlates more with lateral brain displacement than with downward transtentorial herniation. The different types of herniation syndromes are described in (Table 18.3). It is important to keep in mind that different herniation syndromes can occur in a sequence or combination. For instance, an expanding hemispheric mass lesion resulting in lateral brain displacement may initially produce subfalcine herniation, followed by uncal herniation as a combination of downward and lateral displacement ensues.

Subfalcine herniation results from lateral displacement of the brain from mass lesions that are positioned rostrally in the cranial vault, at the level of the lateral ventricles or above (Fig. 18.6). *Transtentorial herniation* can result from lateralized (uncal) or bilateral (central) downward displacement. In *uncal herniation*, brain stem signs are initially lateralized. Typically, there is early compression of the oculomotor nerve by the inferomedial temporal lobe with ipsilateral pupillary enlargement. Alertness may not be altered until the pupil is dilated, at which point there may be an acceleration of signs, with unilaterally and then bilaterally fixed pupils and oculomotor palsy, hyperventilation or ataxic breathing, and progressive unresponsiveness. Typically, a lateralized motor deficit progresses to symmetric and bilateral flexor and then extensor posturing, as the caudal most level of injury progresses to the upper brain stem. During the downward course of transtentorial herniation, there may be hemiparesis ipsilateral or oculomotor nerve compression contralateral to the cerebral lesion, which can be attributed to compression of the contralateral midbrain peduncle against the tentorial edge (*Kernohan notch*). Aqueduct obstruction and posterior cerebral artery compression may further raise supratentorial pressure. If the process is not halted, there is progression to deep coma, apnea, bilaterally unreactive pupils, ophthalmoplegia, and eventually, circulatory collapse and brain death.

FIGURE 18.5 Eye response: *E4*, eyelids open or opened, tracking, or blinking to command; *E3*, eyelids open but not tracking; *E2*, eyelids closed but open to loud voice; *E1*, eyelids closed but open to pain; *E0*, eyelids remain closed with pain. Motor response: *M4*, thumbs-up, fist, or peace sign; *M3*, localizing to pain; *M2*, flexion response to pain; *M1*, extension response to pain; *M0*, no response to pain or generalized myoclonus status. Brain stem reflexes: *B4*, pupil and corneal reflexes present; *B3*, one pupil wide and fixed; *B2*, pupil or corneal reflexes absent; *B1*, pupil and corneal reflexes absent; *B0*, absent pupil, corneal, and cough reflex. Respiration pattern: *R4*, not intubated, regular breathing pattern; *R3*, not intubated, Cheyne-Stokes breathing pattern; *R2*, not intubated, irregular breathing; *R1*, breathes above ventilatory rate; *R0*, breathes at ventilator rate or apnea. (From Wijdicks EFM, Bamlet WR, Maramattom BV, et al. Validation of a new coma scale: the FOUR score. *Ann Neurol*. 2005;58[4]:585-593.)

TABLE 18.3 Herniation Syndromes

Types	Mechanism of Herniation/Complications
Subfalcine	<ul style="list-style-type: none"> • Mechanism: lateral shifting displacement of the brain by a compartmentalized hemispheric mass lesion at the level of the ventricles or above • Classic causes: malignant MCA infarction, acute subdural or epidural hematoma • Imaging: midline shift with ipsilateral widening of the perimesencephalic cisterns • Clinical: contralateral hemiparesis progressing to bilateral motor posturing and coma, with late ipsilateral CN III palsy due to stretching of the oculomotor nerve • Complications: delayed ipsilateral ACA pericallosal infarction due to compression against the falx
Central transtentorial	<ul style="list-style-type: none"> • Mechanism: downward displacement of the brain by a bilateral supratentorial mass lesion, with craniocaudal pressure on diencephalon with downward displacement • Classic causes: massive bilateral intraventricular hemorrhage leading to acute obstructive hydrocephalus, massive global cerebral edema • Imaging: bilateral loss of the perimesencephalic cisterns and downward displacement of the midbrain tectum into the posterior fossa • Clinical: early Parinaud syndrome (loss of upgaze and convergence, retraction nystagmus) followed by rostrocaudal loss of brain stem reflexes associated with progression from decorticate to decerebrate posturing • Complications: stretching of small penetrating vessels leading to diencephalic and brainstem infarction, sometimes pituitary damage • Less common dorsal pressure leading to Parinaud syndrome (limitation of upward eye movements, usually with impairment of pupillary light reflex and difficulty with convergence)
Uncal transtentorial	<ul style="list-style-type: none"> • Mechanism: displacement of medial temporal lobe over free tentorial edge by a temporal lobe mass lesion or during the late stages of lateral and downward herniation • Classic causes: intracerebral mass lesions for example intracerebral hematoma, subdural hematoma, brain tumor • Imaging: prominent medial displacement of the uncus into the tentorial notch • Clinical: early ipsilateral dilated pupil due to CN III compression and ipsilateral or contralateral hemiparesis/posturing • Complications: trapping of the contralateral lateral ventricle due to compression of the third ventricle and aqueduct; compression of posterior cerebral arteries with resultant infarction
Tonsillar	<ul style="list-style-type: none"> • Mechanisms: displacement of cerebellar tonsils into the foramen magnum → compression of medulla and fourth ventricle • Classic cause: acute cerebellar ICH or rapidly expanding tumor • Imaging: herniation of cerebellar tonsils into the foramen magnum at level of the medulla • Clinical: impaired respiratory and cardiac function, neck stiffness, flaccid paralysis, and coma • Complications: secondary obstructive hydrocephalus due to obstruction of the

Upward
herniation

- Mechanisms: displacement of superior cerebellar vermis upward leading to compression of dorsal mesencephalon, blood vessels, and aqueduct
- Classic cause: acute cerebellar ICH or rapidly expanding tumor
- Imaging: cerebellar mass lesion with effacement of quadrigeminal cistern and upward displacement of midbrain tectum
- Clinical: impaired consciousness, loss of pupillary and oculocephalic reflexes
- Complications: secondary obstructive hydrocephalus due to obstruction of the cerebral aqueduct

MCA, middle cerebral artery; CN, cranial nerve; ACA, anterior cerebral artery; ICH, intracranial hemorrhage.

In *central transtentorial herniation* (as in thalamic hemorrhage), consciousness is rapidly impaired, and abnormalities of brain stem reflexes progress in rostrocaudal fashion. Pupils initially are of normal or small diameter and react to light, lateral eye movements and corneal reflexes are preserved, and bilateral spasticity progresses to flexor posturing. This stage is referred to as *diencephalic syndrome* because the level of injury is localized to the level of the thalamus. As herniation progresses, the pupils become fixed in mid position (midbrain pupils); this is followed by loss of pontine level brain stem reflexes (corneal and oculocephalic) and sometimes by pinpoint unreactive pupils (pontine pupils). Eventually, only medullary function remains (gag and cough), and after this, abolished brain death ensues.

The major lesions causing transtentorial herniation are traumatic (e.g., epidural, subdural, or intraparenchymal hemorrhage), vascular (e.g., ischemic or hemorrhagic), infectious (e.g., abscess or granuloma, including lesions associated with AIDS), and neoplastic (primary or metastatic). CT or MRI locates and often defines the lesion.

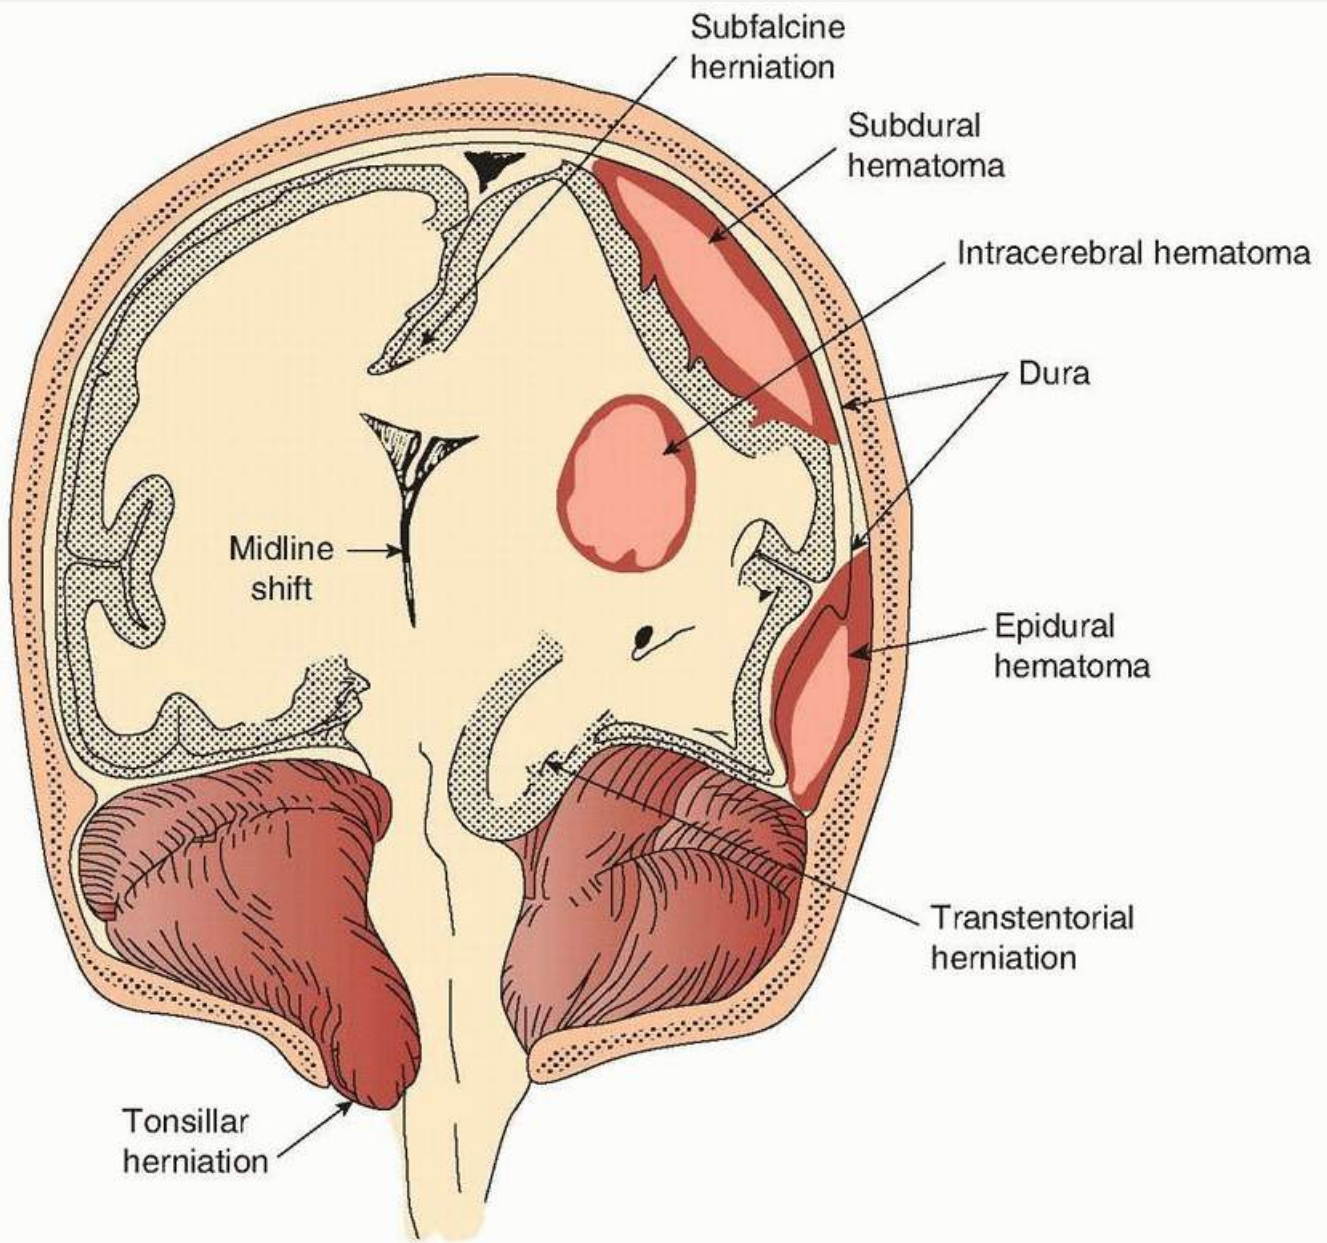

FIGURE 18.6 Herniation syndromes.

COMA FROM INFRATENTORIAL STRUCTURAL LESIONS

Infratentorial structural lesions may compress or directly destroy the brain stem. Such lesions may also cause brain herniation either transtentorially upward (with midbrain compression) or downward through the foramen magnum, with distortion of the medulla by the cerebellar tonsils. Abrupt tonsillar herniation causes apnea and circulatory collapse; coma is then secondary, for the medullary reticular formation has little direct role in arousal. In coma, *primary infratentorial structural lesions* are suggested by bilateral weakness or sensory loss, crossed cranial nerve and long-tract signs, miosis, loss of lateral gaze with preserved vertical eye movements, dysconjugate gaze, ophthalmoplegia, short-cycle CSR, and apneustic or ataxic breathing. The clinical picture of pontine hemorrhage (i.e., sudden coma, pinpoint but reactive pupils, and no eye movement) is characteristic, but if the sequence of signs in a comatose patient is unknown, it may not be possible to tell whether the process began supratentorially or infratentorially without the use of imaging. Infrequent brain stem causes of coma include multiple sclerosis and central pontine myelinolysis.

COMA FROM METABOLIC OR DIFFUSE BRAIN DISEASE

In metabolic, diffuse, or multifocal encephalopathy, cognitive and respiratory abnormalities occur early; there is often tremor, asterix, or multifocal myoclonus. Gegenhalten, frontal release signs (e.g., snout,

suck, or grasp), and flexor or extensor posturing may occur. Except in anoxia-ischemia and anticholinergic intoxication, the pupils remain reactive. The eyes may be deviated downward, but the presence of sustained lateral deviation or disconjugate eyes argues against the diagnosis of a metabolic disturbance. Metabolic disease, however, may cause both focal seizures and lateralizing neurologic signs, often shifting but sometimes persisting (as in hypoglycemia and hyperglycemia).

Arterial blood gas determinations are especially useful in diagnosing metabolic coma. Of the diseases listed in Table 18.4, psychogenic hyperventilation is more likely to cause delirium than stupor but may coexist with hysterical coma. Cognitive change associated with metabolic alkalosis is usually mild. Metabolic and diffuse brain diseases causing coma are numerous, but the diversity is not overwhelming. Most entities listed in Table 18.5 are described in other chapters.

HYSTERIA AND CATATONIA

Hysterical (conversion) unresponsiveness is rare. Clinically indistinguishable from malingering, it is usually associated with closed eyes, eupnea or tachypnea, and normal pupils. The eyelids may resist passive opening and, when released, may close abruptly rather than with smooth descent; lightly stroking the eyelashes causes lid fluttering. The eyes do not slowly rove but move with saccadic jerks, and ice water caloric testing causes nystagmus rather than sustained deviation. The limbs usually offer no resistance to passive movement, yet demonstrate normal tone. Unless organic disease or drug effect is also present, the EEG pattern is one of normal wakefulness.

Catatonia is a behavioral disturbance characterized by wakeful unresponsiveness with minimal or no spontaneous purposeful behavior or speech. It is most commonly associated with depression, schizophrenia, toxic psychosis, or other brain diseases. There may be akinetic mutism, grimacing, rigidity, posturing, catalepsy, or excitement. Respirations are normal or rapid, pupils are large but reactive, and eye movements are normal. The EEG is usually normal.

LOCKED-IN SYNDROME

Infarction, hemorrhage, or rarely, central pontine myelinolysis may destroy the basis pontis, producing total paralysis of the

P.161

lower cranial nerve and limb muscles, with preserved alertness and respiration. At first glance, the patient appears unresponsive, but examination reveals voluntary vertical eye movements, including blinking. (Even with facial paralysis, inhibition of the levator palpebrae may produce partial eye closure). Communication is possible with the use of purposeful blinking or eye movements to indicate “yes,” “no,” or in response to letters.

VEGETATIVE STATE AND MINIMALLY CONSCIOUS STATE

Persistent impairment of consciousness in the postacute hospitalization phase is categorized into MCS and UWS, formerly known as vegetative state. Patients with UWS have sleep-wake cycles, intact cardiorespiratory function, and primitive responses to stimuli but without evidence of inner or outer awareness present for at least 1 month (Table 18.6). In contrast, patients with MCS intermittently show signs of self or environmental awareness, which may include those verbal command, visual tracking, and context-specific emotional responses. Identifying this state is important, as it may represent a transitory state on the road to recovery.

Patients who survive coma usually show varying degrees of recovery within 2 to 4 weeks; those who enter UWS may recover further, even fully. Emerging data indicate that much of our formerly pessimistic assumptions regarding outcome of comatose patients are likely based on self-fulfilling prophecies. Recent studies indicate

that one-third of UWS patients die in the ICU, whereas one-fifth remain in the UWS state and half recover consciousness by the time they are discharged from the ICU. In the Multi-Society Task Force study, patients remaining in the UWS 3 months after traumatic brain injury were associated with a 35% rate of recovery of consciousness at 1 year and 16% of these patients recovered independent function by 1 year after injury. The majority (> 80%) of patients remaining in MCS at 3 to 6 months after injury will improve, some eventually demonstrating no disability. Patients with traumatic brain injury tend to have better recovery compared to those with anoxic-ischemic injury. Much research is currently directed toward identifying predictors of who will recover to which state at what time. Amantadine hydrochloride 100 mg t.i.d. has been shown to accelerate the pace of functional recovery among patients with UWS and MCS after severe traumatic brain injury [Level 1].¹ Also under study are the use of the pharmacologic interventions (e.g., zolpidem) and thalamic stimulation.

BRAIN DEATH

Unlike the UWS in which the brain stem is intact, the term *brain death* means that the cerebrum and the brain stem are both permanently destroyed. The only spontaneous activity is cardiovascular; apnea persists in the presence of hypercarbia sufficient for respiratory drive, and the only reflexes present are those mediated by the spinal cord. In adults, brain death rarely lasts more than a few days and is always followed by circulatory collapse despite persistence on a ventilator. In the United States, brain death is equated with legal death. When criteria are met, artificial ventilation and BP support are appropriately discontinued, regardless of whether or not organ harvesting is intended. Detailed information on how to diagnose and manage brain death in the ICU is provided in Chapter 19.

TABLE 18.5 Diffuse Brain Diseases or Metabolic Disorders that Cause Coma

Deprivation of oxygen, substrate, or metabolic cofactor

Hypoxia

Diffuse ischemia (cardiac disease, decreased peripheral circulatory resistance, increased cerebrovascular resistance, widespread small-vessel occlusion)

Hypoglycemia

Thiamine deficiency (Wernicke-Korsakoff syndrome)

Disease of organs other than brain

Liver (hepatic coma)

Kidney (uremia)

Lung (carbon dioxide narcosis)

Pancreas (diabetes, hypoglycemia, exocrine pancreatic encephalopathy)

Pituitary (apoplexy, sedative hypersensitivity)

Thyroid (myxedema, thyrotoxicosis)

Parathyroid (hypo- and hyperparathyroidism)

Adrenal (Addison or Cushing disease, pheochromocytoma)

Other systemic disease (cancer, porphyria, sepsis)

Exogenous poisons

Sedatives and narcotics

Psychotropic drugs

Acid poisons (e.g., methyl alcohol, ethylene glycol)

Others (e.g., anticonvulsants, heavy metals, cyanide)

Abnormalities of ionic or acid-base environment of CNS

Water and sodium (hypo- and hypernatremia)

Acidosis

Alkalosis

Magnesium (hyper- and hypomagnesemia)

Calcium (hyper- and hypocalcemia)

Phosphorus (hypophosphatemia)

Disordered temperature regulation

Hypothermia

Heat stroke

CNS inflammation or infiltration

Leptomeningitis

Encephalitis

Acute toxic encephalopathy (e.g., Reye syndrome)

Parainfectious encephalomyelitis

Cerebral vasculitis

Subarachnoid hemorrhage

Carcinomatous meningitis

Primary neuronal or glial disorders

Creutzfeldt-Jakob disease

Marchiafava-Bignami disease

Adrenoleukodystrophy

Gliomatosis cerebri

Progressive multifocal leukoencephalopathy

Seizure and postictal states

CNS, central nervous system.

TABLE 18.6 Criteria for Determination of Unresponsive Wakefulness State (Formerly Known as Vegetative State)

1. No evidence of awareness of self or surroundings. Reflex or spontaneous eye opening may occur.

2. No meaningful and consistent communication between examiner and patient, auditory or written. Target stimuli not usually followed visually, but sometimes, visual tracking present. No emotional response to verbal stimuli.

3. No comprehensible speech or mouthing of words

4. Smiling, frowning, or crying inconsistently related to any apparent stimulus

5. Sleep-wake cycles present

-
6. Brain stem and spinal reflexes variable, e.g., preservation of sucking, rooting, chewing, swallowing, pupillary reactivity to light, oculocephalic responses, and grasp or tendon reflexes

 7. No voluntary movements or behavior, no matter how rudimentary; no motor activity suggesting learned behavior; no mimicry. Withdrawal or posturing can occur with noxious stimuli.

 8. Usually intact BP control and cardiorespiratory function. Incontinence of bladder and bowel.

BP, blood pressure.

P.163

FUTURE DIRECTIONS

Functional imaging and EEG studies applying task-based or resting state paradigms may offer more objective means to study patients with impaired consciousness. These studies have indicated that some patients who appear comatose may have preserved higher cognitive processing suggesting intact consciousness. These imaging and electrophysiologic techniques may offer more quantifiable and objective endpoints to study impairment of consciousness in natural history studies and clinical trials.

Brain Death

Eelco F. M. Wijdicks

INTRODUCTION

Brain death is the preferred term to summarize an apneic patient with not only irreversible coma from a massive brain injury but loss of all brain stem reflexes and uncontrolled diuresis and hypotension from loss of vascular tone. Nothing else should explain this condition and characteristically, it is due to an acute catastrophic bihemispheric and diencephalic injury. Brain death remains uncommon because such progression would require not only involvement of both hemispheres of the brain but also loss of brain stem function. Typically, this clinical situation would be an acute massive hemispheric lesion (e.g., cerebral hemorrhage) compressing and sequentially damaging the mesencephalon, pons, and medulla oblongata (Fig. 19.1). The brain stem is very resilient to injury and it would take a substantial shift (from mass effect) or poor perfusion (from basilar artery occlusion or massively increased intracranial pressure) for it to get permanently damaged. This core neurologic principle—the brain stem to be the last brain structure to go out of function—is the most important attribute to our understanding of brain death. Once brain stem function is lost, breathing stops first and the heart soon thereafter. If in the acute phase the patient can be intubated, placed on a mechanical ventilator, sufficiently oxygenated, fluid resuscitated, and vasopressors and vasopressin added, this agonal sequence can potentially be prevented.

Once an untreatable catastrophic neurologic structural injury has been proven and the brain stem reflexes have disappeared, recovery does not occur, and there is no known effective medical or surgical intervention. Irreversibility is determined by this diagnosis and involves testing of absent motor responses, loss of all brain stem reflexes, and observation of apnea after a CO₂ challenge in a patient temporarily detached from the ventilator.

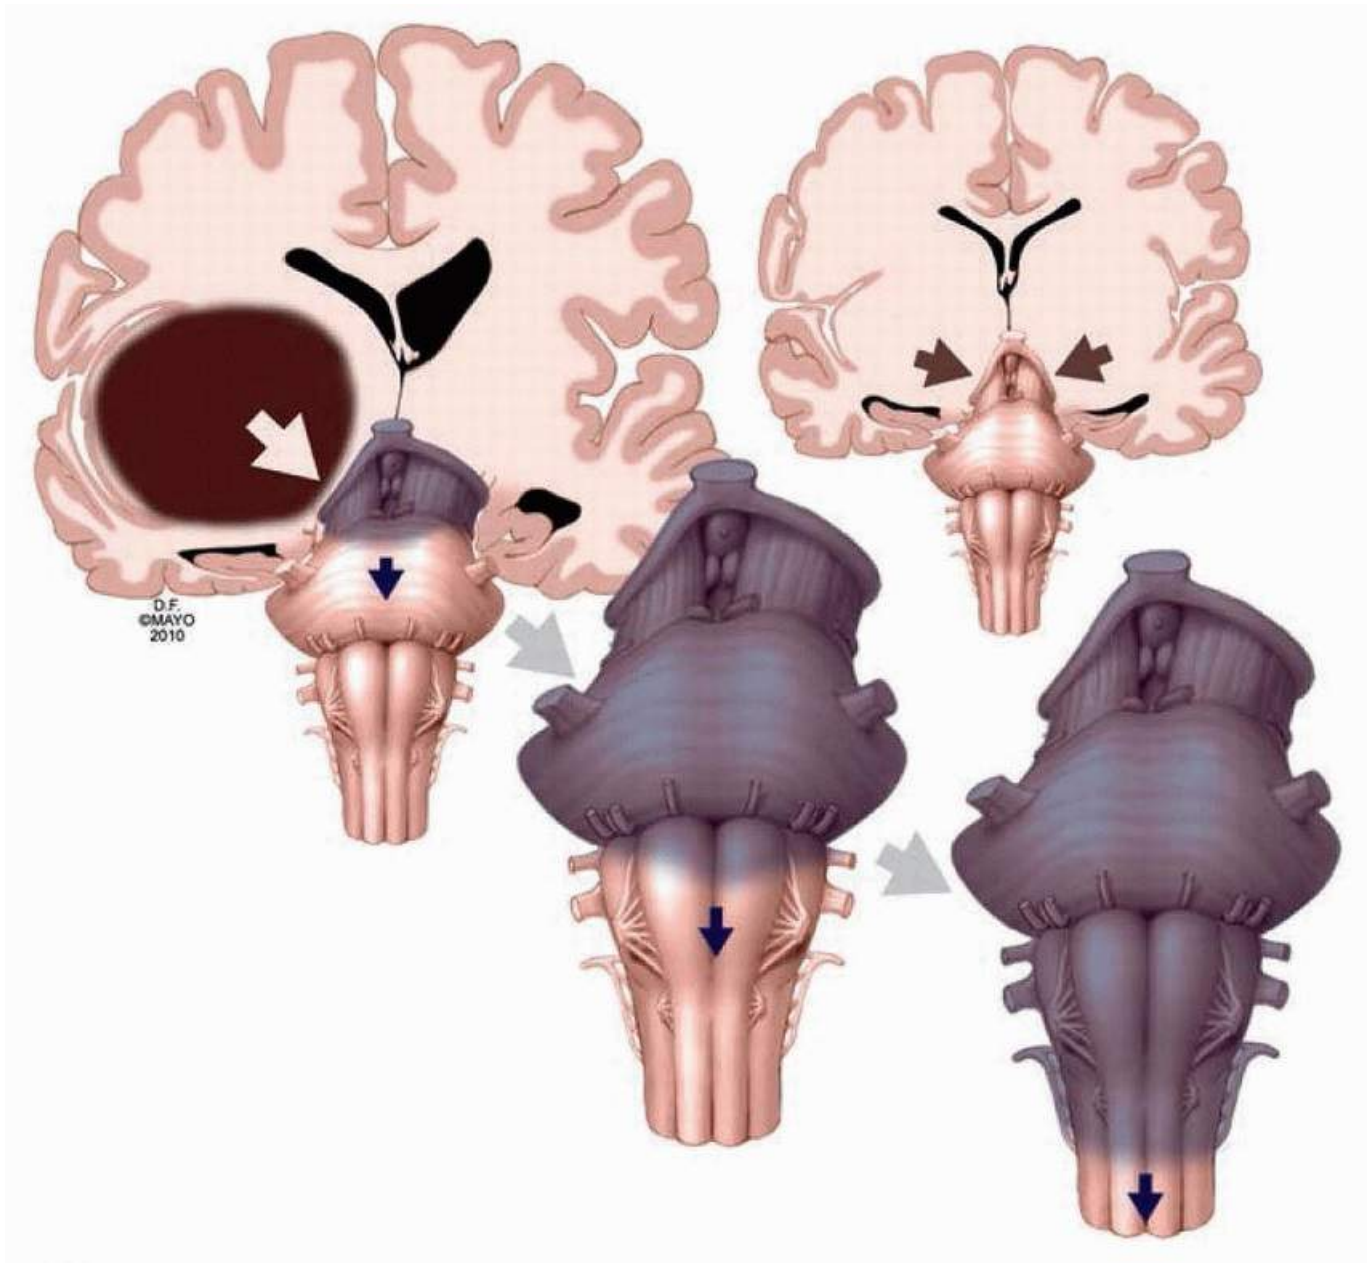

FIGURE 19.1 Supratentorial lesions (mass, cerebral edema) leading to rostrocaudal damage of the brain stem and eventually to brain death. *Arrows point at direction of tissue compression and loss of function.* (Courtesy of the Mayo Foundation for Medical Education and Research.)

The determination of brain death is a fundamental skill for the neurologist but experience could be waning. In many regions, the incidence of brain death has declined over the last decade. It is possible that family members may decide to withdraw when the situation is already hopeless and do not want to wait any further. Improved neurosurgical care, in particular early decompressive craniotomy, may also have contributed.

Brain death determination is relatively straightforward. Physicians should work through a set of criteria and not be swayed by supposedly quicker options. This chapter provides ways on how to proceed with this evaluation and how to prevent common pitfalls.

THE CLINICAL DIAGNOSIS OF BRAIN DEATH

Declaring a patient brain dead can be considered in a comatose patient with a major destructive brain injury, loss of at least three brain stem reflexes, and no evidence of a breathing effort. A more formal assessment, however, may only proceed when the patient worsens even more, when all medical or neurosurgical interventions are futile, and when there are no confounding factors or alternative explanations. The clinical examination starts

a patient with a massive acute brain injury has no motor response to pain, fails to grimace to pain, has absent brain stem reflexes, and does not trigger the ventilator. Commonly, the patient has become hypotensive and polyuric from diabetes insipidus and has been placed on vasopressors. Using this starting point, many patients will fulfill the criteria of brain death after detailed neurologic examination. With any other (earlier) starting point, there is a greater chance that there will be retained brain stem function and even spontaneous breathing when the patient is briefly disconnected.

DETERMINE THE CAUSE OF BRAIN DEATH

Brain death evaluation involves several sequential steps. First, there is nothing more important than to be very certain that all possible confounding factors have been excluded. This implies there can be no lingering effects of prior sedation, other confounding medications, or prior use of illegal drugs or alcohol. A reasonable guideline is to calculate five to seven times the drug's elimination half-life in hours and allow that time to pass before clinical examination is performed. Examples of long elimination half-life drugs are phenobarbital (100 hours), diazepam (40 hours), amitriptyline (24 hours), primidone (20 hours), and lorazepam (15 hours). A commonly used short-acting benzodiazepine is midazolam, but the elimination may still take 3 hours. Prior use of therapeutic hypothermia may substantially slow down the metabolism of medications such as lorazepam and fentanyl used to support the procedure. Substantial alcohol levels should be excluded, but alcohol content below the legal alcohol limit for driving (blood alcohol content 0.08%) is acceptable to determine brain death. Absence of neuromuscular blockade (defined by the presence of four twitches with a train of four with maximal ulnar nerve stimulation) should be demonstrated but is likely if the patient has tendon reflexes (or breathes). Furthermore, absence of severe electrolyte, acid-base, or endocrine disturbances (defined by marked acidosis or any substantial deviation from the normal values) should be documented. A core temperature greater than 32°C must be present, but preferably, there should be near normothermia (36°C to 37°C), which can be achieved with a warming blanket—assuming the patient is not a victim of environmental severe hypothermia. Systolic blood pressure should be greater than 90 mm Hg because pupil size and light reflex can fully disappear with lower values. Only after these confounders have been addressed should a more formal examination proceed.

IMAGING CONFIRMATION OF BRAIN DEATH

Next, the computed tomography (CT) scan should be carefully reviewed and expectedly demonstrate massive brain destruction. Abnormalities may include a large mass with brain tissue shift, multiple hemorrhagic lesions, or diffuse cerebral edema with obliteration of basal cisterns. CT scan can be initially normal if the patient has been imaged very early after cardiopulmonary arrest. However, in the patients with anoxic-ischemic encephalopathy who eventually fulfill these criteria, brain edema or marked hypodensities in thalami, caudate nuclei, and basal ganglia are typically seen on a repeat CT scan. A normal CT should under no circumstances be acceptable. In some cases of cardiac arrest, a magnetic resonance imaging can be helpful to demonstrate the full extent of ischemic tissue damage compatible with brain death.

CLINICAL EXAMINATION

The main components of neurologic examination and technique of the apnea test in a patient suspected of brain death are summarized in [Table 19.1](#).

Cranial Nerves

Clinical examination can proceed after these aforementioned hurdles have been cleared. The examination begins with evaluation of pupillary responses. Pupils should be midposition (4 to 6 mm) and unresponsive to light. A magnifying glass or handheld pupillometer can be helpful, in particular, when there is an uncertainty

about the reactivity of pupils. One should be aware that atropine used during cardiopulmonary resuscitation may cause pupillary dilation, but intravenous (IV) drugs do not change reactivity. The corneal reflex is tested with squirting water on the cornea or by touching with a tissue and no blink response should be seen. (Subtle blink responses may be only a movement of eyelashes.) Oculocephalic reflexes (“doll's eyes”) should be absent bilaterally (fast turning of the head to both sides should not produce any ocular movement). The oculovestibular response (“cold calorics”) should be absent. The head should be elevated 30 degrees. Approximately 50 mL of ice water is then infused in the external auditory canal. No eye movement should be observed for 2 minutes. The examination then proceeds with evaluation of gag and cough reflexes, both of which should be absent. Gag reflex could be tested by a movement of the endotracheal tube but is far more reliable with sticking a gloved finger of the examiner deep in the back of the throat moving the uvula. Cough reflex should be tested by deep bronchial suctioning and with at least two passes.

Motor Responses to Pain

The comatose patient should be unresponsive to verbal or painful stimuli. Standard noxious stimuli include compression of the supraorbital nerves, forceful nail bed pressure, and bilateral temporomandibular joint compression. Eye opening to noxious stimuli should be absent. No motor response should be observed. Some motor responses may be preserved and the challenge is to label them as “spinal responses.” They may occur with neck flexion and nail bed compression but are absent with supraorbital nerve compression. These responses are not classifiable as decorticate or extensor responses because that would imply an intact subcortical circuitry. These responses are uncommon—and far less common than claimed in the literature—but include triple flexion responses, finger flexion or extension, head turning, and slow arm lifting. These movements do, on occasion, cause concern for the family members (and later even transplant surgeons) and have to be properly explained and documented in the medical record.

Apnea Testing

Finally, absent breathing is proven with a formal apnea test. The apnea test is best performed under controlled circumstances and with disconnection of the mechanical ventilator. The ventilator may spuriously indicate a breathing drive of the patient and this phenomenon—caused by minimal pressure or volume changes in the breathing circuit—is quite commonly not recognized. There is a real concern that some patients with “retained breathing drive” may have been excluded from formal testing, or worse, a prolonged waiting time for the respiratory drive to “disappear” may have led to premature cardiac arrest in a potential organ donor.

The apnea test is a complex testing procedure. The patient is prepared (preoxygenation, reducing positive end-expiratory pressure to 5 cm of H₂O and drawing a baseline blood gas), then disconnected from the ventilator, while an oxygen source is provided with an oxygen flow catheter placed at the level of the carina. The oxygenation diffusion method is very safe method with few aborted tests. Demonstration of apnea with a rise in PCO₂ to

P.166

60 mm Hg or 20 mm Hg about a normal baseline value after completion of the brain stem reflexes defines brain death and death of the patient (the time of the second blood gas is best used as the official time of death).

TABLE 19.1 Twenty-five Clinical Assessments to Diagnose Brain Death

Prerequisites (all must be checked)

1. Coma, irreversible and cause known

2. Neuroimaging explains coma.

3. Sedative drug effect absent (*if indicated, order a toxicology screen*)

4. No residual effect of paralytic drug (*if indicated, use peripheral nerve stimulator*)

5. Absence of severe acid-base, electrolyte, or endocrine abnormality

6. Normal or near-normal temperature (*core temperature $\geq 36^{\circ}\text{C}$*)

7. Systolic blood pressure >100 mm Hg

8. No spontaneous respirations

Examination (all must be checked)

9. Pupils nonreactive to bright light

10. Corneal reflexes absent

11. Eyes immobile, oculocephalic reflexes absent (*tested only if C-spine integrity ensured*)

12. Oculovestibular reflexes absent

13. No facial movement to noxious stimuli at supraorbital nerve or temporomandibular joint or absent snout and rooting reflexes (*neonates*)

14. Gag reflex absent

15. Cough reflex absent to tracheal suctioning

16. No motor response to noxious stimuli in all four limbs (*Spinally mediated reflexes are permissible and triple flexion response is most common.*)

Apnea testing (all must be checked)

17. Patient is hemodynamically stable (*systolic blood pressure ≥ 100 mm Hg*).

18. Ventilator adjusted to normocapnia (*PaCO_2 35-45 mm Hg*)

19. Patient preoxygenated with 100% FiO_2 for 10 min (*$\text{PaO}_2 \geq 200$ mm Hg*)

20. Patient maintains oxygenation with a PEEP of 5 cm H₂O.

21. Disconnect ventilator.

22. Provide oxygen via an insufflation catheter to the level of the carina at 6 L/min or attach T-piece with CPAP valve at 10 cm H₂O.

23. Spontaneous respirations absent

24. Arterial blood gas drawn at 8-10 min, patient reconnected to ventilator

25. PaCO₂ ≥60 mm Hg or 20 mm Hg rise from normal baseline value or

Apnea test aborted and ancillary test (EEG or cerebral blood flow study) confirmatory

Documentation

- Time of death (*use time of blood gas result or time of ancillary test*)
-

Brain death guideline recommendations

- Newborn (≥37 wk gestational age) to 30 days: two examinations, two separate physicians, 24 h apart
-

- 30 days to 18 yr: two examinations, two separate physicians, 24 h apart
-

- 18 yr or older: one examination (*A second examination is needed in six U.S. states: CA, CT, FL, IA, KY, LA.*)
-

C-spine, cervical spine; PEEP, positive end-expiratory pressure; CPAP, continuous positive airway pressure; EEG, electroencephalogram; CA, California; CT, Connecticut; FL, Florida; IA, Iowa; KY, Kentucky; LA, Louisiana.

ANCILLARY TESTS TO CONFIRM THE DIAGNOSIS OF BRAIN DEATH

Technical tests to support the clinical diagnosis of brain death have been developed and may demonstrate absent blood flow to the brain or absent electrical activity of the cortex ([Table 19.2](#)). These tests have considerable inaccuracy and should not replace, in any way, a clinical assessment. Interpretation of these tests, when results are not obvious, remains difficult and results of multiple tests may not be matching. Elevating an ancillary test to a diagnostic test may lead to errors in brain death determination. Ancillary tests are used in less than 5% of patients diagnosed with brain death and are better generally avoided. These tests have mostly been

used when there is an inability to perform an apnea test (due to poor oxygenation of the patient, hemodynamic instability, or evidence of prior chronic CO₂ retention). Some countries in the world legally require performing these tests, but in the United States, there is no such requirement. Once the patient is declared brain dead and time of death is documented in the medical record, decisions can be made without further hesitation

P.167

and should first involve notification of organ donation agencies. Refusal of organ donation (in estimated 30% of cases) will lead to withdrawal of support.

TABLE 19.2 Tests Commonly Used for the Confirmation of Brain Death

- 1. Electroencephalography (EEG):** Confirmation of neocortical death can be documented by at least 30 min of electrocerebral silence, using a 16-channel instrument with increased gain settings, according to guidelines developed by the American Electroencephalographic Society. If any brain wave is present, the diagnosis of brain death cannot be made. EEG confirmation of brain death is also not valid in patients exposed to sedatives or toxins because they can directly suppress the brain electrical activity.
- 2. Digital subtraction or CT angiography:** Complete absence of intracranial blood flow above the level of the proximal internal carotid and vertebral arteries confirms the diagnosis of brain death.
- 3. Radioisotope cerebral imaging:** The complete absence of cerebral perfusion can also be established using radionuclide angiography or single-photon emission computed tomography (SPECT).
- 4. Transcranial Doppler ultrasonography:** A velocity profile showing systolic spikes with absent or reversed diastolic flow is consistent with the cessation of cerebral blood flow and brain death.

CT, computed tomography.

BRAIN DEATH IN CHILDREN

Brain death in children was recently revisited by a multidisciplinary task force. Most concerns regarding interpretation of neurologic examination are in neonates several months old, and the advanced skills of a neonatologist are needed to obtain reliable findings. Examination of a child in an incubator remains limited, and neurologists should be aware of incompletely developed brain function and motor response. The new pediatric guideline suggests a 24-hour interval between examinations by two physicians in neonates and children from 37-week gestation to the end of the first month. However, in children aged 1 month or older, the pediatric guidelines still impose two examinations 12 hours apart by two different attending physicians. Two examinations in children are different from adults but the need for such a distinction is highly questionable. The guideline also recommends that physicians be competent to perform examinations in infants and neonates but speculatively suggest that these examinations be performed by pediatric intensivists and neonatologists, pediatric neurologists and neurosurgeons, pediatric trauma surgeons, and pediatric anesthesiologists with critical care training.

COMMON DIAGNOSTIC CHALLENGES AND PITFALLS

The examination and later communication with distraught family members requires experience. There are situations that can easily create unease and uncertainty. Some common mistakes are shown in [Table 19.3](#). Most

pitfalls relate to premature assessment of the patient and suggesting the patient might be brain dead when there has not been a formal evaluation.

Therapeutic hypothermia has become a common treatment of comatose patients following cardiopulmonary resuscitation. However, the category of patients who fulfill brain death after cardiopulmonary resuscitation more often are hemodynamically unstable, and many of them die from irreversible cardiac shock before brain death can be determined. The clinical examination of brain death may be difficult to complete due to persistent hypotension and use of multiple vasopressors. The apnea test may also be compromised due to the presence of significant pulmonary edema from cardiac failure. How to assess these patients after prior use of therapeutic hypothermia and use of sedative drugs remains unclear, and it may be prudent not to proceed with a brain death examination at all.

TABLE 19.3 Common Misjudgments in the Diagnosis of Brain Death

- Incomplete testing

- Examination in a patient with confounders (mostly recently administered medication, drug, and alcohol use)

- Use of cerebral blood flow study as a diagnostic test

- Misinterpretation of ancillary test

- Misinterpretation of “spinal reflexes”

- Premature discussion with family about brain death and organ donation

The most important challenge for physicians is to perform a complete examination in patients with primary lesion in the brain stem. More often than not, physicians will find patients with a primary brain stem lesion or a compressed brain stem from a cerebellar lesion that do not fulfill all criteria of brain death and may even benefit from aggressive intervention (ventriculostomy or suboccipital craniotomy). A destructive primary brain stem lesion is as irreversible lesion as the one that involves the hemispheres and brain stem, and it is therefore unnecessary to perform an ancillary test. These tests often will show preserved blood flow when the intracranial pressure has not increased to extreme values, and early electroencephalography may show nonreactive alpha or spindle coma patterns.

Ancillary testing demonstrating complete intracranial circulatory arrest by catheter or CT angiography or a radionuclide brain perfusion study remains very problematic if used to confirm brain death in the setting of confounding medications, hypothermia, or metabolic disarray.

INTENSIVE CARE UNIT MANAGEMENT OF THE POTENTIAL ORGAN DONOR

Brain death eventually leads to severe homeostatic derangements and cardiac arrest, despite mechanical ventilation and aggressive life support measures. This inexorable progression toward multisystem organ failure creates a challenge in managing the potential organ donor, in whom the goal is to maintain and optimize organ viability for transplantation.

A suggested algorithm for critical care management of the potential organ donor is shown in [Table 19.4](#). Most patients become hypotensive due to sudden loss of resting sympathetic tone and require IV pressors at the time brain death occurs, and soon thereafter, they develop diabetes insipidus (because antidiuretic hormone secretion ceases). *Arginine vasopressin* is the first-line therapy for hypotension in brain death because it works effectively and also because it guards against central diabetes insipidus, which also occurs in the majority of brain dead patients. Adrenergic vasopressors such as norepinephrine or dopamine can also be added, but their usefulness can be limited by tachyarrhythmias, severe peripheral vasoconstriction, or aggravation of sympathetically mediated myocardial injury. In some cases, continued hypotension will respond to thyroid and glucocorticoid hormone replacement, indicating a relative deficiency of these hormones.

To maintain adequate systemic organ perfusion, large volumes of isotonic fluid resuscitation in the form of normal saline, plasmalyte, or lactated Ringer solution should be given in the range of 100 to 250 mL/h. The goal of euvolemia can be assessed targeting mean arterial pressure of greater than 65 mm Hg, central venous pressure of greater than 5 mm Hg, and a cardiac index of greater than 3.0 L/min/m² and be documenting lack of respiratory variation of the inferior vena cava diameter with ultrasound. Reversal of hypernatremia due to untreated diabetes insipidus is best accomplished by calculating the free water deficit and replacing it over 24 to 48 hours with a concomitant infusion of 5% dextrose solution.

The situation usually deteriorates when brain dead patients are maintained on a ventilator for a prolonged period of time. Hypothermia, metabolic acidosis, renal failure, and adult respiratory distress syndrome may all occur. The key to management is to be ready for these complications. Even with meticulous attention to cardiovascular, acid-base, and electrolyte homeostasis, organ viability in most adult patients with brain death can be maintained for only 72 to 96 hours.

TABLE 19.4 Protocol for Management of the Potential Organ Donor in the Intensive Care Unit

- | |
|--|
| 1. Insert a central venous catheter or two large-bore peripheral IV lines. |
| 2. Insert an arterial line for continuous BP monitoring. Maintain mean arterial pressure >65 mm Hg with stepwise intervention: |
| A. 1,000 mL 0.9% saline fluid bolus (two times at 10-min intervals) |
| B. Arginine vasopressin (Pitressin) 2.4-4.0 U/h |
| C. Norepinephrine starting at 5 µg/kg/min, titrated up to a maximal dose of 30 µg/kg/min |
| D. If hypotension is refractory to dopamine and/or IV vasopressin, perform a thyroxine (T ₄) replacement protocol: |
| i. Administer as sequential IV boluses: |
| a. Dextrose 50% (1 amp) |

b. Methylprednisolone 1 g

c. Regular insulin 4-10 units

d. Levothyroxine 20 µg

- ii. If the BP responds to the above boluses, start levothyroxine 5 µg/h as a continuous infusion and titrate to maintain the MAP >65 mm Hg. Note that thyroxine can precipitate cardiac arrhythmias, particularly in younger, hypokalemic patients.

3. Start baseline maintenance IV flow: 0.9% saline at 100-250 mL/h.

A. Adjust the maintenance IV flow to target a euvolemic state with CVP >5 mm Hg.

4. Correct any existing free water deficits due to untreated diabetes insipidus.

A. Check serum sodium levels every 6 h.

B. If sodium level is >150 mmol/L, calculate the free water deficit and replace it with an infusion of D5W over 24-48 h.

5. Adjust fraction of inspired oxygen and positive end-expiratory pressure to maintain oxygen saturation >94%.

6. Transfuse blood for a hemoglobin level <7.0 g/dL.

7. Insert a Foley catheter. Measure fluid input and urine output and monitor urine specific gravity every 2 h. If the urine output over 2 h is >500 mL with specific gravity of 1.005 or lower, begin treatment for DI:

A. If the patient is in frank DI with negative fluid balance, administer arginine vasopressin 6-10 units IVP.

B. Start IV pitressin 2.4-4.0 U/h titrated to maintain UO <200 mL/h.

8. Check the fingerstick glucose level every 4 h. If fingerstick glucose level is >180 mg/dL, begin an insulin drip (100 units regular insulin in 1,000 mL 0.9% saline) starting at 20 mL/h (2 U/h), titrated to maintain blood glucose between 120 and 180 mg/dL.

IV, intravenous; BP, blood pressure; MAP, mean arterial pressure; CVP, central venous pressure; D5W, 5% dextrose in water; DI, diabetes insipidus; IVP, intravenous push; UO, urine output.

CONCLUSIONS

Brain death examination requires expertise and follows a stepwise protocol. It is an obvious enough fact that

the diagnosis of brain death is complex due to its clinical testing, in determination of confounding factors, and in the interpretation of ancillary tests. The responsibilities of neurologists are substantial also because it eventually involves organ transplantation.

INTRODUCTION

This chapter provides a framework for understanding the basic principles of x-ray (roentgenogram) production and computed tomography (CT) image formation along with appropriate window and level parameters for evaluation of intracranial pathologies. In addition, the common indications for CT are discussed along with precautions and recommendations related to CT usage and iodinated contrast. Advanced CT modalities including CT perfusion and CT angiogram are given special consideration.

DESCRIPTION

CT is based on image reconstruction from sets of quantitative x-ray measurements through the head. A beam of x-rays serves as the source of photon energy, which is received by a detector. Although the exact physics of x-ray production is beyond the scope of this chapter, this section will try to simplify the basic principles of x-ray production important for image formation. Briefly, x-ray beams are generated when electrons, produced in the cathode of the tube unit, strike the anode target. The potential difference across the tube is measured as peak kilovoltage (kVp). Thus, increasing the kVp increases the energy of x-rays produced, which will increase penetration of the beam during image production but decrease contrast (and vice versa). Imaging intravenous (IV) or oral contrast in CT imaging is based on the differential attenuation of the x-ray beam through various tissues. As the electron density of the tissue increases, the attenuation increases (giving a “whiter” image). Therefore, the bony calvarium appears “white” compared to soft tissue and air because of its greater attenuation.

Modern CT scanners use highly collimated x-ray beams, which are rotated over many different angles to obtain a differential absorption pattern across various rays through a slice of a patient's body. A circular scanner gantry houses the x-ray source and detectors; the plane of the circle can be tilted to perform scans at a range of angles from axial to coronal, depending on head position and scanner specifications. The x-ray source rotates around the patient's head, and the x-ray attenuation through the section plane is measured in compartments called *voxels*. A voxel is a volume element similar to a picture element, or pixel, with the added dimension of section thickness to create an image volume component. Through projection reconstruction, the computer creates or builds the image from more than 800,000 measurements per image plane and assigns a number to each voxel according to its x-ray attenuation (which is proportional to tissue electron density averaged over the volume of the voxel). These values are termed *Hounsfield units* (HU) ([Table 20.1](#)) in honor of Nobel Prize winner Sir Godfrey Hounsfield who first developed CT technology in 1973.

CT of the head differentiates cerebrospinal fluid (CSF) and brain as well as white matter and cortical gray matter, delineates the deep gray nuclei from the internal capsule, and images the skull and skull base in detail. Noncontrast computed tomography (NCCT) of the brain is especially useful for identifying acute hemorrhage, which is easily and reliably visualized as higher density than normal brain or CSF. Typically, intracranial arteries are not well delineated on standard NCCT. Iodinated water-soluble contrast agents, which have high x-ray density, when administered intravenously enhance differences in tissue density, demonstrate vasculature and vascular pathology, and detect areas of blood-brain barrier breakdown.

A major limitation of CT has been imaging the posterior fossa, where linear artifacts appear because bone

selectively attenuates the low-energy components of the x-ray beam; the resulting “beam hardening” creates dense or lucent streaks that project across the brain stem and may obscure underlying lesions in the brain stem and cerebellum. However, new detector technology and image-processing algorithms have reduced this artifact in the latest CT scanners, improved spatial resolution, and reduced the radiation dose. Current CT technology allows scan time per section (“slice”) to be shortened to less than 1 second to minimize motion artifact. Multisection helical CT can acquire contiguous thin sections to produce three-dimensional (3D) data sets of an entire body part, such as the neck or head. Rapidly, repeated acquisitions can be used to acquire dynamic computed tomography angiography (CTA) and computed tomography perfusion (CTP) studies, which will be discussed later in this chapter.

TABLE 20.1 Hounsfield Units for Common Structures

Structure	HU
Air (blackest)	-1,000
Fat	-100 to -50
Water	0
Cerebrospinal fluid	0-15
White matter	20-30
Gray matter	35-45
Acute hemorrhage ^a	45-65
Bone (whitest)	>500

^aIn patients with anemia or iron deficiency, Hounsfield unit values for hemorrhage may be lower.

HU, Hounsfield unit.

FIGURE 20.1 NCCT of the head with standard brain (A) and narrow stroke (B) windows in a patient with acute right-sided weakness. Stroke windows reveal loss at the left insular ribbon (*arrow*), which was not clearly visualized on conventional windows.

WINDOWS AND LEVELS

Although CT imaging can display 4,096 shades of gray, the human eye can only visualize between 16 and 32 shades of gray, which is well beyond human perception. “Windowing” allows users to narrow the range of shades of gray, which in turn adjusts the contrast scale. Two factors that can be adjusted by the user are the window width (W) and the window level (L). The W determines the range of shades of gray that can be displayed. Therefore, “narrowing the window” would increase the contrast of the image. The L determines the center of the W. By convention, users can decrease the W by dragging the mouse from right to left, increasing the contrast. The L can be decreased by dragging the mouse from top to down on monitors.

Although the default “brain window” (80 W 40 L) is suitable for assessing a wide range of pathologies, there are several other important windows for neuroimaging to assess for subtle abnormalities. For example, evaluation of parenchymal hypodensity as a marker for early infarct in stroke patients may be improved by using narrow windows (35 W 35 L) (Fig. 20.1). Additionally, subdural hemorrhages are often located at the convexities adjacent to bone and may be difficult to identify due to beam hardening and volume averaging. Using wider windows may assist in countering these limitations (Fig. 20.2). Lastly, bone windows (2,000 W 200 L) are formed with wide ranges and centered above soft tissues and are best for evaluating for subtle nondisplaced calvarial fractures (Fig. 20.3).

FIGURE 20.2 NCCT of the head with standard brain (A) and wider subdural windows (B) in a patient after fall. Subdural windows reveal a subdural hematoma at the left parietal convexity (arrow), which is not clearly visualized on conventional windows.

ROLE OF COMPUTED TOMOGRAPHY

For reasons of cost, speed, and availability, CT remains widely used for screening in the acute evaluation of trauma, stroke, and infections (Table 20.2). CT is widely accepted as the more reliable method for detection of acute brain parenchymal or extra-axial hemorrhage, especially subarachnoid hemorrhage. It is particularly useful for patients who are neurologically or medically unstable, uncooperative, or claustrophobic, as well as for patients with pacemakers or other metallic implants that may be contraindications for magnetic resonance imaging (MRI). The principle drawback of CT is its use of ionizing radiation, which will be discussed at the end of this chapter. Although there are numerous indications for obtaining a CT examination of the central nervous system, this section will briefly focus on the appropriate use of CT in common clinical scenarios.

P.171

FIGURE 20.3 NCCT of the head with standard brain (A) and bone (B) windows in a pediatric patient after fall. Bone windows (right, at arrow) reveal a nondisplaced hairline fracture at the right temporal bone, which is not visualized on conventional windows.

HEAD TRAUMA

An NCCT is the most appropriate first study for evaluation of acute head trauma. In patients with moderate or high risk for intracranial injury, there is consensus that postinjury NCCT is useful in excluding intracerebral hematoma, midline shift, or increased intracranial pressure. Additionally, NCCT is also very sensitive for identification of acute trauma in patients with minor head injury with the following risk factors: headache, vomiting, drug/alcohol intoxication, age older than 60 years, short-term memory deficit, physical findings of supraclavicular trauma, and/or seizure. CT's advantage for evaluation of traumatic injury includes its sensitivity for acute hemorrhage, fractures, and mass effect. CT is limited by its relative insensitivity to lesions adjacent to bony surfaces (i.e., at the greater sphenoid wing) due to streak artifact. Additionally, diffuse axonal injury (DAI) may go undetected.

HEADACHE

Routine screening head CT is generally not warranted in patients with chronic headaches in the absence of focal neurologic symptoms, change in headache pattern, or history of seizure activity. Several studies have confirmed the low yield of neuroimaging in individuals with isolated headaches and have reported a 0.4% yield for treatable

lesions. However, neuroimaging is likely to be of greater yield for particular patient populations. For example, patients with cancer, immunocompromised status, or other systemic illness are more likely to have a “positive” scan. Imaging may also offer greater yield in headaches associated with trauma, abrupt or worsening headache, headache radiating to the neck or suspected meningitis, positional headache, or temporal headaches in older patients. Regarding suspected meningitis, CT imaging is often performed prior to lumbar puncture to assess for elevated intracranial pressure.

TABLE 20.2 Common Indications for Emergency Computed Tomography Examination

Acute or chronic focal neurologic deficit

Head or facial trauma

Headache

Change in mental status

New-onset seizure

SUBARACHNOID HEMORRHAGE

NCCT imaging remains the most appropriate choice of imaging for patients with suspected subarachnoid hemorrhage (SAH), and failure of obtaining a head CT accounts for 73% of misdiagnosis. Patients diagnosed with SAH require imaging of the cerebral vasculature, which may include CTA, magnetic resonance angiography (MRA), or direct catheter angiography. CTA has gained popularity and is frequently used for its noninvasiveness and sensitivity and specificity comparable to that of cerebral angiography.

STROKE

Initial workup for patients with suspected acute stroke is an NCCT in patients who are candidates for IV tissue plasminogen activator (TPA) in order to differentiate between hemorrhagic and ischemic infarcts. NCCT remains the standard of care imaging modality for exclusion of intracranial hemorrhage. In considering patients for endovascular therapies, the American Society of Neuroradiology, American College of Radiology, and Society of NeuroInterventional Surgery have recommended that appropriate imaging options include NCCT followed by digital subtraction angiography, or NCCT with CTA and perfusion CT, or MRI (with perfusion) and MRA. Although NCCT has relatively low sensitivity to early ischemic injury compared to magnetic resonance diffusion imaging, it is not recommended that these findings be used to withhold IV TPA treatment. With regard to CTP and CTA, its use has gained increased popularity in acute stroke evaluation and will be discussed in the subsequent section.

COMPUTED TOMOGRAPHY PERFUSION AND ANGIOGRAPHY

Spiral CT increases scanning speed and image acquisition to less than 1 second per section and allows large-volume acquisitions that can be used for 3D presentation of anatomic information. Advances in CT technology have widened the extent of coverage per scan rotation from 2 cm (32 slices) to 4 cm (64 slices) and most recently, to 16 cm (320 slices), which allows a set of images of the entire head to be obtained in a few rotations as the patient moves through

the scanner or in as little as a single subsecond scan rotation in a stationary patient using the widest detector array. Rapidly repeating the scan acquisitions at two or three times per second during a bolus of IV contrast produces a set of “dynamic” images through a volume of tissue as wide as the detector array. This approach, with the widest detector array on a cone beam computed tomography (CBCT), can be used to produce whole-brain “real-time” 4D images of blood flow through the intracranial vessels (CTA) combined with “functional” images of brain parenchymal blood flow (CTP) in a total time of 1 minute, with a single IV contrast bolus injection.

CTA allows vascular imaging with IV contrast agents. Without contrast, intracranial vessels are not well seen on CT, unless abnormally large or dense—as with a thrombus. As previously described, modern CT scanners allow for rapid imaging, which permits noninvasive arterial phase imaging. Advantages of CTA over catheter angiography include more widely available technology; less specialized skill requirements; and no risk of dissection, stroke, or pseudoaneurysm at groin site. A limitation of CTA is the time-consuming processing required to edit out bone and calcium and to generate 3D surface renderings, although this has improved with the availability of specialized software that partially automates this process. *Maximum intensity projection* (MIP) reformations or 3D renderings with surface shading can be used to display vascular anatomy and abnormalities such as stenosis or aneurysm with either of these approaches.

CT perfusion allows quantitative measures of cerebral blood volume (CBV), cerebral mean transit time (MTT), time-to-peak (TTP), and cerebral blood flow (CBF). These parametric maps can be easily generated at a work station, following the IV bolus administration of contrast. Perfusion imaging measurements can be used as a quick screening method in assessment of acute cerebral ischemia in major vascular territories and for differentiating between infarct and penumbra, with results comparable to MRI perfusion. Specifically, the infarct core, that is, region of irreversible injury, has been described as prolonged MTT, decreased CBV, and decreased CBF. The ischemic penumbra, potentially salvageable tissue, is described as prolonged MTT and TTP with normal or increased CBV and resultant mildly reduced CBF, thought to reflect compensatory vasodilatation. The combination of NCCT, CTA, and CTP allows CT imaging to provide a complete evaluation of acute stroke.

IODINATED CONTRAST ADMINISTRATION

Contrast-enhanced computed tomography (CECT) is used to detect lesions that involve breakdown of the blood-brain barrier, such as brain or spinal tumors, infections, and inflammatory conditions. CECT is often used to rule out cerebral metastases. However, it is less sensitive than gadolinium-enhanced MRI (Gd-MRI), which is also better for detection of primary intracranial tumors and infections. IV CT contrast agents are based on iodine, and the older agents are classified as high-osmolar contrast media (HOCM). Newer, nonionic agents, classified as low-osmolar contrast media (LOCM), are less allergenic, and they cause less morbidity than do HOCM. The majority of patients receiving IV iodinated contrast media will have suffer no ill effects. With use of LOCM, the overall incidence of reactions is between 0.2% and 0.7% with severe and life-threatening reactions occurring between 0.01% and 0.02%.

With regard to the risk factors, history of prior contrast reaction is associated with a five times greater likelihood of a subsequent contrast reaction. Other risk factors include history of anaphylaxis, atopy, asthma, and significant cardiac disease. Of note, history of shellfish allergy is no longer considered a risk factor for contrast administration. In patients at increased risk for allergic reaction, several premedication strategies have been proposed by the American College of Radiology ([Table 20.3](#)).

TABLE 20.3 Premedication Strategies for Patients with Known Risk Factors to Intravenous Iodinated Contrast Agents

Elective Prednisone: 50 mg PO at 13 h, 7 h, and 1 h before contrast injection
or
Methylprednisolone: 32 mg PO 12 h and 2 h before contrast injection
plus
Diphenhydramine: 50 mg IV, IM, or PO 1 h before contrast

Emergent In decreasing order of desirability:
Methylprednisolone sodium succinate: 40 mg
or
Hydrocortisone sodium succinate: 200 mg IV q4h until contrast injection
plus
Diphenhydramine: 50 mg IV 1 h prior to contrast injection

PO, by mouth; IV, intravenous; IM, intramuscular.

Data from the American College of Radiology. *ACR Manual on Contrast Media, Version 9*. Reston, VA: American College of Radiology, ACT Committee on Drugs and Contrast Media; 2013.

Another important consideration for iodine-based IV contrast agents is contrast-induced nephrotoxicity (CIN), which is defined as an acute deterioration in renal function following IV iodinated contrast administration in the absence of other nephrotoxic event. However, the majority of the prior literature studying the incidence of CIN has failed to include a control group. In one study with a control group by Newhouse et al. involving 30,000 patients at a single institution, half of the control group (patients who did not receive contrast medium) displayed a change in serum creatinine of at least 25% and a change of 0.4 mg/dL in 40%. This study concluded that had some of these patients received IV iodinated contrast, a creatinine rise would have been attributed to it, rather than to physiologic variation. Nonetheless, it is important to recognize risk factors described for CIN, which includes preexisting renal insufficiency.

There is no universally agreed upon threshold of serum creatinine elevation (or degree of renal dysfunction) to contraindicate intravascular iodinated contrast administration. With regard to prevention against CIN in patients receiving contrast, studies suggest that adequate hydration is beneficial. Although an accepted ideal infusion rate has yet to be established, isotonic fluids are

P.173

preferred (i.e., lactated Ringer or 0.9% normal saline). Protocols using sodium bicarbonate solution infusion or N-acetylcysteine exist for reducing the risk of CIN (Table 20.4). These are safe and reasonable therapeutic options when IV contrast is required for patients with chronic renal insufficiency, although their efficacy is not established.

TABLE 20.4 Premedication Strategies for Patients at Risk for Contrast-Induced Nephropathy

1. A 3 mL/kg bolus 1 h prior to procedure followed by 1 mL/kg/h for 6 h postprocedure
2. N-acetylcysteine 600 mg PO/IV 12 h preprocedure, followed by 600 mg q12h PO/IV postprocedure × three doses

PO, by mouth; IV, intravenous.

Magnetic Resonance Imaging

Vesselin Zdravkov Miloushev

Angela Lignelli

INTRODUCTION

Magnetic resonance imaging (MRI) is a noninvasive medical imaging technique. The images created by MRI often appear similar to gross-anatomic specimens. The major strength of MRI is the ability to distinguish different soft tissues and identify pathologic abnormalities. It is indispensable to modern neurologic practice for diagnosis, confirmation, and characterization of neurologic conditions, as well as for monitoring response to therapy. Although MRI signal abnormalities can be very sensitive to pathologic processes, in isolation, the findings may lack specificity, requiring thorough integration of clinical information. The main weaknesses of MRI are cost, inherent low signal to noise necessitating high magnetic fields as well as lengthy exam times, and distortion of images by artifacts. The MRI scanner consists of a bore that is generally small and constricting, creating anxiety or claustrophobia in many patients. In addition, implanted devices can be ferromagnetic and therefore contraindicated for MRI imaging, for example, most pacemakers. As in all radiologic procedures, contrast agents should be administered when the benefit of improved diagnostic accuracy outweighs their generally low risk. In the following paragraphs, the physics of MRI and technical considerations will be discussed. In addition, the application of basic imaging sequences and advanced imaging methods will be reviewed.

PHYSICS OF MAGNETIC RESONANCE IMAGING

MRI is based on Fourier transform nuclear spin spectroscopy of water protons. Clinical imaging is performed on the nuclear spin of water protons because water is abundant in biologic tissues and protons have relatively greater sensitivity in a magnetic resonance than other nuclei.

In the classical description relevant for clinical imaging, MRI can be understood by considering the spin properties of protons to be equivalent to small magnetic dipoles that align in a magnetic field. In the quantum mechanical description of proton magnetic resonance, individual proton spins exist as a combination (superposition) of two quantized energy states, transitions between which can be manipulated using radiofrequency pulses and delays. The very large number of water protons leads to behavior of biologic tissues in the magnetic field that can be thought of as net magnetization. This longitudinal magnetization can be *tipped* from the aligned state by a radiofrequency excitation pulse. The change in angle from the original aligned state is called the *flip angle*. Once in the transverse plane, the magnetization begins to rotate (precess) around the magnetic field at a specific resonant frequency called the *Larmor frequency* (~43 MHz per tesla for protons). This precessional motion in turn generates a time-varying voltage in a receiver coil. The specific resonance frequency depends on the nucleus being imaged, its local environment, and the magnetic field strength.

Relaxation of the signal back to equilibrium is described by the T1 and T2 exponential time constants. Relaxation of magnetization is not a spontaneous process but rather a phenomenon that is due to underlying molecular motion and molecular interactions. The BPP theory of relaxation named after Bloembergen, Purcell, and Pound has proven accurate and permits calculation of relaxation times from first principles. The two principal relaxation mechanisms are termed *T1* and *T2 processes*, which are relevant to clinical imaging and approximately depend on the molecular tumbling rate or rather the rotational diffusion of individual molecules. The T1 time constant describes the recovery of longitudinal magnetization back to the equilibrium aligned state (after a time T1 ~63% of the magnetization has realigned). The T2 time constant describes the decay of magnetization in the transverse

plane (after a time T_2 ~63% of the magnetization has decayed).

IMAGE CREATION

MRI creates images by applying linear spatial magnetic field gradients so that different parts of the human body resonate at different frequencies. One dimension can be sampled directly (called the *frequency dimension*), whereas other dimensions can be sampled indirectly (called *phase dimensions*). By combining multiple gradient directions, two-dimensional or three-dimensional images can be constructed.

The MRI signal is composed of time-dependent damped sinusoids and requires Fourier transformation to convert it to a power spectrum that is the image. The term *k-space* is used to refer to the time-dependent data. This is sometimes a source of confusion because the Fourier transform is very similar to its own inverse and acquisition of time-dependent MRI data in k-space is essentially equivalent to acquisition of different frequency components of the image. For this reason, it is often noted that the center of the k-space image determines image contrast (low-frequency components), whereas the edges of the k-space image determine detail in the image (high-frequency components).

Since the first live human images were obtained in the late 1970s, the field has drastically expanded to include a wide variety of clinical applications. The sequence of radiofrequency pulses, gradient pulses, and intervening time delays used to prepare magnetization and the methods of sampling k-space are referred to as the *pulse sequence*. Different pulse sequences are also tailored for specific applications. The two basic sequences are gradient echo and spin echo techniques, upon which additional sequences can be derived. Gradient echo sequences refocus magnetization following a radiofrequency pulse using a field gradient, whereas spin echo sequences refocus magnetization using a radiofrequency inversion (180-degree) pulse. Spin echo sequences are generally less susceptible to artifacts because artifacts are also inverted by the refocusing pulse and subsequently cancel out.

P.175

CLINICAL MAGNETIC RESONANCE IMAGING SYSTEMS

Clinical imaging systems are rated by the strength of the main magnetic field, referred to as the B_0 field, measured in tesla (1 T = 10,000 gauss ~15,000-40,000 the earth's magnetic field). The majority of clinical imaging systems use field strengths of 1.5 or 3 T. The term *high field* in the context of clinical imaging refers to magnet systems operating at 7 to 9 T. High-field systems have clear benefits in terms of improved anatomic resolution and increased signal to noise but are more prone to artifacts and require more radiofrequency power (higher specific absorption rate). Higher field magnets are typically closed-bore, meaning that they are shaped like long tube or cylinder. A variety of open-bore magnets is also commercially available. These magnets are more accommodating to variations in patient body habitus and typically create a less claustrophobic environment. Completely open-bore magnets operate at lower field strengths than closed-bore systems, with resultant lower resolution that may compromise clinical diagnosis.

Multiple components of the magnetic imaging system influence the ultimate sensitivity in detecting the magnetic resonance signal and generating a distortion-free image. One important physical factor that is changed between different applications is the radiofrequency coil. A variety of receive and transmit/receive coils are available for specific applications to the brain, head, neck, and spine. These include including bird cage-type coils for imaging the brain, surface coils, multichannel, and parallel imaging coils, all of which have different trade-offs in terms of size of allowed imaging volume, as well as sensitivity and speed of imaging.

MAGNETIC RESONANCE IMAGING SAFETY

The main safety considerations in MRI include the powerful main magnetic field, rapidly changing magnetic field gradients, deposition of radiofrequency power, sound pressure levels, and safety concerns related to contrast

agents. The powerful magnetic field produced by an MRI scanner is a major safety consideration because objects can become dangerous projectiles when placed in the field. Moreover, non-MRI-compatible implanted devices or metallic foreign bodies pose a danger because of local tissue-heating effects and movement of the object in respect to critical structures. Commonly encountered devices in clinical practice include implanted cardiac devices (e.g., cardiac pacemakers) as well as others such as infusion pumps, cochlear implants, and a variety of surgical implants such as some aneurysm clips. Recently, MRI-compatible cardiac devices have been devised and new MRI-compatible implanted surgical devices are being developed. However, precaution needs to be taken with every implanted device to ensure MRI compatibility and patient safety. Before the patient is even brought near the magnetic field, which is never turned off, a thorough safety check by appropriately trained medical personnel must be performed.

Once inside the MRI scanner, some patients may experience a variety of physical effects in addition to the possibility of claustrophobia. Federal limits on the main magnetic field strength imposed by the U.S. Food and Drug Administration are 8 T for adults and 4 T for neonates. Fields greater than these limits may pose a risk. Limits are also placed on the speed of the rapidly switching magnetic field gradients in MRI due to the possibility of neural or cardiac depolarization resulting in pain, auras, or possibly cardiac arrhythmias. Regulatory limits are also placed on the rate of energy deposition by radiofrequency pulses (similar to limits placed on cell phones for example). This limit is referred to as the *specific absorption rate* and meant to prevent heating damage of body tissues.

Gadolinium chelates are commonly used contrast agents in MRI because of the local relaxivity effects that lead to T1 shortening and resultant bright signal on T1-weighted images. Other contrast agents including manganese-based contrast agents and superparamagnetic iron oxides are currently less common in clinical practice. The risk of contrast administration in the context of MRI includes contrast reactions that may be life threatening. The deposition of gadolinium in tissues and resulting fibrosis, commonly known as *nephrogenic systemic fibrosis* (NSF), has been reported in patients with significantly reduced renal function necessitating appropriate screening.

BASIC SEQUENCES

For the purpose of clinical imaging, there are many sources of image contrast. Dynamic processes on the molecular level such as flow-related and diffusion effects and a variety of relaxation mechanisms are responsible for the power of MRI to generate contrast between different biologic tissues.

The basic sequences that are weighted for specific sources of image contrast are as follows:

- T1-weighted
- T2-weighted
- Fluid-attenuated inversion recovery T2-weighted
- Diffusion-weighted
- Susceptibility-weighted
- Post-contrast-enhanced images

T1-WEIGHTED AND T2-WEIGHTED IMAGING

The two core sequences in magnetic resonance are T1-weighted and T2-weighted sequences, which individually emphasize either the T1 or the T2 relaxation time of tissues. *T1-weighted* imaging emphasizes *short T1* relaxation times as bright signal; tissues composed of spins with long T1 relaxation times will appear relatively lower signal intensity (dark) on T1-weighted images. The main clinical use of T1 imaging is to display brain and

spinal cord anatomy. However, T1-weighted images are also useful to evaluate for subacute hemorrhage, lipids, paramagnetic metals, or proteinaceous composition of lesions, which all shorten the T1 relaxation time and appear bright on T1-weighted images. T1-weighted images also serve as the baseline comparison to contrast-enhanced images. T1-weighting can be accomplished by either decreasing the *repetition time* (TR) between successive excitations thus preventing magnetization from fully relaxing to equilibrium or by changing phase of successive radiofrequency pulses thus causing destructive interference (referred to as *spoiled gradient echo* or SPGR).

The main clinical use of T2 imaging is to display brain and spinal cord pathology, as evidenced by increased tissue water content. *T2-weighted* images emphasize *long T2* relaxation times as a bright signal. Tissues composed of spins with short T2 relaxation times will appear dark on T2-weighted images. However, susceptibility effects resulting in local field inhomogeneities also decrease the T2 time (this type of effect is sometimes referred to as *T2**). T2 weighting can be accomplished by increasing the time the magnetization spends in the transverse plane, or *time to echo* (TE), prior to acquisition. Different from both T1-weighted and T2-weighted images, proton-density (PD) weighted images are obtained with a short TE to minimize relaxation losses and long TR to allow more magnetization to recover between successive excitations.

P.176

Fluid-attenuated inversion recovery (FLAIR) is the preferred sequence for demonstrating subtle brain pathology. FLAIR images are obtained by preparing magnetization with a radiofrequency inversion pulse, which inverts the equilibrium alignment. As the magnetization relaxes back to the aligned state with the T1 time constant, it temporarily becomes negligible as it crosses zero and timing detection at this time can essentially null signal from spins with a specific T1. Although FLAIR sequences can be T1-weighted or T2-weighted, in common clinical parlance, the FLAIR method refers to FLAIR T2-weighted images. The main advantage of FLAIR images is sensitivity to detect a broad array of pathologic processes and is specifically useful for the evaluation of white matter diseases in the brain. The archetypal example is multiple sclerosis, which is characterized by periventricular white matter lesions, radially oriented to the bodies of the lateral ventricles (requiring both axial and sagittal FLAIR sequences for complete assessment) ([Fig. 21.1](#); see [Fig. 21.6](#)).

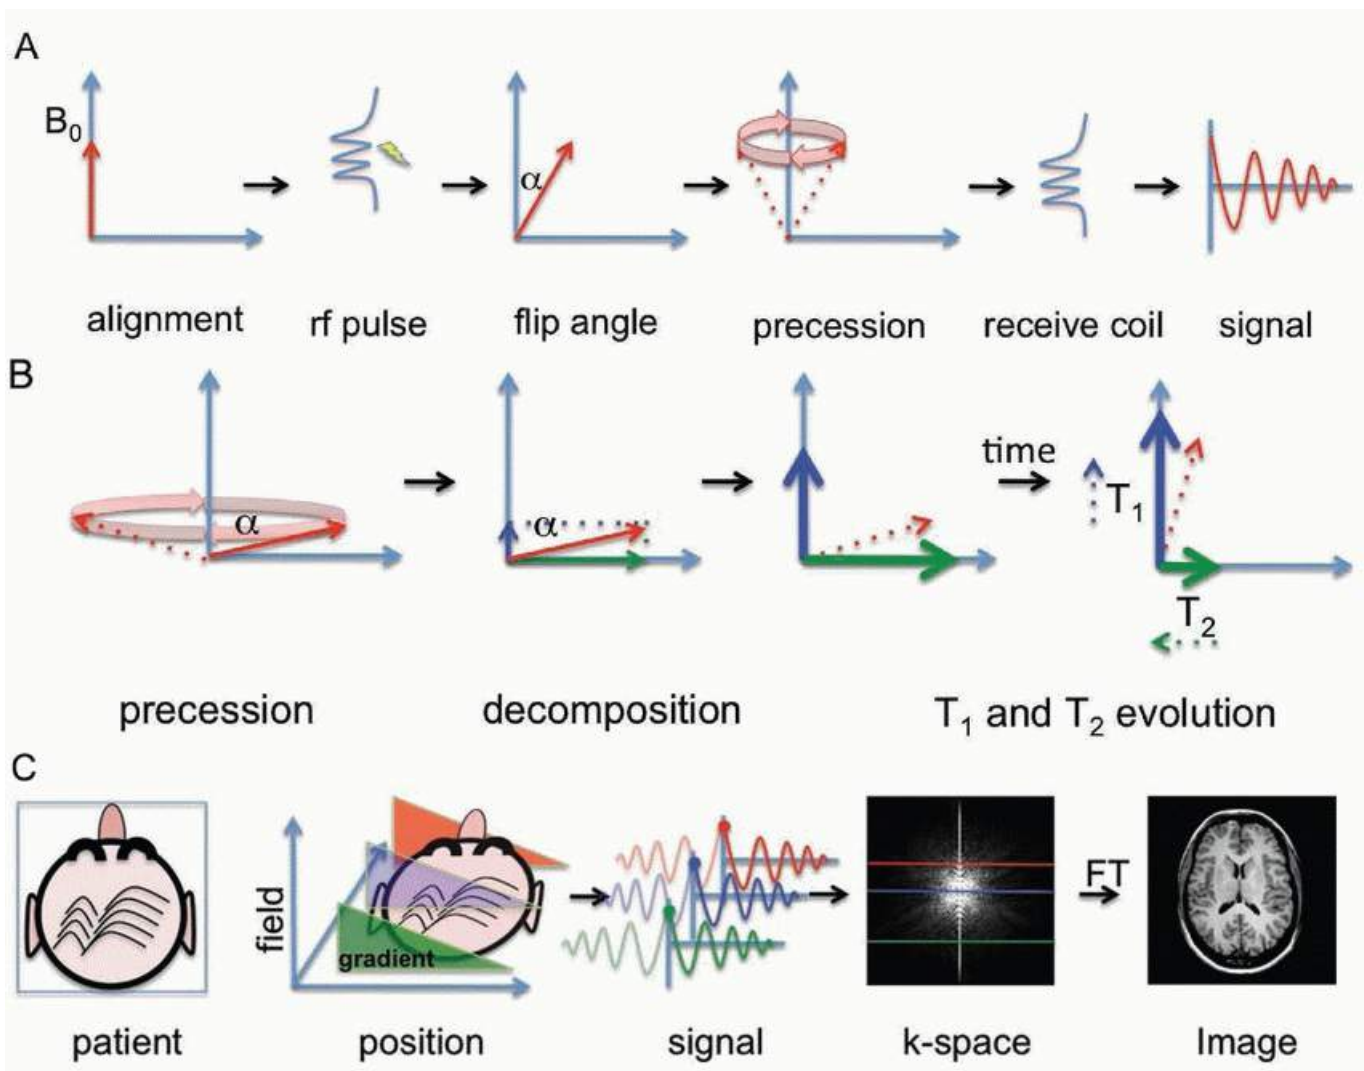

FIGURE 21.1 Schematic representation of magnetic resonance. **A:** Magnetization (*red arrow*) aligns along the main magnetic field (B_0). A radiofrequency pulse generated by a transmit coil tips the magnetization from the aligned state by a flip angle (α). The magnetization precesses around the main magnetic field. The precessional motion results in a time-varying voltage in a radiofrequency receive coil, which is recorded as the magnetic resonance signal. **B:** While the magnetization precesses around the magnetic field, the decay of magnetization can be described by two separate exponential time constants. The magnetization vector can be decomposed into a longitudinal component parallel to the main magnetic field and a transverse component orthogonal to the main magnetic field. The T_1 time describes the relaxation of magnetization back to the equilibrium-aligned state. The T_2 time constant describes the decay of transverse magnetization. **C:** Images are created in magnetic resonance by applying multiple field gradients, which positionally encode the magnetic resonance signal. In this schematic of a patient's head, directly acquiring signal from each gradient direction allows encoding of the frequency dimension. Applying an additional increasing orthogonal gradient with every frequency encoding gradient allows encoding of the phase dimension. The signal from one gradient direction thus corresponds to one line of k-space. Once all of the lines of k-space are filled, a Fourier transform (FT) is used to make an image representation.

Individual tissues have characteristic appearance on T1-weighted, T2-weighted, and FLAIR images. For example, cerebrospinal fluid (CSF) has a relatively long T1 and long T2 relaxation time and thus appears dark on T1-weighted images and bright on T2-weighted images (Fig. 21.2A and B). CSF appears dark on FLAIR images because these images are specifically calibrated to suppress CSF or “free” water (Fig. 21.2C). White matter in the adult is fully myelinated and appears slightly bright on T1-weighted images and dark on T2-weighted images

(see Fig. 21.2A and B). Gray matter is brighter than white matter on T2-weighted images, whereas the reverse is true for T1-weighted images. Parenchymal hemorrhage can have a variety of appearances on T1- and T2-weighted images based on its components. In the brain, hemorrhage evolves predictably and its appearance can be used to infer its age. T2 prolongation (bright on T2-weighted images) correlates with hyperacute hemorrhage and late subacute hemorrhage, whereas T1 shortening (bright on T1-weighted images) correlates with early and late subacute hemorrhage. These characteristic appearances are summarized in Table 21.1.

FIGURE 21.2 Normal T1-weighted, T2-weighted, FLAIR, and inversion recovery (IR) images. **A:** Normal T1-weighted images of the brain and cervical spine. White matter is bright and gray matter is dark. CSF signal is dark. **B:** Normal T2-weighted images of the brain and cervical spine. Gray matter is bright and white matter is dark. CSF signal is bright. **C:** Normal FLAIR image of the brain and IR image of the cervical spine. On the FLAIR image, CSF signal is suppressed and appears dark; white matter is dark and gray matter is bright similar to a T2-weighted image. On the IR image of the cervical spine, fat is suppressed and there is increased contrast in the spinal cord.

QUANTIFICATION OF T1 AND T2 TIMES

T1 and T2 relaxation time constants can be quantified to provide information of dynamic properties on a molecular level. Relaxation can also be measured during the application of a continuous radiofrequency pulse; in this case, the relaxation time constants are referred to as $T1\text{-}\rho$ and $T2\text{-}\rho$ (ρ referring to a rotating reference frame used in the theoretical description). Magnetization transfer imaging, as well as chemical exchange saturation transfer (CEST) imaging are additional methods that rely on using a radiofrequency pulse to attenuate magnetization. These emerging methods are currently confined to the research setting but hold promise for future clinical applications.

DIFFUSION-WEIGHTED IMAGING

Diffusion-weighted imaging (DWI) is invaluable for the detection of early ischemic brain injury (Fig. 21.3). Like T1

and T2 processes, DWI creates image contrast by exploiting dynamic molecular properties, specifically translational diffusion, by applying multidirection

diffusion sensitizing field gradients. In clinical practice, DWI is typically performed for water although applications to other molecules have been reported. The “effect” of the diffusion gradient sequence is often quantified using a b-value. For adults, a b-value = 1,000 s/mm² is typically used, whereas b-value = 1,500 s/mm² is sometimes preferred in pediatric cases. In routine clinical practice, DWI is typically detected using an echo planar imaging (EPI) technique due to the speed of imaging. EPI is a gradient echo technique that can acquire the entirety of k-space within one excitation by interweaving frequency and phase dimensions.

TABLE 21.1 Usual Appearance of Normal Structures on T1-Weighted, T2-Weighted, FLAIR, DWI/ADC, and GRE or SWI Images

	T1-Weighted	T2-Weighted	FLAIR	DWI/ADC	GRE or SWI
CSF	Dark	Bright	Dark	Dark/bright	Bright
White matter or gray matter brighter	White matter brighter	Gray matter brighter	Gray matter brighter	Gray matter brighter/white matter brighter	Variable
Acute infarct	Dark	Bright	Bright	Bright/dark	Variable
Hemorrhage	Bright if early or late subacute	Bright if hyperacute or late subacute	Variable	Variable	Dark
Edema	Dark	Bright	Bright	Variable/bright	Isointense

FLAIR, fluid-attenuated inversion recovery; DWI, diffusion-weighted imaging; ADC, apparent diffusion coefficient; GRE, gradient-recalled echo; SWI, susceptibility-weighted imaging; CSF, cerebrospinal fluid.

Diffusion imaging is considered a quantitative technique, permitting the calculation of an apparent diffusion coefficient (ADC), which measures the extent to which the diffusivity of water is restricted from free diffusion, presumably due to structural barriers such as cell membranes or association of water with larger molecules that have lower diffusion coefficients. The most useful application of DWI is in acute stroke imaging (see Fig. 21.3A). This occurs most frequently in the setting of cellular bioenergetic failure and cytotoxic brain edema due to cerebral hypoxia/ischemia. Acute and early subacute infarcts display restricted diffusion and are easily detected as bright regions on DWI. Differentiation of acute infarcts from late subacute infarcts, both of which can appear bright on DWI (known colloquially as *T2 shine through*), can be accomplished by examination concurrent ADC image. Acute to early subacute infarcts truly demonstrate restricted diffusion and appear dark on the ADC image (see Fig. 21.3B). Subacute to chronic infarcts are bright on DWI due to T2 shine through and appear isointense to bright on the ADC image.

FIGURE 21.3 Acute left middle cerebral artery (MCA) infarct. **A:** The DWI image shows bright signal in the left MCA territory. **B:** The corresponding ADC image shows dark signal confirming an acute or early subacute infarct. **C:** The corresponding FLAIR image shows mild associated increased signal compatible with edema. **D:** MRA of the circle of Willis shows absent flow-related enhancement of the left distal M1 MCA segment (*arrow*) compatible with occlusion. Irregularity is also noted of the contralateral right M1 segment.

Other conditions including uncontrolled status epilepticus and prion diseases (e.g., Creutzfeldt-Jacob disease) may demonstrate increased cortical DWI signal. Restricted diffusion can also be observed in hemorrhage and for tissues/neoplasms with high cellular density in the case of active inflammation and within the center of abscesses. DWI is specifically useful in the evaluation of brain tumors, where foci of restricted diffusion raise suspicion for an aggressive hypercellular tumor component, which may predate contrast enhancement.

GRADIENT-RECALLED ECHO AND SUSCEPTIBILITY-WEIGHTED IMAGING

The primary clinical use of gradient-recalled echo (GRE) or susceptibility-weighted imaging (SWI) is sensitivity to the presence of small amounts of hemorrhage. SWI or GRE images generate image contrast from differences in underlying magnetic susceptibility. Differences in susceptibility are interpreted to represent

P.179

underlying paramagnetic or diamagnetic species and have important implications for characterizing tissue components such as calcification or iron content. SWI are slightly different from GRE images in that they depict intracranial vessels and are considered more sensitive than conventional GRE. Methods to quantify susceptibility are called *quantitative susceptibility mapping* (QSM). In the research setting, quantitative methods have applications in more accurate dating of hemorrhage, quantifying contrast agent enhancement, and in the evaluation for neurodegenerative disease associated with heavy metal deposition.

GADOLINIUM CONTRAST ENHANCEMENT

The use of intravenous paramagnetic contrast agents, typically gadolinium chelates, is invaluable in MRI. Enhancement is defined as increased T1 shortening following administration of contrast, and the concept is further developed in the context of magnetic resonance perfusion imaging. The presence of contrast enhancement in the brain parenchyma signifies a breakdown of the blood-brain barrier and has important implications for characterizing lesions from brain tumors and metastases to infectious and inflammatory etiologies (see [Fig. 21.3D](#)).

Several structures in the brain lack a blood-brain barrier such as the pineal gland and pituitary gland and normally enhance. Vascular enhancement is variable. Vessels are typically bright on SPGR type T1 postcontrast images but have a variable appearance on spin echo T1-type images, depending on flow rate and other imaging parameters. In the spine, enhancement can be observed in the epidural veins as well as the soft tissues. Dedicated magnetic resonance angiographic images may be necessary to characterize some vascular

malformations, and conventional catheter angiography may be necessary to evaluate subtle vascular malformations.

In some situations, contrast-enhanced imaging may not be appropriate. Examples include contraindications to contrast such as prior severe allergic reactions or renal failure. In the setting of possible or prior allergic reaction, premedication with a standard steroid algorithm is necessary if the benefit of contrast to make a diagnosis outweighs the risks. Many imaging protocols such as for the evaluation of infarct, hypertensive hemorrhage, or acute spinal cord compression do not typically require postcontrast imaging. In the setting of an evolving infarct or parenchymal hemorrhage, contrast enhancement is sometimes seen and may in fact present a diagnostic dilemma in the absence of adequate clinical history.

MAGNETIC RESONANCE ANGIOGRAPHY AND MAGNETIC RESONANCE VENOGRAPHY

Vascular structures in the head and neck can be imaged noninvasively using MRI without the use of intravenous contrast agents as well as with contrast. Primary clinical applications include evaluating for stenosis, thrombosis, dissection, and aneurysm in the vascular structures of the head or neck. The *time-of-flight* (TOF) method relies on vascular flow to bring *fresh* unrelaxed spins into the imaging volume. As a result, vessels that contain flowing spins appear bright and are easily delineated. The *phase contrast* (PC) or *velocity encoding* (VENC) method detects phase changes of spins moving through a gradient. *Contrast-enhanced magnetic resonance angiography* (MRA) methods rely on the T1 shortening effects of gadolinium chelates, which are directly injected intravenously. Appropriate timing of a bolus of contrast and imaging can provide individual arterial and venous phases.

In the neck, MRA is commonly used to assess the patency of the carotid and vertebral systems, although ultrasound (US) and neck computed tomography angiography (CTA) may be used as well. Specific protocols used at individual imaging facilities depend on the resources available and the pretest probability for abnormalities in the specific patient population. The American College of Radiology (ACR) Appropriateness Criteria give equally high recommendations for carotid US, CTA, and MRA for screening in the setting of a physical exam finding, such as a carotid bruit. However, in the setting of focal neurologic deficit, MRA and CTA are preferred over US.

Noncontrast MRA of neck, using two-dimensional (2D) and three-dimensional (3D) TOF methods may be sufficient to exclude hemodynamically significant carotid stenosis. One limitation of noninvasive TOF techniques, however, is turbulent or slow flow, which can lead to loss of signal and overestimate the degree of stenosis, leading to false-positive results. This is specifically true in the carotid bulb or the V3 vertebral artery segments, which are sensitive to flow artifacts (Fig. 21.4A and B). Contrast-enhanced MRA is considered the most sensitive noninvasive imaging method for the diagnosis of 70% to 99% internal carotid artery stenosis with meta-analytic estimates of sensitivity equal to 85% (95% CI, 69% to 93%) and specificity equal to 85% (76% to 92%). Furthermore, in cases of carotid or vertebral arterial dissection, subtle luminal changes may be better evaluated with additional T1-weighted or proton-density weighted fat-saturated images in addition to contrast-enhanced methods.

In the intracranial circulation, TOF MRA methods are well suited to evaluate for vessel patency and aneurysm formation (Fig. 21.4C and D). In the setting of screening for aneurysm, for example, when there is a positive family history, the ACR Appropriateness Criteria gives slightly higher recommendations to the use of CTA over MRA given the higher resolution of CTA and absence of flow artifacts.

The use of contrast-enhanced MRA methods is preferred when evaluating aneurysms following intervention, such as coiling or stenting or when evaluating cerebrovascular malformations. Time-resolved contrast-enhanced methods (in which successive acquisitions can provide multiple arterial and venous phases) in the head and neck are typically applied when the temporal profile of enhancement is important. Examples include

differentiating low- from high-flow vascular malformations or slow flow from complete occlusion.

Magnetic resonance venography is used clinically to evaluate for patency of the dural venous sinuses in the setting of venous sinus stenosis or thrombosis. 2D TOF (Fig. 21.4E) and velocity encoding (VENC) techniques (Fig. 21.4F) are typically employed. Time-resolved postcontrast methods are useful, however, when an abnormality is identified to differentiate flow artifacts or partial stenosis/occlusion from complete occlusion.

Outside of the head and neck, MRA can be applied to the spine to evaluate for vascular malformations. Lastly, although magnetic resonance angiography and venography are useful techniques, some subtle vascular malformations may only be identified on conventional catheter angiography, and this must be considered if there is the need to completely exclude an underlying vascular malformation.

MAGNETIC RESONANCE IMAGING ARTIFACTS

MRI is subject to a multitude of artifacts, which in general refers to image representations that are distortions of the true underlying anatomy. Artifacts can both introduce nonexistent structures or obscure anatomy. Artifacts can originate from any of the multiple

P.180

steps in signal generation, acquisition, and processing in addition to the underlying properties of biologic tissues and patient cooperation.

FIGURE 21.4 MRA and magnetic resonance venography. **A:** MRA of the neck delineates the carotid and vertebral arteries. Note the in-plane flow artifact (*arrow*) in the V3 segments of the vertebral artery. **B:** Contrast-enhanced MRA arterial phase shows resolution of flow artifacts. **C:** Normal MRA of intracranial vessels. **D:** MRA depicts a right supraclinoid carotid artery aneurysm (*arrow*). **E:** 3D TOF magnetic resonance venography depicts the dural venous sinuses. **F:** Velocity encoded magnetic resonance venography of the dural venous sinuses.

Some of the most commonly encountered artifacts arise from motion, either due to voluntary or involuntary patient motion (Fig. 21.5A) or biologic flow phenomena such as in vascular structures or pulsation of CSF (Fig. 21.5B). Flow phenomena lead to either increased or decreased signal within vascular structures, similar to effects exploited in noncontrast TOF MRA. Patient motion or pulsating structures such as vessels result in ghosting-type artifacts in clinical images (Fig. 21.5C). Ghosting artifacts also arise in EPI (called *N/2 ghosts*) due to distortions between successive echoes.

Susceptibility artifacts arise when there are distortions of the local magnetic field. This can be due to air-tissue interfaces or implanted metallic material. These artifacts are commonly encountered in the setting of dental

hardware (such as fillings or braces), aneurysm clips, or spine fusion hardware. Usually, these artifacts lead to loss of signal in adjacent structures, but they may also result in increased signal, for example in FLAIR imaging (Fig. 21.5D and E).

Aliasing artifacts are common when the field of view in the phase encoding dimension is too small; structures outside the field wrap within the image. It is important to note that these artifacts can arise from any phase encode direction.

Stray radiofrequency interference leads to so-called zipper artifacts (Fig. 21.5F). For this reason, MRI rooms are electrically shielded and must be operated with the door closed. Many additional artifacts are described in MRI, related to chemical shift effects, coil, and radiofrequency inhomogeneity.

CLINICAL MAGNETIC RESONANCE IMAGING

MRI attains significantly higher contrast between different biologic tissues compared to other cross-sectional imaging techniques such as CT or US. For this reason, MRI is considered the most precise and sensitive imaging modality for detecting CNS tissue pathology. Appropriateness criteria comparing MRI and CT in the select neurologic scenarios are provided in Table 21.2. The approach to three major paradigms, infarction, white matter disease, and tumors is discussed in the following sections.

CEREBROVASCULAR DISEASE

MRI has revolutionized stroke imaging. Acute infarcts are bright on DWI and display restricted diffusion on ADC images (see Fig. 21.3). Mass effect and vasogenic or cytotoxic edema can be evaluated on associated T2-weighted or FLAIR images. The presence of hemorrhage can be identified on SWI or GRE images. The size of the infarct can be quantified and the specific vascular territories involved can be delineated. Various scoring scales may be used to determine prognosis or indicate treatment based on imaging. Concurrently, performed vascular imaging can show causative vascular disease, such as stenosis, thrombosis, or dissection.

The approach to stroke imaging begins with close inspection of the DWI for increased diffusion-weighted signal relative to the background of normal structures. Once a lesion is identified, evaluation of the ADC image can confirm an acute or early subacute infarct, which is dark relative to background. Evaluation of the SWI or GRE images is used to look for evidence of hemorrhage or hemorrhagic conversion. It is important not to confuse hemorrhage with an acute infarct, both of which may show restricted diffusion. Additional sequences including T2 and FLAIR images are used to evaluate for mass effect, cytotoxic and vasogenic edema. Some authors suggest that inspection of the concurrent FLAIR images may differentiate between acute and subacute infarcts when clinical information is incomplete or unavailable.

The specific structures involved in stroke and multiplicity of infarcts help to differentiate individual vascular territories from embolic-type infarcts and diffuse ischemia/hypoxia. Stroke imaging typically is performed in conjunction with vascular imaging such as MRA or CTA of the head and neck with attention specifically focused on determining if vascular occlusion is responsible for the

infarct (see Fig. 21.3D). Perfusion imaging in stroke is sometimes performed to determine the size of the territory at risk and guide intervention.

FIGURE 21.5 MRI artifacts. **A:** Motion artifact results in ghosting on a FLAIR image. **B:** Flow artifact due to CSF pulsations in the lateral ventricles (*arrow*). **C:** Ghosting artifact due to pulsatile flow in the transverse sinuses (*arrow*). **D:** Susceptibility artifact leads to increased signal in the frontal region due to failure of CSF suppression. **E:** Corresponding susceptibility artifact due to dental hardware is shown on a T1-weighted image. **F:** Zipper artifact due to stray radiofrequency interference.

TABLE 21.2 American College of Radiology Appropriateness Criteria

	MRI Brain without Contrast	MRI Brain without and with Contrast	CT Head without Contrast	CT Head without and with Contrast
New focal neurologic deficit <3 h (e.g., acute stroke)	8	8	9	3
Transient ischemic attack	8	8	8	3
Suspected parenchymal	6	6	9	7

hemorrhage

Ataxia, slowly progressive

Appropriateness ratings for brain MRI versus head CT without and with contrast (non-MRA/CTA) are provided for selected neurologic conditions. The ratings range from 1 to 9, with “usually appropriate” studies rated 7 to 9, “may be” appropriate rated 4 to 6, and “usually not appropriate” rated 1 to 3. Level of evidence is generally based on expert opinion. A complete list and background evidence may be obtained at www.acr.org/Quality-Safety/Appropriateness-Criteria.

MRI, magnetic resonance imaging; CT, computed tomography.

P.182

WHITE MATTER DISEASE

Abnormalities in the white matter are best identified on FLAIR images. The differential diagnosis of white matter disease includes demyelinating and dysmyelinating etiologies, vasculitic and vasospastic processes, infection and inflammatory processes, toxic/metabolic etiologies, edema, trauma, seizures, as well as neoplasm and hypoxic/ischemic processes including arterial and venous infarcts. Characterizing these processes and narrowing the differential diagnosis require concurrent integration of clinical information and a complete set of MRI sequences.

As an example, we discuss an approach to multiple sclerosis (MS), an archetypal disease process with imaging abnormalities on brain and spine MRI (Fig. 21.6). The approach to MS begins with thorough inspection of the FLAIR images for abnormal signal specifically involving the white matter. Supratentorially, lesions are typically identified in the periventricular, deep, and subcortical/juxtacortical white matter and corpus callosum, as well sometimes the basal ganglia, although cortical disease burden in MS is not well delineated on FLAIR imaging. Sagittal FLAIR images are invaluable for confirming subtle lesions on axially acquired sequences and for evaluating the corpus callosum. T2-weighted images are preferred for the evaluation of white matter lesions in the brain stem and cerebellar white matter due to artifacts in the posterior fossa on FLAIR images. After lesions are identified, their acuity is estimated based on associated diffusion abnormality and contrast enhancement, both of which would suggest acute demyelinating lesions. Finally, because MS patients undergoing treatment may be immunosuppressed, it is important to evaluate for superimposed infection such as progressive multifocal encephalopathy (PML).

In the spine, the approach to MS concentrates on using T2-weighted images and IR T2-weighted images. IR T2-weighted images are similar to FLAIR images in that they also employ an inversion pulse; however, they are timed not to suppress CSF signal but rather to increase the conspicuity of lesions and suppress signal from fat. As in the brain, the presence of contrast enhancement is used to identify acute lesions. It is important to remember that patient symptoms may not be due to demyelinating lesions in the spinal cord but rather to degenerative changes, such as disk herniations.

FIGURE 21.6 Multiple sclerosis. **A:** Characteristic white matter lesions of multiple sclerosis depicted on an axial FLAIR image. **B:** Low signal intensity of the lesions on T1-weighted images suggests chronic lesions. **C:** Sagittal FLAIR image depicts the radial orientation of white matter lesions characteristic of multiple sclerosis.

BRAIN AND SPINAL CORD TUMORS

Tumors are defined by the presence of mass effect, where normal structures are displaced or infiltrated and display abnormal signal characteristics including postcontrast enhancement. Despite common belief, contrast enhancement does not always correlate with World Health Organization (WHO) tumor grade. For example, both grade I pilocytic astrocytoma and grade IV glioblastoma typically display postcontrast enhancement. On the other hand, grade III anaplastic astrocytoma may not display contrast enhancement. FLAIR imaging is indispensable in brain tumor imaging because FLAIR imaging demonstrates nonenhancing tumor components but also associated mass effect and edema (Fig. 21.7). One of the main problems in evaluating brain tumors is distinguishing tumor recurrence (progression) from posttreatment changes (pseudoprogression). For this reason, tumor imaging typically entails advanced MRI methods such as magnetic resonance perfusion imaging and magnetic resonance spectroscopy, in addition to correlation with other modalities such as nuclear medicine ^{18}F -fluorodeoxyglucose positron emission tomography (FDG-PET) or thallium single-photon emission computed tomography (SPECT).

The approach to assessment of brain tumors begins with localization of the lesion in the intra-axial or extra-axial space. Subsequent evaluation of mass effect and definition of the mass on T1-weighted, T2-weighted, FLAIR, or postcontrast images is performed. The adjacent parenchyma is evaluated for associated edema or infiltration. Diffusion-weighted images are used to evaluate associated ischemic changes or hypercellular components of the tumor. SWI or GRE images are used to evaluate for associated hemorrhage or calcifications. Given the heterogeneity of brain tumors, the location, appearance, signal characteristics, enhancement, or comparison to prior studies are all integrated to arrive at a differential diagnosis.

FIGURE 21.7 Glioblastoma. **A:** Post-contrast-enhanced image shows a large enhancing mass with central necrosis. **B:** FLAIR image depicts the associated white matter abnormality compatible with a combination of edema and nonenhancing tumor. **C:** ADC image shows restricted diffusion in components of the tumor suggestive of increased cellular density.

ADVANCED MAGNETIC RESONANCE IMAGING METHODS

FUNCTIONAL MAGNETIC RESONANCE IMAGING

Functional magnetic resonance imaging (fMRI) refers to the use of magnetic resonance for the localization of cerebral activation. The most commonly employed technique takes advantage of hemodynamic coupling of cerebral activation to indirectly infer cerebral activation. The blood oxygen level-dependent (BOLD) contrast mechanism results from a relative increase in the concentration of oxyhemoglobin (a paramagnetic species) compared to deoxyhemoglobin (a diamagnetic species) in response to cerebral activation. This change can be detected using rapid MRI sequences typically employing gradient echo sequences sensitive to T2* contrast, allowing cerebral activation to be imaged in the brain. Some authors have proposed using DWI to map cerebral activation but this is not common.

FIGURE 21.8 fMRI and diffusion tensor imaging. **A:** Preoperative fMRI showing activation of primary motor cortex during a motor task in a patient with a left frontal neoplasm. **B:** Preoperative fMRI showing activation of left frontal language processing area during a verb generation task. **C:** Fiber tracking performed based on diffusion tensor data showing displacement of the left frontal tracts by the left frontal mass.

fMRI can be performed in conjunction with specific task paradigms (Fig. 21.8A and B). This type of fMRI has current clinical applications for mapping the cortical location of known cognitive and motor functional units and has specific use in presurgical and pretherapeutic planning. Examples include mapping the primary motor and visual cortices or localizing language activation areas.

In the research setting, the technique has been applied to monitor a variety of psychiatric disorders. When acquired without a specific task paradigm, the technique is referred to as *resting state fMRI*, which maps connectivity features of the so-called default-mode neural networks (DMN).

DIFFUSION TENSOR IMAGING

Diffusion tensor imaging (DTI) is a technique that can quantify the directional dependence of diffusion of water. Clinically, DTI is most commonly applied to assess the integrity of white matter tracts (Fig. 21.8C). Normal white matter tracts are densely packed, which creates an anisotropic environment. Diffusion perpendicular to white matter tracts is relatively hindered compared to diffusion parallel to white matter tracts. Therefore, measuring the direction of greatest diffusion will estimate the dominant orientation of white matter tracts. Measuring multiple directions of diffusion can subsequently be used to define a diffusion tensor. The diffusion tensor information can then be postprocessed to generate images with white matter tracts. More advanced approaches, such as Q-ball and diffusion spectrum imaging, provide a more general description of diffusion and have improved performance in resolving crossing white matter fibers. The current clinical application of DTI is definition of white matter tracts in presurgical and pretherapeutic planning. A multitude of applications of DTI to variety of neurologic conditions including stroke, MS, dementia, and traumatic brain injury primarily reside in the research setting. In part, this is due to lack of standardization of acquisition and postprocessing techniques as well data lacking on clinical use and effect on patient outcomes.

MAGNETIC RESONANCE SPECTROSCOPY

Magnetic resonance spectroscopy (MRS) is considered an advanced imaging technique within MRI, although it is an integral part in the formation of anatomic magnetic resonance images. In the absence of an applied field gradient, different nuclei can be resolved by their chemical shift. MRS in clinical practice typically refers to spatially selective acquisition (single or multiple voxel) of proton spectra, where care has been taken to suppress the dominant water resonance, thus increasing sensitivity for the resonances of small molecules. In the brain, the most commonly observed resonances belong to *N*-acetylaspartate (NAA) (2.0 ppm—interpreted to signify normal neuronal tissue), creatine (3.0 ppm—interpreted to signify energy stores), choline (3.2 ppm—interpreted to signify components of the cell membrane and myelin), and lactate (doublet at 1.3 ppm—interpreted to signify anaerobic metabolism) (Fig. 21.9). The lactate doublet resonance corresponding to the lactate methyl protons is inverted at an echo time of 144 milliseconds compared to 288 milliseconds due to J-coupling effects with the lactate methine proton.

Additional metabolites such as inositol/myoinositol (interpreted as a marker of astrocytes and astrogliosis seen in MS lesions), glutamate/glutamine, and several amino acids such as alanine (described in meningiomas) and glycine can also be observed. The relative amplitude of the resonance peaks reflects the relative concentrations of metabolites; however, it should be noted that in general, relaxation effects may alter resonance amplitudes, highlighting attention to the time-to-echo (TE). In general, more metabolites are seen with a shorter TE. In routine clinical practice, spectroscopy is often used as a problem-solving technique, for example, in an attempt to differentiate tumor recurrence from posttreatment effects (higher choline-to-creatine ratios tend to be observed with recurrent brain tumors than radiation necrosis; see Fig. 21.10C) or to evaluate for inborn errors of metabolism such as mitochondrial disorders and leukodystrophies (the presence of a lactate peak may signify a mitochondrial disorder such as mitochondrial encephalomyelopathy, lactic acidosis, and stroke [MELAS]). MRS

has also been used to directly observe 2-hydroxyglutarate, a metabolite that accumulates in isocitrate dehydrogenase (IDH) mutant glioblastoma tumors, and thus constitutes a biomarker for IDH status in glioma.

MAGNETIC RESONANCE PERFUSION IMAGING

Magnetic resonance perfusion is a method of quantifying blood flow through biologic tissues. The method is usually applied to the brain but has been extended to other parts of the body including the spine. The relevant measures include measurement of cerebral blood volume, cerebral blood flow, and mean transit time.

This is achieved in MRI using a *first-pass* or *bolus-tracking* method that records the signal reduction that occurs when rapidly repeated images are acquired during the first passage of an intravascular bolus of paramagnetic contrast, usually a gadolinium chelate. The images produced are called *perfusion-weighted images* (PWI) or *dynamic susceptibility contrast* (DSC) *images*. Gradient echo images with EPI type detection are usually used because they provide the ability to image very rapidly to track the contrast bolus.

The time course of the signal change during the passage of the bolus can be used to obtain the cerebral blood volume (CBV), mean transit time (MTT), and their ratio, the cerebral blood flow ($CBF = CBV/MTT$). Because of the technical difficulty in measuring the arterial input function of the contrast bolus, perfusion maps are semiquantitative and are best interpreted as relative rather than absolute perfusion values (rCBV, rMTT, and rCBF). If the arterial

P.185

input function is known, then a measure of permeability of the extravascular-extracellular space known as *k-trans* can be calculated. Algorithms exist in clinical practice for quantifying the permeability of tissues to contrast (called *leakage*) from modeling of the perfusion time course without knowledge of the exact arterial input function.

FIGURE 21.9 MRI spectroscopy. **A:** DWI shows an acute infarct in the right superior frontal lobe. **B:** Voxel (*square*) is placed in the right superior frontal image on the corresponding FLAIR image. **C:** MRS performed at an echo time of 144 milliseconds shows choline, creatine, and NAA resonances with relative decrease of the NAA resonance. An inverted lactate doublet is present compatible with anaerobic metabolism in the setting of an infarct.

Magnetic resonance perfusion can be performed without contrast with the arterial spin labeling (ASL) method. Similar to TOF MRA, the ASL method depends on inflow of spins through vessels. ASL may provide more quantitative information without the need for arterial input functions but is less widely available than contrast bolus tracking methods.

Clinical applications of magnetic resonance perfusion include cerebrovascular disease. In cases of stroke or vasospasm, measures of perfusion delay, such as MTT, are sensitive indicators of small reductions in cerebral perfusion that can delineate relatively hypoperfused vascular territories. In this way, magnetic resonance perfusion is similar to CT perfusion methods, but can be performed without ionizing radiation, and permits direct correlation with other magnetic resonance images. Outside of cerebrovascular disease imaging, clinical

applications of magnetic resonance perfusion include brain tumors and metastases. These applications focus on assessment of CBV, which correlates with histologic tumor grade and characterizes response to treatment of the tumor (Fig. 21.10A and B).

FIGURE 21.10 Magnetic resonance perfusion imaging and MRS in recurrent high-grade glioma. **A:** Post-contrast-enhanced image showing abnormal enhancement (*red square*) in the posterior right parietal region. **B:** Magnetic resonance perfusion image shows a focus of increased relative cerebral blood volume (*red square*) suggestive of recurrent tumor. **C:** MRS at a TE of 288 milliseconds shows elevated choline and decreased NAA resonances suggestive of recurrent tumor. A lactate doublet is present.

EMERGING MAGNETIC RESONANCE IMAGING METHODS

Recent advances in MRI aim to drastically improve the resolution of images and speed of imaging as well as to significantly extend clinical applications. The emergence of high field (>7 T) imaging systems promises improvements in signal to noise and image resolution as well as functional imaging. Similarly, improvements in imaging speed have been a constant focus since the inception of MRI. Recent advances rely on undersampling and subsequent reconstruction using nonlinear methods. One of the most popular of such methods called

compressed-sensing holds promise for implementing near real-time imaging, especially when combined with methods to improve signal to noise.

Although magnetic resonance is a very powerful technique to study structure and dynamic processes on a molecular level, its application to biologic systems is primarily limited by its inherent low signal to noise. As a result, low-concentration molecules involved in metabolism and other cellular functions are essentially inaccessible by conventional techniques. This limitation is primarily evident in MRS, where multidimensional experiments could in theory characterize a multitude of metabolites, provided there was sufficient signal to noise. The goal of emerging methods called *hyperpolarization* (HP) is to increase nuclear spin polarization and

P.186

thus drastically increase signal to noise. A primary application of HP-MRI is the study of in vivo transient interactions through HP of small metabolites suited to probing varied processes such as metabolism and oxidative stress or as agents of perfusion. HP-MRI is a promising technique for combining the intrinsic biologic tissue contrast, temporal and chemical shift resolution, as well as sensitivity to dynamic processes of magnetic resonance with molecular imaging.

Perhaps the most important advancement in clinical imaging comes from contemporary advances in information technology and quantitative image-processing methods. The availability of electronic medical records and digitally archived images has permitted the correlation of imaging features with molecular pathology and development of a new field of *radiogenomics*. This field is predicated on correlation of quantitative image analysis features with molecular markers and information pertaining to patient diagnosis, prognosis, and treatment response available within the electronic medical record. This revolution in medicine embraces the heterogeneity of pathologic processes and individual responses in the patient population and seeks to tailor therapeutics for maximal efficacy.

Positron Emission Tomography and Single-Photon Emission Computed Tomography

William Charles Kreisl

INTRODUCTION

Molecular imaging is used in the clinical practice of nuclear medicine and in medical research to better understand the biochemical processes that underlie human disease. Two examples of molecular imaging are positron emission tomography (PET) and single-photon emission computed tomography (SPECT). In both PET and SPECT, patients are administered a radioactive compound with a pharmacokinetic behavior that targets a molecular pathway related to the pathology of a certain disease.

PET and SPECT allow highly sensitive and selective measurement of specific biologic changes in the human body. Agents are administered in amounts too small to cause pharmacologic effects ("trace" doses) so as to avoid perturbation of the biochemical pathway being studied. Many radioactive compounds used in PET and SPECT reversibly bind to a target protein via ligand-receptor kinetics. In these cases, the radioactive ligand is referred to as a radioligand. However, some radioactive compounds used for PET or SPECT do not bind a target protein. For example, [^{15}O]H₂O is used to measure perfusion, as the uptake of this compound reflects the flow of blood into a given tissue. A [^{15}O]H₂O PET scan therefore does not measure the binding of water to any receptor, but rather it traces the flow of blood to different tissues (Fig. 22.1). In this case, the term radiotracer is more appropriate. A broader term that applies to all compounds used with PET or SPECT is radiopharmaceutical, reflecting that the radioactive compounds used in molecular imaging are given the same regulatory considerations as drugs.

BASIC PRINCIPLES

Both PET and SPECT employ the physical phenomenon of radioactive decay, which occurs in radionuclides that are unstable due to incompatible number of protons and neutrons or excess energy.

In PET imaging, radionuclides are proton rich and as a result undergo decay and emission of a positron. An example of a radionuclide is carbon-11 (^{11}C), which has six protons and five neutrons. Unstable due to the greater number of protons than neutrons, ^{11}C undergoes a decay event in which a proton is converted to a neutron and the nucleus emits a positron and a neutrino. The positron will then zigzag around the vicinity of the decay event, losing energy as it collides with electrons of neighboring atoms, until it comes almost to rest and combines with an electron. Because a positron and electron are of equal mass but opposite charge, this event results in an annihilation encounter, with two 511 keV gamma rays (photons) emitted at about 180 degrees from each other. Other examples of positron-emitting radionuclides used for PET are ^{18}F , ^{15}O , and ^{13}N .

In SPECT imaging, radionuclides exist in a metastable state and decay from their excited state to ground state, resulting in emission of a single photon. The gamma-emitting radionuclides $^{99\text{m}}\text{Tc}$ and ^{123}I are commonly used for SPECT.

FIGURE 22.1 Example of [^{15}O] H_2O perfusion scan. The patient with Alzheimer disease has lower cerebral perfusion in the parietal cortex bilaterally (*arrows*) than the age-matched cognitively normal control subject. (Image courtesy of Robert Innis and William Charles Kreisl, Molecular Imaging Branch, National Institute of Mental Health.)

RADIOPHARMACEUTICALS AND SELECTION OF RADIONUCLIDES

Radionuclides are combined with a pharmaceutical through a series of synthetic steps to create a radiopharmaceutical. Radiopharmaceuticals are administered either intravenously or orally and once in the biologic system, they interact with different molecules based on the kinetic properties of the pharmaceutical to which the radionuclide is attached. The radionuclide will then undergo nuclear decay as described earlier, ultimately resulting in the emission of two photons in the case of PET and a single photon in the case of SPECT. The radiation exposure to the patient is a function of the radionuclide used and the amount of radiopharmaceutical administered. Radionuclides with longer half-lives (e.g., ^{18}F , $t_{1/2} = 110$ minutes) result in larger exposure than those with shorter half-lives (e.g., ^{11}C , $t_{1/2} = 20.5$ minutes). However, the advantage of radiopharmaceuticals with long half-lives is that they may be synthesized offsite and delivered to medical facilities, providing greater availability for clinical use. Use of radiopharmaceuticals with short half-lives is limited to facilities capable of onsite synthesis.

DETECTION, ACQUISITION, AND DISPLAY OF SIGNAL

When radiopharmaceutical decay events occur inside a PET or SPECT scanner, crystals in a scintillation detector absorb the photons and then emit pulses of light that are then amplified, sorted, and registered as a count. The sum of these counts creates a tomographic map of all the decay events that occur within the view of the scanner. The result is an image that represents the different densities of radioactivity throughout the tissues captured by the

scanner. The basis of PET and SPECT imaging is that the majority of decay events occur in proximity to where the radiopharmaceutical is acting on the molecular target of interest. The sensitivity of PET and SPECT is a function of the fraction of emitted photons that contribute to the total image. In PET, coincidence detection of the pair of photons that are emitted per decay event allows greater efficiency than in SPECT, which captures only the single photons that approach the detector at certain angles. Therefore, PET is generally more sensitive than

SPECT and is more frequently used for quantitative imaging, although absolute quantitation has been reliably attained with SPECT.

PET and SPECT images reflect only the amount of radioactivity detected by the scanner. The scanner cannot distinguish between sources of radioactivity (which radionuclide or which radiopharmaceutical was administered). Therefore, sufficient time (at least six half-lives of the radionuclide) must pass between consecutive scans on the same subject; otherwise, the second scan will be contaminated from residual signal from the first. In addition, once injected, radiopharmaceuticals are broken down by enzymes in the liver and other tissues (including brain in some instances) leading to the generation of radiolabeled metabolites. If these metabolites are generated in the brain or cross from the blood into the brain, they will contribute to the total signal in the resulting images, potentially confounding accurate quantification. For this reason, using radiopharmaceuticals that do not generate radiometabolites that cross the blood-brain barrier is beneficial. Another problem is cross-selectivity and nonspecific binding. If a radiopharmaceutical binds more than one receptor in the brain, the resulting image will overestimate the density of the intended target. As radiopharmaceuticals must be lipophilic to cross the blood-brain barrier, they often bind nonspecifically to lipids throughout the brain. Both specific binding to the target protein and nonspecific binding contribute to the signal seen on the resulting image. However, only the specific binding component represents the density of the target protein. Therefore, a high ratio of specific to nonspecific binding is favorable for reliable PET and SPECT measurements.

CLINICAL APPLICATIONS

The sensitivity of PET and SPECT are ideal for measuring specific biochemical changes in the brain. However, the expense of molecular imaging limits its cost-effectiveness in clinical practice. This is particularly true when diagnoses can be made with reasonable confidence using other techniques or when the results of molecular imaging are unlikely to alter management of the patient. Therefore, PET and SPECT imaging have a limited role in clinical neurology. However, as new disease-modifying therapies for neurologic disorders become available, molecular imaging may provide a critical role in predicting and monitoring treatment response.

The following radiopharmaceuticals are currently approved by the U.S. Food and Drug Administration (FDA) for indications in clinical neurology.

GLUCOSE IMAGING

The 2-deoxy-2-[^{18}F]fluoro-D-glucose (FDG) is structurally identical to D-glucose except for the substitution of ^{18}F for a hydroxyl group at the 2' position. Like glucose, FDG is taken up by cells using the glucose transporter and phosphorylated by hexokinase in the first step of glycolysis. Once phosphorylated, FDG becomes charged and therefore trapped in the cell. Lacking a 2' hydroxyl group, [^{18}F]FDG-6-phosphate cannot undergo further metabolism. The concentration of FDG in cells therefore reflects the metabolic activity, both in taking up FDG via active transport and its phosphorylation during glycolysis.

Positron Emission Tomography Using ^{18}F -fluorodeoxyglucose in Epilepsy

Although the most widely used PET radiopharmaceutical for clinical applications, FDG is only approved by the FDA for cancer staging and evaluation, measuring myocardial viability in patients with coronary artery disease, and detecting seizure foci in epilepsy patients. In the case of epilepsy, during a seizure, the cells at the focus of epileptic activity will have greater metabolic demand and take up more FDG than surrounding cells. Therefore, focal increase in FDG-PET signal can identify epileptic foci if the scan is performed during a seizure. Between seizures, the epileptic focus often has lower metabolic demand than normal brain tissue, as repeated seizures are associated with decrement in baseline function. Therefore, interictal FDG-PET may show an area of

hypometabolism (reduced FDG uptake) in the seizure foci. These findings may aid the neurosurgeon in planning surgical excision for treatment of refractory epilepsy.

Positron Emission Tomography Using ^{18}F -fluorodeoxyglucose in Dementia

FDG-PET is often used off-label to assist in diagnosis of dementia, particularly when attempting to distinguish Alzheimer disease from frontotemporal dementia (Fig. 22.2). Patients with Alzheimer disease typically show a signature pattern of FDG hypometabolism in the temporal and parietal cortices bilaterally. Patients with frontotemporal dementia, in contrast, show early hypometabolism in the prefrontal cortex, particularly in behavioral variant frontotemporal dementia. These differing patterns of hypometabolism may aid the clinician in making the correct diagnosis, particularly when both behavioral and memory symptoms are present in the same patient. Although not FDA approved for this purpose, the Centers for Medicare & Medicaid Services (CMS) provides reimbursement for FDG-PET when used for this indication.

DOPAMINE IMAGING

loflupane I^{123} (DaTscan) is a SPECT radiopharmaceutical that binds to presynaptic dopamine transporters (Fig. 22.3). loflupane I^{123} is approved to aid clinicians in distinguishing tremor caused

P.189

by neurodegenerative parkinsonian syndromes from that caused by essential tremor. In the former, loss of dopaminergic neurons that originate in the substantia nigra will result in fewer presynaptic dopamine transporters in the striatum. Patients with neurodegenerative parkinsonian syndrome will have reduced striatal signal on DaTscan, whereas a patient with essential tremor will have normal signal.

FIGURE 22.2 Using FDG-PET to distinguish Alzheimer disease from frontotemporal dementia. The Alzheimer disease patient on the left shows biparietal hypometabolism (*white arrows*), whereas the frontotemporal dementia patient on the right shows bifrontal hypometabolism (*yellow arrows*). (Image courtesy of Robert Innis and William Charles Kreisl, Molecular Imaging Branch, National Institute of Mental Health.)

FIGURE 22.3 A normal Ioflupane I^{123} (DaTscan) SPECT scan. The SPECT signal is concentrated in the striatum bilaterally, reflecting normal density of presynaptic dopamine transporters and intact nigrostriatal dopaminergic innervation.

PERFUSION IMAGING

$[^{99m}Tc]$ -hexamethyl-propylene amine oxime (HMPAO) (*Neurolite*) and $[^{99m}Tc]$ ethylcysteinate dimer (ECD) (*Ceretec*) are SPECT radiopharmaceuticals approved as adjunct in detecting areas of abnormal cerebral perfusion in patients who have had a stroke. These SPECT scans are often performed after vasodilatory challenge with acetazolamide to measure cerebrovascular reserve. SPECT perfusion imaging can also be used to identify ictal foci in patients with seizures or status epilepticus. Because reduced blood flow typically localizes to neurodegeneration, perfusion SPECT may also be used to distinguish different types of dementia.

AMYLOID IMAGING

Several PET radiopharmaceuticals that label the β -amyloid plaques found in Alzheimer disease have been developed (Fig. 22.4). These compounds bind to amyloid in neuritic plaques more strongly than diffuse plaques and do not label soluble amyloid at all. As studies suggest that amyloid plaque deposition occurs years prior to symptom onset, amyloid PET may be of particular use in early diagnosis of Alzheimer disease to distinguish mild cognitive impairment caused by Alzheimer disease versus that caused by other entities. Because non-Alzheimer diagnoses such as cerebral amyloid angiopathy and dementia with Lewy bodies may be associated with amyloid

deposition in brain, and up to one-third of older cognitively normal adults have incidental amyloid positivity on PET, a positive amyloid scan should not be taken as proof positive of an Alzheimer disease diagnosis. However, a negative scan is considered inconsistent with the known neuropathology of Alzheimer disease. The amyloid-detecting radiopharmaceutical [^{11}C] Pittsburgh compound B has been widely used in Alzheimer disease research; however, the short half-life of ^{11}C makes its clinical use impractical. [^{18}F] Florbetapir (*Amyvid*), [^{18}F]flutemetamol (*Vizamyl*), and [^{18}F]florbetaben (*Neuraceq*) have longer half-lives and have been approved by the FDA to assist clinicians in the diagnosis of Alzheimer disease. In 2013, the CMS decided not to provide coverage for amyloid PET imaging for diagnosis of Alzheimer disease, except for patients participating in certain studies under a Coverage with Evidence Development program. As the cost of amyloid imaging remains prohibitive to most patients, the most practical advantage may be in enriching clinical trials so as to avoid accidental inclusion of patients with non-Alzheimer diagnoses.

FIGURE 22.4 Example of amyloid PET imaging. [^{11}C] Pittsburgh compound B PET shows binding in amyloid plaque-rich cortical areas in the patient with Alzheimer disease but not the age-matched cognitively normal control subject. Binding in the control subject is limited to nonspecific binding in white matter. INTRODUCTION

Neurovascular ultrasound includes two major ultrasound imaging technologies: extracranial ultrasound (duplex ultrasound or Color Doppler) and transcranial ultrasound (transcranial Doppler). Together, these techniques provide a real-time, noninvasive, comprehensive, and affordable evaluation of the major brain-supplying arteries. Besides, these imaging technologies are repeatable and portable and therefore can be performed at bedside, emergency rooms, or at any other patient care settings. Extracranial Doppler and transcranial Doppler have become an integral part of the evaluation of patients with cerebrovascular disease or in asymptomatic individuals at an increased risk of vascular disease. These technologies are also an integral part of primary and comprehensive stroke centers. The most established clinical situations for the use of neurovascular ultrasound include the early detection and characterization of extracranial and intracranial atherosclerosis and occlusive disease; the evaluation of cerebral hemodynamic consequences of proximal arterial occlusive disease; monitoring of response to treatment of acute or chronic occlusive atherosclerotic disease; the time course and reversibility of cerebral vasospasm after subarachnoid hemorrhage; the detection of cerebral emboli in patients with cardiac, aortic, and carotid disease; and selection of sickle cell patients for blood transfusion as an effective imaging technology in primary stroke prevention. Neurovascular ultrasound is often used to complement other neuroimaging technologies such as magnetic resonance angiography (MRA) and computed tomography angiography (CTA). All of these neuroimaging techniques provide concordant results when performed in accredited laboratories. If discrepancies arise, conventional two-dimensional angiography may be indicated, mainly if an immediate interventional revascularization procedure is considered.

EXTRACRANIAL ULTRASOUND (DUPLIX ULTRASOUND OR COLOR DOPPLER)

Extracranial ultrasound is the noninvasive method of screening the extracranial carotid and vertebral arteries for an atherosclerotic disease with the lowest risk and cost. It provides real-time imaging of anatomy, physiology (hemodynamics), and pathophysiology of the extracranial circulation. Extracranial ultrasound is used in the risk stratification of patients with symptomatic or latent cerebrovascular disease as well as in asymptomatic patients to detect the presence of carotid stenosis and to evaluate other carotid artery phenotypes, including carotid plaque size, plaque echomorphology, intima-media thickness (IMT), and carotid stiffness.

Imaging modes of extracranial ultrasound include the *brightness* or *B mode*, where ultrasound echoes are displayed in various levels of gray; *color* or *C mode*, where the Doppler signal of blood flow velocities is displayed in color; *Doppler* or *D mode*, where shift in echoes is obtained from the moving blood particles and displayed as a Doppler spectrum of blood flow velocities; *power mode*, where the Doppler signal of blood flow is displayed independent of the angle of insonation and is therefore magnified; and *motion* or *M mode*, where motion of interfaces is recorded along the depth axis. An ultrasound system that combines the B and D modes is called *duplex ultrasound*, and if B, C, and D modes are combined, it is called “triplex” or *Color Doppler*. All modern ultrasound systems are now equipped with all of these imaging modes.

CAROTID ULTRASOUND CRITERIA FOR DETECTION OF CAROTID STENOSIS

Traditionally, carotid stenosis is usually defined as stenosis greater than 50% by carotid ultrasound criteria. The most important ultrasound measures in assessing carotid stenosis are peak systolic (PS) velocity, end-diastolic

(ED) velocity, and velocity ratios. These are applied in prestenotic, stenotic, and poststenotic regions. The degree of stenosis is also assessed visually from gray-scale ultrasound images and crosschecked with Color Doppler imaging, which can guide Doppler velocity determination in order to select the most critical part of stenosis for Doppler velocity examination. The examples of carotid ultrasound criteria for the degree of carotid stenosis are widely available. The Society of Radiologists in Ultrasound has published multidisciplinary consensus on diagnostic criteria to grade the internal carotid artery (ICA) stenosis using Duplex ultrasound [Level 1]1 (Table 23.1). These criteria can be used as a template for new vascular laboratories as well as to validate individual laboratory criteria for the estimation of carotid stenosis (Fig. 23.1). Because of Doppler velocity measurement variability and specific patient populations, there are discrepant criteria for Doppler parameters of carotid stenosis. Each carotid ultrasound laboratory must, therefore, develop and validate its own criteria to grade carotid stenosis. These parameters must be validated with other imaging modalities and/or surgical findings and an ongoing quality control program must be implemented.

ASSESSMENT OF CAROTID ARTERY AFTER CAROTID ENDARTERECTOMY AND STENTING

Carotid imaging shows changes in the carotid artery wall after successful carotid surgery or stenting. Special attention needs to be paid to the evaluation of the arterial wall changes at the edges of carotid reconstruction where incomplete plaque removal and residual stenosis can be detected. In addition, Doppler velocities may show values above normal through the reconstructed part of the artery likely due to flow remodeling or increased stiffness in the stented segments. If PS velocities at maximal narrowing in the reconstructed artery is greater than 150 cm/s and the PS ratio between stenotic and prestenotic (or prestented) segment is greater than 2, then significant restenosis likely occurred (Fig. 23.2).

TABLE 23.1 The Society of Radiologists in Ultrasound Multidisciplinary Consensus Criteria for Carotid Stenosis

Degree of Stenosis	ICA PSV (cm/s)	Plaque	ICA/CCA PSV ratio	ICA EDV (cm/s)
Normal	<125	None	<2	<40
<50%	<125	<50% diameter reduction	<2	<40
50%-69%	125-230	≥50% diameter reduction	2.0-4.0	40-100
70% to near occlusion	>230	≥50% diameter reduction	>4	>100
Near occlusion	High, low, or undetectable	Visible, detectable lumen	Variable	Variable
Occlusion	Undetectable	Visible, no detectable lumen	Not applicable	Not applicable

ICA, internal carotid artery; PSV, peak systolic velocity; CCA, common carotid artery; EDV, end-diastolic velocity.

Data from Grant EG, Benson CB, Moneta GL, et al. Carotid artery stenosis: gray-scale and Doppler US diagnosis—Society of Radiologists in Ultrasound Consensus Conference. *Radiology*. 2003;229(2):340-346.

SENSITIVITY AND SPECIFICITY OF DUPLEX ULTRASOUND IN DETECTING CAROTID STENOSIS

Extracranial ultrasound is accurate and reliable in detecting carotid stenosis. The positive predictive value (PPV) of carotid ultrasound as compared to conventional angiography is 82% to 97%. In a large meta-analysis of 17 studies comparing carotid ultrasound with carotid angiography, carotid ultrasound had a pooled sensitivity of 86% (95% CI, 84% to 89%) and a pooled specificity of 87% (95% CI, 84% to 90%) for carotid stenosis [Level 1].² For diagnosis of occlusion, carotid ultrasound had a sensitivity of 96% (95% CI, 94% to 100%). Although there can be considerable variation in the accuracy of duplex scanning among laboratories, accreditation programs such as Intersocietal Accreditation Commission (IAC) set standards for performance and accuracy of vascular testing.

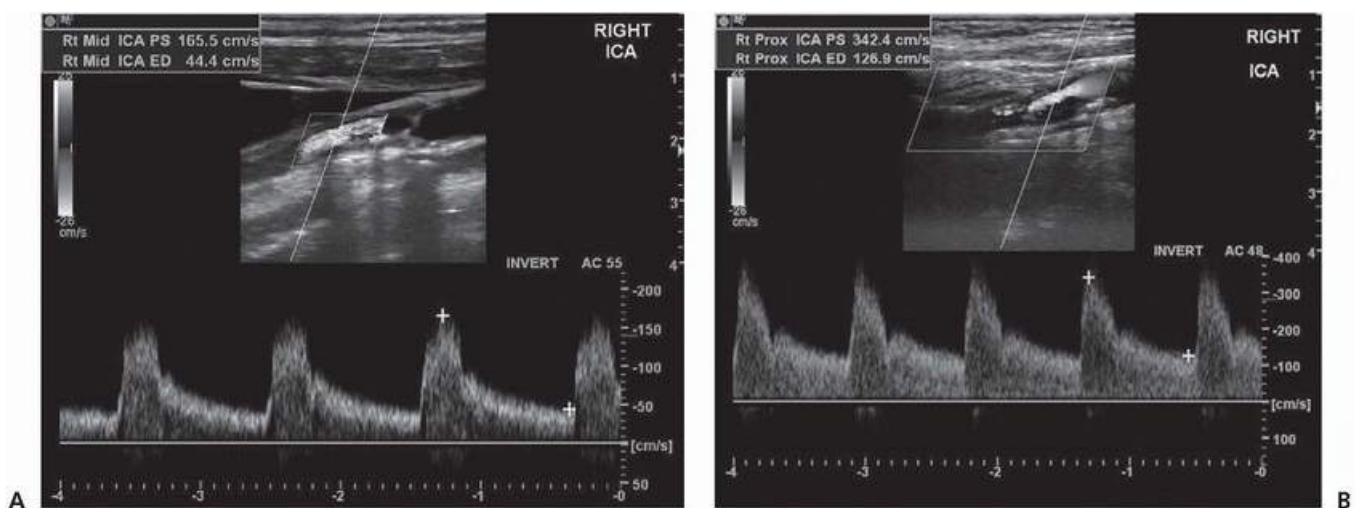

FIGURE 23.1 Two Color Doppler carotid artery studies, each showing different degree of the extracranial internal carotid stenosis. The studies show B mode (brightness mode) ultrasound image (gray scale) of the internal carotid artery (ICA) with corresponding atherosclerotic plaque, C mode (color mode) with color-coded blood flow velocity in the chosen volume sample (*the selected box in the image*), and D mode (Doppler mode) with the blood flow waveforms representing the velocity profile calculated from the Doppler shift (waveforms shown with velocity in cm/s in each picture from the chosen volume sample (represented by the *diagonal line* within the color-selected box). The peak systolic (PS) and end-diastolic (ED) velocities are marked with the yellow calipers in both pictures and used for the assessment of the degree of carotid stenosis. Two examples of varying degrees of ICA stenosis are presented: **(A)** ICA stenosis of 40% to 60%, with PS velocity of 165.5 cm/s and ED velocity of 44.4 cm/s (or 50% to 70% stenosis using the Society of Radiologists in Ultrasound Multidisciplinary Consensus Criteria¹); and **(B)** with ICA stenosis of 60% to 80% (or >70% using the Society of Radiologists in Ultrasound consensus), with PS velocity of 342.4 cm/s and ED velocity of 126.9 cm/s and moderate turbulent blood flow.

CAROTID ULTRASOUND OF CAROTID PLAQUE SIZE, MORPHOLOGY, AND CAROTID INTIMA-MEDIA THICKNESS

Carotid ultrasound provides information on plaque size (regardless of the degree of stenosis) and plaque echomorphology.

P.193

The presence of small nonstenotic carotid plaque on ultrasound is an independent predictor of future stroke and other cardiovascular disease independent of the degree of stenosis, although it is related to the degree of carotid stenosis. Detection of plaque ulceration by ultrasound imaging is limited. However, plaque surface irregularity is easy to detect on ultrasound and was shown to be associated with an increased risk of stroke. Ultrasound may help characterize plaque using a qualitative scoring system (echolucent or echodense; homogenous or heterogeneous plaque) as well as by the quantitative, computer-assisted echodensity parameters, such as the gray-scale median (GSM) index, recently shown to be clinically relevant in the prediction of stroke. Echolucent carotid plaque (soft) has been associated with an increased risk of first-ever stroke or myocardial infarction in asymptomatic individuals. Echodense carotid plaque (calcified) is in general considered to be of a good prognostic feature based on the lower rates of stroke, but recent studies have shown opposite results with an increased risk of stroke. Similar observation was reported for coronary calcium score. This presumably paradoxical effect of plaque calcification may be explained by the fact that echodense plaque is not a cause of stroke but rather a marker of presence of an “active” plaque in other vascular beds, which then can explain its association with increased vascular risk.

FIGURE 23.2 Carotid in-stent stenosis. Color Doppler of the common carotid artery and the internal carotid artery shows stent placed in both arteries. The lumen in the proximal internal carotid artery is reduced. The peak systolic (PS) and end-diastolic (ED) velocities are marked with the yellow calipers in spectral image and used for the assessment of in-stent stenosis. In the narrowing segment, PS velocity was 218.9 cm/s and ED velocity 51.1 cm/s, which indicates in-stent stenosis greater than 50%.

Carotid IMT is a measure of subclinical atherosclerosis shown to be associated with an increased risk of stroke and other cardiovascular disease. It has been used extensively as an outcome measure in numerous clinical trials testing the effect of lipid, blood pressure, and glucose-lowering medications. It has been associated with traditional vascular risk factors across different age groups, including in children and young adults. The American Society of Echocardiography and Society for Vascular Medicine have supported the use of carotid IMT in vascular risk stratification in moderate-risk individuals and outlined the recommendations for the IMT protocols [Level 1].³

DUPLEX ULTRASOUND OF THE VERTEBRAL ARTERIES

The ultrasound evaluation of the vertebral arteries (VAs) is similar to that of the carotid arteries. Examination of the VA is, however, limited by its anatomy because VA, unlike the carotid, cannot be traced continuously when it passes within the transverse processes of cervical vertebrae. Therefore, ultrasound examination of the extracranial VA is reliable only at the origin, intervertebral segments, and at the atlas-loop portion. Color Doppler and Power Doppler are particularly useful in assessing the caliber of VAs. Use of other diagnostic technologies (MRA, CTA, and even conventional angiography) is often recommended in symptomatic patients with suspected VA stenosis on Duplex ultrasound.

CONTRAST-ENHANCED ULTRASOUND

Contrast-enhanced ultrasound vascular imaging has been recently introduced as a novel extracranial ultrasound imaging. Intravenous ultrasound contrast agents are gas-filled microbubbles, which serve as intravascular reflectors of ultrasound waves. The potential clinical use of contrast-enhanced ultrasound has been proposed in different vascular beds including the carotid arteries. It is particularly useful in the situations of poor visualization of high-grade carotid stenosis or suspected occlusion, complex carotid plaques, and evaluation of plaques with suspected ulcerations. It also provides a novel, noninvasive method for the assessment of the vasa vasorum and the vascularization of the atherosclerotic plaque neovascularization, possibly helping in the risk stratification of patients with high risk of plaque rupture. In the future, the use of targeted microbubbles may further enhance the diagnostic capabilities of vascular ultrasound by detecting specific molecular processes important in the pathophysiology of atherosclerosis.

INDICATIONS FOR EXTRACRANIAL ULTRASOUND EXAMINATION

The guidelines for noninvasive vascular testing and indications for vascular ultrasound has been proposed by the American Society of Echocardiography and the Society for Vascular Medicine and Biology and adopted by other professional organizations, Centers for Medicare and Medicaid Services (CMS), and private insurers [Level 1].⁴ *Indications for carotid artery ultrasound* include the following:

- Evaluation of patients with cerebral ischemia, stroke, or TIA
- Evaluation of patients with a cervical bruit
- Evaluation of pulsatile mass in the neck
- Evaluation of blunt neck trauma
- Preoperative evaluation of patients undergoing major cardiovascular or other major surgical procedures, including cardiac, liver, and kidney transplant
- Drop attacks or syncope (rare indications primarily seen in vertebrobasilar insufficiency or bilateral carotid artery disease)
- Vasculitis involving extracranial arteries
- Follow-up of patients with known carotid artery disease
- Evaluation of postoperative patients following carotid endarterectomy or carotid stenting

- Evaluation of suspected subclavian steal syndrome
- Evaluation of suspected carotid or VA dissection

INTRACRANIAL ULTRASOUND (TRANSCRANIAL DOPPLER)

Transcranial Doppler (TCD) is a noninvasive ultrasound technology that monitors blood flow velocity and blood flow direction in large intracranial arteries. Using a probe with great tissue-penetration properties, it is possible to insonate the major vessels of the circle of Willis, the distal intracranial segments of the VAs, and much of the length of the basilar artery (BA). Current TCD devices have a color-coded B mode and Power Doppler display. TCD provides only spectrum analysis of blood flow velocities, whereas transcranial Color Duplex Imaging (TCDI) provides spectrum analysis as well as color-coded imaging of the intracranial vessels and visualization in Power Doppler. Recently, transcranial Power Motion Doppler (PMD) has been introduced. PMD continuously displays flow intensity and direction of blood flow over 6 cm of intracranial space. Its advantage is in easier insonation, which allows inexperienced individuals to learn technique faster. Any of these TCD technologies produce the spectral signal that allows estimation of the degree of arterial stenosis.

Arteries of the circle of Willis are insonated through temporal, orbital, suboccipital (foramen magnum), and submandibular acoustic “windows.” The measures used include distance from the probe, direction of flow (toward or away from the probe), flow velocities, and waveform characteristics.

INDICATIONS FOR TRANSCRANIAL DOPPLER ULTRASOUND

The American Institute of Ultrasound in Medicine (AIUM) has published practice guidelines [Level 1]⁵ for the performance of TCD for adults and children. *TCD indications in adults* include the following:

- Detection and follow-up of stenosis or occlusion in a major intracranial artery in the circle of Willis and vertebrobasilar system and monitoring of thrombolytic therapy in acute stroke
- Detection of cerebral vasculopathy
- Detection and monitoring of vasospasm in patients with subarachnoid hemorrhage
- Evaluation of collateral pathways of intracranial blood flow, including after intervention
- Detection of circulating cerebral microemboli
- Detection of right-to-left shunts
- Assessment of cerebral vasomotor reactivity
- As an adjunct in the confirmation of the clinical diagnosis of brain death
- Intraoperative and periprocedural monitoring to detect cerebral embolization, thrombosis, hypoperfusion, and hyperperfusion
- Evaluation of sickle cell disease to determine the stroke risk
- Assessment of arteriovenous malformations
- Detection and follow-up of intracranial aneurysms
- Evaluation of positional vertigo or syncope

Additional *TCD applications in children* include the following:

- Assessment of intracranial pressure and hydrocephalus

- Assessment of hypoxic ischemic encephalopathy
- Assessment of dural venous sinus patency

TABLE 23.2 Recommendations and Level of Evidence for the Use of Transcranial Doppler by the American Academy of Neurology Therapeutics and Technology Assessment Subcommittee

Setting/Disease/Condition	Rating of Recommendation/Level of Evidence
Sickle cell disease	Type A, Class I
Detection and monitoring of angiographic vasospasm	Type A, Class I-II
Detection of cerebral circulatory arrest/brain death	Type A, Class II
Intracranial steno-occlusive disease	Type B, Class II-III
Vasomotor reactivity testing	Type B, Class II-III
Monitoring carotid endarterectomy	Type B, Class II-III
Cerebral microembolism detection	Type B, Class II-IV
Monitoring cerebral thrombolysis	Type B, Class II-III
Monitoring coronary artery bypass graft surgeries	Type B-C, Class II-III
Right-to-left cardiac shunts	Type A, Class II
Intracranial occlusive disease	Type B, Class II-IV

Type A, established as useful/predictive recommendation; **Type B**, probably useful/predictive; **Type C**, possibly useful/predictive; **Class I**, evidence provided by prospective study in broad spectrum of persons with suspected condition, using a “gold standard” to define cases, where test is applied in blinded evaluation, and enabling assessment of appropriate tests of diagnostic accuracy; **Class II**, evidence provided by prospective study in narrow spectrum of persons with suspected condition or well-designed retrospective study of broad spectrum of persons with suspected condition (by gold standard) compared with broad spectrum of controls where test is applied in blinded evaluation and enabling assessment of appropriate tests of diagnostic accuracy; **Class III**, evidence provided by retrospective study where either persons with established condition or controls are of narrow spectrum and where test is applied in blinded evaluation; **Class IV**, any design where test is not applied in blinded fashion or evidence provided by expert opinion or descriptive case series.

From Sloan MA, Alexandrov AV, Tegeler CH, et al; Therapeutics and Technology Assessment Subcommittee of the American Academy of Neurology. Assessment: transcranial Doppler ultrasonography: report of the Therapeutics and Technology Assessment Subcommittee of the American Academy of Neurology. *Neurology*. 2004;62(9):1468-1481.

In the American Academy of Neurology report [Level 1],⁶ the highest level of evidence was given to the use of TCD for the screening of children aged 2 to 16 years with sickle cell disease for stroke risk (Type A, Class I) and the detection and monitoring of angiographic vasospasm after spontaneous subarachnoid hemorrhage (Type A, Class I to II) (Table 23.2).

Sickle Cell Disease

TCD is an important tool for the selection of children with sickle cell disease in need of blood transfusion and who should stay on blood transfusion to sustain the benefit for prevention of stroke. In the STOP (Stroke Prevention Trial in Sickle Cell Anemia) trials, TCD detection of time-averaged maximum mean flow velocity

P.195

(MFV) of 200 cm/s (not mean velocity) on two separate examinations in middle cerebral artery (MCA) or TICA (terminal ICA) was used to determine the need for blood transfusion that resulted in 90% relative risk reduction of first-ever stroke. Moreover, longterm follow-up results from the STOP trials indicated that persistent elevation in TCD velocities in these patients is indicative of ongoing increased risk of stroke.

Intracranial Stenosis and Occlusion

Stenosis of greater than 50% lumen narrowing can reliably be detected in arterial segments with anatomically favorable insonation angles, particularly in the M1 segment of the MCA. Significant narrowing of intracranial arteries results in focal increases in flow velocities, turbulent flow, and increased waveform pulsatility at the level of stenosis. Compensatory collateral flow from uncompromised vessels to deprived areas may result in flow reversal and augmentation of flow. Because some patients have suboptimal temporal windows, failure to obtain a waveform reading does not imply vessel occlusion unless a prior study had demonstrated vessel patency. An intracranial stenosis of the major intracranial arteries should be suspected when the normal hierarchy of the flow velocities is disrupted. The flow in the MCA should be greater than in the anterior cerebral artery (ACA), where blood flow velocities should be greater than in the posterior cerebral artery (PCA) or BA and VA. The difference in these disrupted MFV should be greater than 20%. According to the SONIA (Stroke Outcomes and Neuroimaging of Intracranial Atherosclerosis) criteria [Level 1],⁷ the TCD MFV cut-off for more than 50% stenosis for MCA is greater than 100 cm/s and for VA and BA is greater than 80 cm/s (Fig. 23.3).

Sensitivity and Specificity of Transcranial Doppler in Detecting Intracranial Stenosis

TCD can reliably detect stenosis in M1 segment of MCA, ICA syphon and terminal ICA, terminal VA, proximal BA, and P1 segment of PCA. The sensitivity of TCD for stenosis in these segments is 85% to 90% and specificity is 90% to 95%. PPV is 85% and negative predictive value (NPV) is 98%, with lower accuracy values for posterior circulation. In the SONIA trial [Level 1],⁷ the accuracy of TCD in detection of intracranial steno-occlusive disease was superior to CTA or digital subtraction angiography (DSA) for ruling out than ruling in stenosis (having a higher NPV than PPV) for all intracranial arterial segments.

FIGURE 23.3 Example of TCD study of the both MCA (**A, left and B, right**) in patients with the right MCA stenosis. The spectral velocities are obtained at the depth of 50 cm from both sides of the head overlying the temporal bone. The blood flow velocity profile of the Doppler shift is calculated from the blood in the MCA flowing toward the probe (*the blue arrow on the left side of both images directed toward the probe*). The image on the left (**A**) represents the normal spectral flow with PS velocities of about 160 cm/s and ED velocities of about 60 cm/s. The image on the right (**B**) represents the high-grade MCA stenosis with systolic blood flow velocities over 320 cm/s and ED blood flow velocities of 200 cm/s and marked turbulent flow.

Detection of Arteriovenous Malformations

Arteriovenous malformations (AVMs) are direct communications between the arterial and venous systems, without an intervening capillary bed. No resistance vessels exist to impede or regulate flow, and flow measurements from feeding vessels typically demonstrate elevated velocities and low-resistance waveforms. Because of the large volume of flow that traverses an AVM, flow patterns may also be altered in vessels not directly connected to the AVM, resulting in altered waveform recordings. TCD is sensitive for the detection of medium- to large-sized AVMs. TCDI may provide more information about anatomic characteristics of AVMs than regular TCD.

Vasospasm in Subarachnoid Hemorrhage

TCD has become a standard procedure for the detection, quantification, and monitoring of arterial vasospasm after subarachnoid hemorrhage or head trauma. Most clinically important spasm occurs in the proximal cerebral vessels, which are accessible to TCD insonation. TCD monitoring, however, is limited in identifying vasospasm in distal cerebral arteries. TCD flow velocity criteria appear to be most reliable for detecting angiographic MCA and BA vasospasm. Mean MCA velocities greater than 120 cm/s are indicative of moderate vasospasm, whereas velocities greater than 200 cm/s show severe vasospasm. A Lindegaard ratio (MFV MCA/ICA) greater than 3 is suggestive of vasospasm, whereas a ratio of 6 or greater

reliably predict the presence of clinically significant angiographic vasospasm. In addition, a sudden rise in MCA MFV by greater than 65 cm/s or by 20% increase is suggestive of vasospasm. TCD is most useful in monitoring the temporal course of vasospasm to help guide the timing of diagnostic and therapeutic angiographic interventions.

Cerebral Microemboli Detection

TCD can detect microemboli or high-intensity transient signal (HITS), which account for up to 70% of all ischemic

strokes. Most of these emboli originate not only from carotid atherosclerosis but also from cardiac diseases including atrial fibrillation, prosthetic heart valves, right-to-left cardiac shunt (patent foramen ovale [PFO]), aortic arch atheroma, vertebral disease, and stenosis in other intracranial arteries. Criteria for microemboli are established by the consensus committee at the Ninth International Cerebral Hemodynamic Symposium [Level 1],⁸ which defines microembolus as a TCD signal with (1) random occurrence during the cardiac cycle; (2) brief duration (embolic signals should be transient lasting <300 ms); (3) high intensity (at least 3 dB higher than the background blood flow signal); (4) primarily unidirectional signal within the Doppler spectrum; and is (5) accompanied by an audible component (“snap,” “chirp,” or “pop”).

Cerebral Vasomotor Reactivity Testing

TCD can be used to assess cerebral hemodynamic reserve. When arterial perfusion is compromised, distal regulating arterioles dilate to allow more flow and to prevent cerebral ischemia. However, when perfusion is severely impaired, the arterioles are maximally dilated and cerebral vasomotor reactivity (CVR) decreases or disappears, indicating a state of exhausted cerebrovascular reserve or “miserable” perfusion. Impaired CVR may predict impending ischemia in patients with extracranial or intracranial artery stenosis or occlusion. CVR tests include the breath-holding index, blood pressure changes, or the carbon dioxide (CO₂) inhalation test. Impaired CVR has been found in various conditions, including severe carotid artery stenosis, stroke, sleep apnea, and congestive heart failure. CVR is not a direct measure of cerebral autoregulation, but new methods that include correlations between flow velocities and spontaneous fluctuations in blood pressure have been developing to assess cerebral autoregulation.

Sonothrombolysis

TCD may be effective as an adjunct therapy to intravenous thrombolysis after acute MCA occlusion. Application of *intravascular low-intensity ultrasound* at the site of occlusion may enhance the outcome after ischemic stroke without the administration of tissue plasminogen activator (tPA). Also, augmentation of tPA-associated thrombolysis with standard diagnostic TCD monitoring has been safe and associated with a higher arterial recanalization rate. The CLOTBUST trial showed that patients with acute stroke treated with sonothrombolysis (tPA + 2 MHz TCD) had more dramatic clinical recovery and arterial recanalization (25% vs. 8%) without an increased risk of symptomatic hemorrhage. This resulted in a trend toward better outcome, with more patients having modified Rankin score of 0 to 1 at 3 months after stroke (42% vs. 29%). In addition, gaseous microspheres, initially developed as ultrasound contrast agents, can further increase the effectiveness of tPA. A microsphere dose-escalation study showed sustained complete recanalization rates of 67% in patients receiving TCD monitoring with perflutren lipid microspheres compared to controls receiving tPA alone with no increase in hemorrhage rate. TCD with the administration of microspheres is an emerging application in acute stroke management. Currently, a novel operator-independent TCD device for delivery of ultrasound energy has been tested in phase III efficacy trial of sonothrombolysis (named CLOTBUSTER).

LIMITATIONS OF TRANSCRANIAL DOPPLER

TCD is highly operator dependent. It requires technical skills, detailed three-dimensional knowledge of cerebrovascular anatomy and its variations, and global understanding of brain hemodynamics. The use of TCD is also limited by the 10% to 15% rate of inability to perform TCD due to inadequate acoustic windows, which is prevalent in blacks, Asians, and elderly women. This is related to thickness and porosity of the bone, which causes attenuation of the ultrasound energy transmission. TCD examination is also limited to the large cerebral basal arteries, and it cannot directly examine a status of local cerebral blood flow. These limitations of TCD are the main reason for its underutilization, and most of them can be overcome by vascular laboratory accreditation and proper training and certification of sonographers and interpreting physicians.

Angiography and Endovascular Neuroradiology

Charles A. Bruno Jr

Daniel H. Sahlein

INTRODUCTION

Interventional neuroradiology (INR) or endovascular surgical neuroradiology (ESNR) encompasses all invasive diagnostic and therapeutic interventions for diseases, often neurovascular, of the central nervous system and often the skull base, neck, spinal cord, and paraspinal soft tissues. INR is a continually evolving field that has made tremendous strides over the last several decades based largely on technologic advances leading to more therapeutic options and improvements in procedure safety and efficacy, leading to increasing acceptance of endovascular therapies by the biomedical neuroscience community.

TECHNIQUE

Cerebral angiography provides high-resolution images of the extracranial and intracranial cerebral vasculature (Fig. 24.1). The procedure is performed by accessing the femoral artery and threading a small catheter into the precerebral vessels.

The first cerebral angiogram in a living patient was performed by Egas Moniz in the early 1920s. During its infancy, cerebral angiography was performed via direct percutaneous puncture of the cervical carotid and vertebral arteries. This remained the principle technique for cerebral angiography until the late 1960s when the transfemoral approach was introduced. Transfemoral catheterization offered several advantages, not the least of which included access to all four cerebral vessels with one puncture, improved patient comfort, less need for general anesthesia, the ability to perform cerebral angiography on an outpatient basis, and diminished stroke risk because of limited trauma to the precerebral arterial circulation. In the modern medical era, cerebral angiography is overwhelmingly performed via the transfemoral approach.

FIGURE 24.1 Major arterial vessels that supply the brain as viewed on a lateral angiogram. **A:** Anterior and posterior cerebral arteries. **B:** Middle cerebral artery. (Adapted from Marshall R, Mayer S. *On Call Neurology*. 3rd ed. Philadelphia: Saunders; 2007.)

Although advances in noninvasive imaging of the cerebral vasculature have markedly improved over the last two

decades, catheter angiography remains the gold standard for imaging cerebral blood vessels. Catheter angiography has two significant advantages over noninvasive vascular imaging; improved temporal resolution, meaning images can be acquired at a rate of 10 per second versus approximately 1 per second for computed tomography (CT) and magnetic resonance imaging (MRI); and spatial resolution—the voxel size (smallest unit for which there is only one signal, akin to a pixel on a cathode ray television) for fluoroscopy on the latest equipment is 0.1×0.1 mm versus an average of $0.4 \times 0.4 \times 3$ mm for CT and $1.0 \times 1.0 \times 0.9$ mm for an average clinical MRI. [Figure 24.2](#) demonstrates both the differences in spatial and temporal resolution between postcontrast MRI and digital subtraction catheter angiography.

Mastery of both its acquisition and interpretation serves as the foundation for all interventional procedures. Modern catheter angiography is a relatively safe procedure associated with a low complication rate when performed by neurointerventionalists even in a highly complex patient population.

P.199

FIGURE 24.2 A-C: Three sequential transaxial T1-weighted postcontrast images from a 64-year-old male who presented with seizure. The images demonstrate a left frontotemporal brain arteriovenous malformation (AVM)

(*white arrows*). On the MRI, it is difficult to distinguish nidus from draining vein. Nidal measurements are important for surgical and radiotherapy risk assessment. **D-F**: Lateral images from a catheter cerebral angiogram from the same patient. **D**: Early arterial phase. Note the very clear identification of nidus on an image with no draining veins (*white arrows*). Also note two proximal arterial aneurysms (*black arrowheads*). (*continued*)

FIGURE 24.2 (*continued*) **E**: Slightly later in the arterial phase. The nidus has now completely opacified (*white arrows*) and there is the suggestion of very early venous opacification (*white arrowhead*). **F**: Venous phase: an excellent demonstration exclusively of veins draining the nidus. The nidus is drained by the vein of Trolard (*white arrow*), which drains secondarily into the anterior frontal veins (*white arrowhead*). There is deep venous drainage into the basal vein of Rosenthal (*black arrow*), which drains out via the Vein of Galen and straight sinus (*white and black arrowhead*).

CONDITIONS DIAGNOSED AND TREATED WITH ANGIOGRAPHIC TECHNIQUES

Angiography is useful for diagnosing a variety of conditions that affect the brain and spinal cord ([Table 24.1](#)). Because of its invasive nature, angiography functions as both a diagnostic and therapeutic modality. Major conditions that can be diagnosed or treated with angiographic techniques are discussed in the following sections. The most common complications of diagnostic and interventional angiographic procedures include stroke due to vessel occlusion or thrombosis and hemorrhage due to vessel perforation, dissection, and groin hematoma.

CEREBRAL ANEURYSMS

Cerebral aneurysms constitute a relatively common cerebrovascular abnormality with a prevalence of approximately 4%. Subarachnoid hemorrhage (SAH) is the most feared and common clinical presentation (see [Chapter 39](#)). Endovascular treatment of cerebral aneurysms has evolved dramatically over the past two decades and can now be offered as a viable alternative to craniotomy and microsurgical clipping in most cases.

TABLE 24.1 Conditions Diagnosed by Angiography

1. Occluded or stenotic vessels

2. Arterial dissections

3. Aneurysms

4. Arteriovenous malformations and other vascular malformations

5. Vasculitic narrowing (“beading”)

6. Dural venous sinus thrombosis (“venous phase”)

Early endovascular endeavors to treat intracranial aneurysms used detachable balloons, pushable microcoils, and liquid embolic agents with varying degrees of procedural efficacy and safety. In 1991, Guido Guglielmi revolutionized endovascular treatment of cerebral aneurysms with the Guglielmi detachable coil (GDC). The GDC is designed with a thrombogenic platinum coil attached to a stainless steel delivery guide wire or mandrel. Once the coil is correctly positioned within the aneurysm, an electric current is applied to the guide wire, thereby electrolytically dissolving the soldered connection between the coil and delivery mandrel. The guide wire is subsequently removed and another coil can be advanced into the aneurysm until the aneurysm is completely excluded from the arterial circulation (i.e., no longer fills with contrast). A wide range of aneurysm morphologies can be treated because of the intrinsic compliance of the coil helix.

Treatment with GDC offers durable, long-term protection from aneurysm rebleeding. The rate of rebleeding following coil embolization is directly proportional to the percentage of the aneurysm that remains patent. Not surprisingly, the percentage of residual aneurysm patency following coil embolization is dependent on aneurysm neck size—the size of the opening connecting the aneurysm to the flowing blood. Small aneurysms with wide necks and large aneurysms (which typically have large necks as well) are most likely to be incompletely treated following coil embolization. To aid in the endovascular coil embolization of wide-necked aneurysms, balloon remodeling was introduced.

The *balloon remodeling technique* involves temporary inflation of a nondetachable balloon within the parent artery over the aneurysm neck during coil placement. The inflated balloon provides a resistive barrier to keep the coil within the aneurysm during and after deployment, preventing migration into the parent artery. The balloon

P.201

remodeling technique is particularly useful in treating ruptured aneurysms with challenging neck anatomy because of the necessity of double antiplatelet therapy (usually aspirin and clopidogrel) when a permanent intravascular stent is used. Disadvantages of the technique include potential ischemia secondary to blood flow arrest, migration of the coil mass after the balloon is deflated, and intimal damage and thrombosis related to repeated inflation of the balloon.

A more recent iteration in the evolution of endovascular aneurysm treatment involves moving the matrix of reconstruction from the aneurysm sac (endosaccular) to the parent artery lumen (endoluminal) via the use of a stent. The procedure involves placement of a permanent cylindrical cage or stent (current available devices include the Neuroform stent, Enterprise stent, LVIS Device, and LVIS Jr. Device) across the neck of an aneurysm to act as a resistive barrier, preventing the deployed coils from herniating into the parent artery. There are three traditional techniques for coiling with stent assistance. One technique involves placing a stent within the parent artery across the neck of an aneurysm and subsequently accessing the aneurysm with a microcatheter through

the wall of the stent. An alternative approach involves using two catheters in which a coil catheter tip is advanced into the aneurysm after which a stent is deployed across the aneurysm neck, effectively “jailing” the first catheter between the stent and the arterial wall. The final technique involves coiling the aneurysm with balloon assistance and subsequently placing a stent across the neck of the aneurysm. *Stent-assisted coiling* offers several advantages over coiling alone or balloon remodeling including creating a permanent buttress for the coil mass, decreasing blood flow across the neck of the aneurysm (potentially facilitating hemostasis within the aneurysm), and providing a scaffold for endothelialization.

The newest technology in aneurysm treatment namely *flow-diverting stents* are designed as endoluminal-only aneurysm treatment constructs. The first of these devices, the *Pipeline embolization device* (PED), represents a major paradigm shift in the endovascular treatment of intracranial aneurysms (Fig. 24.3). The PED is a braided stent with approximately 30% total metallic coverage versus less than 10% for the Neuroform and Enterprise stents. The PED is ideal for the treatment of large or giant, wide-necked, and fusiform aneurysms, as the stent construct can be deployed across the diseased segment of artery, rapidly resulting in hemostasis and slowly endothelializing over the course of months. In a cohort of anterior circulation aneurysms with a mean aneurysm size of 18 mm and a mean neck size of 9 mm treated with the PED, 74% of aneurysms were completely cured at 6 months and 87% at 1 year, with a 6% incidence of major ipsilateral stroke or neurologic death. Although flow diversion is a promising technique, careful analysis and follow-up of treated patients is required to determine its safety and efficacy. Stent placement requires the long-term use of dual antiplatelet agents to prevent thrombosis, potentially problematic in the setting of acute SAH.

FIGURE 24.3 A: Two volumetric reconstructions from a catheter cerebral angiogram demonstrating a wide neck, giant aneurysm in a 72-year-old patient with worsening headaches. **B:** Three lateral catheter cerebral angiograms (left internal carotid artery injection). On the *left* is the pretreatment angiogram that demonstrates the aneurysm (*white arrows*). In the *center* is the angiogram immediately following placement of three pipeline embolization devices. Note that the angiogram is in the venous phase and yet contrast is still opacifying the

aneurysm (*white arrows*), a function of the hemostatic feature of the flow-diverting stent. On the *right* is the 6-month follow-up angiogram demonstrating complete aneurysm cure.

Choosing between endovascular and open surgical treatment of intracranial aneurysms is a complex decision, often dependent on local preferences and physician skill and experience. Nevertheless, two randomized trials have compared the two options in the setting of SAH. The International Subarachnoid Aneurysm Trial (ISAT) was a prospective, randomized, multicenter trial designed to compare the safety and efficacy of endovascular coiling with microsurgical clipping [Level 1].^{1,2} The study enrolled 2,143 patients between 1994 and 2003 with ruptured cerebral aneurysms and randomly assigned them to microsurgical clipping ($n = 1,070$) or endovascular coiling ($n = 1,073$). The primary outcome was death or dependence for activities of daily living at 1 year. This study showed that in this population of patients with small to moderate size anterior circulation aneurysms, endovascular coiling was safer

P.202

than surgical clipping: 24% of patients in the coiling arm were dead or dependent versus 31% in the clipping arm, a 23% relative risk reduction. At 5 years, there was a small but statistically significant increased risk of recurrent bleeding in the coil arm, but the risk of death was slightly albeit statistically significantly lower in the coiled group than in the clipped patients [Level 1].³ The Barrow Ruptured Aneurysm Trial (BRAT) reported remarkably similar results. BRAT prospectively treated 471 aneurysm patients, alternating between coiling and clipping. Overall, 34% of patients in the clipping arm were dead or dependent at 1 year compared to 23% in the coil arm, a statistically significant difference [Level 1].⁴ Nevertheless, 33% of those originally assigned to coiling crossed over to the clipping arm, reinforcing the need for open surgical treatment of difficult-to-coil aneurysms for the foreseeable future.

ARTERIOVENOUS MALFORMATIONS

Brain arteriovenous malformations (AVMs; see also [Chapter 41](#)) are subpial connections between arteries and veins that lack a normal capillary bed and articulate via a tangled network of dysplastic vessels known as a *nidus*, resulting in a direct connection between the arterial and venous systems. As is the case with aneurysms, rupture is the most feared complication of an AVM, with a risk of 1% to 4% per year.

Current therapeutic options for brain AVMs include microsurgical resection, radiosurgery, and endovascular embolization. Endovascular embolization tends to play an adjunct role in the treatment plan, typically in devascularizing the nidus prior to microsurgical resection, although it has been used increasingly as the sole treatment option. Embolization can also be used prior to or following radiosurgery and has also been used successfully to alleviate clinical symptoms and preserve or improve neurologic function in inoperable lesions. The liquid embolic agents *n*-butylcyanoacrylate (NBCA) and Onyx, a copolymer of ethylene vinyl, are the primary agents used for the endovascular treatment of cerebral AVMs.

Treatment of unruptured brain AVMs remains controversial. The Randomized trial of Unruptured Brain Arteriovenous malformations (ARUBA) compared outcomes in patients with unruptured brain AVMs who were treated with medical management with those treated with surgical or interventional therapy [Level 1].⁵ A total of 223 patients were enrolled in the study: 114 were assigned to interventional therapy, whereas 109 patients received medical management alone. The study was prematurely halted because the risk of death or stroke was significantly lower in the medical management group than in the interventional therapy group.

DURAL ARTERIOVENOUS FISTULAS

Cranial or spinal dural arteriovenous fistulas (DAVFs; see also [Chapter 41](#)) are acquired pathologic shunts between dural arteries and dural venous sinuses. DAVFs are located within the leaflets of the dura matter and lack a distinctive vascular nidus. The pathogenesis of DAVFs is unknown, although multiple associations have

been described including head trauma, infection, hypercoagulable states, and sinus thrombosis. Signs and symptoms include pulsatile tinnitus and exophthalmos, cranial nerve deficits, cognitive impairment, venous infarction, intracranial hemorrhage, and even death, depending on fistula location, duration of disease, and venous drainage pattern. DAVFs most commonly occur in the transverse/sigmoid and cavernous sinuses.

DAVFs are dynamic lesions that may either spontaneously regress or progress. For this reason, close clinical and radiologic monitoring is critical. Treatment should be pursued for all lesions with cortical venous drainage or intolerable symptoms. First-line management of DAVFs is endovascular embolization via the transarterial route, transvenous route, or a combination of both. Transarterial embolization is typically performed with a liquid embolic agent such as NBCA or Onyx. Although cures are sometimes difficult to achieve through the transarterial route, it may be the only viable option in certain circumstances where transvenous embolization is not possible because of limited venous access to the fistula site due to stenosis or thrombosis.

Transvenous embolization is performed by retrograde catheterization of the involved dural sinus or cortical vein followed by deposition of coils and/or liquid embolic material at the site of inflow of the arteriovenous shunt. Transvenous embolization has been shown to have a high likelihood of cure and is often used to treat transverse/sigmoid sinus and cavernous sinus DAVFs. Detachable coils are deployed to form a scaffolding, after which pushable fibered coils, which are more thrombogenic and much less expensive, can then be added to achieve complete occlusion of the venous segment.

ACUTE ISCHEMIC STROKE

Globally, stroke remains the leading cause of disability and the second leading cause of death worldwide. Over the last two decades, the management of acute ischemic stroke (AIS) has dramatically changed with the introduction of novel pharmacologic and endovascular therapies aimed at arterial recanalization and reperfusion of ischemic brain tissue (see [Chapter 35](#)). Although the mainstay of emergency treatment for AIS is tissue plasminogen activator (TPA), endovascular therapy is increasingly being used in conjunction with thrombolytic therapy for patients with large-vessel occlusion (LVO) (see also [Chapter 15](#)).

Initial efforts at endovascular stroke therapy focused on intraarterial (IA) administration of thrombolytics. The Prolyse in Acute Cerebral Thromboembolism II (PROACT II) study demonstrated that prourokinase, when given to patients with proximal middle cerebral artery (MCA) occlusion within 6 hours of onset of AIS, significantly improved clinical outcome at 90 days as compared to a control group given only intravenous heparin [**Level 1**].⁶ Patients who received IA prourokinase demonstrated a 66% recanalization rate, with 40% having good clinical neurologic outcomes at 90 days as compared to 25% in the control arm. PROACT-II remains the only randomized trial supporting IA thrombolysis, which is not U.S. Food and Drug Administration (FDA) approved for the treatment of AIS. Many neurointerventionalists use IA thrombolytics off-label as adjunct to mechanical thrombectomy for distal small branch occlusions that may be difficult to access with larger mechanical devices.

The Mechanical Embolus Removal in Cerebral Ischemia (MERCI) retriever system was approved by the FDA in 2004 as the first mechanical thrombectomy device for removing clot in AIS patients. The MERCI retriever is a nitinol corkscrew-shaped microcatheter-deployed device that is advanced through occlusive thrombus and then pulled back to ensnare clot and allow it to be removed. The mechanical embolectomy is done through an 8- or 9-French balloon guide catheter that arrests antegrade flow and allows for aspiration during the clot retrieval process. The MERCI retriever system has undergone numerous redesigns since its introduction.

In 2008, the FDA approved a second endovascular device, the Penumbra aspiration system. This device is composed of two main components, a reperfusion catheter used for clot aspiration and a

P.203

separator or wire with a short segment of thickness near the tip used for mechanical breakdown of the thrombus. In the Penumbra Pivotal Stroke trial, a single-arm study of AIS patients presenting within 8 hours of onset,

recanalization was achieved in 82% of the treated occluded arteries. More recently, Penumbra has introduced a larger aspiration catheter, the 5 Max Ace, which is designed for clot aspiration without the separator. ADAPT, a direct aspiration first-pass technique using this device, has been shown to be safe and effective for arterial thrombectomy.

FIGURE 24.4 The “stentriever” stroke devices. The Solitaire device is depicted above the Trevo device.

Stent retrievers (or *stentriever*s) are the latest devices available for acute stroke treatment. These soft, self-expanding stents are adherent to and deployed at the end of a guide wire. Two devices are commercially available in the United States at present, the Solitaire (Medtronic) and Trevo (Stryker) devices (Fig. 24.4). Stentriever s are temporary self-expanding stents that when deployed capture thrombus and simultaneously restore blood flow by displacing clot peripherally against the artery wall. This positioning often temporarily restores blood flow, giving the brain a few minutes of restored perfusion. After a waiting period of several minutes, the stent is retrieved with the hope that the thrombus is removed as well, typically adherent to the stent. Several “passes” may be required to achieve satisfactory results and there is a possibility of breaking up the clot and creating distal emboli. Nevertheless, the stentriever s are a safe and effective tool for thrombectomy in AIS, with recanalization rates approaching 80% [**Level 1**].^{7,8}

Uncontrolled cohort studies of patients with LVO treated with endovascular therapy have consistently shown that outcome is improved when vessel recanalization is achieved. Despite these observations, three large studies published in 2013 comparing endovascular therapy (alone or in combination with TPA) with TPA alone failed to show clinical benefit, raising serious questions about the efficacy of this approach [**Level 1**].^{9,10,11} These trials were characterized by low recanalization rates in the endovascular treatment arms related to use of the older clot removal systems, long treatment windows, and variable patient selection criteria. In an unplanned post hoc analysis of these trials, LVO patients who were successfully recanalized again were shown to have better outcome than those who were not (Fig. 24.5). In 2014, the Multicenter Randomized Clinical Trial of Endovascular Treatment for Acute Ischemic Stroke in the Netherlands (MR CLEAN) reported significant improvement in 3-month outcome with no effect on mortality when TPA followed by endovascular therapy was compared to endovascular therapy alone (33% vs. 19% with good outcome) [**Level 1**].¹² Unlike these prior studies, MR CLEAN enrolled only patients with LVO documented by CT angiography, attained shorter intervention times, and relied exclusively on stent retriever technology, resulting in a near complete or complete recanalization rate of 75% compared to 33% in the patient treated with TPA alone (see Chapter 35 for details) [**Level 1**].¹²

FIGURE 24.5 Ninety-day rates of good functional outcome stratified by degree of arterial recanalization. Note that in patients with good and complete recanalization (thrombolysis in cerebral infarction [TICI] grades 2b and 3), met the prespecified end point of 10% greater good functional outcome. (From Manning NW, Campbell BC, Oxley TJ, et al. Acute ischemic stroke: time, penumbra, and reperfusion. *Stroke*. 2014;45:640-644.)

EXTRACRANIAL AND INTRACRANIAL ARTERIAL OCCLUSIVE DISEASE

Endovascular treatment of carotid atherosclerotic disease is now considered to be a viable alternative to the gold standard treatment, carotid endarterectomy (CEA), in appropriately selected patients [Level 1].^{13,14} Using current devices and techniques, carotid artery balloon angioplasty and stent placement (CAS) and CEA have nearly equivocal rates of complications, making the choice of therapy based more on medical comorbidities, carotid artery anatomy, and local clinical practice and expertise. A multidisciplinary team approach should be used to determine the most appropriate treatment for an individual patient. The risks and benefits of best medical management versus CEA versus CAS must be weighed before any intervention is considered.

CAS can be performed under conscious sedation or general orotracheal anesthesia. Prior to the procedure, patients are placed on dual antiplatelet agents, typically aspirin 81 mg and clopidogrel 75 mg for 7 to 10 days. Aspirin function and P2Y12 inhibition studies (platelet aggregometry) are performed before the procedure to ensure adequate platelet inhibition. Once femoral access is obtained, anticoagulation in the form of heparin is given to achieve an activated clotting time (ACT) of greater than 250. The ACT is checked every 30 to 60 minutes throughout the case and heparin is redosed as needed. A guide catheter is advanced just proximal to the stenosis, which is then crossed with a distal embolic protection device, a semipermeable membranous filter on a wire, which is placed within the distal cervical internal carotid artery. Alternatively, a proximal flow reversal system can be used in which a balloon tip catheter in the common carotid artery is used to establish antegrade flow arrest and a second balloon is positioned in the external carotid artery. Blood therefore flows retrograde down the internal carotid artery into the catheter. A venous shunt can be temporarily established via external tubing connecting to a femoral venous sheath to promote retrograde arterial flow during the period of arterial occlusion. After angioplasty with a balloon, stent deployment is performed. In general, the stent should be longer than the lesion and have a diameter corresponding to the largest diameter of the artery where stent placement is anticipated.

The use of intracranial balloon angioplasty for treatment of intracranial atherosclerotic disease has become increasingly controversial. The Stent Placement versus Aggressive Medical Management for the Prevention of Recurrent Stroke in Intracranial Stenosis (SAMMPRIS) was a randomized, multicenter trial comparing revascularization using stent angioplasty of the cerebral arteries versus medical therapy alone for symptomatic intracranial atherosclerotic disease. The study was stopped by the data safety monitoring board after 451 patients were enrolled because of significantly higher 30-day stroke or death rate in the stenting group than the medical management group (14.7% vs. 5.8%) [Level 1].¹⁵ The study made no effort to distinguish between patients with thromboembolic versus perfusion failure-related infarcts, a critical physiologic difference in patients being assessed for reperfusion [Level 1].¹⁵ Nevertheless, the selection criteria for use of intracranial stents has become more stringent, and use has declined.

Electroencephalography and Evoked Potentials

Nicolas Gaspard

Emily J. Gilmore

ELECTROENCEPHALOGRAPHY

INTRODUCTION

Electroencephalography (EEG) and evoked potentials (EPs) measure the electrical activity generated by neural structures. They allow for the functional assessment of the central nervous system and are often complimentary to imaging studies. Electrophysiologic studies are especially important to the differential diagnosis when neurologic disorders are unaccompanied by detectable alterations in brain morphology. This chapter is an overview of the current capabilities and limitations of these techniques in clinical practice.

NORMAL ELECTROENCEPHALOGRAPHY

The EEG measures electrical potentials resulting from the summation of the postsynaptic activity of cortical neurons. Although generated by cortical cells, these potentials are influenced by ascending projections from subcortical structures such in the thalamus and upper brain stem. Most commonly, the EEG is recorded with electrodes placed on the scalp. The scalp EEG presents a very low resolution view of electrical activity of the brain that favors contributions from the lateral convexities due to attenuation and blurring from overlying tissue layers.

The EEG varies greatly with the state of arousal. The main feature of the normal EEG during wakefulness in adults is the posterior dominant rhythm (PDR), also called *alpha rhythm*. This rhythm consists in an 8- to 13-cycle-per-second (cps) sinusoidal activity that is best observed over the parietal and occipital regions bilaterally (Fig. 25.1). In a relaxed individual, the alpha rhythm manifests with eye closure and attenuates with alerting or eye opening.

FIGURE 25.1 Normal EEG in an awake 37-year-old man. The posterior dominant rhythm attenuates with eye opening.

Sleep is divided in four stages on the basis of EEG, eye movements, and muscle activity. Stage N1, or drowsiness, is characterized by the disappearance of the posterior dominant rhythm, which is replaced by low-voltage slower activity. Sharp waves maximal at the vertex, called *vertex sharp waves*, also occur. Stage N2 is defined by the presence of sleep spindles (12 to 14 cps sinusoidal activity that is maximal over the central regions) but also features vertex sharp waves, K complexes (large amplitude diphasic slow waves usually brought up by auditory stimulation and often occurring in close temporal proximity to a spindle [Fig. 25-2]), and positive occipital sharp transients of sleep (POSTS; surface-positive check mark-like waveforms occurring singly or in trains in the occipital regions). Slow waves of sleep (0.5-1 cps) progressively occupy most of the recording during stage N3. During REM sleep, the EEG resembles the EEG of drowsiness, but rapid eye movements and general atonia are present. In adults, REM occurs about 90 minutes after sleep onset and thus is not usually seen on routine studies.

EEG activity undergoes major changes with age. In neonates, these changes occur on a nearly daily basis and knowledge of the conceptional age is required for proper interpretation. Sleep-wake cycles can be identified on the basis of characteristic EEG patterns that are beyond the scope of this chapter. A PDR that is reactive to eye opening becomes visible in most children by 4 months of age. With increasing age, the frequency of the PDR progressively increases, reaching 6 cps in most children at 1 year and 8 cps in

P.207

most children at 4 years. Sleep spindles appear at 2 months but do not become synchronous in most children until the age of 2 years. Normal delta activity persists during wakefulness through childhood, adolescence, and early adulthood but becomes progressively less prominent and more intermittent and restricted to the posterior regions (*posterior slow wave of youth*).

FIGURE 25.2 Normal EEG in a 25-year-old man during stage N2 sleep. Sleep spindles (*dashed boxes*) and K complex (*solid box*).

ABNORMAL ELECTROENCEPHALOGRAPHY

Epilepsy

The EEG is the most single important ancillary test for the diagnosis of epilepsy. Epileptiform discharges include spikes (< 70 ms), polyspikes, sharp waves (70-200 ms), spike-and-slow-wave complexes, sharp-and-slow-wave complexes. Other nonspecific findings in epilepsy include focal polymorphic slowing and intermittent rhythmic delta activity.

Not only can the presence of epileptiform discharges (EDs) confirm a clinical suspicion of epilepsy, but the localization and type of discharge also helps to identify the diagnosis of a specific syndrome (Table 25.1). A proper syndromic classification is paramount to ensure adequate management, as different syndromes may call for different treatments. It should be noted that EDs may occasionally be absent in a minority of patients who have epilepsy. The first routine EEG obtained after an inaugural seizure demonstrates EDs in approximately 30% to 50% of cases. This proportion increases to a maximum of 80% to 90% after the third routine EEG and subsequent EEGs do not raise this proportion further. Longer recordings, sleep recordings, and so-called activation procedures, such as hyperventilation, intermittent photic stimulation, and sleep deprivation can be performed to increase the sensitivity of the EEG.

Conversely, EDs are seen in 1% to 2% of EEGs of individuals without a history of epilepsy. This proportion is higher in children and in siblings of patients with epilepsy.

In addition to diagnosis, EEG results also help with the management of epilepsy. A finding of interictal EDs after a single seizure increase the likelihood of seizure recurrence and therefore influences the decision about whether to treat with antiepileptic drugs. Similarly, the presence of interictal EDs increases the likelihood of seizure recurrence when consideration is being given to discontinuing antiepileptic drugs after a period of seizure control. Finally, in the setting of convulsive status epilepticus, EEG can be extremely helpful in determining whether individuals with prolonged postictal cognitive impairment (usually >30 minutes) are experiencing electrographic seizures (up to 50%) or nonconvulsive status epilepticus (up to 14%).

Finally, so-called benign epileptiform variants should not be confused for *bona fide* EDs. These variants are physiologic activity with a somewhat sharp morphology that may resemble spikes or sharp waves but can be readily dismissed after careful inspection. This distinction is important, as it is not uncommon to encounter patients who carry a diagnosis of medically refractory epilepsy but turn out to have nonepileptic spells and in whom a normal variant has been mislabeled as an ED.

Focal Brain Lesion or Dysfunction

With the advances of brain imaging, the usefulness of EEG for the diagnosis of focal brain injury has significantly decreased. However, EEG remains the only way to assess the epileptogenic potential of a cerebral lesion. The hallmark of focal brain injury is the presence of localized nonrhythmic delta (1 to 4 cps) or theta (5 to 7 cps) activity, referred to as *focal polymorphic slowing* (Fig. 25.3). As a rule of thumb, delta activity is associated with more destructive lesions than theta activity. *Focal attenuation of fast activity*, the absence of normal alpha or beta (14 to 30 cps) activity over a region of the scalp indicates focal cortical injury. Both focal slowing and attenuation can be seen in the absence of a focal lesion (Fig. 25.4). In this case, they represent the presence of focal cerebral dysfunction as a result of a postictal state or, rarely, migraine. *Lateralized periodic discharges* (LPDs; also referred to as *periodic lateralized epileptiform discharges* or PLEDs) usually indicate the presence of an acute destructive lesion with a high epileptogenic potential, usually stroke, neoplasm, or encephalitis, as up to 85% of patients will experience seizures during the acute phase of their illness (Fig. 25.5). They

can occasionally be seen in the aftermath of a seizure in patients with chronic epilepsy or with a remote brain injury. Rarely, LPDs are associated with clinical manifestations (time-locked contralateral myoclonus, visual

hallucinations, etc.).

TABLE 25.1 Electroencephalography Features of Major Epileptic Syndromes

Syndrome	EEG Features
Ohtahara syndrome	Suppression-burst pattern during sleep and wakefulness
Early myoclonic encephalopathy	Suppression-burst pattern during sleep
West syndrome	Hypsarrhythmia (highly disorganized background with arrhythmic and asynchronous high-amplitude slow waves and multifocal spikes)
Lennox-Gastaut syndrome	Slow (≤ 2.5 cps) generalized spike-and-wave complexes Generalized paroxysmal fast activity Slowed background
Benign idiopathic focal epilepsy of childhood	Focal (often bilateral independent or multifocal) sharp waves or spikes Normal background
Childhood absence epilepsy	≥ 3 cps generalized spike-and-wave complexes Normal background
Juvenile myoclonic epilepsy	≥ 3 cps (often up to 6 cps) generalized spike-and-wave and polyspike-and-wave complexes Normal background
Localization-related epilepsy	Focal spikes, sharp waves, or spike-and-wave complexes Sometimes focal polymorphic or rhythmic slow activity

EEG, electroencephalography.

Diffuse Brain Dysfunction or Injury

Toxic, metabolic, diffuse hypoxic-ischemic, and other global insults to the brain result in generalized nonspecific EEG changes. Mild encephalopathy is characterized by slowing of the posterior dominant rhythm and a generalized excess of polymorphic theta activity. With more pronounced brain dysfunction, the posterior dominant rhythm is lost and replaced by a mixture of theta and delta activity. These changes are described as *generalized polymorphic slowing*. In more severe cases, cerebral activity consists mostly of delta activity, which may become monotonous. At this point, *reactivity to external stimulation* (noise, noxious stimuli) may be lost. In the most severe forms of encephalopathy, there is attenuation ($< 20 \mu\text{V}$) or even suppression ($< 2 \mu\text{V}$) of all cerebral activity.

A *suppression-burst pattern* in which periods of suppression alternate with bursts of high amplitude activity, can

also be seen in severe cases (Fig. 25.6). *Generalized rhythmic delta activity* (GRDA; often frontal and intermittent; FIRDA) is another nonspecific finding of encephalopathy, although it can be seen with lesions in the frontal lobes. *Generalized periodic discharges* (GPDs) are repetitive waveforms that occur either at periodic or quasiperiodic intervals of 0.5 to 3 cps. They can be encountered in any type of encephalopathy, at a moderate to severe stage, and are associated with an increased risk of seizures. *Triphasic waves* are a subtype of GPDs with a typical morphology (Fig. 25.7). They were initially thought to be specific of hepatic encephalopathy. They can in fact be seen in most metabolic or toxic encephalopathies and even during or after status epilepticus. A major role of the EEG in patients with acute confusion and obtundation is to identify those who suffer from nonconvulsive status epilepticus.

FIGURE 25.3 Diffuse slowing in a 72-year-old woman with sepsis. The posterior dominant rhythm is not visible. The background consists of admixed theta and delta activity.

FIGURE 25.4 Focal slow activity (*boxes*) with attenuation of the posterior dominant rhythm (*dashed lines*) over the right hemisphere in a 64-year-old woman with a glioblastoma multiforme.

FIGURE 25.5 Left hemispheric lateralized periodic discharges (LPDs; *boxes*) at approximately one per second in a 52-year-old man with herpes encephalitis.

Neurodegenerative disorders affecting the cortex and subcortical structures can be associated with similar nonspecific findings, albeit most often mild (i.e., slowing of the posterior dominant rhythm, diffuse excess of theta activity, and FIRDA).

Occasionally, the EEG discloses patterns that point toward a specific diagnosis. In Creutzfeldt-Jakob disease, severe

disruption of the background and periodic discharges (LPDs or more commonly GPDs) occur, always within 3 months after the onset. Huntington disease is associated with a progressive attenuation of cerebral activity. At least 50% of patients with anti-*N*-methyl-D-aspartate (NMDA) receptor encephalitis show a typical pattern of rhythmic delta activity overridden by beta activity, which has been termed *extreme delta brush* due to its resemblance to normal delta brushes of neonates.

FIGURE 25.6 Suppression-burst pattern following cardiac arrest in a 54-year-old man. Periods of suppression are interrupted by bursts of sharply contoured delta and theta activity.

FIGURE 25.7 Generalized periodic discharges with triphasic morphology (triphasic waves) at 1.5 per second in a 35-year-old man with acute liver failure. Each discharge consists of three phases: (1) a small-amplitude negative sharp wave followed by (2) prominent positive sharp wave and (3) a negative slow wave.

LONG-TERM MONITORING

Epilepsy Monitoring Unit

Long-term EEG monitoring, simultaneously with audio and video recording, can be performed in dedicated epilepsy monitoring units (EMU) to not only capture interictal epileptiform activity but also characterize patients' typical spells. These recordings are useful to clarify the nature of spells of uncertain etiology and assist in the

P.211

determination of seizure type and epilepsy syndrome (Figs. 25.8 and 25.9). The EEG shows typical changes in all patients during generalized or complex partial seizures but can remain normal during simple partial seizures. In patients with medically refractory epilepsy, long-term monitoring provides invaluable electroclinical correlations that will contribute to the assessment of potential candidates for resective surgery. If the results of monitoring with scalp EEG and other ancillary tests (magnetic resonance imaging [MRI], positron emission tomography [PET] scan with 18F-fluorodeoxyglucose [FDG], etc.) are inconclusive, patients may benefit from invasive EEG, either with cortical electrodes (electrocorticography, ECoG) or with depth electrodes implanted stereotactically (stereo-EEG). These invasive studies offer better spatial resolution and can identify a seizure focus that was not detected or well-circumscribed with scalp EEG. They also permit the delineation of functional cortical areas through electrical cortical stimulation mapping.

FIGURE 25.8 Three-cycle-per-second generalized spike-and-wave complexes in a 6-year-old girl with childhood absence epilepsy.

FIGURE 25.9 Left temporal spike-and-wave discharges in a 32-year-old man with mesial temporal lobe sclerosis and epilepsy. The discharges (*boxes*) are maximal over the left anterior inferior temporal region (F7, T3, F9, and T9).

Intraoperative Neuromonitoring

Given the exquisite sensitivity of cortical neurons to ischemia, the EEG can detect reduction in cortical perfusion at an early and reversible stage. This can be advantageously used to monitor for cerebral ischemia secondary to carotid clamping during carotid endarterectomy. EEG monitoring may identify those patients who would benefit from the use of a vascular shunt during

P.212

the procedure in order to restore adequate perfusion. Conversely, shunts, which have an associated risk of complications, can be avoided in those patients in whom the EEG remains normal. EEG monitoring has also been advocated during cardiac and aortic surgery, but its use in this indication has been limited to selected academic centers.

ECoG can be used during awake neurosurgery to map functional cortical areas and to delineate the critical limits of a resection. Intraoperative ECoG recordings can also be used to identify epileptogenic regions for resection.

Critical Care Electroencephalography Monitoring

Continuous EEG monitoring is increasingly used in the critical care setting. These prolonged recordings are currently indicated to detect and monitor treatment of nonconvulsive seizures, clarify the nature of abnormal motor activity, and to monitor brain function during drug-induced coma.

Between 15% and 20% of critically ill patients develop seizures during their acute illness. Half of them will develop status epilepticus. Risk factors include acute brain injury, a chronic seizure disorder, younger age, sepsis, and severe alteration of consciousness (i.e., stupor and coma). Up to 90% of these seizures are nonconvulsive and will be missed if EEG monitoring is not performed. There is mounting evidence that nonconvulsive seizures have detrimental metabolic and hemodynamic effect

and contribute to secondary brain injury and poorer outcome. A monitoring period of 24 hours is required to detect 90% of these seizures. A longer period is required in comatose patients and in patients with LPDs. A 60-minute EEG will miss half of the patients who have seizures. Episodes of abnormal spontaneous motor activity do not always correspond to seizures. Nonepileptic myoclonus, tremor, clonus, and rigors are frequent among acutely ill patients. Continuous EEG monitoring will help clarify the nonepileptic nature of these episodes and avoid the unnecessary and potentially harmful prescription of antiepileptic drugs. Deep sedation with high-dose barbiturates is sometimes performed to control refractory intracranial hypertension. In this indication, the EEG is used to monitor sedation, with the aim of maintaining a suppression-burst pattern.

EEG abnormalities have prognostic values after traumatic and anoxic brain injury. Malignant patterns of suppression-burst, suppression, and low-voltage unreactive widespread delta activity are almost invariably associated with poor outcome. Other possible applications of EEG monitoring include early detection of delayed cerebral ischemia after aneurysmal subarachnoid hemorrhage.

EVOKED POTENTIALS

INTRODUCTION

EPs are potentials generated by the nervous system in response to stimuli.

Somatosensory, auditory, and visual pathways can be investigated using simple sensorial stimulation and recording from neural structures, whereas motor pathways are explored by transcranial magnetic stimulation of the motor cortex and recording of muscle response. EPs have a low signal-to-noise ratio, being of much lower amplitude than spontaneous activity, and require the averaging of a large number of responses to be identified.

Clinically, EPs are functional tests, which can be viewed as an extension of the neurologic examination. They can provide objective confirmation of the existence of a lesion that may have been suggested by ambiguous or subtle signs or symptoms. Additionally, they can also reveal dysfunction of sensory pathways that is not clinically apparent. Finally, they have the capacity to localize a suspected lesion.

EPs are composed of a stereotyped sequence of waveforms that are labelled by their polarity (negative [N] or positive [P]) and their peak latency from the time of stimulation (expressed in milliseconds). Dysfunction of sensory or motor pathways due to disease or injury leads to increased waveform latency, whereas complete interruption of conduction or destruction of the neural generators results in the absence of waveforms.

SOMATOSENSORY-EVOKED POTENTIALS

Somatosensory-evoked potentials (SSEPs) are elicited by light electrical stimulation of peripheral nerves and reflect sequential activation of structures along the afferent sensory pathways, principally the dorsal column lemniscal system. Upon stimulation of the median nerve, the following responses are clinically useful: first the N9 (Erb's point potential), representing the afferent volley entering the brachial plexus; the N13, generated by postsynaptic activity in the gray matter of the spinal cord; the P14, generated by the caudal medial lemniscus in the lower brain stem; the N18, generated by the rostral brain stem; and finally the N20, reflecting the activation of the somatosensory cortex (Fig. 25.10). Similar responses can be recorded upon stimulation of the posterior tibial nerves.

SSEPs are altered by most conditions affecting the somatosensory pathways, including stroke, tumors, traumatic injury, and demyelinating disorders. They are abnormal in 50% to 60% of patients with multiple sclerosis (MS), even in the absence of clinical signs or symptoms.

FIGURE 25.10 Normal SSEPs obtained by stimulation of the median nerve at the wrist. (Courtesy of Nicolas Mavroudakos, MD, PhD.)

FIGURE 25.11 SSEP obtained by stimulation of the median nerves at the wrist in a patient with postanoxic brain injury. N13 and P14 potentials, generated in the brain stem, are identified. N20 potentials, generated in the cortex, are not identified, indicating a poor prognosis. (Courtesy of Nicolas Mavroudakis, MD, PhD.)

SSEPs are increasingly used for prognostication in comatose patients after anoxic or traumatic brain injury. The absence of N20 after the rewarming period is almost invariably associated with a poor outcome (Fig. 25.11).

SSEPs are also commonly used to monitor the integrity of the spinal cord during high-risk neurosurgical, orthopedic, and vascular interventions. They are also increasingly used to monitor the integrity of the brain function during high-risk cardiovascular surgery, as loss of the N20 indicates early ischemia at a reversible stage.

VISUAL-EVOKED POTENTIALS

Visual-evoked potentials (VEPs) are obtained by stimulation with an alternating checkerboard pattern of black and white squares (i.e., white squares change to black and vice versa at a regular frequency). This stimulation with pattern reversal produces an occipital positive response with a mean latency of 100 milliseconds (P100). VEPs are performed for each eye individually. Because fibers from the temporal side of the retina decussate at the optic chiasm, an abnormal P100 after stimulation of one eye implies the presence of a prechiasmatic lesion, affecting the retina or the optic nerve on the side of the stimulation. An abnormal P100 upon stimulation of both eyes may be caused either by bilateral prechiasmatic and/or retrochiasmatic lesions. Unilateral retrochiasmatic lesions usually do not significantly alter the P100. Acute optic neuritis is initially accompanied by an attenuation of the P100 (Fig. 25.12). In the postacute phase, although the P100 may return to almost normal amplitude, it is significantly delayed. Abnormal VEPs are found in up to 70% of patients with MS, even in the absence of a history of optic neuritis. These findings are nonspecific and can also be seen in other conditions, including demyelinating disorders (acute disseminated encephalomyelitis [ADEM], anti-neuromyelitis optica [NMO] spectrum), ischemic optic neuropathy, compression of the optic nerve, cataracts, glaucoma, toxic and metabolic optic neuropathy, degenerative disorders, and retinal disease. In the setting where a patient reports visual loss, a normal VEP strongly favors a psychogenic disorder (i.e., hysteria or malingering).

BRAIN STEM AUDITORY-EVOKED RESPONSES

Brain stem auditory-evoked potentials (BAEPs) consist of five waveforms, labelled I to V, of which waves I, III, and V are the most important from a clinical point of view. The nature of the generators of the responses is largely unclear but it is believed that wave I is generated by the peripheral portion of the acoustic nerve, whereas

P.214

wave III and V are probably generated in the brain stem by the superior olivary complex and the inferior colliculus, respectively.

FIGURE 25.12 Visual-evoked potentials in patient with probable multiple sclerosis. The P100 after stimulation of the **left** eye is normal, whereas there is a significant delay after stimulation of the **right** eye. (Courtesy of Nicolas Mavroudakis, MD, PhD.)

FIGURE 25.13 Auditory-evoked potentials (AEPs) in a patient with a meningioma in the right pontocerebellar angle. With left stimulation, waves I to V are identified and have a normal latency. With right stimulation, only wave I (generated in the peripheral acoustic nerve) is identified; subsequent waves generated in the brain stem are not visible, indicating impairment of auditory pathways in the right pons and/or midbrain. (Courtesy of Nicolas Mavroudakos, MD, PhD.)

BAEPs are abnormal in most cases of tumors of the cerebellopontine angle, such as acoustic neuroma. Abnormalities include delay or absence of all waves after wave I and absence of all waves (Fig. 25.13).

BAEPs are also sensitive to lesions affecting the auditory pathways in the brain stem. They are almost always abnormal in the case of intrinsic tumors of the brain stem. They are preserved when the auditory pathways are spared, as may occur in vascular lesions of the pontine tegmentum causing a locked-in syndrome. BAEPs abnormalities are frequent in patients with multiple sclerosis and in other demyelinating conditions.

FIGURE 25.14 Motor-evoked potentials by transcranial magnetic stimulation of the motor cortex and by stimulation of the cervical spinal cord. The response is recorded with surface electromyogram (EMG) electrodes over the first dorsal interosseus. The delay between the two responses is the central conduction time in the corticospinal tract. (Courtesy of Nicolas Mavroudakos, MD, PhD.)

In comatose patients, BAEPs are normal when the cause is metabolic or toxic. They are abnormal when the brain stem is directly affected between the midbrain and the lower pons by a primary infratentorial lesion or by herniation due to a supratentorial mass. The absence of all waves subsequent to wave I carries a poor prognosis, whereas the presence of wave V is associated with good outcome. BAEPs are relatively insensitive to sedative drugs, including anesthetic doses of barbiturates. They can be used as a confirmatory test of brain death, even in the presence of doses of barbiturates that induce an isoelectric EEG. Absence of all waves or the sole persistence of wave I indicates brain death.

MOTOR-EVOKED POTENTIALS

Motor-evoked potentials (MEPs) assess the integrity of motor pathways. They are elicited by transcranial magnetic stimulation of the primary motor cortex. Muscle compound potentials are recorded and the latency of response can be measured. Stimulation can also be delivered at the spinal cord level allowing for calculation of central conduction time by subtracting the latency after spinal cord stimulation from the latency after cortical stimulation (Fig. 25.14). MEPs are increasingly used in association with SSEPs to monitor spinal cord integrity during surgery.

Seth L. Pullman

INTRODUCTION

Advances in electronics enabled clinical assessment of peripheral nerve and muscle physiology in the mid-20th century, spawning the neurologic specialty of clinical neurophysiology. Electrodiagnostic techniques have become increasingly computerized and are indispensable for the proper diagnosis and management of patients with neuromuscular disease. Despite technologic improvements, a basic understanding of the principles, potential errors, and disease-specific effects are essential for meaningful interpretation and conclusions. This chapter provides a brief overview of nerve conduction studies (NCS), needle electromyography (EMG), special neuromuscular junction, and central motor function techniques.

NERVE CONDUCTION STUDIES

SENSORY AND MOTOR NERVE CONDUCTION STUDIES

NCS measure the speed and strength of an electrical impulse conducted along a peripheral nerve. Typically, the impulse is generated using a bipolar stimulator placed on the skin surface over the anatomic course of the tested nerve. The intensity and duration of this transcutaneous stimulus is gradually increased until all available axons within that nerve are depolarized, sparking an action potential that travels down the nerve to the recording site. For *sensory NCS*, the recording electrodes are placed on the skin surface overlying the nerve (usually over a pure sensory branch) at some distance from the stimulation site ([Fig. 26.1](#)).

FIGURE 26.1 Setup for sensory NCS. A bipolar stimulator is placed over the median nerve at the wrist, and self-adhesive recording electrodes are placed over the median sensory branches over the index finger, ensuring that only sensory nerve responses are recorded. A self-adhesive ground electrode is placed over the dorsum of the hand.

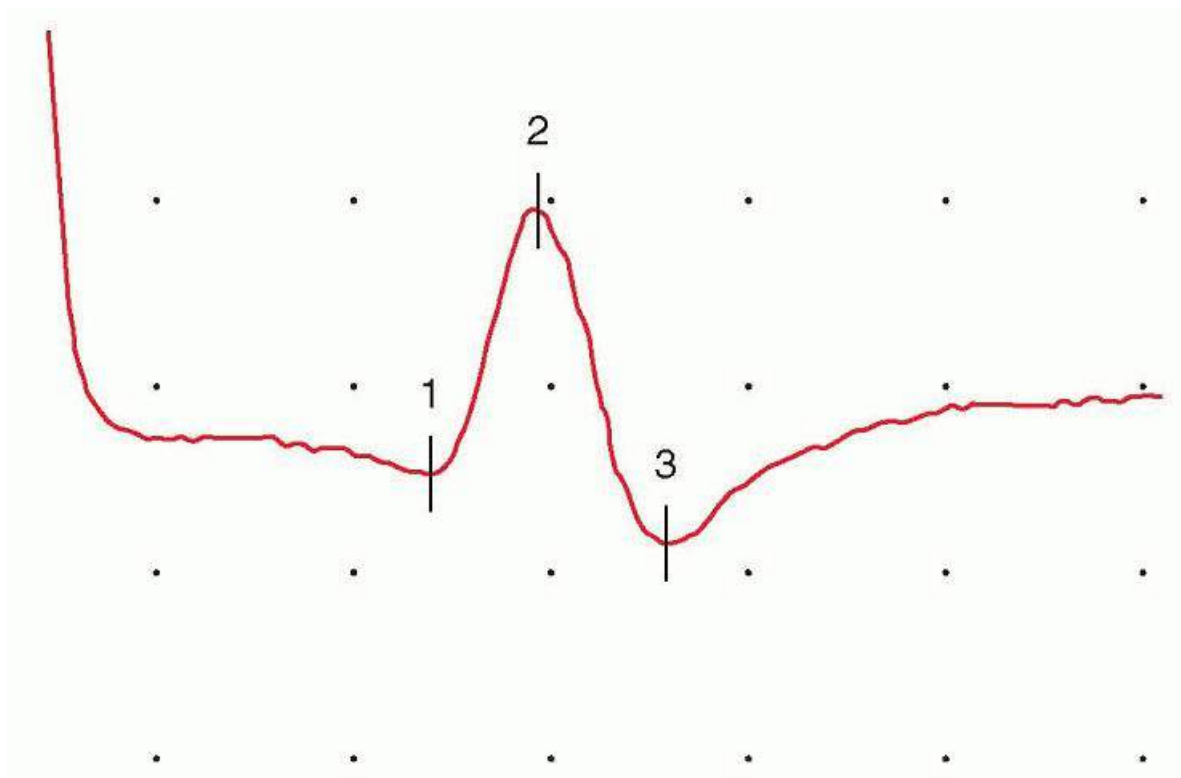

FIGURE 26.2 SNAP, recorded using the setup depicted in Fig. 16.1. The horizontal space between two dots, or graticules (one division), is assigned a specific value (the time base shown is 1 millisecond per division) to enable time measurements. Vertical divisions are also assigned a specific value to enable measurement of

stimulus strength (the gain or sensitivity; 10 μV per division as shown). The time between the stimulus artifact and the waveform peak (the sensory peak latency) is 2.75 milliseconds, and the peak-to-peak waveform amplitude is 13.2 μV , within the normal range. Onset latency is needed to calculate a conduction velocity.

When an action potential passes under these bipolar recording electrodes, a *sensory nerve action potential* (SNAP) waveform is recorded and displayed (Fig. 26.2). The SNAP is produced by large Ia sensory axons and not small-diameter A or C fibers.

Motor NCS are performed similarly, except that the recording electrodes are placed over the motor endplate region of an innervated muscle, rather than over the nerve itself (Fig. 26.3).

For motor NCS, the action potential passes down the nerve, triggers acetylcholine release at the neuromuscular junction, and produces muscle membrane depolarization. The recording electrodes capture the electrical potential generated by depolarization of the innervated muscle, subsequently generating a waveform known as the *compound motor action potential* (CMAP) (Fig. 26.4). Care must be taken to maximally but not excessively stimulate nerve axons at each stimulation site. Multiple other technical considerations can impede quality NCS and must be controlled as much as feasible, including standardized procedures, temperature maintenance, accurate electrode placement and measurement, interference avoidance, detection of anatomic anomalies, and stimulation of unintended nerves.

Although modern equipment is computerized with digital processing and storage to capture and analyze the data, the waveform display owes its origins to the cathode ray oscilloscope. By convention, the x-axis of the tracing is the time base (or sweep speed) in milliseconds, whereas the y-axis measures the impulse strength.

P.217

The waveform *amplitude*, measured either in microvolts (sensory waveforms) or millivolts (motor waveforms), reflects the summated number of responsive nerve axons. The time difference between the stimulus and the waveform onset, one of several measures of nerve speed, is the *distal latency*. Using this value and the measured distance between the stimulating and recording points, a *nerve conduction velocity* may be calculated for sensory nerves (m/s). Some prefer to measure the latency to the sensory waveform peak instead of the onset and to compare this value to controls. Similarly, the *distal motor latency* is measured from the stimulation point to the waveform onset and compared to control values; some laboratories use a standard distance from the stimulation point and the muscle to improve reliability. Because of the non-nerve-related components of the motor system including the neuromuscular junction and muscle membrane depolarization, motor NCS require additional stimulation sites to calculate conduction velocity. A waveform from a second, typically more proximal, stimulation site is captured and the time difference between the two waveforms is measured. This step subtracts out the time for the nonnerve factors and assesses only the motor nerve components. The distance between the two sites (mm) divided by the time difference (ms) provides the *conduction velocity* of that segment (m/s). Additional segments may be added by stimulating further sites along the nerve course. Accuracy is reduced, however, if the stimulation points are too close together. A difference of 10 cm is typical except for special circumstance, such as short-segment studies across the elbow in the assessment of ulnar neuropathy. Another consideration is the accessibility of the nerve to surface stimulation.

FIGURE 26.3 Setup for motor NCS. The bipolar stimulator is placed over the median nerve at the wrist and recording electrodes are placed over the median-innervated abductor pollicis brevis. The resultant muscle depolarization produces the recorded waveform. Note that sensitivities are in the millivolt, rather than microvolt, range.

It is important to measure and control limb temperature; cold limbs influence many electrodiagnostic measures. The most significant effect is on conduction velocity, with a conduction velocity fall on average of $2 \text{ m/s}/^\circ\text{C}$ and latency increase of approximately $0.2 \text{ ms}/^\circ\text{C}$ below ideal.

Because muscle tissue is much more electrically potent than nerve fibers, the CMAP is approximately 3 orders of magnitude larger than the SNAP, and its amplitude is measured in millivolts rather than microvolts. Otherwise, latency and amplitude measures are similar to the SNAP.

FIGURE 26.4 A CMAP. These three responses were recorded from the extensor digitorum brevis muscle of the foot following stimulation of the peroneal nerve at three different sites: the ankle (*top waveform*), just below the fibular head (*middle waveform*), and above the knee (*bottom waveform*). The recording sensitivity was 5 mV per division, and the sweep speed was 5 milliseconds per division. Onset latencies are 4.0, 11.1, and 13 milliseconds, respectively, predictably increasing as the distance between the stimulating and recording electrodes increases. Subtracting one onset latency from another yields the time for the impulse to travel from one stimulation point to the other. The measured distance is divided by this value to produce the segmental conduction velocity in meters per second. The amplitude is measured from baseline to peak.

Both latency and conduction velocity depend on an intact, myelinated nerve; myelin and the saltatory conduction it fosters are essential for rapid action potential propagation. In contrast, the waveform amplitude depends primarily on the number of functioning axons within the nerve. Significant slowing of conduction velocity or prolongation of latency usually implies demyelinating injury, whereas loss of amplitude usually correlates with axonal loss or dysfunction. However, axonal loss also may mildly slow conduction velocity by eliminating the fastest conducting axons. When demyelination is severe enough, a complete block of transmission in most axons

can occur; demyelination results in a loss of local current and an insufficient charge to activate the next node of Ranvier. NCS may be used to demonstrate the conduction block. In this situation, recordings made from nerve stimulation above the site of injury produce waveforms with a much lower amplitude and area than recordings made from stimulation below the site of demyelination of the same nerve. When severe enough, this loss of waveform amplitude due to block of impulse transmission in a

P.218

group of axons at a single site is known as a *conduction block* and is an important diagnostic feature of acquired demyelinating neuropathies (Fig. 26.5). If some but not all fibers show reduced conduction velocity without a conduction block, the increased range of velocities may produce *temporal dispersion*, a broadened waveform that demonstrates increased waveform duration but a lesser reduction in waveform area. Despite the fact that certain accessible nerves dominate most NCS, techniques are described for most recognized peripheral nerves; studies for uncommon procedures are performed on the basis of clinical necessity.

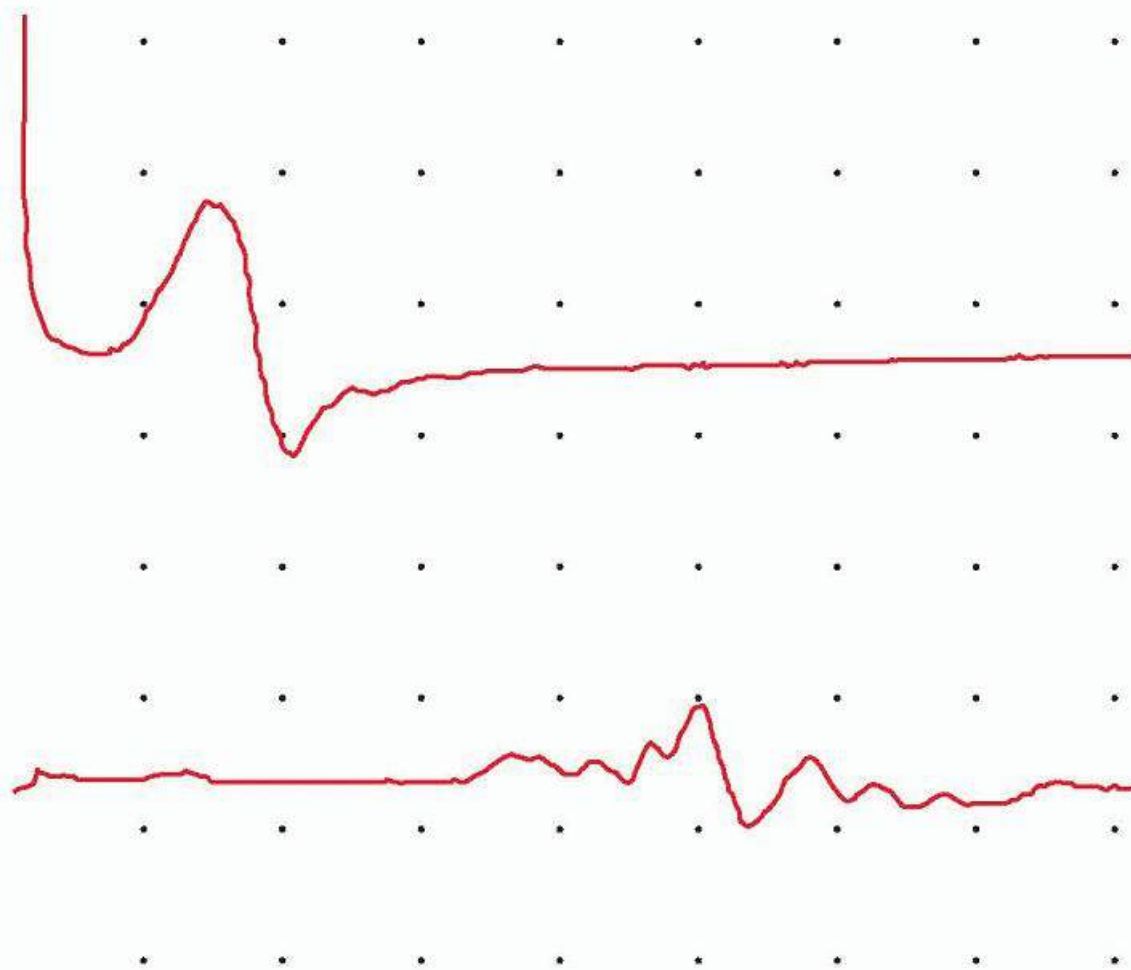

FIGURE 26.5 Conduction block with temporal dispersion. Two CMAPs recorded from the abductor hallucis muscle of the foot following stimulation of the tibial nerve at the ankle and the knee (*top and bottom*, respectively) in a patient with demyelinating neuropathy. The sensitivity was 1 μV per division, and the sweep speed was 5 milliseconds per division. When stimulation is moved from the ankle to the knee, the recorded waveform decreases in amplitude (from 1.1 to 0.5 mV, a 54% decline); its duration lengthens; and its morphology becomes irregular and complex. These findings suggest significant demyelination of the nerve segment between the stimulation sites, with partial conduction block. An increased range of axonal conduction times between different axons, caused by differential involvement, produces increased waveform duration as the distance between stimulation and recording sites increases (*temporal dispersion*). A 30% increase is considered to be significant in motor axons.

LATE RESPONSES

Routine NCS are limited to accessible segments in the proximal and distal arms and legs. Nerve roots are not easily stimulated and *long-latency reflex* tests are typically used to assess these most proximal segments. When a stimulus is delivered to the distal nerve, action potentials are propagated both proximally and distally. The impulse traveling up the motor axons (in a direction opposite to the normal flow or *antidromic*) eventually reaches the anterior horn cells. The anterior horn cells then generate a second nonsynaptic action potential that travels back down the axon into the muscle (in the direction paralleling the normal flow or *orthodromic*), where it is recorded as a much smaller waveform known as the *F wave*, named because it was originally recorded foot muscles (Fig. 26.6).

The time required for this round trip up and down the motor nerve is measured as *the F-wave minimal latency*. Although pathology at any point along the nerve may prolong the F-wave latency, if normal function of the distal nerve is documented by motor NCS in the more distal nerve sites, F-wave prolongation must be the result of slowing in the proximal segment.

FIGURE 26.6 A series of F waves recorded from the thenar eminence following repeated median nerve stimulations in a patient with cervical radiculopathy. The screen is split with lower sensitivity (5 mV per division) to the left of the dotted line to show the full CMAPs generated by distal stimulation and higher sensitivity (200 μ V per division) to the right to allow visualization of the much smaller F-wave responses. The sweep speed is 10 milliseconds per division. The dark vertical line marks the latency of the earliest F-wave potential in the group (minimal F latency).

A different long-latency response, *the H reflex* (named after Hoffmann, who first described it in 1918), may be elicited in the legs by electrical stimulation of the Ia sensory nerve afferents in the tibial nerve at the knee while recording over the soleus muscle. (The type Ia sensory fiber [also called the *primary afferent fiber*] is a component of the muscle spindle that monitors stretch velocity.) The contraction resulting from soleus activation is analogous to the monosynaptic stretch reflex pathway elicited by testing the tendon reflex. Thus, the H reflex is the electrical equivalent of the ankle jerk reflex and aids primarily in the assessment of S1 nerve root disease and involvement of sensory fibers. In adults, the H reflex is not normally found in other muscles except for the flexor carpi radialis. F waves are present in nearly all nerves. By analyzing motor and sensory nerve conduction and long-latency responses in multiple nerves, the nature of a given neuronal injury (axonal, demyelinating, or both) and its geographic distribution may be identified, aiding in the diagnosis of neuronopathy, radiculopathy, plexopathy, mononeuropathy, and polyneuropathy.

OTHER SPECIALIZED REFLEX TESTS

Numerous other reflex tests are described and uncommonly performed. The *blink reflex* is one exception. This relatively simple to perform test assesses both trigeminal and facial nerve pathways. Recording electrodes are placed on the orbicularis oculi bilaterally

P.219

and the supraorbital nerve is stimulated. An ipsilateral R1 response is seen on the stimulated side only. A later R2 complex response is seen bilaterally. Differing patterns are evident in trigeminal or facial neuropathy and central pontine or medullary disease.

NEEDLE ELECTROMYOGRAPHY

BASIC CONCEPTS

Complementary to NCS is assessment of clinically relevant muscles using needle EMG. A sterile, disposable, needle recording electrode is placed directly into the selected muscle, which is then activated by voluntary contraction at differing levels of effort. Anterior horn cell action potentials propagate impulses to the end of multiple axonal branches and initiate neuromuscular junction transmission, thereby activating individual muscle fibers; normally every muscle fiber innervated by a motor neuron fires following a nerve action potential. A single motor axon with all of its multiple branches and innervated muscle fibers is known as a *motor unit*. The strength of a muscle contraction is determined primarily by the number of activated motor units and motor unit firing rates. The recording characteristics of the EMG needle enable live recording and analysis of individual and aggregate motor unit waveforms. Two types of electrode are most commonly used. *Monopolar electrodes* are flexible solid stainless steel needles coated with inert material so that only the bare tip can record activity. The reference point is typically a surface electrode on the skin. *Concentric electrodes* are a rigid stainless steel cannula that includes a specialized central wire. The activity is recorded from the wire and referenced to the cannula. Monopolar needles record from a larger territory, which is slightly better for spontaneous activity discussed later. Concentric electrodes record from a smaller area and are better for motor unit analysis also discussed later. Some consider monopolar electrodes to be less painful but the difference is minimal when ultrasharp disposable electrodes are used. Either electrode is acceptable for use.

INSERTIONAL AND SPONTANEOUS ACTIVITY

During the needle EMG examination, three major categories are assessed: *spontaneous activity*, *motor unit configuration*, and *motor unit recruitment*, including the *interference pattern*. Different areas of the muscle are explored to ensure a representative sample and to detect focal changes. Insertional activity is the brief burst of electrical activity provoked by the EMG needle as it moves through the muscle, generating a cluster of transient high-frequency spikes lasting from 50 milliseconds to a few hundred milliseconds. In some disorders, the

insertional activity is consistently prolonged or reduced with each movement of the needle, but the distinction is often subjective and not considered by most to be diagnostic. Once needle movement has ceased, no other electrical activity should normally appear as long as the muscle remains at rest. Reduced insertional activity is present in muscle replaced by nonexcitable tissue, such as fat or connective tissue.

Muscle fibers that have lost innervation through motor axon injury or muscle degeneration or necrosis may undergo spontaneous depolarization, generating brief spikes (*fibrillations*) and *positive sharp waves* in the resting muscle; sharp waves usually fire in a regular pattern with a frequency of 0.5 to 15 Hz (Fig. 26.7). This activity is generated by individual myocytes. Waveforms similar to fibrillations normally occur at the muscle endplate region and must be distinguished; the *endplate spikes* also fire at faster semirhythmic rates. Also recorded at the endplate region is *endplate noise*, a disturbance of the baseline that correlates with miniature endplate potentials.

FIGURE 26.7 Spontaneous activity in a resting muscle. This tracing was recorded from the triceps muscle of a patient with cervical radiculopathy. A positive sharp wave, named for its sharp initial positive (downward) deflection, is seen on the *left*. On the *right*, a smaller triphasic fibrillation is seen. These potentials are markers of active denervation and result from the random, spontaneous depolarization of denervated single muscle fibers.

Abnormal spontaneous activity is the hallmark of denervating axonal injury at any point from the anterior horn cell to the nerve terminal (e.g., radiculopathy, plexopathy, axonal polyneuropathy, mononeuropathy) but is also prominent in inflammatory myopathies, such as polymyositis or dermatomyositis because of isolation of section of muscle from the endplate region producing functional denervation. Lesser degrees of spontaneous activity may be observed in other myopathies with muscle fiber necrosis (e.g., myotonic dystrophy, Duchenne or limb girdle muscular dystrophy) and in some toxic, metabolic, and infectious myopathies (e.g., myoglobinuria [rhabdomyolysis] or viral myositis). Spontaneous activity typically begins to initially occur at 10 to 14 days after denervation but is more evident 3 to 4 weeks after onset and may persist for a protracted time unless that muscle fiber is reinnervated.

Other aberrant involuntary discharges may appear with certain neurogenic or myopathic disorders.

Fasciculations are isolated spontaneous discharges of whole or partial motor units and are prominent in motor neuron disease, benign fasciculation syndrome, and disorders of nerve excitability. Fasciculations may be visible as a muscle twitch, EMG needle sudden movement, or recordable discharge. *Complex repetitive discharges* are relatively nonspecific machine-like phenomena more common in chronic neurogenic conditions. These discharges are very regular and start and stop abruptly. The origin is considered to be a stable circuit created between several adjacent muscle fibers. *Myotonic discharges* are distinctive revving motor-like discharges with more limited associations, including myotonic dystrophy and myotonia congenita; however, acquired conditions can also demonstrate these findings. Waxing and waning frequency and amplitude are characteristic. *Myokymic discharges* are repetitive, grouped, nerve-generated discharges (doublets or multiplets) and occur commonly in

the facial muscles from diverse cause but are uncommon in the limbs. Limb myokymic discharges suggest radiation injury, timber rattlesnake venom, or certain channelopathies. The origin is nerve components. Most rare are the very rapid *neuromyotonic discharges*, characteristic of Isaac syndrome or other forms of motor unit hyperactivity.

MOTOR UNIT CONFIGURATION

Assessment of the waveform generated by motor unit activation (*the motor unit potential* or MUP) yields important information

P.220

(Fig. 26.8). MUP parameters include waveform duration, amplitude, and morphology (number of turns or baseline crossings). Motor unit characteristics are best assessed by capturing MUPs with the aid of a trigger and delay line, so that the waveform can be frozen and assessed. The duration is measured from the point where the waveform deviates from the baseline to the point where a stable baseline returns following the waveform. The amplitude is typically measured from the largest waveform-positive and waveform-negative peaks. *Polyphasic* waveforms have five or more phases, determined by the number of times the waveform crosses the baseline plus one. Waveform turns or phase reversals are considered as well. MUPs that contain more than seven or more turns are considered by some to be *complex MUPs*. Both polyphasic and complex MUPs are indicators of desynchronization seen in all forms of chronic neuromuscular disease that affects neurogenic or myogenic components. Small percentages of these potentials are evident in normal muscle as well, typically less than 12%. Some MUPs include a small additional time-locked component following a return to baseline—a *satellite potential*. Because a muscle may contain hundreds of motor units, the EMG examination must include a representative sample of motor units collected at varying levels of voluntary contraction.

FIGURE 26.8 A normal MUP. This waveform was recorded from the biceps muscle with a concentric needle electrode as the first potential recruited during minimal voluntary contraction in a normal subject. Sweep speed was 10 milliseconds per division and sensitivity was 500 μV per division. This waveform has an amplitude of 1.4 mV, a duration of 12.5 milliseconds, and a simple morphology with three turns.

Diseases of the motor nerve and muscle alter these motor unit parameters in characteristic ways. When motor axons fail, the associated muscle fibers lose their innervation. However, branches from surviving motor axons in

the same nerve may reinnervate these denervated muscle fibers in a process called *collateral reinnervation*. Over the course of several months, this compensatory repair process gradually expands both the total number of muscle fibers innervated by surviving motor units, as well as the geographic territory spanned within the muscle. Reinnervated motor units produce abnormally enlarged MUPs of long duration, high amplitude, and increased complexity, which are markers of chronic neurogenic injury (Fig. 26.9).

In contrast, myopathies destroy or inactivate some muscle fibers in most or all of the motor units within a muscle, thereby reducing both the number and distribution of fibers within each unit, producing abnormally small MUPs of short duration, low amplitude, and increased complexity (Fig. 26.10).

FIGURE 26.9 A neurogenic MUP. This waveform was recorded during voluntary activation of the gastrocnemius muscle with a concentric needle electrode in a patient with a distal diabetic neuropathy. Sweep speed was 5 milliseconds per division and sensitivity was 1 mV per division. This waveform has a high amplitude of 10 mV and a significantly increased duration of 29 milliseconds, and is highly complex, with more than 10 turns. This motor unit likely innervated a number of muscle fibers denervated from loss of other motor axons, producing the characteristic MUAP changes in neurogenic conditions.

In normal individuals as well as patients with neuropathic or myopathic disorders, there is a wide range of sizes of individual MUPs. The size of the motor neuron, motor axon, and corresponding motor unit specifies the available strength, maximal firing rate, and fatigue resistance of that unit. In addition, different muscles may have divergent average motor unit size depending on the muscular function. For example, an extraocular muscle may have relatively few muscle fibers per motor unit to deliver small precise movements in contrast to a proximal hip girdle muscle where high fatigue resistance predominates. Thus, the characteristics of a small number of MUPs are insufficient for a definitive diagnosis. Determining the mean duration of 20 MUPs is one reliable way to

separate neuropathic from myopathic disorders. Normal values, generated in Copenhagen, for the mean durations of most muscles in each decade of life were published in 1975 and are widely used. However, qualitative MUP assessment invokes the same process by assessing a number of different MUPs without quantitative measurement. This assessment requires experience with the process and specific muscle undergoing testing.

Disorders of the neuromuscular junction, as in myasthenia gravis, may also prevent activation of enough fibers, owing to cumulative neuromuscular junction blockade, to produce myopathic-appearing MUPs. Following severe nerve injury, the earliest phases of reinnervation and the latest phases of denervation during neurogenic atrophy may also produce short-duration motor units (*nascent units*) when the initial few muscle fibers are reinnervated.

P.221

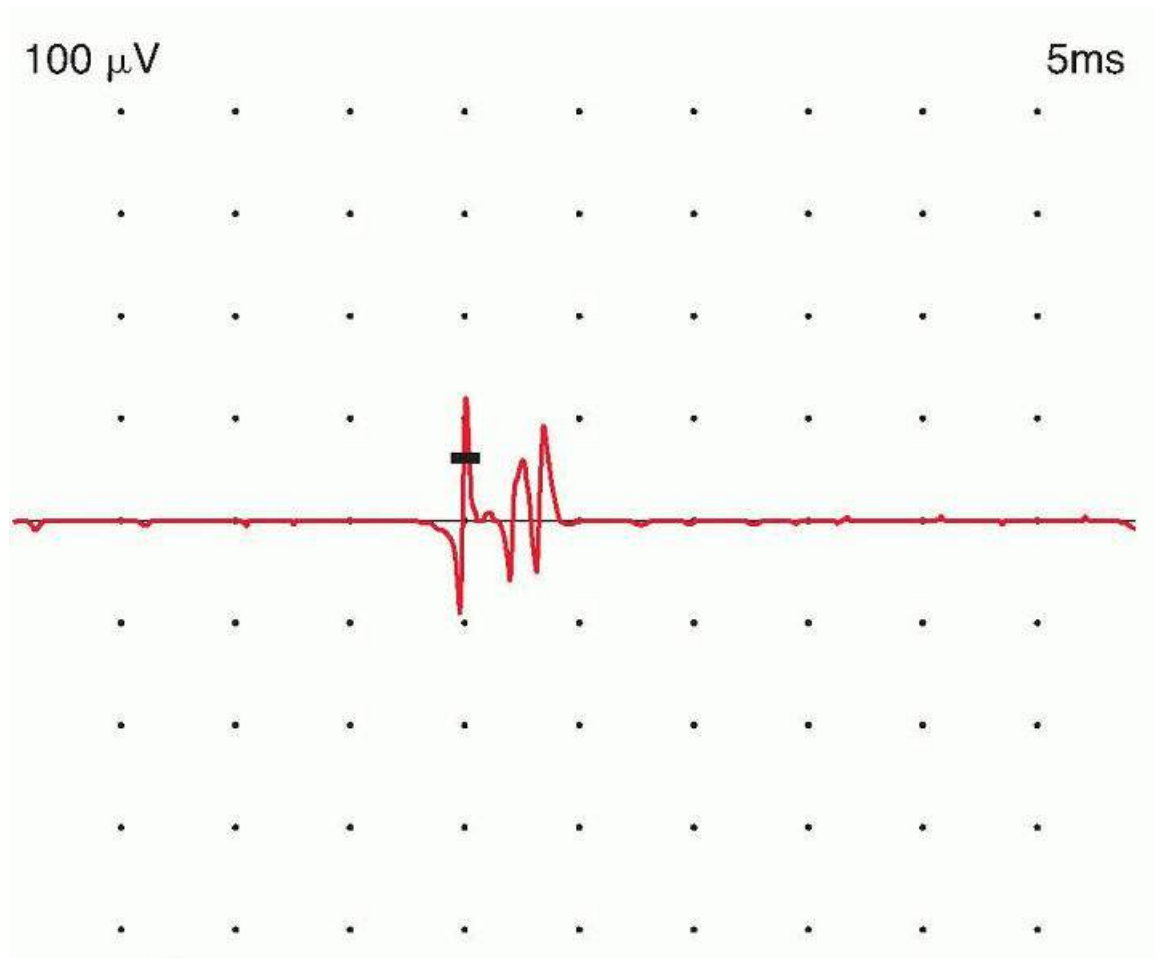

FIGURE 26.10 A myopathic MUP. This waveform was recorded during voluntary activation of the vastus lateralis muscle with a concentric needle electrode in a patient with polymyositis. Sweep speed was 5 milliseconds per division and sensitivity was 100 μV per division. This waveform has a low amplitude of 210 μV and a short duration of 7 milliseconds and is complex with eight turns. As individual muscle fibers within a motor unit drop out during myopathic injury, the electric potential generated shrinks proportionately, resulting in decreased MUAP amplitude and duration and increasingly complex morphology from reduced synchronization.

RECRUITMENT AND INTERFERENCE PATTERNS

Needle EMG also enables assessment of motor unit recruitment patterns. As a muscle begins to contract at the lowest force levels, the first recruited motor unit begins to fire repeatedly at a specific frequency, usually at a minimum of 4 to 5 Hz. As demand for more strength increases, the firing frequency of the motor unit increases until a second motor unit is recruited. The specific firing frequency of the first recruited motor unit at the moment the second motor unit appears is *the recruitment frequency*. Abnormally high recruitment frequencies appear as

motor units are lost, forcing surviving units to fire at faster and faster rates before additional units appear because of reduced numbers of motor units available for recruitment. In contrast, because most motor units are smaller and weaker, owing to loss of muscle fibers, lower recruitment frequencies are seen in myopathies (*early recruitment*). Consequently, multiple motor units must be activated earlier than in normal subjects to generate the same levels of force. Following damage to upper motor neuron pathways, recruitment is disordered, and motor units may fire at a slower than needed rate despite true maximal voluntary effort, as disrupted descending impulses improperly modulate firing frequency. The *firing ratio* is calculated by dividing the firing frequency (firing rate of the fastest firing MUP) over the number of different MUPs activated. This ratio is typically around five. In other words, if the fastest MUP fires at 15 Hz, one expects to see three total firing MUPs. Neurogenic processes increase this ratio.

FIGURE 26.11 A normal interference pattern. This dense, overlapping group of MUP waveforms was recorded with a concentric needle electrode from the biceps muscle during maximal voluntary contraction in a normal subject. The pattern represents the simultaneous activation of all the functional motor units within that muscle. The sweep speed was 100 milliseconds per division and the sensitivity was 1 mV per division.

The *interference pattern* is the overlapping pattern generated by the simultaneous activation of large numbers of MUPs during maximal contraction; the spike density and the amplitude of the summated response (*envelope amplitude*) are assessed. This response typically appears as a dense band of competing waveform activity at slow sweep speeds, which normally obscures the baseline tracing (Fig. 26.11). Normal recruitment from low to intermediate to full contraction should produce a full interference pattern with a conical onset, as amplitudes increase progressively with the recruitment of larger and larger motor units to generate increasing force. *Incomplete or reduced interference patterns* (despite maximal contraction) are seen in advanced denervating disorders as more and more motor units drop out, ultimately leaving a *picket-fence* pattern, termed *discrete recruitment* (Fig. 26.12).

Maximal voluntary effort must be elicited before interference patterns are accurately assessed because poor

volitional effort also produces an incomplete pattern; weakness due to central motor neuron injury may also result in reduced recruitment. In contrast, full *interference patterns, despite weakness*, occur with myopathic disorders. A full pattern appears almost immediately with minimal effort, owing to the large numbers of weakened motor units that are required to generate low levels of force. This pattern also has low envelope amplitude because the size of the constituent MUPs is reduced. Advanced methods that attempt to minimize the effects of voluntary effort (cloud analysis) are available on most machines but are not routinely applied, partly from limited normative data.

P.222

FIGURE 26.12 A reduced interference pattern. This pattern of MUP waveforms was recorded with a concentric needle electrode from the biceps muscle of a patient with amyotrophic lateral sclerosis during maximal voluntary contraction. The sweep speed was 100 milliseconds per division and the sensitivity was 2 mV per division. Instead of the normal, dense band of overlapping MUAPs observed in the normal subject (see Fig. 16.11), a “picket-fence” pattern (*discrete recruitment*) representing the activation of only one rapid firing motor unit emerges because so many motor units have been lost. The MUAP amplitude of the most prominent surviving unit is increased (8 to 10 mV), consistent with collateral reinnervation.

NERVE CONDUCTION STUDIES AND ELECTROMYOGRAPHY APPLICATIONS

A wide range of neuromuscular and central disorders may benefit from electrodiagnosis. Many specific applications are discussed in other sections dedicated to specific conditions. Some common examples include focal mononeuropathy, multifocal neuropathy, axonal and demyelinating polyneuropathy, motor neuronopathy, myopathy, myositis, and radiculopathy. A proper electrodiagnostic medicine consultation relies on a targeted clinical assessment so that the study design is focused on the clinical problem at hand and includes assessment of sufficient but not excessive numbers of clinically relevant nerves and muscles. Small-diameter fibers may be assessed by other means, most commonly skin biopsy for determination of epidermal nerve fiber density. Nerves are amenable to ultrasonography; however, this technology is currently considered to be a supplemental adjunct to electrodiagnostic methods described. A guideline found level B evidence for use of ultrasound in the diagnosis of suspected carpal tunnel syndrome. Magnetic resonance imaging (MRI) of nerve is increasing sophisticated with higher power magnetic fields and improved protocols. However, imaging of nerve and muscle is also adjunct information that typically identifies potential sites of nerve swelling and muscle signal changes that do not provide information on the disease type or process. MRI can identify atrophic muscles. Practice parameters and diagnostic criteria exist for some common conditions, including but not limited to carpal tunnel syndrome, ulnar neuropathy, amyotrophic lateral sclerosis, chronic inflammatory demyelinating polyneuropathy, polyneuropathy,

and others. In nearly all cases, both sensory and motor NCS and needle EMG are performed. Timely reporting of results is required that includes numeric data described earlier and written assessment of the normality of obtained values. A diagnostic conclusion based on the data acquired is expected. In some cases, guidance on disease severity, time course, and prognosis is possible.

TESTS OF NEUROMUSCULAR TRANSMISSION

REPETITIVE NERVE STIMULATION

Repetitive nerve stimulation (RNS) studies assess neuromuscular transmission using a standard motor nerve conduction setup (see [section “Nerve Conduction Studies”](#)) to deliver a series of supramaximal stimulations to a motor nerve at a specific frequency while recording each generated CMAP. CMAP trains of 4 to 10 waveforms are usually recorded at rates from 2 to 3 Hz (low-frequency stimulation). By convention, the waveforms within each train are displayed horizontally on the same baseline from left to right ([Fig. 26.13](#)).

Trains are then evaluated either for decreases in consecutive CMAP size (as assessed by area and amplitude, from the first to a later potential, typically the fourth or fifth, and expressed as percentage decrement) or for increases in size (usually expressed in percentage increments). Most protocols include one baseline train, followed by a brief period of voluntary exercise without stimulation, and then followed by one immediate, postexercise train and several more trains at intervals over the next 1 to 5 minutes. The role of exercise is explained in the following text. For high-frequency stimulation studies, either transcutaneous stimulation at rates of 20 to 50 Hz or maximal voluntary contraction itself, which provides painless activation of the nerve at similar rates, is used. However, high-frequency RNS studies are quite painful and very infrequently used in clinical practice; scenarios almost exclusively are for presynaptic disorders such as Lambert-Eaton myasthenic syndrome (LEMS), organophosphate poisoning, or botulism (as described

P.223

later in the chapter and in Chapter 137) when the patient is unable to provide voluntary muscle activation.

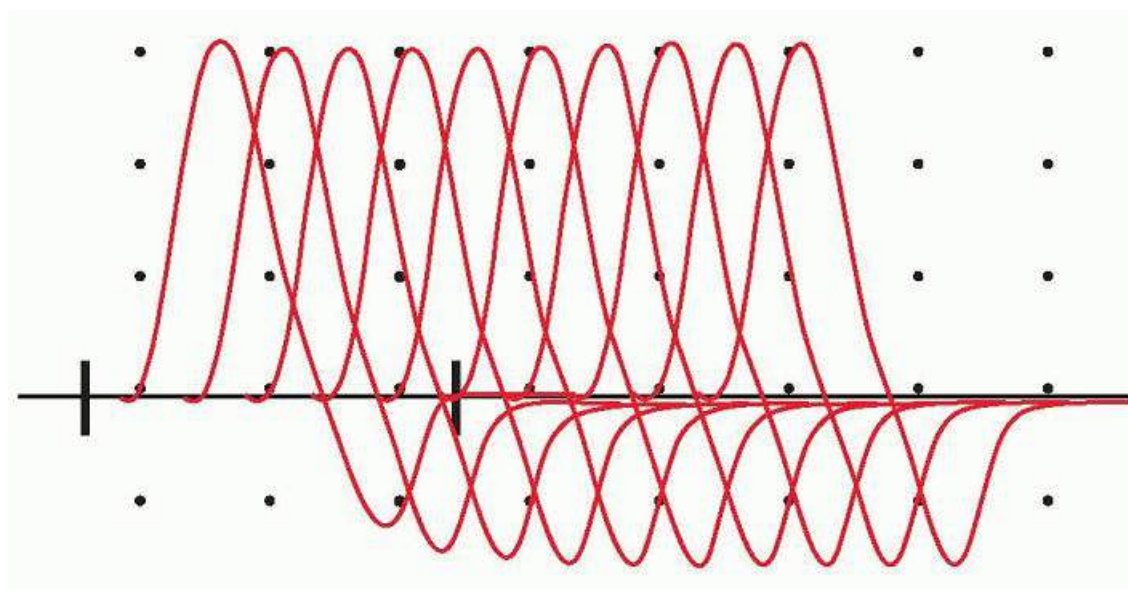

FIGURE 26.13 RNS. A train of 10 CMAPs recorded from the thenar eminence following RNS of the median nerve at a frequency of 3 Hz, arrayed in the order of stimulation (*left to right*). Each individual CMAP is normal, and no significant change in CMAP amplitude or area is observed during repetitive stimulation.

POSTSYNAPTIC NEUROMUSCULAR JUNCTION DYSFUNCTION

Patients with postsynaptic neuromuscular junction dysfunction, most commonly caused by myasthenia gravis, may demonstrate decremental responses following low-frequency stimulation. During normal neuromuscular

junction transmission, depolarization of the motor axon induces acetylcholine release from the nerve terminal; the transmitter diffuses across the synaptic cleft to activate a group of acetylcholine receptors on the muscle fiber, each of which generates a local depolarization. These summated depolarizations ultimately reach threshold and generate a muscle action potential, which then initiates muscle fiber contraction. Declining release of acetylcholine normally occurs with stimulation at low frequencies; however, because postsynaptic acetylcholine receptors are abundant, these declines do not affect neuromuscular transmission, ensuring adequate muscle fiber depolarization despite the lower levels of acetylcholine released (*safety margin*). However, in myasthenia and some rare genetic postsynaptic disorders, the decline in acetylcholine release becomes critical because there are fewer functional acetylcholine receptors. The result is failure of neuromuscular transmission at multiple neuromuscular junctions with continued stimulation. As increasing numbers of muscle fibers drop out with successive stimulation, the size of the overall summated CMAP also decreases (Fig. 26.14). Rare hereditary disorders of neuromuscular junction physiology (congenital myasthenia) cause differing effects on this test depending on the affected component.

Additionally, the size (amplitude or area) of a single CMAP immediately after brief exercise, in myasthenia, may increase by 10% to 50% or more compared to the baseline (preexercise) CMAP. This phenomenon, known as *postexercise facilitation* or *posttetanic potentiation*, is attributed to a temporary increase in acetylcholine release after a brief maximal contraction because of transiently heightened presynaptic calcium influx. Postexercise facilitation is assessed by comparing the first CMAP in the first train acquired immediately after exercise to the amplitude of the first CMAP in the preexercise train. In addition to postexercise facilitation of CMAP amplitude, any decrement in the baseline train may transiently improve immediately after exercise (*decrement repair*). However, after this transient repair, decrement typically worsens in trains recorded over the next 3 to 4 minutes, often dipping below baseline (*postactivation exhaustion*) as reserve acetylcholine levels are exhausted. Decrement ultimately returns to preexercise levels within 10 minutes. The decrement is typically greater in proximal and bulbar muscles but is simpler and more reliably performed in distal muscles.

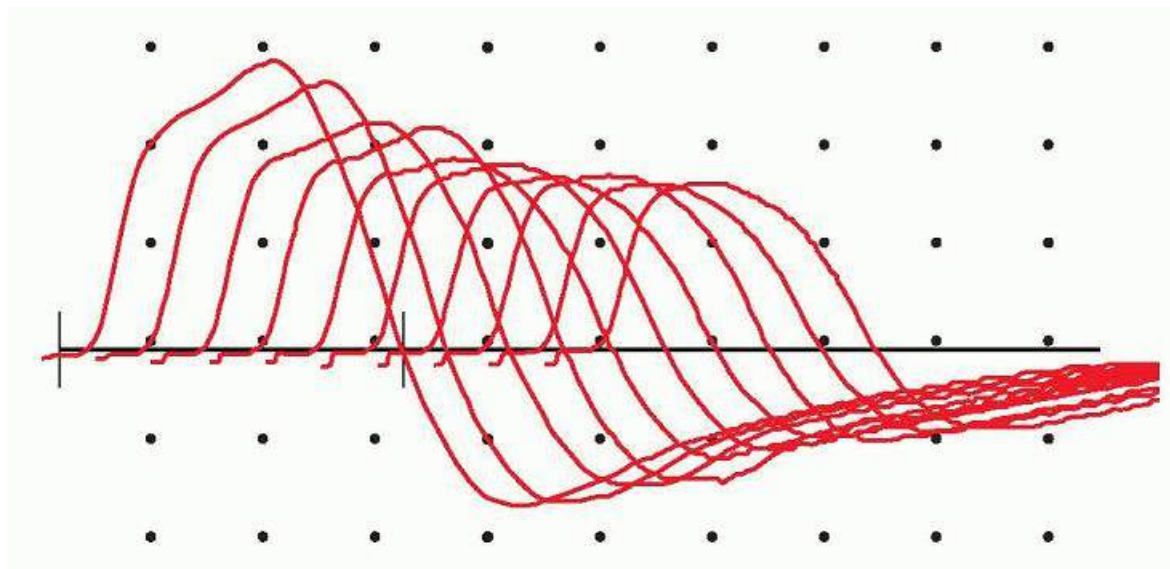

FIGURE 26.14 Decrement during RNS. Progressive decreases in the size of CMAPs were recorded from the thenar eminence during a train of RNS at 3 Hz in a patient with myasthenia gravis. Losses in both amplitude and area of 40% to 50% appeared during RNS, owing to transmission failure at increasing numbers of neuromuscular junctions.

PRESYNAPTIC NEUROMUSCULAR JUNCTION DYSFUNCTION

In the presynaptic LEMS and some cases of botulism, the CMAP amplitude may be reduced on routine NCS, and low-frequency RNS produces decrement similar to that seen in postsynaptic dysfunction. Both the low baseline

CMAP and the decrement seen on low-frequency stimulation are the result of the combination of normal decline in acetylcholine release at low rates of stimulation superimposed on the diminished release of acetylcholine resulting from antibody blockade of the presynaptic voltage-gated calcium channel (LEMS) or disruption of the mechanisms of acetylcholine release (botulism). High-frequency RNS, in contrast, characteristically leads to CMAP increment (facilitation) over 1 to 2 seconds, usually exceeding 100%. The pain of high-frequency stimulation may be avoided by having the patient voluntarily contract the muscle with maximum force for 10 to 20 seconds, after which a second single CMAP is immediately obtained; this “exercise test” shows postexercise facilitation comparable in magnitude to the increment observed after high-frequency stimulation.

SINGLE-FIBER ELECTROMYOGRAPHY

Another test of the neuromuscular junction is single-fiber electromyography (SFEMG). A specialized reusable electrode or small concentric disposable electrode is used that records single muscle fiber potentials. When an axon is selectively stimulated and a single muscle fiber action potential is measured (*stimulated SFEMG*), the interval between stimulus and response varies with each stimulus. This normal variation results from the fluctuating time required for electrochemical transmission across the junction and is quantitated as *jitter*. *Volitional SFEMG* recordings are more commonly performed and measure jitter by assessing the differences between two voluntarily activated muscle fibers from the same motor unit. With neuromuscular dysfunction, jitter increases, and in severe cases, complete block of neuromuscular transmission may be documented. SFEMG is the single most sensitive assay of neuromuscular junction dysfunction in myasthenia gravis, having a sensitivity of greater than 95% when applied to a clinically affected muscle (Fig. 26.15A and B).

P.224

FIGURE 26.15 A: Single-fiber EMG in a normal subject. In this tracing, 50 to 100 consecutive discharges generated by two single muscle fibers from the same motor unit during voluntary activation of the frontalis muscle are superimposed. The tracings are arrayed so that the first (*left*) potential is fixed with each discharge. Consequently, the variability in the time between the firing of the first (*left*) and second (*right*) potential with each discharge (the interpotential interval) is illustrated solely as variation of the second waveform. This effect, quantitated as *jitter*, is due to the variable time required for neuromuscular transmission to produce an action potential from discharge to discharge. **B:** Single-fiber EMG in a patient with myasthenia gravis during volitional activation of the frontalis muscle using the same recording methods described in **A**. This tracing illustrates increased variability in neuromuscular transmission and clearly differs from that of the normal subject above. The jitter in this fiber pair was 160 microseconds, well above the upper limits of the normal range.

Although SFEMG is highly sensitive, it is not specific and may be abnormal in any condition causing damage to

nerve or muscle that produces reinnervation. Consequently, it is essential to perform other electrodiagnostic methods and a careful clinical assessment before considering SFEMG. SFEMG is most useful for confirming neuromuscular junction dysfunction in suspected myasthenia gravis when other tests are equivocal or negative and other conditions that produce muscle weakness are assessed (see [Fig. 26.11](#)).

TRANSCRANIAL MAGNETIC STIMULATION

Transcranial magnetic stimulation (TMS) evokes compound motor potentials through noninvasive stimulation of the cortex. TMS has become an important method for studying the conductivity and excitability of the corticospinal system, abnormal cortical circuitry in neurologic diseases, and the reorganization of sensorimotor and visual systems after peripheral and central lesions. Electromagnetic induction may stimulate neural tissue. TMS is accomplished through the generation of high-intensity current (5 to 10 kiloampere) and discharged as a quick pulse through wire coils placed on the surface of the head. The coils induce a magnetic flux of short duration (100 to 200 microseconds) and high intensity (1 to 2 T). The magnetic fields, in turn, induce electrical current in the underlying cerebral cortex. TMS delivery devices are embedded in a nonconductive plastic or rubber material and typically fashioned into figure eight, butterfly, or flat or concave circular shapes and applied near the part of the brain under study. The various shapes and sizes are designed to distribute or focus the induced magnetic fields. Round coils generate more diffuse magnetic fields and figure eight coils produce a narrower region of neural activation.

Stimulus intensity is expressed as a function of either the motor threshold or the percentage of machine output. TMS is less painful than transcranial electrical stimulation (TES), which causes uncomfortable shocks in the underlying skin and muscle. Unlike TES, which directly excites cortical long tracts, the induced electrical fields of TMS preferentially stimulate neural elements oriented parallel to the surface of the brain (i.e., primarily interneurons). TMS pulses are associated with benign acoustic clicks and mild scalp or facial muscle activation. A momentary sense of disorientation at maximal stimulation may be felt. However, there are virtually no clinical cognitive or sensory effects at low intensities of TMS stimulation. Waveform recordings are usually obtained from a contralateral distal limb muscle, the motor-evoked potential (MEP).

TMS may be delivered as a single pulse, in paired pulses, or as repetitive trains of stimulation (rTMS). Paired pulse and rTMS are powerful in studying human brain function, transiently stimulating or inhibiting different brain areas in awake and behaving subjects. Effects of rTMS on cortical excitability and inhibition outlast (for minutes to hours) the stimulation itself, a characteristic that could lead to therapeutic applications. Clinical trials have been conducted primarily not only in depression but also in Parkinson disease, epilepsy, obsessive-compulsive disorders, and schizophrenia.

SINGLE-PULSE TRANSCRANIAL MAGNETIC STIMULATION

Following a single TMS, the MEP latency and amplitude measure the integrity of pathways and membrane excitability characteristics of the upper motor neuron. Central motor conduction time is calculated by subtracting the peripheral MEP latency (i.e., cervical or lumbosacral proximal roots to distal limb muscles) from the

P.225

total conduction latency (i.e., TMS to MEP onset of the same muscle) and is obtained with a single, maximal TMS over the primary motor cortex ([Fig. 26.16](#)).

Prolongation of the central motor conduction time may originate with the loss of large myelinated motor axons subsequent to degeneration, and the test assesses upper motor neuron (UMN) dysfunction. Central motor conduction time, as well as other TMS measures, is helpful in diagnosing and following progression in patients with upper motor neuron diseases, such as amyotrophic lateral sclerosis (ALS). However, central motor conduction time may be of limited value when large-diameter axons remain normal or in diseases where long-tract integrity is known to be normal, such as Parkinson disease.

As a measure of UMN functional integrity, TMS may detect abnormalities when there are no clinical UMN signs. TMS may reveal subtle subclinical UMN dysfunction and help clarify the diagnosis of ALS, as well as the relationship between ALS and its variants (100), including progressive muscular atrophy where there may be subclinical UMN changes.

FIGURE 26.16 Transcranial magnetic stimulation (TMS) in a normal subject. These tracings show the motor-evoked responses recorded from the right and left abductor digiti minimi (ADM) muscle of the hand and the right and left tibialis anterior (TA) muscles, following stimulation of the cerebral cortex with the stimulator placed over the vertex of the skull (traces A1 to A4) and following stimulation of the spine; cervical stimulation for the ADM and lumbosacral stimulation for the TA is shown in traces B5 to B8. Latencies, in milliseconds, from stimulation to the onset of the waveform recorded from the muscle are shown in the *first column* (LAT1). Central-conduction latency (i.e., time from cortex to spinal segment) is calculated by subtracting the peripheral-conduction latency (i.e., time from spine to muscle) from the total conduction latency (i.e., time from cortex to muscle) and is shown in *SEGMENT table, final column* (DIFF).

MEP amplitudes and latencies are influenced by multiple factors, including configuration and placement of the TMS coil, stimulus intensity, presence of conditioning pulses, muscle facilitation, and degree of phase

cancellation. Suprasegmental modulation of MEPs may be inferred in several ways, including demonstration of relatively unchanged F-wave properties under the same stimulus conditions. Motor threshold is defined as the lowest stimulus intensity that evokes MEPs of 50 μ V in amplitude in 5 of 10 trials. Stimulus intensity is expressed as a percentage of the TMS device's maximum output. MEP amplitude is usually measured peak to peak, increases with stimulus intensity, and plateaus at 80% of the amplitude of the wave produced by peripheral stimulation.

P.226

Voluntary muscle activation during TMS lowers the motor threshold and increases the MEP amplitude and is associated with shorter latency. This facilitation may result from an increased number and synchronization of descending impulses from the motor cortex or from reafferent facilitation at the spinal level. Recruitment is measured by plotting a stimulus-response curve of stimulus intensity versus MEP amplitude. The slope of this curve is normally increased by facilitation, as well as by maneuvers that enlarge cortical representation of muscles, such as highly skilled, fine motor actions. Temporal summation may also follow repeated delivery of stimuli. In the first minutes following rTMS trains at low frequency (1 Hz), the amplitude of single-pulse MEP decreases. Conversely, high-frequency (>10 Hz) stimulation increases the response; these patterns resemble long-term depression and facilitation.

SILENT PERIOD

The cortical or central silent period is measured from an actively contracting muscle, representing suppression of voluntary EMG activity for up to 300 milliseconds after a single TMS. The cortical silent period is an important method of assessing inhibitory mechanisms in neurologic disease. The silent period typically follows an MEP but may be induced by subthreshold stimuli that do not produce an MEP. This *negative effect* is mechanistically distinct from the positive effect seen in MEP induction. Although the origin of the initial segments of the cortical silent period are controversial, the latter part of the silent period is modulated by central mechanisms.

REPETITIVE TRANSCRANIAL MAGNETIC STIMULATION

The first TMS capacitors could recharge only after several seconds and thus allow only single TMS pulses. With technical advances, rTMS output increased from just under 1 Hz to pulse trains up to 50 Hz. rTMS at frequencies greater than 20 Hz increases cerebral blood flow and neuronal excitability, whereas low-frequency rTMS (1 to 2 Hz) has the opposite effect. The therapeutic potential of TMS is of interest as a painless and relatively safe alternative to electroshock therapy, which has lasting motor benefit in severe parkinsonism. Enhanced cortical excitability is suggested by increased MEP amplitude after rTMS and by persistent focal metabolic enhancement as demonstrated by positron emission tomography (PET). However, rTMS may have negative effects on the motor system, so the underlying mechanisms must be more fully understood before widespread use may be expected.

The authors acknowledge significant contributions from authors of earlier editions of this section, especially Dale J. Lange, MD.

INTRODUCTION

Recognition of disorders producing autonomic dysfunction continues to increase the demand for noninvasive clinical testing in order to validate clinical diagnoses. Because autonomic systems affect virtually all organ systems, symptoms produced are multiple and varied, often affecting functions not considered by neurologists. Because many autonomic complaints can appear to be nonspecific, objective assessment is desirable in many instances. Laboratories testing autonomic function are increasingly available in part due to reliable noninvasive techniques. However, formal training opportunities in this neurologic specialty remain limited.

TABLE 27.1 Selected Tests of Autonomic Function**Cardiovagal***Well established*

HR variability to cyclic deep breathing

HR response to the VM (VR)

HR response to standing (30:15 ratio)

Other

Diving reflex/cold face test

HR variability at rest

HR response to cough

Spectral analysis of HR signals (frequency domain)

Transfer function analysis (nonlinear dynamics)

Adrenergic*Well established*

BP response to the VM (phase IV and late phase II)

BP response to orthostatic stress

- Head-up tilt

- Standing

Other

Sustained handgrip test

Squat test

BP response to alternate stressors

- Lower body negative pressure

- Neck suction

- Lying down

- Liquid meal

Plasma catecholamine levels (supine/standing)

Microneurography

Mental stress tests

Cold pressor test

Spectral and transfer function BP analysis

Sudomotor

Well established

Sympathetic skin response (SSR)

Quantitative sudomotor axon reflex test (QSART)

Thermoregulatory sweat test (TST)

Silastic sweat imprint testing

Skin biopsy for sweat gland innervation

Additional or Investigational Methods

Pharmacologic challenges

Vasomotor testing

Pupillary testing (pharmacologic)

Pupillometry, pupillography

Urodynamics/cystometrogram with bethanechol

GI motility studies

GI manometry

Salivary testing/Schirmer test

Penile plethysmography, papaverine injection

Neuroendocrine tests

Neurogenic flare test

Quantitative direct and indirect test of sudomotor function (Q-DIRT)

Cardiac PET scanning

HR, heart rate; VM, Valsalva maneuver; VR, Valsalva ratio; BP, blood pressure; GI, gastrointestinal; PET, positron emission tomography.

Unlike other systems, autonomic function is not directly assessed. Instead, responses of complex overlapping reflex loops are measured after controlled perturbations, most commonly heart rate (HR), blood pressure (BP), and sweating. Techniques to evaluate autonomic function are numerous and continue to be devised, but only a limited number are considered to be suitable for routine clinical application ([Table 27.1](#)). Tests of cardiovagal, adrenergic, and sudomotor function are most commonly performed and are recognized, standard clinical measures. Consensus recommends use of a standardized testing battery in a controlled setting. Bedside screening tests complement a clinical evaluation; some techniques can be performed with limited equipment such as an electrocardiography (ECG) or electromyography (EMG) machine.

P.228

The primary testing goal is to identify autonomic failure and to assess and quantify disease severity. In some cases, determining the systems involved, such as parasympathetic, sympathetic, or panautonomic, can refine diagnostic possibilities. In most instances, localization to central, preganglionic, or postganglionic dysfunction is not possible. The effects of medications, environmental conditions, dehydration, and acute illness should be

minimized during testing. Selected commonly performed tests are briefly discussed in this chapter.

SELECTED TESTS

HEART RATE VARIABILITY

Measures of HR variability are simple to record and are sensitive indicators of parasympathetic function. Cyclic deep breathing at 6 breaths per minute is the best validated stimulus; both afferent and efferent pathways are vagally mediated and blunted by anticholinergic agents. Most commonly, beat-to-beat HR is recorded, and R-R intervals or sequential HR data are measured, and the resultant enhanced sinus arrhythmia is analyzed with one of numerous methods; the test is currently the best cardiovagal measure available. Age-segregated normative ranges are well described. Other parasympathetic cardiovagal tests include measures of HR variability during rest, coughing, diving reflex, standing, squatting, and active lying down. The HR response to Valsalva maneuver (VM) is discussed later. Spectral and frequency HR analysis is an important research tool that has not been adequately validated for routine clinical application, although commercial automated testing devices using these methods are employed typically by nonneurologists and cardiologists.

SYMPATHETIC MEASURES

The VM is a reliable and reproducible method that provides information for both parasympathetic and sympathetic function if beat-to-beat HR and BP data are recorded. Devices that noninvasively record continuous BP are typically used; multiple machines are commercially available. The subject blows into a closed tube at 40 mm Hg for 15 seconds while HR and BP are recorded. Isolated Valsalva ratio (VR) HR recording requires minimal equipment but more information is gathered with less chance of misinterpretation if continual BP is recorded. The VM BP waveform is divided into four distinct phases (I to IV). Phases I and III signify nonspecific transmitted pressure and release from the maneuver, which initially causes cardiac output and BP to drop, providing the test stimulus. Normally, peripheral vasoconstriction and increased HR produce partial or full reversal of the BP decline, marking early (BP drop) and late (BP recovery) phase II. After Valsalva ends, the BP slowly overshoots and later returns to baseline (phase IV overshoot). Adrenergic insufficiency causes phase II to progressively deepen or fail to correct. Phase IV may fail to overshoot. Phase II recovery is likely mediated by α -adrenergic stimulation and phase IV by β -adrenergic supported by pharmacologic studies. HR normally increases during the Valsalva period and then overshoots below baseline values.

The VR is calculated by dividing the R-R interval of the HR nadir over the HR peak. Normative values are well established and decline with age. The baroreflex index is also measurable and correlates well with traditional invasive methods. The HR response is affected by both atropine and β -blockade. The isolated HR response can be measured on most current EMG devices. Abnormalities are evident in a high percentage of patients with autonomic failure and significant autonomic neuropathy; the BP findings are more sensitive than tilt studies, which are described later. Abnormalities also correlate with the severity of diabetic autonomic neuropathy and diabetes disease duration. Patients with orthostatic intolerance or the *postural orthostatic tachycardia syndrome* (POTS) may show excessive phase II decline and insufficient recovery but additionally markedly enhanced phase IV overshoot and a high VR.

STANDING AND THE 30:15 RATIO

Standing initiates a coordinated sequence of reflexes to maintain BP and therefore cerebral perfusion. Simple HR and BP responses to standing are important bedside markers of autonomic integrity, but further information is gained by laboratory testing. Most labs, however, use passive tilting. Responses are best measured after a supine rest period of 15 to 30 minutes, but shorter periods suffice. Baseline values are recorded and readings are taken at least every minute for 2 to 5 minutes. Leg muscle contraction necessary for active standing triggers an exercise reflex that transiently reduces BP that can mimic orthostatic hypotension. Pressure normally returns

to baseline levels within 1 to 2 minutes but can be delayed for 3 to 15 minutes in patients with mild orthostatic intolerance. This phenomenon is why standing BP measures must be delayed. The 30:15 ratio, the R-R interval ratio of the HR nadir around beat 30 after standing divided by the HR peak near beat 15, is reduced by inadequate parasympathetic function. A BP decrease of 20 mm Hg systolic or 10 mm Hg diastolic within 3 minutes is considered significant; triggered symptoms are also noted. The recognition of delayed or slowly declining BP has been noted that can be missed by shorter measurement periods. Fifteen percent of cases in one series had BP declines between 3 and 10 minutes after head-up tilt, and nearly 40% occurred after 10 minutes suggesting milder adrenergic insufficiency than patients with more acute declines.

TILT TABLE STUDIES

Orthostatic challenge with passive upright tilting is the standard method used in most laboratories. Tilting employs slightly different physiologic mechanisms to active standing; however, testing is more easily controllable, enables reproducible tilting angles, simplifies BP monitoring at heart level, and is easier for patients with neurologic impairment. Neurogenic orthostatic hypotension from autonomic failure or HR changes characteristic of primary orthostatic intolerance are generally evident within the first 5 to 15 minutes of tilting. In contrast, prolonged studies are often needed to trigger reflex or vasovagal syncope, which are further delayed or require pharmacologic challenge. Tilt angles range from 60 to 90 degrees depending on the laboratory (Fig. 27.1). ECG recordings are continuously monitored, and serial BP measurements are recorded with a manual cuff with an automated sphygmomanometer or ideally with continuous BP monitoring. Additional systems can be simultaneously monitored in special circumstances such as electroencephalography (EEG), transcranial Doppler, or noninvasive cardiac impedance plethysmography. The BP measurement point is maintained at heart level. Orthostatic hypotension, however, is a sign and not a disease; diagnosis of central autonomic disorders or autonomic neuropathy also depends on clinical assessment and other autonomic tests (see Chapter 112). Similar to active standing, a systolic BP decline of 20 mm Hg is considered to be abnormal, but most centers require at least a 30 mm Hg drop. Although drops of this magnitude may be asymptomatic, ideally, the patient's typical symptoms are reproduced during testing. Diastolic BP declines of 10 mm Hg are significant.

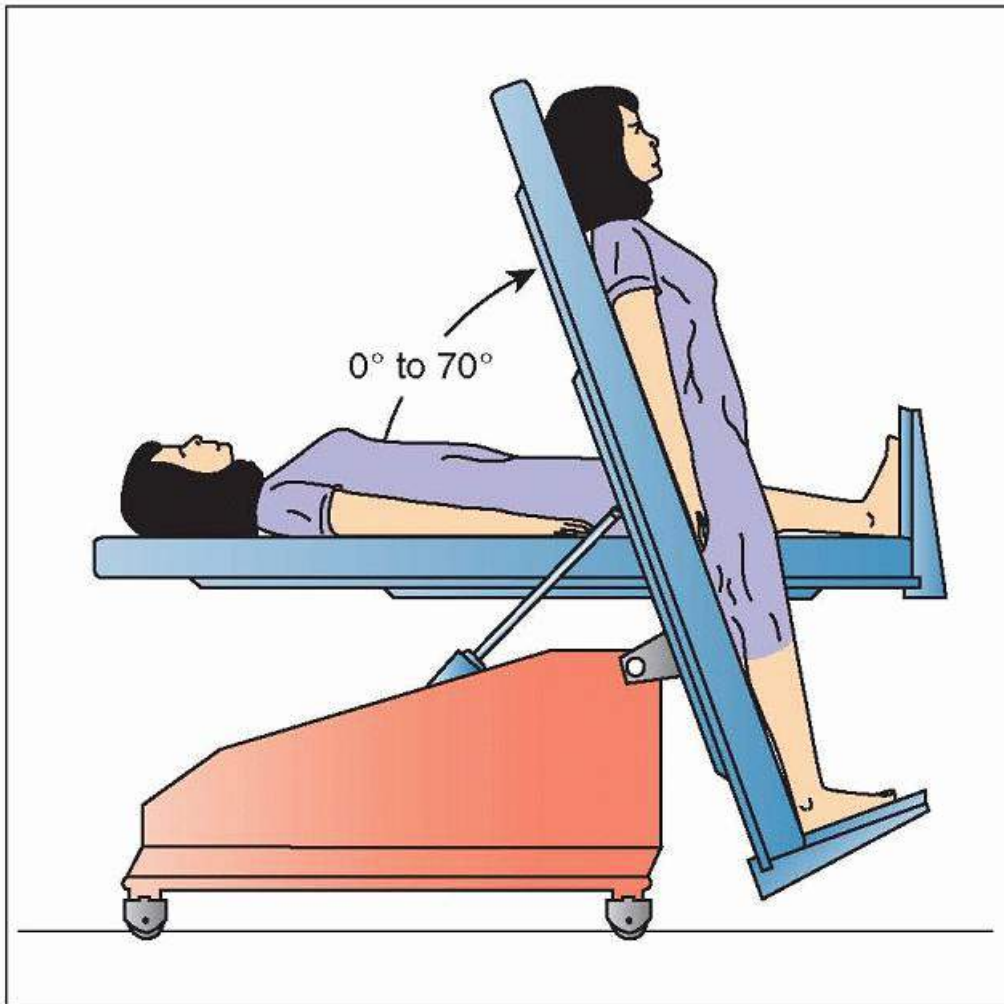

FIGURE 27.1 Tilt table.

Patients with autonomic failure often have impaired HR response despite orthostatic hypotension. In contrast, orthostatic intolerance (POTS) patients have excessive HR increases commonly defined as a 30-beats-per-minute (bpm) increase usually with a rate exceeding 120 bpm and induced symptoms. Asymptomatic orthostatic hypotension is prevalent, especially in elderly patients. Confirmation of benign, recurrent vasovagal syncope, which comprises the majority of unexplained recurrent syncopal cases, is the most frequent use of cardiologic tilt table testing. Unexplained noncardiac syncope is increasingly recognized in older patients, including reflex or situational triggers, carotid sinus hypersensitivity, and acute events with subclinical autonomic failure.

Multiple other techniques that test adrenergic responses have been devised. Orthostatic stress can be enhanced by lower body negative-pressure chambers but primarily only in research applications. The *sustained handgrip test* is performed by continual handgrip at 30% of maximal strength, which normally elevates diastolic BP by at least 10 to 15 mm Hg within 3 to 5 minutes; some normal controls, however, have minimal BP elevation. *Mental stress* is an older method to elevate BP that has unclear use. The *cold pressor test* is another long-standing means to elevate BP that is surprisingly still performed. The subject immerses a hand into ice water for 3 to 5 minutes and BP increases similar to the handgrip test are produced. Measurement of supine and standing *plasma norepinephrine* and other catecholamine levels is a somewhat useful but relatively insensitive marker of adrenergic function. In this circumstance, supine pressure levels characteristically are low and fail to increase adequately with upright tilting. Levels increase poorly with both central and peripheral causes of autonomic failure and rise excessively in pheochromocytoma and some forms of orthostatic intolerance. Nearly unrecordable norepinephrine and epinephrine and increased dopamine levels are characteristic of dopamine β -hydroxylase deficiency. *Microneurography* directly records sympathetic nerve traffic; insertion of a tungsten

microelectrode directly into a nerve fascicle enables recording bursts of muscle or skin sympathetic impulses. This powerful technique has important research applications but has limited clinical use and requires considerable expertise and specialized equipment.

TESTS OF SUDOMOTOR FUNCTION

Heat and cold intolerance are prevalent symptoms. Thermal homeostasis is a complex process that relies on both sweating and vasomotor control for heat elimination and shivering and nonshivering mechanisms for heat production and conservation. Disorders producing excessive sweating, with or without neurologic dysfunction, are generally treated by other specialties, usually dermatologists. Vasomotor assessment is possible using laser Doppler techniques but is not highly reliable; however, measurement of sweat gland activity and assessment of sweat gland innervation are commonly performed methods. Reproducible and generally accepted tests are discussed in this chapter.

The *quantitative sudomotor axon reflex test* (QSART) records chemically induced dynamic sweat output. The test basis is an axon reflex induced by chemically stimulating muscarinic eccrine sweat gland receptors with iontophoresed acetylcholine. This activation induces an antidromic response up a cholinergic axon and induces an orthodromic signal down to a different and isolated group of sweat glands. The sweat produced in this isolated chamber is measured over time. Denervated sweat glands fail to function. Testing requires specialized but commercially available equipment, is reproducible, and correlates variably with epidermal nerve fiber density skin biopsy analysis as a measure of small-diameter nerve integrity. Many, but not most, centers have the necessary equipment. The *thermoregulatory sweat test* (TST) assesses sweat output over the anterior body surface in response to a thermal stimulus. This approach uses a physiologic stimulus (core temperature increase) and simultaneously assesses wide areas of skin. An indicator dye, usually alizarin red and not iodine, is applied. The subject is heated to a predetermined degree in a temperature-controlled chamber and the color change is recorded. Abnormal patterns are readily apparent, but normal variant patterns can complicate interpretation. The test has limited availability, but a simpler more localized testing form is evolving. *Sweat imprint techniques* are additional sudomotor testing methods that rely on inducing sweat using heat or cholinergic agents and recording the resultant output on a recording medium; a special quickhardening silastic media is typical. Droplet numbers and density are later counted usually by automated and computerized methods using a confocal microscope. Sensitivity and specificity are similar to other methods.

The *sympathetic skin response* (SSR) is a simple to record, popular, and widely available technique well known for over a hundred years. The response, however, is a highly complex multisynaptic reflex with sudomotor activity as the final efferent arm. Both sweat glands and surrounding skin tissue provide the response generators. Interest stems primarily from the simplicity of recording and lack of need for specialized equipment. Multiple protocols are used with various methods. Electrical shock is the most common stimulus; other triggers include startle, cough, deep inspiration, and magnetic stimulation. Responses are best recorded over the palm and sole, ideally all four limbs simultaneously. The evoked amplitude is the most sensitive indicator but is variable and habituates with repeated trials. The range of reported normal values is correspondingly wide; no uniform methods or consensus normative values are accepted. Numerous pitfalls hamper meaningful SSR interpretation, so the test is not recommended in isolation. Anticholinergic medications dampen responses. Sensory deficits such as sensory neuropathy may blunt the noxious effect of electrical, but not respiratory, stimuli. Anxiety and distractions can produce unprovoked responses. Patients with hereditary

hyperhidrosis syndromes often have recurrent spontaneous discharges that can blunt measured responses. Responses from the palms are severely reduced or eliminated from sympathectomy but usually eventually return. In addition to epidermal nerve fiber density determination, some skin biopsy samples include sweat glands. The innervating nerves can be stained with PGP9.5 identically to small sensory nerve fibers. However, the simple

consensus rules used to count fibers are not applicable with these complex structures. Methods to estimate the density of innervation were devised and are commercially employed and available. Measures reliably distinguish patients with diabetic neuropathy from controls. Reduced sweat gland innervation also correlated with TST measures in one cohort of 10 patients. Other techniques to measure or image small nerve fibers are evolving.

OTHER ORGAN/SYSTEM-SPECIFIC TESTS

Multiple other systems are testable. Some measures are less reliable, difficult to perform, require special expertise, or need further evaluation. Some are performed by specialists in other fields, such as pupillography, gastrointestinal motility and manometry studies, cystometry and urodynamic studies, and sexual dysfunction testing.

USE IN CLINICAL PRACTICE

Current autonomic testing batteries have multiple well-validated, sensitive, and noninvasive tests available that can help confirm, quantify, and characterize clinical autonomic disorders. A multispecialty consensus panel in 2009 recommended that there is level B evidence of autonomic testing to be considered as part of a neuropathy evaluation, especially in the setting of suspected autonomic involvement and there is level C evidence for testing patients with purely sensory neuropathy. Autonomic testing is also potentially useful in the assessment of parkinsonian syndromes, multiple system atrophy, acute and chronic autonomic neuropathy, atypical syncope, and other disorders with suspected autonomic insufficiency or autonomic dysregulation. Multiple clinical syndromes can benefit from testing to guide symptomatic and disease-specific therapy and to aid with diagnosis and management.

Vision, Hearing, and Balance Testing

J. Kirk Roberts

INTRODUCTION

As with all neurologic complaints, diagnosis begins with a proper history and physical examination.

Appropriate testing supplements the examination and provides more refined measures of neurologic function and impairment. The neurologist may order or request testing that is performed by another physician or a technician in another specialty, or the neurologist may supervise, interpret, or perform the test. In either circumstance, the neurologist should understand the test and its appropriate use. This section will review some commonly performed vision, hearing, and balance tests.

VISION TESTING

VISUAL ACUITY

Visual acuity measures central or foveal vision. Testing usually involves reading letters of different sizes but may involve identifying other symbols. The Snellen chart, which uses letters, and the E chart, which uses the letter E in various orientations, are commonly used tests (Fig. 28.1). Testing is typically done at a distance, to approximate infinity, often 20 ft, and the smallest row read accurately is the visual acuity. If distance vision cannot be performed, then near vision may be tested at a distance of 15.7 inches. For those with such poor vision that the largest letter on the eye chart cannot be read, acuity can be recorded, in order of worsening vision by counting fingers, hand motion, and finally light perception or no light perception. So-called normal vision using the foot as the unit of measurement is defined as 20/20 and means the person can see detail at 20 ft that a person with normal eyesight would see at 20 ft. Thus, a person with 20/40 vision can see at 20 ft what a person with normal vision would see at 40 ft. In the metric system, normal visual acuity is reported as 6/6 (meters), and in the decimal system, normal eyesight is reported as 1.00. However, many have vision that is better than 20/20. Moreover, distance vision and near vision acuity may differ because of hyperopia, myopia, or presbyopia. Specialized testing has been developed to evaluate visual acuity in infants, preverbal children, and others who cannot identify the letters or symbols.

COLOR VISION

Color vision testing is most commonly evaluated with Ishihara plates. This test consists of a series of plates with colored dots with a pattern of different colored dots forming a number or a shape. This test was originally designed to test for congenital disease, which is most commonly red-green color deficiency. There are other tests of color vision that include blue-yellow testing. Congenital color vision deficiency is not rare and is more common in men than women. Acquired color vision deficiencies typically, although not strictly, divide into loss of red-green vision in optic nerve disorders and blue-yellow vision in retinal or macular disorders.

VISUAL-EVOKED POTENTIALS

Visual-evoked potentials (VEPs), also known as *visual-evoked responses* (VERs), are recorded by measuring brain electrical activity over the occipital lobe in response to repetitive visual stimulation (see Chapter 25). Typically, the P100 wave is the most useful response, and its latency and amplitude are measured. Responses, including latency and amplitude, are measured for each eye, with latency prolongation having the most clinical significance. Ocular, retinal, and visual pathway dysfunction may affect the VEP responses. For the neurologist, the VEP is most commonly used in the evaluation of optic neuritis, where there is a prolonged latency from one

eye and/or an elevated interocular latency, as long as ocular and retinal pathology has been excluded.

ELECTRORETINOGRAM

The flash electroretinogram (fERG) tests retinal function and is not affected by damage more central, such as in the optic nerve.

FIGURE 28.1 Snellen chart.

VISUAL FIELDS

Visual field testing is commonly performed in the neurologist office using finger motion and finger counting (see [Chapter 3](#)). More formal testing such as Goldman kinetic perimetry uses a test light of various sizes and intensities which is moved from the periphery to the center of the of vision and thus establishes a boundary of visual detection for each level of stimulus. Most visual field testing is now automated (e.g., Humphrey) with lights of varying intensities and sizes appearing in different areas of the visual field while the patient's eye is focused

on a specific spot (Fig. 28.2). Although the ophthalmologist uses visual fields to monitor a variety of eye conditions, the neurologist is generally monitoring them in patients with occipital lesions or pituitary lesions with pressure on the optic nerve or chiasm.

OPTICAL COHERENCE TOMOGRAPHY

Optical coherence tomography (OCT) is a relatively recent test that uses light scattering to produce cross-sectional images of the retina with a resolution that allows evaluation of the different layers. It has been used in neurologic applications to measure the retinal nerve fiber layer which reflects the state of the optic nerve. It is reduced, for example, in patients with multiple sclerosis with optic neuritis.

HEARING TESTING

AUDIOGRAM

The audiogram or pure tone testing plots the threshold of hearing in decibels (dB) with standardized frequencies, typically from 125 Hz to 8 kHz. Normal hearing is typically better than 15 dB. Each ear is tested, and both air and bone conduction hearing may be tested. Speech audiometry evaluates how softly someone is able hear words and to understand them. Impedance audiometry includes tympanometry, which measures the changes in acoustic impedance with changes in air pressure and basically measures the compliance of the eardrum.

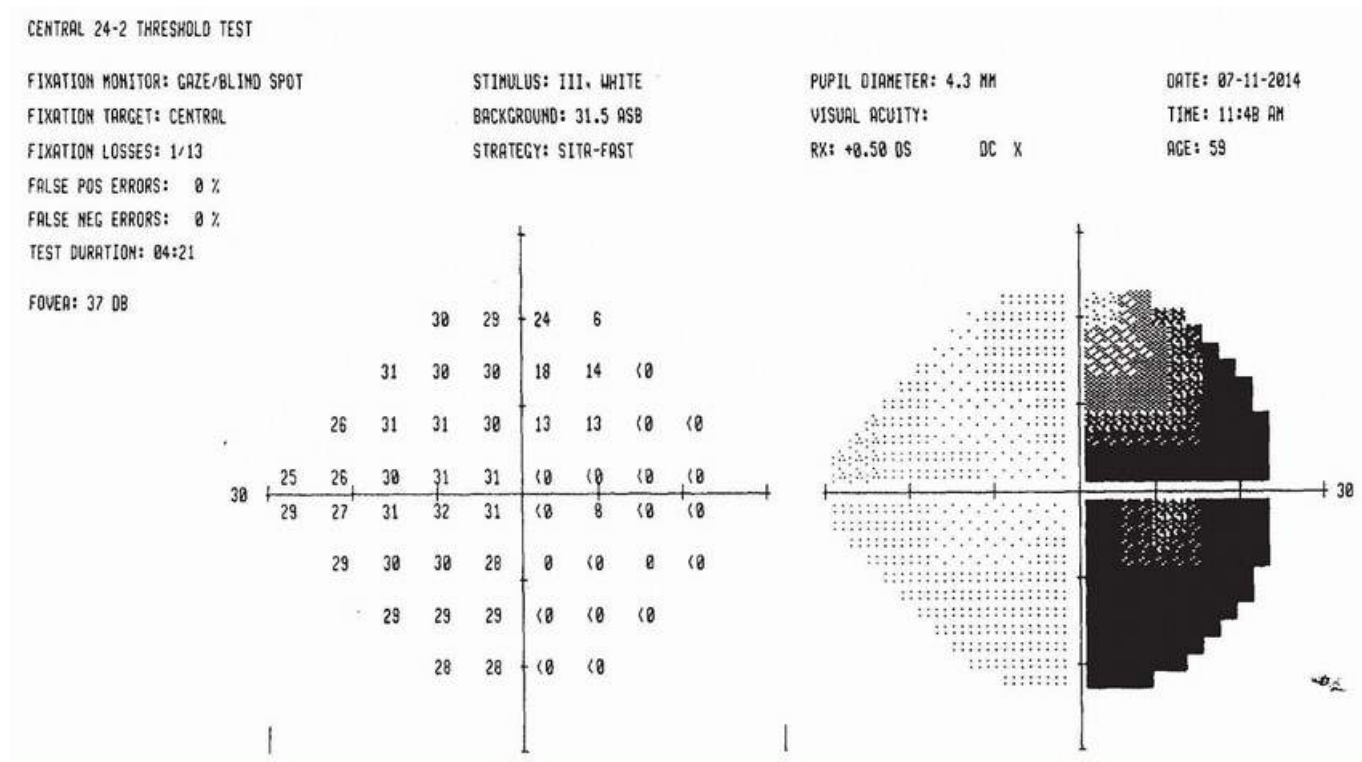

FIGURE 28.2 Computerized automated visual field report showing a right homonymous hemianopia.

BRAIN STEM AUDITORY-EVOKED POTENTIALS

Brain stem auditory-evoked potentials (BAEPs), also known as *brain stem auditory-evoked responses* (BAERs) or *auditory brain stem responses* (ABRs), are the auditory equivalent of the VEP (see Chapter 25). In this test, the patient listens to auditory clicks, and electrical responses are generated at specific anatomic points along the auditory pathway: wave I at the cochlear nerve, wave III at the superior olivary nucleus, and wave V at the inferior colliculi. BAEPs were typically used in the diagnosis of multiple sclerosis and in the evaluation for an acoustic neuroma, but magnetic resonance imaging (MRI) has largely supplanted this testing. Electrocochleography (ECOG) is another evoked potential measuring the electrical response of the cochlea to sound. It is used to aid in the diagnosis of Ménière syndrome and in perilymph fistula, although its use is controversial. Otoacoustic

emissions (OAEs) measure sounds produced by the ear and are useful in that, if present, indicate a relatively normal functioning cochlea with at least near-normal hearing. However, they are not that helpful in determining the cause of hearing loss.

BALANCE TESTING

ELECTRONYSTAGMOGRAPHY/VIDEONYSTAGMOGRAPHY

Electronystagmography (ENG), which uses electrodes to record eye movements, has largely been supplanted in clinical practice by videonystagmography, in which goggles with infrared cameras

P.233

are used to track eye motion (Fig. 28.3). The test can be divided into three components: ocular motor testing, tests for spontaneous and positional nystagmus, and caloric testing. Ocular motor testing measures saccade velocity, accuracy, and latency along with gain for smooth pursuit and optokinetic nystagmus. The second part includes an evaluation for spontaneous nystagmus with and without fixation. Positional testing includes the Dix-Hallpike maneuver and lateral head and body turn looking for nystagmus associated with canalolithiasis or cupulolithiasis in the posterior, lateral, or anterior canal. Lastly, bithermal caloric testing is completed to evaluate the response of the vestibular system. Conventionally, water irrigation is used, but more and more are using air because of the ease of performing. The vestibular system generates the slow phase, and the velocity of the slow phase is measured in degrees per second, and the responses between the two ears are compared. More specifically, Jongkees formula is used to calculate a relative vestibular reduction by subtracting the sum of the left cool and left warm response from the sum of the right cool and right warm response and then dividing by the sum of all four responses. More than 20% to 25% asymmetry is considered abnormal. Bilateral dysfunction can be suggested by markedly reduced responses (sum total responses <20 degrees per second), but this might also be due to anatomic or technical issues. The use of air, which is potentially less stimulating than water, is of particular concern in this setting.

FIGURE 28.3 Videonystagmography.

ROTARY CHAIR

Rotary chair testing adds additional certainty to vestibular testing particularly if the ENG is inconclusive and most importantly if bilateral vestibular dysfunction might be present. The rotary chair may also be useful if mechanical obstruction of the ear canal impedes ENG bithermal caloric testing. As it sounds, in this test, a patient is rotated while eye movements are recorded. The chair is moved either sinusoidally or with step changes in velocity, and eye movements are recorded for gain, phase, and symmetry. Responses to optokinetic stimulation and a test of visual fixation suppression are also measured. In a patient with bilateral vestibular dysfunction, for example, gain is reduced, and there is a phase lead. Although patients with unilateral vestibular dysfunction may also show abnormalities of gain and phase, rotary chair testing is not sensitive to the side of the dysfunction.

VESTIBULAR-EVOKED MYOGENIC POTENTIALS

Vestibular-evoked myogenic potentials (VEMPs) are a relatively less commonly used test meant to evaluate the saccule and the inferior vestibular nerve. In this test, the response of the sternocleidomastoid to auditory stimuli is recorded. Of note, hearing does not seem necessary for VEMPs. In general, VEMPs are considered abnormal if there is a significant asymmetry or they are low or absent. In addition, thresholds to generate VEMPs may be abnormally low in patients with perilymphatic fistula or superior canal dehiscence. Some have reported that VEMPs are low or have a higher threshold in Ménière syndrome, but their use in diagnosing this disorder is questionable. Similar responses may also be seen in muscles other than the sternocleidomastoid, such as the eye muscles.

COMPUTERIZED DYNAMIC POSTUROGRAPHY

Computerized dynamic posturography (CDP) attempts to quantify balance disorders. In this test, the patient stands on a horizontal platform, which can translate or incline, along with measuring the forces exerted by the patient's feet, and can also alter the visual surround. Testing systems that do not include all of the mentioned are less useful. A common testing protocol includes the sensory organization test, which includes six subtests. The subtests grow progressively more difficult by altering the conditions including eyes open or closed, flat or tilted floor, and vertical or tilted visual surround. CDP is not necessarily abnormal in those with vestibular disorders and is therefore complementary to vestibular testing.

Sleep Studies

Andrew J. Westwood

Carl W. Bazil

INTRODUCTION

The National Institutes of Health estimate that 50 to 70 million Americans are affected by sleep problems (see [Chapter 114](#)). Sleep deprivation and disorders have been linked to chronic medical diseases such as stroke and diabetes but also to mental health issues and to an increased risk of accidents, particularly motor vehicle accidents. Lack of sleep is not a trivial concern as many patients (and physicians) perceive; it is a very real public health problem.

Evaluation of sleep is complex and is a multidisciplinary analysis. Given the vast spectrum of sleep problems such as sleep-disordered breathing, parasomnias, insomnia, narcolepsy, bruxism, nightmare disorder, circadian rhythm disorders, and nocturnal enuresis, several medical specialties, dentists, and psychologists take an interest in sleep disorders. For physicians, subspecialty certification in sleep medicine can be obtained following primary certification in anaesthesia, internal medicine, pediatrics, neurology, psychiatry, or otolaryngology. Although detailed medical history and examination are critical in the diagnostic evaluation, subjective reports of sleep concerns are marred by recall bias because the primary problem often occurs during sleep such that the patient may be partly or completely unaware of the problem, and observations by bed partners or housemates will also be limited. Validated questionnaires and sleep logs (including those now available as smartphone applications) provide somewhat more detailed, albeit still subjective, information about sleep and can be helpful. For many disorders, however, testing is required for more objective evaluation of physiologic parameters in sleep and to direct correct treatment.

INDICATIONS FOR DIAGNOSTIC SLEEP TESTING

The need for diagnostic testing, and the specific test required, depends on the clinical suspicion and the question at hand. In general, sleep tests evaluate the quality and quantity of sleep along with other physiologic parameters. The major tests used include polysomnography, a measure of overnight sleep and associated phenomena; multiple sleep latency testing, a measure of the ability to fall asleep during the day; and maintenance of wakefulness test, a measure of the ability to stay awake during the day. Additionally, actigraphy uses movement as a surrogate for sleep and can give useful information about sleep patterns over days to weeks. Each of these will be discussed in detail in the following text.

Polysomnography is not usually indicated for suspected insomnia (delayed or interrupted sleep) or circadian rhythm disturbances, as these are generally diagnosed by history. However, if the condition remains refractory to treatment, polysomnography may be indicated to look for other causes. Obstructive sleep apnea is probably the most common reason for overnight polysomnography, as testing is required for diagnosis no matter how high the suspicion. Signs of sleep apnea include excessive daytime somnolence, snoring, morning headache, frequent nocturia, obesity, and a narrow airway; however, all are rarely present in a given individual. Restless legs syndrome is a clinical diagnosis wherein the patient is aware of uncomfortable sensations in the limbs (usually legs but sometimes arms or trunk) that keep him or her awake at night. This may be treated without testing; however, many of these patients will also have periodic limb movements—repetitive movements during sleep that are typically unrecognized by the patient or bed partner and can result in unrefreshing sleep. Periodic limb movements can also occur in the absence of restless legs syndrome. Suspected narcolepsy requires

polysomnography to ensure the absence of other causes of sleepiness. This is followed by multiple sleep latency testing; very short sleep latency and presence of rapid eye movement (REM) in more than one nap are highly suggestive of narcolepsy. Parasomnias may sometimes be diagnosed without testing, but due to the possible confusion between them, association with other sleep disorders such as obstructive sleep apnea, and differential diagnosis that sometimes includes nocturnal seizures, polysomnography is often advisable. Parasomnias include night terrors, rhythmic movement disorder, and sleepwalking (especially in adults) and REM behavior disorder. When nocturnal seizures are in the differential, polysomnography should be performed with simultaneous video electroencephalography (EEG).

POLYSOMNOGRAPHY

The in-laboratory polysomnogram is the gold standard diagnostic test of most sleep disorders (Table 29.1). Clinical polysomnography consists of the simultaneous recording of multiple physiologic variables, allowing objective documentation of sleep state and for evaluation of common sleep disorders. Practitioners will routinely use a minimum of four EEG channels, covering the occipital and central regions required for scoring of sleep, but most will use more. Electro-oculography (EOG); mentalis electromyography (EMG); surface EMG of the anterior tibial muscles for detection of leg movements in sleep; electrocardiography (ECG); and measurement of nasal and oral airflow, respiratory effort, and oxygen saturation as well as audio and video recording are also standard. Additional variables analyzed may include CO₂ monitoring and esophageal manometry.

The recordings are analyzed at 30-second intervals or epochs. Each epoch is evaluated based on muscle tone, EOG, and EEG to determine sleep stage or wakefulness. Each epoch is also evaluated for abnormalities in respiratory flow/pressure, oxygen saturation, heart rate, and any movements (Fig. 29.1). The American Academy of Sleep Medicine provides guidance on recommended scoring for sleep stage, respiratory disturbances (apneas, hypopneas, respiratory-related arousals), as well as limb movements. Once each epoch has been analyzed, a convenient way to display this significant amount of data is the hypnogram. This can show the macroarchitecture over the course of the entire night and can

P.235

be modified to provide additional information such as timings of respiratory disturbances and body position.

TABLE 29.1 Indications for Polysomnography

- Diagnosis of sleep-related breathing disorders
- PAP titrations for sleep-related breathing disorders
- Preoperative evaluation prior to upper airway surgery for snoring or obstructive sleep apnea
- Follow-up after good clinical response to oral appliance treatment
- Follow-up after surgical treatment
- Recurrence of symptoms despite initial response to surgical or dental treatments
- Follow-up in patients with substantial weight loss after PAP initiation

-
- Follow-up in patients with substantial weight gain after PAP initiation
-
- Insufficient response to PAP therapy despite a good initial response
-
- Patients with systolic or diastolic heart failure with sleep complaints despite optimal cardiac treatments
-
- Patients with neuromuscular disorders and sleep complaints despite optimal sleep hygiene
-
- Narcolepsy (followed by MSLT)
-
- Periodic limb movement disorder
-
- Uncertainty of restless legs syndrome

PAP, positive airway pressure; MSLT, multiple sleep latency test.

Based on Kushida CA, Littner MR, Morgenthaler T, et al. Practice parameters for the indications for polysomnography and related procedures: an update for 2005. *Sleep*. 2005;28(4):499-521.

Polysomnography must always be interpreted in the context of potentially relatable history. Therefore, patients should ideally fill out sleep logs for at least 1 week prior to the test. Medications and napping on the day of the study should be noted, and it is often helpful to have the patient's impression of his or her sleep during the study. A patient with 6 hours of documented sleep on polysomnography who believes only 1 to 2 hours of sleep occurred likely has a diagnosis of paradoxical insomnia.

EVOKING PARASOMNIAS

Parasomnias such as sleepwalking and sleep terrors typically arise from slow-wave sleep (stage N3). They may not occur on a nightly basis. In order to increase the yield of recording such events, a patient may sometimes be asked to restrict his or her sleep the night prior in order to provoke a rebound of slow-wave sleep. There is some data that deliberate external stimuli, such as sound, during slow-wave sleep may also cause provocation of the events.

EVALUATING RAPID EYE MOVEMENT BEHAVIOR DISORDER

Recording of dream enactment behavior during REM sleep ([Fig. 29.2](#)) is helpful, however not required to support a diagnosis of REM behavior disorder. One of the cardinal features of this disorder is the lack of atonia during REM sleep. Atonia is usually identified in the chin lead; however, it may be present in one or more limb leads. Some practitioners may apply additional leads to all four extremities in cases where REM behavior disorder is a concern. It is important to note that melatonin can suppress the atonia and should be stopped prior to the study.

PORTABLE POLYSOMNOGRAPHY MONITORING

Obstructive sleep apnea is a prevalent condition within the general population. In those with no significant comorbidities such as neuromuscular weakness, heart failure, seizure disorder, or morbid obesity, a

simplified version of the in-laboratory polysomnogram may be warranted. There are many devices for the ambulatory polysomnogram, or home sleep test, and can range from detecting three variables (typically oxygen saturation, pulse, and flow) to a thorough evaluation including ECG and EEG. The benefits of the test are typically in cost-saving as well as being beneficial for individuals who may not sleep well in unknown environment. As portable testing typically does not allow reliable sleep scoring and does not include video or limb EMG, it is not indicated for evaluation of suspected parasomnias, REM behavior disorder, or periodic limb movement disorder.

This home version can be a useful screening tool for obstructive sleep apnea but can lack sensitivity, as it yields limited data in many cases because it relies on the individual to comment if they were asleep and readjust the equipment themselves. In-laboratory polysomnography may be required if the study remains unrevealing or if the apnea-hypopnea index is borderline, yet suspicion for obstructive sleep apnea remains high. Subsequent in-laboratory testing is also needed if portable testing is negative for obstructive sleep apnea and evaluation is then required for other sleep disorders.

OTHER DIAGNOSTIC SLEEP TESTS

MULTIPLE SLEEP LATENCY TEST

Patients with excessive daytime sleepiness may be evaluated by the multiple sleep latency test (MSLT), a series of five nap opportunities (sometimes four or six) with sleep recordings at 2-hour intervals throughout the day. “Normal” sleep for that individual is recommended for 7 days prior to the test and any medications that can disrupt sleep architecture, particularly antidepressants, should ideally be discontinued 2 weeks prior to the study. Polysomnography should be performed the night prior to testing so that prior sleep is documented. If significant obstructive sleep apnea is noted on polysomnography, the MSLT is typically not performed. A minimum of 6 hours of sleep should occur during polysomnography to reliably proceed with an MSLT.

Sleep onset is defined as the first epoch of nonwakefulness. The nap is terminated 15 minutes after sleep onset. If no sleep occurs, each recording session is terminated after 20 minutes. The sleep latency (the time it takes to fall asleep) is determined for each nap and provides an objective measure of daytime sleepiness. If no REM sleep occurs in four naps, the test may be terminated. Similarly, if REM occurs in at least two of four naps, testing is considered complete. If, however, REM has occurred in only one of four naps, the patient is generally given the fifth nap in order to determine whether narcolepsy is likely.

Sleep latency over the course of the naps is averaged (20 minutes is used as time onset if the patient does not fall asleep). Additionally, any REM periods are counted; REM within 15 minutes is considered abnormal. These are described as sleep-onset rapid eye movement periods (SOREMPs). If an SOREMP is obtained in the prior night polysomnography, this can also be taken into consideration.

FIGURE 29.1 A: A 4-minute recording of stage R (REM sleep) showing cessation of airflow with continued abdominal and chest movements during apneic pauses illustrated by the *red arrows*. Note the snoring ceases with airflow and oxygen saturation declines. This is consistent with obstructive sleep apnea. **B:** A 4-minute recording of N1 and N2 (non-REM sleep) showing cessation of airflow and abdominal and chest movements illustrated by the *red arrows*. This is consistent with central sleep apnea. EEG, electroencephalography; ECG, echocardiography; O₂, oxygen.

FIGURE 29.2 Single epoch of phasic R sleep (*red arrows* indicate rapid eye movements) with movements of both the left and right legs (*blue arrows*). EEG, electroencephalography; ECG, echocardiopgraphy; O₂, oxygen.

The main indication of this study is to support the diagnosis of narcolepsy. Individuals with narcolepsy tend to have mean sleep latencies of 3 ± 3 minutes. However, 16% of normal individuals will have a sleep latency of less than 5 minutes. Patients with narcolepsy typically have a mean sleep latency of less than 8 minutes and demonstrate at least two naps with sleep-onset REM. Although there is significant overlap of the mean sleep latencies of normal individuals and those who complain of excessive sleepiness, normal is considered to be a mean sleep latency of greater than 10 minutes.

SOREMPs can also be seen as a result of obstructive sleep apnea, sleep deprivation, drugs/drug withdrawal, or narcolepsy; in these cases, only one is typically seen in an MSLT. Two SOREMPs have 78% sensitivity and 93% specificity for narcolepsy. Notably, no large systematically collected repository of normative MSLT data is known to exist, and normal values for individuals younger than 6 years of age have not been established.

MAINTENANCE OF WAKEFULNESS TEST

The maintenance of wakefulness test (MWT) measures the time a patient is able to remain awake in a low-light environment during four 40-minute (sometimes 20-minute) attempts. The patient is instructed to remain awake in a semirecumbent position, without any stimulating behaviors. The test may provide more information about the patient's ability to sustain wakefulness, but the validity of test results to real-life experience is unclear. It is sometimes used to evaluate driving performance in individuals who may be at high risk of daytime sleepiness.

Sleep onset is defined as three epochs (90 seconds) of continuous stage 1 sleep or one epoch of any other stage of sleep. A total of 97.5% of normal sleepers stay awake for an average of 8 minutes or more during the MWT. Falling asleep in an average of less than 8 minutes during the test would be considered abnormal. Results show that from 40% to 59% of people with normal sleep stay awake for the entire 40 minutes of all four trials.

EVALUATION OF CIRCADIAN RHYTHM DISTURBANCES

As well as the intrinsic characteristic of a person's sleep, extrinsic factors placed on the timing of the sleep-wake cycle may disrupt the ability of an individual to sleep when necessary. Several variants have been described including the delayed and advanced sleep phase syndromes, shift work disorder, and jet lag disorder. Diagnosis

may be made simply through history taking; however, patient recall of sleep patterns over time may be limited and there are instruments that may be useful to support the diagnosis.

ACTIGRAPHY

The essence of actigraphy is based on the concept that movement is limited during sleep. A device typically worn on the nondominant wrist monitors movement over a specific duration of time, typically up to 2 weeks, and is typically correlated to a diary of activity (Fig. 29.3). The parameters on some devices can be used to assess specifics such as the frequency of limb movements that occur during sleep. Studies that compare actigraphy to sleep with polysomnography show that it is a reasonable, although not perfect, surrogate measurement for sleep. It is clearly not practical (or necessary) to do formal polysomnography for weeks at a time to determine sleep patterns.

Many commercially available applications now use the principle of actigraphy to allow patients to track their sleep. Actigraphy applications using smartphone accelerometers have limited use, as most require movement of the bed rather than the person, and are

P.238

not well correlated with actual sleep. In contrast, other linked accelerometry devices may be worn on the body (typically the arm); these are likely reasonably similar to actigraphy and have potential to be viewed by the clinician to help with diagnosis and to monitor treatment progress.

FIGURE 29.3 Actogram of activity for 12 days. Each day is plotted on a row and quantity of movement is indicated by *black*. This is typically correlated with a log by the individual. Periods with limited movement likely correlate with sleep (*red arrows*). Periods of absolute lack of movement (*red stars*) suggest removal of the watch.

BIOMARKERS OF CIRCADIAN RHYTHM

Several variables are used to evaluate the sleep-wake rhythm, principally for research purposes and to a lesser extent in clinical practice. Melatonin or its metabolites can be measured in the urine, blood, or saliva. Melatonin secretion begins in the evening hours and peak overnight. During the daytime hours, levels are barely detectable. Dim light melatonin onset (DLMO) is the point at which melatonin levels reach 2 pg/mL in plasma or 4

pg/mL in the saliva. It can also be measured as the mean of three daytime samples plus two times the standard deviation of these three daytime samples. It typically occurs 2 hours before bedtime provided that lighting is dim. DLMO is considered the standard measure of circadian pattern. For example, a patient with delayed sleep phase phenomenon would have very late DLMO (3 to 5 am). A patient with shift work sleep disorder would continue to show DLMO during the typical work shift.

Core body temperature usually peaks in the late afternoon. Sleep typically occurs on the downward slope and ends about 2 hours following the nadir. Loss of normal core body temperature rhythm can be diagnosed with continuous temperature monitoring, but this is not a convenient method for determining circadian pattern clinically.

SUBJECTIVE REPORTING OF SLEEP

In addition to reports of sleep complaints, a patient can keep a log of their sleep-wake cycle over time (Fig. 29.4). This can be used in combination with actigraphy, particularly when evaluating for paradoxical insomnia. It can also be used to visually evaluate potential sleep-wake disorders as well as help to ensure the patient is getting sufficient sleep prior to polysomnography, which may otherwise alter sleep architecture.

Many questionnaires related to sleep exist, with most particularly focusing on obstructive sleep apnea or snoring, whereas others may evaluate the quality of sleep, degree of sleepiness, or the inability to sleep. A frequently used questionnaire in many practices is the Epworth Sleepiness Scale. Rating eight situations on a scale of 0 to 3 for severity of sleepiness results in a possible total of 24. A level of 10 or more typically indicates excessive sleepiness. Persons with narcolepsy may have scores around 16, although this is varied between individuals. Not only is it used for diagnostic purposes but can also be quickly and easily used to monitor efficacy of treatment. It is important to know that the Epworth shows very limited correlation with the objective sleepiness seen on MSLT. Patients with severe sleepiness due to obstructive sleep apnea, for example, may be observed to fall asleep in the waiting room but score normally on the Epworth. This supports that patients are often unaware or in denial of their own sleepiness; nevertheless, the Epworth can be useful in documenting a patient's perception of his or her drowsiness.

Other questionnaires are typically used as a screening tool for potential sleep disorders. There are over 14 questionnaires that

P.239

exist for the evaluation of sleep-disordered breathing. Although many can help increase the sensitivity for sleep apnea, the diagnosis can only be made through the use of polysomnography. There are also at least five available questionnaires to evaluate for REM sleep behavior disorder but ultimately, a polysomnogram determines the diagnosis and excluded mimickers such as periodic limb movement disorder or obstructive sleep apnea.

FIGURE 29.4 Sleep diary. The individual is asked to shade the boxes indicating their estimated sleep. Here, the individual has a delayed sleep phase syndrome typically not sleeping until 2 am or later. Note that on the day of a nap in the afternoon, the individual remains awake during the typical hours of sleep. Further information could be added such as time of medication, times of caffeine intake or exercise, and time getting into and out of bed.

OTHER LABORATORY TESTING

NARCOLEPSY

In rare circumstances or for research purposes, laboratory tests may be useful to confirm a suspicion of narcolepsy. In individuals who have narcolepsy type 1 (associated with cataplexy), a lumbar puncture can be performed. Cerebrospinal fluid (CSF) levels of hypocretin-1 of less than 110 ng/mL are diagnostic with 87% sensitivity and 99% specificity for narcolepsy type 1. The majority of patients with idiopathic hypersomnia and narcolepsy type 2 have normal CSF hypocretin-1 levels. Genetic testing can also be helpful in some circumstances. The allele HLA-DQB1*0602 is present in over 90% of individuals with narcolepsy type 1, 56% of type 2 narcolepsy, and 52% of individuals with idiopathic hypersomnia. However, it is found in between 12% and 35% of healthy individuals.

RESTLESS LEGS SYNDROME

Restless legs syndrome (RLS) is a clinical diagnosis based on an urge to move limbs (not necessarily legs or a leg) that is typically worse in the evening or inactivity that is temporarily relieved by movement and not due to position, cramps, or pain (see [Chapter 75](#)). Secondary causes may include anemia, uremia, thyroid dysfunction, or venous disease. Of particular note is that a ferritin level of less than 50 µg/L, sometimes 75 µg/L despite being considered to be within the normal range, is treated with exogenous iron supplementation. Single nucleotide polymorphisms in some genes have been associated with an increased risk of RLS; however, these are not diagnostic. For example, variants in the gene BTBD9 can be seen in 75% of individuals with RLS but also in 65% of those who have never had the syndrome.

IMAGING

Imaging is not routinely performed as part of a workup for sleep disturbances. However, rare presentations of

narcolepsy have resulted from strokes or demyelinating lesions in the brain stem. Hypoperfusion in the thalami of individuals with Kleine-Levin syndrome during symptomatic periods can be seen on singlephoton emission computed tomography (SPECT) or positron emission tomography (PET) imaging. Brain imaging should be considered in any individual with respiratory arrests not typical of obstructive sleep apnea or that occur during wakefulness. In a subset of individuals with congenital central hypoventilation syndrome—respiratory arrests during sleep, typically seen in childhood as a result of inborn failure of autonomic control of breathing—there is a higher incidence of neural crest tumors such as neuroblastomas.

Neuropsychological Evaluation

Yaakov Stern

INTRODUCTION

Before the availability of high-resolution imaging, neuropsychological evaluation played a role in lesion localization. Currently, neuropsychological testing remains a valuable adjunct to neurologic evaluation, assisting in the diagnosis of dementia and in evaluating or quantifying cognition and behavior in development, brain diseases, and clinical treatment, as well as in research.

STRATEGY OF NEUROPSYCHOLOGICAL TESTING

Conditions that affect the brain often cause cognitive, motor, or behavioral impairment that can be detected by appropriately designed tests. Defective performance on a test and certain patterns of test performance may suggest specific pathology. Alternatively, patients with known brain changes may be assessed to determine how the damaged brain areas affect specific cognitive functions. Before relating test performance to brain dysfunction, however, other factors that affect test performance must be considered.

Typically, test performance is compared with normal values derived from populations similar to the patient in age, education, socioeconomic background, and other variables. Scores significantly below the mean expected values imply impaired performance. Performance sometimes can be evaluated by assumptions about what might be expected from the average person (e.g., repeating simple sentences or simple learning and remembering).

Unfortunately, comparable data may not exist for the patient being tested. This problem is common in the elderly and those with language and cultural differences. This situation may be addressed by collecting local, normal characteristics that are more descriptive of the local clinical population or by evaluating the cognitive areas that remain intact. In this way, the patient guides the clinician in terms of the level of performance that should be expected in possibly affected domains. Other factors that also influence test performance include the patient's current mood, anxiety, depression or other psychiatric disorders, medication, and the patient's motivation to participate fully.

Patterns of performance, such as strengths in some cognitive domains and weaknesses in others, have been associated with specific conditions based on empiric observation and knowledge of the brain pathology associated with those conditions. Observation of these patterns may aid in diagnosis.

TEST SELECTION

Neuropsychological tests in an assessment battery come from many sources. Some were developed for academic purposes (e.g., intelligence tests) and others for experimental psychology. The typical clinical battery consists of a series of standard tests that have been proved useful and are selected for the referral issue. These tests should have established reliability and validity. A tradeoff exists between the breadth of application and ease of interpretation, available from standard batteries, and the ability to pinpoint specific or subtle deficits offered by more experimental tasks that are useful in research but have not yet been standardized.

Most tests are intended to measure performance in specific cognitive or motor domains, such as memory, spatial ability, language function, or motor agility. These domains may be subdivided (e.g., memory may be considered verbal or nonverbal; immediate, short term, long term, or remote; semantic or episodic; public or autobiographic; or implicit or explicit). However, no matter how focused a test is, multiple cognitive processes are likely to be invoked. An ostensibly simple task, such as the Wechsler Adult Intelligence Scale (WAIS) Coding subtest

(previously called *Digit Symbol Coding*), which uses a table of nine digit-symbol pairs to fill in the proper symbols for a series of numbers, assesses learning and memory, visuospatial abilities, motor abilities, attention, and speeded performance. In addition, tests may be failed for more than one reason: Patients may draw poorly because they may not appreciate spatial relationships, because they plan the construction process poorly, or because they are distractible or lack motivation. Relying solely on test scores may lead to spurious conclusions.

TESTS USED IN A NEUROPSYCHOLOGICAL EVALUATION

INTELLECTUAL ABILITY

Typically, a test such as the WAIS-IV or the Wechsler Intelligence Scale for Children-IV is used to assess the present level of intellectual function for adults and children respectively. These tests yield a global IQ score and index scores that are standardized, so that 100 is the mean expected value at any age (with a standard deviation of 15).

The WAIS-IV consists of 10 core and 5 supplemental subtests (Table 30.1). The 10 core subtests comprise the full scale IQ. In previous WAIS versions, verbal and performance IQ estimates were calculated. In contrast, the WAIS IV emphasizes a set of index scores based on groups of subtests, each assessing a broad, separate class of cognitive abilities. These include Verbal Comprehension, Perceptual Reasoning, Working Memory, and Processing Speed. The WAIS-IV also adds a General Ability Index, which consists of selected subtests from the Verbal Comprehension and the Perceptual Reasoning subtests. The intention of this index score is to assess cognitive abilities that are not as susceptible to changes in processing speed and working memory. For the individual subtests, scaled scores range from 1 to 19, with a mean of 10 and a standard deviation of 3; the average range for subtest scaled scores is from 7 to 13.

The overall IQ and index scores supply summary information about the level of general intelligence and broad ability categories. The neuropsychologist is often more interested in the “scatter” of subtest scores, which indicates strengths and weaknesses.

P.242

The subtests are often better considered as separate tests, each assessing specific areas of cognitive function. There are many other tests of general intelligence, including some that are nonverbal.

TABLE 30.1 Subtests of the Wechsler Adult Intelligence Scale-IV Arranged by the Four Index Groups

Verbal Comprehension	Verbal Concept Formation, Verbal Reasoning, Knowledge Acquired from Environment
Similarities	Derive relevant superordinate category or similarity for word pairs; abstract verbal reasoning
Vocabulary	Name pictures and define words; often used to assess “premorbid” level of ability
Information	Answer questions that address a broad range of general knowledge topics; ability to acquire, retain, and retrieve general factual knowledge
(Comprehension)	Answer questions based on understanding of general principles and social situations

Perceptual Reasoning	Perceptual and Fluid Reasoning, Spatial Processing, Visual-Motor Integration
Block design	Arrange blocks with red, white, and half-red and half-white sides to form 14 designs; spatial perception, visual abstract processing, and problem solving
Matrix reasoning	Identify the picture that completes a pattern using pattern completion, classification, analogy, or serial reasoning; classic measure of fluid intelligence
Visual puzzles	View a completed puzzle and select three response options that, when combined, reconstruct the puzzle; visual perception and organization, nonverbal reasoning
(Picture completion)	Determine the missing feature in pictures; visual perception
(Figure weights)	View a scale with missing weight(s) and select the response option that keeps the scale balanced; quantitative and analogical reasoning
Working Memory	Attention, Concentration, Mental Control, Reasoning
Digit span	Standardized assessment of digits forward and backward. In addition, hear a sequence of numbers and recall those numbers in ascending order; attention, concentration, mental control
Arithmetic	Verbal arithmetic problems; mental manipulation, concentration, attention, short- and long-term memory, numeric reasoning ability
(Letter-number sequencing)	Listen to a combination of numbers and letters and recall first the numbers in ascending order and then the letters in alphabetical order. Sequential processing, mental manipulation, attention, concentration, memory span, short-term auditory memory.
Processing Speed	Ability to Quickly and Correctly Scan, Sequence, and Discriminate Simple Visual Information, Short-Term Visual Memory, Attention, Visual-Motor Coordination
Symbol search	Scan a search group and indicate whether one of the symbols in the target group matches; processing speed, visual discrimination
Coding	Using a key, copy symbols that are paired with numbers; processing speed, short-term visual memory
(Cancellation)	Scan a structured arrangement of shapes and mark target shapes; processing speed, visual selective attention

Supplementary subtests are indicated by parentheses. Comments describe the subtests and identify

some select cognitive features that they tap.

MEMORY

The subclassifications of memory have evolved from clinical observation and experimentation; most are important to the assessment (Table 30.2).

For example, preservation of remote memories, despite the inability to store and recall new information, is the hallmark of specific amnesic disorders. Other subclassifications are used to evaluate different clinical syndromes.

PROCESSING SPEED

Processing speed is defined as either the amount of time it takes to process a set amount of information or the amount of information that can be processed within a certain amount of time. In the WAIS IV, it is assessed with the Coding and Symbol Search subtests. Another commonly used test is pattern comparison, where two patterns are presented and the test taker must decide as quickly as possible if they are the same or different.

PERCEPTUAL

Neuropsychologists may provide a standardized version of neurologists' perceptual tasks: double (simultaneous) stimulation in touch, hearing, or sight; stereognosis; graphesthesia; spatial perception; or auditory discrimination.

VISUAL PERCEPTUAL AND CONSTRUCTION

Some tasks tap basic perceptual abilities. For example, the Benton Judgment of Line Orientation test assesses a person's ability to match the angle and orientation of lines.

Construction, typically assessed by drawing or assembly tasks, requires both accurate spatial perception and an organized

P.243

motor response. The Block Design subtest of the WAIS-IV is example of an assembly task. In the Rey-Osterrieth Complex Figure, the patient is asked to copy a figure that contains many details embedded within an organizing framework. In addition to the scores these tests yield, the clinician attends to the patient's construction performance to determine factors that may underlie poor performance (e.g., a disorganized impulsive strategy may be more related to anterior brain lesions, whereas difficulty aligning angles may arise from parietal lobe injury).

TABLE 30.2 Typical Subclassifications of Memory Addressed by Neuropsychological Tests

Verbal and nonverbal	Memory for material that is or is not verbally encoded
Immediate, short term	Length of time between exposure to material and recall. The length of time has implications for how long term and remote the memory may be stored and retrieved.
Semantic and episodic	Memory for encodable knowledge, such as vocabulary or facts about the world, as opposed to memory for events
Public and	Memory for public, commonly known events vs. events that occurred in one's own

autobiographic	life
Implicit and explicit	Memory tested on tasks that do not require conscious, explicit recollection of recent exposures (such as motor skills, procedural skills, classical conditioning, or priming) vs. tasks that demand explicit recall of prior information (such as recall or recognition tasks)
Working	Similar to what in the past has been called short-term memory, working memory provides a buffer for briefly holding on to information, such as a telephone number or the name of a newly met person. It is also important for tasks that require mental manipulation of information, such as multistep arithmetic problems. For many theorists, working memory also has a more important role at the work space where recalled information is actually used, manipulated, and related to other information, allowing complex cognitive processes such as comprehension, learning, and reasoning to take place.

LANGUAGE

“Mapping” of different aphasic disorders to specific brain structures was one of the early accomplishments of behavioral neurology. In neuropsychological assessment, this model is often followed. Comprehension, fluency, repetition, and naming are assessed in spoken or written language. Language deficits typically indicate dominant hemisphere pathology, although naming deficits and other verbal difficulties are evident in various forms of dementia as well.

EXECUTIVE

The ability to plan, sequence, and monitor behavior has been called “executive function.” These functions, often linked to the prefrontal cortex, rely on and organize other intact cognitive functions that are required components for performance. Several schemes for classifying executive functions: For example, Miyake et al. (2000) identified three separable functions in a meta-analytic study: mental set shifting, information updating and monitoring, and inhibition of prepotent responses. Here we summarize several task classifications typically included under the umbrella of executive function. Others, not described here, include planning, insight, and social cognition and behavior.

Working memory describes the ability to hold several pieces of information in the mind for a short period of time and manipulate them. For example, the Letter-Number Sequencing subtest of the WAIS-IV require patients to listen to a series of randomly ordered letters and numbers and then state first the numbers in numeric order and letters in alphabetical order.

One test of *inhibition* is the Stroop Color-Word Test. The patient is given a series of color names printed in contrasting ink colors (e.g., the word “blue” printed in red ink) and is asked to name the color of the ink. The response set must be maintained while the subject suppresses the alternate (and more standard) inclination to read words without regard to the color of the print.

Set shifting tasks require the patient to shift attention between one task and another or to alternate strategies. One commonly used task is the Wisconsin Card Sort, which uses symbols that may be sorted by color, number, or shape. Based only on feedback about whether each card was or was not correctly placed, the subject must infer an initial sort rule. At intervals, the sort rule is changed without the subject's knowledge; subjects must switch based only on their own observation that the current rule is no longer effective. Other set shifting tasks use explicit cues to indicate which rule should be used.

Fluency refers to the ability to use one or more strategies that maximize the production of responses while avoiding response repetition (Ruff, Allen et al., 1994). Word fluency tests are typically considered measures of executive function because they tap organizational strategies required for retrieval and recall, as well as self-monitoring, self-initiation, and inhibition. Two often-used verbal fluency tasks are letter fluency, where the patient is given a fixed period of time to name as many words as possible that begin with a specific letter and semantic fluency where the task is to name as many words as possible in a specific category.

MOTOR AND PRAXIS

Tests of motor strength, such as grip strength, and of motor speed and agility, such as assessing speed and peg placement, establish lateral dominance and focal point of impairment. In some diseases, such as the dementia of AIDS, reduced motor agility is part of the diagnosis. Tasks such as the grooved pegboard assess manual dexterity and sensorimotor integration. They can identify lateralized brain damage because both hands are tested. The grooved pegboard task contains 25 holes with randomly positioned slots and pegs which have a key along one side. Pegs must be rotated to match the hole before they can be inserted. The patient is asked to insert the pegs into the holes as rapidly as possible.

Higher order motor tasks, such as double-alternating movements or triple sequences, are used to assess motor sequencing or programming, as opposed to pure strength or speed.

P.244

ATTENTION

The ability to sustain attention is often tested by cancellation tasks, in which the patient must detect and mark targets embedded in distractors, or by computerized continuous performance tests (CPTs), which measure accuracy, response time, and variability in response time as a function of time on task. CPTs assess sustained attention over relatively long time intervals (10 to 20 minutes) and are frequently used in the assessment of attention deficit disorder. Mental tracking tasks such as Digit Span Forward may also be included in this category.

CONCEPT FORMATION AND REASONING

Brain damage is often associated with concrete reasoning. Tests of concept formation include verbal tasks, such as proverb interpretation, and nonverbal tasks, where underlying concepts must be extracted from visual displays. Tests of abstract reasoning include the Similarities subtest of the WAIS-IV, where the subject must explain how two words are alike. The quality of the response is judged. A general classification response that is pertinent to both words receives a higher score than a specific property or function that is relevant to both.

Perceptual reasoning can be assessed with tasks such as matrix reasoning. This task usually involves a series of figures in which there is a discernible pattern, with one figure in the series left blank. The patient is asked to choose, from an array of possibilities, what figure would complete the series or pattern.

PERSONALITY AND EMOTIONAL STATUS

Mood may affect test performance. At minimum, the neuropsychologist notes the psychiatric history and probes for current psychiatric symptoms. Standardized mood rating scales are also available. Many neuropsychologists use standardized personality scales to aid in diagnosis and test interpretation.

CLINICAL OBSERVATION

Along with the formal scores, the intake interview and testing period afford an extensive period to observe the patient under controlled conditions. These clinical observations are valuable for diagnosis. Formal test scores capture only certain aspects of performance. The patient's problem-solving approach or the nature of the errors

made may be telling. Also important in timed tasks is determining whether the patient may complete them with additional time or is actually incapable of solving them. Another important dimension of assessment is the patient's ability to learn and follow directions for the many tests.

More subtle aspects of behavior include responses or coping abilities when confronted with difficult tasks, the ability to remain socially appropriate as the session progresses, and the subjects' appreciation of their own capacities.

REFERRAL ISSUES

Neuropsychological testing is useful for the diagnosis of some conditions and is a tool for evaluating or quantifying the effects of disease on cognition and behavior. The tests may assess the beneficial or adverse effects of drug therapy, radiation, or surgery. Serial evaluations give quantitative results that may change with time. In temporal lobectomy for intractable epilepsy, tests that help identify the location of dysfunction are required in presurgical evaluation to minimize the possibility of adverse effects. Specific referral issues are summarized in the following paragraphs.

DEMENTIA

Testing may detect early dementing changes and discriminate them from "normal" performance. It also helps to obtain information contributing to differential diagnosis, either between dementia and nondementing illness, such as depression versus dementia, or between alternate forms of dementia (e.g., Alzheimer disease, dementia with Lewy bodies, or vascular dementia). Test results may also confirm or quantify disease progression and measure efficacy of clinical interventions.

OTHER BRAIN DISEASE

The effects on cognitive function of stroke, cancer, head trauma, Parkinson disease, Huntington disease, multiple sclerosis, brain infection, or other conditions may be investigated. Testing may be prompted by the patient's complaints. The evaluation helps to clarify the cause or extent of the condition.

EPILEPSY

Testing is part of the presurgical evaluation to determine whether cognitive deficits are consistent with electroencephalography and possibly magnetic resonance imaging (MRI) evidence of focal dysfunction. Additionally, test results, together with knowledge of the proposed surgery, can be used to predict risk of postoperative cognitive decline or the probability of postoperative improvement. Nonsurgical patients are frequently assessed to address memory, attention, and mood issues associated with epilepsy and antiepileptic medications.

TOXIC EXPOSURE

Testing may evaluate the consequences of toxic or potentially toxic exposures, either on an individual basis or for particular exposed groups (e.g., factory workers). Exposures may include metals, solvents, pesticides, alcohol and drugs, or any other compounds that may affect the brain.

MEDICATION

The potential effect of medications on the central nervous system may be evaluated in therapeutic trials or clinical practice. For example, in trials of agents used to treat Alzheimer disease, neuropsychological tests are typically primary measures of drug efficacy. In clinical practice, adverse or therapeutic effects of newly introduced medications may be evaluated.

PSYCHIATRIC DISORDERS

Testing may help in the differential diagnosis of psychiatric and neurologic disorders, especially affective disorders and schizophrenia. It may also assess cognition and areas of competence in patients with these

conditions.

LEARNING DISABILITY

Testing may evaluate learning disabilities and the residuals of these disabilities in later life. Behavioral disorders, ADD, autism, dyslexia, and learning problems are common referral issues.

EXPECTATIONS FROM A NEUROPSYCHOLOGICAL EVALUATION

The minimum that a neuropsychological evaluation yields is an extensive investigation of the abilities of the patient. In these cases, although the studies do not lead to a definite diagnosis, they help

P.245

determine the patient's capacities, establish a baseline from which to track the future, and advise the patient and family.

Sometimes, the evaluation suggests that additional diagnostic tests would be useful. For example, if a patient's pattern of performance deviates substantially from that typically expected at the current stage of dementia, a vascular contribution may be considered. Similarly, evaluation may suggest the value of psychiatric consultation or more intensive electroencephalographic recordings.

Many times the neuropsychologist may offer a tentative diagnosis or discuss the possible diagnoses compatible with the test findings. Neuropsychological evaluation may not yield a diagnosis without appropriate clinical and historical information. In the context of multidisciplinary testing, however, it may provide evidence to confirm or refute a specific diagnosis. In this case, testing might best be considered an additional source of information to be used by the clinician for diagnosis in conjunction with the neurologic examination and laboratory tests.

HOW TO REFER

The more information the examiner has at the start, the more directly the issues may be addressed. For example, if MRI has revealed a particular lesion, tests may be tailored specifically to better understand the lesion. The examination is not an exploration of the ability to detect a lesion but is rather a contribution to understanding the implications of the lesion. Similarly, the more explicit the referral question, the more likely the evaluation may yield useful information. Besides providing the relevant history, a useful referral describes the problem to be assessed. This is often a statement of the differential diagnosis being entertained. Alternately, the neurologist or the family may simply want to document the current condition or explore some specific aspect of performance, such as language.

Lumbar Puncture and Cerebrospinal Fluid Analysis

Nancy J. Edwards

Tareq Saad H. Almaghrabi

Kiwon Lee

INTRODUCTION

Accessing the cerebrospinal fluid (CSF) compartment—typically via lumbar puncture (LP)—is one of the key skills every neurologist should have. Proper analysis of CSF findings may result in a diagnosis (even if the neurologic examination and neuroimaging have not); furthermore, LP and the removal of CSF may be therapeutic in certain cases. This chapter will review step by step the technique of the LP, including advances in the procedure (e.g., ultrasound guidance); in addition, we outline here a guide for the interpretation of CSF findings in various neurologic disorders ranging from infectious to demyelinating to neoplastic.

LUMBAR PUNCTURE

TECHNIQUES

Careful positioning of the patient is often the key to performing a successful LP. Patients may be placed in either a lateral recumbent position with the spine flexed—head bowed, knees bent, and drawn up into the torso, for example, the “fetal position” (Fig. 31.1). Alternatively, patients may sit upright with the neck and back flexed forward (typically resting on a table). The lateral recumbent position should be used if an opening pressure is needed. As the conus medullaris ends at the level of the L1 and L2 interspace in 94% of adults, this level should be avoided during LP. Instead, the L3-L4, L4-L5, and L5-S1 interspaces are appropriate for needle puncture. These interspaces can be identified via palpation of bony landmarks. The line joining the superior aspect of the iliac crests posteriorly (the intercrystal line) identifies the L4 spinous process or L3 and L4 interspace.

The interspace for needle insertion should be marked and the skin overlying the LP site should be sterilized and draped using standard aseptic technique. Local anesthetic—usually 1% lidocaine—is then applied; the 25-gauge needle should be used to raise a skin wheal at the LP site and the longer, 20-gauge needle should then be used to infiltrate the deeper layers. The spinal needle (with stylet in) is then inserted through the skin wheal into the interspinous space. Ideally, needle insertion should be midline, orthogonal to the plane of the back. To reduce the risk of post-LP headache, the bevel should be parallel to the longitudinal fibers of the dura; if the patient is in the lateral recumbent position, the bevel should face up and if the patient is sitting upright, the bevel should face to one side. Theoretically, this allows dural fibers to be separated rather than cut. The spinal needle is then advanced slowly at a slightly cephalad angle (directed toward the umbilicus) in order to follow the contour of the spinous processes. The needle will pass through the supraspinous ligament and the ligamentum flavum, perhaps resulting in a “pop” when the dura is pierced and the subarachnoid space is entered. The stylet should then be removed and CSF should readily appear at the needle hub if in the subarachnoid space. If instead CSF does not flow, the stylet should be replaced and the needle advanced or withdrawn incrementally, with frequent removal of the stylet, until CSF is obtained or bone encountered.

FIGURE 31.1 Proper positioning for lumbar puncture. Position the patient's back at the edge of the bed with the head flexed and the legs curled up in the fetal position. Place a pillow under the head. Hips are parallel to each other and perpendicular to the bed. The spinal needle should be parallel to the bed. (Adapted from Marshall R, Mayer S. *On Call Neurology*. 3rd ed. Philadelphia: Saunders; 2007.)

ULTRASOUND GUIDANCE

Ultrasound visualization of landmarks may significantly improve the rate of LP success. This is particularly true in certain patient populations where palpation of landmarks may be challenging—neonates, pregnant women, obese patients, and patients with generalized edema, for example. One large meta-analysis of 14 studies and 1,334 patients revealed a significant reduction in the risk of failed or traumatic LPs and epidural catheterizations with the use of ultrasound guidance. The absolute risk reduction was 0.63, resulting in a number needed to diagnose of 16 to avoid one failed tap.

To perform an ultrasound-guided LP, the linear probe (higher resolution of superficial structures) should be used. The first view that should be obtained is the transverse view—the goal of this view is to determine an accurate anatomic midline by identification of the spinous process (Fig. 31.2A). To obtain this view, the probe is placed perpendicularly to the long axis of the spine. The spinous process will appear as a hyperechoic white convex rim with an anechoic shadow (or the anechoic shadow itself can simply be used if the rim is not identified). The midline should be marked and the longitudinal view should then be obtained (using the midline as a reference). The goal of the longitudinal view is to determine the spinal interspace—where the spinal needle will be inserted. To obtain this view, the transducer should be rotated into the sagittal/longitudinal plane with the probe marker pointing cephalad. Identify the hyperechoic spinous process again and then adjust the probe cephalad and caudad in order to center the probe/image between two contiguous, crescent-shaped spinous processes; the interspace will be the hypoechoic gray gap in between (see Fig. 31.2B). This interspace should also be marked. Remove the probe and extend the transverse/longitudinal markings until they intersect; this intersection represents the ideal position for the spinal needle to be inserted.

FIGURE 31.2 Ultrasound-guided LP. **A:** Transverse view. The anechoic shadow below *A* represents the spinous process—the midline; *B* localizes the transverse process. **B:** Longitudinal view. The interspace (*asterisk*) is located between the two crescentic-shaped, hyperechoic spinous processes (*S*).

CEREBROSPINAL FLUID ANALYSIS

CEREBROSPINAL FLUID PLEOCYTOSIS

Basic analysis of the CSF begins with red blood cell (RBC) and white blood cell (WBC) analysis and measurements of protein and glucose, although an extensive variety of additional tests can also be ordered (Table 31.1). The normal WBC count of CSF ranges from 0 to 5 lymphocytes or monocytes per cubic millimeter. Rarely, a single polymorphonuclear (PMN) cell may be identified from a large volume tap; the presence of two or greater PMNs, though, should be considered abnormal. A myriad of neurologic disorders can result in a CSF pleocytosis, ranging from acutely life-threatening (bacterial meningitis) to entirely chronic (as can be seen in patients with HIV).

Assessing the magnitude of pleocytosis along with the relative predominance of neutrophils to lymphocytes is often key, as is the clinical history—specifically whether the neurologic symptoms are acute or chronic in nature. For instance, a patient presenting with acute encephalopathy and a neutrophil-predominant CSF pleocytosis should be presumed to have bacterial meningitis (and promptly treated as such). In general, patients with acute bacterial meningitis have a CSF WBC count of several thousand (although the range may be from hundreds to >60,000). Furthermore, a CSF sample with greater than 33% neutrophils, a protein concentration of greater than 100 mg/dL, and a glucose level of less than 50% of the serum glucose level is strongly suggestive of bacterial meningitis. Exceptions include bacterial meningitis due to *Listeria* (often with a lymphocytic rather than neutrophilic pleocytosis), early viral or atypical (fungal/mycobacterial) infections that may initially recruit neutrophils into the CSF, neuroinvasive disease due to West Nile virus, and neuroinflammatory disorders (neuro-Behcet, Sweet syndrome).

In an acutely ill patient with a lymphocytic CSF pleocytosis, viral meningoencephalitis is often the cause. The WBC count generally ranges from 10 to 1,000 cells/mm³ and is composed primarily of

P.248

mononuclear cells. The cornerstone of etiologic diagnosis is the detection of viral nucleic acid sequences in the CSF via polymerase chain reaction (PCR). In cases of suspected viral meningoencephalitis, CSF PCRs for the enteroviruses along with the herpesviruses (herpes simplex virus 1 and 2, cytomegalovirus, varicella-zoster virus, Epstein-Barr virus (EBV), and in immunocompromised patients, human herpesvirus-6) should be sent, along with

serologic testing for HIV. Serologic testing for several additional viruses can be considered (West Nile virus, St. Louis encephalitis virus, Eastern equine encephalitis virus, Venezuelan equine encephalitis virus, and La Crosse virus).

TABLE 31.1 Common Cerebrospinal Fluid Tests

- Cell count

- Protein and glucose levels

- Gram stain and culture

- VDRL test

- India ink test (for *Cryptococcus neoformans*)

- Wet smear (for fungi and amebae)

- Stain and culture for AFB (for tuberculosis)

- Cryptococcal antigen titers

- pH and lactate levels (abnormal in MELAS)

- Oligoclonal bands (abnormal in multiple sclerosis)

- IgG index (intrathecal IgG production)

- IgG and IgM antibody titers (for viral infections, compare to serum)

- Lyme disease antibody titers (compare with serum titers) and Western blot

- Latex agglutination bacterial antigen tests (for pneumococcus, meningococcus, and *Haemophilus influenzae*)

- Viral isolation studies

- Cytology (requires fixation in formalin)

- Polymerase chain reaction for Lyme disease, tuberculosis, and causes of viral encephalitis

- CSF ACE activity (abnormal with tuberculosis or sarcoidosis)

- 13-9-9 protein (elevated in Creutzfeldt-Jacob disease)

VDRL, Venereal Disease Research Laboratory; AFB, acid-fast bacilli; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke; IgG, immunoglobulin G; IgM, immunoglobulin M; CSF, cerebrospinal fluid; ACE, angiotensin-converting enzyme.

In patients with chronic neurologic symptoms and a lymphocytic CSF pleocytosis, an atypical infection such as fungal, tuberculous, or spirochetal should be considered. Etiologic diagnosis can be made via these CSF studies: India ink staining, fungal cultures, assays for cryptococcal antigen or histoplasma antigen, and *Coccidioides* complement fixation antibodies; acid-fast bacilli smear and culture, PCR for *Mycobacterium tuberculosis*; Venereal Disease Research Laboratory (VDRL) in conjunction with serum testing for syphilis; and antibodies against *Borrelia burgdorferi*. That being said, a chronic lymphocytic CSF pleocytosis may also be caused by various noninfectious disorders, including neoplasm (central nervous system [CNS] lymphoma, leptomeningeal carcinomatosis), paraneoplastic encephalitis, autoimmune/demyelinating disorders (CNS vasculitis, neurosarcoidosis, neuromyelitis optica [NMO], multiple sclerosis [MS]), and even medications or toxins (nonsteroidal anti-inflammatory drugs [NSAIDs], sulfa drugs, intravenous immunoglobulin, carbamazepine). Therefore, the clinical history along with neuroimaging is often vital for the diagnostic interpretation of a chronic lymphocytic CSF pleocytosis.

The CSF findings in the various meningitides are summarized here in [Table 31.2](#).

There are two frequently encountered caveats to the interpretation of a CSF pleocytosis—the first being CSF obtained from a traumatic LP and the second being CSF obtained from an external ventricular drain (EVD). Inadvertent needle trauma to a capillary or venule during LP will introduce additional WBCs from the peripheral blood into the CSF, increasing the total number of WBCs. A useful rule of thumb if a traumatic LP is suspected is to subtract 1 WBC for every 500 to 1,000 RBCs present in the CSF. Alternatively, the following formula can be used, especially in patients with an abnormal peripheral WBC count:

$$WBC (CSF) = \frac{WBC (blood) \times RBC (CSF)}{RBC (blood)}$$

In the neurocritical care unit, patients may have an EVD inserted into the lateral ventricle to aid in CSF diversion or to monitor intracranial pressure. CSF can be easily sampled through this drain and is often sampled to exclude nosocomial meningitis/ventriculitis associated with the drain itself. Whether a truly pathologic pleocytosis (e.g., one due to meningitis/ventriculitis) is present in EVD-sampled CSF can be challenging to ascertain; patients who have EVDs inserted for CSF diversion may have high RBC counts in the ventricular system (for instance, those with subarachnoid hemorrhage or intracerebral hemorrhage) and the aforementioned corrections for RBCs are not entirely valid for EVD CSF samples. Furthermore, patients with large volumes of blood in the subarachnoid or ventricular compartments often develop an inflammatory response with an elevation in the WBC count in ventricular CSF. To aid with the diagnosis of meningitis/ventriculitis in patients with EVDs, the cell index, in conjunction with CSF Gram stain and culture, can be used. The cell index is calculated as follows:

$$Cell\ index = \frac{WBC (CSF) \div RBC (CSF)}{WBC (blood) \div RBC (blood)}$$

A cell index of 1 is (by definition) normal. And although there is no explicit cutoff for an “abnormal” cell index, a significant rise in the cell index from one day to the next may signal the presence of infection.

HYPOGLYCORRHACHIA

A reduced CSF glucose level may be caused by impaired glucose transport into the CSF (for instance, due to severe disruption of the blood-brain barrier and its glucose transporter, GLUT1) or as a result of increased glucose use within the CNS. There are a

P.249

handful of pathologies that typically result in an abnormally low CSF glucose and as such, hypoglycorrhachia can be a very helpful diagnostic clue. In general, a CSF glucose of 45 mg/dL to 80 mg/dL is considered normal, although this is dependent on a fairly normal range of serum glucose (70 to 120 mg/dL). Of greater usefulness is the CSF-to-serum glucose ratio, as this is relatively constant through a wide range of serum glucose levels. The normal CSF-to-serum glucose ratio is 0.6 to 0.8; a ratio less than 0.5 is abnormal and should prompt urgent evaluation.

TABLE 31.2 Cerebrospinal Fluid Findings in Various Meningitides

Type	Leukocytes (mm ³)	Protein (mg/dL)	Glucose (mg/dL)
Acute bacterial	>1,000 although ranges from several hundred to >60,000; PMNs predominate	100-500, occasionally >1,000	5-40; typically a CSF-to-serum glucose ratio of <0.33
Viral	5-1,000; lymphocytes predominate (although early in the disease course, PMNs may predominate)	Frequently normal or slightly elevated; generally <100	Normal (although rarely reduced in cases of LCMV, CMV, paramyxoviruses, HSV)
Tuberculous	25-100; rarely >500; lymphocytes predominate (although early in the disease course, PMNs may predominate)	Elevated, 100-200	Low; <45 in 75% of cases
Cryptococcal	0-800; lymphocytes predominate	20-500	Often reduced; average 30
Syphilitic	Average 500; primarily lymphocytes	100	Generally normal although may be mildly reduced
Sarcoid	0 to <100	Slight to moderate elevation	May be reduced in 18%-50% of patients
Leptomeningeal carcinomatosis	0 to several hundred; cytology may reveal malignant cells	Elevated	Low in 40%-75% of cases

PMNs, polymorphonuclear cells; CSF, cerebrospinal fluid; LCMV, lymphocytic choriomeningitis virus; CMV, cytomegalovirus; HSV, herpes simplex virus.

TABLE 31.3 Causes of Hypoglycorrhachia

Bacterial meningitis

Fungal meningitis

Tuberculous meningitis

Meningitis due to spirochetes (syphilis, Lyme)

CNS lymphoma

Leptomeningeal carcinomatosis

Neurosarcoidosis

CNS, central nervous system.

The principal causes of a reduced CSF-to-serum glucose ratio are listed in [Table 31.3](#). Several infectious meningitides—bacterial, fungal, tuberculous, and spirochetal—are often heralded by hypoglycorrhachia. For instance, in one study of adults with bacterial meningitis, 70% had CSF glucose concentrations of less than 50 mg/dL. The CSF-to-serum glucose ratio in patients with bacterial meningitis is generally less than 0.33; a ratio of less than 0.23 in patients with acute meningitis had a positive predictive value of 99% for a bacterial etiology.

Fungal meningitis is also associated with low CSF glucose—generally 20 to 40 mg/dL in one-half to two-thirds of patients. *Mycobacterium tuberculosis* meningitis characteristically depresses the CSF glucose; in one study of CSF culture-positive patients, the mean admission CSF glucose level was 23 mg/dL. Hypoglycorrhachia has also been reported in patients with Lyme disease and syphilitic meningitis, although the reduction in CSF glucose is often modest compared to cases of bacterial meningitis. The CSF glucose level in patients with viral meningitis is classically normal; that being said, rare cases of viral meningitis due to cytomegalovirus (CMV), paramyxoviruses, and lymphocytic choriomeningitis virus have been associated with low CSF glucose.

Other causes of hypoglycorrhachia include CNS lymphoma (approximately 10% of patients), leptomeningeal carcinomatosis (40% of patients), neurosarcoidosis (18% of patients), and lupus cerebritis/vasculitis (8% of patients). Patients with aneurysmal subarachnoid hemorrhage may have transient reductions in their CSF glucose (usually 4 to 8 days postictus). And finally, hypoglycorrhachia has been reported in patients who have received intrathecal injections of corticosteroids.

CEREBROSPINAL FLUID FINDINGS IN INFLAMMATORY AND DEMYELINATING DISORDERS

Although a detailed description of the CSF findings across the gamut of autoimmune and demyelinating neurologic disorders is beyond the scope of this chapter, there are certain CSF generalizations we can refer to.

For instance, a mild lymphocytic pleocytosis and modest elevation in protein is frequently encountered in these patients. Approximately, one-third of patients with MS, optic neuritis, transverse myelitis, and even acute disseminated encephalomyelitis will have a mild lymphocytic pleocytosis. A greater proportion of patients with neurosarcoidosis and NMO will have a lymphocytic pleocytosis, and in the proper clinical context, a CSF pleocytosis of greater than 50 WBC/mm³ or greater than 5 PMNs/mm³ is strongly supportive of a diagnosis of NMO.

Even if the CSF cell count and protein are normal, evidence of an active intrathecal humoral immune response is often fundamental to the diagnosis of a neuroinflammatory disorder. During CNS inflammation, CSF immunoglobulin G (IgG) content may preferentially increase above serum levels, reflecting intrathecal synthesis. A routinely used estimate of intrathecal IgG synthesis is the IgG index, calculated as follows:

$$\text{IgG index} = \frac{\text{IgG (CSF)} \div \text{IgG (serum)}}{\text{albumin (CSF)} \div \text{albumin (serum)}}$$

An IgG index greater than 0.70 to 0.75 is often considered elevated (although parameters range depending on the clinical laboratory processing the sample). As an adjunct to the IgG index, the detection of unique oligoclonal bands (OCBs) within the CSF—distinct from those found in the serum—provides qualitative evidence of intrathecal Ig production. If 2 or more distinct CSF bands (bands absent from a corresponding serum sample) are detected, OCBs are considered to be positive. In MS patients, for instance, approximately 90% will have either an elevated IgG index or two or greater OCBs in the CSF, and these CSF findings may even precede a diagnosis of MS based on clinical history (or radiology) alone.

CEREBROSPINAL FLUID CYTOLOGY

Diagnosis of a CNS malignancy via CSF cytology is highly specific and relatively noninvasive (compared to biopsy, for instance)—unfortunately, the sensitivity of CSF cytology ranges from low to moderate. Several factors may alter the yield of CSF cytology, including the site sampled (lumbar vs. cisterna magna), the volume of CSF collected, the number of specimens examined, tumor location/grade, and the extent of leptomeningeal disease. The sensitivity of CSF cytology across CNS malignancies is outlined in [Table 31.4](#). In general, repeated sampling will increase the yield of CSF cytology; for instance, in patients with leptomeningeal carcinomatosis, 41% to 71% will have a positive cytopathology on the first CSF sample, whereas 79% to 92% will have a positive cytology with repeated sampling. These findings form the basis for the recommendation that three large-volume (ideally >20 mL; >10 mL at the very least) LPs should be analyzed for malignant cells in patients with presumed leptomeningeal disease. Furthermore, CSF samples should be promptly delivered to the cytopathology laboratory for processing as autolysis begins within 1 to 2 hours of sample collection. In cases where primary CNS lymphoma is suspected, several additional CSF studies may aid in diagnosis. Immunophenotyping the CSF via flow cytometry can considerably increase the diagnostic yield by differentiating monoclonal B lymphocyte populations from reactive polyclonal lymphocytes even if the sample is relatively hypocellular. And in patients with HIV, CNS lymphoma is strongly associated with transformation of malignant cells by EBV; as such, EBV PCR in CSF has a high sensitivity and specificity for the diagnosis of CNS lymphoma in this particular patient population.

TABLE 31.4 Cerebrospinal Fluid Cytology Yield

Type of CNS Malignancy	Percentage of Patients with Positive Cytology	Notes
------------------------	---	-------

Malignant glioma	7-66 (more than one sample)	
Parenchymal metastatic lesions	2-10	
Primary CNS lymphoma	16-26 (single sample)	Flow cytometry = higher yields EBV PCR as an adjunct in HIV +
Leptomeningeal carcinomatosis	47-92	41-71 with one sample; increasing yields with repeat sampling

CNS, central nervous system; EBV, Epstein-Barr virus; PCR, polymerase chain reaction.

Brain, Nerve, and Muscle Biopsy

John F. Crary

Thomas H. Brannagan III

Kurenai Tanji

INTRODUCTION

Biopsy of nervous and muscle tissue remains a critical tool. Any potential benefits associated with having a tissue-based diagnosis must be carefully weighed against the risks associated with the procedure. Brain, muscle, and nerve biopsies are always performed in the context of an interdisciplinary team, which can include neurologists, internists, neuroradiologists, neurosurgeons, and neuropathologists. To ensure appropriate assessment of the biopsy, a high level of communication between providers is of the utmost importance. In most cases, brain biopsy should be a last resort, reserved for clinical settings where all other diagnostic modalities have been exhausted. However, modern surgical techniques have helped to minimize complications and the risk of obtaining a non-diagnostic biopsy in some disorders, the benefit in establishing a diagnosis and thus treatment plan may outweigh the risks of the procedure. In addition, modern molecular techniques are increasingly being applied, greatly increasing the use of biopsy specimens. Although the widespread deployment of next-generation sequencing technology has obviated the need for biopsy in some settings, these modern ancillary studies have not supplanted classical histomorphologic analysis. In this chapter, we will provide an overview of the critical issues associated with the brain, muscle, and nerve biopsy. We will also discuss the use of skin biopsies for epidermal nerve fiber density analysis.

BRAIN BIOPSY

INDICATIONS

Certain general considerations must be weighed before referring a patient for a brain biopsy. General risks associated with brain biopsy are similar to those associated with any surgical procedure, including deep vein thrombosis, postoperative hemorrhage, infection, etc. Patients on anticoagulant treatment might need to make adjustments given the risk of postoperative intracranial hemorrhage in the brain. Other complications include stroke, seizures, and cerebrospinal fluid (CSF) leak (fistula). Given the risks, it is generally accepted that all other diagnostic modalities must be exhausted before proceeding to brain biopsy.

An essential consideration prior to biopsy is determining the likelihood that the answer will lead to a change in patient management. Should, for example, the expected diagnoses have similar or no disease-modifying treatments, then the decision to proceed to a biopsy should be questioned. Furthermore, there is often a window of opportunity for the biopsy to be useful clinically. If the patient has deteriorated beyond the point to which a reasonable recovery in function can be anticipated, the biopsy might also be of limited value. Further, the ability of the neuropathologist to recognize diagnostic features in the tissue is highest during the active phase of a disease. Once the pathology has run its course, secondary changes in the tissue can predominate and increase the likelihood of a nondiagnostic biopsy. Treatment effects, such as brain irradiation or steroids, may also mask diagnostic changes. For example, in a patient with a possible diagnosis of central nervous system (CNS) lymphoma, the use of systemic steroids should be deferred unless essential in the context of clinical care (i.e., as a component of treating brain herniation), as treatment can make the biopsy nondiagnostic. Thus, it is essential that empiric treatments be used

judiciously should a patient be a candidate for brain biopsy.

Brain biopsies have a prominent place in the treatment and management of CNS neoplasms. For mass lesions, partial brain resection and/or biopsy may be performed, depending on the functional importance of the region that contains the lesion. For malignant brain tumors, resections have the additional advantage of being both diagnostic and therapeutic in the form of debulking. Watchful waiting might be considered for benign brain tumors. Certain brain tumors in vital regions of the brain, such as brain stem gliomas, or eloquent cortical regions might not be amenable to a full resection, but guided stereotactic biopsy might be performed in some cases.

Brain biopsies are generally not required for most CNS infections, as other forms of diagnosis are often definitive. Viral, bacterial, and fungal organisms can be identified with other diagnostic modalities, including with CSF sampling. In ambiguous contexts, a brain biopsy might be performed. Such biopsies are often of highest clinical use when two pathogenic processes with contradictory treatments are under consideration, for example, infectious versus autoimmune. Immunocompromised patients also provide a special setting where a broad differential diagnosis might trigger consideration of a brain biopsy.

In the case of age-related neurodegenerative disorders, brain biopsy is rarely performed. However, a biopsy may be considered in the setting of a rapidly progressive dementia, when there is a reasonable chance that a treatable cause might be uncovered, which cannot be diagnosed by other means. Recent advances have led to the ability to diagnose specific autoimmune encephalitides using antisera. Moreover, CSF biomarkers have shown increasing use in diagnosing Alzheimer disease and prion disease. These advances have altered referral patterns, perhaps decreasing the total number of subjects undergoing brain biopsy for rapidly progressive dementia but increasing the diagnostic yield.

Brain biopsy is not indicated for ischemic stroke, but brain tissue may be sampled in the setting of hemorrhagic stroke to assess the vasculature for cerebral amyloid angiopathy. Vascular abnormalities may be resected surgically, and histopathologic analysis of such lesions is generally of only modest use.

BRAIN BIOPSY REQUIRES AN INTERDISCIPLINARY APPROACH

Brain biopsies are always performed in the context of an interdisciplinary team. The neurologist plays a critical role in the clinical workup and referring patients to biopsy only when all other

P.252

diagnostic modalities have been exhausted. Next, the neurologist will work closely with both the neuroradiologist and neurosurgeon to identify a radiographically evident lesion that is amenable to biopsy. Although “blind” biopsies of the nondominant (usually right) frontal cortex are often performed, targeting a specific lesion is thought to provide the most informative results. If a biopsy is indicated, an open biopsy consisting of 1 cm³ full-thickness biopsy that contains gray matter, leptomeninges, and subcortical white matter is considered optimal by most neuropathologists. However, if the lesion is located within a vital or eloquent brain region, stereotactic core biopsies, sometimes measuring just a few millimeters, can provide diagnostic material.

During surgery, neurosurgeons often call on the neuropathologist to perform a *frozen section*. These intraoperative consultations are a means to rapidly obtain some diagnostic information and involve rapidly freezing tissue and cutting followed by hematoxylin and eosin (H&E) staining. Although these tissue sections are of only limited diagnostic value, given the severe tissue artifacts that develop, the information provided may be helpful to guide surgical decision making. Another use of the frozen section is confirming the presence of lesional tissue within the biopsy, which also decreases the likelihood of a nondiagnostic biopsy. Critically, the preliminary diagnostic impression obtained through a frozen section must be interpreted with caution, as it is not uncommon for revision following additional sampling and ancillary studies.

NEUROPATHOLOGIC INTERPRETATION OF THE BRAIN BIOPSY

Classical histopathologic examination by a neuropathologist remains the foundation of brain biopsy interpretation. Tissue sections from formalin-fixed brain are mounted on glass slides, stained with the H&E, and examined microscopically. The H&E stain allows for visualization of the cytoarchitecture and all the cellular types in the brain, including neurons and glia. Other stains are in routine use, including variations of the Bielschowsky silver stain, which is excellent for visualizing neuronal processes. Connective tissue stains such as trichrome, reticulin, or van Gieson are particularly useful for vascular pathology. Congo red and thioflavin are useful for visualizing amyloid. Gram, Gömöri methenamine silver (GMS), and the Ziehl-Neelsen (acid-fast bacilli) stains are routinely used for microorganisms.

Various ancillary studies are routinely used in neuropathology. Immunohistochemical stains are commonly employed in various contexts, particularly in the setting of neoplasms, where molecular alterations can be detected with both diagnostic and prognostic relevance. Many molecular tests require fresh (nonfixed) frozen tissue, and a portion of the specimen must be set aside for this purpose prior to processing. Should an infectious etiology be a consideration, tissue cultures are ideally performed using swabs of the surgical site, but fragments of fresh tissue can be submitted after surgery provided that it has not been fixed or contaminated. If lymphoma is a consideration, brain tissue can be used for flow cytometry to characterize the neoplastic population, but CNS lymphoma is most often of the diffuse large B-cell type, and these fragile cells generally do not perform well for this test. Alternatively, cultures of the tissue may be grown for cytogenetic analysis. Electron microscopy is generally of only very limited use in the setting of brain biopsies. Next-generation DNA and RNA sequencing is increasingly being applied to brain tumors for subclassification and targeted treatments. Also, next-generation sequencing can detect very low levels of pathogen DNA/RNA and may become more widely deployed in the future for this use.

MUSCLE BIOPSY

A muscle biopsy may be warranted when neurologic examination, laboratory tests, and electrophysiologic studies suggest a neuromuscular disease. Microscopic examination can help to distinguish between neurogenic and myogenic disorders and can also provide assistance in subclassifying myopathies and in rendering a specific diagnosis. With the advent of new genetic techniques including standard candidate gene sequencing, high-throughput sequencing of specialized gene panels, whole exome, and even whole genome sequencing, several genetic myopathies are diagnosed without invasive muscle biopsy. However, prior to embarking on exhaustive and often costly genetic investigations, a muscle biopsy chosen by thorough history taking and careful neurologic examination may provide an important aid in identifying the most likely cause of the disease that could be treatable. For example, the presence of widespread inflammation suggests an acquired inflammatory myopathy as distinguished from other acquired or hereditary myopathies such as muscular dystrophy. Vasculitis and amyloidosis are often associated with a neuropathy but both disorders may also be identified in muscle. The decision to perform a muscle biopsy should also include noninvasive tools including blood test (e.g., electrolytes, glucose, thyroid-stimulating hormone, vitamin D, creatine kinase [CK], and autoimmune screen), electrodiagnostic studies, and other laboratory tests. Imaging studies, such as magnetic resonance imaging (MRI), have been increasingly incorporated into the evaluation of muscle diseases. When combined with a biopsy, MRI can provide preoperative information about the muscle and adjacent structures (e.g., fascia and subcutaneous tissue). In some cases, the MRI may disclose a characteristic pathologic involvement of muscle groups, which may lead directly to a genetic test and obviate the need for a biopsy.

The best muscles for biopsy are those moderately affected by the disease. MRI may be helpful in selecting a muscle that is most likely to provide diagnostic findings histologically. Severely atrophic muscles, prior injection or electromyography examination sites, or previously traumatized muscles must be avoided. Patients with

myoglobinuria or rhabdomyolysis should have the biopsy performed 6 to 8 weeks following the episode to allow muscle to recover from myonecrosis, because extensive and active myonecrosis/regeneration on biopsy may obscure the underlying pathology. The most commonly investigated muscles are the deltoid, biceps, and vastus lateralis, when proximal weakness predominates. In patients with distal weakness, the anterior tibialis or gastrocnemius can be chosen depending on anterior or posterior predominance in weakness or atrophy. The clinical history should be available to the pathologist who examines the biopsy, to apply optimal histologic, histochemical, immunohistochemical, or electron microscopic techniques, to detect the important pathology in the tissue.

Technically, an accurate *morphologic diagnosis* requires formalin-fixed tissue to be processed for routine histology, rapidly and properly frozen tissue for histochemical and immunohistochemical preparations, and glutaraldehyde-fixed tissue for possible electron microscopic examination. Preserving a separate piece of snap frozen muscle is helpful for potential biochemical enzymatic assay(s) of glycogenolytic and glycolytic pathways; lipid metabolism; or mitochondrial respiration, electrophoresis for the protein expression study of muscle proteins, or genetic study.

When the routine histology of muscle demonstrates large or small groups of atrophic fibers, it is most suggestive of a *neurogenic disorder*. In contrast, *myopathic features* include a significantly

P.253

increased fiber size, an increased number of internally nucleated fibers, necrotic and/or regenerating fibers, and abnormal intracytoplasmic storage material or inclusions. In chronic myopathies, notable endomysial fibrosis is often present. Inflammatory myopathies tend to display widespread, often multifocal, inflammatory infiltrates in the endomysium and/or perimysium. The diagnosis of vasculitis, infectious or noninfectious granulomatous diseases, and amyloidosis can be established by routine histologic evaluation.

Histochemical staining techniques applied on cryosections help classify the fiber types (e.g., myosin adenosine triphosphatase [ATPase]) and delineate cytologic abnormalities. A neurogenic disease can demonstrate fiber-type grouping and/or target/targetoid fibers, best demonstrated by myosin ATPase and nicotinamide adenine dinucleotide tetrazolium reductase, respectively. In certain myopathies, fiber-type predominance (e.g., congenital myopathy) or selective fiber atrophy (e.g., steroid myopathy, critical illness myopathy, and collagen vascular disease) may occur. A variety of cytologic abnormality associated with myopathies, such as cores, nemaline rods, tubular aggregates, caps, hyaline bodies, reduced bodies, cytoplasmic bodies, cytoplasmic mass, significantly increased mitochondria (ragged red fibers), excessive intracytoplasmic glycogen or lipid, and increased lysosomal reactivity with or without fiber vacuolation, are best characterized by proper histochemical preparations. Certain enzymatic deficiencies in metabolic myopathy can be histochemically demonstrated. These include myophosphorylase deficiency (glycogenosis type V), phosphofructokinase deficiency (type VII), myoadenylate deaminase deficiency, and cytochrome c oxidase (respiratory chain complex IV) deficiency (mitochondrial myopathy).

In the new molecular era, immunohistochemical staining using the antibodies against certain proteins, immunoexpressions of which are affected directly or indirectly by DNA mutation, can offer an excellent guide to select candidate gene(s) to be molecularly investigated. Genetic defects of dystrophin, sarcoglycan proteins, dysferlin, caveolin 3, emerin, merosin (α 2-laminin), collagen VI, carbohydrate side chain of α -dystroglycan, and others can be reliably tested in the tissue. When a muscular dystrophy demonstrates on biopsy morphologically indistinguishable abnormalities from those of other acquired myopathies, immunohistologic staining may help establish the cause of the disease. Further, immunohistochemical detection of a specific protein deficiency may find the cause of otherwise nonspecific clinical symptoms in patients without typical dystrophic muscle weakness, such as persistent CK elevation (so-called benign hyperCKemia), myoglobinuria/rhabdomyolysis, myalgia, or cramp. The other advantage of immunohistochemical staining is found in the analysis of inflammatory

myopathies. The immunohistochemical detection of inflammatory markers (e.g., major histocompatibility complex [MHC] class I antigens) and immunocytologic typing of lymphocytic infiltrates may aid subclassification of immune-mediated inflammatory myopathies such as dermatomyositis, polymyositis, and inclusion body myositis.

In summary, to promptly establish an accurate and clinically meaningful diagnosis for patients with muscle disorders posing diagnostic challenges, it is essential to wisely minimize the number of investigations that could be extremely costly, especially under the increasing availability of commercial testing. Although new generation sequencing methods face their own challenges including consent and interpretation of the sequenced data, traditional diagnostic methods such as muscle biopsy remain important tools in narrowing the differential diagnosis.

NERVE BIOPSY

Nerve biopsy is indicated in patients with peripheral neuropathy when additional information about the etiology and severity of the disorder is needed. Although the indications have generally decreased in the last 20 years, mostly due to increasing availability of molecular diagnostic testing for hereditary peripheral neuropathies, certain specific disorders require tissue diagnosis or characterization. These include vasculitis, sarcoid neuropathy, amyloidosis, leprosy neuropathy, chronic inflammatory demyelinating polyneuropathy (CIDP), especially cases with clinically and/or electrophysiologically atypical and/or asymmetric presentation, neuropathy associated with monoclonal gammopathy, toxic neuropathy, storage disorders, and other systemic disorders with peripheral nervous system involvement. Several central nervous system diseases, for instance, metachromatic leukodystrophy, adrenoleukodystrophy, Krabbe disease, Lafora disease, neuronal lipofuscinosis, and other lysosomal storage diseases, may clinically involve the peripheral nerve. Nerve biopsy may also be helpful in identifying sporadic cases of genetically defined neuropathy or be required in the follow-up of patients with genetically diagnosed neuropathy with unusual clinical presentations. In children, the pathologically characteristic features in nerve may establish the diagnosis of giant axonal neuropathy and neuroaxonal dystrophy.

The human sural nerve is the most widely studied nerve in health and disease and is generally recommended for biopsy. If mononeuritis multiplex clinically spares the sural nerve, another cutaneous nerve can be selected. For example, in most patients with suspected vasculitic neuropathy, a combined superficial fibular (peroneal) nerve/fibularis (peroneus) brevis muscle biopsy through a single incision on the lateral aspect of the leg is the most efficient and cost-effective procedure. For a comprehensive morphologic diagnosis, the removed nerve specimen is conventionally divided into three parts: buffered formalin-fixed for paraffin-embedded sections; buffered glutaraldehyde-fixed for epoxy resin sections, teasing fiber analysis, and electron microscopic assessment; and frozen for potential immunofluorescent study.

The routine histology of nerves demonstrate diagnostic features of vasculopathy (vasculitis, arteriolosclerosis, embolus, intravascular malignancy, etc.), amyloid deposition, sarcoidosis, inflammation, infiltration of nerve by hematologic neoplasia, leprosy, giant axon neuropathy, and polyglucosan body disease. The hematologic neoplasia invading the nerve may be distinguished from reactive processes using immunocytologic lymphocytic markers. Immunoglobulin light-chain deposition secondary to plasma cell dyscrasia can be identifiable by in situ hybridization or by immunofluorescence study for kappa and lambda light chains. If a sizable amyloid deposit is histologically detected, the tissue may be useful for amyloid typing by mass spectroscopy. In general, however, most neuropathies do not show distinctive or specific morphologic findings in paraffin sections, and usually require examination of semithin epoxy resin sections that are significantly thinner than paraffin sections, offering a better resolution of histology. Combined with observation of the teased myelinated fibers, axonopathy can be distinguished from demyelinating neuropathy. *Axonopathy* is recognized by marked depletion of nerve fibers associated with endoneurial fibrosis, with or without myelin debris or axonal regeneration. Teased fibers may exhibit prominent wallerian degeneration of myelinated fibers in an active phase of the disease. These

axonopathic features can be seen in vasculitic neuropathy, toxic (iatrogenic) neuropathies, alcoholic neuropathy, amyloid neuropathy, and various neuropathies associated with metabolic

P.254

disease, nutritional defect, and infectious disease. Segmental demyelination and remyelination, recognized in section as thinly myelinated fibers or onion bulb (concentric layers of Schwann cell processes) formation, are often the result of *primary demyelinating disorders* (e.g., immune-mediated and inherited). The teasing fiber analysis may further illustrate myelin changes such as excessive myelin wrinkling and folding and tomacula formation (irregular thickening of myelin within internodes), and the semiquantitative analysis of those myelin alterations may be informative in identifying the presence of pathologic demyelinating condition, as a low degree of myelin irregularity can be physiologically associated with aging.

Electron microscopic examination is useful to further delineate the pathology of axons, myelin, Schwann cells, or interstitial tissue (e.g., accumulation of neurofilaments, organelles, or protein aggregation in axon; widened, uncompacted, or irregularly folded myelin lamellae; various intracellular inclusions or deposits) and is essential for the assessment of unmyelinated fibers.

For various autoimmune polyneuropathies, many serum autoantibodies directed against peripheral nerve glycoconjugate antigens have been identified as putative targets to date, and the direct *immunofluorescent study* using nerve frozen sections could be used to demonstrate possible immunoglobulin and complement deposits within the myelin sheath. For example, intense and widespread deposits of the C3 component of complement and immunoglobulin M (IgM) along the myelin sheath could help distinguish neuropathy associated with IgM paraproteinemia from a morphologically or clinically resembling CIDP.

In summary, in the new genetic era, conventional nerve biopsy can still offer clinically useful information, when it is wisely chosen. However, it is noted that in various neuropathies with a multifocal nature, findings in the nerve biopsy may not be representative of primary pathology taking place at other sites of the nerve, particularly at a nerve root level, and that the diagnostic usefulness of nerve biopsy must be assessed on a case-by-case basis.

SKIN BIOPSY

Skin biopsy is primarily used to evaluate cutaneous sensory and autonomic nerves, and clinically, it has been widely used as a useful diagnostic tool for acquired and hereditary small-fiber neuropathy by the quantification of *intraepidermal nerve fiber density* (IENFD). The clinical course of certain systemic autoimmune diseases including celiac disease and Sjögren syndrome may be complicated by small-fiber symptoms. Skin biopsy has also been used in detection of other neuropathies such as small-fiber-predominant polyneuropathy and distal symmetric neuropathy. Given the minimally invasive nature, it enables multiple sampling from different biopsy sites (e.g., proximal and distal sites in a same limb of the patient) for comparison or monitoring patients over the clinical course. For IENFD analysis, epidermal axons are immunohistochemically visualized in the tissue sections, commonly using the antibody against a panaxonal marker, PGP9.5 (a ubiquitin hydrolase: a major protein of nerve cells including axons and dendrites), and are counted in a given length of the epidermis. The quantitative analysis of nerve fibers requires normative values, and in patients with small-fiber neuropathy, the IENFD tends to be significantly low. Morphologic abnormalities in the epidermal axons (e.g., short length, small diameters, and complicated branching patterns) may precede the actual dropout of the epidermal axons. The *current limitation* of skin biopsy include the following: (1) Skin biopsy does not provide the specific differentiation of pathogenic mechanism/cause of the disease and (2) except in a clinical trial setting, the observation of skin biopsy rarely changes clinical management especially in diseases where the cause of neuropathy is already known.

Recent expansion of skin biopsy use includes evaluation of patients with autonomic disorders such as diabetes, chemotherapy-induced autonomic neuropathy, and autonomic dysfunctions in neurodegenerative disorders by

semiquantification of the autonomic innervation to sweat glands or arrector pili muscle. However, reliability and correlation with neuropathy scores have been debatable in the published methods, and availability of normative values is limited. In research, however, skin biopsy has been used to date in a wide range of studies, including detection of changed voltage-gated sodium channel expressions in small-fiber neuropathy and assessment of dermal myelinated fibers in demyelinating disease.

In summary, skin biopsy is a unique minimally invasive biopsy technique, and the quantification of IENFD remains a reliable diagnostic tool for small-fiber neuropathy, with high diagnostic specificity and relatively good sensitivity which cannot be readily detected by nerve conduction study. Indications of skin biopsy may be increased in the future, with potential development of biomarkers to gain further insight into the functional abnormality of small fibers.

Intracranial Pressure and Neurocritical Care Monitoring

Charles L. Francoeur

Stephan A. Mayer

INTRODUCTION

Monitoring plays a fundamental role in the daily practice of neurocritical care. Bedside neuromonitoring supplements clinical evaluation and imaging with the underlying goal of detecting physiologic derangements before neurologic deterioration and irreversible damage occurs. This chapter introduces continuous bedside neuromonitoring modalities that are in use in the most advanced neurocritical care units around the world. Although no study has tested whether “multimodality” monitoring improves outcome, these advanced systems allow for recognition of real-time pathologic events that we were unable to identify just a few years ago and provide new insights into the complex pathophysiology of severe brain injury.

INTRACRANIAL PRESSURE MONITORING

PHYSIOLOGIC PRINCIPLES

Monro-Kellie Doctrine and Intracranial Pressure

The rigid skull is filled with incompressible content, namely brain (1,400 mL), cerebrospinal fluid (CSF) (150 mL), and blood (75 mL). In normal state, with blood outflow being equal to blood inflow, CSF absorption equals CSF production (~20 mL/h) and intracranial pressure (ICP) lies between 5 and 15 mm Hg in the supine position (8 to 20 cm H₂O).

If any one of those compartments increases in volume, as in the case of obstructive hydrocephalus, or a new mass lesion is added (a subdural hematoma for example), buffering mechanisms are called upon. The first adaptive process is egress of CSF in the spinal canal, provided there is no obstruction to flow. The second step is shifting of blood from the capacitance vessels (veins) out of the intracranial compartment. Once these buffering mechanisms are exhausted, intracranial compliance is reduced and ICP quickly rises (Fig. 33.1).

Secondary neurologic injury occurs with ICP over 20 mm Hg, and elevated ICP above this threshold after traumatic brain injury (TBI) or subarachnoid hemorrhage (SAH) correlates with increased mortality. The magnitude of ICP elevation (especially >40 mm Hg), the duration of intracranial hypertension, as well as its refractoriness to treatment are all associated with higher mortality.

Cerebral Perfusion Pressure

Arterial blood carries oxygen and glucose, which are necessary for neuronal function and survival. Cerebral perfusion pressure (CPP), defined as the difference between mean arterial pressure and ICP, is the main determinant of cerebral blood flow (CBF):

$$CPP = MAP - ICP$$

CPP values below 50 to 60 mm Hg can begin to cause cerebral ischemia, and systemic hypotension strongly correlates with mortality in TBI patients.

FIGURE 33.1 Compliance is the change in pressure per change in unit of volume ($\Delta P/\Delta V$). Once compensatory mechanisms are overwhelmed, compliance dramatically decreases, meaning that with a smaller increment in intracranial volume, a much more dramatic increase in pressure develops.

Intracranial Pressure Waveform

ICP is pulsatile with pressure deflections that correspond to transient increases in cerebral blood volume with systole. Bedside displays will show an ICP waveform with three components (Fig. 33.2): an initial percussive wave which occurs at the start of systole and under normal conditions in greatest amplitude (called *P1*), a secondary tidal wave then occurs which reflects brain recoil or elastance (*P2*), followed by a third tidal wave created by closure of the aortic valve at the start of diastole (*P3*). In states of reduced intracranial compliance, the ICP pulse pressure typically increases, and the amplitude of *P2* exceeds that of *P1* in the ICP waveform, as the “shock” of systolic inflow becomes less absorbable.

FIGURE 33.2 ICP waveform. *P1*, the percussive wave, comes from arterial transmission through the choroid plexus. *P2*, the tidal wave, reflects brain tissue elastance. As it rises, so does *P2*. When *P2* exceeds *P1*, it has an excellent sensitivity to predict incoming increase in ICP. The third and final wave (*P3*) is secondary to aortic valve closure, a corollary of the arterial dirotic notch.

Pathologic Intracranial Pressure Elevations

In patients with raised ICP, pathologic ICP waveforms may occur. Lundberg A waves (or plateau waves) represent prolonged periods (> 10 minutes) of high ICP (>20 mm Hg) (Fig. 33.3). They are caused by sustained vasodilation and abruptly occur when either CPP or intracranial compliance are low (see also Figure 107.4). Severe plateau waves preceding the onset of brain death can last for hours and reach levels as high as 50 to 100 mm Hg. Lundberg B waves are shorter duration (<10 minutes), low amplitude elevations (<20 mm Hg) that indicate that intracranial compliance is compromised.

EXTERNAL VENTRICULAR DRAINAGE

Since the landmark study published by Lundberg in 1960, external ventricular drainage (EVD) has been the gold standard for ICP monitoring. It consists of a catheter blindly inserted into the lateral ventricle and connected via fluid-filled tubing to an external pressure transducer. Insertion is usually on the right side just anterior to the coronal suture roughly in the midpupillary line approximately 6 cm deep, although other approaches are described. The fluid-filled system relays the pulsatile waveform to a transducer, which is then converted to a digital signal. The ICP number displayed at the bedside represents the mean pressure. The hydrostatic reference point is the Foramen of Monro, which is estimated using the external acoustic meatus or the tragus.

EVD placement has the advantage of allowing therapeutic CSF drainage, making it the monitoring of choice in case of elevated ICP secondary to hydrocephalus. Depending on the indication, height of the EVD drip chamber is kept from 0 to 20 cm above the tragus, with lower levels causing a higher hourly CSF drainage rate. With a conventional EVD system, either ICP can be monitored with the system clamped or CSF can be drained but not both at the same time. Some EVD systems are equipped with a fiberoptic pressure transducer at the tip, which allows for simultaneous pressure monitoring and CSF drainage.

FIGURE 33.3 Lundberg A (plateau) wave, with characteristic “mirror” reduction in CPP. The plateau wave is terminated by an infusion of dopamine, which leads to an elevation in mean arterial pressure and reversal of the brain's vasodilated state. ICP, intracranial pressure; CPP, cerebral perfusion pressure; MAP, mean arterial pressure.

The main complications of EVD placement are insertional bleeding and infection. Clinically significant (requiring intervention) bleeding rates are 1% or less, but the risk of infection (ventriculitis) ranges from 5% to 15%. As for any other invasive devices, aseptic insertion technique, limited manipulations, and quick removal are the best ways to keep infectious complications to a minimum.

Safe discontinuation of an EVD is accomplished by performing a 24-hour clamp trial. If the ICP remains below 20 mm Hg, the patient remains stable, and a follow-up CT shows no interval ventricular enlargement, the EVD can be safely removed.

INTRAPARENCHYMAL INTRACRANIAL PRESSURE MONITORS

Intraparenchymal devices are now the most commonly used method of ICP monitoring, and they are as reliable and accurate as EVD. In most systems, a fiberoptic or strain gauge pressure transducer is located at the catheter tip, which is inserted 0.5 to 1 cm into the cerebral parenchyma. Although often placed on the nondominant side, insertion should be ipsilateral to the lesion aiming for the brain parenchyma most at risk

of secondary injury. The risk of insertional bleeding with a parenchymal ICP monitor is lower than that of an EVD, and the risk of infection is negligible.

INDICATIONS FOR INTRACRANIAL PRESSURE MONITORING

As a general rule, there are here indications for placement of an EVD or ICP monitor:

1. The patient is comatose (generally Glasgow Coma Scale [GCS] score ≤ 8).
2. Brain imaging indicates that the patient is at risk for elevated ICP due to the presence of significant intracranial mass effect.
3. Aggressive intensive care unit (ICU) care is warranted.

The Brain Trauma Foundation issued updated recommendations in 2015 regarding indications for ICP monitoring of severe TBI patients (Table 33.1). Other considerations include when clinical exam is likely to be lost for a moderate to long period of

P.257

time, especially if associated with physiologic derangement, for example, during major surgery or a difficult to ventilate acute respiratory distress syndrome (ARDS) patient. Obstructive hydrocephalus is also a clear indication for EVD insertion. Recent guidelines from the International Multidisciplinary Consensus Conference on Multimodality issued recommendations for ICP monitoring in non-TBI patients (Table 33.2). Examples given in the consensus include massive ischemic stroke, meningitis, hypoxic-ischemic injury, and hepatic fulminant failure. Any pathology complicated by elevated ICP might benefit of such monitoring when clinical exam is not trustworthy, as it allows optimization of cerebral hemodynamics through CPP manipulation, aggressive ICP treatment, as well as detection of new catastrophic events.

TABLE 33.1 Indications for Intracranial Pressure Monitoring in Traumatic Brain Injury Patients

Level of Evidence	Indication
Level I and II A	There is insufficient evidence to support a level I or II A recommendation for this topic.
Level II B	Management of severe TBI patients using information from ICP monitoring is recommended to reduce in-hospital and two-week post-injury mortality.

GCS, Glasgow Coma Scale; CT, computed tomography; TBI, traumatic brain injury.
From Guidelines for the Management of Severe Traumatic Brain Injury, 4th Edition; Brain Trauma Foundation, 2015.

EFFECT OF INTRACRANIAL PRESSURE-DIRECTED THERAPY ON OUTCOME

There is a strong association between elevated ICP, especially if refractory to treatment, and poor

outcome. Retrospectives studies, databases analysis, and a meta-analysis show that 20 mm Hg is a powerful threshold for identifying patients at risk for death or poor outcome after TBI and also suggest a mortality benefit with ICP monitor-based management.

Of course, a monitoring device alone cannot improve the outcome of a disease. Only a treatment protocol based on the results of monitoring can impact on survival and recovery.

In 2012, the Benchmark Evidence from South American Trials: Treatment of Intracranial Pressure (BEST TRIP) trial compared two ICP treatment protocols, one triggered by ICP values exceeding 20 mm Hg and the other triggered by clinical examination and serial imaging results alone [Level 1].¹ Outcome was similar with a tendency toward more efficiency in the ICP monitor arm (less hypertonic saline, less hyperventilation, less barbiturates). The external validity was problematic with poor prehospital care and even worse postdischarge management with few to no patients receiving rehabilitation. The medical community still believes ICP monitoring is an essential component of severe TBI management, although the possibility has been raised that perhaps more sophisticated triggers of therapy that take into account the state of autoregulation and intracranial compliance need to be explored. Current management algorithms for treatment of ICP are presented in Chapter 107.

TABLE 33.2 Indications for Intracranial Pressure Monitoring in Nontraumatic Brain Injury Patients

Level of Evidence	Indication
Moderate	Patients at high risk or those with clinical or radiologic evidence of acute symptomatic hydrocephalus
Low	SAH, ICH, and other non-TBI conditions in patients at risk for elevated ICP based on clinical and/or imaging features
Low	All poor-grade SAH patients with consideration for multimodality monitoring
Low	Patients who undergo hemicraniectomy in the setting of cerebral edema

SAH, subarachnoid hemorrhage; ICH, intracerebral hemorrhage; TBI, traumatic brain injury; ICP, intracranial pressure.

BRAIN OXYGENATION MONITORING

PHYSIOLOGIC PRINCIPLES

The human brain, although only 2% of the total body weight, consumes 20% of total body oxygen. Approximately 90% of the energy is used by neurons mainly for synaptic activity and to preserve ionic gradients. The energy substrate is high-energy adenosine triphosphate (ATP) produced from glucose through aerobic metabolism. In the absence of continuous oxygen delivery, ATP production ceases within

seconds. Osmotic gradients are lost, edema sets in, intracellular calcium rises, and early apoptotic mechanisms are triggered. With new technology, early detection and reversal of brain hypoxia is feasible in the neuro-ICU. Two invasive bedside techniques allow for brain oxygenation monitoring: *brain tissue oxygen partial pressure* (PbtO₂) and *jugular venous oxygen saturation* (SjvO₂) monitoring.

Both SjvO₂ and PbtO₂ are dependent on CBF, arterial O₂ content, and cerebral O₂ consumption (CMRO₂). AVDO₂, the arteriovenous difference in O₂ content, can be simplified as SaO₂ - SjvO₂ because other parameters, such as hemoglobin, remain constant during cerebral transit.

$CMRO_2 = CBF \times AVDO_2$, where $AVDO_2 \approx SaO_2 - SjvO_2$

PbtO₂ is also influenced by arterial oxygen pressure (PaO₂). With other factors being constant, a PaO₂ of less than 65 mm Hg results in impaired ability to perform complex tasks, and with a PaO₂ less than 30 mm Hg, loss of consciousness ensues.

Low PbtO₂ values are often seen in severe neurologic injuries sometimes despite normal ICP and CPP values. Imaging cannot reliably predict brain tissue hypoxia because some episodes result from cellular distress and increased oxygen demand related to seizures, shivering, or other hypermetabolic states.

Available data strongly suggest an independent association of the burden of brain tissue hypoxia with poor outcome both in TBI and SAH patients. Taken together, these findings underlie the rationale for incorporating invasive brain oxygenation monitoring as a management option for life-threatening brain injury. Use of either SjvO₂ or PbtO₂ monitoring is recommended for patients at risk of cerebral ischemia according to the latest International Multidisciplinary Consensus Conference on Multimodality Monitoring.

JUGULAR VENOUS OXYGEN SATURATION MONITORING

This technique employs continuous oximetry in the jugular bulb to analyze oxygen content of cerebral venous drainage. The six major cranial sinuses, running between the dura mater and the cranial periosteum, end up forming the left and right internal jugular veins (IJVs). The IJV starts with the jugular bulb, a small dilation at the jugular foramen, into which the cerebral hemispheres, the cerebellum, and the brain stem drain. Venous blood from extracranial sources make up less than 5% of net blood flow in the jugular bulb. Sampling necessitates retrograde placement of a catheter in the IJV up to the bulb. The tip of the catheter, verified with a lateral or anteroposterior x-ray, should lie at the level of the mastoid bone above the lower border of C1.

Normal SjvO₂ values range between 55% and 75%. Low values suggest insufficient O₂ delivery to the brain to meet metabolic needs, which may reflect either high CMRO₂, low CBF, or both. Values under 45% are associated with cellular dysfunction. One limitation of SjvO₂ is that it reflects global oxygenation; regional ischemia can be missed. It has been estimated that 13% of the

P.258

brain volume must be ischemic to impact on SjvO₂. Another technical point is that improper catheter placement will mean a greater contamination by extracranial blood reducing sensitivity to detect brain hypoxia.

SjvO₂ values above 75% suggest hyperemia from loss of autoregulation resulting in excessive cerebral vasodilation, which can occur after TBI or in states of diffuse inflammation or low oxygen consumption, which can occur with hypothermia, barbiturate anesthesia or extensive cerebral infarction.

BRAIN TISSUE OXYGEN PRESSURE MONITORING

The most commonly used technologies for PbtO₂ measurement today are based on use of a Clark electrode (Licox) and oxygen quenching methods using a microchip at the catheter tip (Raumedic). The Clark electrode has two metallic electrodes surrounded by electrolytes and a membrane. Oxygen from the interstitial space diffuses through the membrane and is reduced at the cathode, which changes the voltage difference between the two electrodes. The more oxygen, the more the voltage change measured. The oxygen quenching method uses a lanthanide polymeric matrix that luminesces at different wavelengths based on regional oxygen tension. A fiberoptic cable detects these wavelengths and transmits a continuous output signal.

The tip of the probe should be located in the white matter, where normal PbtO₂ levels range from 25 to 50 mm Hg (Table 33.3). A postinsertion CT scan is mandatory to confirm positioning and interpret readings because placement in hemorrhagic or infarcted tissue results in uninterpretable readings near zero. An equilibration period of 60 minutes is expected, and an oxygen challenge (5 minutes 100% fraction of inspired oxygen [FiO₂]) is performed daily to make sure of the proper monitor functioning: It should lead to a threefold PbtO₂ increase, provided CBF is adequate.

The volume of brain tissue sampled with this focal form of monitoring ranges from 15 to 20 mm³. As with ICP monitoring, the area of probe insertion should be carefully considered; areas most at risk of secondary injury are the best target. An example would be in the vascular territory of the ruptured aneurysm, which is at highest risk for developing delayed cerebral ischemia.

PbtO₂ measured with different technologies are not interchangeable, and the most cited values come from data obtained with Clark electrode technology (see Table 33.3). Values with the oxygen quenching systems tend to run higher.

CLINICAL USE

PbtO₂ monitoring is an adjunct to ICP monitoring in comatose patients. A low PbtO₂ can help detect a new critical event, such as vasospasm after SAH or seizure. A reassuring value, on the contrary, may be an argument for permissive ICP. PbtO₂ change is a way to evaluate the patient's response to delayed cerebral ischemia (DCI) treatment with hemodynamic augmentation therapy. It can also be used to carefully titrate hyperventilation therapy or to detect a detrimental ventilation strategy. Some observational studies suggest that combining ICP/ CPP and PbtO₂-based management leads to better outcomes in TBI or SAH patients.

TABLE 33.3 Brain Tissue Oxygen Partial Pressure Thresholds (Clark Electrode Technology)

PbtO ₂ Value (mm Hg)	Interpretation
>50	Hyperemia or inability to extract O ₂
25-50	Normal
<20	Hypoxia

<10

Severe hypoxia

PbtO₂, brain tissue oxygen partial pressure.

CEREBRAL BLOOD FLOW MONITORING

PHYSIOLOGIC PRINCIPLES

Adequate CBF is critical to proper function and survival of neurons. Avoidance of hypoperfusion is essential to limit secondary injuries (Fig. 33.4). *Autoregulation* is the intrinsic capacity of the cerebral vasculature to adapt to changing pressure and maintain constant CBF by varying the caliber of its resistance vessels at the precapillary level. In healthy individuals, autoregulation allows for a stable level of brain perfusion across a wide range of blood pressures. In pathologic states such as TBI, SAH, ICH, or ischemic stroke, however, autoregulation often fails, putting the brain at high risk for ischemia or hyperemia.

The partial pressure of carbon dioxide also has a potent effect on cerebral resistance vessels. The change is not mediated directly by CO₂ but rather by hydrogen ions that determine the pH level. The effect of respiratory acidosis or alkalosis on CBF is fast (within minutes) but short-lived (<24 hours), as homeostatic mechanisms lead to a reequilibration of pH. Iatrogenic hyperventilation produced with mechanical ventilation (low PCO₂, high pH) can theoretically aggravate ischemia in the acute phase of TBI or ischemic stroke, which is why current guidelines caution against aggressive hyperventilation for ICP control in these conditions.

The partial pressure of oxygen does not affect CBF as long as it is within normal range; however, a PaO₂ below 50 mm Hg will increase CBF significantly as occurs with hypoxia-associated cerebral edema (see Chapter 107).

CONTINUOUS CEREBRAL BLOOD FLOW MONITORING TECHNIQUES

CBF monitoring is meant to detect hypoperfusion before it leads to irreversible ischemia and while it is still amenable to treatment. Two available continuous bedside modalities are available.

Thermal Diffusion Flowmetry

Thermal diffusion flowmetry (TDF) is an invasive technique that allows quantitative continuous measurement of regional cerebral blood flow (rCBF) measured in mL/100g/min. The probe is inserted 25 mm into the brain and comprises a thermistor at the tip and a temperature sensor a few millimeters proximal. Tiny temperature fluctuations are produced by transiently heating the thermistor tip; according to the Fick principle, the resulting change in temperature at the proximal sensor is inversely related to CBF.

Real-time dynamic rCBF data have been correlated with xenon computed tomography (Xe-CT) perfusion studies and PbtO₂ monitoring. Studies relating rCBF to outcome are limited. Because the probe is located in the subcortical white matter, 15 mL/100g/min is a reasonable threshold for defining critical hypoperfusion. Low CBF values alone, however, do not necessarily imply active ischemia because low CBF can also be coupled to a low rate of cerebral metabolism. Concurrent PbtO₂ or SjvO₂ monitoring is helpful in differentiating low CBF states.

FIGURE 33.4 Autoregulation allows for a constant CBF in the face of changing CPP by varying the vessels caliber (*red line*). Over the limit of around 150 mm Hg of CPP in a healthy brain, there is endothelial injury and blood-brain barrier disruption with luxury perfusion and edema formation. Under 50 mm Hg of CPP, vasodilatation is maximal and CBF becomes directly proportional to CPP with great risks of hypoperfusion. Both hyperemia and reactive vasodilation can increase ICP when intracranial compliance is reduced (*green line*). With vasodilatory cascade physiology (*shaded blue*), vasodilation in response to low CPP drives up cerebral blood volume (CBV) ICP. With perfusion pressure breakthrough physiology (*shaded orange*), vasodilation from hydrostatic forces increases CBV and ICP. CBF, cerebral blood flow; ICP, intracranial pressure.

One of the main limitations of TDF is its focal nature; the data is highly dependent on the probe's location. Other technical limitation is the 5-minute recalibrations that occur every 30 minutes during which monitoring is unavailable. Infectious and bleeding complications are well under 1%.

Laser Doppler Flowmetry

Laser Doppler flowmetry (LDF) is an invasive technique that provides continuous qualitative assessment of local microvascular perfusion. The fiberoptic laser probe emits laser light, illuminating approximately 1 mm³ of brain tissue, and the photoreceptor detects a portion of the light that is scattered back. The frequency shift of the light, based on the Doppler-effect paradigm, allows for evaluation of red blood cell velocities. Mathematical algorithm correlate the Doppler shift to CBF expressed as arbitrary units. Although correlation with gold standard measurements of CBF is high, LDF does not provide absolute CBF value and can only be used as a trend monitor. It is prone to many artifacts and has limited use in neurocritical care units.

CEREBRAL MICRODIALYSIS

PHYSIOLOGIC PRINCIPLES

Brain energetic function is dependent on ATP production. One molecule of glucose is metabolized to pyruvate and, in the presence of oxygen, will enter the Krebs cycle and produce a total of 38 moles of ATP. In the absence of oxygen, pyruvate will be metabolized into lactate, a much less efficient energy-producing pathway with a yield of only 2 moles of ATP. Lactate can be used as a source of energy production by neurons when glucose is unavailable. If the whole glycolysis process is accelerated, for example, in the presence of

catecholamines or fever, both pyruvate and lactate will be elevated. If hypoxemia is present, only lactate will increase, as pyruvate is anaerobically consumed with lactate as an end product. This is the logic behind the use of lactate-to-pyruvate ratio (LPR) to detect anaerobic metabolism, an important physiologic marker of ischemia (Fig. 33.5).

Another important mechanism of neuronal injury is excitotoxicity. Glutamate is the main excitatory amino acid, and levels are kept low by astrocytes responsible for converting glutamate back to glutamine. This is an energy-dependent process and metabolic failure will lead to elevated glutamate levels. This will mediate excessive intracellular calcium influx and neuronal damage.

When cellular metabolism fails, one of the final common pathways is loss of cellular integrity and membrane degradation. Release of phospholipids ensues, which are converted to free fatty acids and glycerol. This makes glycerol a marker of advanced cellular damage.

FIGURE 33.5 Efficient ATP production from glucose necessitates oxygen. Without O₂ or if the cells are unable to use it, the pathway shifts to lactate production.

MICRODIALYSIS MONITORING

Microdialysis allows for bedside monitoring of brain tissue biochemistry. The probe is a 0.6-mm double-lumen catheter with a semipermeable membrane that allows free diffusion of water and solutes down a concentration gradient. Isotonic fluid is perfused at a constant rate of 0.3 $\mu\text{L}/\text{min}$ and the perfusate is collected and analyzed hourly. The probe is usually 2 cm deep, close to white matter.

Almost any molecule present in the interstitial fluid can be measured in a laboratory setting; the commercially available biomarkers for clinical use are lactate, pyruvate, glucose, glycerol, and glutamate (Table 33.4). One of the most clinically useful indices is the LPR. Values over 20 to 25 correlates with worse outcome in TBI and SAH patients, and a ratio over 40 is used to define “metabolic distress.” LPR elevation can be further defined as type I or type II depending on trends in pyruvate levels. Type I LPR elevation is present when pyruvate is decreased with a marked increase in lactate; it is attributed to a lack of oxygen. In type II, pyruvate is normal or elevated indicating mitochondrial failure and a normal supply of metabolic substrates.

Low brain glucose levels (normally 1 to 2 mmol/L) are also related to outcome in SAH and TBI patients, especially when less than 0.50 mmol/L. An LPR ratio greater than 40 combined with a brain interstitial glucose level less than 0.5 mmol/L is termed *metabolic crisis* and is associated with poor outcome and a

high risk of death among comatose patients. Active glucose transport across the blood-brain barrier into the central nervous system (CNS) is impaired after severe brain injury, which may further compromise brain energetic function. Low levels of brain glucose associated with metabolic crisis despite normal CBF has been reported with blood glucose levels in the normal range. For this reason, microdialysis is useful for helping to minimize the risk of critical brain tissue hypoglycemia when continuous insulin infusion is used to control stress hyperglycemia.

CLINICAL USE

A useful aspect of microdialysis monitoring is that derangements can precede impending deterioration, including elevated ICP in TBI patients or delayed neurologic injury in SAH patients. Severe derangements can be used to trigger emergent decompressive neurosurgical intervention, induction of hypothermia, or angiography to reverse ongoing ischemia.

CONTINUOUS ELECTROENCEPHALOGRAPHY

Technical advances and the era of digitization have made continuous electroencephalography (cEEG) monitoring an essential tool in neurocritical care. Specific uses include detection of seizures, titration of therapy for status epilepticus, monitoring for DCI in SAH patients, and coma prognostication. Refer to Chapter 25 for a detailed discussion of basic electroencephalography (EEG) physiology and interpretation. Listed in the following sections are some of the recommended indications for EEG monitoring in the ICU setting (Table 33.5).

TABLE 33.4 Threshold Values in Brain Interstitial Tissue of Selected Biomarkers Associated with Worse Outcome

Biomarker	Threshold Values
Glucose (mmol/L)	<0.7 or >2.6
Lactate (mmol/L)	>4
Pyruvate (μ mol/L)	<70
LPR	>40
Glutamate (mmol/L)	>20

LPR, lactate-to-pyruvate ratio.

TABLE 33.5 Indications for Continuous Electroencephalography in the Intensive Care Unit according to the Neurocritical Care Society and the European Society of Intensive Care Medicine

- All patients with ABI and unexplained and persistent altered consciousness

- All patients having suffered a seizure that are not back to their functional baseline 60 min after receiving AED

- During therapeutic hypothermia and within 24 h of rewarming in all comatose patients after cardiac arrest

- All comatose ICU patients without ABI but with unexplained impairment of mental status or unexplained neurologic deficits, particularly in those with severe sepsis or renal/hepatic failure

- In comatose SAH patients, in whom neurologic examination is unreliable, to detect DCI

ABI, acute brain injury; AED, antiepileptic drug; SAH, subarachnoid hemorrhage; DCI, delayed cerebral ischemia.

SEIZURE DETECTION

One of the main goals of cEEG is seizure detection. Ten percent to 50% of comatose patients have nonconvulsive seizures or nonconvulsive status epilepticus (NCSE) when monitored with cEEG depending on the primary diagnosis, and the vast majority are clinically undetectable (Table 33.6). Nonconvulsive seizures can directly produce depressed level of consciousness and are associated with poor outcome after all forms of acute severe brain injury.

TABLE 33.6 Yield of Continuous Electroencephalography for Detecting Nonconvulsive Seizures or Status Epilepticus in Selected Conditions

Condition	Yield
After termination of convulsive status epilepticus	48%
Lobar intracerebral hemorrhage	36%
Encephalitis or meningitis	36%
Cardiac arrest	22%
Traumatic brain injury	22%
Poor grade SAH	18%
Septic encephalopathy	16%

SAH, subarachnoid hemorrhage.

In TBI patients, nonconvulsive seizures are associated with elevated ICP, metabolic crisis, and long-term hippocampal atrophy. Duration of monitoring is an important factor in the ability to detect seizures: A 30-minute spot EEG has approximately one-third the sensitivity of a 24-hour cEEG study. A minimum of 48 hours of cEEG monitoring is required to attain greater than 90% sensitivity for detecting nonconvulsive seizures or NCSE.

Surface cEEG in comatose patients often detects periodic or rhythmic patterns that appear to be highly epileptiform but fail to meet conventional diagnostic criteria for electrographic seizures. The term *ictal-interictal continuum* has been used to describe these patterns, which typically create vexing diagnostic and treatment dilemmas. Intracortical (or depth) EEG monitoring is an invasive form of focal electrical brain monitoring that can be used in addition to multimodality monitoring of CBF and PbtO₂ to determine whether these ictal-interictal patterns are truly ictal or not. Intracortical EEG has two to three times the sensitivity of surface EEG for detecting electrographic seizures in comatose patients.

TITRATION OF THERAPY FOR STATUS EPILEPTICUS

cEEG is essential for guiding therapy for refractory status epilepticus (see also [Chapter 6](#)). Delays in efficient treatment of status epilepticus leads to less therapeutic success and higher mortality. Almost 50% of patients who present with convulsive status epilepticus who fail to recover consciousness after initial therapy continue to have evidence of nonconvulsive seizures or NCSE. Failure to urgently detect and treat these seizures leads to prolonged coma and increasing refractoriness to therapy. The EEG target of continuous infusion treatments for NCSE (i.e., midazolam, propofol, ketamine, or pentobarbital) can range from simple elimination of ictal discharges to induction of burst suppression depending on the clinical scenario.

MONITORING FOR DELAYED CEREBRAL ISCHEMIA AFTER SUBARACHNOID HEMORRHAGE

EEG is very sensitive to brain physiology, and changes in the EEG pattern are a promising way to detect DCI after SAH. Reduction in alpha variability and the alpha-to-delta ratio has been found to signal the imminent onset of DCI. Most interestingly, those changes can precede the onset of clinical symptoms by 1 to 2 days.

COMA OUTCOME

Trends in the background EEG over several days of monitoring has prognostic value in coma. After cardiac arrest, improvement of the background from near isoelectric attenuation to burst suppression to a continuous pattern of diffuse slowing implies improving brain function and a more hopeful prognosis. Absence of a posterior dominant (i.e., alpha) rhythm or reactivity of the background EEG to painful stimuli are poor prognostic signs; recovery of these findings implies a better chance of recovery. Comatose patients with electrographic seizures or generalized periodic epileptiform discharges (PEDs) have a worse prognosis than those with lateralized PEDs, who in turn have a worse prognosis than those with no epileptiform activity. The presence normal sleep architecture implies an extremely good likelihood of eventual recovery of consciousness.

LIMITATIONS OF CONTINUOUS ELECTROENCEPHALOGRAPHY

The main limitations of cEEG monitoring are technical and logistic. The recordings are subject to multiple artifacts from eye movement to electrostatic artifacts. The continuous recordings constitute an incredible amount of data to be interpreted, and conclusions can vary from one reader to another. Automated systems are being developed, but cEEG remains for now a cost and labor-intensive modality requiring expert technical and medical staff.

MULTIMODALITY MONITORING DATA ACQUISITION AND ANALYSIS

Since the advent of ICP monitoring, the number of monitored physiologic parameters in neurocritical care has grown faster than our ability to integrate it to a meaningful clinical management plan without special tools that allow us to store, review, and analyze the data. In addition to the brain-specific measurements discussed in this chapter, clinicians must take into account systemic physiologic variables such as heart rate, blood pressure, temperature, and end-tidal CO₂. The amount of data to integrate can be overwhelming.

The primary goal of ICU multimodality monitoring is to act as an alarm system to detect harmful physiologic processes before they lead to irreversible damage. A secondary goal is to allow neurointensivists to optimize the physiologic environment to prevent secondary injury from occurring altogether. In order to do so, modern ICUs will be increasingly grounded within an informatics infrastructure that allows for real-time synchronized data acquisition, storage, and analysis. Raw data must be processed to differentiate signal from noise and to eliminate artifacts. Complex analysis systems are being developed to allow for automated event detection and to minimize unnecessary alarms. Information displays must be optimized to avoid information overload and assist in clinical decision making. All of this implies a greater role for informatics and artificial intelligence in neurocritical care units in the future. A stand-alone data acquisition system is commercially available at present (Moberg Research Inc., Ambler, PA), and two systems exist for data display and analysis (ICU Pilot, Mdialysis, Stockholm, Sweden; ICM+, University of Cambridge, England).

Genetic Testing and DNA Diagnosis

Jill S. Goldman

Jacinda B. Sampson

INTRODUCTION

Enormous advances in genetic technology are changing what we know about the molecular mechanisms and causes of neurologic disease. As a result, genetic testing is becoming more common and, at the same time, more complicated. The need for both clinicians and patients to understand the various types of genetic tests and the implication of genetic results is greater than ever. This chapter will review the process of genetic counseling, the genetic mechanisms that influence the appropriate choice of different types of genetic tests, and interpretation of genetic results.

THE PROCESS OF GENETIC COUNSELING

OBTAINING THE FAMILY HISTORY

A review of family history and drawing of a pedigree are the essential first steps for determining the likelihood of a neurogenetic disease. A carefully constructed pedigree can guide the differential diagnosis by indicating whether any family history exists and, if it does, the possible mode of inheritance. At least a three-generation family history should be obtained, which includes ethnicity, age of onset of symptoms, age and cause of death, diagnoses determined by genetic testing, and known history of consanguinity. Specific family history questions can help to narrow the differential diagnosis. As an example, consider the patient with ataxia: a family history that includes mental retardation or premature ovarian failure would suggest a diagnosis of fragile X-associated tremor ataxia syndrome. Similarly, for a patient with amyotrophic lateral sclerosis (ALS) and a family history of dementia, a likely cause is a hexanucleotide expansion in *C9orf72*. An Ashkenazi Jewish background in the presence of Parkinson disease could indicate a *LRRK2* or *GBA* mutation and, in the presence of dystonia, a *Tor1A* deletion (Table 34.1).

A lack of family history, however, does not rule out a genetic diagnosis. A negative family history may be due to lack of information, early death, autosomal recessive inheritance, undisclosed adoption, false paternity, or de novo mutations (mutations that first appeared in the patient).

THE GENETIC COUNSELING DISCUSSION

The process of genetic counseling and testing differs, depending on whether the patient is being seen prior to diagnostic testing of a symptomatic patient or for predictive testing of an at-risk family member. Regardless, enough time should be given to genetic counseling to provide the patient/family with the understanding of the implications of testing. Clinicians may refer to the National Society of Genetic Counselors (<http://www.nsgc.org>) if they wish to locate a genetic counselor in their area. In general, patients should be encouraged to attend all counseling sessions with a support person who can help them interpret the information and support them through the process.

Even when testing is being performed to assist in diagnosis, the nature and genetics of the disorder; the implications of a positive result for other family members; the benefits, risks, and limitations of testing; and an emotional impact of testing should be discussed (Table 34.2).

Pretest counseling for predictive genetic testing is an opportunity for anticipatory guidance. Patients should be asked how they would feel both over the short term and long term upon receiving a positive or negative result.

They should consider how a positive or negative result would impact their life decisions including relationships, school or work choices, financial decisions, and reproductive choices. Many patients may need referrals for psychological counseling to help them work through the decision to test. In fact, the Huntington disease genetic testing protocol, which is used by many centers for predictive testing for fatal, untreatable neurogenetic conditions, advocates for a psychiatric assessment of all patients prior to predictive testing (Table 34.3).

As with counseling for diagnostic genetic testing, the benefits, risks, and limitations of testing should be covered. In general, predictive testing should not be performed without confirmation of a genetic diagnosis (and known mutation) in another family member. Without a known mutation in the family, a negative result may falsely reassure the individual, or a discovery of a variant of unknown significance will be inconclusive without other informative cases in the family.

Genetic results should be given in person, especially when they are predictive. While delivering the results, the clinician should review the meaning of the test result for the patient and family members, assess the psychological state of the patient and refer for psychological counseling as necessary, determine a plan of action, and give information about appropriate disease associations and support groups. When a positive result has been given, the clinician should check in with the patient/family following the posttest session.

GENETIC PHENOMENOLOGY

The genetics of neurologic disease is complicated by an array of genetic mechanisms. When considering a genetic etiology, all of these phenomena warrant attention and discussion with patients.

INCOMPLETE AND AGE-DEPENDENT PENETRANCE

Penetrance is the likelihood that an individual carrying a pathogenic mutation will develop the disorder caused by that gene. Incomplete penetrance can be found in many autosomal dominant conditions. Examples of incomplete penetrance include *DYT1* early-onset dystonia (about 30% of carriers develop symptoms) and *LRRK2*-related Parkinson disease (age-dependent penetrance increasing during the life span with 35% to 80% by age 75 years). Penetrance sometimes correlates with certain mutations within the

P.264

gene but may also be influenced by other largely unknown genetic or environmental factors. In some disorders such as myoclonusdystonia (ϵ -sarcoglycan or *SGCE*), the sex of the transmitting parent determines penetrance (most symptomatic individuals have inherited the mutation from their father).

TABLE 34.1 Family History Questions for Differential Diagnosis of Neurogenetic Disorders

Disorder	Specific Questions: “Has any family member ever had ...”
Dementia	Dementia Memory problems or other cognitive problems Language or speech problems Personality or behavioral change Mental illness including depression Any other neurologic disease such as Parkinson disease, ALS Movement or gait disorder Strokes Migraines Seizures

Neuromuscular disease

- Gait or walking problems
- Weakness
- Heart problems
- Developmental delay
- Learning disabilities
- Dementia or cognitive impairment
- Language or speech problems
- Personality or behavioral change
- Psychiatric illness including depression
- Vision problems, including early-onset cataracts
- Infertility
- Diabetes

Movement disorders

- Dementia or cognitive impairment
- Learning disabilities or mental retardation
- Language or speech problems
- Personality or behavioral change
- Mental illness including depression
- Gait or walking problems
- Weakness
- Vision problems

Movement disorders

- Infertility
- Tremor
- Seizures
- Writer's cramp or cramps in other muscles
- Abnormal posture
- Tics or other abnormal movements
- Alcoholism
- Clumsiness
- Immune deficiency
- Cancer
- Heart problems
- Hearing loss

Neuropathies

- Walking problems
- Numbness, tingling, or pain in limbs
- Clumsiness
- Difficulty fitting shoes

Neurocutaneous disorders

- Birthmarks or spots on skin
- Seizures
- Hearing problems
- Vision problems
- Tumors or growths that were removed
- Bumps on skin
- Scoliosis
- Mental retardation or learning disabilities
- Heart problems, arrhythmias

Kidney problems
Stroke

Epilepsy

Seizures, spasms
Periods of staring or seeming vacant
Headaches
Vision problems
Learning disabilities, autism, or autism spectrum disorders

ALS, amyotrophic lateral sclerosis.

PHENOTYPIC VARIABILITY

Neurogenetic disorders can have remarkable inter- and intrafamilial variability in severity of symptoms, type of symptoms, age of onset, and disease course. Consider spinal muscular atrophy (SMA), which can occur in infancy as a severe and rapidly fatal condition (SMA type 1) to onset in childhood (SMA type 2) to onset in adolescence or adulthood (SMA type 3) due to the influence of the modifier gene, *SMN2*. Hexanucleotide repeat expansions in the gene *C9orf72* can cause frontotemporal degeneration, ALS, or both. Additional phenotypes that have been reported with this gene include ataxia, parkinsonism, Alzheimer-like dementia, and psychosis. *DYT1* can cause severe childhood dystonia with contractures, adult-onset writer's cramp, or no symptoms at all. Some genotype/phenotype correlations exist, as with the D178N mutation in *PRNP*, which, when present on the same

P.265

chromosome with the polymorphism codon 129M, causes fatal familial insomnia but, when with 129V, causes Creutzfeldt-Jakob disease. Another example is dystrophinopathy, where inframe deletions are more likely to result in the milder Becker muscular dystrophy phenotype, and out-of-frame deletions result the more severe Duchenne muscular dystrophy phenotype, but there are frequent exceptions to the reading frame rule. At other times, unknown factors seem to influence gene expression.

TABLE 34.2 Genetic Counseling Discussion Points

Disorder symptoms and course

Genetics of the disease

- Gene/genes
 - Modes of inheritance
 - Penetrance
 - Degree of variability in symptom expression
-

Implication of genetic testing for family members

-
- Recurrence risk for children
-

- Risk for siblings
-

- Carrier status of parents
-

Benefits of genetic testing

- Diagnosis
 - Clinical trial candidacy
 - Management, if applicable
 - Ability to make reproductive choices, including preimplantation genetic diagnosis
 - More information for life planning
 - End of uncertainty
-

Risks of genetic testing

- Possible insurance discrimination (life, long-term care, and disability insurances), particularly for presymptomatic individuals
 - Emotional impact
 - For diagnostic testing—confirmation of risk to children
 - For predictive testing—knowledge that one will (may) develop disorder
-

Limitations of genetic testing

- May not discover the genetic cause
 - Variants of unknown significance
 - For predictive testing: inability to predict age of onset, severity, or exact symptomology, incomplete penetrance (if applicable)
-

- The need to identify a mutation in an affected family member prior to predictive testing

Communication of test result

- Will the genetic result be shared with family or others? If so, how and when?
-

- Right of relative not to know—encourage family discussion before results are in.

POLYNUCLEOTIDE REPEAT EXPANSION AND ANTICIPATION

Many examples of polynucleotide repeat disorders are found in neurogenetic disease. These include Huntington disease (HD), many of the spinocerebellar ataxias (SCAs), fragile X-associated tremor ataxia syndrome (FXTAS), and the myotonic dystrophies. Age of onset for these diseases roughly correlates with the number of repeats; however, repeat size is not an accurate clinical predictor of age of onset. Expansion of the allele size occurs during gamete formation so that the repeat number can increase, and therefore, age of onset can decrease with successive generations. This phenomenon is called *anticipation*. Contractions occasionally occur. Depending on the disorder, expansion is more common when being inherited from one parent over the other. For HD, SCAs, and FXTAS, expansion usually occurs in the father. In myotonic dystrophy type 1, large expansions more often occur in the mother and can result in a congenital form of the disease. Additionally, these conditions have ranges of repeats whereby the carrier is asymptomatic or will have a very late onset but can transmit an expansion to their children. Thus, a negative family history for these disorders is not uncommon.

GENETIC HETEROGENEITY

Many neurogenetic diseases are multigenic. Presently, over 25 loci for dystonia and over 50 loci for hereditary spastic paraparesis have been reported. Testing for such conditions can be expensive and problematic. Although certain types of gene panels may be appropriate, the ordering clinician has to evaluate which genes are being tested and how. For some of the genes, such as *PARK2*, when sequencing does not reveal a mutation, duplication/deletion testing should be ordered.

PLEIOTROPY

Many genes causing neurologic conditions can cause problems in other systems as well. Examples of pleiotropy include hearing loss in fascioscapulohumeral muscular dystrophy and cataracts in myotonic dystrophy. For this reason, pointed questions about associated symptoms can help to clarify an otherwise negative family history.

PHENOCOPIES

Neurologic conditions such as Alzheimer and Parkinson diseases represent some of the most common conditions in the population.

P.266

Finding a genetic etiology for one of these diseases in one family member does not necessitate that another family member has the mutation, especially with an older onset.

TYPES OF GENETIC TESTS

Many options now exist for genetic testing of neurologic disease. Determining the most appropriate test is essential because they do not all analyze the same types of mutations. The ordering physician may want to consult with a geneticist, genetic counselor, or laboratory director before testing to ensure that they are ordering the correct test and that the test has clinical use. The cost of testing, and whether it will be covered by insurance, is another factor to consider. The types of genetic tests and their appropriate use are described in the following section.

MICROARRAY

Microarray detects large deletions and duplications by detecting the relative signal of markers (single nucleotide polymorphisms or SNPs) spaced through the genome; loss of a copy by a deletion results in a decreased signal; a duplication results in increased signal at that point. Microarray does not detect single nucleotide point mutations nor does it define the exact breakpoints of a deletion or duplication, only that it is present between the normal and changed copy number SNP. Microarray cannot pick up balanced translocations that can be seen on karyotypes but can pick up unbalanced ones. Insertions or deletions smaller than the spacing between microarray markers can be detected using a multiple ligation polymerase assay with polymerase chain reaction (PCR) primers designed to bind to an exon in question; if both primers can bind, they are ligated and amplified by PCR. If one primer is not able to bind its target sequence due to a deletion, no signal will be detected for the primer pair for that exon.

TESTING FOR POLYNUCLEOTIDE REPEAT DISORDERS

Small repeat sizes can be directly sequenced after PCR. Larger ones may require southern blot testing, where genomic DNA is cut with restriction enzymes around the repeat motif and separated on a gel. At larger sizes, polynucleotide repeat disorders may appear to be a smear rather than a single band—this reflects a range of repeat sizes called *somatic mosaicism*.

SANGER SEQUENCING

Primers are designed bracketing the sequence of interest, allowing PCR amplification followed by sequencing, an excellent way of detecting missense mutations or small deletions or duplications falling within the bracketing primers.

NEXT-GENERATION SEQUENCING

Genomic DNA is fragmented into small pieces which are then sequenced and aligned by comparison to the reference human genome. This technique is excellent at detecting point mutations and small insertions/deletions but cannot detect larger insertions, deletions, or polynucleotide repeats and can have difficulty aligning highly homologous sequences or detecting areas with high guanine-cytosine content. It can be used for designing panels of genes using a reagent to capture those sequences of interest. It can also be used for the whole exome or the whole genome.

TESTING STRATEGY

More than one type of test may be available for a disorder, and more than one gene may cause a disorder. A panel may be useful by including other genetic disorders on the differential, avoiding serial testing. A single gene or panel may be less expensive, with a faster turnaround time, than exome or genome sequencing.

Pretest counseling is vitally important for genetic testing, as most laboratories require informed consent. Patients and families should be counseled about the cost of testing, time until results, probability of finding a mutation, and limitations of a selected test. Counseling should also include information on whether insurance will cover the costs and their financial responsibility, whether the chosen test is the end of the diagnostic odyssey or if there may be more testing in their future and how a confirmation of genetic diagnosis may affect their prognosis, their medical care, and their family. It is important to allow sufficient time for these discussions and questions.

Acute Ischemic Stroke

Charles C. Esenwa

Barry M. Czeisler

Stephan A. Mayer

INTRODUCTION

Ischemic stroke is defined as an episode of neurologic dysfunction caused by vascular stenosis or occlusion leading to focal cerebral, spinal cord, or retinal infarction within a specific vascular territory. With the development of acute reperfusion therapies, streamlined algorithms for management of acute ischemic stroke (AIS) are necessary for effective treatment. Management revolves around the processes of (1) early diagnosis, including early stroke recognition and notification of emergency medical services (EMS); (2) rapid clinical and radiologic assessment; (3) early administration of intravenous (IV) thrombolytic therapy; (4) consideration for advanced reperfusion techniques; and (5) specialized poststroke management in either a stroke unit or neurologic intensive care unit (neuro-ICU).

EPIDEMIOLOGY

An estimated 650,000 AIS occur each year in the United States alone. The most significant individual risk factors for ischemic stroke include hypertension, diabetes mellitus, cigarette smoking, poor nutrition, physical inactivity, cardiac dysrhythmia, alcohol consumption, and obesity. In-hospital mortality after AIS is comparatively rare, occurring in approximately 5% of cases, and is associated with increasing age, stroke severity, history of atrial fibrillation, previous stroke, carotid stenosis, diabetes mellitus, and history of coronary artery disease. Functional disability and morbidity from post-stroke complications occur much more commonly, affecting the majority of patients. As a result, only half of AIS patients are discharged home, whereas the remainder requires further care in skilled nursing facilities, rehabilitation, or palliative care centers.

PATHOBIOLOGY

Despite making up only 2% of total body weight, the brain consumes 20% of the body's total energy and relies on a constant supply of glucose and oxygen to maintain function and structural integrity. Each minute, nearly 1 L of blood is supplied to the brain through the carotid arteries and, to a lesser extent, the vertebrobasilar system. To ensure a constant cerebral blood flow (CBF) across a range of blood pressures and metabolic states, cerebral vessels constrict or dilate in response to changes in the concentration of carbon dioxide, oxygen, and vessel wall shear stress related to velocity of blood flow. The primary mediator of vasodilation is nitric oxide, which is released by endothelial cells and acts to relax the circumferential smooth muscle cells in the tunica media.

CEREBRAL BLOOD FLOW REDUCTION

When cerebral perfusion pressure falls below approximately 60 mm Hg due to either systemic hypotension or local arterial blockage, autoregulatory vasodilation cannot compensate leading to decreased CBF from its normal range of 50 to 60 mL/100g/min (Fig. 35.1). When CBF falls below 30 mL/100g/min, regional exchange of nutrients and oxygen fails within the neurovascular unit (endothelial cell, surrounding pericytes, basement membrane, perivascular astrocytes, and adjoining neurons) resulting in pathologic depolarization of neurons and glia and suppression of the normal electrical activity as evidenced by slowing and attenuation of the electroencephalographic background (Fig. 35.2). Sustained severe hypoperfusion, with CBF levels falling below 20 mL/100g/min, triggers a cascade of ischemic injury that can lead to irreversible neuronal necrosis and cerebral infarction.

INFARCT CORE AND PENUMBRA

With decreases in CBF below 20 mL/100g/min, assuming a normal rate of neuronal metabolism, brain tissue progresses from a state of reversible electrical dysfunction to a "penumbral" state of excitotoxic damage and programmed cell death (apoptosis). *Penumbra* is an ancient Latin term that refers to the shadow that advances across the land in advance of the complete darkness of a solar eclipse. In modern stroke therapy, penumbral tissue is brain tissue in the shadow of death.

Failure of the sodium/potassium transmembrane adenosine triphosphate (ATP) pump occurs first, causing neurons and glia

P.268

to depolarize. Widespread depolarization causes uncontrolled release of excitatory neurotransmitters such as glutamate, which in turn leads to an intracellular influx of calcium and sodium. Once the phase of excitotoxicity and apoptosis has set in, a phase of bioenergetic failure occurs with ionic pump dysfunction and loss of normal transmembrane sodium and calcium gradients.

FIGURE 35.1 Cerebral autoregulation. With autoregulation intact (*red line*), CBF begins to fall below a normal range of 60 mL/100g/min and hits a critical ischemic level of approximately 20 mL/100g/min. When autoregulation is impaired or absent (*green line*), CBF can fall to critical levels when MAP is as high as 50 mm Hg. MAP, mean arterial pressure. CBF, cerebral blood flow.

FIGURE 35.2 Progression of ischemic tissue to infarction over time as a function of CBF. A CBF level below 20 mL/100g/min is the level below which tissue progresses through a phase of reversible ischemic injury to infarction. Lower CBF produces more intense ischemia and faster progression to infarction.

FIGURE 35.3 Dynamics of infarct core and penumbra topography over time in focal ischemia. In the earliest minutes to hours, only a portion of the total brain territory at risk is ischemic as a small core of infarct begins to form. Between 2 and 4 hours, the penumbra moves peripherally in a dynamic fashion around a progressively infarct core and collateral failure may lower CBF in some of the outermost regions of the territory at risk to ischemic levels. Beyond 4 hours, the penumbra evolves into a relatively thin rim of ischemic tissue around a large core of infarcted tissue making reperfusion less effective, as amount of salvageable tissue dwindles and the risk of hemorrhagic infarction increases.

In the infarct core, where the bioenergetic failure is greatest, these massive electrolyte shifts cause water to passively follow its osmotic gradient resulting in cellular swelling and eventual lysis. The resultant edema, termed *cytotoxic edema* as it results from intracellular swelling, manifests within minutes of the initial insult and can be detected with magnetic resonance imaging (MRI) as hyperintensity on diffusion-weighted imaging (DWI) sequences.

The core of the infarct is surrounded by an area of relative hypoperfusion, the ischemic penumbra, in which CBF is sufficient to temporarily support cell survival but insufficient to maintain normal cellular function indefinitely (Fig. 35.3). Penumbral tissue may be salvageable if adequate perfusion to the territory can be restored in a timely fashion, which is the basis for all AIS reperfusion therapies. Penumbral tissue, however, is inherently unstable and commonly will progress to completed infarction over time, making *time to reperfusion* the most important therapeutic factor for improving neurologic outcome and preventing mortality after AIS.

COMPLETED INFARCTION

It is estimated from human and experimental studies that the time from vessel occlusion to fully completed infarction in most cases ranges from 3 to 6 hours depending on the quality of collateral flow. Once the tissue becomes necrotic and infarcted, it is easily visible on both computed tomography (CT) and fluid-attenuated inversion recovery (FLAIR) MRI images. CBF is maintained at near normal levels up to the margin of a completed infarct where it rapidly drops to undetectable levels as long as the affected vessel remains occluded. Over the next several days, the infarct progressively swells. Ischemic cells that progress to frank tissue infarction release various proinflammatory cytokines and proteases that disrupt the architecture and function of the neurovascular unit, increasing permeability of the blood-brain barrier. Apoptosis is triggered through the function of various inflammatory processes, including the receptor/ligand combination of the CD95 receptor and tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) and mitochondrial membrane release of cytochrome *c* oxidase, both of which lead to activation of the intrinsic programmed cell death cascade and delayed cell death. This delayed neurologic injury could in theory be prevented with neuroprotective agents, although none has proven to be of use in clinical trials.

The parenchymal inflammatory response results from upregulation of endothelial cell leukocyte adhesion receptors that cause

P.269

leukocyte adhesion and transmigration into the affected tissue and is responsible for the prolonged process of tissue inflammation and remodeling after an infarct is completed, as the swelling resolves and the involved regions convert to gliotic scar tissue.

ETIOLOGY OF ISCHEMIC STROKE

The microscopic process of acute cerebral infarction is preceded by macrovascular occlusion of the territory in question. Accurate classification of AIS etiology is important to understand post-stroke prognosis, quantify the risk of recurrence, and guide strategies for secondary stroke prevention. Although imperfect, the Trial of Organon in Acute Stroke Treatment (TOAST) classification criteria is the most widely accepted ischemic stroke classification system and includes the following five subtypes: large artery atherosclerosis (15% to 40%), cardioembolic (15% to 30%), small-vessel occlusion or “lacunar” (15% to 30%), cryptogenic (up to 40%), and “other” cause (<5%) (Fig. 35.4).

LARGE-ARTERY ATHEROSCLEROSIS

Atherosclerotic plaque may develop at any point along the extracranial or intracranial arterial tree but is usually seen at vessel-branch points where turbulent flow occurs, most commonly at the common carotid bifurcation, vertebral artery origin, vertebralbasilar junction, or the origin of the middle or anterior cerebral arteries. Atherosclerotic plaque causes ischemic stroke by one of two mechanisms: hypoperfusion across a region of critical stenosis or, more commonly, plaque rupture leading to thrombus formation and subsequent distal embolization of thrombus or plaque fragments.

Artery-to-artery embolism occurs when fragments of atherosclerotic plaque or fresh thrombus formed on top of the plaque embolize to occlude a distal vessel. Plaques with a lipid-rich necrotic core and thin fibrous cap pose a risk of spontaneous rupture and activation of the coagulation cascade leading to superimposed thrombus formation. Biomechanical forces induced by turbulent blood flow along this irregular portion of vessel can act to destabilize the cholesterol plaque or dislodge a superimposed thrombus. When this happens, the thrombus may rapidly dissolve causing the clinical symptoms to be fleeting or absent, or it may persistently occlude a distal vessel leading to lasting symptoms of AIS.

FIGURE 35.4 Stroke subtypes. This figure shows the TOAST classification criteria for ischemic stroke and the estimated relative distribution of stroke within each category.

Clinically, ischemia from large-artery atherosclerosis is difficult to distinguish from stroke originating from the heart (cardioembolic stroke). Favoring the former are repeated transient ischemic attacks or completed infarcts within the same vascular territory, the best example of which is repeated episodes of painless *transient monocular blindness* related to ipsilateral carotid artery atherosclerosis. This condition, known as *amaurosis fugax*, results from cholesterol embolism from the carotid plaque causing occlusion of the central retinal artery or one of its branches. When the lumen of the carotid artery is nearly occluded, transient attacks can also be due to retinal hypoperfusion, clinically manifesting as vision loss with exposure to bright light. Similarly, repeated episodes of vertigo, diplopia, hemiparesis, hemianesthesia, gait unsteadiness, and even loss of consciousness can be a sign of high-grade vertebral or basilar artery stenosis.

CARDIOEMBOLIC STROKE

Cardioembolic stroke includes all strokes caused by a cardiac source of thromboembolism. Most commonly, cardioembolism occurs from thrombus formed in the left atrial appendage of the heart in patients with atrial fibrillation, but cardioembolism can also result from a diseased native or prosthetic heart valve or ventricular wall thrombus resulting from recent myocardial infarction or severe dilated cardiomyopathy. Cardioembolic strokes can also result from neoplastic causes, such as atrial myxoma or marantic endocarditis, or infectious causes such as infectious endocarditis. Radiologically, scattered strokes at the gray-white matter junction that occur in both hemispheres, or in both the anterior and posterior circulation, are most commonly cardioembolic in origin. However, strokes that appear in association with proximal large-vessel

P.270

occlusions or that appear most consistent with small-vessel infarction can also be seen after cardioembolism.

SMALL-VESEL INFARCTION

Lacunar strokes from small-vessel occlusion are clinically defined by five general subtypes: (1) pure motor hemiparesis, (2) pure sensory syndrome, (3) mixed sensorimotor syndrome, (4) ataxic hemiparesis, and (5) clumsy-hand dysarthria, although various other manifestations can occur depending on the territory of the vessel involved. These strokes result from blockage of small perforating arteries arising from the middle cerebral artery (lenticulostriate), the posterior cerebral or posterior communicating arteries (tuberthalamic, paramedian, posterior choroidal, inferolateral), and basilar artery (pontine perforators). These vessels are prone to segmental arterial wall disorganization and fibrosis, a process known as *lipohyalinosis*, and microatheroma formation. Over time, the arterial wall thickens and the vessel lumen is compromised causing a region of acute ischemia that is usually smaller than 1.5 cm in diameter. Hypertension is the greatest risk factor, although diabetes, age, and smoking may contribute as well. Lacunar infarction occurs most commonly in the basal ganglia, thalamus, internal capsule, corona radiata, and pons. Imaging helps distinguish lacunar stroke from other types of stroke by their subcortical location and relatively small size.

UNDETERMINED CAUSE OF STROKE

The etiology of up to 40% of strokes remains *cryptogenic*, or undetermined, even after extensive laboratory and radiologic investigation. However, many of these patients may in fact have undiagnosed atrial fibrillation with studies showing that 10% to 20% of “cryptogenic” stroke patients are found to have occult atrial fibrillation after prolonged cardiac monitoring. Although patent foramen ovale (PFO) and atrial septal defect are also associated with cryptogenic stroke in younger patients, PFO closure is not yet of proven efficacy for the prevention of stroke recurrence.

OTHER CAUSES OF STROKE

The “other” causes of stroke category makes up less than 5% of AIS, and it is defined by a specific disease process that is shown to have a temporal relationship or association to the stroke. In addition, diagnostic investigation should not reveal any other more-common mechanism. Examples include stroke due to hematological disorders (e.g., hypercoagulability, sickle cell anemia), infectious or inflammatory disease, intrinsic disease of the arterial wall (i.e., vasculopathy), vessel dissection, migraine-associated infarction, genetic disorders, or iatrogenic causes.

CLINICAL MANIFESTATIONS

Ischemic strokes can be defined clinically by the nature of the associated neurologic deficit with signs and symptoms fitting into defined syndromes representing specific vascular territories (Fig. 35.5). Knowledge of the following major stroke syndromes can oftentimes accurately predict the territory of infarction and specific vessel involved (Table 35.1). Exceptions arise when there is underlying preexisting CNS injury, presence of collateral circulation, or variations in the vascular or brain anatomy that can produce atypical or unexpected clinical presentations.

MIDDLE CEREBRAL ARTERY INFARCTION

Infarction of the middle cerebral artery (MCA) produces clinical syndromes that depend on the extent of the infarct and the side and level of vessel occlusion. Proximal, or branch MCA occlusion, can affect both the deep and the cortical hemispheric structures or deep structures only when there is robust collateral vascularization supplying the cortex. Isolated ischemia of the deep cerebral structures—mainly the internal capsule, basal ganglia, and corona radiata—occurs due to blockage of the lenticulostriate artery origins causing contralateral hemiparesis and possibly hemisensory loss that often is indistinguishable from a lacunar syndrome. Larger deep infarcts (“striatocapsular infarction”) that affect cortical connections to the thalamus and optic radiations can cause the cortical syndromes of hemineglect, aphasia, and homonymous hemianopia or quadrantanopia.

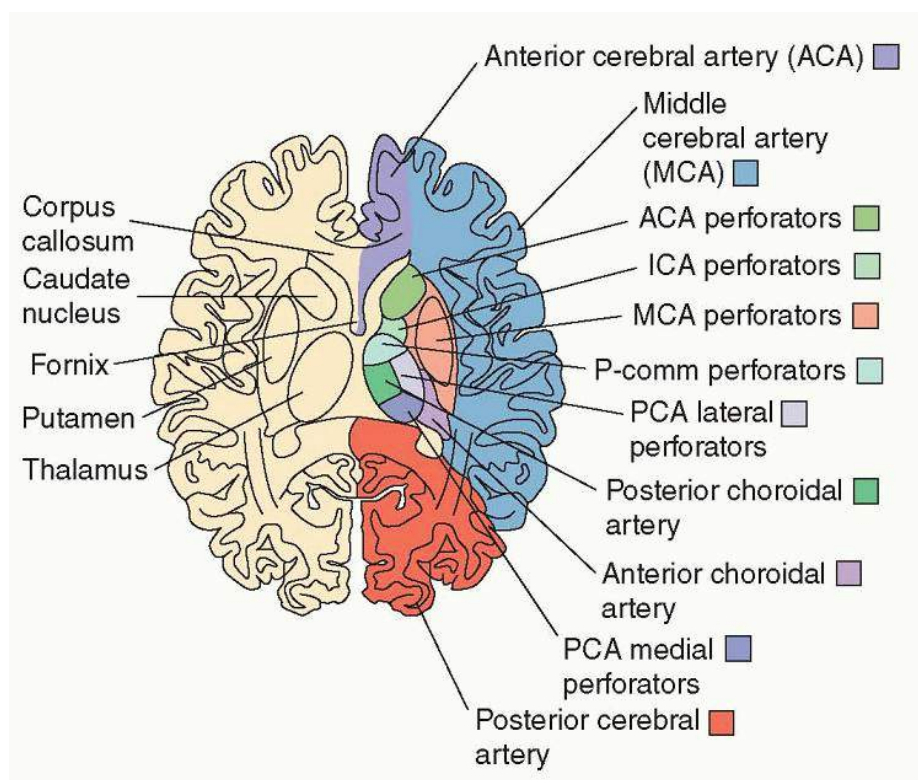

FIGURE 35.5 Cerebral vascular supply. ICA, internal carotid artery; posterior cerebral artery.

Cortical ischemia in the MCA territory is encountered in isolation when vessel occlusion is localized to the superior or inferior MCA divisions (the number and location of these branch arteries can vary). Damage to either hemispheric cortex can cause contralateral limb weakness, contralateral sensory loss, astereognosia (inability to identify objects using touch), agraphesthesia (inability to recognize writing traced on the skin), diminished two-point discrimination, contralateral visual field deficits, and gaze deviation towards the damaged side. Ideational apraxia (inability to understand the purpose of an object or manipulate it) follows left-sided or bilateral hemispheric damage.

Syndromes resulting from a dominant (usually left) hemispheric lesion include aphasia (language dysfunction), bilateral ideomotor apraxia (inability to perform learned motor tasks), and buccolingual apraxia (inability to voluntarily direct mouth and tongue movements). The type and severity of aphasia depends on the location and size of the infarct. A superior MCA branch occlusion will affect the anterior perisylvian cortex and specifically

the inferior frontal gyrus to produce Broca (expressive) aphasia that is characterized by decreased or absent word fluency and inability to write but with preserved comprehension. When aphasia is expressive or global, hemiparesis is also usually present and severe. Inferior branch MCA occlusion, affecting the posterior perisylvian cortex and specifically the superior temporal gyrus and temporoparietal junction, produces Wernicke (receptive) aphasia, which is characterized by preserved fluency and prosody but incomprehensible content, semantic and phonemic paraphasic errors, impaired comprehension, and inability to read, name, or repeat.

Receptive aphasia is often associated with a homonymous hemianopia or quadrantanopia, but hemiparesis can be mild or even absent. Gerstmann syndrome (left-right confusion, finger agnosia, acalculia, and agraphia) follows infarction of the dominant angular gyrus.

TABLE 35.1 Syndromes of Cerebral Infarction

Arterial Distribution	Subdivision	Syndrome
Middle cerebral	Main trunk	Variable combination of hemiplegia, hemianesthesia, gaze deviation/preference, hemianopia and global aphasia (dominant hemisphere), or profound multimodal hemineglect (nondominant hemisphere)
	Upper division	Variable combination of hemiparesis, hemianesthesia, gaze deviation, and expressive (Broca) aphasia (dominant hemisphere) or hemineglect (nondominant)
	Lower division	Variable combination of hemianopia or quadrantanopia, mild or absent hemiparesis, receptive (Wernicke) aphasia (dominant hemisphere), or hemineglect and behavior disorder (nondominant)
	Perforating branches	Contralateral hemiparesis occasionally seen in combination with ataxia or dysarthria
Internal carotid		Can be asymptomatic or cause any of the following: ipsilateral monocular blindness, transient limb shaking, or a combination of middle cerebral and anterior cerebral artery syndromes
Anterior cerebral		Variable combination of hemiparesis and sensory loss of the contralateral leg more than the arm, transcortical motor aphasia (dominant hemisphere), motor neglect (nondominant hemisphere), impaired responsiveness ("abulia"), gait apraxia, ideomotor apraxia, or tactile anomia (nondominant hemisphere)
Posterior cerebral	Main trunk	Variable combination of hemianopia or quadrantanopia, alexia, color anomia, inability to perceive parts of an objects as a whole ("simultanagnosia"), face blindness ("prosopagnosia"), amnesia, agitated delirium (especially when bilateral), or cerebral blindness (with bilateral injury)
	Perforating branches	<i>Thalamus</i> : pure sensory stroke that may leave a residual pain syndrome ("thalamic pain syndrome"), ataxia, aphasia (dominant), hemineglect (nondominant), visual field deficits, memory loss, or behavioral disturbances <i>Subthalamic nucleus</i> : hemiballism <i>Midbrain</i> : various eye movement abnormalities, depressed level of arousal, hemianesthesia, hemiparesis, hemiataxia, hemiparkinsonism

Infarction of the nondominant (usually right) parietal lobe produces contralateral hemispatial neglect or an inattention to sensory inputs or motor outputs to the contralateral half of the environment or body. Specific findings include visual neglect (that can involve the entire contralateral visual field or be specific to various objects), anosognosia (lack of awareness of neurologic deficits), asomatognosia (inability to recognize one's limb on the affected side), and allochiria (spatial transposition resulting in the patient attending to the ipsilateral hemispace when presented with a stimulus on the neglected contralateral side). Constructional apraxia (inability to assemble or draw objects) may result from damage to either hemisphere but is more obvious in nondominant hemispheric lesions. Although speech content or the propositional aspect of speech is preserved, a nondominant hemispheric lesion may cause deficits in the pragmatics, or sociolinguistic aspects of speech, involving tone and inferred intent.

ANTERIOR CEREBRAL ARTERY INFARCTION

Anterior cerebral artery (ACA) infarction most commonly causes contralateral leg hemiparesis and/or hemisensory loss, although many other features may also be seen. Similar to watershed infarcts, ACA territory infarcts can cause transcortical aphasia of the motor type. *Motor neglect*, or a disinclination to use the contralateral limb despite the absence of weakness, is often encountered and is due to dysfunction of the prefrontal supplementary motor cortex. Bilateral ACA infarction often results in executive dysfunction with motor inertia and *abulia* (paucity of spontaneous behaviors) or even *akinetic mutism* (awake unresponsiveness). *Gait apraxia*, although typical of bilateral lesions, can also result from unilateral strokes. *Alien hand syndrome* (unwilled motor activity) or hemiballism of the contralateral arm can result from injury to the anterior corpus callosum or medial frontal cortex. *Utilization* and *imitation behavior* are neurobehavioral syndromes that can occur with unilateral prefrontal infarcts. With

utilization behavior, the patient automatically and impulsively grabs objects that appear within visual field and are within reach. Imitation behavior is automatic and involuntary imitation of the examiner's movements.

Occlusion of the recurrent artery of Heubner, a large perforating artery arising from the proximal ACA, leads to infarction of the head of the caudate, anterior internal capsule, and anterior putamen. Common clinical features include dysarthria, motor perseveration, contralateral hemiparesis, abulia, and incontinence.

INTERNAL CAROTID ARTERY INFARCTION

Acute carotid occlusion causes acute hemispheric hypoperfusion that, in the absence of a patent circle of Willis, can manifest as seizure, contralateral limb shaking, or holohemispheric infarction of both the ACA and MCA territories. Occasionally, and especially in the presence of a robust circle of Willis, occlusion of the internal carotid artery (ICA) spares the ACA and produces a clinical scenario indistinguishable from branch MCA infarction. If collateral

P.272

flow across the posterior communicating artery, anterior communicating artery, or pial arteries is adequate, the occlusion can be clinically silent or only affect smaller susceptible areas. By contrast, ICA occlusion with poor collateral or a distal ICA "T occlusion" can lead to catastrophic holohemispheric infarction with sparing of only the posterior cerebral artery (PCA) territory (thalamus and medial temporal and occipital lobes).

BORDER ZONE INFARCTION

Border zone (or watershed) territories occur at the boundaries between the anterior, middle, and posterior cerebral arteries and are susceptible to ischemia in acute carotid occlusion or global hypoperfusion. *Superficial border zone infarction* occurs high along the convexity of the corona radiata between the deep and cortical structures anteriorly between the ACA and MCA territories or posteriorly between the MCA and PCA territories (Fig. 35.6). This pattern of infarction occurs when collateral flow is able to supply the majority of the involved territories but is unable to "meet" between territories. Resulting symptoms form a combination of weakness, hemisensory loss, and cortical signs. Transcortical aphasia of the expressive or receptive type with relatively preserved ability to repeat is also common. ACA-MCA watershed infarcts primarily cause arm weakness because the affected region corresponds anatomically with neurons in the motor strip that innervate the upper extremities. When bilateral, as occurs with cardiac arrest, ACA-MCA watershed infarctions result in *man-in-the-barrel syndrome* characterized by proximal bilateral arm and leg weakness with relative preservation of facial and distal extremity strength.

Internal border zone infarction (see Fig. 35.6) can occur with total ICA occlusion or with large MCA branch occlusions. Noncollateralized deep penetrating arteries that descend from the cortex to the lateral wall of the ventricles represent the most hemodynamically vulnerable "distal field" in this scenario. The result is a pattern of multiple small deep infarcts involving the deep white matter of the corona radiata and centrum semiovale.

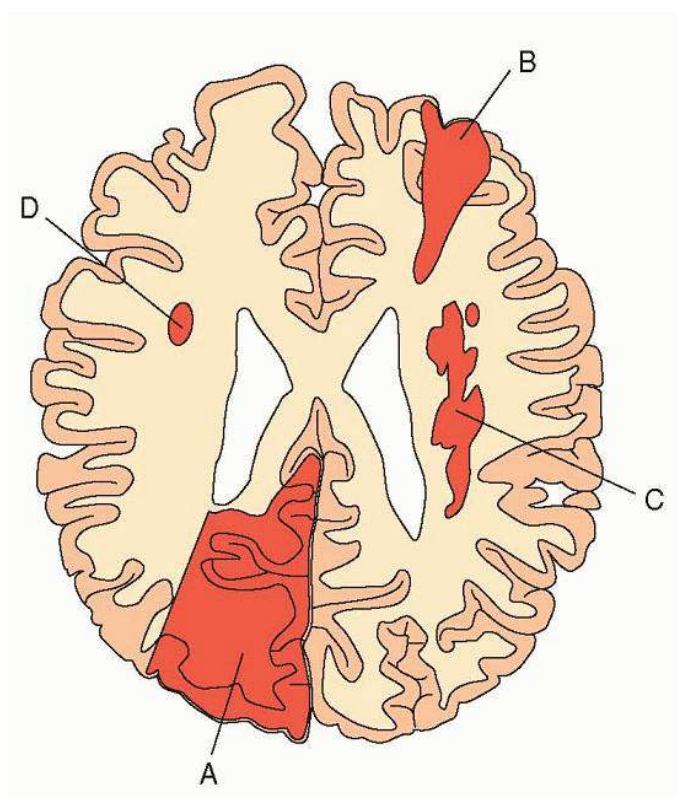

FIGURE 35.6 Schematic representation of different topographic patterns of cerebral infarction. (A) Territorial infarction (from PCA occlusion). (B) Watershed borderzone infarction (between the territories of the ACA and the MCA). (C) Internal border zone infarction (deep MCA territory). (D) Lacunar infarction (lenticulostriatepenetrating artery occlusion). (Adapted from Marshall R, Mayer S. *On Call Neurology*. 3rd ed. Philadelphia: Saunders; 2007.)

ANTERIOR CHOROICAL ARTERY INFARCTION

The anterior choroidal artery is the last branch of the ICA originating just proximal to the ACA-MCA bifurcation. It traverses posteriorly to supply a

number of structures, including the internal capsule, lateral thalamus, and the lateral geniculate body or optic radiations. Thus, occlusion of the anterior choroidal artery results in the classic syndrome of contralateral hemiparesis, hemianesthesia, and homonymous hemianopia. Occasionally, cortical symptoms such as aphasia or hemineglect can result from disruption of thalamocortical white matter tracts.

POSTERIOR CEREBRAL ARTERY

Occlusion of the PCA will cause infarction of the occipital and inferior temporal lobes. The usual presentation is sudden onset of a contralateral homonymous hemianopia. Bilateral occipital lobe lesions can cause Anton syndrome (cortical blindness unrecognized by the patient). Charles Bonnet syndrome, or release visual hallucinations, can also be seen in cortical blindness from bilateral occipital lobe injury. Balint syndrome is seen in bilateral parietooccipital junction infarcts and is characterized by simultanagnosia (inability to perceive parts of an object as a whole), oculomotor apraxia (incoordination of gaze), and optic ataxia (poor hand coordination using visual guidance). Hemineglect, although uncommon with occipital lesions, can be seen when the injury extends to the parietal lobe. Left PCA infarcts that involve either the deep white matter of the temporoparietal junction or the splenium of the corpus callosum may cause alexia without agraphia, a type of disconnection syndrome between the nondominant occipital cortex and the language processing area in the dominant parietotemporal cortex. Inferomedial temporal lobe infarction may cause agitated delirium or global amnesia.

Proximal PCA infarction affecting the thalamic perforating arteries will lead to infarction of the thalamus or midbrain. If the ventral posterior nucleus of the thalamus is preferentially affected, the patient will have contralateral hemianesthesia. Hyperpathia may subsequently develop in a condition called the *Dejerine-Roussy* or *thalamic pain syndrome*. As the thalamus serves as a relay to the cortex, thalamic infarction can also cause a variety of atypical symptoms such as ataxia, aphasia (dominant), hemineglect (nondominant), visual field deficits, memory loss, or behavioral disturbances.

Lethargy or coma can result if the reticular activating system in the midbrain or thalami is affected and will often be accompanied by a combination of oculomotor abnormalities. Alterations in consciousness are especially common in the presence of an anatomically variant artery, termed the *artery of Percheron*, which supplies the bilateral medial thalami and rostral midbrain from a single vessel originating on a unilateral PCA. Midbrain lesions, when posterior, cause Parinaud syndrome characterized by sustained conjugate downgaze, upgaze paralysis, convergence or retraction nystagmus, lid retraction or Collier sign, and pupillary light-near dissociation.

VERTEBROBASILAR TERRITORY INFARCTION

The basilar artery is the main conduit to supply the PCA arteries and basilar thrombosis can manifest with a combination of medullary, pontine, midbrain, and posterior cortical signs. Basilar thrombosis

P.273

leading to infarction of the anterior pons bilaterally causes “locked-in” syndrome: complete bilateral face, arm, and leg paralysis with isolated preservation of vertical eye movements and preservation of consciousness (see [Chapter 18](#)). Infarcts resulting from small-vessel thrombosis of the pontine perforating arteries cause a combination of cranial nerve dysfunction, long tract signs including weakness, reflexive posturing or hyperreflexia, sensory loss, and/or cerebellar findings. Small anterior pontine strokes can also produce lacunar syndromes without cranial nerve deficits that are clinically indistinguishable from anterior circulation lacunes. Oculomotor or gaze palsies, including internuclear ophthalmoplegia and skew deviation, or nystagmus, are also common. “Top of the basilar” syndrome refers to occlusion of bilateral distal basilar and proximal PCA thalamic and midbrain penetrating arteries from embolism. The result is a pattern of bilateral small-vessel infarcts involving the midbrain and thalami with asymmetric vertical gaze abnormalities and skew deviation, changes in level of consciousness, and variable bilateral motor and sensory deficits.

Infarction of the lateral medulla occurs when the posterior inferior cerebellar artery or a branch of the vertebral artery is affected. What results is a lateral medullary or *Wallenberg syndrome*, which is characterized by vertigo, ipsilateral ataxia, loss of pain and temperature sense in the ipsilateral face and the contralateral arm and leg, dysphagia, and ipsilateral oculosympathetic syndrome (Horner syndrome). Other brain stem infarct syndromes are described in [Table 35.2](#).

DIAGNOSIS

SYMPTOM RECOGNITION

Delay in prehospital recognition of stroke symptoms is the greatest barrier to prompt treatment and a major factor in explaining why only 6% of patients with AIS receive fibrinolytic therapy. Despite the established benefit of timely assessment and the potential for neurologic recovery with early treatment, only approximately 20% of patients present within 2 hours of symptom onset and approximately 25% within the therapeutic window of 4.5 hours. Limited insight and lack of community-level awareness to the time-sensitive nature of treatment are partly to blame, with studies suggesting that only 5%

P.274

of people in an urban population have knowledge of at least three stroke symptoms. The mnemonic FAST (face, arm, speech, time to call 911) has been disseminated using multiple community education efforts, in efforts to raise awareness about stroke symptoms and the urgent nature of seeking medical care. Public education efforts such as this play a critical role in increasing the proportion of patients who present within the therapeutic time window.

TABLE 35.2 Syndromes of Brain Stem Infarction

Syndrome	Artery Affected	Structure Involved	Manifestations
----------	-----------------	--------------------	----------------

Medial syndromes	Medulla	Paramedian branches of basilar artery	Emerging fibers of 12th nerve	Ipsilateral paralysis of tongue	
			Corticospinal tract	Contralateral limb paresis/paralysis	
			Medial lemniscus	Contralateral hemianesthesia	
	Inferior pons	Paramedian branches of basilar artery	Pontine gaze center, near or in nucleus of sixth nerve	Paralysis of gaze to side of lesion	
			Emerging fibers of sixth nerve	Ipsilateral abduction paralysis	
			Corticospinal tract	Contralateral limb paresis/paralysis	
	Superior pons	Paramedian branches of basilar artery	Medial longitudinal fasciculus	Internuclear ophthalmoplegia	
	Lateral syndromes	Medulla	Posterior inferior cerebellar artery or vertebral artery branches	Emerging fibers of ninth and 10th nerves	Dysphagia, hoarseness, ipsilateral paralysis of vocal cord; ipsilateral loss of pharyngeal reflex
				Vestibular nuclei	Vertigo, nystagmus
Descending tract and nucleus of fifth nerve				Ipsilateral facial analgesia	
Solitary nucleus and tract				Taste loss on ipsilateral half of tongue posteriorly	
Spinothalamic tract				Contralateral sensory loss	
Hypothalamospinal tract				Ipsilateral oculosympathetic dysfunction ("Horner syndrome")	
Inferior pons		Anterior inferior cerebellar artery	Emerging fibers of seventh nerve	Ipsilateral facial paralysis	
			Solitary nucleus and tract	Taste loss on ipsilateral half of tongue anteriorly	
			Cochlear nuclei	Hearing loss, tinnitus	
			Spinothalamic tract	Contralateral sensory loss	
Mid-pons		Anterior inferior cerebellar artery and circumferential branches of basilar	Motor nucleus of fifth nerve	Ipsilateral jaw weakness	
			Emerging sensory fibers of fifth nerve	Ipsilateral facial numbness

POSITIVE SCREEN if any questions are positive		

Los Angeles Motor Scale	Points		
	0	1	2
Facial strength	Normal	Droop	—
Arms outstretched	Normal	Drifts down	Falls rapidly
Grip strength	Normal	Weak grip	No grip

POSITIVE SCREEN for stroke with high likelihood of large vessel occlusion for a score of 2 or more.

Once EMS is activated, first responders must quickly and accurately characterize the symptoms of a stroke. Prehospital stroke scales should be used to assist in the screening and rapid triage process [Level 1].¹ The most widely used are the Cincinnati Prehospital Stroke Scale, the Los Angeles Prehospital Stroke Screen, and the Face Arm Speech Test (FAST) (Table 35.3). Rapid stroke assessment should be followed by activation of the acute stroke chain of care beginning with prehospital notification, which has been shown to increase the use of intravenous tissue plasminogen activator (IV tPA) and decrease the time from symptom onset to treatment [Level 1].¹

INITIAL HOSPITAL EVALUATION

The American Heart Association and American Stroke Association (AHA/ASA) guidelines recommend that all patients suspected of having an acute stroke be brought to stroke-certified centers to ensure a standardized level of care [Level 1].¹ On arrival to the emergency department, the patient must undergo rapid clinical and diagnostic evaluation in preparation for potential treatment. Initial history should be directed at defining the deficit and specific time of onset or last known time when the patient was seen normal. The clinician must then perform a rapid neurologic assessment using the National Institutes of Health Stroke Scale (NIHSS). The NIHSS (see Table 15.3) ranges from 0 to 42 with higher scores signifying greater neurologic deficit.

IMAGING

Computed Tomography

Noncontrast head computed tomography (NCHCT) is widely available, rapid, and extremely sensitive for detecting acute blood products (see also Chapter 20). Its value in distinguishing cerebral hemorrhage from presumed ischemia has made obtaining a NCHCT a vital and necessary step in the assessment of acute stroke. Early CT findings in AIS include loss of gray-white differentiation (seen first in the insular cortex), obscuration of gray matter in the basal ganglia, and acute thrombus visualized in the proximal MCA, also known as the *dense MCA* sign (Fig. 35.7A). However, CT findings in AIS are not reliably seen until after 6 hours from stroke onset, thus normal imaging in the setting of a clinical stroke syndrome suggests an ischemic etiology. The Alberta Stroke Programme Early CT Score (ASPECTS) can be helpful in quantifying signs of acute ischemia on NCHCT (see Fig. 15.3). The ASPECTS and NIHSS scores can help predict functional outcome and response to treatment.

Magnetic Resonance Imaging

Although CT is the most sensitive imaging modality for acute hemorrhagic stroke, MRI, and specifically DWI, is the most sensitive modality for detecting ischemic stroke within the first 6 hours of onset (Fig. 35.7D). Despite its superior sensitivity, however (see also Chapter 21), the use of MRI in the acute management of AIS is limited due to its relative unavailability in most emergency departments and the prolonged time necessary for image acquisition. Despite its superior sensitivity, small infarcts and those in the posterior circulation may not be seen on DWI, especially in the early hours after infarction. Although these issues limit its utility in the acute setting, obtaining an MRI after treatment decisions are made can be helpful in confirming the presence of ischemic stroke, identifying the specific stroke location, and helping to diagnose the stroke etiology.

Vascular Imaging

Computed tomography angiography (CTA) allows for acute evaluation of the cervical and cerebral vessels by opacifying the vasculature with IV contrast delineating any irregularities, stenoses, or occlusions (Fig. 35.7B). Magnetic resonance angiography (MRA) detects flow within blood vessels allowing for visualization of vasculature and any “flow voids” that occur within them but, similar to MRI, is limited by the time necessary for image acquisition. Special MRI techniques such as vessel wall imaging and arterial spin labeling can show details of the vessel wall and flow dynamics within the vessel, but their role in the clinical setting remains investigational. Ultrasound evaluation of the carotid arteries or the proximal intracranial vasculature can provide information about the direction of blood flow and define sites of arterial stenosis or occlusion. Although vessel imaging is not recommended for all cases of AIS, its use in select patients may help in planning for interventional therapies.

Perfusion Imaging

A computed tomography perfusion (CTP) study can be performed along with CTA measuring the time to arrival and volume of contrast arriving in various areas of the brain by repeatedly scanning during a timed IV contrast injection (Fig. 35.7C). The opposite hemisphere is used for comparison, and images are created to show relative amounts of CBF, cerebral blood volume (CBV), and mean transit time (MTT) of contrast. Perfusion imaging may help differentiate the penumbra from core infarct. The penumbra retains cerebrovascular autoregulation and experiences vasodilation and recruitment of collateral vessels in response to relative hypoperfusion. It is defined by a low CBF and prolonged MTT with a compensatory increase in CBV caused

P.275

by vasodilation. The ischemic core, in contrast, loses its physiologic ability to autoregulate and therefore has blood shunted away from it creating a relative deficit in CBV. If the penumbra further destabilizes, autoregulation fails and the area with low CBV expands.

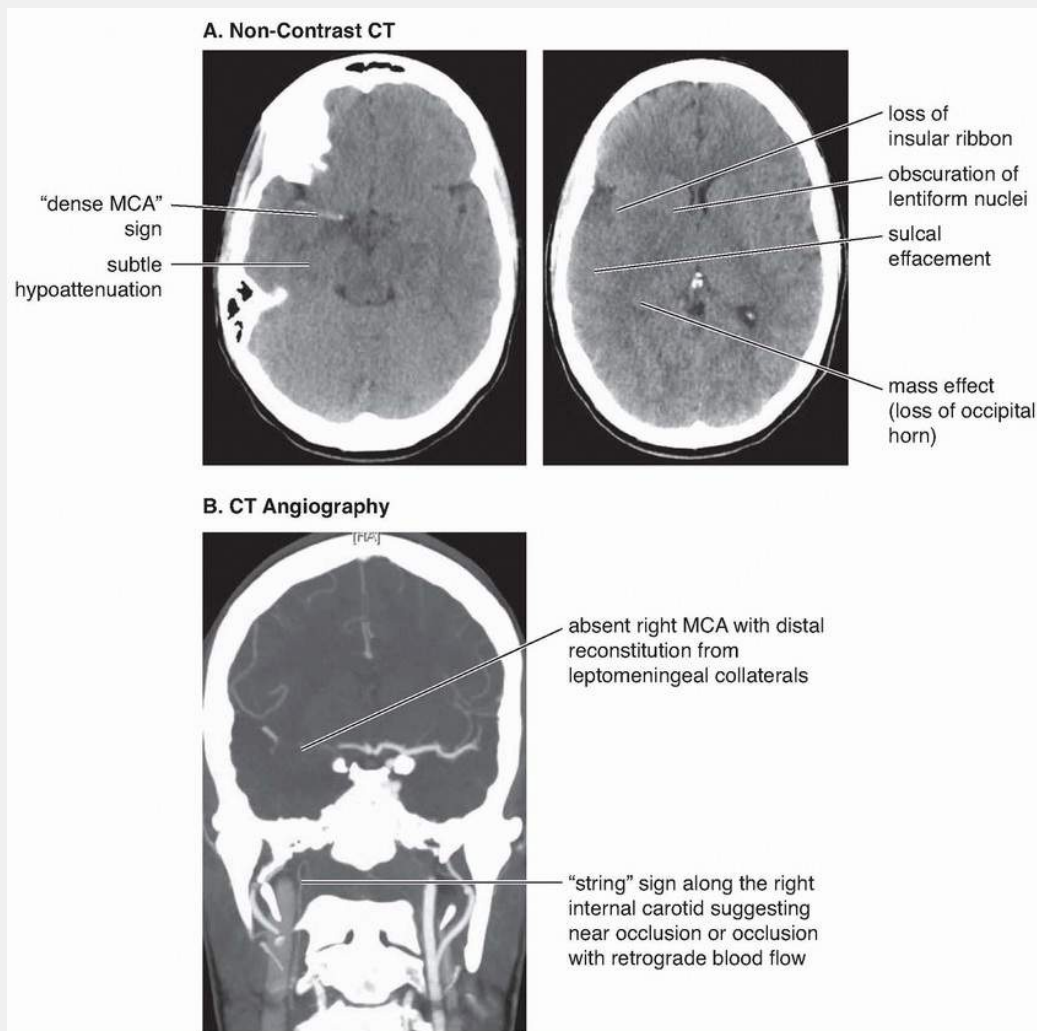

FIGURE 35.7 Acute ischemic stroke imaging. This figure shows the stepwise imaging approach for a patient presenting with acute onset of left-sided weakness and right gaze deviation. The initial NCHCT (A) shows early infarct signs in the right hemisphere. CTA (B) shows an absent right ICA and right MCA. (continued)

Magnetic resonance perfusion (MRP) imaging is similar to CTP and can distinguish infarcted from at-risk tissue by comparing perfusion imaging to DWI sequences, but it is more time consuming than CTP. Despite their theoretical value, studies using perfusion techniques to guide the need and timing for reperfusion therapies have not shown an improvement in clinical outcomes. The use of perfusion imaging is therefore not routinely recommended, although it can be employed to answer specific clinical questions on a case-by-case basis.

ACUTE TREATMENT

Estimations based on mathematical modeling suggest that 1.9 million neurons and 14 billion synapses are lost for every minute of ischemia in a large-vessel AIS. Stroke expansion is usually complete within 4 to 6 hours of onset, at which point all potentially salvageable areas of penumbra are irreversibly infarcted. Emergency treatment with IV tissue-plasminogen activator (tPA) is

P.276

the fundamental therapy used to achieve reperfusion for AIS. Benefit directly correlates with time to treatment with a linear relationship between shorter onset-to-needle time and improved 3-month functional outcome. Benefit levels off after 4.5 hours and soon after the risk of reperfusion causing hemorrhagic transformation exceeds the ability to rescue penumbral tissue at risk. Rapid onset-to-treatment time will always remain the most important factor in the treatment of AIS.

C. CT Perfusion

Cerebral blood volume (CBV) – decreased in the deep right MCA territory

Mean transit time (MTT): prolonged in the entire right MCA territory

Cerebral blood flow (CBF): Decreased in a large portion of the right MCA territory

D. MRI

Diffusion weighted imaging (DWI): hyperintensity in the deep right MCA territory signifying acute infarct

Fluid attenuated inversion recovery (FLAIR): one year follow up showing chronic infarct in the deep structures with relative preservation of the cortex

FIGURE 35.7 (continued) CT perfusion (C) shows an area of core infarct defined by a low CBV, prolonged MTT, and decreased CBF surrounded by a widespread area of tissue at risk defined by relatively stable CBV, prolonged MTT, and decreased CBF. On MRI, the DWI sequence in the acute setting and the FLAIR sequence 1 year later (D) confirmed that only the presumed core area had infarcted and not the hemisphere as a whole, probably due to good leptomeningeal collaterals. CT, computed tomography; MRI, magnetic resonance imaging.

INTRAVENOUS THROMBOLYSIS

The only currently U.S. Food and Drug Administration (FDA)-approved medical treatment for AIS is IV tPA. As onset-to-treatment time increases, the effectiveness of tPA diminishes and the risk of hemorrhage increases. Optimal treatment involves the administration of tPA as quickly as possible up to 3 hours from symptom onset for most patients and 4.5 hours in a select group of patients [Level 1].^{2,3} The original 3-hour time window is largely based on the National Institute of Neurological Disorders and Stroke (NINDS) trial from 1995, which showed that administration of IV tPA within 3 hours of symptom onset led to an improved clinical outcome at 3 months with a 13% absolute increase in good functional recovery compared to placebo despite an approximate 6% absolute risk increase in symptomatic intracerebral hemorrhage (ICH) with IV tPA. This translates to a number needed to treat of eight patients to achieve good recovery in one patient who would have otherwise had a poor outcome.

A pooled analysis of the Alteplase Thrombolysis for Acute Noninterventional Therapy in Ischemic Stroke (ATLANTIS), European Cooperative Acute Stroke Study (ECASS) I and II, and NINDS trials showed that administration of tPA up to 4.5 hours after symptom onset appeared beneficial, which prompted the ECASS III trial. ECASS III excluded patients older than age 80 years, those with a baseline NIHSS score higher than 25, those with a history of diabetes and prior ischemic stroke, and those on anticoagulation

P.277

regardless of international normalized ratio (INR) values. A benefit was seen for tPA administration within the 3- to 4.5-hour range, albeit milder than that seen in the original NINDS trial. The AHA/ASA therefore recommends the use of IV tPA up to 4.5 hours after ischemic stroke symptom onset in patients younger than 80 years of age who are not on anticoagulation and do not have both comorbid diabetes and history of stroke [Level 1].³ A practical protocol and checklist for IV tPA use is provided in Chapter 15.

Contraindications to Intravenous Thrombolysis

Current contraindications for IV tPA are based on the inclusion criteria used in the original NINDS trial. However, these rigorous contraindications may not necessarily define the full population of patients who might benefit from tPA. Table 15.5 shows the relative strength of various contraindications to tPA therapy based on published experience since the original NINDS trials.

WEAK TO MODERATE RELATIVE CONTRAINDICATIONS

Minor symptoms, a rapidly resolving deficit, seizures, and hypo- or hyperglycemia at presentation are examples of relative contraindications. Despite these initial relative exclusions, most patients with minor or resolving deficits should in fact be considered for IV tPA treatment, as a subanalysis of the NINDS trial confirmed the benefit of tPA administration in this population. Seizure at time of presentation is also considered by most experts to be a relative rather than an absolute contraindication. The main concern here is treating a stroke mimic, although data suggests that the rate of hemorrhagic complications in stroke mimics treated with IV tPA is very low. Onset seizures are rare in AIS but do not increase the risk of hemorrhagic conversion per se. Blood glucose should be measured and corrected in all patients because hypo- or hyperglycemia can lead to neurologic deficits mimicking acute stroke, and hyperglycemia has been associated with an increased risk of hemorrhagic conversion after thrombolysis. Nonetheless, it may be reasonable to give IV tPA if the index of suspicion for a true stroke is high and glucose levels can be readily normalized during and after the treatment period. Blood pressure higher than 185/110 mm Hg is a moderate relative contraindication to treatment. In most cases, blood pressure can be quickly controlled with a continuous IV infusion of nicardipine or clevidipine (see [Table 38.3](#) for dosing) and IV tPA given once blood pressure is successfully lowered.

ABSOLUTE TO STRONG RELATIVE CONTRAINDICATIONS

The presence of cerebral hemorrhage on initial head CT, early infarction already involving greater than one-third of the MCA territory, or treatment beyond the 4.5-hour time window are absolute contraindications to IV thrombolysis (see [Table 15.5](#)). A weak level of anticoagulation with warfarin (INR 1.7-2.0) or stable mild thrombocytopenia (platelet count 50,000 to 100,000) are strong relative contraindications to IV tPA; in the proper circumstances, it might be reasonable to treat as long as a relative increment in hemorrhagic conversion is recognized and accepted. The use of novel anticoagulants, including dabigatran, rivaroxaban, and apixaban are more problematic because they do not produce reliable changes in prothrombin time (PT)/INR or partial thromboplastin time (PTT), and other assays are not readily available. The current consensus is to avoid using IV tPA and seek intra-arterial reperfusion strategies in patients who have taken a novel oral anticoagulant within 48 hours of presentation. It is important to note that tPA should never be delayed while waiting for a platelet count or INR in a patient with no suspicion of having a coagulation disturbance by history. Studies have shown that the risk of encountering clinically significant thrombocytopenia or coagulopathy in tPA candidates in whom the history did not suggest a possible abnormality was only 0.2% to 0.3%.

As many as one-third of dissection patients can present with acute neurologic symptoms from ischemic stroke. Suspected aortic dissection is an absolute contraindication to thrombolysis, as IV tPA can worsen the dissection and prove fatal. Patients with characteristic chest or back pain should therefore be screened with urgent CTA of the chest to rule out aortic dissection prior to further consideration of thrombolysis.

Complications of Thrombolysis

HEMORRHAGIC CONVERSION

Hemorrhagic conversion of the infarcted tissue bed is a known complication after stroke, and risk is significantly increased in patients treated with IV tPA. Hemorrhagic conversion is classified as hemorrhagic infarction or parenchymal hematoma (PH) depending on radiologic characteristics. Hemorrhagic infarction is defined by hemorrhagic petechiae within the stroke bed and is not associated with a worsened outcome, whereas PH is defined by blood occupying either less than 30% of the stroke bed with mild spaceoccupying effect (PH1) or over 30% with significant mass effect (PH2). Only PH2 is as associated with an increase in mortality. Hemorrhagic conversion usually manifests with headache, nausea, vomiting, worsened neurologic deficit, and/or altered level of consciousness. Risk factors for hemorrhagic conversion after thrombolysis include advanced age, increased onset-to-treatment times, higher NIHSS (stroke severity), hyperglycemia, and hypertension before or after tPA administration. The SEDAN score ([Table 35.4](#)) is a well-validated tool that can help to identify IV tPA candidates with greater than the normal 3% risk of symptomatic hemorrhagic conversion.

ANGIOEDEMA

tPA-associated angioedema and/or anaphylaxis occurs in 1% to 5% of cases usually beginning 30 to 120 minutes after tPA infusion. Patients taking angiotensin-converting enzyme (ACE) inhibitors are at higher risk, but all patients receiving tPA should be monitored closely for signs of angioedema and airway compromise.

P.278

Should angioedema occur, administration of steroids, antihistamines, and/or epinephrine can be considered depending on severity and comorbidities.

TABLE 35.4 The SEDAN Score for Predicting Risk of Hemorrhagic Conversion with IV tPA

Sugar (blood glucose level)	
• 145-216 mg/dL	+1
• >216 mg/dL	+2

Early infarct signs	+1
Dense MCA (or other vessel) sign on admission CT	+1
Age older than 75 yr	+1
NIHSS >9 points	+1
TOTAL	0-6

Total scores range from 0 to 6. The approximate risk of symptomatic hemorrhagic conversion for a score of 0, 1, 2, 3, 4, or 5+, respectively, are 1%, 3%, 6%, 10%, 20%, and 30%. IV tPA, intravenous tissue plasminogen activator; MCA, middle cerebral artery; NIHSS, National Institutes of Health Stroke Scale.

From Strbian D, Engelter S, Michel P, et al. Symptomatic intracranial hemorrhage after stroke thrombolysis: the SEDAN score. *Ann Neurol*. 2012;71:634-641.

ENDOVASCULAR THERAPIES

Successful recanalization after large-vessel occlusion is associated with improved prognosis, and early reperfusion has been consistently shown to result in better long-term functional outcome than later reperfusion. Unfortunately, IV tPA leads to recanalization less than 50% of the time in large-vessel occlusion on average, with smaller and more distal clots responding more favorably compared with the large proximal clots that cause massive infarcts. One study using transcranial Doppler after IV tPA found recanalization rates for distal MCA, proximal MCA, and distal ICA locations to be 44%, 29%, and 10%, respectively. Recanalization after tPA is also dependent on clot length, with lower rates of recanalization seen for clots greater than 8 mm in length. Due to the relatively low recanalization rates seen with IV tPA in large proximal vascular occlusions, intraarterial thrombolysis with tPA (IA tPA), mechanical thrombectomy, and sonothrombolysis with high-frequency ultrasound have all been proposed as viable adjuncts to tPA in large-vessel occlusion.

Intra-arterial Thrombolysis

The first endovascular therapy developed for treatment of ischemic stroke was intra-arterial (IA) delivery of thrombolytics beginning in the 1990s. Initial studies showed favorable recanalization rates, which prompted the Prolyse in Acute Cerebral Thromboembolism (PROACT) II trial. In this study, 180 patients with proximal MCA occlusion within 6 hours of symptoms onset were randomized to IA prourokinase plus IV heparin versus IV heparin alone. Recanalization rates were 66% in the study group compared to 18% in the control group. Although mortality was similar in both, good functional outcome at 3 months was seen in 40% of the endovascular therapy group compared to 25% in the placebo group despite a higher rate of symptomatic ICH in the prourokinase group (10% vs. 2%). Mechanical thrombectomy devices have proven to be more effective at achieving recanalization than IA tPA, although IA thrombolysis continues to be used in adjunct to these newer devices.

Mechanical Thrombectomy

The Merci device was the first cerebral clot extraction device approved for use in acute large-vessel occlusion. Initial small and uncontrolled studies of this corkscrew-like device demonstrated recanalization in 40% to 60% of patients, with recanalization rates improving to 70% when thrombectomy was combined with IA tPA. The second available device was Penumbra, a suction device that showed recanalization rates of up to 80% within 8 hours of stroke in the Penumbra Pivotal Stroke Trial. The newest and most effective clot extraction devices are the intrathrombus retrievable stent devices. The Trevo and Solitaire intrathrombus “stentriever” devices were individually tested head-to-head with the Merci device and showed significantly higher rates of recanalization.

TRIALS OF CORKSCREW AND SUCTION DEVICES

Despite evidence showing increased recanalization rates with use of endovascular techniques of mechanical thrombectomy and or administration of IA tPA, the first randomized controlled trials evaluating the efficacy of endovascular therapies for improving neurologic outcome after AIS were not published until 2013. The Interventional Management of Stroke III (IMS III) Trial randomized patients who had already received IV tPA within 3 hours of stroke onset to additional endovascular therapy beginning within 5 hours of onset versus no additional treatment (IV tPA alone). The study did not show a benefit in functional outcomes at 3 months for tPA plus adjunctive endovascular therapy administered within 5 hours of stroke onset compared to tPA administration alone. The Local Versus Systemic Thrombolysis for Acute Ischemic Stroke (SYNTHESIS) trial randomized patients within 4.5 hours of stroke onset to IV tPA alone or within 6 hours of onset to endovascular intervention alone. Good functional recovery at 3 months was seen in 35% of the IV tPA group compared to 30% in the endovascular intervention group. The Mechanical Retrieval and Recanalization of Stroke Clots Using Embolectomy (MR-RESCUE), published concurrently with IMS III and SYNTHESIS, also failed to show benefit of endovascular intervention compared to IV tPA in patients with perfusion deficits determined by MR or CTP imaging.

The negative results in these trials prompted questions regarding optimal timing of therapy, patient selection, and the role of thrombectomy devices. In IMS III, for example, the mean time from stroke onset to start of endovascular therapy was longer than 4 hours and although not reported, time to recanalization likely exceeded the 4.5 hours that is accepted as beneficial for IV thrombolysis. Similarly, in SYNTHESIS, the endovascular group received intervention 1 hour later than the group receiving IV tPA, and in MR-RESCUE, the mean time from stroke onset to groin puncture was greater than 6 hours. IMS III and SYNTHESIS also did not confirm large-vessel occlusion prior to intervention, and

consequently, nearly 25% of patients in IMS III randomized to the intervention group did not actually receive any intervention. For SYNTHESIS, if no large-vessel occlusion was seen on angiography, IA tPA was infused into the suspected vascular territory based on clinical exam, which is not likely to be an effective therapy. Finally, the newest retrievable stent devices were used infrequently in these trials because they were not yet available when the trials began, making it more difficult to achieve high rates of recanalization. Only 30% to 40% of patients in the intervention groups in IMS III and MR-RESCUE attained greater than 50% recanalization in affected territory compared with expected recanalization rates of 60% to 80% with the stent retriever devices.

STENTRIEVER TECHNOLOGY

In 2014, a well-designed randomized trial—Multicenter Randomized Clinical Trial of Endovascular Treatment for Acute Ischemic Stroke in the Netherlands (MR CLEAN)—employed more accurate patient selection measures than IMS III and SYNTHESIS, and unlike these two trials used retrievable stent thrombectomy devices. The proportion of patients with minimal or no disability at 90 days was 33% in those treated with IA therapy and tPA compared to 19% with tPA alone: a number needed to treat of seven patients to prevent one outcome of moderate or severe disability (Table 35.5). There was no effect on mortality. Mean time from stroke onset to IV tPA was 1 hour and 15 minutes and to groin puncture was 4 hours and 20 minutes. Follow-up CTA showed no residual large-vessel occlusion in 75% of the IA + tPA group and 33% of the tPA-only group.

In the spring of 2015, the Endovascular Treatment for Small Core and Anterior Circulation Proximal Occlusion with Emphasis on Minimizing CT to Recanalization Times (ESCAPE), SWIFT PRIME, and four additional randomized controlled trials comparing mechanical thrombectomy to tPA alone reported superior outcomes with intra-arterial treatment (Table 35.5). The preponderance of evidence supporting endovascular “bridging” therapy after administration of IV tPA will likely result in national recommendations for endovascular treatment as (1) an adjunctive treatment in patients with documented large-vessel occlusion of onset less than

P.279

6 hours who have already received IV tPA or (2) sole treatment for patient with large vessel occlusion of less than 6 hours who have contraindications for IV tPA or are out of the 4.5-hour time window for IV tPA [Level 1].4,5,6,7,8,9,10

TABLE 35.5 Recent Trials of Intra-Arterial Therapy for Acute Ischemic Stroke

Trial	N	Imaging Selection*	NIHSS	Time Window for IAT	TICI 2B-3 for IAT group	mRS 0-2 (%)			Mortality (%)			
						IAT†	Control	NNT	OR [95% CI]	IAT	Control	OR [95% CI]
MR CLEAN ⁴	500	LVO	≥2	≤ 6 h	59%	33%	19%	7	2.1 [1.4 to 3.4]	21%	22%	NS
EXTEND-IA ⁵	70	LVO and favorable CT perfusion	None	≤ 6 h	86%	71%	40%	3	4.2 [1.4 to 12]	9%	20%	NS
ESCAPE ⁶	315	LVO and favorable collaterals on multiphase CTA	≥6	≤ 12 h	72%	53%	29%	4	1.7 [1.3 to 2.2]	10%	19%	0.5 [0.3 to 0.8]
REVASCAT ⁷	206	LVO	≥6	≤ 8 h	66%	44%	28%	6	2.0 [1.1 to 3.5]	18%	15%	NS

*All studies except for THERAPY used CT angiography for confirmation of LVO.

†Treatment arms were IAT +/- IV tPA (if eligible) vs. Best Medical Management except for EXTEND-IA and SWIFT-PRIME which required IV tPA in the interventional group.

‡THERAPY trial terminated early due to other positive trials (planned enrollment of 692 patients) and was therefore underpowered to show significant results for this outcome.

mRS, modified Rankin scale; IAT, intra-arterial therapy; TICl, Thrombolysis in Cerebral Infarction score; LVO, large vessel occlusion; CTA, CT angiography; NCHCT, noncontrast head CT; tPA, tissue-plasminogen activator; NA, not available; NS, non-significant.

COMPLICATIONS

Like IV tPA, endovascular therapy carries an increased risk of symptomatic ICH that varies depending on the technique used and timing of intervention. Although earlier IA thrombolysis studies like PROACT II reported a rate of 10%, recent studies report rates of symptomatic ICH of around 6%. Asymptomatic hemorrhage is much more common and may even signify adequate reperfusion within the ischemic territory. Other complications of endovascular therapy include thrombus fragmentation with distal embolization, device malfunction, groin hematoma, and the rare vessel rupture.

CRITICAL CARE OF STROKE

Intensive care of stroke depends on a team approach and adherence to protocols that support best practices. Closed ICUs that provide around-the-clock availability of neurointensivists are important because this model has been shown to reduce costs, improve outcomes, and decrease hospital length of stay. These benefits may be the result of (1) organizational improvements, including the development of urgent interhospital transfer systems; (2) the uniform institution of best medical practices; (3) improved access to specialized neuroimaging, monitoring, and therapeutic techniques; and (4) the creation of physician and nursing care teams with special expertise in caring for neurologic patients. The use of checklists (Table 35.6) has been shown to improve outcome in stroke units and neurocritical care units.

TABLE 35.6 Stroke Unit Checklist

- BP goal <180/105 mm Hg for 24 h if IV tPA was given
- BP goal <220/120 mm Hg if no IV tPA was used
- Serial monitoring of vital signs
- Serial monitoring of neurologic deficits
- Dysphagia screen
- Aspirin (PO or rectal)^a
- Enoxaparin 40 mg SC daily (heparin 5,000 units t.i.d. if renal dysfunction)^a
- Place sequential compression device
- High-dose statin
- Neurovascular work-up: Carotid and intracranial Dopplers, CTA or MRA
- Cardiac workup: ECG, serial troponins, telemetry, echocardiogram
- Screen: hemoglobin A1c, lipid panel, toxicology, urinalysis
- Remove Foley

^aContraindicated in the first 24 hours after thrombolysis.

BP, blood pressure; PO, by mouth; SC, subcutaneous; ECG, electrocardiogram.

A systematized and multidisciplinary approach to poststroke management initiated in a specialized stroke unit or neuro-ICU has been shown to minimize common complications after stroke and should be used whenever possible [Level 1].¹ Aside from the prevention of poststroke complications, evaluation for stroke etiology and management aimed at limiting stroke recurrence should ensue in the period immediately following AIS. For details, refer to the chapter on secondary stroke prevention.

CLINICAL SYNDROMES

Malignant Middle Cerebral Artery Infarction

Large hemispheric or *malignant MCA* infarction is a massive stroke that occurs as a result of ICA or proximal MCA occlusion resulting in cerebral edema that leads to herniation and death in 40% to 80% of patients without treatment. Malignant MCA infarction is essentially a hemispheric compartment syndrome, in which swelling and increased local tissue pressure leads to extension of the ischemic territory, herniation, and compressive injury of the brain stem. Patients with acute infarction involving over half of the MCA territory are at risk, whereas 95% of those with infarction affecting more than two-thirds of the MCA territory will progress to herniation. Imaging, including CT and MRI, can be used as early as 6 hours after infarction to predict malignant evolution. These patients should be managed in a neuro-ICU to allow for detecting of early neurologic deterioration and prompt treatment of cerebral edema if it occurs. Monitoring of intracranial pressure (ICP) is not useful because the swelling is focal, and patients can herniate from cerebral edema without developing a rise in ICP. The definitive treatment to prevent herniation and mortality is hemicraniectomy, but bolus osmotherapy with hypertonic saline and mannitol are effective temporizing measures. Therapeutic hypothermia has been tested as a treatment for malignant cerebral edema but has not been shown to improve outcome. In most patients, medical therapies should be used as a bridge to decompressive surgery and not as standalone therapy.

Three trials for decompressive hemicraniectomy in malignant MCA infarction have been performed, although all were underpowered to show efficacy. As they used similar inclusion criteria, a prespecified combined analysis of these trials was performed and showed an absolute risk reduction of 51% for death or severe disability and a 23% absolute increase in the proportion of patients who were alive and able to walk independently at 6 months compared with conservative medical management. These results corresponded to a number needed to treat of two patients to prevent one death and four patients to turn what would have been one death to a patient living with a moderate level of functional disability but still able to walk independently. As a result, hemicraniectomy is recommended for the treatment of malignant MCA infarction in patients younger than 60 years of age when the procedure is in line with the wishes of the patient or the patient's family [Level 1].⁵ None of the three trials included patients older than age 60 years, but a subsequent study, the Decompressive Surgery for the Treatment of Malignant Infarction of the Middle Cerebral Artery (DESTINY) II trial, showed a mortality reduction from 70% to 33% of patients, but with worsened neurologic outcomes compared to younger patients. There was not a significant increase in the survivors with mild or moderate disability, as nearly all of the survivors were bedbound or unable to walk independently. This expected prognosis for older patients should be discussed with family members prior to making any treatment decisions.

Cerebellar Infarction

Cerebellar infarction represents approximately 3% of total ischemic strokes. In cases of a large cerebellar infarction, cytotoxic edema in the limited compartment of the posterior fossa can lead to brain stem compression, hydrocephalus from obstruction of the fourth ventricle, and tonsillar or upward herniation. The peak period of deterioration is 72 hours, although patients may deteriorate earlier or as many as 10 days after the ischemic insult. Signs of worsening edema include drowsiness, gaze disturbance, hemiparesis, and hyperreflexia. The onset of these clinical signs is often insidious, and coma can develop rapidly without intervention, necessitating that all patient with large cerebellar infarction be closely monitored in an intensive care setting. In cases where brain stem compression or hydrocephalus appear, posterior fossa craniectomy is highly effective at preventing mortality and allowing for good functional outcome, although randomized trials have not been performed. Management with an external ventricular drain (EVD) or excision of the infarcted tissue can also effectively alleviate compression but carries the risk of upward herniation by lowering the supratentorial pressure. Thus, decompressive surgery should be the initial intervention considered in most cases.

Basilar Artery Occlusion

Basilar artery occlusion carries a mortality of up to 90% without treatment. Those who survive are often left with significant functional deficits ranging from ataxia or weakness to *locked-in* syndrome. Given its poor natural history, aggressive attempts at reperfusion, even beyond the accepted range of therapy for ischemic stroke in other locations, are often considered. Although IV tPA within 4.5 hours remains the only proven treatment option, anecdotal data shows potential benefit of IA thrombolysis or mechanical thrombectomy as long after stroke onset as 24 hours. For patients with mild to moderate symptoms, IV tPA and close monitoring may be sufficient. However, for those who present with severe symptoms, IV tPA, IA tPA, and/or mechanical thrombectomy are all appropriate considerations.

Cervical Artery Dissection

Carotid and vertebral artery dissections are uncommon etiologies of stroke causing only 2% of all cases. However, they account for a much higher proportion of AIS in young patients causing 10% to 25% of all strokes in this population. The most common risk factor is cervical twisting or trauma, but presentations can be spontaneous or resulting from an underlying arteriopathy such as fibromuscular dysplasia, Marfan syndrome, or Ehlers-Danlos syndrome type IV. Clinical presentations of internal carotid dissection include facial pain, headache, neck pain, an incomplete oculosympathetic syndrome (Horner syndrome with preserved sweat response), and contralateral stroke symptoms, such as hemiparesis or aphasia. When strokes occur, they most often result from artery-to-artery embolism but can also occur in a watershed territory from arterial narrowing or occlusion of the dissected vessel.

Although no randomized trials have been done comparing management options in acute cervical artery dissection, several meta-analyses have shown no difference in mortality or stroke occurrence in patients treated with antiplatelet agents versus those treated with anticoagulation. Nevertheless, anticoagulation is often used in patients with evidence of multiple infarcts, those with a free-floating thrombus within the lumen of the vessel, or in those with microemboli demonstrated by transcranial Doppler. In contrast,

patients with large infarcts or intracranial extension of their dissection should be treated with antiplatelet agents due to an increased risk of bleeding

with anticoagulation.

COMPLICATIONS OF STROKE

Neurologic Deterioration

Neurologic deterioration occurs in up to 40% of patients in the first 24 hours after AIS and is associated with a history of diabetes, high blood glucose concentrations, stroke severity, and early signs of edema on imaging. Although most forms of deterioration are due to progressive extension of the infarct core into surrounding penumbra, the causes of neurologic worsening are diverse and often require further investigation. All patients should undergo general and neurologic examination to determine the nature and extent of clinical change. Vital signs are important, especially because fever can cause deterioration and changes in blood pressure in either direction can have deleterious effects.

If neurologic worsening directly coincides with relative hypotension, trials of increasing cerebral perfusion can be used to confirm the presence of a blood pressure-dependent deficit. Administration of IV fluids, positioning the patient in the Trendelenburg position, or infusion of a vasopressor such as phenylephrine (starting at 20 µg/min, titrated upward to raise blood pressure by 20%) can be trialed followed by a repeat neurologic examination. If there is clinical improvement correlating to a higher mean arterial pressure, a blood pressure goal can be maintained using vasopressor agents administered under close observation in an intensive care setting. Vascular and perfusion imaging with CT or MRI may be useful at this point to evaluate for high-grade vascular stenosis and downstream perfusion/infarction mismatch.

Patients with large infarcts are more likely to develop hemorrhagic conversion, which, when symptomatic, usually presents with relatively abrupt changes in clinical signs and may be accompanied by symptoms of headache, nausea, and vomiting. Noncontrast head CT is indicated in such settings to evaluate for signs of hemorrhage. If a hemorrhage with associated mass effect is found, the clinician should reverse any form of anticoagulation or antiplatelet therapy (see [Table 15.4](#)).

If preliminary evaluations with examination, vital signs, and imaging do not reveal an etiology for neurologic worsening with depressed level of consciousness, EEG may be considered to evaluate for nonconvulsive seizure activity. Early seizures after AIS occur in approximately 5% of cases and are more common in cortical infarcts but can also occur after subcortical strokes. Although primary seizure prophylaxis is not recommended, treatment with antiepileptic agents is warranted after a seizure has occurred.

Blood Pressure Management

A *U-shaped* relationship exists between blood pressure on admission and clinical outcome, with both extremes conferring a poor outcome. The optimal blood pressure goal in AIS remains undefined. However, studies have consistently found that an acute fall in blood pressure, specifically a systolic decrease of higher than 20 mm Hg, is associated with poor functional outcome and increased mortality. Hypotension should be avoided in the acute phase of stroke, and any attempts at lowering blood pressure should be done slowly.

Current practice for those who have not received thrombolytic therapy is to allow permissive hypertension of up to 220/120 mm Hg for 24 to 48 hours, after which point antihypertensive therapy is started and slowly titrated to an extended goal toward normotension. This upper limit should be adjusted accordingly for patients with heart failure, valvular heart disease, or coronary artery disease in order to prevent any cardiac injury or complications. Similarly, in patients with hemorrhagic conversion or brain edema, blood pressure targets should be individualized at lower levels. A strict blood pressure goal of lower than 180/105 mm Hg should be maintained for 24 hours in those treated with IV tPA in order to limit secondary ICH [**Level 1**].¹

Infectious Complications

ASPIRATION PNEUMONIA

Dysphagia occurs in nearly 40% of stroke patients and is associated with a significant increase in the incidence of pneumonia. Of all the medical complications after stroke, pneumonia carries the highest proportion of attributable risk for mortality. All stroke patients should undergo an early dysphagia screen using an objective test, such as a simple bedside water swallow test. Comprehensive evaluation by a speech-language pathologist followed by barium esophagography or videofluoroscopy may be necessary. Early recognition of dysphagia can lead to prevention techniques and therapies, such as maintaining patients in a sitting position after feeding and providing oral care, which may reduce morbidity and mortality associated with aspiration-related pneumonia. When necessary, a nasogastric or nasoduodenal feeding tube should be placed for nutritional support and medication administration. If prolonged dysphagia is expected, a percutaneous endoscopic gastrostomy allows for extended nutritional support.

URINARY TRACT INFECTION

Urinary tract infection occurs in 10% to 15% of stroke-related hospitalizations and is associated with worsened neurologic and functional outcomes. Risk factors for urinary tract infection include increasing age, female sex, poststroke disability, urinary retention, and, most importantly, urinary catheterization. Avoiding urinary catheterization and early removal of urinary catheters reduces the risk of catheter-associated urinary tract infections.

Venous Thromboembolism

Patients with stroke are at high risk for developing deep vein thrombosis (DVT) due to hemiparesis and immobility. Studies done in the absence of pharmacologic DVT prophylaxis suggest that DVT occurs in as many as 40% to 50% of hemiplegic patients within 2 weeks of stroke onset. The associated risk of pulmonary embolism is 15% in untreated patients, which can lead to early death following AIS.

Although unfractionated heparin has been proven effective for DVT prophylaxis, the Prevention of VTE After Acute Ischemic Stroke with Low-

Molecular Weight Heparinoid Enoxaparin (PREVAIL) trial showed that enoxaparin 40 mg daily (q.d.) was more effective at preventing DVT than unfractionated heparin administered twice daily. Pneumatic sequential compression devices are also effective when used independently and provide an added benefit when used in addition to pharmacologic DVT prophylaxis. Early mobilization is also effective in preventing DVT and provides added benefits in functional recovery. Current guidelines recommend pharmacologic DVT prophylaxis in all stroke patients, unless there is a substantial risk of bleeding that would outweigh the potential benefits, in which case nonpharmacologic options should be employed [Level 1].¹² Pharmacologic DVT prophylaxis should also be held for 24 hours after tPA administration.

TABLE 35.7 Risk Factors for Death or Poor Functional Outcome after Ischemic Stroke

STROKE OUTCOMES

Outcome after stroke is defined as the level of functional impairment or death months to years after the insult. Stroke is the third leading cause of death and the leading cause of disability among adults. Accurately predicting a patient's outcome can aid the clinician decide the best management approach and help the patient, and their family, establish appropriate expectations for quality of life. Using retrospective data from various cohorts, a number of prediction models have been established to predict long-term stroke outcomes at the time of the acute stroke. Stroke severity, which can be assessed with the NIHSS, and patient age have consistently proven predictive of outcome. Specific exam features that have been cited include upper extremity plegia and inability to walk independently. Others frequently cited factors include infarct volume, fever, diabetes, and congestive heart failure (Table 35.7). Outcome after ischemic stroke can be improved by care in a dedicated stroke unit, using a systematic approach to minimizing preventable medical complications, and instituting early rehabilitation (see Chapter 152).

Transient Ischemic Attack

Randolph S. Marshall

INTRODUCTION

Transient ischemic attack (TIA) describes neurologic symptoms of ischemic origin that last less than 24 hours. In fact, most attacks last only a few minutes to an hour. Often called a *mini-stroke*, a TIA may have ominous implications. About one in three people who have stroke risk factors and experience an authentic TIA will eventually have a stroke during their lifetime, with about half occurring within a year of the initial TIA.

PATHOBIOLOGY

TIA's have more than one mechanism. When severe carotid or vertebrobasilar stenosis is present, transient ischemia can be caused by low flow distally; such TIA's are typically brief and stereotyped, presenting with repeated episodes of the same syndrome. TIA's of this hemodynamic type may occur only during upright posture or during transient hypotension or cardiac arrhythmia. When TIA's are caused by embolism—from the heart, aorta, or proximal large-vessel atherosclerotic plaque or dissection—they may last longer, as the embolus transiently occludes a distal arterial branch before spontaneously dissolving. Less commonly, permanent small-vessel occlusion with evidence of a small infarct on magnetic resonance (MR) diffusion-weighted imaging (DWI) can result in a transient deficit lasting up to 24 hours before resolving (“cerebral infarction with transient symptoms”). A newer “tissue-based” definition of TIA restricts the diagnosis to brief episodes of focal neurologic dysfunction—typically less than 1 hour—without imaging evidence of acute infarction on computed tomography (CT) or MR imaging.

Small-vessel TIA's may result from lipohyalinosis and arteriolosclerosis of small penetrating vessels, such as the lenticulostriate branches of the middle cerebral artery, or penetrators of the vertebral and basilar arteries. Intracranial or extracranial arterial dissection may produce hemodynamic compromise or embolism. Fibromuscular dysplasia and Ehlers-Danlos type IV predispose to dissection. Vasospasm-related TIA may respond to calcium channel blockers.

TIA's have also been associated with hyperviscosity—polycythemia, sickle cell anemia, and thrombocythemia as well as with cerebral venous thrombosis, bacterial endocarditis, and temporal arteritis—and may clear with correction of these underlying disorders. TIA's in cocaine users may be the result of drug-induced cerebral vasospasm.

CLINICAL MANIFESTATIONS

Symptoms vary with the arterial territory involved. *Transient monocular blindness* (TMB or *amaurosis fugax*) due to ischemia in the territory of the central retinal artery consists of blurring or darkening of vision, peaking within a few seconds (sometimes as if a curtain had descended) and usually clearing within minutes. The most important cause of TMB is proximal internal artery stenosis producing either hemodynamic compromise or embolism. Hollenhorst plaques resulting from cholesterol microemboli may be seen in retinal artery branches.

Carotid territory TIA's that involve the brain produce varying combinations of limb weakness and sensory loss, aphasia, or hemineglect. Posterior circulation TIA's cause symptoms referable to the cerebrum (visual field loss or cortical blindness), brain stem (cranial nerve and long-tract symptoms, sometimes crossed or bilateral), and cerebellum. Some TIA's produce transient “lacunar syndromes” such as pure hemiparesis or pure hemisensory loss. TIA's can cause paroxysmal dyskinesias, including tremor, ataxia, limb dystonia, and myoclonic jerking.

Coarse irregular shaking of an arm or leg lasting seconds to a minute, so-called limb-shaking TIA, and sometimes precipitated by a change to upright posture, is often associated with critical carotid artery stenosis or occlusion. Although rare, high-grade stenosis or complete occlusion of both internal carotid arteries and the proximal basilar artery can lead to “drop attacks.”

In the *subclavian steal syndrome*, stenosis of the subclavian or innominate artery proximal to the origin of the vertebral artery leads to brain stem, cerebellar, or even cerebral symptoms, often manifested during exertion and sometimes accompanied by symptoms of arm claudication. The syndrome results from diversion of anterograde flow via the patent vertebral artery retrograde down the contralateral vertebral artery distal to the occlusion, depriving the basilar artery of blood flow.

Recurrent TIAs of the same type are more likely to be the result of perfusion failure due to critical narrowing or occlusion of the involved artery than of embolism.

DIAGNOSIS

The diagnosis of TIA may be difficult to ascertain when symptoms are ambiguous (e.g., staggering or drop attacks; dizziness, lightheadedness, or syncope; vertigo; fleeting diplopia; transient amnesia; atypical visual disturbance in one or both eyes such as flashes, distortions, or tunnel vision; a heavy sensation or “tiredness” in one or more limbs; or paresthesias in an area of fixed sensory loss or briefly affecting only one limb). The differential diagnosis of TIAs includes migraine, cardiac arrhythmia, seizures, hypoglycemia, compressive neuropathy, conversion, and neurosis. Multiple stereotyped current focal deficits with complete recovery between events should in particular raise the question of recurrent focal seizures.

Although TIAs are defined in terms of their clinical reversibility and are presumed to signify ischemia too brief or incomplete to cause infarction, imaging frequently demonstrates appropriately located infarcts. DWI-detected abnormalities are especially likely when symptoms last more than an hour, and those lasting longer than 3 hours show infarcts in 70% of cases. This is supported by evidence that neurologic deficits reemerged upon giving intravenous midazolam to TIA patients whose initial deficits had resolved and who did not have evidence of infarction on DWI, suggesting that TIA may cause a structural lesion.

P.286

TABLE 36.1 Diagnostic Tests for the Evaluation of Transient Ischemic Attack

In most patients

✓ Electrocardiogram

✓ Carotid imaging (Doppler, MR, or CT angiography)

✓ Transthoracic echocardiography

In selected patients

✓ Portable cardiac rhythm monitoring (Holter or event-loop monitoring)

✓ Erythrocyte sedimentation rate (rule out giant cell arteritis)

✓ Toxicology screen

✓ Hypercoagulable workup (see [Chapter 118](#))

Patients with a documented small infarct or compelling history of TIA should undergo a standard ischemic stroke workup to identify a potentially treatable cause of recurrent stroke ([Table 36.1](#)).

TREATMENT

Prevention of subsequent stroke is the primary concern in a patient diagnosed with TIA. Treatment is identical to secondary prevention in patients diagnosed with acute ischemic stroke, as discussed in [Chapter 35](#).

OUTCOME

Authentic TIAs are associated with a high risk of subsequent stroke. In 1,707 patients presenting with TIA to an emergency department, 10% had a stroke within the next 90 days, and in half, the stroke occurred within the first 48 hours of the TIA. Retinal TIAs had about half this rate of stroke (5% within 90 days). In four European studies combining 2,416 patients who presented with ischemic stroke, 15% to 26% of ischemic strokes were preceded by a TIA and 43% of TIAs occurred within 7 days of the stroke.

The best validated tool for assessing the risk of stroke after TIA is the “ABCD²” score, in which points are assigned for particular risk factors and presenting features of the TIA, with scores ranging from 0 to 7. A higher score implies a higher 90-day risk of stroke. For each score, the risk of subsequent stroke is consistently greater if an acute infarct identified on CT or MR is associated with the syndrome ([Table 36.2](#)).

Since initial publication of the ABCD² score, attempts to add additional scale items have been added, including the presence of more than one TIA (ABCD³), DWI-positive image, or the presence of greater than 50% carotid stenosis (ABCD³-I) or intracranial arterial stenosis (ABCD³-I[c/i]). Each of these scores adds a small degree of incremental predictive value compared to the original ABCD² score at the expense of simplicity. For clinical use and ease of communication, we recommend use of the standard ABCD² score while recognizing that multiple TIA events, cerebral infarction with transient symptoms, or evidence of significant extracranial or intracranial stenosis further increases the 90-day stroke risk.

Crescendo TIAs—two or more attacks within 24 hours—should be considered a medical emergency. Particularly concerning is the *capsular warning syndrome*: multiple brief attacks of motor impairment due to disease involving small lenticulostriate or basilar penetrating arteries. Asymptomatic coronary artery disease is especially common in patients with carotid stenosis and should be checked for. The overall risk of stroke, myocardial infarction, and vascular death remains high for at least 10 to 15 years in patients with a history of TIA.

TABLE 36.2 ABCD² Score

FEATURES

POINTS

A	Age: 60 years or older	1
B	Blood pressure: ≥ 140 mm Hg systolic or ≥ 90 mm Hg diastolic or history of hypertension	1
C	Clinical: speech impairment without weakness (1 point) or unilateral weakness (2 points)	1 or 2
D	Duration: 10-59 min (1 point), ≥ 60 min (2 points)	1 or 2
D	Diabetes: a history of diabetes mellitus (1 point)	1
90-Day Stroke Risk	With Infarction	Without Infarction
≥ 6	19%	6%
6	17%	3%
4	8%	2%
3	4%	2%
2	4%	$\leq 1\%$
≤ 1	$< 1\%$	$\leq 1\%$

Hypoxic-Ischemic Encephalopathy

Alexandra S. Reynolds

Sachin Agarwal

INTRODUCTION

Hypoxic-ischemic encephalopathy (HIE) is a term used to describe cerebral dysfunction after a global insult to the brain. Mechanisms of such damage include prolonged interruption of blood flow and/or oxygen, most commonly after cardiac arrest.

EPIDEMIOLOGY

Approximately 630,000 cardiac arrests occur in the United States per year with an overall 14% survival to discharge. Despite an increased survival from all-rhythm cardiac arrest, the mortality is at least 50% in those who have survived to the hospital admission and overall disease-specific mortality is around 90%. Brain injury alone is the primary cause in 68% of patients. Among all out-of-hospital cardiac arrest patients between 2000 and 2006, patients who found in asystolic arrest had the worst outcomes (1% survival to discharge and 0.5% 30-day survival), whereas those with shockable initial rhythm (ventricular fibrillation [VF] or pulseless ventricular tachycardia) had the best outcomes (15%-20% survival to discharge). Those with pulseless electrical activity (PEA) fell somewhere in the middle (5%-8% survival to discharge). In general, the faster the return to spontaneous circulation (ROSC), the better the outcome.

These numbers do not capture the neurologic morbidity associated with cardiac arrest. Those who survive may still have significant neurologic deficits including personality changes and problems with memory. Further, a proportion of patients will ultimately remain in minimally conscious or persistent vegetative states. The true proportions are unknown because of high rates of withdrawal of care in patients who remain comatose after a cardiac arrest leading to a “self-fulfilling prophecy.”

PATHOBIOLOGY: CAUSES OF HYPOXIC-ISCHEMIC ENCEPHALOPATHY

CARDIAC ARREST

Cardiopulmonary arrest is a complex process that causes diffuse damage to the brain. The initial mechanisms of damage include hypoxemia and hypoperfusion due to circulatory arrest. However, as the cardiac arrest progresses, damage is caused by resultant hypoglycemia, acidosis, and toxin accumulation (see following text). The model of cardiac arrest resuscitation involves three time-sensitive ischemic-reperfusion phases, including electrical, circulatory, and metabolic. Although rapid reperfusion is needed after ischemia, it can also paradoxically contribute to tissue injury and destruction. Various mechanisms of cell death, including necrosis, apoptosis, and autophagy-associated cell death, have been implicated. Tissue necrosis results in swelling and this is exacerbated by rebound hyperemia from reperfusion as well as progression of the inflammatory cascade. On a molecular level, reintroduction of glucose causes formation of nitric oxide and oxygen free radicals that can induce DNA damage and consumption of NAD⁺ leading to a second round of cell death. Studies involving cellular, animal, and human models suggest that therapeutic hypothermia (TH) has the potential to mitigate these deleterious processes ([Table 37.1](#)) even after a period of ischemia. Models where hypothermia was initiated before reperfusion have resulted in the most cellular protection.

PROLONGED HYPOTENSION

Hypotension results in preferential injury to parts of the central nervous system that lie in between vascular distributions. Areas supplied by narrowed arteries are also at risk for hypoperfusion in low-flow states like carotid stenosis or in heart failure with low cardiac output. Low cerebral blood flow results in patchy ischemic infarctions. Watershed areas in the brain affected by hypotension include the cortical border zones between the anterior cerebral and middle cerebral arteries (ACA-MCA) and middle cerebral and posterior cerebral arteries (MCA-PCA) or internal border zone areas in the periventricular white matter or the deep structures supplied by the recurrent artery of Heubner and the anterior choroidal and

P.289

lenticulostriate arteries. In the spinal cord, the anterior portion of the midthoracic distribution is considered to be the watershed region; however, one study showed disproportionate damage to the lumbosacral spinal cord after prolonged hypotension and/or cardiac arrest.

TABLE 37.1 Mechanisms of Neuroprotection with Therapeutic Hypothermia

Metabolic	Decreased cerebral metabolism (6%-10%/°C below 37°C) Inhibition of mitochondrial injury and dysfunction Decreased production of toxic metabolites and free radicals
Neuroinflammatory	Decreased generation of inflammatory proteins Decreased release of glutamate and decreased neuroexcitotoxicity
Vascular	Decreased vascular permeability and edema Decreased cerebral thermopooling, reducing local hyperthermia
Cellular	Decreased ion pump dysfunction and decreased intracellular calcium influx Decreased cell membrane leakage and cytotoxic edema Decreased apoptosis and proteolysis
Other	Decreased spreading depression-type depolarizations Suppression of epileptic activity Decreased coagulation activation with formation of fewer microthrombi

HYPOXIA

Pure hypoxic hypoxia can occur in the absence of circulatory breakdown, in the case of aspiration, hanging/strangulation, or drowning. Hypoxic damage to the brain occurs solely due to decreased partial pressure of blood oxygen and results in a lesser degree of injury than combined hypoxic-ischemia. However, prolonged hypoxia will progress to cardiac arrest. Once oxygen supply to the brain is interrupted, adenosine triphosphate (ATP) stores only last for minutes. After energy-dependent membrane ion transport starts to fail, damaged cells release excitotoxic glutamate, intracellular calcium begins to accumulate and activates proteases and phospholipases, and damage is propagated via inflammatory cascades. Intracellular influx of calcium in surrounding areas leads to diffuse cell death. The areas particularly susceptible to hypoxic damage are hippocampal CA1 neurons, thalami, cerebellar Purkinje cells, and cortical pyramidal cells in layers 3, 5, and 6. Among the cortical areas, perirolandic areas are most vulnerable because of the high concentration of *N*-methyl-D-aspartate (NMDA) receptors. White matter injury also occurs because of damage to oligodendroglial cells.

CARBON MONOXIDE POISONING

Carbon monoxide (CO) primarily exerts harmful effects to the brain by causing hypoxemia in a so-called anemic-histotoxic hypoxia. As in hypoxic hypoxia, preservation of circulation portends a lesser damage to the brain. CO preferentially binds to heme proteins and displaces bound oxygen because of its greater affinity for hemoglobin. CO thus limits oxygen-carrying capacity of blood and impairs mitochondrial function of the tissues attempting to use oxygen, resulting in a hypoxic and acidotic state. Ultimately, CO poisoning causes intravascular and intracellular oxidative stress, inflammation, and apoptosis. The cortical laminae and basal ganglia are particularly prone to damage. Additional reports of delayed demyelination in the centrum semiovale have been published. In severe cases, cardiac toxicity can occur resulting in hypotensive brain injury as well.

CYANIDE POISONING

Cyanide poisoning causes metabolic failure by inhibiting oxidative phosphorylation. It results in direct metabolic damage to the brain but ultimately causes mixed injury due to early cardiac failure. Cyanide impairs oxidative phosphorylation by inhibiting the mitochondrial cytochrome oxidase a_3 complex. Mitochondria are unable to produce ATP and increased glycolysis occurs, quickly resulting in a metabolic acidosis as pyruvate is reduced to lactate. Coronary artery vasoconstriction occurs and cardiac output decreases suddenly, causing hypotension and cardiac shock. The brain is damaged not only from this hypotension but also from metabolic failure on a cellular level.

PROFOUND HYPOGLYCEMIA

Glucose is the primary source of energy for the brain in both adults and in infants, and prolonged or repeated hypoglycemic episodes can therefore cause significant injury to the brain. Concurrent hypoglycemia also exacerbates the damage caused by hypoxemia. Brain damage usually occurs once serum glucose levels fall below 20 mg/dL. Mechanisms of cell death with hypoglycemia are similar to hypoxia, including excitotoxic glutamate and aspartate release and involvement of NMDA receptors. More recent studies have shown that activation of poly (ADP ribose) polymerase-1 (PARP-1), release of zinc from nerve terminals, and activation of calcium-dependent protease calpain also contribute to neuronal death. Further, depolarization of the mitochondrial membrane leads to apoptosis. The parts of the brain most sensitive to low-glucose levels are the hippocampus (CA1, CA3, and dentate gyrus), caudate, putamen, and insular cortex.

Damage from hypoxic-ischemic injury also changes as the brain matures. In neonates, HIE often results in parietooccipital and thalamic damage, whereas in infants, basal ganglia damage is more frequent and in children, parietotemporal changes are seen.

CLINICAL FEATURES

The clinical manifestations of HIE can range from mild changes in cognition to coma. Damage to the hippocampus can result in memory deficits. Damage to the basal ganglia can present as a variety of movement disorders. Thalamic damage can result in a wide variety of symptoms from sensory changes to dementia or coma. Damage to the Purkinje cells results in cerebellar dysfunction. Cortical damage can result in inattentiveness, executive dysfunction, or aphasia. Because of the resistance of the deep gray matter of the brain stem to anoxic injury compared with the neocortex, HIE often results in coma with preservation of brain stem reflexes. However, brain death can occur with prolonged hypoxic-ischemic injury.

Watershed injury in the brain can manifest as proximal greater than distal extremity weakness and ultimately spasticity ("man-in-a-barrel syndrome"). Watershed injury to the spinal cord results in an "anterior cord syndrome" or Beck syndrome, including motor paralysis below the level of the lesion, loss of pain and temperature but intact proprioception and vibratory sensation, and loss of bowel and/or bladder control.

Lance-Adams syndrome, or posthypoxic action myoclonus, can occur several days after recovery from hypoxic injury to the brain.

The rare syndrome of delayed posthypoxic leukoencephalopathy (DPHL) following seemingly full recovery from a comatose state can occur days to weeks after the initial insult. The onset is usually insidious and can manifest as personality changes, irritability, inattentiveness, confusion, and memory problems. This can progress to include extrapyramidal motor symptoms and, in some cases, eventually coma or death. Those patients who survive stabilize to one of two ultimate syndromes: either parkinsonism with hallucinations or odd behaviors, or akinetic mutism. DPHL may occur as a result of any cause of HIE mentioned earlier but is most often seen in cases of acute CO poisoning or opioid overdose. The main histopathologic patterns seen in this syndrome are demyelination in the centrum semiovale and necrosis of the cortical laminae and basal ganglia, which correlate with brain magnetic resonance imaging (MRI) features. Severity and persistence of DPHL sequelae have been correlated to the presence and persistence of low signal intensity on the apparent diffusion coefficient (ADC) map on cranial MRI.

DIAGNOSIS

IMAGING

CT head is usually normal immediately after hypoxic-ischemic insult. In severe injury, there can be evidence of loss of the gray-white junction within hours ([Fig. 37.1A](#)). After 24 to 48 hours, linear

P.290

hyperdensities outlining the cortex develop, corresponding to laminar necrosis of the cortex. After days, the “reversal sign” develops where cerebral white matter appears hyperdense than cortical gray matter.

Pseudosubarachnoid hemorrhage can also occur when the falx cerebri and tentorium cerebelli appear hyperdense as compared to the adjacent injured parenchyma (see [Fig. 37.1B](#)).

FIGURE 37.1 Imaging findings after HIE. CT scan done **(A)** 12 hours and **(B)** 10 days after a neardrowning episode. **A:** There is diffuse loss of gray-white matter differentiation and severe global cerebral edema. There are bilateral, but right greater than left, hypodensities of the basal ganglia. **B:** The diffusely attenuated white and gray matter result in a pseudosubarachnoid hemorrhage appearance of the relatively hyperdense dura. DWI **(C)** and ADC **(D)** sequences of an MRI done 2 days after a primary respiratory arrest showing restricted diffusion in the bilateral hippocampi (*arrows*) and diffusely throughout the cortex. **E:** Susceptibilityweighted imaging (SWI) sequence in coronal section done 7 days after a PEA arrest showing areas of laminar necrosis in the posterior parietal lobes (*arrows*). **F:** FLAIR sequence 10 days after cardiopulmonary arrest only showing mild swelling and indistinctness of the gray-white junction in the bilateral parietal lobes (*arrows*). **G:** DWI sequence of an MRI done 11 days after a PEA arrest resulting from a type A aortic dissection. There are scattered foci of restricted diffusion along the ACA-MCA and MCA-PCA border zones, more prominent on the right, consistent with watershed infarct.

MRI brain is the earliest way to visualize damage, as early cytotoxic edema can be visualized on diffusion-weighted imaging (DWI) and can be quantified using the ADC (see [Fig. 37.1C-G](#)). Importantly, DWI and ADC changes may not be apparent early on and thus early imaging may underestimate the injury burden.

Moreover, there may be attenuation of ADC values for every 1°C decrease in body temperature. DWI sequences can pseudonormalize by seven days but T2 hyperintensities on fluid-attenuated inversion recovery (FLAIR) sequences develop after the first week. The damage is most often symmetric and corresponds in location to the neuronal subtypes that are preferentially damaged (see pathobiology section). With time, focal laminar necrosis can be seen due to deposition of blood products (see Fig. 37.1E). In one small study, changes occurring over time within the same patient were analyzed. The location of the injury shifts with time from the initial hypoxic-ischemic event, starting in the cerebellum and basal ganglia in days 1 and 2, moving to the cortex around days 3 to 5, and involving subcortical white matter on days 6 to 12. Pronounced hippocampal abnormalities on DWI—the so-called bright hippocampus sign—has been associated with extremely poor outcomes (see Fig. 37.1C,D). In the case of DPHL, MRI findings are pathognomonic, with diffuse T2 hyperintensities predominantly in the dorsal frontal and parietal lobes.

SOMATOSENSORY-EVOKED POTENTIALS

A noninvasive way to evaluate the functioning of the somatosensory system in a comatose patient is by performing evoked potentials. There are multiple types of evoked potentials including auditory and visual; however, somatosensory-evoked potentials (SSEPs) are most commonly used after a hypoxic-ischemic event or cardiac arrest. SSEPs are done by providing a transcutaneous electrical stimulation along a peripheral nerve, most commonly the median nerve. The impulse is then tracked as it travels up the peripheral nerve to the elbow (N5), Erb point in the brachial plexus (N9), the posterior column of the midcervical cord (N13), and ultimately to the contralateral primary sensory cortex (N20). In cases of significant cortical damage, the N20 can be absent (Fig. 37.2).

ELECTROENCEPHALOGRAPHY

The 2006 AAN practice parameters emphasized the importance of identifying electrographic seizures and burst suppression for prognostication, but minimal data was available at that time. In last few years, there have been many studies describing the evolution

P.291

of electroencephalography (EEG) during hypothermia and after rewarming. The occurrence of seizures more in the first 24 hours, that is, during hypothermia phase, was to be an unexpected observation. Therefore, many experts recommend early and prolonged EEG monitoring. Most studies have confirmed an incidence of seizures in 25% of patients, and status epilepticus at any point during the hospital course is thought to be a bad prognostic indicator. However, patients have achieved good outcomes after seizures were detected and treated aggressively. The most common finding on EEG is generalized periodic discharges that are also known to be a precursor of seizures and thus poor outcomes, but more systematic evaluation of different patterns needs to be done. EEG background features like continuity and reactivity have also been shown to be predictive of outcomes, i.e., persistence of continuous background and EEG reactivity in first few days of the event is associated with good recovery. Further research in this area is warranted and eventually inclusion of appropriate, well-studied EEG patterns should be a part of multimodal prognostication paradigm.

FIGURE 37.2 Median nerve somatosensory-evoked potentials. **A:** The normal SSEP tracing including the N5 waveform at the elbow, N9 at Erb point, N13 at the cervical cord, and N20 at the contralateral sensory cortex. **B:** An absent N20 after hypoxic-ischemic injury from cardiac arrest. TREATMENT

GENERAL CONCEPTS

Intracranial pressure (ICP) can increase after cardiac arrest both because of reflex hyperemia post arrest and because of global cerebral edema in cases of significant global injury. High ICP and low cerebral perfusion pressures (CPP) are associated with poor outcomes. ICP also increases with seizure activity. Hyperoxia is correlated with worse outcomes in humans. Each 100 mm Hg increase in PaO₂ above the normal level of 100 mm Hg is associated with 24% increased risk of mortality. Unnecessary increases in the fraction of inspired oxygen should be avoided. The goal for PaCO₂ should be on the higher end of normocapnia, as lower ends of the threshold are associated with decreased cerebral blood flow (CBF).

SEIZURES

With cortical damage comes the potential for development of complex, evolving epileptiform discharges and/or seizures. Early detection and treatment of seizures is paramount to prevent further brain damage. Myoclonic status epilepticus, characterized as a poor prognostic marker in pre-TH era, has been questioned by more recent small studies and case reports. The definition involved spontaneous, unrelenting, generalized, multifocal myoclonus involving face, limbs, and axial musculature but no EEG correlate was needed for the diagnosis. EEG monitoring with a trial of paralytic to remove muscle artifact, if necessary, should be attempted and if the patient is found to be in electrographic status epilepticus, they should be treated aggressively.

THERAPEUTIC HYPOTHERMIA

Beginning in the 1950s, cardiothoracic surgeons used moderate hypothermia (28°C to 32°C) during cardiac surgery to prevent brain ischemia. The idea of cooling after unexpected cardiac arrest and subsequent

resuscitation, however, was not seriously pursued until the early 1990s, when animal studies became popular. In 2002, two randomized controlled trials were published suggesting that patients in cardiac arrest with an initial rhythm of VF who remained comatose after ROSC had better outcomes after mild TH to 32°C to 33°C for 12 to 24 hours [Level 1].^{1,2} More recently, it was shown that there is no benefit to cooling to 33°C when compared to 36°C [Level 1].³ It is recommended that all comatose survivors of cardiac arrest be cooled, despite there being a dearth of data supporting cooling after PEA or asystole. TH is neuroprotective in many ways (see Table 37.1). The hypothermia protocol is complex (Table 37.2) and requires close monitoring for shivering via the Bedside Shivering Assessment Scale (BSAS) (Table 37.3). Sometimes, EEG can detect microshivering that is not palpable on the neck or thorax. Shivering must be treated aggressively, as it increases metabolic demand, raises the patient's core temperature, causes tachycardia, and can increase ICP.

TABLE 37.2 Hypothermia Checklist

Contraindications

Absolute contraindications:

- Refractory bleeding at a noncompressible site or uncontrollable bleeding
 - Severe and recurrent symptomatic bradycardia requiring pacing or continuous medial therapy
-

Relative contraindications (consider cooling to 36°C instead of 33°C):

- Acute multisystem organ failure due to prolonged arrest
- Hemodynamic instability requiring more than two vasopressors and/or recurrent cardiac arrests
- Mild bradycardia
- Concurrent meningitis
- Severe systemic infection and/or sepsis
- Significant trauma with high risk of internal bleeding
- Severe baseline neurologic or medical disorders
- Pregnancy or postpartum patient
- Head trauma with intracranial bleeding

Induction of Hypothermia

- Immediate initiation of cooling with ice packs, infusion of cold saline, and cooling blanket (protecting the skin from direct contact)
-
- Use of one of the following devices: Arctic Sun (superficial cooling pads) or Alsius or Innercool (intravascular temperature modulation devices)
-
- Administration of one-time paralytic dose for expediting cooling with rocuronium or vecuronium
-
- Central temperature monitoring with bladder or esophageal probe
-
- Maintain temperature for 24 hours after initiation of hypothermia.
-

Shivering

- cEEG to detect microshivering
-
- Goal Bedside Shivering Assessment Scale (BSAS) ≤ 1
-
- Acetaminophen 650 q4h standing
-
- Buspar 30 mg PO q8 standing
-
- Meperidine 25 mg IV q6h PRN shivering
-
- BAIR hugger set at 43°C for skin counterwarming
-
- If shivering refractory, can start Mg gtt at 0.5-1 g/h with goal Mg level 3-4 mEq/L
-
- If shivering still refractory, can add fentanyl, propofol, or dexmedetomidine gtts
-
- If shivering remains refractory to sedation, start neuromuscular blockade (must be on sedation) with vecuronium 0.1mg/kg IV qh or rocuronium or cisatracurium gtts.
-

Seizures and Myoclonus

- Continuous EEG to identify seizures
-
- Treat seizures aggressively with phenytoin, valproic acid, levetiracetam, or benzodiazepines.
-

- Noncortical myoclonus (i.e., Lance-Adams syndrome) has no effect on outcome but can be treated for comfort with levetiracetam, valproic acid, gabapentin, or benzodiazepines.

Rewarming to Normothermia

- Rewarm at 0.1 to 0.2°C/h to a goal of 37°C.
-
- Shivering is most common during rewarming and should be treated aggressively.
-

Other Monitoring

- Electrolytes should be monitored and repleted to a goal of K = 3.0 mEq/L, as overrepletion can result in hyperkalemia during rewarming.
-
- Platelets should be transfused for goal >20,000 or >50,000 if active bleeding.
-
- Send serum NSE daily for 3 days.

cEEG, continuous electroencephalography; PO, by mouth; IV, intravenous; PRN, as needed; Mg, magnesium; gtt, drip; EEG, electroencephalography; NSE, neuron-specific enolase.

TABLE 37.3 Bedside Shivering Assessment Scale

Score		Location of Shivering
0	None	None detected on palpation of masseter, neck, and chest muscles
1	Mild	Shivering localized to neck and thorax only
2	Moderate	Shivering involves gross movement of the arms and trunk.
3	Severe	Shivering involves gross movement of the arms, legs, and trunk.

OUTCOME

In 2006, the American Academy of Neurology published guidelines for prognostication in comatose survivors of cardiac arrest after an exhaustive review of the literature (Fig. 37.3). Features that nearly guaranteed poor outcome were early clinical (not electrographic) myoclonic status epilepticus, absent N20 responses on SSEPs in the first 72 hours after arrest, absent corneal or pupillary reflexes or extensor or absent motor response to pain at 72 hours, and serum neuron-specific enolase (NSE) greater than 33 µg/L.

Subsequent studies looking at routine use of hypothermia in comatose patients post arrest have revealed an unacceptably high false-positive rate of almost every feature (see Fig. 37.3). These findings have prompted further studies on prognostic factors that may be valid for use in the posthypothermia era.

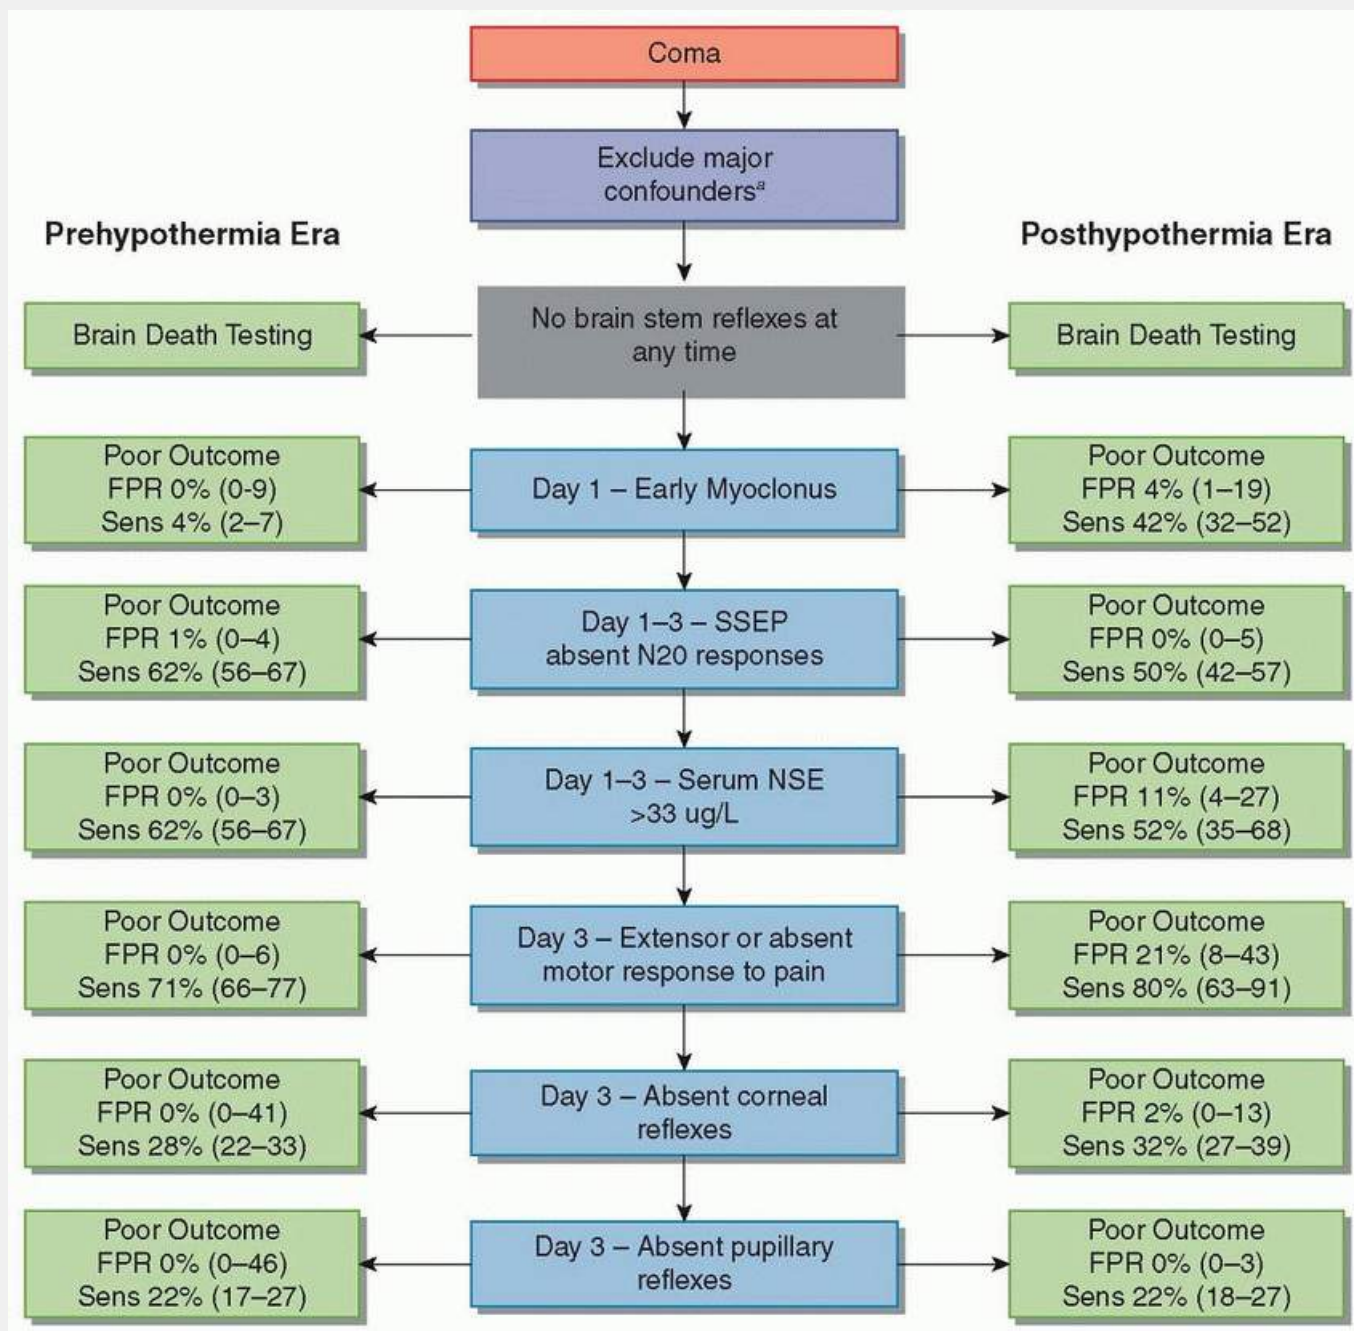

FIGURE 37.3 Prognostication algorithm in comatose survivors of cardiac arrest. On the *left* appear false-positive rate (FPR) and sensitivity of each feature in the prehypothermia era, on the *right* in the posthypothermia era. For posthypothermia era, in cases of multiple studies, the data from the study with the largest number of subjects were used. ^aMajor confounders at the time of examination include hypothermia, sedatives/hypnotics, and paralytics. (Adapted from Wijdicks EF, Hijdra A, Young GB, et al. Practice parameter: prediction of outcome in comatose survivors after cardiopulmonary resuscitation [an evidence-based review]: report of the Quality Standards Subcommittee of the American Academy of Neurology. *Neurology*. 2006;67:203-210.)

Other biomarkers being studied as predictors of clinical outcome include brain-specific markers such as S100-B and micro-RNAs, inflammatory markers including C-reactive protein and the interleukins, and neurohormonal markers such as copeptin. The role of imaging in prognostication is also being studied. In

particular, MRI has been studied in an attempt to quantify extent of cerebral damage on ADC. Ultimately, there may be a combination of biomarker and imaging data that may aid in prognostication when the patient's outcome is otherwise indeterminate based on clinical exam, NSE, and SSEP.

It is important to keep in mind the so-called self-fulfilling prophecy that occurs in clinical practice and is a limitation in many studies on outcome after cardiac arrest. There is always a temptation to prognosticate earlier and earlier due to scarcity of resources, anxious families, and astronomical health care costs. Additionally, results of tests that may not accurately predict outcome in the post-TH era can influence clinician decision making. These tests are studied as predictors of outcome but often directly affect the clinician's decision making and counseling to families—thereby confounding any study of outcome. Moving forward, outcome measures need to be changed from survival to degree of neuropsychological impairment in survivors.

Intracerebral Hemorrhage

Stephan A. Mayer

Fred Rincon

J. P. Mohr

INTRODUCTION

Intracerebral hemorrhage (ICH) is defined as the acute spontaneous bleeding into the brain parenchyma (Fig. 38.1). Primary ICH results from microscopic small artery degeneration in the brain, caused either by chronic, poorly controlled hypertension (80% of cases) or amyloid angiopathy (20% of cases). Secondary ICH refers to intraparenchymal bleeding from a diagnosable anatomic vascular lesion or cause of coagulopathy (Table 38.1).

EPIDEMIOLOGY

The overall incidence of ICH is estimated to be 12 to 15 cases per 100,000/yr. As the least treatable and most devastating form of stroke, ICH is a leading cause of mortality, morbidity, and disability in the United States and worldwide, accounting for 10% to 30% of all stroke hospital admissions. Many ICH patients require long-term health care, and only 20% of patients regain functional independence. About 40% to 80% of ICH patients die within the first 30 days, and half of all deaths occur within the first 48 hours.

RISK FACTORS

Hypertension and older age are the strongest predictors of incident ICH. Studies have shown that noncompliance with antihypertensive medications increases the risk of ICH, and control of blood pressure has been shown to reduce this risk. Chronic hypertension causes a small-vessel vasculopathy characterized by fragmentation, degeneration, and the eventual rupture of small penetrating vessels within the brain termed *lipohyalinosis*. Commonly affected structures include the basal ganglia and thalamus (50%), lobar regions (33%), and brain stem and cerebellum (17%). On pathologic examination, the pattern of small-vessel damage is characterized by (1) degeneration of medial smooth muscle cells; (2) small miliary aneurysms associated with thrombosis and microhemorrhages; (3) accumulation of nonfatty debris; and (4) hyalinization of the intima, preferentially at bifurcation points and distal portions of the vessel. It is unclear why some patients develop deep brain infarcts and others develop hemorrhages, but some have implicated the sudden rupture of microaneurysms, also known as Charcot-Bouchard microaneurysms, as the basis for ICH. Other nonmodifiable risk factors for ICH include male gender and African-American or Japanese race/ethnicity.

Low cholesterol levels have been implicated as a risk factor for primary ICH, although there is controversy regarding this association, as the results from case-control and cohort studies and prospective randomized trials of cholesterol reduction have yielded conflicting results. Heavy alcohol intake has been implicated as a risk factor for ICH in several studies. In theory, alcohol may affect platelet function and coagulation physiology and enhance vascular fragility.

FIGURE 38.1 Basal ganglia ICH with hematoma followed by expansion and IVH.

Cerebral amyloid angiopathy (CAA) is an important risk factor for ICH in the elderly (Fig. 38.2). CAA is characterized by the deposition of β -amyloid protein in small- to medium-sized blood vessels of the brain and leptomeninges, which may undergo

P.296

fibrinoid necrosis. It can occur as a sporadic disorder, in association with Alzheimer disease, or with certain familial syndromes (apolipoprotein E2 and E4 allele). Brain tumors, sympathomimetic drugs, coagulopathies, cavernomas, and arteriovenous malformations also cause brain hemorrhages. Further differential diagnoses of underlying pathologies are summarized in Table 38.1. Although treatment with anticoagulants or fibrinolytic agents entails a higher risk of hemorrhage with increasing doses, the role of aspirin intake in this context is controversial. The detection of microbleeds in gradient echo magnetic resonance imaging (MRI) implies that aspirin is a risk factor for hemorrhage in patients on anticoagulant therapy; MRI evidence of microhemorrhages should prompt reconsideration of the indications for anticoagulation.

PATHOBIOLOGY

Abrupt arterial rupture leads to rapid accumulation of blood within the brain parenchyma and increase in local tissue pressure followed by the abrupt onset of shearing forces and physical destruction. In addition to the relative mass effect, the hematoma itself induces three early pathophysiologic changes in the surrounding brain tissue: (1) neuronal and glial cell death due to apoptosis and inflammation, (2) vasogenic edema, and (3) breakdown of the blood-brain barrier (BBB).

Hematoma expansion is an important cause of early neurologic deterioration, and ICH volume is a powerful predictor of outcome after primary ICH. An expanding hematoma may result from persistent bleeding and/or rebleeding from a single arteriolar rupture. Some studies have reported evidence of ICH growth from bleeding into an ischemic penumbra zone surrounding the hematoma, but studies have not confirmed the existence of ischemia in the hypoperfused area in the periphery of the hematoma. Because ischemia does not explain the changes and degree of neurologic dysfunction that occurs after the hemorrhage, neurotoxic and inflammatory mechanisms have more recently been implicated in the pathogenesis of perihemorrhagic tissue damage.

Peri-ICH edema may be produced by local and systemic inflammatory mediators that enhance tissue damage either directly or indirectly by the activation of leukocytes, generation of prostaglandins and leukotrienes, and activation of the complement. Intracerebral blood is in part directly responsible for the formation of local edema after ICH.

CLINICAL MANIFESTATIONS

Because most spontaneous hemorrhages arise from tiny vessels, the accumulation of a hematoma takes time and explains the smooth onset of the clinical syndrome over minutes or hours.

The progressive course, frequent vomiting, and headache are major points that help to differentiate hemorrhage from infarction.

The *putamen* is the site most frequently affected. When the expanding hematoma involves the adjacent internal capsule, there is a contralateral hemiparesis, usually with hemianesthesia and hemianopia and, in large hematomas, aphasia or impaired awareness of the disorder. However, small self-limiting hematomas close to the capsular region may occasionally mimic lacunar syndromes featuring pure motor or sensory deficits. When the hemorrhage arises in the *thalamus*, hemianesthesia precedes the hemiparesis. Once contralateral motor, sensory, and visual field signs are established, the main points that distinguish the two sites are (1) conjugate horizontal ocular deviation in putaminal hemorrhage and (2) impaired upward gaze in thalamic hemorrhage. *Pontine* hemorrhage usually plunges the patient into coma with quadriplegia and grossly disconjugate ocular motility disorders, although small hemorrhages may mimic syndromes of infarction. Primary spontaneous hemorrhages within the *mesencephalon* or the *medulla* remain objects of debate and are rare curiosities. When they occur, the anatomic involvement is usually secondary to hemorrhage originating in neighboring diencephalic, cerebellar, or pontine regions. In the *cerebral lobes*, there is an as-yet-unexplained predilection for hemorrhages to occur within the posterior two-thirds of the brain. When they affect one or more cerebral lobes, the syndrome is difficult to distinguish, clinically, from infarction because progressive evolution and vomiting are much less frequent in infarction; also, lobar white matter hematomas often result from arteriovenous malformations, amyloid angiopathy, tumors, or other causes that only uncommonly affect the basal ganglia, thalamus, and pons.

Cerebellar hemorrhage warrants separate description because the mode of onset differs from that of cerebral hemorrhage and because it often necessitates surgical evacuation. The syndrome usually begins abruptly with vomiting and severe ataxia (which usually prevents standing and walking); it is occasionally accompanied by dysarthria, adjacent cranial nerve (mostly sixth and seventh) affection, and paralysis of conjugate lateral gaze to one side, findings that may mislead clinicians into thinking the disease is primarily in the brain stem. However, a cerebellar origin is suggested by the lack of changes in the level of consciousness and lack of focal weakness or sensory loss.

Enlargement of the mass does not change the clinical picture until there is enough brain stem compression to precipitate coma, at which point it is too late for surgical evacuation of the hemorrhage to reverse the disorder. This small margin of time between an alert state and an irreversible coma makes it imperative to consider the diagnosis in all patients with this clinical syndrome and is a reason to have patients who present in the emergency room with vomiting of undetermined origin attempt to stand and walk.

DIAGNOSTIC STUDIES

Nonenhanced computed tomography (CT) scan of the brain is the method of choice to evaluate the presence of ICH (see [Fig. 38.1](#)). CT scan evaluates the size and location of the hematoma, extension into the ventricular system, degree of surrounding edema, and anatomic disruption. Hematoma volume, a powerful predictor of 30-day mortality, can be easily calculated from CT scan images by use of the $ABC \div 2$ method, which involves multiplying the diameter of the hematoma in three dimensions and dividing by two ([Fig. 38.3](#)). CT angiography may reveal secondary ICH due to an aneurysm or arteriovenous malformation, or active contrast extravasation into the clot ("spot sign"), which implies an increased risk of early hematoma growth when identified soon after the onset of symptoms. MRI techniques such as gradient echo (GRE, T2*) are highly sensitive for the diagnosis of ICH as well (see [Fig. 38.2](#)). MRI in patients with atypical ICH patterns on CT may disclose a cause of secondary ICH (i.e., tumor, arteriovenous malformation, or hemorrhagic infarction up to 20% of cases). Conventional diagnostic cerebral angiography should be reserved for patients in whom secondary causes of ICH are suspected, such as aneurysms, arteriovenous malformations, cortical vein or dural sinus thrombosis, or vasculitis. Findings on CT scan or MRI that should prompt angiographic study include the presence of subarachnoid hemorrhage (SAH), intraventricular hemorrhage (IVH), underlying calcification, or lobar hemorrhage in nonhypertensive younger patients. Diagnostic catheter angiography should be strongly considered in all patients with primary IVH and younger nonhypertensive patients with lobar ICH.

FIGURE 38.3 ICH volume measurement. (A) Largest hemorrhage axial diameter. (B) Largest axial diameter perpendicular to A on same slice. (C) Vertical hemorrhage diameter (number of slices with hemorrhage multiplied by slice thickness). For this example, $ABC/2 = (4.4 \text{ cm} \times 3.1 \text{ cm} \times 3.5 \text{ cm})/2 = 23.9 \text{ cm}^3$. (From Beslow LA, Ichord RN, Kasner SE, et al. ABC/XYZ estimates intracerebral hemorrhage volume as a percent of total brain volume in children. *Stroke*. 2010;41:691-694, with permission.)

MEDICAL MANAGEMENT

Prehospital care of ICH follows similar guidelines as for other types of stroke, where the objective is to provide rapid access to medical facilities capable of dealing with stroke patients. In the emergency department, ICH patients should be triaged rapidly with CT scans to access stroke units or intensive care units (ICUs). Observation in an ICU or a similar setting is strongly recommended for at least the first 24 hours because the risk of neurologic deterioration is highest during this period and because the majority of patients with brain stem or cerebellar hemorrhage have depressed level of consciousness requiring ventilatory support. A protocolized checklist for care in the ICU is recommended to ensure standardization of best practices (Table 38.2).

P.298

TABLE 38.2 Medical Management Checklist for Acute Intracerebral Hemorrhage

Blood pressure	<ul style="list-style-type: none"> • Maintain mean arterial pressure <140 mm Hg with continuous infusion labetalol (2-10 mg/min) or nicardipine (5-15 mg/h) • If stuporous or comatose, measure ICP and maintain CPP >70 mm Hg.
Reversal of anticoagulation	<ul style="list-style-type: none"> • For elevated INR: vitamin K 10 mg IVP and 4F-PCC <ul style="list-style-type: none"> ◦ INR 2 to <4: 25 U/kg; not to exceed 2,500 units

- INR 4-6: 35 U/kg; not to exceed 3,500 units
- INR >6: 50 U/kg; not to exceed 5,000 units
- For heparin: protamine sulfate 10-50 mg slow IVP (1 mg reverses approximately 100 units of heparin)
- For thrombocytopenia or platelet dysfunction: desmopressin 0.3 µg/kg IVP and/or transfuse 6 units of platelets
- Expedited INR reversal for lifesaving neurosurgical intervention: recombinant activated factor VII 40-80 µg/kg (approximately 3.0-6.0 mg) IVP

Intracranial hypertension

- Elevate head of bed to 30 degrees
- Mannitol 1.0-1.5 g IV
- Hyperventilate to PCO₂ of 30 mm Hg

Fluids and nutrition

- Normal (0.9%) saline at 1.0 mL/kg/h
- Begin enteral feeding via nasoduodenal tube within 24 hours.

Seizure prophylaxis

- For coma with intracranial hypertension or acute seizures: fosphenytoin (15-20 mg/kg) followed by 300 mg IV daily or levetiracetam 1,000 mg b.i.d. for 7 days

Physiologic homeostasis

- Cooling blankets to maintain T ≤37.5°C
- Insulin drip to maintain glucose 120-180 mg/dL

4F-PCC, four-factor prothrombin complex concentrate containing factors II, VII, IX, and X.

EMERGENCY REVERSAL OF ANTICOAGULATION

Hemostatic abnormalities should be corrected as rapidly as possible. Patients at risk include those on oral anticoagulants (OACs) for several indications, antiplatelet agents, and congenital or acquired factor or platelet deficiencies. The incidence of ICH related to OACs has increased over the last decade. Vitamin K antagonists (VKAs) are the most commonly prescribed OACs, but new novel oral anticoagulant (NOAC) agents that inhibit thrombin or factor Xa such as dabigatran, rivaroxaban, and apixaban are increasingly being offered.

Patients with ICH receiving warfarin should be reversed immediately with a four-factor prothrombin complex concentrate (PCC) (25 to 50 U/kg depending on the baseline international normalized ratio [INR] level) and vitamin K 10-mg intravenous push (IVP). Four-factor PCCs contain vitamin K-dependent coagulation factors II, VII, IX, and X; normalize the INR more rapidly than fresh frozen plasma (FFP); and can be given in much smaller volumes much more rapidly [**Level 1**].¹ Treatment should never be delayed in order to check coagulation tests when a patient has acute ICH and a stated history of OAC use. Recent reports have also described the use of recombinant activated factor VIIa (rFVIIa), a powerful prohemostatic agent, to speed the reversal of warfarin anticoagulation in ICH patients. A single intravenous dose of rFVIIa can normalize the INR within minutes, with larger doses producing a longer duration of effect. A typical dose for reversing warfarin is 4 mg. rFVIIa has the drawback of a 5% risk of thromboembolic complications (ischemic stroke or myocardial infarction) and thus is only used to expedite lifesaving neurosurgical intervention.

Patients with ICH who have been anticoagulated with unfractionated or low molecular weight heparin should be reversed with protamine sulfate, and patients with thrombocytopenia or platelet dysfunction can be treated with a single dose of desmopressin (DDAVP) 0.3 µg/kg, platelet transfusions (6 to 8 units), or both (see [Table 38.2](#)). Newer agents such as direct thrombin inhibitors and factor Xa inhibitors provide a new challenge for the reversal of coagulopathy-related ICH, as no antidote currently exists. In the case of recent dabigatran ingestion, hemodialysis has been suggested. Potential reversal strategies included factor VIII inhibitor bypassing activity (FEIBA), PCCs, or rFVIIa. In this setting, consultation with a hematologist is also indicated.

BLOOD PRESSURE CONTROL

Acute ICH often leads to extreme arterial hypertension. Excessive reduction in blood pressure (BP) after ICH in the setting of

impaired autoregulation can result in exacerbation of ischemic injury, whereas lack of BP control can theoretically exacerbate early hematoma growth and vasogenic edema. Single-center studies and a systematic review have reported an increased risk of deterioration, death, or dependency with extremely high or low admission BP after ICH. Although current American Heart Association (AHA) guidelines recommend a systolic BP (SBP) target of less than 180 mm Hg and mean BP target of less than 130 mm Hg, a recent phase 3 trial showed that lowering of SBP to less than 140 mm Hg compared to less than 180 mm Hg within 6 hours of onset resulted in no difference in mortality and borderline improvement in the extent of disability among survivors [Level 1].² Eligible patients in this study included patients with mild ICH (median Glasgow Coma Scale [GCS] 14, interquartile range [IQR] 12 to 15) and small ICH volumes (median volume 11, IQR 6 to 20 mL). Therefore, the results cannot be extrapolated to all subpopulations of ICH patients,

P.299

particularly more severe critically ill ICH patients with comorbidities and larger hematomas with impaired autoregulation. Current AHA guidelines suggest that intracranial pressure (ICP) monitoring should be used in patients with large hematomas and depressed level of consciousness to ensure that cerebral perfusion pressure (CPP) is maintained above 60 mm Hg. A more recent study of 18 comatose ICH patients using brain multimodality monitoring showed that CPP levels greater than 80 mm Hg were associated with a reduced risk of critical brain tissue hypoxia, which in turn was associated with increased mortality. The Antihypertensive Treatment in Acute Cerebral Hemorrhage (ATACH) trial also confirmed the feasibility and safety of early rapid BP reduction in ICH. Both Intensive Blood Pressure Reduction in Acute Cerebral Haemorrhage Trial (INTERACT-II) and ATACH have shown that although early and intensive BP lowering is clinically feasible, for eligible patients, there is no clear effect on mortality.

Given the need to precisely control BP levels in the setting of impaired autoregulation, use of fast-acting continuous infusion agents with intra-arterial monitoring is recommended. Preferred agents are β -blockers (intravenous [IV] labetalol) and calcium channel blockers (nicardipine and clevidipine) (Table 38.3). Use of nitroprusside has drawbacks because this agent is associated with higher rate of medical complications and may exacerbate cerebral edema and ICP. Clevidipine, an ultra-short-acting, dihydropyridine L-type calcium channel blocker with rapid onset and offset of action, has also recently been approved for the reduction of BP. Comparative studies have demonstrated that clevidipine is as safe and effective as nitroglycerin, sodium nitroprusside, or nicardipine for reducing BP but has greater ability to maintain a given target range. Oral and sublingual agents are not preferred because of the need for immediate and precise BP control. Although no prospective study has addressed the timing of conversion from IV to oral antihypertensive management, this process can generally be started between 24 and 72 hours as long as the patient's critical condition has been stabilized.

CEREBRAL EDEMA

Large-volume ICH carries the risk of developing cerebral edema (Chapter 107) and elevated ICP. Brain swelling can progress for many days after the onset of ICH but most often drives neurologic deterioration within the first 72 hours in patients with hemorrhages exceeding 30 mL in volume. The presence of IVH further increases ICP and the risk of mortality. This effect is primarily related to the development of obstructive hydrocephalus and alterations of normal cerebrospinal fluid (CSF) flow dynamics. Patients with large-volume ICH, intracranial mass effect, and coma may benefit from ICP monitoring, although this intervention has not been proven to benefit outcomes after ICH.

TABLE 38.3 Parenteral Vasoactive Agents in Neurologic Emergencies: Preferred Antihypertensives and Vasopressors

Drug	Mechanism	Dose	Onset	Duration	Common Adverse Effects	Cautions
Labetalol	α_1 , β_1 , β_2 antagonist	20-80 mg bolus every 10 min, up to max 300 mg;	5-10 min	3-6 h	Bradycardia (heart block), dizziness, nausea, vomiting, scalp tingling,	Asthma, COPD, LV failure, second- or third-degree AV block

		0.5-2 mg/min infusion			bronchospasm, orthostatic hypotension, hepatic injury	
Esmolol	β1 antagonist	500 µg/kg bolus, 50-300 µg/kg/min infusion	1-2 min	10-30 min	Bradycardia (heart block), hypotension, nausea, bronchospasm	Asthma, COPD, LV failure, second- or third-degree AV block
Nicardipine	L-type CCB (dihydropyridine)	5-15 mg/h infusion	5-10 min	30 min to 4 h	Reflex tachycardia, headache, nausea, flushing, local phlebitis	LV failure, severe AS, cardiac ischemia
Enalaprilat	ACE inhibitor	0.625 mg bolus, then 1.25-5 mg every 6 h	15-30 min	6-12 h	Variable response, precipitous fall in BP in high- renin states headache, cough	Acute MI, h/o hypersensitivity
Fenoldopam	DA-1 agonist	0.1-0.3 µg/kg/min infusion	5-15 min	30 min to 4 h	Tachycardia, headache, nausea, dizziness, flushing	Glaucoma, liver disease (cirrhosis with portal HTN)
Clevidipine	L-type CCB (dihydropyridine)	1-2 mg/h infusion	2-4 min	5-15 min	Headache, nausea, vomiting	Soybean allergy
Nitroprusside^a	Nitrovasodilator (arterial and venous)	0.25-10 µg/kg/min infusion	Immediate	1-4 min	Nausea, vomiting, muscle twitching, sweating, thiocyanate and cyanide intoxication	Coronary artery disease, elevated ICP

COPD, chronic obstructive pulmonary disease; LV, left ventricle; AV, atrioventricular; CCB, calcium channel blocker; AS, aortic stenosis; ACE, angiotensin-converting enzyme; MI, myocardial infarction; HTN, hypertension.

^aNitroprusside is becoming less favored for use in neurologic emergencies (see text).

Data from Rose JC, Mayer SA. Optimizing blood pressure in neurological emergencies. *Neurocrit Care*. 2004;1;287-299.

Management of cerebral edema should be guided by measurement of ICP with an external ventricular drainage or parenchymal monitor, with efforts directed at maintaining ICP less than 20 mm Hg and CPP greater than 70 mm Hg. Therapy should be directed by an algorithm that includes sedation, BP optimization, bolus osmotherapy, controlled hyperventilation, mild hypothermia, and, as a last resort, salvage hemicraniectomy in selected younger patients (see [Chapter 107](#) for a detailed protocol). Empiric ICP therapy in the emergency department typically starts with 1.0 to 1.5 g/kg of 20% mannitol solution via a peripheral IV. Placement of a central venous line also allows administration of hypertonic saline solution, such as 30 to 60 mL of 23.4% saline solution given as a slow IVP over 10 to 20 minutes. Qureshi et al. demonstrated the effectiveness of 23.4% saline solution over 10% saline and mannitol during imminent transtentorial herniation in a canine model of ICH. Apart from a negative trial of glycerol given within 48 hours of ICH onset, no prospective randomized control trials have compared the effectiveness of the different osmotic agents available for the management of increased ICP in ICH. Effectiveness of hyperosmolar therapy for control of ICP depends on rapid institution of therapy and achieving higher differences in baseline osmolarity. Corticosteroids such as dexamethasone do not improve the outcome of ICH and are not indicated for the treatment of cerebral edema associated with this condition [**Level 1**].³

SEIZURES

Twelve percent of ICH patients experience convulsive seizures during their hospitalization; the risk is increased with lobar location. Seizure activity in ICH patients should aggressively be diagnosed and treated. Patients with ICH may benefit from prophylactic antiepileptic therapy (antiepileptic drugs [AEDs]), but no randomized trial has addressed the use of AEDs in the setting of ICH so current guidelines do not endorse the use of AEDs for ICH patients without seizures. Continuous electroencephalographic (EEG) monitoring is recommended in all comatose patients in order to detect convulsive seizures or status epilepticus. Even with anticonvulsant therapy, continuous EEG monitoring reveals electrographic seizure activity in 20% of comatose patients. It is unclear whether midazolam infusion or other aggressive measures to eliminate these seizures can improve outcome. If seizures have not occurred, anticonvulsants should be discontinued at discharge because they can hamper neurologic recovery during rehabilitation.

MEDICAL SUPPORT

For patients requiring ventilatory support, maintain normoxia, avoid routine hyperoxygenation, and prevent ventilator-associated infections. Additional measures in the stroke unit or ICU include evaluation and assessment of speech and swallowing for nutritional support, maintenance of normoglycemia (goal <180 mg/dL), gastrointestinal prophylaxis for intubated patients, and deep venous thrombosis prophylaxis, which can be safely started 48 hours after ICH onset. Early enteral feeding should be initiated via a nasoduodenal feeding tube within inpatients who lack the capacity to swallow to combat malnutrition and muscle wasting. Body temperature should be maintained at normal with antipyretics and surface cooling as needed.

SURGICAL MANAGEMENT

The most urgent treatment consideration for ICH is often whether to proceed emergently with surgical evacuation or ventricular drain placement. Owing to the irreversible nature of secondary brain injury related to herniation and ICP, results are always better when definitive measures to reverse these processes are performed as soon as possible. Delayed surgical intervention triggered by clinical deterioration must always be tempered by realization that an earlier procedure would have been the better plan.

VENTRICULAR DRAINAGE

External ventricular drainage is indicated in all stuporous or comatose patients with IVH and ventricular enlargement in whom aggressive support is indicated. This lifesaving procedure, which can be performed at the bedside, decompresses the intracranial vault and arrests the process of downward brain stem herniation by allowing drainage of bloody CSF into a drainage receptacle. Connecting the drainage system to a pressure transducer also allows measurement of ICP.

CRANIOTOMY

Apart from cases suffering cerebellar hemorrhage, any decision on whether, how, and when to intervene neurosurgically after ICH is subject to intense debate and awaits further data from ongoing prospective trials. To date, all clinical trial attempts have failed to show a superiority of hematoma evacuation over medical therapy for supratentorial ICH [**Level 1**].^{4,5} However,

these trials did not enroll patients if the investigator felt that emergency surgery was clearly a lifesaving intervention, leading to inclusion bias. Many experts feel that urgent craniotomy can improve the outcome of younger patients with large lobar hemorrhages and a deteriorating course due to mass effect.

In contrast to supratentorial ICH, it is widely accepted that patients with cerebellar hemorrhages exceeding 3 cm in diameter benefit from emergent surgical evacuation. Abrupt and dramatic deterioration to coma can occur within the first 24 hours of onset in these patients. For this reason, it is generally unwise to defer surgery in these patients until further clinical deterioration occurs.

As emergent craniotomy has been unable to improve neurologic outcome after ICH, the role of other surgical techniques such as minimally invasive surgery (MIS) has gained importance over the last decade. The advantages of MIS over conventional craniotomy include reduced operative time, the possibility of performance under local anesthesia, and reduced surgical trauma. Additional strategies currently under extensive research are thrombolytic therapy and surgical removal of hematomas, intraventricular administration of thrombolytics for IVH, and hemicraniectomy with duraplasty (Fig. 38.4).

SECONDARY PREVENTION

The risk of recurrent ICH is 2% per year in patients with chronic hypertension, and in those patients with diastolic BP higher than 90 mm Hg, the rate of recurrence is as high as 10% per year. BP reduction significantly decreases the risk of ICH and other forms of stroke and is unequivocally the most effective method for primary and secondary prevention of ICH. In the Perindopril Protection Against Recurrent Stroke Study (PROGRESS) trial, a BP regimen perindopril, an angiotensin-converting enzyme inhibitor, was found to be more effective than placebo for preventing recurrent stroke among both hypertensive and nonhypertensive individuals following incident stroke or TIA [Level 1].⁶ Survivors of lobar ICH

P.301

and most patients with deep hemispheric ICH who have history of atrial fibrillation should not be offered long-term anticoagulation therapy. Conversely, patients with high risk of thromboembolic events and low recurrent risk of ICH may benefit from long-term anticoagulation therapy.

FIGURE 38.4 Lifesaving hemicraniectomy in a patient with lobar ICH considered otherwise lethal.

PROGNOSIS

The mortality of ICH is 35% to 50% at 30 days and 47% at 1 year. Factors that consistently predict mortality or adverse outcomes in ICH have been studied extensively. Independent predictors for 30-day and 1-year mortality include Glasgow Coma Scale and/or depressed level of consciousness, age, ICH volume, presence of IVH, and infratentorial origin. A simple clinical grading scale, the *ICH Score* (Table 38.4), permits calculation of mortality, allowing use of uniform terms and enhancing communication between physicians. The mortality rates for scores of 0, 1, 2, 3, 4, and 5 are 0%, 13%, 26%, 72%, 97%, and 100%, respectively. Additional factors associated with high mortality after ICH include the presence of SAH, wide pulse pressure, history of coronary artery disease, and hyperthermia. Factors associated with good outcomes include a low National Institutes of Health Stroke Scale (NIHSS) score and low temperature on admission.

Except in the most severe cases, caution is warranted when communicating a hopeless prognosis before aggressive efforts have been made to resuscitate victims of ICH. It has become increasingly evident that physicians tend to underestimate the chances of a good outcome and that many poor outcomes result from self-fulfilling prophecies of doom. Mortality after ICH is reduced in patients cared for in a specialty neurologic ICU. This is presumably the result of adherence to best medical practices, early transition to rehabilitation, and being cared for by a team or health care professionals who take an active interest in promoting survival and recovery.

Subarachnoid Hemorrhage

Stephan A. Mayer

Gary L. Bernardini

Robert A. Solomon

INTRODUCTION

Subarachnoid hemorrhage (SAH) accounts for 5% of all strokes; it affects nearly 30,000 people each year in the United States, with an annual incidence of 1 per 10,000. Saccular (or berry) aneurysms at the base of the brain cause 80% of all cases of SAH. Nonaneurysmal causes of SAH are listed in [Table 39.1](#). SAH most frequently occurs between ages 40 and 60 years, and women are affected more often than men.

SAH due to the rupture of an intracranial aneurysm is a devastating event; approximately 12% of patients die before receiving medical attention, and another 20% die after admission to the hospital. Of the two-thirds of patients who survive, approximately one-half remain permanently disabled, primarily due to neurocognitive deficits and depression. Advances in neurosurgery and intensive care, including an emphasis on early aneurysm clipping and aggressive therapy for vasospasm, have led to improved survival over the last three decades, with a reduction in overall case fatality from approximately 50% to 20% in high-volume centers.

PATHOLOGY AND EPIDEMIOLOGY OF INTRACRANIAL ANEURYSMS

Saccular aneurysms most often occur at the circle of Willis or its major branches, especially at bifurcations. They arise where the arterial elastic lamina and tunica media are defective and tend to enlarge with age. The typical aneurysm wall is composed only of intima and adventitia and can become paper thin. Many aneurysms, particularly those that rupture, are irregular and multilobulated, and larger aneurysms may be partially or completely filled with an organized clot, which occasionally is calcified. The point of rupture is usually through the dome of the aneurysm.

TABLE 39.1 Nonaneurysmal Causes of Subarachnoid Hemorrhage

- Idiopathic perimesencephalic SAH

- Arteriovenous malformation

- Intracranial arterial dissection

- Cocaine and amphetamine use

- Mycotic aneurysm

- Pituitary apoplexy

- Moyamoya disease

- Central nervous system vasculitis

- Sickle cell disease

- Coagulation disorders

- Primary or metastatic neoplasm

SAH, subarachnoid hemorrhage.

Eighty-five percent to 90% of intracranial aneurysms are located in the anterior circulation, with the three most common sites being the anterior communicating artery complex (approximately 40%), the junction of the posterior communicating and internal carotid artery (approximately 30%), and the middle cerebral artery at the first major branch point in the sylvian fissure (approximately 20%). Posterior circulation aneurysms most often occur at the apex of the basilar artery or at the junction of the vertebral and posteroinferior cerebellar artery. Saccular aneurysms of the distal cerebral arterial tree are rare. Nearly 20% of patients have two or more aneurysms; many of these are “mirror” aneurysms on the same vessel but on the contralateral side.

Intracranial aneurysms are uncommon in children but occur with a frequency of 2% in adults, suggesting that approximately 2 to 3 million Americans have an aneurysm. However, more than 90% of these are small (< 10 mm) and remain asymptomatic throughout life. The annual risk of rupture of an asymptomatic intracranial aneurysm is approximately 0.7%. Important risk factors for the initial rupture of an aneurysm include increasing size, prior SAH from a separate aneurysm, and basilar apex and posterior communicating artery location ([Table 39.2](#)). The most powerful of these risk factors is size: for example, internal carotid artery aneurysms < 7 mm in diameter bleed at a rate of approximately 0.1% per year, compared to an annual rate of 8% for those >25 mm in size. Other risk factors for aneurysm rupture in approximate order of importance include cigarette smoking, aneurysm-related headache or cranial nerve compression, heavy alcohol use, a family history of SAH, female sex (especially when postmenopausal), multiple aneurysms, hypertension, and exposure to cocaine or other sympathomimetic agents. In deciding whether to treat an unruptured intracranial aneurysm, the risks associated with repair should always be balanced against the patient's estimated lifetime risk of hemorrhage without repair.

The prevalence of aneurysms increases with age and is higher in patients with atherosclerosis, a family history of intracranial aneurysm, or autosomal dominant polycystic kidney disease (PCKD). Intracranial aneurysms have also been associated with Ehlers-Danlos syndrome, Marfan syndrome, pseudoxanthoma elasticum, coarctation of the aorta, and sickle cell disease. Screening for unruptured intracranial aneurysms with magnetic resonance angiography (MRA) is indicated in patients with PCKD and in family members who have two or more first-degree relatives with intracranial aneurysms; testing is positive in 5% to 10% of these individuals.

CLINICAL FEATURES

SAH usually commences with an explosive “thunderclap” headache followed by stiff neck. The pain is often described as “the worst headache of my life.” The headache is usually generalized, but focal pain may refer to the site of aneurysmal rupture (e.g., periorbital pain related to an ophthalmic artery aneurysm). Commonly

associated symptoms include loss of consciousness, nausea and vomiting, back or leg pain, and photophobia. In patients who lose consciousness, tonic posturing may occur and may be difficult to differentiate from a seizure. Although aneurysmal rupture often occurs during periods of exercise or physical stress, SAH can occur at any time, including sleep.

TABLE 39.2 Five-Year Cumulative Hemorrhage Rates of Unruptured Aneurysms According to Size and Location

	<7 mm				
	No Prior SAH	Prior SAH ^a	8-12 mm	13-25 mm	≥25 mm
Cavernous carotid artery (N = 210)	0	0	0	3.0%	6.4%
ACA, MCA, ICA (not intracavernous) (N = 1,037)	0	1.5%	2.6%	14.5%	40%
Posterior circulation or P-comm (N = 445)	2.5%	3.4%	14.5%	18.4%	50%

^aRefers to prior subarachnoid hemorrhage from a separate intracranial aneurysm.

SAH, subarachnoid hemorrhage; ACA, anterior communicating or anterior cerebral artery; MCA, middle cerebral artery; ICA, internal carotid artery; P-comm, posterior communicating artery.

From Wiebers DO, Whisnant JP, Huston J III, et al; International Study of Unruptured Intracranial Aneurysms Investigators. Unruptured intracranial aneurysms: natural history, clinical outcome, and risks of surgical and endovascular treatment. *Lancet*. 2003;362:103-110.

More than one-third of patients give a history of suspicious symptoms days or weeks earlier, including headache, stiff neck, nausea and vomiting, syncope, or disturbed vision. These prodromal symptoms are often due to minor leaking of blood from the aneurysm and are therefore referred to as “warning leaks” or “sentinel headaches.” Initial misdiagnosis of SAH occurs in approximately 15% of patients, and those with the mildest symptoms are at greatest risk. Approximately 40% of misdiagnosed patients experience subsequent neurologic deterioration due to rebleeding, hydrocephalus, or vasospasm before reaching medical attention, with increased morbidity and mortality.

Stiff neck and the Kernig sign are hallmarks of SAH. However, these signs are not invariably present, and confusion and low back pain are sometimes more prominent than headache. Preretinal or subhyaloid hemorrhages—large, smooth-bordered, and on the retinal surface—occur in up to 25% of patients and are practically pathognomonic of SAH.

The most important determinant of outcome after SAH is the patient's neurologic condition on arrival at the hospital. Alterations in mental status are the most common abnormality; some patients remain alert and lucid; others are confused, delirious, amnesic, lethargic, stuporous, or comatose. The modified Hunt and Hess grading scale serves as a means for risk stratification for SAH based on the first neurologic examination (Table 39.3).

Patients classified as grade I or II SAH have a relatively good prognosis, grade III carries an intermediate prognosis, and grades IV and V have a poor prognosis. Focal neurologic signs occur in a minority of patients but may point to the site of bleeding; hemiparesis or aphasia suggests a middle cerebral artery aneurysm, and paraparesis or abulia suggests an aneurysm of the proximal anterior cerebral artery. These focal signs are sometimes due to a large hematoma, which may require emergency evacuation.

In 10% of patients with nontraumatic SAH and in two-thirds of those with negative angiography, computed tomography (CT) reveals blood confined to the perimesencephalic cisterns, with the center of bleeding adjacent to the midbrain and pons (Fig. 39.1). Patients with “perimesencephalic” SAH always have normal findings on neurologic examination and a benign clinical course; rebleeding and symptomatic vasospasm or hydrocephalus almost never occur. The source of hemorrhage in these patients is presumably venous.

Symptoms and signs of an unruptured intracranial aneurysm may result from compression of adjacent neural structures or thromboembolism. These aneurysms are often, but not always, large or giant (> 25 mm). Aneurysms of the posterior communicating artery frequently compress the oculomotor nerve (almost always affecting the pupil). Aneurysms of the intracavernous segment of the internal carotid artery may damage the third, fourth, fifth, or sixth cranial nerves, and their rupture can lead to formation of a carotid-cavernous fistula. Less often, large aneurysms compress the cortex or brain stem, causing focal neurologic signs or seizures. Thrombosis within the aneurysmal sac occasionally sends emboli to the artery's distal territory, causing transient ischemic attacks or infarction. In the absence of SAH, some patients experience sudden, severe headache without nuchal

P.305

rigidity, perhaps related to aneurysmal enlargement, thrombosis, or meningeal irritation; these symptoms can clear with aneurysm clipping.

TABLE 39.3 Mortality according to the Hunt-Hess Grading Scale for Aneurysmal Subarachnoid Hemorrhage

Grade	Clinical Findings	Hospital Mortality (%)	
		1968	2012
I	Asymptomatic or mild headache	11	3
II	Moderate to severe headache or oculomotor palsy	26	3
III	Confused, drowsy, or mild focal signs	37	9
IV	Stupor (localizes to pain)	71	24
V	Coma (posturing or no motor response to pain)	100	71
TOTAL		35	20

Data are from 275 patients reported by Hunt and Hess in 1968 and 1,200 patients treated at Columbia University Medical Center between 1996 and 2012.

FIGURE 39.1 Two CT images of SAH. **A:** Diffuse thick SAH is seen in the anterior interhemispheric and bilateral sylvian fissures and the quadrigeminal cistern. A left middle cerebral artery aneurysm was identified. **B:** Perimesencephalic SAH; only a small focus of blood in the interpeduncular cistern is identified. No aneurysm was identified.

DIAGNOSIS

COMPUTED TOMOGRAPHY

CT should be the first diagnostic study for establishing the diagnosis of SAH because it is readily available and interpretation is straightforward. When SAH is misdiagnosed, the most common error is failure to obtain a CT scan. CT most commonly demonstrates diffuse blood in the basal cisterns (see Fig. 39.1); with more severe hemorrhages, blood extends into the sylvian and interhemispheric fissures, ventricular system, and over the convexities. The distribution of blood can provide important clues regarding the location of the ruptured aneurysm. CT may also demonstrate a focal intraparenchymal or subdural hemorrhage, ventricular enlargement, a large thrombosed aneurysm, or infarction due to vasospasm. The sensitivity of CT for SAH is 90% to 95% within 24 hours, 80% at 3 days, and 50% at 1 week. Accordingly, a normal CT never rules out SAH, and a lumbar puncture should always be performed in patients with suspected SAH and negative CT. Magnetic resonance imaging (MRI) can also be used to make the initial diagnosis of SAH or can be used to detect a completely thrombosed aneurysm if the initial angiogram is negative.

LUMBAR PUNCTURE

The cerebrospinal fluid (CSF) is usually grossly bloody. SAH can be differentiated from a traumatic tap by a xanthochromic (yellowtinged) appearance of the supernatant fluid after centrifugation. However, xanthochromia may take up to 12 hours to appear. The CSF pressure is nearly always high and the protein elevated. Initially, the proportion of CSF leukocytes to erythrocytes is that of peripheral blood, with a usual ratio of 1:700; after several days, a reactive pleocytosis and low glucose levels may arise from a sterile chemical meningitis caused by the blood. Red blood cells and xanthochromia disappear in about 2 weeks, unless hemorrhage recurs.

ANGIOGRAPHY

Cerebral angiography is the definitive diagnostic procedure for detecting intracranial aneurysms and defining their anatomy (Fig. 39.2). Although the increasing availability and image quality of CT and MRA has allowed some centers to use these tests to make the initial diagnosis, a four-vessel (bilateral internal carotid and vertebral artery injections) angiogram is mandatory when those tests are negative. Moreover, angiography performed during coiling or after surgical clipping is generally advisable to evaluate the adequacy of aneurysmal repair and to screen for smaller secondary aneurysms that may be missed by CT or MRA. Vasospasm, local thrombosis, or poor technique can lead to a false-negative angiogram. For this reason, patients with a negative angiogram at first should have a follow-up study 1 to 2 weeks later; an aneurysm will be demonstrated in about 5% of these cases. The exception to this rule is found in patients with “perimesencephalic” SAH who usually do not require follow-up angiography.

FIGURE 39.3 The daily percentage probability for the development of symptomatic vasospasm (*solid line*) or rebleeding (*dashed line*) after SAH. Day 0 denotes day of onset of SAH. SAH, subarachnoid hemorrhage.

COMPLICATIONS OF ANEURYSMAL SUBARACHNOID HEMORRHAGE REBLEEDING

Aneurysmal rebleeding is a dreaded complication of SAH. The risk of rebleeding is highest within the first 24 hours after the initial aneurysmal rupture (4%) and remains elevated (approximately 1% to 2% per day) for the next 4 weeks (Fig. 39.3). The cumulative risk of rebleeding in untreated patients is 20% at 2 weeks, 30% at 1 month, and 40% at 6 months. After the first 6 months, the risk of rebleeding is 2% to 4% annually. Poor clinical grade and larger aneurysm size are the strongest risk factors for in-hospital rebleeding. The prognosis of patients who rebleed is poor; approximately 50% die immediately, and another 30% die from subsequent complications. Although rebleeding is often attributed to uncontrolled hypertension, elevated blood pressure has not been convincingly linked to an increased risk of aneurysm rebleeding. Endogenous fibrinolysis of clot around the rupture point of the aneurysm may be a more important causative mechanism.

VASOSPASM

Delayed cerebral ischemia (DCI) from vasospasm accounts for a large proportion of morbidity and mortality after SAH. Progressive arterial narrowing develops after SAH in approximately 70% of patients, but delayed ischemic deficits develop in only 20% to 30%. The process begins 3 to 5 days after the hemorrhage, becomes maximal at 5 to 14 days, and gradually resolves over 2 to 4 weeks. Accordingly, deterioration attributable to vasospasm never occurs before the third day after SAH and occurs with peak frequency between 5 and 7 days (see Fig. 39.3). There is a strong relationship between the amount of cisternal blood seen on initial CT and the risk for development of symptomatic ischemia; for uncertain reasons, the presence of large amounts of blood in the lateral ventricles adds to this risk (Table 39.4). Symptomatic vasospasm usually involves a decrease in level of consciousness, hemiparesis, or both, and the process is usually most severe in the immediate vicinity of the

aneurysm. In more severe cases, the symptoms develop earlier after aneurysm rupture, and multiple vascular territories are involved.

Although thick subarachnoid blood is the principal precipitating factor, the precise cause of arterial narrowing after SAH is poorly understood. Vasospasm is not simply due to vascular smooth muscle contraction, and changes in vessel caliber develop slowly over several days. Inflammatory arteriopathic changes are seen in the vessel wall, including subintimal edema and infiltration of leukocytes. The prevailing view is that substances released from the blood clot interact with the vessel wall to cause inflammatory arterial spasm. Putative mediators with intrinsic vasoconstrictive properties include oxyhemoglobin, hydroperoxides and leukotrienes, free radicals, prostaglandins, thromboxane A2, serotonin, endothelin, platelet-derived growth factor, and other inflammatory mediators. Cortical spreading depression may further contribute to DCI after SAH by creating prolonged neuronal depolarization in conjunction with a paradoxical reduction in local cerebral blood flow.

HYDROCEPHALUS

Acute symptomatic hydrocephalus occurs in 15% to 20% of patients with SAH and is primarily related to the volume of intraventricular and subarachnoid blood. In mild cases, hydrocephalus causes lethargy, psychomotor slowing, and impaired short-term memory. Additional findings may include limitation of upward

P.307

gaze, sixth cranial nerve palsies, and lower extremity hyperreflexia. In more severe cases, acute obstructive hydrocephalus leads to elevated intracranial pressure and stupor or coma. Progressive brain stem herniation eventually results from continued CSF production unless a ventricular catheter is inserted.

TABLE 39.4 Modified Fisher Computed Tomography Rating Scale for the Prediction of Symptomatic Vasospasm

Grade	Criteria	Percentage of Affected Patients	Frequency of	
			Delayed Cerebral Ischemia	Infarction
0	No SAH or IVH	5%	0%	0%
1	Minimal/thin SAH, no biventricular IVH	30%	12%	6%
2	Minimal/thin SAH, <i>with</i> biventricular IVH	5%	21%	14 %
3	Thick SAH, no biventricular IVH	43%	19%	12%
4	Thick SAH, <i>with</i> biventricular IVH	17%	40%	28%
	All patients	100%	20%	12%

Thick SAH is defined as completely filling at least one cistern or fissure.

SAH, subarachnoid hemorrhage; IVH, intraventricular hemorrhage.

From Claassen J, Bernardini GL, Kreiter K, et al. Effect of cisternal and ventricular blood on risk of delayed cerebral ischemia after subarachnoid hemorrhage: the Fisher scale revisited. *Stroke*. 2001;32:2012-2020.

Delayed hydrocephalus may develop 3 to 21 days after SAH. The clinical syndrome is that of normal pressure hydrocephalus, with failure to fully recover and prominent symptoms of dementia, gait disturbance, and urinary incontinence. The clinical response to ventriculoperitoneal shunting is usually excellent. Overall, 20% of SAH survivors require shunting for chronic hydrocephalus.

GLOBAL CEREBRAL EDEMA AND EARLY BRAIN INJURY

CT often demonstrates a characteristic form of global brain edema after poor-grade SAH (Fig. 39.4). This finding is most common in patients who experience loss of consciousness at the onset of bleeding, suggesting a transient episode of intracranial circulatory arrest with subsequent reperfusion injury to the brain. Global cerebral edema after SAH has been linked to an increased risk of mortality, disability, and cognitive dysfunction among survivors. MRI performed within 72 hours shows a distinctive pattern of symmetric ischemic injury in 70% of Hunt-Hess grade IV or V patients, most often involving the anterior cerebral artery territories, a process termed *early brain injury*. The relative contribution of acute ischemia, reperfusion injury, microvascular dysfunction, and inflammation in early brain injury remains poorly understood.

SEIZURES

Clinically obvious tonic-clonic seizures occur in 5% of SAH patients during hospitalization and in another 10% in the first year after discharge. Seizures after SAH are related primarily to focal pathology, including large subarachnoid clots, subdural hematoma, or cerebral infarction. Ictal events at the onset of bleeding do not portend an increased risk of late seizures. With continuous electroencephalographic monitoring, nonconvulsive seizures or status epilepticus can be detected in up to 20% of poor-grade patients and has become increasingly recognized as a cause of otherwise unexplained clinical deterioration after SAH, with ominous implications for prognosis.

FIGURE 39.4 Global edema on the admission CT scan (SAH day 0) in a 55-year-old man with a Hunt-Hess grade V SAH from a left anterior communicating artery aneurysm which was clipped. Note the complete

effacement of all convexity sulci and presence of “fingerlike” extensions of white matter lucencies to the cortical surface. A follow-up scan on SAH day 18 showed complete normalization of the CT findings. SAH, subarachnoid hemorrhage. (From Claassen J, Carhuapoma JR, Kreiter KT, et al. Global cerebral edema after subarachnoid hemorrhage: frequency, predictors, and impact on outcome. *Stroke*. 2002;33:1225-1232.)

FLUID AND ELECTROLYTE DISTURBANCES

Hyponatremia and intravascular volume contraction frequently occur after SAH and reflect homeostatic derangements that favor excessive free-water retention and sodium loss. Hyponatremia occurs in 5% to 30% of patients after SAH and is usually related to inappropriate secretion of antidiuretic hormone and free-water retention. This process may be further exacerbated by excessive natriuresis that occurs after SAH (“cerebral salt wasting”), related to elevations of atrial natriuretic factor and the glomerular filtration rate. Whereas hyponatremia after SAH is usually asymptomatic, untreated sodium losses resulting in intravascular volume contraction can increase the risk of DCI in the presence of vasospasm. To minimize the development of hypovolemia and hyponatremia after SAH, patients should be given large volumes of isotonic crystalloid, with restriction of other potential sources of free water.

NEUROGENIC CARDIAC AND PULMONARY DISTURBANCES

Severe SAH is typically associated with a surge in catecholamine levels and sympathetic tone, which in turn can lead to neurogenic cardiac dysfunction, neurogenic pulmonary edema, or both (see also [Chapter 115](#)). Transient electrocardiographic abnormalities occur in 50% to 100% of SAH patients but usually do not produce symptoms. In some poor-grade patients, however, cardiac enzyme release and a reversible form of neurogenic “stunned myocardium” can occur. Hypotension, hypoxia, and reduction of cardiac output may occur acutely, leading to impaired cerebral perfusion in the face of increased intracranial pressure or vasospasm. Neurogenic pulmonary edema, characterized by increased permeability of the pulmonary vasculature, may occur in isolation or in combination with neurogenic cardiac injury.

FEVER

Fever develops in 80% of SAH patients at some time and may result from infection or “central” fever. Poor-grade patients with intraventricular blood often experience sustained fever that can lead to worsening of level of consciousness and exacerbation of ischemic injury caused by vasospasm. For these reasons, aggressive fever control in SAH patients with surface or intravascular cooling systems are recommended.

ANEMIA

SAH leads to a contraction of red blood cell mass. Combined with phlebotomy and volume resuscitation, all patients become progressively anemic during the first 10 days after SAH, and 20% to 40% require blood transfusions. With symptomatic vasospasm, even mild anemia (serum hemoglobin < 10 mg/dL) can cause reduced oxygen delivery to ischemic brain tissue and should be avoided.

TREATMENT

The initial goal of treatment is to prevent rebleeding by excluding the aneurysmal sac from the intracranial circulation while preserving the parent artery and its branches. Once the aneurysm has been secured, the focus shifts toward monitoring and treating vasospasm and other secondary medical complications of SAH. This is best performed in an intensive care unit (ICU).

EMERGENCY MANAGEMENT

The diagnosis of SAH is almost always made in the emergency department. Management at this juncture should focus on (1) minimizing ongoing brain injury in poor-grade patients with mental status changes and (2) reducing the risk of aneurysm rebleeding prior to an effective repair procedure. In Hunt-Hess grades IV and V patients, the immediate concern is ensuring adequate perfusion and oxygenation of the brain. Patients with impaired ability to protect the airway should be intubated, supplemental oxygen should be given as needed, and hypotension should be treated aggressively with fluids and vasopressors to maintain a mean arterial pressure of 90 mm Hg. Stuporous or comatose patients with extensive SAH or intraventricular blood on CT should be empirically treated for intracranial hypertension with 1.0 g/kg of 20% mannitol prior to placement of an external ventricular drain. Medical interventions that may reduce the risk of acute aneurysm rebleeding include control of arterial hypertension (systolic blood pressure < 160 mm Hg), intravenous (IV) loading with an antifibrinolytic agent (epsilon aminocaproic acid 4 g followed by 1 g/h until 4 hours prior to angiography, for a maximum of 72 hours after SAH onset) [Level 1]¹, and administration of an anticonvulsant to minimize the risk of acute seizure activity (phenytoin 20 mg/kg IV is most commonly used).

SURGICAL MANAGEMENT

In the 1980s, neurosurgeons began to abandon the traditional practice of delaying surgery until several weeks after aneurysmal rupture, in favor of early clipping within 48 to 72 hours. This change in practice became feasible with safer microsurgical techniques. Nonetheless, surgery still remains hazardous, with a 5% to 10% risk of major morbidity or mortality in most cases; smaller aneurysms have a lower risk of procedural complications than larger aneurysms. Besides preventing early rebleeding, early surgery also permits aggressive treatment of vasospasm with hypertensive hypervolemic therapy, which can be dangerous with an unprotected aneurysm. Although early surgery was at one time reserved for patients in good clinical condition (Hunt-Hess grades I to III), this approach has been extended to all but the most moribund patients. The advent of endovascular coil embolization has been a major advance because it is a treatment option for high-risk patients who are not good candidates for early surgery.

The management of asymptomatic unruptured aneurysms is controversial. Most neurosurgeons recommend surgery for aneurysms larger than 5 mm, as long as the hoped-for benefit of surgery (reduced lifetime risk of bleeding) outweighs the risks. In good hands, the risk of major morbidity or mortality from clipping of an unruptured aneurysm is 2% to 5%; the risk is highest for large aneurysms and for aneurysms of the basilar artery.

FIGURE 39.5 **A:** Cerebral angiogram demonstrates a left-pointing, 3-mm, midbasilar aneurysm (*closed arrow*) and vasospasm of both vertebral arteries (*open arrows*), the distal basilar artery, and the proximal right posterior cerebral artery. **B:** Significant increase in luminal diameter of the right vertebral artery after balloon angioplasty (*arrows*). **C:** Microcatheter positioned at the neck of the midbasilar aneurysm. **D:** Midbasilar aneurysm (*arrow*) with no residual filling after packing with a single platinum detachable coil. (Courtesy of Dr. Huang Duong.)

FIGURE 39.6 Distribution of modified Rankin Scale (mRS) outcome scores in the ISAT trial, which compared surgical clipping to endovascular coiling as the primary treatment for SAH due to ruptured intracranial aneurysm. The results showed that 190 of 801 (23.7%) patients allocated to coil treatment were

dependent or dead at 1 year (mRS 3 to 6), compared with 243 of 793 (30.6%) allocated neurosurgical clipping ($P = .0019$).

ENDOVASCULAR THERAPY

Endovascular coil embolization, introduced in the early 1990s, is a safe and effective alternative to surgical clipping for treating ruptured intracranial aneurysms. Endovascular packing of aneurysms (Fig. 39.5) with soft, thrombogenic detachable platinum

P.309

coils leads to nearly complete obliteration of smaller aneurysms (< 12 mm in diameter) in 80% to 90% of cases, with an acceptable complication rate of approximately 9% (see also Chapter 24). The long-term risk of postprocedural rebleeding is minimal after successful clipping or coiling, and there is fairly compelling evidence that the less invasive coiling procedure is safer. In the International Study of Aneurysm Treatment (ISAT), 2,134 SAH patients with predominantly small (< 10 mm) anterior circulation aneurysms were randomly assigned to clip or coil therapy. Those treated with coils were 23% less likely to be dead or disabled 1 year later (Fig. 39.6) [**Level 1**].² Reasons for the observed improvement in outcome with coils are unclear but may include lower risk of perioperative rebleeding, reduced physical manipulation of the brain, less delayed ischemia from vasospasm, or other unidentified factors. Aneurysms with wide necks are less amenable to coil embolization because it is harder for the aneurysmal sac to contain the coil; in some cases, it is necessary to place a stent in the parent vessel across the aneurysm neck and deploy coils through the stent. The main disadvantage of endovascular treatment is the requirement for periodic reevaluation to ensure durable occlusion of the aneurysm. Approximately 5% of coiled patients develop recurrent dilatation at the neck of the original aneurysm and that requires repeat coil embolization or delayed surgical clipping.

Large, expanding aneurysms of the intracavernous internal carotid artery can be treated with proximal endovascular occlusion. Before permanent occlusion, a trial balloon occlusion is performed to determine whether there is adequate collateral flow through the circle of Willis to prevent symptomatic ischemia in the ipsilateral hemisphere. If the test occlusion is negative, an extracranial-intracranial bypass procedure may be considered before permanent occlusion is attempted.

INTENSIVE CARE MANAGEMENT

A suggested algorithm for the postoperative management of SAH is outlined in Table 39.5. All patients with SAH should be monitored in an ICU, where neurologic examinations can be performed frequently. Blood pressure control can be liberalized once the aneurysm has been repaired and brain perfusion becomes the dominant

P.310

consideration. Anticonvulsants are discontinued on the first postoperative day in good-grade patients who have not had a seizure; anticonvulsant prophylaxis is continued for approximately 1 week in poor-grade patients.

TABLE 39.5 Critical Care Management Protocol for Acute Subarachnoid Hemorrhage

Blood pressure	<ul style="list-style-type: none">• Control elevated blood pressure during the preoperative phase (systolic BP <160 mm Hg) with IV labetalol, nicardipine, or clevidipine to prevent rebleeding.
Rebleeding	<ul style="list-style-type: none">• Epsilon aminocaproic acid 4 g IV upon diagnosis followed by 1 g/h until

prophylaxis	aneurysm repair, for a maximum of up to 72 h after ictus
IV hydration	<ul style="list-style-type: none"> • Normal (0.9%) saline or a balanced isotonic solution (i.e., Plasma-Lyte) at 1.0-1.5 mL/kg/h
Laboratory testing	<ul style="list-style-type: none"> • Periodically check complete blood count and electrolytes. • Obtain serial ECGs and check admission cardiac troponin I (cTI) to evaluate for cardiac injury; perform echocardiography in patients with abnormal ECG findings or cTI elevation.
Seizure prophylaxis	<ul style="list-style-type: none"> • Fosphenytoin (15-20 mg/kg) or levetiracetam 1g IV; discontinue on postop day 1 unless patient has seized, is poor grade, or has focal cortical pathology or is otherwise unstable
Vasospasm prophylaxis	<ul style="list-style-type: none"> • Nimodipine 60 mg PO every 4 hours until day SAH 21 or discharge
Physiologic homeostasis	<ul style="list-style-type: none"> • Cooling blankets to maintain $T \leq 37.5^{\circ}\text{C}$ • Insulin drip to maintain glucose 120-180 mg/dL • Transfuse to maintain hemoglobin >7.0 g/dL (in the absence of active cerebral or cardiac ischemia).
Ventricular drainage	<ul style="list-style-type: none"> • Emergent external ventricular drain (EVD) placement in all stuporous/comatose patients (Hunt-Hess IV/V), as well as lethargic patients with hydrocephalus • Begin trials of clamping external ventricular drain and monitoring ICP on day 3 after placement. • Perform ventriculoperitoneal shunting during subacute phase of illness in patients with persistent cognitive dysfunction and ventriculomegaly
Vasospasm diagnosis	<ul style="list-style-type: none"> • Transcranial Doppler sonography every 1-2 days until the 10th day after SAH • CT angiography on days 4-8 after SAH if high risk
Therapy for symptomatic vasospasm	<ul style="list-style-type: none"> • Place patient in Trendelenberg (head down) position. • Infuse 500 mL 5% albumin or 1 L of 0.9% saline over 30 minutes. • If the deficit persists, raise the systolic BP with phenylephrine or norepinephrine until the deficit resolves (target 180-220 mm Hg). • If refractory, monitor cardiac output and add dobutamine or milrinone to maintain cardiac index ≥ 4.0 L/min/m². • Transfuse to maintain hemoglobin >10.0 g/dL. • Emergency angiogram for intra-arterial verapamil or cerebral angioplasty unless the patient responds well to the above measures

Adapted from Komotar R, Schmidt JM, Starke RM, et al. Resuscitation and critical care of poor grade subarachnoid hemorrhage. *Neurosurgery*. 2009;64(3):397-410.

Most centers advocate the use of aggressive fluid resuscitation with isotonic crystalloid (with or without additional colloids) to prevent volume contraction, although this has not been proven to reduce the risk of symptomatic ischemia from vasospasm. A central venous or pulmonary artery catheter is used in high-risk patients to guide fluid administration on the basis of target cardiac filling pressures. The calcium channel blocker nimodipine reduced the frequency of delayed ischemic deterioration by about 30% in several clinical trials; this effect was attributed to reduction of calcium entry into ischemic neurons or by improvement in microcollateral flow because no effect on angiographic spasm was demonstrated [Level 1].³

Use of dexamethasone in acute SAH is controversial; it is often used in the perioperative period for brain relaxation. No specific evidence suggests that it is beneficial, although it may reduce the headache sometimes associated with vasospasm. Externalized ventricular drains are used to treat obstructive hydrocephalus in patients who are stuporous or comatose, but these devices carry a risk of infection (10% overall) and therefore should be removed once intracranial pressure is stable during a 24-hour clamping trial. Serial lumbar puncture is used to treat hydrocephalus in patients who are following commands.

Transcranial Doppler (TCD) ultrasonography is widely used to diagnose vasospasm of the larger cerebral arteries after SAH. Accelerated blood flow velocities, which occur as flow is maintained through narrowed arteries, have a sensitivity and specificity of 90% for angiographic vasospasm of the proximal middle cerebral artery, but they are less sensitive for detecting spasm of the anterior cerebral or basilar arteries. Increased TCD velocity does not imply increased likelihood of developing ischemia from vasospasm. For this reason, a CT perfusion scan is obtained between SAH days 4 and 8 to determine whether cerebral blood flow is regionally compromised.

FIGURE 39.7 Mortality after SAH according to the primary cause of death or neurologic devastation leading to withdrawal of support. Data are from 3,521 patients enrolled in the Cooperative Aneurysm Study between 1980 and 1983 and 1,019 patients enrolled in the Columbia University Outcomes Project between 1996 and 2006. Numbers represent the percentage of all SAH patients who died as a direct consequence of the listed variable. (From Komotar R, Schmidt JM, Starke RM, et al. Resuscitation and critical care of poor grade subarachnoid hemorrhage. *Neurosurgery*. 2009;64[3]:397-410.)

Treatment of acute symptomatic vasospasm relies on increasing blood volume, blood pressure, and cardiac output in an attempt to improve cerebral blood flow through arteries in spasm that have lost the capacity to autoregulate. Crystalloid or colloid solutions are given to maintain pulmonary artery diastolic pressure

greater than 14 mm Hg or central venous pressure greater than 8 mm Hg. Pressors such as norepinephrine or phenylephrine are used to elevate systolic blood pressure to levels as high as 180 to 220 mm Hg. Hypertensive-hypovolemic-hemodilution (“triple-H therapy”) of this type results in clinical improvement in about 70% of patients; cerebral angioplasty can lead to dramatic improvement in patients with severe deficits that are refractory to hemodynamic augmentation (see [Fig. 39.4](#)).

Vasospasm can lead to clinically “silent” brain infarction in poor-grade patients who are stuporous or comatose and require sedation to assist in mechanical ventilation. To detect ischemia at its earliest stages, many centers rely on continuous EEG and invasive monitoring of brain tissue oxygen and cerebral blood flow to provide real-time information about the adequacy of cerebral perfusion and autoregulatory capacity (see also [Chapter 33](#)). Trends indicating a reduction in brain perfusion generally trigger a trial of induced hypertension or urgent referral for angiography.

OUTCOME

Approximately 20% of SAH patients treated at high-volume centers do not survive to discharge. In contrast to older patients indicating that delayed ischemia from vasospasm is the major cause of death and disability after SAH, most mortality today is related to the acute effects of hemorrhage in poor-grade patients ([Fig. 39.7](#)). Important risk factors for mortality or poor functional recovery after SAH include poor clinical grade, advanced age, large aneurysm size, aneurysm rebleeding, cerebral infarction from vasospasm, and global cerebral edema. Medical complications such as fever, hyperglycemia, and anemia have also been linked to poor outcome.

P.311

In contrast to the focal neurologic deficits that typically follow ischemic stroke, survivors of SAH are disabled primarily by cognitive impairment. Neuropsychological testing reveals long-term problems in memory, concentration, psychomotor speed, visuospatial skills, or executive function in 60% to 80% of SAH patients. Depression and anxiety are also common. These disturbances do not lead to the outward appearance of disability but can affect work, relationships, and quality of life; about 50% of SAH patients do not return to their previous level of employment. Cognitive and physical rehabilitation are essential for maximizing recovery in severely affected patients.

OTHER KINDS OF MACROSCOPIC ANEURYSMS

FUSIFORM OR DOLICHOECTATIC ANEURYSMS

These circumferential vessel dilatations usually involve the carotid, basilar, or vertebral arteries. Atherosclerosis probably plays a role in their formation, but a developmental defect of the wall may be present in some. Fusiform aneurysms seldom become occluded with thrombus and rarely rupture. If bleeding occurs, treatment often requires proximal vessel occlusion.

MYCOTIC ANEURYSM

Mycotic aneurysms are caused by septic emboli, which are most often formed by bacterial endocarditis ([Chapter 61](#)). They are usually only a few millimeters in size and tend to occur on distal branches of pial vessels, especially those of the middle cerebral artery. Mycotic aneurysms have been reported in up to 10% of endocarditis patients, but arteriography is not routinely performed, and the incidence is probably underestimated. Pyogenic segmental arteritis from septic emboli in the absence of frank aneurysm formation can also lead to intracranial hemorrhage. Because rupture is fatal in 80% of patients with mycotic aneurysms, cerebral

arteriography should be performed when endocarditis is accompanied by suspicious headaches, stiff neck, seizure, focal neurologic symptoms, or CSF pleocytosis. Although mycotic aneurysms occasionally disappear radiographically with antimicrobial therapy, the outcome cannot be predicted, and the aneurysm should be treated surgically as soon as possible.

PSEUDOANEURYSM

Dissection of an intracranial vessel, which usually results from trauma, can lead to extension of blood from the false lumen through the entire vessel wall. The extravasated blood is contained by either a thin layer of adventitia or the surrounding tissues and does not have a true aneurysmal wall, hence the designation *pseudoaneurysm*. If a vessel traversing the subarachnoid space is affected, SAH can result. Treatment may require endovascular or surgical vessel occlusion or trapping, or angioplasty and stenting of the involved segment.

VASCULAR (ARTERIOVENOUS) MALFORMATIONS

Vascular malformations account for less than 5% of all cases of SAH (see also [Chapter 41](#)). Intracranial and spinal vascular malformations can be classified into five main types: (1) arteriovenous malformations (AVMs), which are high-flow and most often symptomatic; (2) dural arteriovenous fistulas; (3) cavernous malformations; (4) capillary telangiectasias; and (5) venous malformations. More than 90% of vascular malformations are asymptomatic throughout life. Bleeding may occur in patients at any age but is most likely to occur in patients younger than 40 years. They are occasionally familial, and in 7% to 10% of cases, AVMs coexist with saccular aneurysms.

AVMs are a conglomerate of abnormal arteries and veins with intervening gliotic brain tissue; they resemble a “bag of worms.” When bleeding from an AVM occurs, reported initial mortality has ranged from 4% to 20%. Early rebleeding is far less likely than after aneurysm rupture, but recurrent hemorrhage occurs in 8% to 18% of patients annually over the next several years. For patients without hemorrhage, the risk of bleeding is 2% to 4% per year. Besides prior hemorrhage, risk factors for bleeding from an AVM include deep location and exclusively venous drainage, small size, a single draining vein, and high feeding-artery pressure.

The diagnosis of an AVM is made by MRI and arteriography. Small or thrombosed AVMs, especially in the brain stem, are occasionally missed by arteriography but detected by MRI, which better demonstrates the relationship of the malformation to surrounding brain and identifies its nidus. MRI is the preferred screening procedure for detecting vascular malformations; if surgery is contemplated, conventional angiography is required to delineate the vascular supply. Dural and spinal cord AVM should be kept in mind in patients with radiographically unexplained SAH.

Treatment depends on the location of the AVM and the age and condition of the patient. Direct surgical resection, endovascular glue embolization, and directed-beam radiation therapy with a linear accelerator or Gamma Knife are the main treatment modalities. The long-term value of these treatments is unclear. Embolization is most useful for shrinking the malformation before surgery or radiation; it is occasionally curative as a single mode of therapy.

Cerebral Venous and Sinus Thrombosis

Natalie Organek

Jennifer A. Frontera

INTRODUCTION

Cerebral venous thrombosis (CVT) is thrombosis of the venous channels that drain blood from the brain (Fig. 40.1). Often, it is associated with other conditions causing thrombi, but not infrequently, its cause remains unknown. CVT commonly presents with isolated headache but also must be kept on the differential for causes of cerebral ischemia, hemorrhage, and even coma. CVT image findings may be subtle but are important because overlooking them can have catastrophic consequences. Treatment recommendations for CVT had been controversial for many years, although anticoagulation remains the mainstay of treatment. Overall, the outcome for CVT is positive; if it is treated early, recurrence rates are low.

EPIDEMIOLOGY

CVT is an uncommon disorder affecting a variable patient population. CVT in adults is thought to affect about 5 people per 1 million every year. Most accounts estimate that CVT represents slightly less than 1% of all strokes. The International Study on CVT (ISCVT), the largest multicenter collaboration of consecutively enrolled symptomatic CVT patients older than 15 years with imaging confirmation, collected data on 624 patients from 24 countries and 89 centers and found the following epidemiologic data for CVT: median age was 37 years (age range 16 to 86 years), 74% of enrollees were female. These data is in keeping with the general belief that, although it can affect any age or sex, in the adult population, CVT is largely a disorder of young to middle-aged females.

The Canadian Pediatric Ischemic Stroke Registry (CPISR) is one of the largest pediatric CVT registries and involved 16 pediatric tertiary care centers in Canada collecting data on 160 consecutive cases of radiologically confirmed CVT in children 0 to 18 years old. These data demonstrated an incidence of pediatric CVT to be about 6.7 per 1 million people, slightly more common than adult CVT. Among the 160 children enrolled, 54% were younger than 1 year old (with 43% younger than 1 month of age) and 54% were male. This follows the general understanding that the pediatric CVT population largely involves very young children and the female preponderance seen in adult CVT is not present in pediatric CVT populations.

PATHOBIOLOGY

CVT has been attributed to numerous causes, yet even after extensive workup, almost 30% of CVT diagnoses remain idiopathic. ISCVT found that thrombophilia (34.1%) and oral contraception (54%, overall data corrected for females of childbearing age) accounted for a significant portion of the causes of CVT. Other important causes of CVT were puerperium (14%, overall data corrected for females of childbearing age) and pregnancy (6%, overall data corrected for females of childbearing age). Additionally, infection (especially of the ear, sinus, mouth, face, and neck) contributed to 12% of CVT cases in their data set, and malignancy (within and outside of the central nervous system [CNS], both solid tumor and hematologic) was found to have caused 7% of CVT in the ISCVT population. Regarding genetic causes, Marjot et al. performed a meta-analysis of 26 studies: This included 1,183 CVT patients, explored six genes, and demonstrated a statistically significant association between CVT and two genes: factor V Leiden (OR = 2.40; 95% CI, 1.75 to 3.30; $P < .00001$) and prothrombin

gene mutation (OR = 5.48; 95% CI, 3.88 to 7.74; $P < .00001$). Finally, more than 44% of subjects were found to have more than one cause of CVT, an important fact to remember when exploring causes of CVT in hopes of preventing reoccurrence. [Table 40.1](#) summarizes common causes of CVT.

In contrast to adult data, the most common cause of CVT in children is infection. In the CPISR data, acute infection was most commonly found in neonates (children younger than 1 month; 84%). Perinatal complications (51%) and dehydration (30%) were also common causes of CVT in the neonatal population. In older children (older than 1 month but younger than 18 years), chronic illness was the most common risk factor, especially connective tissue disorders (23%), hematologic disease (20%), and cancer (13%). Similar to the adult data, the CPISR data found prothrombotic states to be an important cause of CVT in neonates (20%) and children (54%).

CLINICAL FEATURES

The variable clinical presentation is one of the challenges of CVT. In adults, the disorder typically presents with symptoms attributed to increased intracranial pressure (ICP) associated with inability to drain the thrombosed vessel or focal neurologic disease ascribed to cerebral venous ischemia or hemorrhage.

Diffuse progressive headache over hours to days is the most common presentation in patients with CVT, although thunderclap and migrainous-type headache have also been described. Importantly, isolated headache without other neurologic findings or signs of elevated ICP occurred in 25% of confirmed CVT in the ISCVT cohort.

When CVT does cause an increase in ICP, patients commonly present with the following neurologic signs: papilledema, diplopia (most commonly due to sixth nerve palsy), headache which worsens with recumbency, nausea/vomiting, and encephalopathy. In addition to signs of increased ICP, focal neurologic deficits following cerebral ischemia or hemorrhage are also important clinical presentations in patients with CVT. The actual signs of the focal brain injury are attributed to the site of venous ischemia and are therefore variable but include focal weakness, sensory changes, visual field deficits, and aphasias. Further confounding this picture in CVT, the superior sagittal sinus, the most commonly involved cerebral venous structure in CVT, drains both cerebral hemispheres and therefore when thrombosed can cause bilateral deficits complicating neurologic localization. A small yet clinically important subset of CVT patients are those with deep CVT. CVT affecting the basal ganglia or thalamus is commonly bilateral and can lead to venous ischemia or hemorrhages. CVT affecting the deep parts of the brain tend to be more severe and quickly results in profound deficits including altered mental status and coma.

TABLE 40.1 Common Causes of Cerebral Sinus Thrombosis

Drugs	Oral contraceptives (especially in combination with tobacco and/or prothrombotic disease), hormone replacement therapy, asparaginase chemotherapy, tamoxifen, steroids, androgens
Hematologic diseases	Polycythemia, thrombocythemia, paroxysmal nocturnal hemoglobinuria
Hypercoagulable state	Protein C, S, or antithrombin III deficiency; factor V Leiden mutation; prothrombin gene mutation; antiphospholipid syndrome (lupus anticoagulant/anticardiolipin antibody); nephrotic syndrome; hyperhomocysteinemia
Infections	Encephalitis; cerebritis; meningitis; mastoiditis; otitis; sinusitis; infections of the

mouth, face, and neck

Inflammatory diseases	Vasculitis, lupus, Wegener granulomatosis, inflammatory bowel disease, Behçet disease, thromboangiitis obliterans, sarcoidosis
Malignancy	CNS tumors with invasion of the venous sinus, hematologic cancers, hypercoagulable state due to malignancy
Obstetric	Pregnancy and puerperium
Trauma (including iatrogenic)	Head injury, lumbar puncture, neurosurgical procedures

CNS, central nervous system.

The cavernous sinuses are a unique set of cerebral sinuses. They are deep bilateral structures at the base of the cerebrum that house the internal carotid artery, ophthalmic vein, branches of the sphenoid and superficial middle cerebral veins, as well as cranial nerves III, IV, V1, V2, and VI. Venous thrombosis affecting the cavernous sinuses are associated with palsies affecting these cranial nerves as well as pain, ptosis, chemosis, and proptosis. Increased intraocular pressure due to poor venous drainage can lead to loss of visual acuity. Most cavernous sinus thromboses are related to infection, typically due to *Staphylococcus aureus*, although *Streptococcus pneumoniae*, gram-negative rods, anaerobes, and occasionally fungal infections may be culprits. Spread of symptoms to the contralateral eye via the intracavernous sinuses may occur within 24 to 48 hours of the initial presentation and is pathognomonic for cavernous sinus thrombosis. [Table 40.2](#) summarizes common syndromes associated with CVT.

P.315

TABLE 40.2 Common Cerebral Venous Thrombosis Syndromes

CVT Location	Symptoms
Superior sagittal sinus	Large vein, symptoms depend on location affected Motor deficits (can be bilateral due to central location) Psychiatric symptoms (when affecting the frontal lobes) Seizures due to cortical location
Transverse sinus	Aphasias when they affect areas of speech
Cerebral cortical vein	Deficit varies depending on location of CVT Seizures due to cortical location
Deep venous system	Change in mental status Coma Bilateral deficits due to central location

Cavernous sinus

Palsies affecting cranial nerves III, IV, V1, V2, or VI
Orbital pain

CVT, cerebral venous thrombosis. Adapted from Frontera J, ed. *Decision Making in Neurocritical Care*. New York: Thieme; 2009.

Clinical presentation for CVT in children is similar to adults except in neonates where seizure is more common. In the CPISR database, 71% of neonates (children younger than 1 month old) with CVT had seizure attributed to CVT, in contrast to only 48% of non-neonate CPISR children and 44% of CVT patients older than 15 years.

FIGURE 40.2 Axial T2 MRI (A) and coronal MRV (B) demonstrating a thrombus at the torcula (*white arrow in A*) and at the transverse sinus (*white arrow in B*).

DIAGNOSIS

CVT is a pathology known for its infrequent as well as variable clinical presentation both of which can complicate diagnosis. Delays in diagnosis of CVT are not uncommon; therefore, a high level of suspicion must be maintained in the proper clinical context. Diagnosing CVT begins with a thorough patient history and physical examination. Elements discovered in these investigations help to determine the necessary laboratory and radiologic evaluation.

The key to diagnosis in CVT is direct imaging of the cerebral venous system. Both computed tomography venography (CTV) and magnetic resonance venography (MRV) have been studied in CVT; they have been found to be equivalent imaging techniques in CVT. [Figure 40.2A](#) demonstrates CVT in the torcula on T2 magnetic resonance imaging (MRI) and in the left transverse sinus on MRV ([Fig. 40.2B](#), *white arrows*). Drawbacks associated with CTV include radiation exposure, contrast allergy, and limited use in renal failure. MRV is limited in patients with pacemakers and requires significant time that is typically unavailable in urgent neurologic evaluations. Distinguishing thrombosis from venous hypoplasia can complicate interpretation of MRV and CTV imaging. Parenchymal MR imaging sequences can be useful in making this distinction ([Table 40.3](#)) and is particularly useful for diagnosing cavernous sinus thrombosis.

Conventional digital subtraction angiography was the gold standard for the diagnosis of CVT for many years, although, for the most part, it is currently reserved for inconclusive CTV or MRV imaging or when endovascular intervention is required. In patients with persistent symptoms or those with previously diagnosed CVT and a change in symptoms, repeat imaging should be considered to evaluate for new CVT as well as propagation of known thrombus.

In 2011, the American Heart Association (AHA) and the American Stroke Association (ASA) created the statement for health care professional on the diagnosis and management of

P.316

cerebral venous thrombosis [Level 1],² which reviewed, among other topics, invasive and noninvasive CVT diagnostic imaging modalities. In the AHA/ASA review, noncontrast CT of the brain was the most common imaging modality for patients with new neurologic symptoms. Noncontrast head CT is often unremarkable but may demonstrate subtle signs suggestive of the CVT, namely, hyperdensities in the cerebral veins. This finding is present in only about one-third of patients. The most well-known noncontrast head CT finding in CVT is the dense triangle found in the posterior sagittal sinus called the *filled delta* sign. There is often a delay in visualization of this sign for days, but once present, it typically persists for weeks, which make it likely to be most helpful with late presentation of CVT. More often, noncontrast head CT demonstrates nonspecific indirect signs of CVT including CT hypodensities and a decrease in ventricular size both associated with parenchymal edema. Nonenhanced head CT is also helpful in demonstrating cerebral venous infarctions or intracerebral hemorrhage (ICH), which characteristically are in vascular distributions inconsistent with more common arterial disease. Perhaps most importantly, noncontrast CT is helpful in ruling out other causes for the clinical presentation. In CVT, contrast-enhanced CT may demonstrate the “empty delta sign” wherein the thrombus creates a filling defect in the cerebral venous system and, therefore, becomes “empty.” Finally, as with most cerebrovascular disease, MRI of the brain can be helpful in demonstrating earlier signs of venous infarct associated with CVT.

CVT laboratory workup is focused on determining the cause and should include basic labs as well as an evaluation for hypercoagulability. Anticoagulation can affect the outcome of the hypercoagulable labs, and therefore, these should be examined prior to initiating anticoagulation treatment for CVT. Table 40.4 lists laboratory workup for CVT.

TABLE 40.3 Using Magnetic Resonance Imaging to Age Cerebral Blood

Phase	Time	T1	T2	Hemoglobin
Acute	1-3 days	Isodense	Dark	Deoxyhemoglobin
Early subacute	3-7 days	Bright	Dark	Methemoglobin
Late subacute	7-14 days	Bright	Bright	Methemoglobin
Chronic	>14 days	Dark	Dark	Hemosiderin

Adapted from Frontera J, ed. *Decision Making in Neurocritical Care*. New York: Thieme; 2009.

TABLE 40.4 Laboratory Workup for Cerebral Venous Thrombosis

Basic labs	CBC, chemistry, liver function testing, antinuclear antibody
Hypercoagulable workup (test prior to starting anticoagulation)	Coagulation studies, homocysteine, factor V Leiden mutation, prothrombin gene mutation, antiphospholipid and anticardiolipin antibodies, lupus coagulant, protein C and S, antithrombin III, fibrinogen
Specific testing (patient specific)	Urine protein (if nephrotic syndrome is suspected)

CBC, complete blood count.

D-dimer has been explored as a possible diagnostic marker for CVT, but high pretest probability remains paramount. Meng et al. performed a prospective study of confirmed CVT in 94.1% of patients who had elevated D-dimer and during the acute phase, the sensitivity and specificity of predicting CVT with D-dimer were 94.1% and 97.5%. Similarly, in a meta-analysis of 1,134 CVT cases by Dentali et al., D-dimer was found to have a mean sensitivity of 93.9% and mean specificity of 89.7%. The AHA/ASA CVT statement [Level 1]² reviewed sensitivity and specificity of a number of studies exploring D-dimer and CVT and suggests D-dimer may be helpful in those with very low suspicion of CVT but cannot be used to preclude further evaluation in patients in whom there is a strong clinical suspicion.

Diagnosis of CVT in children is similar to adults in that, most importantly, although CVT is rare and has a nonspecific presentation, it must not be left off a comprehensive differential in children with appropriate neurologic symptoms. As described earlier, this may be especially challenging in neonates who more commonly present with seizure but have otherwise nonspecific presentation. In general, CVT imaging is very similar in children and adults, but neonatal physiologic differences must be considered. The hypointensity of the immature unmyelinated brain as well as the hyperintensity of physiologic polycythemia associated with neonates can mimic the “delta sign” and is therefore known as the *pseudodelta sign*. This CVT mimic in neonates is easily clarified with administration of contrast material. Additionally, in neonates, transfontanellar ultrasound has been explored for CVT diagnosis but was generally found unreliable especially in nonocclusive thrombus and therefore has limited use in neonatal CVT without confirmation with other imaging modalities.

TREATMENT

CVT treatment is typically trimodal: The mainstay of treatment is (1) anticoagulation, (2) treatment of the underlying etiology when appropriate (i.e., antimicrobial for cases involving infection) and (3) symptomatic treatment (headache management, addressing increased ICP). In patients who present with seizure, antiepileptic drugs (AEDs) are indicated.

Anticoagulation is essential for preventing CVT propagation and to prevent systemic thrombosis in those with underlying hypercoagulable states. Einhäupl et al. studied 20 patients with CVT (confirmed on imaging) who were randomized to intravenous unfractionated heparin (UFH) versus placebo. The study was stopped prematurely due to the obvious benefit of treatment with anticoagulation. Additionally, this group

documented two ICHs, both in the placebo group (none among the anticoagulation treatment group). Subsequently, in a study by de Bruijn et al. [Level 1],¹ 59 patients with CVT were randomized to low molecular weight heparin

P.317

(LMWH) versus placebo. The placebo group was more likely to have a poor outcome compared with the treatment group, and no ICHs occurred in either group. The current AHA guidelines for CVT recommend initial anticoagulation with UFH or weight-based LMWH in full doses followed by vitamin K antagonists regardless of the presence of ICH [Level 1].² It is important to note that anticoagulation *should be administered for CVT even in the context of intracranial hemorrhage*. Concurrent with the present AHA recommendations, the ISCVT investigators compared the outcomes of CVT patients treated with UFH and LMWH and found a better efficacy and safety for LMWH. Additionally, a randomized controlled trial of 66 CVT patients also explored treatment with UFH and LMWH and found LMWH to have a significantly lower mortality in CVT compared to UFH [Level 1].³ Most recently, in 2012, the American College of Chest Physicians formally recommended initial treatment for CVT with either dose-adjusted heparin or LMWH followed by oral anticoagulation for 3 to 6 months for most patients and lifelong anticoagulation for CVT patients with permanent risk factors for recurrent events [Level 1].⁴ Finally, women of childbearing age with CVT present a unique challenge. In women with a history of CVT, oral contraceptives should generally be avoided and in pregnant women with a history of CVT, prophylaxis with LMWH during future pregnancies and in the postpartum period may be reasonable [Level 1].⁵

The data for endovascular invasive therapy, including direct endovascular thrombolysis and thrombectomy, to this point has not proven to provide greater benefit than anticoagulation alone except for case reports and small case series in patients with CVT who clinically deteriorate while on anticoagulation and in those who have an absolute contraindication to anticoagulation (such as hemodynamically significant hemorrhage or allergy to anticoagulation agents). Options for endovascular treatment include local infusion of recombinant tissue plasminogen activator as well as mechanical thrombolysis using balloons and rheolytic catheters. Thrombolysis adds the additional risks of parenchymal and systemic hemorrhage beyond the risks incurred by heparin or LMWH alone. In light of the recent advances in endovascular therapy, open surgical treatment for CVT is limited mostly to those patients with large cerebral venous infarcts who develop clinical and radiologic signs of herniation and may benefit from decompressive hemicraniectomy. In patients with symptomatic intracranial hypertension, efforts to lower ICP should be considered. Elevation of the head of the bed with the head midline to promote venous drainage, osmotic therapy, and management of hypermetabolic states (shivering, fever, seizure, agitation) should be considered as part of routine intracranial hypertension management.

In patients with seizure related to CVT, AEDs should be administered [Level 1]²; however, prophylactic AED use is not advised. Optimum duration of treatment with AEDs in CVT patients with seizure remains unknown. There is a dearth of data regarding treatment of CVT in children; treatment guidelines are largely extrapolated from adult data. AHA/ASA [Level 1]² current recommendations for treating CVT in children older than 1 month of age align with adult recommendations for treatment with anticoagulation even in the context of ICH. Treatment recommendations for children younger than 1 month of age remain controversial and variable. Neonates should be treated with anticoagulation for 6 weeks to 3 months with close imaging follow-up to assess for recanalization with low threshold for stopping anticoagulation at 6 weeks if the venous system recanalizes [Level 1].² AED recommendations in children (and neonates) are similar to that of adults.

OUTCOME

Overall, the outcome for most patients with CVT is positive, but there remains an important minority in whom the disease causes significant morbidity and mortality. According to ISCVT data, about 87% of CVT patients had complete recovery, but about 8% had significant morbidity with an additional mortality rate of about 5%. Similarly, Borhani Haghighi et al. investigated a national cohort of almost 3,500 CVT patients had a mortality rate of 4.39%. Certain characteristics have been found to be associated with poor outcome in CVT including male gender, age older than 37 years, those with significant neurologic deficit and coma, as well as those who develop seizure. In the acute phase of CVT, brain herniation attributed to CVT remains the most common cause of death; in the late stages, mortality associated with CVT is mostly related to the underlying cause of the thrombosis. Rates of CVT recurrence range from 2% to 4%.

In childhood, CVT coma has been shown to predict mortality, but overall, few studies have followed children for more than 2 years after CVT. In the CPISR data (with only over 2 years of follow-up), approximately 75% of neonates and approximately 50% of nonneonates were neurologically normal.

Vascular Malformations

J. P. Mohr

John Pile-Spellman

INTRODUCTION

This chapter deals with a heterogeneous group of central nervous system (CNS) vascular lesions, including true vascular malformations such as arteriovenous malformations (AVMs) and cavernous malformations, acquired fistulas, vascular neoplasms, and other rare vascular disorders.

ARTERIOVENOUS VASCULAR MALFORMATIONS

AVMs are the most common of these rare disorders. They are thought to be congenital, arising in the prenatal period but do not present clinically until middle life. A few are caused by brain contusions which enlarge the normal tiny arteriovenous shunts. Although many remain static anomalies, others enlarge in size and proliferate in vascular complexity, driven by incompletely understood pathophysiologic forces, in animal models related to Notch4 dysgenetic effects.

EPIDEMIOLOGY

AVMs are rare, occurring with a prevalence of 18 per 100,000 individuals. Every year, about 1 out of every 100 people with an AVM will experience a hemorrhage. Current population studies indicate an incident discovery rate of 1.5 per 100,000. The majority of AVMs are thought to remain asymptomatic throughout life. AVM symptoms tend to occur early in life; two-thirds of AVMs become symptomatic before age 40 years.

PATHOBIOLOGY

AVMs are not neoplasms. Most of them are thought to arise in the prenatal period but not present clinically until middle life. A few are caused by brain contusions which enlarge the normal tiny arteriovenous shunts. Although many remain static anomalies, others enlarge in size and proliferate in vascular complexity, driven by incompletely understood pathophysiologic forces, in animal models related to Notch4 dysgenetic effects.

Whether congenital or acquired, AVMs are anatomically limited to the brain, spinal cord, or dura. Those embedded in the brain are most common. Lacking capillaries at the main site of linkage between the arteries and veins, the nidus is a tangle of irregularly sized vascular channels lacking the expected media of arteries, often so thin walled they barely satisfy criteria for veins. Their location varies widely; some limited to the surface of a cerebral hemisphere, fed by a single small artery and draining to the single small vein. At the opposite extreme, others form a huge wedge from the brain surface through the white matter to the ventricular wall (schizencephalic AVM); some so large they occupy a large portion of one hemisphere. A few lie in the subsurface white matter, others limited to deep structures (e.g., basal ganglia, thalamus), brain stem, or spinal cord. Those on the brain surface lying in the border zone between the major cerebral arteries typically have a higher incidence of seizures but a lower hemorrhage rate than those deeper in the brain. Collateral from the adjacent dura may occur. Those that penetrate to the ventricular wall often draw collaterals from the deep vasculature supplying the basal ganglia. Venous drainage may be by superficial or the deep venous systems.

CLINICAL FEATURES

AVMs present most often with bleeding, less often with headaches or seizures, and occasionally with progressive gait disturbance, focal neurologic deficit, or cognitive decline. When hemorrhage occurs, it affects the following

regions: intracerebral (30%), subarachnoid (15%), intraventricular (30%), and various combinations (25%). AVMs are the second most identifiable cause of subarachnoid hemorrhage (SAH) after brain aneurysms, accounting for 5% of all cases of SAH.

The most feared complication of AVMs by far is hemorrhage. Yet compared with aneurysmal rupture, the morbidity of AVM hemorrhage is far less serious; some barely symptomatic, few devastating. The hemorrhage usually arises within the nidus and when limited in volume, displaces adjacent healthy brain with varying degrees of symptoms and signs. For those AVMs that drain to the ventricular wall, bleeding may originate from the venous aspect of the malformation and extend mainly into the ventricle, which presents as intraventricular hemorrhage with hydrocephalus and only minor injury to adjacent brain structures. Larger hemorrhages escape the nidus and dissect into healthy brain tissue like any primary brain hematoma. Arteries feeding the AVM nidus may develop flow-related aneurysms, which may bleed separately, typically causing SAH syndromes.

The risk of an unruptured AVM bleeding on average is closer to 1% than the previously quoted 4% per year. Death from the first hemorrhage ranges between 5% and 20%, depending primarily on the size of the hemorrhage and the presence of ventricular extension. When hemorrhage occurs, some destabilization of the fistula occurs, and it sets the stage for recurrent hemorrhage. Once a bleeding event has occurred, an AVM is more than 5 times more likely to bleed again during the first year, but recurrent hemorrhage occurs in 8% to 18% of patients annually over the next several years. Besides prior hemorrhage, important risk factors for bleeding from an AVM include deep location, small size, and a single draining vein.

AVMs are less often associated with seizures or headaches. No distinctive features separate either the seizures or the types of headache (including migraine) from non-AVM causes (Figs. 41.1, 41.2, 41.3).

DIAGNOSIS

The diagnosis of AVM is made by magnetic resonance imaging (MRI) (Chapter 21) and angiography (Chapter 24) (see Fig. 41.1), less easily by computed tomography (CT) scan and—unless calcified—scarcely even by plan skill films. These tests can be repeated to analyze a change in the size of the AVM, recent bleeding, or the

P.320

P.321

appearance of new lesions. Small or thrombosed AVMs, especially in the brain stem, are occasionally missed by arteriography but detected by MRI, which better demonstrates the relationship of the malformation to surrounding brain and identifies its nidus. If surgery is contemplated, conventional angiography is required to delineate the vascular supply. Dural and cervical spinal cord AVM should be kept in mind in patients with radiographically unexplained SAH, requiring examination of the external carotid arterial supply and cervical vertebral arteries.

FIGURE 41.1 Left parietal AVM. Anteroposterior (A) and lateral (B) subtraction films in the arterial phase of a left internal carotid injection show the anterior cerebral artery supply and early superficial venous drainage of a left parietal AVM. Coronal (C) and axial (D) T2-weighted magnetic resonance images of the same patient show a serpiginous pattern of signal void representing flow in vascular structures. (Courtesy of Drs. J. A. Bello and S. K. Hilal.)

FIGURE 41.2 Right temporal AVM. **A:** Anteroposterior view from arterial phase of right internal carotid arteriogram shows a large enhancing vascular lesion in right temporal region supplied by enlarged branches of right middle cerebral artery. **B:** Lateral view demonstrates prominent early draining cortical veins emanating from AVM. Postembolization anteroposterior (C) and lateral (D) views of right internal carotid arteriogram show interval disappearance of right temporal AVM with multiple metallic coils seen within right middle cerebral arterial feeders. Note normal filling of both anterior and posterior cerebral arteries, thereby confirming increase in blood flow to normal brain structures. Patient did well after embolization with no complications. Follow-up definitive surgery found no evidence of flow within AVM, and the nidus was removed to prevent recurrence. (Courtesy of Drs. S. Chan and S. K. Hilal, Columbia University College of Physicians and Surgeons, New York, NY.)

FIGURE 41.3 MRI scan showing the characteristic “target” lesion of a cavernous malformation.

TREATMENT

Treatment depends on the location of the AVM and the age and condition of the patient. Direct *microsurgical resection*, *endovascular glue embolization*, and *directed-beam radiation therapy* with a linear accelerator or Gamma Knife are the main treatment modalities.

With the advent of MRI, asymptomatic AVMs or those presenting only with headaches or seizures have become increasingly prevalent. The increasing discovery of these conditions before bleeding occurs long posed a management dilemma—whether to take risks of eradicating the lesion, embedded as it is in brain, or await the natural history of hemorrhage, hoping that if it occurs, it will not much damage the adjacent tissues. The recently completed A Randomized trial of Unruptured Brain AVMs (ARUBA) trial indicates that the safer course appears to be delaying intervention unless hemorrhage occurs [Level 1].¹ The *Spetzler-Martin grading scale* is used to stratify the risk of death or major complications from surgery (Table 41.1). Decision making for intervention is complex and relies on clinical expertise, the specifics of the anatomy of the AVM, and the wishes of the patient. Surgery remains the most effective means of eradicating AVMs. For larger or more complex lesions, intravascular occlusive therapy using quick-acting glues can obliterate some AVM feeders, shrinking the malformation before surgery or radiation; it is occasionally curative as a single mode of therapy (see Fig. 41.2). For the deeply lying lesions not suitable for embolization or surgery, focused-beam radiotherapy (radiosurgery) is an alternative therapy. Complete eradication of an AVM is documented with loss of any evidence of early venous filling during the arterial phase of angiography. Despite complete eradication documented by angiogram, a small number of lesions recur.

TABLE 41.1 Spetzler-Martin Grading Scale

<http://internalmedicinebook.com>

	Grade
Size of Nidus	
Small (<3 cm)	1
Medium (3-6 cm)	2
Large (>6 cm)	3
Eloquence of Adjacent Brain	
Noneloquent	0
Eloquent ^a	1
Venous Drainage	
Superficial only	0
Deep	1

^aScores are used only to estimate the risk of surgical AVM resection. Scores range from 1 to 5. Score of 1 denotes low risk of surgical morbidity (approximately 5%). AVMs with a score of 5 are considered inoperable, with a surgical risk approaching 50% or more.

Vein of Galen malformations are a special AVM associated with the deep venous system, often with marked aneurysmal dilatation of the vein of Galen region. The arterial supply may be complex and difficult to occlude by intravascular or surgical techniques. Most present in neonates or young children. Arteriovenous shunting leads to cardiac failure and compression of the midbrain, which causes hydrocephalus. The currently accepted treatment of these lesions is embolization, occasionally followed by surgery.

OUTCOME

Former estimates of morbidity and mortality from AVM hemorrhage have been revised downward. Widely cited annual rates of 4% per year documented in some publications applied predominantly in those with large, complex AVMs who have bled in the past and whose AVM was deemed too daunting for attempted removal. For 49% of those presenting with first hemorrhage at a large referral institution, their morbidity documented by the modified Rankin Scale was one (no significant disability) and showed significantly better outcomes than those with primary brain hemorrhage not from AVM. Hemorrhages arising from venous aspect of the AVM into the ventricle may present with a spectacular-appearing hemohydrocephalus but experience as satisfactory outcome.

DURAL ARTERIOVENOUS FISTULAS

These shunts linking an arterial source directly to a dural sinus arise from a combination of factors: some traumatic, others from venous thrombosis, and some for reasons still not understood. They account for some 10% to 15% of intracranial vascular malformations.

Current classifications cite three types based on the site of venous drainage, presence of cortical venous reflux, and the number of fistulae. The site most affected are the transverse-sigmoid sinus, tentorial, and anterior cranial fossa (including the cavernous sinus) and less often the spinal system or foramen magnum.

P.322

Thrombosis of a large vein or sinus may be a more common cause. Current understanding is that the venous thrombosis creates a high-enough resistance to normal arterial flow as to force creation of new pathways. Closed head injury with trauma to the brain surface—commonly lateral temporal lobe—appears to join or enlarge the existing 90 μ m arteriovenous shunts known to exist in the cerebral vasculature. Once having developed, these fistulas presumably lose their capacity for autoregulation and appear subject to the same forces for enlargement of arteriovenous links elsewhere.

Hemorrhage is the presenting symptom in 20%. Many other dural arteriovenous fistulas present with unusual syndromes of local brain edema, among them complex aphasia and visual disturbances. For fistulas affecting the cavernous sinus, the clinical spectrum is broad: A link to the venous system from a small arterial source may create diagnostic problems suggesting myasthenia gravis or ocular myopathy, less dramatic than the rapidly developing bulging erythematous eye in carotid-cavernous sinus fistula that was created by trauma.

When pursued by angiogram, there is usually delayed filling of the carotid or vertebrobasilar arteries, and those branches having access to a patent vein or sinus (meningeal and other dural arteries) can be dilated and convoluted to a degree seen in AVMs. Treatment is by transarterial or transvenous endovascular methods. Persistence in efforts is often required. Some reports document spontaneous regression.

CAVERNOUS MALFORMATIONS

Cavernous malformations are low-flow, highly focal vascular anomalies; most of them are less than 1 cm in size. They may occur anywhere in the brain. Histologically, they show a distinct cluster of tiny vessels of uniform size, hence the name *cavernous*. The individual vessels and even the cluster are too small to be seen on angiogram and are rarely documented by CT scan but are easily seen on MRI (see [Fig. 41.3](#)), thanks to the hemosiderin-iron composition from the slow flow through the lesion or from asymptomatic hemorrhages. Multiple lesions—some numbering in the many dozens—have been documented in families. Although they may be mistaken for a vascular tumor on imaging, there is no displacement of the surrounding structure.

Approximately two-thirds of cavernous malformations are diagnosed when patients with symptoms of hemorrhage, seizures, headaches, or vague neurologic symptoms occur. The risk of hemorrhage is 6% annually in patients who have already experienced a bleeding event, and the risk gradually goes down with time. The median interval from primary to a repeat hemorrhage is 8 months. The risk of bleeding in patients presenting with symptoms unrelated to hemorrhage is 2% annually. Of the one-third of patients who present with an incidentally discovered cavernous malformation, the bleeding risk is only 0.3% per year.

The bleeding events themselves tend to be low-impact, compatible with gradual breakdown of the malformation and “oozing” of blood over period of hours, in contrast with the violent bleeding events that can occur with rupture of a lenticulostriate artery in the setting of hypertensive intracerebral hemorrhage (see [Chapter 38](#)). The clinical effects of hemorrhage are accordingly usually limited, often causing no or minimal symptoms. Serious deficits are generally restricted to patients with malformations in the brain stem. If hemorrhage has occurred and

the lesion is readily accessible, surgery is usually recommended.

VENOUS MALFORMATIONS

Venous malformations (also deep venous anomalies) have no apparent arterial supply. They are not an AVM, only anomalous venous drainage from normal arterial vessels. They may cause headaches, seizures, or, rarely, hemorrhage (Fig. 41.4). They generally lie in the deep white matter and portions of the brain stem and cerebellum and often have spiderlike venous branches into the adjacent parenchyma (so-called caput medusa). They are easily recognized using CT because of their contrast enhancement. Because they also serve as the venous draining system for the adjacent brain, they are not amenable to obliteration by occlusion of the arterial supply or surgical resection. They generally follow a benign course.

TELANGIECTASIAS

Telangiectasias are collections of engorged capillaries or cavernous spaces separated by relatively normal brain tissue. They are usually small and poorly circumscribed. Although found in any portion of the CNS, they have a propensity for the cerebral white matter. In the Rendu-Osler-Weber syndrome, brain telangiectasias are associated with similar lesions of the skin (mucous membranes, respiratory, gastrointestinal, and genitourinary tracts). Those occurring in the lung may provide a path for septic material for brain abscess formation. The fistulas are usually tiny, and some are not demonstrated despite angiography. Major hemorrhage is rare. Interest in genetic mapping for the remarkable variety of telangiectasias has increased greatly and may well lead to a total reclassification of these lesions separate from the classical clinical description.

STURGE-WEBER DISEASE

The main features of this rare disorder, also known as *Krabbe-Weber-Dimitri disease*, are localized atrophy and calcification of the

P.323

cerebral cortex associated with *capillary malformations*. Any portion of the cerebral cortex may be affected by the atrophic process, but the occipital and parietal regions are most commonly involved. Usually also present is an ipsilateral port-wine-colored facial nevus, usually in the distribution of the first division of the trigeminal nerve. Included among the clinical features may be angiomatic malformations in the meninges, ipsilateral exophthalmos, glaucoma, buphthalmos, angiomas of the retina, optic atrophy, and dilated vessels in the sclera.

FIGURE 41.4 Subtraction posterior fossa angiogram, venous phase. In this anteroposterior view, the characteristic venous malformation is demonstrated (*arrows*).

In the atrophic cortical areas, there is a loss of nerve cells and axons and a proliferation of the fibrous glia. The small vessels are thickened and calcified, particularly in the second and third cortical layers. Small calcium deposits are also present in the cerebral substance, and rarely, there are large calcified nodules. When an angioma is present, it is limited to the meninges overlying the area of shrunken cortex. Although the combination of a port-wine facial nevus and localized cortical atrophy may exist without clinical symptoms, convulsive seizures are usually present from infancy. Mental retardation, glaucoma, contralateral hemiplegia, and hemianopia are also present in most cases.

Sturge-Weber disease can be diagnosed without difficulty from the clinical syndrome. The presence of the cortical lesion can be demonstrated in most cases by the appearance of characteristic shadows in the radiographs. The treatment of Sturge-Weber disease is essentially symptomatic. Anticonvulsive drugs are given for the seizures. Radiation therapy has been recommended, but there is no evidence that it is of any benefit.

SINUS PERICRANII

The disorder is a combination of thin-walled vascular spaces interconnected by numerous anastomoses that protrude from the skull and communicate with the superior longitudinal sinus. The malformation is usually evident in infancy, soft and compressible; it increases in size when the venous pressure in the head is raised by coughing, straining, or lowering the head. It may enlarge slowly over a period of years. The external

protuberance may be seen at any portion of the midline of the skull, including the occiput, but is most often found in the midportion of the forehead. Imaging shows a defect of the underlying bone, through which the lesion communicates with the longitudinal sinus.

VASCULAR TUMORS

These three forms of neoplastic lesions may be variations of the same tumor. Histologically, they are indistinguishable but share similar clinical features.

HEMANGIOBLASTOMAS

Hemangioblastomas are composed of primitive vascular elements and are rare, accounting for 1% to 2% of all intracranial neoplasms. They occur at all ages, but young and middle-aged adults are more frequently afflicted. In children, they are almost as common in the posterior fossa as are meningiomas. Symptoms are generally present for approximately a year before the diagnosis is made. Male incidence predominates. *Von Hippel-Lindau disease* is defined by the coexistence of hemangioblastoma and multiple angiomas of the retina, cysts of the kidney and pancreas, and, occasionally, renal cell carcinomas, and capillary nevi of the skin. There is a familial incidence in 20% of cases. Only 10% to 20% of the hemangioblastomas, however, are associated with the systemic signs known as the *Lindau syndrome*. All gradations of clinical expression between the full syndrome and incomplete manifestations may be seen in the same family. Associated with these disorders are pheochromocytoma, syringomyelia, and polycythemia (which disappear after resection of the neoplasm but returns with recurrence).

Hemangioblastomas occur predominantly in the cerebellum and are often associated with large cysts that are surrounded by a glial wall containing yellow proteinaceous fluid, the result of secretion, and hemorrhage from the tumor. It resembles the cyst and mural nodule of the cystic cerebellar astrocytoma but has a distinctive vascular appearance on an angiogram. They may be multiple, in which case difficulty in achieving a cure or total removal of the lesion may be encountered. They have no dural attachment.

Hemangioblastoma can also occur in the spinal cord or in the medulla in the area postrema. They rarely occur in the supratentorial area, where they may be confused with angioblastic meningiomas.

Clinical features of the hemangioblastoma of the cerebellum are symptoms typical of any cerebellar mass, such as headache, papilledema, and ataxia. When the tumor is multiple, lesions may involve the brain stem and upper cervical cord as well. Spinal cord hemangioblastomas are often associated with syrinx formation.

Hemangioblastoma of the cerebellum can be diagnosed without difficulty with MRI and angiography. The diagnosis is even more certain when the tumor is associated with angiomas of the retina and polycythemia. Treatment is surgical, with evacuation of the cyst and removal of the mural nodule; 85% of all patients who undergo this treatment are alive and well 5 to 20 years after surgery. There is a high incidence of recurrence, however, if the tumor is partially removed or is associated with multiple tumors.

ANGIOBLASTIC MENINGIOMA AND HEMANGIOPERICYTOMA

Angioblastic meningioma is grossly identical to other meningiomas but has a significant dural attachment and is located either above or below the tentorium. *Hemangiopericytoma* originates in other areas of the body, presumably from blood vessel elements.

Central Nervous System Vasculitis

Fawaz Al-Mufti

Stephan A. Mayer

INTRODUCTION

Vasculitis affecting the central or peripheral nervous system often presents major diagnostic and therapeutic challenges for physicians because of its variable clinical manifestations and the lack of specific diagnostic tests other than biopsy. Central nervous system (CNS) vasculitis comprises a heterogeneous group of inflammatory diseases that affect leptomeningeal and parenchymal blood vessels of the brain with different but frequently overlapping clinical and pathologic manifestations.

The histopathologic changes of CNS vasculitis essentially consist of an inflammatory infiltrate within the vessel wall associated with necrosis, vessel occlusion and infarction, and in some cases, hemorrhage. The cases of CNS vasculitis are protean: It may occur as an idiopathic primary autoimmune process or within the context of systemic autoimmune disease, as a reaction to an infection such as varicella-zoster or a neurodegenerative process such as amyloid angiopathy, after drug exposure (e.g., cocaine), as a manifestation of radiation exposure, and in the setting of malignancy. Although the precise pathogenesis often remains obscure, in all cases, the immune system plays a central role, and immunosuppressive agents are the cornerstones of treatment.

There are several different classifications for CNS vasculitis. Some classifications are based on the size of the affected vessels (small, medium, large), whereas other classifications are based on histologic features (e.g., granulomatous, lymphomatous, or leukocytoclastic inflammation) or immunologic markers (e.g., the association with antineutrophil cytoplasmic antibodies, or ANCAs, with some forms of vasculitis). CNS vasculitis can also be further broadly classified into primary and secondary vasculitis depending on whether the process is confined to the CNS or is part of a systemic illness.

In 2012, the International Chapel Hill Consensus Conference proposed a revised nomenclature system that groups different vasculitides by taking in consideration multiple factors including size of vessels and whether the vasculitis involves a single organ or is part of a more systemic condition ([Table 42.1](#)).

PRIMARY ANGIITIS OF THE CENTRAL NERVOUS SYSTEM

Primary angiitis of the central nervous system (PACNS) is associated with select inflammation and destruction of small- and medium-sized arteries of the brain parenchyma, spinal cord, and leptomeninges, resulting in symptoms and signs of CNS dysfunction. The term *angiitis* is synonymous with vasculitis and refers to involvement of blood vessels on both the arterial and venous sides of the circulation. PACNS is also frequently referred to as *primary central nervous system vasculitis*.

EPIDEMIOLOGY

The annual incidence rate of PACNS is 2.4 cases per 1 million person-years. The disease affects patients of all ages, peaking at 50 years of age, with a 2:1 male predominance.

PATHOBIOLOGY

The etiology and pathogenesis of PACNS is unknown. Infectious agents such as herpes zoster virus, West Nile virus, and varicellazoster virus have been proposed as possible causes or triggers.

Three main histopathologic patterns are generally seen: granulomatous, lymphocytic, and necrotizing vasculitis. In lymphocytic PACNS, immunohistochemical staining reveals predominant infiltration by memory T cells in and around small cerebral vessels, signifying an antigen-specific immune response occurring in the wall of cerebral arteries.

CLINICAL FEATURES

Due to diffuse involvement of the CNS, the clinical manifestations are variable and nonspecific, with a clinical course ranging from hyperacute to stepwise to chronic and insidious. Mental obtundation and decreased cognition are the most frequent clinical presentations, usually evolving subacutely as a progressive encephalopathy. Other symptoms may include headaches, seizures, and focal neurologic deficits due to ischemic stroke or cerebral hemorrhage. Signs and symptoms of systemic vasculitis, such as peripheral neuropathy, fever, weight loss, or rash, are by definition lacking in PACNS.

DIAGNOSIS

On the basis of clinical experience and evidence from published work, Calabrese and Mallek proposed a set of criteria for the diagnosis of PACNS; the diagnosis is established when all three of the following criteria are met ([Table 42.2](#)).

There is no specific laboratory diagnostic test for PACNS, although routine laboratory testing, serologic evaluations, lumbar puncture results, neuroimaging studies, cerebral angiography, and brain biopsy may all have roles in the evaluation ([Table 42.3](#)). Acute phase reactants such as the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are usually normal in PACNS; elevated levels should raise suspicion of systemic involvement by either an infectious, malignant, or inflammatory process. Both serologic testing and analyses of the cerebrospinal fluid (CSF) are important for excluding secondary causes of CNS dysfunction that may mimic PACNS. Nonspecific abnormalities, primarily leukocyte and protein elevations, are seen on CSF analysis in 80% to 90% of patients with pathologically documented disease.

Magnetic resonance imaging (MRI) typically shows multifocal small-vessel infarcts and hemorrhages of varying age ([Fig. 42.1](#)). These vascular lesions often involve structures that are not typically involved in conventional cerebrovascular disease, such as the corpus callosum. In some cases, large-vessel infarcts, convexity subarachnoid hemorrhage, or small foci of gadolinium enhancement can occur. It is extremely rare for PACNS to cause advanced disease with severe symptoms with a normal MRI.

The gold standard for the detection of vascular abnormalities is digital subtraction angiography. In PACNS, cerebral angiography

P.326

may show areas of ectasia and stenosis referred to as *beading circumferential* or *eccentric vessel irregularities* with sharp cutoffs, delayed arterial emptying, small arteriovenous anastomotic channels, and rarely, microaneurysms ([Fig. 42.2](#)). The main condition that PACNS must be differentiated from a patient with beading on diagnostic angiography is reversible cerebral vasoconstriction syndrome (RCVS), a much more benign condition discussed later in this chapter (see also [Chapter 43](#)). About 4% of patients with primary CNS vasculitis present with a solitary tumorlike mass lesion due to brain tissue inflammation. Given the poor resolution of computed tomography (CT) and magnetic resonance (MR) angiography for distal medium and small blood vessels, these tests have limited sensitivity for diagnosing PACNS.

TABLE 42.1 Vasculitis Syndromes: 2012 International Chapel Hill Consensus Conference

Syndromes	Pathologies
Large-Vessel Vasculitis	
Giant cell (temporal) arteritis	Granulomatous arteritis of aorta and its major branches; predilection for extracranial branches of carotid artery; often involves temporal artery; patients older than 50 years with polymyalgia rheumatica
Takayasu arteritis	Granulomatous arteritis of aorta and major branches; patients younger than age 50 years
Medium-Sized Vessel Vasculitis	
Polyarteritis nodosa	Necrotizing inflammation of medium- or small-sized arteries; no glomerulonephritis or vasculitis of arterioles, capillaries, venules
Kawasaki disease	Arteritis of large, medium-sized, small arteries plus mucocutaneous-lymph node syndrome; coronary arteries often involved; aorta and veins may be involved; usually in children
Small-Vessel Vasculitis	
Granulomatosis with polyangiitis (GPA) (Wegener granulomatosis)	Granulomatous inflammation including respiratory tract and necrotizing vasculitis of small to medium vessels (capillaries, venules, arterioles, arteries); necrotizing glomerulonephritis common
Eosinophilic granulomatosis with polyangiitis (EGPA) (Churg-Strauss syndrome)	Eosinophil-rich granulomatous inflammation of respiratory tract and necrotizing vasculitis of small- to medium-sized vessels; with asthma and eosinophilia
Microscopic polyangiitis (MPA)	Necrotizing vasculitis with few or no immune deposits; affects small vessels (capillaries, venules, arterioles); may involve small- and medium-sized arteries; common features: necrotizing glomerulonephritis and involvement of pulmonary capillaries
IgA vasculitis (IgAV) (Henoch-Schönlein purpura)	Vasculitis with IgA-dominant immune deposits on small vessels (capillaries, venules, arterioles); affects skin, gut, and glomeruli plus arthritis or arthralgia

Cryoglobulinemic vasculitis	Vasculitis with immune deposits on small vessels (capillaries, venules, arterioles); cryoglobulins in serum; skin and glomeruli often involved
Variable-Vessel Vasculitis (VV)	
Behçet disease (BD)	Vasculitis that can affect arteries or veins accompanied by cutaneous, ocular, articular, gastrointestinal, and/or central nervous system inflammatory lesions
Cogan syndrome (CS)	Arteritis (affecting small, medium, or large arteries), aortitis, aortic aneurysms, and aortic and mitral valvulitis accompanied by ocular inflammatory lesions, including interstitial keratitis, uveitis, and episcleritis, and inner ear disease, including sensorineural hearing loss and vestibular dysfunction
Vasculitis associated with systemic disease	Vasculitis that is associated with and may be secondary to (caused by) a systemic disease (e.g., rheumatoid vasculitis, lupus vasculitis)
Vasculitis associated with probable etiology	Vasculitis that is associated with a probable specific etiology (e.g., hydralazine-associated microscopic polyangiitis, hepatitis B virus-associated vasculitis, hepatitis C virus-associated cryoglobulinemic vasculitis, etc.)

IgA, immunoglobulin A
Modified from Jennette JC, Falk RJ, Bacon PA, et al. 2012 revised International Chapel Hill Consensus Conference nomenclature of vasculitides. *Arthritis Rheum.* 2013;65(1):1-11

TABLE 42.2 Diagnostic Criteria for Primary Angiitis of the Central Nervous System

- History or clinical findings of an acquired neurologic deficit of unknown origin after a thorough initial basic assessment
- Cerebral angiography reveals classic features of vasculitis, or a CNS biopsy sample shows vasculitis.
- There is no evidence of systemic vasculitis or any other disorder to which the angiographic or pathologic features can be attributed to.

CNS, central nervous system.

TABLE 42.3 Suggested Laboratory Testing for Central Nervous System Vasculitis

Basic Laboratory Testing

Complete blood count with differential

Serum urea nitrogen and creatinine

Serum aspartate and alanine aminotransferases

ESR and C-reactive protein

Urinalysis

CSF Studies

Cell count (mild to moderate CSF pleocytosis)

CSF protein (range 44-1,034 mg/dL) CSF glucose (usually normal)

Oligoclonal bands

Gram stain and cultures

Cytology and flow cytometry when malignancy is suspected

PCR and IgG, IgM directed at infectious sources (below)

Specialized Laboratory Testing

Antinuclear antibodies

Rheumatoid factor

Antibodies to the Ro/SSA, La/SSB, Sm, and RNP antigens

Antibodies to double-stranded DNA

Antineutrophil cytoplasmic antibodies (ANCA)

Serum C3 and C4

Serum cryoglobulins

Serum and urine protein electrophoresis with immune electrophoresis

Quantitative immunoglobulin levels (IgG, IgM, IgA)

Infectious Etiologies (in appropriate circumstances as indicated)

Bacterial—*Mycoplasma* PCR and serology, antistreptolysin O test (ASOT), syphilis serology, Mantoux skin test

Viral—serology for hepatitis B and C, parvovirus B19, HIV, herpes simplex virus, Epstein-Barr virus (EBV), cytomegalovirus (CMV), varicella

Fungal culture (*Aspergillus*, *Coccidioides*, and *Histoplasma* species)

Parasite: serum anticysticercal antibodies demonstrated by immunoblot assay and CSF ELISA for detection of anticysticercal antibodies or cysticercal antigens

Thrombophilia Investigations

Prolonged activated partial thromboplastin time (aPTT), which does not correct with mixing

Screening for lupus anticoagulant

Anticardiolipin antibody by ELISA

Anti- β 2-microglobulin-1 antibody by ELISA

ESR, erythrocyte sedimentation rate; CSF, cerebrospinal fluid; PCR, polymerase chain reaction; IgG, immunoglobulin G; IgM, immunoglobulin M; IgA, immunoglobulin A; ELISA, enzyme-linked immunosorbent assay.

FIGURE 42.1 Fluid-attenuated inversion recovery (FLAIR) MRI showing multifocal infarcts in a patient with biopsy-proven PACNS.

FIGURE 42.2 Typical angiographic findings in a patient with central nervous system vasculitis. *Arrows point to areas of alternating stenosis and ectasia.* (From Hajj-Ali RA, Ghamande S, Calabrese LH, et al. Central nervous system vasculitis in the intensive care unit. *Crit Care Clin.* 2002;18:897-914).

P.328

Arteries with diameter below 0.4 mm, arterioles, and capillaries are beyond the resolution of conventional angiography, and because PACNS often involves small blood vessels, the sensitivity of angiography in biopsy-proven PACNS cases is only 60%. Thus, a negative angiogram cannot exclude the diagnosis of PACNS. Furthermore, cerebral angiography has limited specificity since not infrequently, patients with angiographic findings interpreted as being positive for vasculitis are not found to have vasculitic changes at brain biopsy. It should be noted that normal biopsy specimens may reflect sample error due to the patchy distribution of inflammation. The false-negative rate of an initial biopsy is 25%; in some cases, two or more biopsies are necessary to establish the diagnosis. The yield of biopsy is improved with larger tissue blocks (i.e., 1 cm³) with inclusion of the overlying meninges and when areas affected with enhancement on MRI are targeted.

TREATMENT

No randomized clinical trials of medical management for PACNS exist. First-line therapy usually starts with glucocorticoids. Fulminant PACNS in hospitalized patients usually starts with empiric intravenous *methylprednisolone*, 15 mg/kg/day for 3 to 5 days, followed by *prednisone*, 1 mg/kg/day to a maximum of 100 mg/day. Less severe disease in outpatients can be started on *prednisone* alone. Glucocorticoids should be continued at the initial dose for 4 to 6 weeks after which a slow taper should be initiated.

Patients with biopsy-confirmed granulomatous variant PACNS should be started on a combination of glucocorticoids and *cyclophosphamide*. *Cyclophosphamide* is given in order to induce remission in either a daily oral regimen (1.5 to 2 mg/kg/day) or a monthly intravenous regimen (600 to 750 mg/m², infused once a month). After induction of remission, typically in 3 to 6 months, *cyclophosphamide* therapy is switched to maintenance therapy with other agents such as mycophenolate mofetil or azathioprine.

In patients with lymphocytic variant PACNS or those in whom the diagnosis is performed by cerebral angiogram and not confirmed by biopsy, an initial glucocorticoid treatment is only followed by *cyclophosphamide* if the neurologic decline is progressive. As a general rule, chemotherapeutic immunosuppressant therapy should only be given to patients with biopsy-proven PACNS.

Treatment response is monitored by periodic reassessment of symptoms and neuroimaging abnormalities. A follow-up MRI should be obtained 4 to 6 weeks after beginning treatment, then every 3 to 6 months throughout therapy, and subsequently according to the evolution of the disease to assess for progression of the disease.

OUTCOME

Earlier descriptions characterized PACNS as a fatal disease, and most cases were diagnosed at autopsy. With better understanding of the disease and with aggressive immunosuppression, more favorable outcomes and improving mortality rate have been reported. Recent reports indicate that the short-term mortality rate is 10% and that 20% suffer severe functional impairment. Mild cognitive deficits and reduced energy level remain common among those with a good functional recovery. Approximately 30% of patients experience a relapse of the disease after going into remission, which requires reescalation of immunosuppression.

AMYLOID β -RELATED ANGIITIS

Amyloid β -related angiitis (ABRA) is a form of CNS vasculitis in which perivascular β -amyloid is thought to act as a trigger for inflammation mediated by CD68+ macrophages and CD3+ T lymphocytes. The condition develops in patients with symptomatic or asymptomatic amyloid angiopathy (see also [Chapter 38](#)), which presents as dementia, gait disorder, and progressive brain hemorrhages (both microbleeds and parenchymal intracerebral hemorrhage). Patients with ABRA often exhibit altered mental status and respond to immunosuppressive treatment. Common CSF findings include an elevated protein and a lymphocytic pleocytosis. MRI often demonstrates T2 hyperintense lesions extending through the cortical white matter and often gray matter, suggestive of breakdown of the blood-brain barrier and a reversible leukoencephalopathy. Cerebral angiography shows beading in a minority of patients, perhaps due to involvement of exclusively medium- and small-sized vessels. In every case on brain biopsy, microglia, macrophages, and T cells surround amyloid-laden vessels. After initiating antiinflammatory treatment consisting of steroids or *cyclophosphamide* for a duration ranging from 2 weeks to several months, a majority of patients with ABRA show improvement. However, some patients

relapse, and other patients do not improve or progressively decline.

CENTRAL NERVOUS SYSTEM VASCULITIS ASSOCIATED WITH SYSTEMIC VASCULITIS

GIANT CELL (TEMPORAL) ARTERITIS

Giant cell arteritis (GCA), also known as *temporal arteritis* because of its predilection for superficial temporal artery involvement, is a large-vessel granulomatous vasculitis. The disease usually affects the aorta or its major branches, with a predilection for the branches of the cervical internal and external carotid arteries and the vertebral arteries. The intracranial vessels are generally spared. GCA is often linked with polymyalgia rheumatica in terms of its systemic manifestations, ESR elevation, and response to steroid therapy.

Epidemiology

GCA has an annual incidence that is highest among white individuals, ranging between 10 and 20 cases per 100,000 among persons older than 50 years of age. The incidence is markedly lower in persons of Asian or African descent in the range of 1 case per 100,000. Although GCA almost never occurs before age 50 years, the incidence increases thereafter, reaching its peak incidence between the ages of 70 and 80 years.

Pathobiology

Although the etiology of GCA is unknown, there appears to be an interplay between increasing age, a genetic predisposition, and infectious triggers that involves both the cellular and humoral immune system, resulting in an acute vascular inflammatory state. Current literature regarding the molecular basis of GCA suggests that activated dendritic cells, residing in the vessel wall, play an important role in the pathophysiology by initiating the pathogenic cascade, recruiting T cells and macrophages to form granulomatous infiltrates.

GCA is a panarteritis, including all the arterial layers. Thrombosis may develop at sites of active inflammation. Fibrosis, scarring, and narrowing or occlusion of the arteries develops secondary to the inflammation, tissue injury, and repair process.

Clinical Manifestations

GCA is classically characterized by a combination of five features:

1. Age older than 50 years,
2. A localized new-onset headache,
3. Tenderness over the temporal artery,
4. An elevated ESR (≥ 50 mm/h), and
5. Biopsy revealing a necrotizing arteritis with a predominance of mononuclear cells or a granulomatous process with multinucleated giant cells.

P.329

The presence of three of the above five criteria is associated with 94% sensitivity and 91% specificity for the diagnosis of GCA. GCA typically presents with a constellation of constitutional symptoms, headache and tenderness over the temporal artery, jaw claudication, visual symptoms, and symptoms of polymyalgia rheumatica (diffuse myalgias and body aches). Because intracranial vascular involvement is rare in GCA, transient ischemic attacks (TIAs) and stroke are usually secondary to embolism or flow failure related to cervical vertebral or internal carotid lesions.

Neurologic manifestations arise in approximately 30% of patients, with more than half being peripheral

neuropathies, followed by one-third with TIA or stroke, one-third with ophthalmologic symptoms, and one-fifth with neuro-otologic syndromes. Ophthalmologic symptoms can include transient monocular blindness (i.e., retinal TIA or amaurosis fugax) due to internal carotid artery stenosis or sustained unilateral visual loss due to anterior ischemic optic neuropathy or occlusion of the central retinal artery (see also [Chapter 9](#)).

Diagnosis

Tests to rule out CNS vasculitis should be performed as delineated in [Table 42.3](#). The classic diagnostic screening test is an ESR, which is elevated in nearly all patients. CRP levels are also elevated, and CRP tends to correlate than ESR with GCA disease activity. Interleukin-6 levels may be used to evaluate disease progression, although this is investigational at this point.

Temporal artery biopsy, evidencing vasculitis with predominance of mononuclear cell infiltration or granulomatous inflammation, usually with multinucleated giant cells, is the gold standard for the diagnosis of GCA. A negative initial temporal artery biopsy may be present and occurs in up to 40% of patients with suspected of GCA. This may be due to sampling error due to skip lesions, biopsy, or attainment of too small a specimen (<2 cm). In the presence of a high index of suspicion, a contralateral biopsy should be performed if the first biopsy is negative. If bilateral temporal artery biopsies are negative, alternate artery biopsy sites should be considered.

Treatment

Treatment recommendations for GCA are based on clinical experience rather than the results of randomized controlled trials with most cases being managed effectively with glucocorticoid monotherapy. Induction therapy with *prednisone* at a dose of 1 mg/kg of body weight per day (maximum of 60 mg/day) is initiated in patients who lack symptoms or signs of ischemic organ damage (e.g., visual loss).

Patients with signs and symptoms suggestive of compromised blood flow to the eyes or the CNS should be managed with *methylprednisolone* at a dose of 1,000 mg/day for 3 consecutive days to more rapidly induce immunosuppression. This is then followed by oral therapy with 1 mg per kilogram of body weight per day (maximum of 60 mg/day) as recommended earlier for uncomplicated GCA. Once tissue necrosis occurs (e.g., optic nerve ischemia with blindness for several hours), it is irreversible.

Treatment initiation for suspected GCA with neurologic involvement should never be delayed until the biopsy is obtained because resolution of the inflammation occurs slowly after the start of treatment and a confirmed pathologic diagnosis can take several weeks or even months to attain.

Despite lack of prospective trials, anecdotal reports suggest some beneficial effects with glucocorticoid-sparing therapies such as *methotrexate*, *cyclophosphamide*, and *tocilizumab* (interleukin-6 receptor antagonist). These therapies may be considered in patients at highest risk of experiencing glucocorticoid-related side effects.

Once clinical signs have subsided and laboratory values have normalized, steroids can be tapered by 10 mg/kg every 2 to 4 weeks, with a substantial slowing of the taper to 1 mg decrements per month once the daily dose of 10 mg is reached. Expert consensus also recommends the addition of *acetylsalicylic acid* (ASA) (75 to 150 mg/day) to reduce the risk of ischemic complications such as visual loss, TIAs, or stroke.

Outcome

GCA tends to run a self-limited course over several months to several years. Rapid clinical improvement following the initiation of treatment is typical. The glucocorticoid dose can eventually be reduced or

discontinued with the average duration of treatment being 2 to 3 years. Fatalities are rare.

POLYARTERITIS NODOSA

Polyarteritis nodosa (PAN) is a systemic necrotizing small- and medium-sized arteritis sparing the arterioles, capillaries, and venules. ANCA are typically negative in PAN; this is important in differentiating it from ANCA-associated vasculitis, which can present almost indistinguishably, both clinically and pathologically.

Epidemiology

PAN is a rare disease occurring in two per million people, with about 25% of cases involving the CNS. Men and women are affected equally. The disease may occur at any age, but the peak incidence is in the fourth to sixth decades of life. With the advent of hepatitis B vaccination, the incidence of hepatitis B virus (HBV)-associated PAN is declining.

Pathobiology

The etiology of PAN remains unknown; immune complex deposition, antigen-specific T-cell-mediated immune responses and reactions to bacterial or viral infection have been postulated. Hepatitis B has been identified as one of the most common triggers for a subset of PAN; this form of arteritis may be monophasic with a good prognosis. PAN has also been reported with hepatitis C virus (HCV), cytomegalovirus (CMV), HIV, and parvovirus B19.

Vascular inflammatory lesions in PAN are segmental and predominate in branching points of small- and medium-sized arteries. Small vessels, including arterioles, capillaries, and venules, are characteristically spared, as are large vessels (the aorta and its major branches). Consequently, glomerulonephritis is not part of the spectrum of PAN. Vessel inflammation starts in the adventitia and vasa vasorum may subsequently progress to include the entire arterial wall, resulting in fibrinoid necrosis. At bifurcations and branch points, multiple small aneurysms can form, and at later stages, angiogenesis becomes apparent. As these lesions progress, they may rupture or occlude the vessel, resulting in hemorrhage or infarction. Vessel biopsies typically show acute necrotizing lesions intermixed with more chronic fibrotic or healing changes, representing different stages of the inflammatory process.

P.330

Clinical Manifestations

The ubiquitous nature of PAN allows for the diverse clinical manifestations, ranging from more chronic, insidious symptoms to acute, life-threatening complications. Nonspecific constitutional manifestations are common early in the course.

Peripheral neuropathy, in the form of mononeuritis multiplex or diffuse sensorimotor peripheral neuropathy, is the most common neurologic disorder. Involvement of the CNS occurs in fewer than 10% of patients with PAN. CNS manifestations range from headache, retinopathy, and encephalopathy with seizures and cognitive decline to cerebral infarction and intracerebral hemorrhage due to involvement of medium-sized vessels. Other symptoms may arise from affection of the cranial nerves or the spinal cord.

Cutaneous hemorrhages, tender erythematous eruptions, subcutaneous nodules, and necrotic ulcers may appear on the trunk or limbs. Variable degrees of renal insufficiency and hypertension may develop secondary to tissue infarction and hematoma formation secondary to rupture of renal microaneurysms. Furthermore, gastrointestinal, hepatic, testicular, or cardiac symptoms may develop.

Diagnosis

The diagnosis of PAN should be considered in all patients with an obscure febrile illness marked by systemic symptoms and chronic peripheral neuropathy. According to the American College of Rheumatology 1990 consensus criteria for the classification of PAN, the diagnosis is 82% sensitive and 87% specific in a patient with systemic vasculitis if there are more than 3 of the following 10 criteria: weight loss (≥ 4 kg), livedo reticularis, testicular pain or tenderness, myalgia, mononeuritis multiplex or other polyneuropathy, hypertension, azotemia, HBV antibody, angiographic occlusion of visceral arteries, or biopsy evidence of granulocytes in vessel wall.

The diagnosis can often be established by biopsy of sural nerve, muscle, or testicle. A high index of suspicion is crucial to diagnose PAN. Basic laboratory tests, liver function studies, and hepatitis (HBV and HCV) serologies help rule out potential etiologies and ascertain the extent of organs affected and their degree of involvement. Acute-phase proteins are typically elevated. There is a leukocytosis with inconstant eosinophilia. Additional specialized autoimmune laboratory testing is valuable in narrowing the differential diagnosis (see [Table 42.3](#)). The presence of myeloperoxidase (MPO) ANCA or proteinase 3 (PR3) ANCA antibodies strongly argues against PAN and in favor of one of the ANCA-associated vasculitides.

Treatment

There is no specific therapy. Treatment varies according to the severity of the disease state ranging from high doses of corticosteroids in milder disease forms to a combination of corticosteroids and immunosuppressive drugs (*azathioprine*, *methotrexate*, or *cyclophosphamide*). Patients with mild PAN and evidence of infection with HBV or HCV should receive antivirals, whereas those with severe hepatitis virus-associated PAN, short-term treatment corticosteroids, and plasma exchange maybe considered until antiviral therapy becomes effective. Plasma exchange may have a role in the acute management of HBV-associated PAN.

Outcome

Untreated PAN is associated with a poor prognosis. The French Vasculitis Study Group described the 1- and 5-year relapse rates for patients with non-HBV-associated PAN as 9.2% and 24%, respectively; the relapse rates for HBV-associated PAN were lower. Most deaths occur within 18 months of disease onset primarily due to renal failure and mesenteric, cardiac, or cerebral infarctions.

BEHÇET SYNDROME

Behçet syndrome is a chronic, multisystem vessel vasculitis that has no predilection to the type or size of vessel. Neurologic involvement occurs in about one in five patients.

Epidemiology

Behçet syndrome is most common in the Middle East and Eastern Asia with prevalence ranges from 13.5 to 35 per 100,000. In North American and Northern European countries, the prevalence is from 1 to 7 per 100,000. There is no gender predilection; the disease typically affects young adults 20 to 40 years of age.

Pathobiology

The exact cause is unknown, but there is increasing evidence that an underlying immune-mediated vasculitis underlies the mucocutaneous lesions. Although vasculitic changes may not be demonstrated in all lesions, the classic finding is a necrotizing leukocytoclastic obliterative perivasculitis with fibrinoid necrosis of postcapillary

venules. Venous thrombosis with lymphocytic infiltration of capillaries, veins, and arteries of all sizes may also be visible. It has been reported that those with active Behçet syndrome have elevated serum levels of several proinflammatory cytokines, perhaps as a result of an aberrant immune reaction due to infectious or environmental pathogens. Numerous reports have found a strong genetic predisposition to develop Behçet disease among those with the HLA-B51 major histocompatibility complex subtype.

Clinical Manifestations

Behçet syndrome is characterized by uveitis and recurrent oral and genital aphthous ulcers. Other manifestations include ocular, cutaneous, joint, gastrointestinal, or CNS inflammatory lesions. Smallvessel vasculitis, thromboangiitis, vessel thrombosis, arteritis, and arterial aneurysms may occur. CNS involvement is present in 20% of patients and can be subdivided into parenchymal (inflammation of the CNS tissue) or nonparenchymal (vascular neuro-Behçet).

Parenchymal disease may be due to lesions in the corticospinal tract, periventricular white matter, basal ganglia, brain stem, and spinal cord. Clinical presentations are often subacute and manifestations may include headache, behavior changes, encephalopathy, acute meningeal syndromes, hemiparesis, hemisensory loss, seizures, cranial neuropathies, cerebellar dysfunction, alterations in mental status, and optic neuropathy. Spinal cord lesions may occur in isolation. Vascular manifestations may include diffuse vasculitis, venous sinus thrombosis, and uncommonly stroke due to arterial thrombosis, dissection, or aneurysm. In contrast to other systemic vasculitides, peripheral neuropathy is not commonly seen in Behçet syndrome.

Diagnosis

Due to the lack of a specific diagnostic laboratory test, the diagnosis is made based on clinical criteria. The Behçet International Study Group (ISG) criteria and the International Criteria for Behçet's Disease (ICBD) both require the presence of recurrent oral ulcers in addition to a constellation of recurrent genital ulcers, eye lesions (anterior or posterior uveitis or retinal vasculitis), or skin lesions (including erythema nodosum, pseudovasculitis, papulopustular lesions, or acneiform nodules consistent with Behçet). The ICBD

P.331

also adds the presence of vascular lesions (superficial phlebitis, deep vein thrombosis, arterial thrombosis, or aneurysm formation) to the diagnostic criteria. Nonspecific markers of inflammation such as proinflammatory cytokines, circulating immune complexes, CSR, and the ESR may be elevated.

Treatment

Treatment is dependent on the severity of the disease and the organ systems involved. Glucocorticoids or other immunosuppressive agents should be considered for treatment of erythema nodosum and pyoderma gangrenosum. Posterior uveitis and neurologic involvement requires prompt treatment with both high-dose glucocorticoids and a second immunosuppressive agent (*azathioprine, tumor necrosis factor [TNF]-alpha inhibitors, cyclosporine, interferon alpha, cyclophosphamide, and methotrexate*).

Outcome

Behçet syndrome typically has a relapsing and remitting course. Delay in diagnosis and treatment increases morbidity and mortality. The greatest morbidity and mortality comes from neurologic, ocular, and large-vessel arterial or venous disease. Mucocutaneous, articular, and ocular diseases are often at their worst in the early years of disease; CNS and large-vessel involvement tends to develop later in the disease course.

Patients with parenchymal CNS involvement have a worse outcome than patients with nonparenchymal vascular involvement, with more frequent recurrent disease, disability, and premature death.

THE ANTINEUTROPHIL CYTOPLASMIC ANTIBODY-POSITIVE VASCULITIDES

ANCA vasculitis is a group of necrotizing small-vessel vasculitides predominantly affecting small vessels (i.e., capillaries, venules, arterioles, and small arteries). ANCA antibodies (usually immunoglobulin G [IgG]) react against antigens in the cytoplasm of neutrophil granulocytes. Specific subtypes of ANCA are based on immunofluorescence patterns and target antigens. Cytoplasmic antineutrophil cytoplasmic antibody (c-ANCA) is directed specifically at proteinase 3 (PR3). Perinuclear antineutrophil cytoplasmic antibody (p-ANCA) antigens include MPO and bacterial permeability increasing (BPI) factor.

The ANCA-associated vasculitides include the following:

1. Granulomatosis with polyangiitis (formerly known as *Wegener granulomatosis*),
2. Microscopic polyangiitis,
3. Eosinophilic granulomatosis with polyangiitis (formerly *Churg-Strauss syndrome*),
4. Renal-limited vasculitis, and
5. Drug-induced vasculitis.

All are associated with ANCAs and a focal necrotizing, often crescentic, pauci-immune glomerulonephritis. The presence or absence of ANCA antibodies does not indicate presence or absence of disease. ANCA is highly correlated with the conditions described in the following sections, but not all patients with the condition test positive for the antibody. The association of ANCA positivity and disease activity remains controversial; however, the reappearance of ANCA after treatment can indicate a relapse.

Granulomatosis with Polyangiitis

The hallmarks of granulomatosis with polyangiitis (GPA), formerly known as *Wegener granulomatosis*, are necrotizing granulomatous inflammation involving the upper and lower respiratory tract, necrotizing glomerulonephritis, and systemic necrotizing vasculitis affecting predominantly small to medium vessels (e.g., capillaries, venules, arterioles, arteries, and veins).

EPIDEMIOLOGY

The annual incidence of GPA is 5 to 10 cases per million population equally affecting males and females between the ages of 65 and 70 years. GPA affects Caucasians more than Asians, Africans, and the Afro-Caribbean and African-American populations.

PATHOBIOLOGY

The immunopathobiology of GPA is complex and involves the generation of ANCA against PR3 in approximately 50% to 80% of GPA patients and against MPO in approximately 10% to 18% of GPA patients. GPA is believed to develop following exposure to infectious (bacterial, mycobacterial, fungal, or viral infections of the upper respiratory tract), environmental, chemical, toxic, or pharmacologic triggers in genetically predisposed individuals who lack tolerance to ANCA self-antigens.

CLINICAL MANIFESTATIONS

Prodromal symptoms may last for weeks to months with constitutional symptoms including fever, migratory arthralgias, malaise, anorexia, and weight loss. GPA has a predilection for the respiratory system and kidneys.

According to criteria of the American Academy of Rheumatology, the diagnosis can be made if there are two of the following four criteria:

1. Oral ulcers or purulent bloody nasal discharge;
2. Abnormal chest film showing nodules, fixed infiltrates, or cavities;
3. Microscopic hematuria; or
4. Biopsy evidence of granulomatous inflammation in the wall of an artery or perivascular tissue.

As with other vasculitic syndromes, GPA affects the peripheral nervous system in the form of a sensorimotor peripheral neuropathy (mononeuritis multiplex) more than the CNS. The CNS is affected in less than 10% of patients. In such cases, intracranial granuloma may arise following direct invasion from the nasal cavity and in turn involvement of the basal cranial nerves. Additionally, aseptic meningeal necrotizing granulomas, encephalopathy, or vasculitis with secondary stroke or venous sinus thrombosis may occur.

DIAGNOSIS

Approximately 90% of patients are ANCA positive and 10% of patients are ANCA negative. The definitive diagnosis is made by biopsy of an affected organ (generally skin, kidney, or lung).

In patients with neurologic manifestations, involvement of the dura with pachymeningitis may be detected on MRI after contrast administration. Because the caliber of the affected vessels may be beyond the spatial resolution of digital subtraction angiography, radiologic confirmation of CNS vasculitis in Wegener granulomatosis is rare. Nerve biopsies may show arteritis in patients with polyneuropathy and no signs of systemic disease.

TREATMENT

Patients should be treated empirically if the clinical suspicion for ANCA vasculitis is high and a tissue diagnosis cannot be obtained in a timely manner. Therapy of GPA has two components: induc

P.332

tion of remission and maintenance using immunosuppressive therapy. Patients with mild disease lacking active glomerulonephritis and organ-threatening or life-threatening manifestations may be treated with a regimen of glucocorticoids in combination with *methotrexate*. Patients with moderate to severe disease who are at imminent risk for organ damage or who have life-threatening manifestations should receive a regimen consisting of glucocorticoids in combination with either *cyclophosphamide* (oral or intravenous) or *rituximab*. Plasma exchange is reserved for patients with GPA or microscopic polyangiitis who have one or more of the following: pulmonary hemorrhage, a positive antglomerular basement membrane antibody, a serum creatinine more than 5.7 mg/dL, and/or requiring dialysis.

OUTCOME

Long-term survival with GPA is improved with immunosuppression, and the natural history of this disease has transformed from being an imminently life-threatening condition to a chronic condition prone to relapse throughout life. Left untreated, approximately 90% of patients will experience severe morbidity or mortality within 2 years. Even with aggressive treatment, GPA continues to be associated with morbidity due to chronic renal, pulmonary, or CNS failure, which affects 12% to 25% of patients within 10 years. Death is generally due to irreversible organ dysfunction and progressive renal failure.

Microscopic Polyangiitis

In microscopic polyangiitis (MPA), a necrotizing vasculitis with few or no immune deposits predominantly affects small vessels (i.e., capillaries, venules, or arterioles) throughout the body. Necrotizing glomerulonephritis is very common, pulmonary capillaritis is common, and neurologic involvement occurs in about half of cases. Granulomatous inflammation is absent.

EPIDEMIOLOGY

The exact incidence and prevalence of MPA are unknown, although the incidence has been estimated to be in the range of six cases per million population affecting men slightly more than women, with an age range of 60 to 65 years.

PATHOBIOLOGY

As with GPA, the immunopathobiology of MPA is complex; there is increasing evidence that MPA is an autoimmune disease, with ANCA antibodies positive in 95% of cases. The pathophysiology involves the generation of ANCA against MPO in approximately 70% and against PR3 in 30% of MPA patients. ANCA, directed against MPO and PR3, activates neutrophils to produce reactive oxygen species and release lytic enzymes causing the detachment and destruction of endothelial cells contributing to the pathophysiology.

CLINICAL MANIFESTATIONS

As with all other systemic vasculitides, multiple organs are affected with MPA, primarily the kidneys in 90% of cases and less frequently the lungs. Renal involvement is manifested by microscopic hematuria and rapidly progressive glomerulonephritis; 10% progress to end-stage renal disease requiring renal replacement therapy. Pulmonary manifestations range from dyspnea, cough, and hemoptysis to pulmonary hemorrhages, secondary to pulmonary capillaritis, which can be life threatening. In contrast to GPA, MPA lacks granulomatous inflammation and involvement of the upper respiratory tract. The nervous system is involved in 50% of cases, with polyneuropathy or mononeuritis multiplex being the most common manifestation. Cerebral vasculitis resulting in tissue ischemia, hemorrhage, encephalopathy, and generalized or focal seizures can also occur.

DIAGNOSIS

Tests to rule out CNS vasculitis should be performed as delineated in [Table 42.3](#). Microscopic hematuria with cellular casts in the urine in addition to proteinuria may be demonstrated on urinalysis. An important diagnostic test is the presence of p-ANCA against with MPO or PR3. In patients with neuropathy, an electromyogram (EMG) may reveal a sensorimotor peripheral neuropathy.

TREATMENT AND OUTCOME

The treatment and outcome of MPA is generally the same as that for GPA, as described earlier.

Eosinophilic Granulomatosis with Polyangiitis

Eosinophilic granulomatosis with polyangiitis (EGPA), previously known as *Churg-Strauss syndrome*, is a multisystem disorder due to small-vessel vasculitis characterized by eosinophil-rich and necrotizing granulomatous inflammation often involving the respiratory tract and necrotizing vasculitis predominantly affecting small to medium blood vessels. Asthma and peripheral blood eosinophilia are other prominent features. Mononeuritis multiplex is the most common form of neurologic involvement.

EPIDEMIOLOGY

The exact incidence and prevalence of EGPA is unknown but it is rare: Estimates are in the range of 10 to 13 cases per million population. The mean age at diagnosis is 48 years without clear gender predominance. There is a higher incidence among asthmatics.

PATHOBIOLOGY

EGPA is classified among the ANCA-positive vasculitides with several characteristics pointing to an immunologic etiology, which include the presence of elevated Th1 and Th2 lymphocyte function, increased eosinophil recruitment, decreased eosinophil apoptosis, and altered humoral immunity in the form of hypergammaglobulinemia and rheumatoid factor positivity. Genetic factors appear to play a role in the pathogenesis as implicated by the association with HLA class and certain interleukin-10 polymorphisms. Histopathologically, EGPA was originally described as a pathologic triad consisting of (1) necrotizing giant cell vasculitis, (2) eosinophilic tissue infiltration, and (3) extravascular necrotizing granuloma formation, but these characteristics rarely coexist in any one patient. Nerve biopsy may demonstrate epineural necrotizing vasculitis with accompanying eosinophil and lymphocyte infiltrates.

CLINICAL MANIFESTATIONS

The American Academy of Rheumatology established six criteria for the diagnosis of EGPA in patients with documented vasculitis. These included the presence of (1) asthma, (2) eosinophilia, (3) a mononeuropathy or polyneuropathy, (4) migratory transient pulmonary opacities detected radiographically, (5) paranasal sinus abnormalities, and (6) biopsy containing a blood vessel showing eosinophil infiltrates in extravascular areas. The presence of four or more of these criteria had a sensitivity of 85% and a specificity of 99% for EGPA.

A peripheral neuropathy, usually mononeuritis multiplex, associated with severe neuropathic pain is seen in up to 75% of

P.333

patients; other neurologic manifestations may include subarachnoid and intracerebral parenchymal hemorrhage and cerebral infarction but these are rare.

DIAGNOSIS

A high index of suspicion is necessary for the diagnosis of EGPA. Tests to rule out CNS vasculitis should be performed (see [Table 42.3](#)). Most patients with EGPA have peripheral blood eosinophilia, although this may be obscured by use of systemic glucocorticoids to control asthma. ANCA is noted in 40% to 60% of EGPA patients with the majority being MPO ANCA. Typical findings on chest high-resolution CT include patchy parenchymal consolidation or ground-glass opacification; nodules may also be noted.

TREATMENT

Systemic glucocorticoids are the cornerstone in EGPA therapy and are usually continued for 6 to 12 weeks and then gradually tapered. *Prednisone* 60 mg daily is a typical starting dose. Patients with severe disease with CNS or cardiac involvement require induction with *cyclophosphamide* in combination with systemic glucocorticoid therapy. Induction is followed by a transition to maintenance therapy with azathioprine or methotrexate and leflunomide to induce disease remission over 12 to 18 months; longer courses are necessary for patients with multiple relapses.

OUTCOME

With the use of systemic glucocorticoids and immunomodulatory medication, the prognosis of EGPA has improved dramatically from a 50% mortality rate among untreated patients within 3 months of onset to a 70% to 90% 5-year survival rate with aggressive therapy. Death usually occurs secondary to cardiac failure, myocardial infarction, renal failure, cerebral hemorrhage, gastrointestinal bleeding, or status asthmaticus.

TABLE 42.4 Differentiating Primary Angiitis of the Central Nervous System (PACNS) and Reversible Cerebral Vasoconstriction Syndrome (RCVS)

	PACNS	RCVS
Gender predominance and mean age at onset	Male, 50 yr	Female, 40 yr
Onset and clinical presentation	Insidious with subacute to chronic onset of headache with focal and nonfocal deficit	Acute onset of thunderclap headache with or without neurologic deficit
Clinical course	Chronic, relapsing	Remission within 1 month, monophasic
Headache	Progressive, dull aching	Severe, throbbing, often thunderclap
CSF findings	Abnormal lymphocytic pleocytosis and elevated protein levels	Normal to near normal
Diagnosis	Leptomeningeal and brain parenchymal tissue biopsy necessary	No biopsy indicated
Common neuroimaging findings	Ischemic, high-intensity T2/FLAIR lesions abnormal MRI images in 100 % of cases	Ischemic, edema, convexity subarachnoid hemorrhage, ICH normal MRI images in 20% of cases
Vascular findings	Normal in one-third of cases. Diffuse abnormalities are often indistinguishable from RCVS; irregular and asymmetric arterial stenoses or multiple occlusions are more suggestive of PCNSV; abnormalities might be irreversible.	Abnormal in all cases; strings of beads appearance of cerebral arteries; abnormalities reversible within 6-12 wk

Histologic findings	Vasculitic changes	Normal
Drug treatment	Glucocorticoids with or without cytotoxic agents	Nimodipine; no glucocorticoids
Immunosuppressive therapy	Essential	Not indicated
Prognosis	Improved with immunosuppressive therapy	Excellent

CSF, cerebrospinal fluid; FLAIR, fluid-attenuated inversion recovery; MRI, magnetic resonance imaging; ICH, intracranial hemorrhage; RCVS, reversible cerebral vasoconstriction syndrome; PCNSV, primary central nervous system vasculitis.

MISCELLANEOUS CAUSES AND MIMICS OF CENTRAL NERVOUS SYSTEM VASCULITIS

REVERSIBLE CEREBRAL VASOCONSTRICTION SYNDROME

Formerly known as *Call-Fleming syndrome*, RCVS is a monophasic self-limited acute cerebral vasoconstriction syndrome (see [Chapter 43](#) for a full discussion). Patients typically present with headache and may develop minor neurologic deficits related to vasogenic edema or small infarcts, seizures, or convexity subarachnoid hemorrhage. Classic beading is seen on digital subtraction angiography that can be indistinguishable from PACNS. The important differences between RCVS and PACNS are that the former syndrome tends to be much more benign and self-limited. Misdiagnosis of RCVS as PACNS ([Table 42.4](#)) and treatment with immunosuppressive agents is not warranted because the condition results from myogenic arterial spasm rather than an autoimmune process causing intramural vessel inflammation. Apart from use of calcium channel blockers such as oral nimodipine 60 mg every 4 hours, treatment is supportive and spontaneous recovery over several weeks is the rule.

INTRAVASCULAR LARGE CELL LYMPHOMA

Intravascular large B-cell lymphoma (IVLBCL) is a rare type of non-Hodgkin lymphoma classified by the World Health Organization as an extranodal diffuse large B-cell lymphoma (LBCL) characterized

P.334

by the selective growth of neoplastic lymphocytes within blood vessel lumina of small vessels, particularly capillaries and venules. This type of lymphoma has also been described as *intravascular lymphomatosis*, *angiotropic large cell lymphoma*, and *malignant lymphoendotheliomatosis*. IVLBCL is not a form of vasculitis per se but is often included in the differential diagnosis of PACNS because it can cause a rapidly progressive pattern of widespread brain infarction in a patient without risk factors for cerebrovascular disease.

Epidemiology

The incidence of IVLBCL is unknown; the median age at diagnosis is in the sixth to seventh decades with no gender predilection.

Pathobiology

The diagnosis of IMLBCL is made by demonstrating large lymphoid cells with high mitotic activity within small to medium blood vessels.

Clinical Manifestations

The clinical presentation is varied and often includes symptoms related to organ dysfunction caused by occlusion of small blood vessels. Constitutional symptoms are seen in 55% to 85 % of patients. IMLBCL is considered a disseminated disease at diagnosis frequently manifesting with CNS and cutaneous symptoms in Western countries or with hemophagocytic syndromes in Asian countries. Rapidly progressive, recurrent ischemic strokes and peripheral neuropathies are frequently seen. CNS symptoms may include progression from lethargy to coma, focal neurologic deficits, seizures, or central hyperventilation. Neurologic symptoms are less commonly seen in patients of Asian descent who frequently present with involvement of the bone marrow, spleen, and liver.

Diagnosis

A wide range of laboratory abnormalities may be seen, ranging from elevated lactate dehydrogenase, β 2-microglobulin, and ESR levels to abnormal liver, renal, or thyroid function tests; anemia; thrombocytopenia; and hypoalbuminemia. CSF analysis only rarely demonstrates malignant cells but CSF cytology and flow cytometry should be obtained. IMLBCL is not typically associated with an obvious extravascular tumor mass, adenopathy, or detectable circulating lymphoma cells in the peripheral blood.

Brain biopsy or deep skin biopsy including the subcutaneous tissues is necessary to confirm the diagnosis. The bone marrow, lymph nodes, peripheral blood, and CSF are often uninvolved. Cerebral MRI findings include infarctions when occlusions occur in small arteries, patchy foci of white matter hyperintensities when the pathology involves the capillaries, mass-like lesions, and thickening of the meningeal vessels with meningeal or focal parenchymal enhancement.

Treatment and Outcome

Accurate and timely diagnosis of IMLBCL is still a problematic issue, and many cases are diagnosed at autopsy. However, in recent years, the heightened awareness of IMLBCL with appropriate investigations has resulted in more patients being diagnosed during life. Treatment of patients with IMLBCL includes a combination of *cyclophosphamide*, *doxorubicin*, *vincristine*, and *prednisone* with *rituximab*, a recombinant anti-CD20 monoclonal antibody (R-CHOP). The addition of *rituximab* has been shown to improve progression-free 2-year survival from 27% to 56%.

INFECTIOUS CENTRAL NERVOUS SYSTEM VASCULITIS

Infection is a well-recognized cause of CNS vasculopathy that can mimic autoimmune PACNS. The spectrum of infections that can cause segmental vascular inflammation of the cerebral arteries ranges includes viruses (e.g., varicella-zoster virus or hepatitis C; see [Chapter 66](#)), bacterial meningitis, or endocarditis (see [Chapters 61](#) and [63](#)); chronic meningitis due to tuberculosis, spirochete infection (e.g., neurosyphilis), or fungal infection (e.g., *Aspergillus*, *Cryptococcus*; see [Chapter 64](#)); rickettsial infection (e.g., Rocky Mountain spotted fever; see [Chapter 63](#)); and parasites (see [Chapter 65](#)). In most cases, the process is believed to be due to direct invasion and proliferation of pathogens in vessel walls with resultant inflammation, although some may develop as a result of an autoimmune response initiated by exposure to a pathogen (e.g., cryoglobulinemic vasculitis in the setting of HCV infection).

Varicella-zoster virus is a frequent cause of viral CNS vasculitis affecting large vessels in immunocompetent hosts while causing a more extensive protracted disease in immunocompromised individuals by affecting small vessels. Hepatitis C has been associated with small-vessel vasculitis related to mixed cryoglobulinemia, which accounts for the majority of cases, or a small- to medium-vessel vasculitis similar to PAN.

Bacterial cerebral vasculitis usually starts as purulent infection at the base of the brain progressing to inflammatory cell infiltration of vessel walls, with subsequent septic thrombosis and thrombophlebitis manifesting clinically as ischemic stroke and hemorrhages. Syphilitic vasculitis usually occurs as part of tertiary syphilis and occurs for 10% to 40% of untreated cases. Diffuse syphilitic vasculitis preferentially involves the cortical arteries and veins, whereas the gummatous vasculitis usually affects proximal middle cerebral artery (MCA) branches. Classic angiographic findings include narrowing of the proximal portions of the cerebral arteries with distal beading due to alternating segmental stenoses and dilatations.

CNS tuberculosis is frequently associated with segmental infectious vasculitis, secondary aneurysm formation, and thromboses causing infarctions of the basal ganglia, cerebral cortex, brain stem, and cerebellum in patients with CNS tuberculosis.

DRUG-INDUCED CENTRAL NERVOUS SYSTEM VASCULITIS

Although the exact incidence and pathobiology is unknown, there is ample evidence that some illicit and therapeutic drugs can result in either a self-limited or more protracted form of cerebral vasculitis. The pathogenesis is likely multifactorial. Drugs with sympathomimetic activity (*amphetamines, cocaine, phenylpropanolamine*) have been frequently implicated in causing biopsy-proven inflammatory cerebral vasculitis, as well as ischemic stroke precipitated by noninflammatory cerebral vasoconstriction.

The clinical diagnosis is one of exclusion based on the temporal relationship between the administration of the offending drugs and clinically evident vasculitis. Management is generally supportive in addition to removal of the instigating agent, which alone is often sufficient to induce prompt resolution of clinical manifestations. There is little data to guide management of severe cases where there is vital organ involvement.

Posterior Reversible Encephalopathy Syndrome and Other Cerebrovascular Syndromes

Sara K. Rostanski

Fawaz Al-Mufti

Claire S. Riley

Joshua Z. Willey

POSTERIOR REVERSIBLE ENCEPHALOPATHY SYNDROME

The posterior reversible encephalopathy syndrome (PRES) has been evolving as a clinical entity for the last 10 years. Several terms have now been used interchangeably to define PRES, including reversible posterior leukoencephalopathy syndrome (RPLS), or by naming the underlying clinical cause. PRES is now recognized as a clinicoradiologic syndrome rather than a distinct disease entity with multiple different etiologies, which share several common features with the reversible cerebral vasoconstriction syndrome.

EPIDEMIOLOGY

Limited data exist to describe the epidemiology of this condition. The literature has mostly been centered around case reports and case series.

PATHOBIOLOGY

Disorders that cause PRES have in common cerebral injury due to failure of the cerebral vasculature to adapt to changes in blood pressure or cerebral hemodynamics or an excessive vascular reactivity in cerebral arterioles. The hallmark clinical entities that most often cause PRES are hypertensive encephalopathy and eclampsia (see also [Chapter 124](#)). A focal process that may share some features of this condition is cerebral hyperperfusion syndrome occurring after carotid endarterectomy. In patients with chronic hemodynamic failure, distal arterioles tend to dilate to reduce cerebral vascular resistance; in clinical scenarios of a sudden increase in cerebral blood flow, these maximally dilated cerebral arteries may not be able to adapt further to changes in cerebral blood flow, leading to cerebral edema and hemorrhage. In addition to impaired autoregulation in the face of hypertension and hyperperfusion, in many cases, PRES is also associated with abnormal capillary permeability in the brain and large-vessel proximal vasoconstriction detectable by angiography. Up to 87% of patients with PRES have diffuse vasoconstriction if studied with angiography, hence, PRES and reversible cerebral vasoconstriction syndrome (discussed later) often overlap and are felt in many cases to share a common pathogenesis. The result is vasogenic edema that preferentially affects the posterior hemispheres of the brain and the white matter more than the gray matter. Interspersed in this picture are scattered microinfarcts and microhemorrhages. The most severe cases can manifest as massive global cerebral edema with transtentorial herniation or larger infarcts or hemorrhages.

CLINICAL FEATURES

The clinical syndrome associated with PRES is dependent on the underlying cause, although regardless of underlying etiology, common clinical symptoms include headache, seizures, loss of visual acuity including blindness, nonlocalizing confusion, and somnolence ([Table 43.1](#)). The neurologic examination will not reveal localizing findings on the mental status, although cases of cortical blindness and Balint syndrome may occur due to involvement of the occipital lobes ([Fig. 43.1](#)). Other described findings include visual field cuts, loss of visual acuity, papilledema, and mild hemiparesis. More prominent bulbar and cerebellar symptoms have been

described in case series where the pathology is restricted to the brain stem. A larger variety of clinical syndromes, which can be localized anywhere in the cerebral hemisphere occurs in the context of severe cases with cerebral infarction or hemorrhage. PRES leading to edema primarily involving the brain stem has also been described (Fig. 43.2).

TABLE 43.1 Approximate Frequency of Clinical Features of Posterior Reversible Encephalopathy Syndrome

Clinical Feature	Frequency
Hypertension	80%
Consciousness impairment	75%
Seizures	70%
Headaches	40%
Visual abnormalities	30%
Nausea and vomiting	20%

DIAGNOSIS

Neuroimaging is essential in the diagnosis of this condition, with magnetic resonance imaging (MRI) providing greater clinical information than computed tomography (CT). The “classical” description in this condition is white matter hyperintensities seen on fluid-attenuated inversion recovery (FLAIR) sequences representing vasogenic edema (see also Chapter 21). The FLAIR changes have a predilection to occipital lobes and adjacent posterior temporal and parietal regions and are not typically associated with cerebral microhemorrhages, infarction, or involvement of gray matter structures. A hallmark of this condition is that these clinical findings improve with treatment of the underlying condition, along with the cerebral vasogenic edema. To some degree, however, the term *posterior reversible encephalopathy syndrome* may be a misnomer, as in several cases, the changes seen clinically or on imaging are neither posterior predominant nor reversible. Common underlying predisposing conditions include hypertensive emergency/malignant hypertension, eclampsia, and medication toxicity (notably FK-506 in prevention of transplant organ rejection). Table 43.2 describes a variety of underlying etiologies for PRES.

The differential diagnosis of PRES includes conditions which have a predilection for causing bilateral involvement of the hemispheres, particularly the white matter, or that affect watershed

P.337

regions between the major vascular territories. These include progressive multifocal leukoencephalopathy, encephalitis, vasculitis, and watershed infarction from cardiac arrest, among others.

FIGURE 43.1 Magnetic resonance FLAIR image of posterior reversible encephalopathy syndrome on admission (A) and 2 weeks after stopping inciting medication (B).

TREATMENT

Management of PRES begins with a careful review of medications and discontinuation of any potential inciting agent. Patients with PRES require the symptomatic measures usually taken in the intensive care unit (ICU). The need for upper airway protection should be evaluated continuously in patients with marked consciousness impairment or seizure activity.

Control of hypertensive emergency, if present, is an important part of the symptomatic management. The aim is not to normalize the blood pressure but rather to decrease the mean arterial pressure (MAP) by 20% to 25% within the first 2 hours and to bring the blood pressure down to 160/100 mm Hg within the first 6 hours. More rapid blood pressure reduction is not recommended because it can aggravate the cerebral perfusion pressure alterations and promote ischemia. Continuous infusion of intravenous (IV) antihypertensive agents is preferred to allow for precise blood pressure control within a tight range. The most commonly used agents include *labetalol*, *nicardipine*, or *clevudipine* if available (see [Table 38.3](#)). Antiepileptic treatment should be initiated on an emergency basis for treatment of clinical or electrographic

seizures or status epilepticus (see also [Chapter 6](#)). All comatose patients should undergo 48 hours of surveillance continuous electroencephalogram (EEG) monitoring in the ICU given the high risk of nonconvulsive seizures. Active seizures should be treated with a full loading dose of lorazepam 0.1 mg/kg IV. Once controlled, patients should be loaded with an IV anticonvulsant such as phenytoin 20 mg/kg IV, followed by 300 mg daily, or valproic acid, 45 mg/kg, followed by 500 mg IV every 6 hours. Refractory status epilepticus after treatment with a full loading dose of a benzodiazepine and IV antiepileptic agent should be treated with midazolam infusion (0.2 mg/kg IV load, followed by a starting dose of 0.2 mg/kg/h), which mandates continuous EEG monitoring and endotracheal intubation.

Patients with PRES due to eclampsia should also be started on magnesium infusion (1 to 2 g/h targeting a serum magnesium level of 2.0 to 3.5 to 4 mmol/L) [**Level 1**].¹ Magnesium infusion is also recommended for any PRES patient with hypomagnesemia.

REVERSIBLE CEREBRAL VASOCONSTRICTION SYNDROME

In 2007, the term *reversible cerebral vasoconstriction syndrome* (RCVS) was proposed to encompass several previously described miscellaneous cerebral vasculitic disorders, which included

P.338

Call-Fleming syndrome, thunderclap headache-associated vasoconstriction, postpartum angiopathy, migraine angiitis, and cerebral vasospasm caused by cocaine, amphetamines, sumatriptan, and other serotonergic and sympathomimetic drugs.

FIGURE 43.2 FLAIR images of posterior reversible encephalopathy syndrome presenting with prominent brain stem involvement (**A-D**). Nine days later, the lesions had significantly resolved (**E-H**).

RCVS is characterized by a monophasic course of diffuse segmental constriction of cerebral arteries that resolves spontaneously within weeks to months. Although the angiographic findings may be indistinguishable from primary angiitis of the central nervous system (PACNS), RCVS is not a chronic condition that requires long-

term immunosuppression. RVCS is not a form of vasculitis because vessel wall inflammatory infiltrates do not occur, although the angiographic findings are similar. The cerebrospinal fluid (CSF) is normal, and the clinical course tends to be benign given the marked and extensive angiographic abnormalities that can occur.

EPIDEMIOLOGY

Due to the lack of epidemiologic studies, the true incidence of RCVS has not been estimated. Since 2007, there has been a surge in the number of RCVS-related publications likely due to increased awareness.

PATHOBIOLOGY

Other than vasoconstriction, there is no known unifying pathologic mechanism that underlies RCVS because it is a syndrome rather than a distinct disease entity. An aberrant sympathetic response of cerebral vasculature is one of the preferred hypotheses resulting in an unpredictable and short-lived failure of normal regulation of cerebral arterial tone. This leads to segmental vasoconstriction and vasodilatation in small cerebral vessels, often triggering thunderclap headaches due to stretching of vasa nervorum within the vessel walls.

RCVS appears to be an intrinsic process that can be triggered by a wide variety of pharmacologic and physical stimuli (Table 43.3). Different precipitating factors, including vasoconstrictive drug exposure (serotonergic or adrenergic agents), recreational drugs, and postpartum state are associated with RCVS in around 50% of cases. Head injuries and neurosurgical interventions have also been associated with RCVS.

PRES occurs in a substantial proportion of patients with RCVS. Hence, a shared pathophysiology between these two overlapping syndromes is highly probable. Severe forms of RCVS are likely to lead to PRES. In the past, it is likely that many of the cases termed *central nervous system vasculitis* and *benign angiitis of the central nervous system* may have actually referred to RCVS.

CLINICAL FEATURES

RCVS affects mainly women, with a mean age at onset of 40 years. In over 80% of cases, patients present with a sudden onset of single or recurrent thunderclap headaches. These headaches differ from those associated with aneurysmal subarachnoid hemorrhage (SAH) because they are usually short lived and intermittent, whereas SAH causes unremitting headaches that persist for days with prominent meningismus. Seizures occur and transient focal deficits in the form of visual, sensory, dysphasic, or motor deficits occur in

P.339

approximately 20% of patients at some point during the course of the illness, either alone or in combination. The focal deficits usually last minutes to hours but in some cases are persistent and associated with focal infarction. Blood pressure surges occur in 40% of patients; it is unclear if these elevations are related to the primary condition or are a reaction to pain or neurologic injury. Rupture or reperfusion injuries involving small leptomeningeal arteries may cause convexity SAHs.

- Carbamazepine

IV, intravenous.

DIAGNOSIS

Calabrese et al. have proposed diagnostic criteria for RCVS that encompass clinical, radiographic, and CSF findings. Because RCVS can mimic PACNS, differentiation is crucial because management is extremely different (Table 43.4). Basic hematologic and metabolic tests, including ESR and liver and renal function tests, are typically normal in RCVS. Tests to rule out CNS vasculitis should be performed as delineated in Table 42.3, but in addition, urine toxicology screens and urinary concentrations of vanillylmandelic acid and 5-hydroxyindoleacetic acid should be measured if pheochromocytoma is suspected.

TABLE 43.3 Precipitants of Reversible Cerebral Vasoconstriction Syndrome

Vasoactive drugs	Illicit drugs: cocaine, amphetamines, lysergic acid diethylamide (LSD), 3,4-methylenedioxymethamphetamine (MDMA, also known as <i>ecstasy</i>) Antidepressants: selective serotonin reuptake inhibitors, serotonin-noradrenaline reuptake inhibitors α -sympathomimetics agents: phenylpropanolamine, pseudoephedrine, ephedrine) Other: triptans, ergot alkaloid derivatives, ginseng
Catecholaminesecreting tumors	Pheochromocytoma Bronchial carcinoid tumor
Immunosuppressants or	Intravenous immunoglobulin

blood products	Tacrolimus Cyclophosphamide Erythropoietin α -Interferon Red blood cell transfusion
Metabolic abnormalities	Hypercalcemia Porphyria Phenytoin intoxication Binge drinking
Neurologic pathologies	Traumatic brain injury Neurosurgical interventions, for example, post carotid endarterectomy Subdural spinal hematoma Cerebral venous thrombosis CSF hypotension Autonomic dysreflexia/paroxysmal sympathetic hyperactivity
Pregnancy and puerperium	Usually peripartum or postpartum Associated with eclampsia or preeclampsia

CSF, cerebrospinal fluid.

Modified from Ducros A. Reversible cerebral vasoconstriction syndrome. *Lancet Neurol.* 2012;11(10):906-917.

A normal CSF profile is the rule, although mild abnormalities in the CSF can be present when subarachnoid or intracerebral hemorrhages exist. If the white blood cell count exceeds 10 cells/ μ L or the protein concentration exceeds 80 mg/dL, analysis of CSF should be repeated after a few weeks to ensure that these abnormalities have normalized.

Up to 50% of patients had a normal initial CT or MRI scan despite the presence of diffuse vasoconstriction on concomitant cerebral

P.340

angiography. By the end of the clinical course, 80% of patients eventually develop lesions on MRI. Common findings include convexity SAH, small discrete intracerebral hemorrhages, and infarcts.

TABLE 43.4 Summary of Critical Elements for the Diagnosis of Reversible Cerebral Vasoconstriction Syndrome

A. Transfemoral angiography or indirect computed tomography angiography or magnetic resonance angiography documenting multifocal segmental cerebral arter vasoconstriction

B. No evidence for aneurysmal subarachnoid hemorrhage

C. Normal or near-normal cerebrospinal fluid analysis (protein level <80 mg/dL, leukocytes <10-15/mm³ and normal glucose level)

D. Severe, acute headaches with or without additional neurologic signs or symptoms

E. Monophasic course without new symptoms more than 1 mo after clinical onset

F. Reversibility of angiographic abnormalities within 12 wk after onset. If death occurs before the follow-up studies are completed, autopsy rules out such conditions as vasculitis, intracranial atherosclerosis, and aneurysmal subarachnoid hemorrhage, which can also manifest with headache and stroke.

Adapted from the International Headache Society criteria for acute reversible cerebral angiopathy and the criteria proposed in 2007 by Calabrese. Headache Classification Subcommittee of the International Headache Society. The international classification of headache disorders.

Cephalalgia. 2004;24:1-160; Calabrese LH, Dodick DW, Schwedt TJ, et al. Narrative review: reversible cerebral vasoconstriction syndromes. *Ann Intern Med*. 2007;146(1):34-44.

Digital subtraction angiography (DSA) is the preferred method for demonstrating multifocal segmental vessel constriction. As is the case with PACNS, CT and magnetic resonance angiography (MRA) do not have sufficient resolution of the distal vasculature to demonstrate small-vessel “beading,” although they can demonstrate spasm of the larger proximal vessels (Fig. 43.3). Findings on angiography may be dynamic, with repeat scans demonstrating resolution of some abnormalities and new vasoconstriction of others. Initial angiography might be normal if performed very early in the course of the disease. Repeat angiography is sometimes useful if the diagnosis remains unclear days to weeks after the performance of an initial study. The onset of headache and cortical SAH may precede the development of vasospasm on vascular imaging, and indeed, elevated flow velocities on transcranial Doppler may predict the small minority of patients who are at risk for developing subsequent ischemic stroke due to severe vasospasm.

TREATMENT

Treatment of RCVS is largely supportive; there are no proven effective pharmacologic agents that can reverse the vasoconstriction, although *nimodipine* 60 mg every 4 hours, *verapamil* 60 mg every 6 hours, and *magnesium sulfate* 1 to 2 g/h IV have all been tried. Prospective and retrospective studies indicate that *nimodipine* 60 mg every 4 hours may help reduce the frequency and severity of headaches, but there is no evidence that it affects vasospasm or outcome. Management focuses on discontinuation or avoidance of precipitating agents, pain control, blood pressure control, antiepileptic drugs for seizure control, and admission to an ICU of neurologic monitoring in severe cases. Steroids are not indicated, as they do not seem to prevent clinical deterioration and may be harmful with regard to side effects such as immunosuppression, hyperglycemia, and psychosis. Intra-arterial vasodilators and balloon angioplasty have been used in severe cases.

FIGURE 43.3 Multifocal beading of the cerebral vasculature, characteristic of reversible cerebral vasoconstriction syndrome. (From Neil WP, Dechant V, Urtecho J. Pearls and oysters: reversible cerebral vasoconstriction syndrome precipitated by ascent to high altitude. *Neurology*. 2011;76:e7-e9.)

OUTCOME

RCVS is generally considered a monophasic, self-limiting condition with a good long-term prognosis. Headaches usually resolve within 3 weeks, and no new symptoms occur more than 1 month after presentation. The angiographic and parenchymal findings typically resolve within 12 weeks. Less than 5% of patients develop fulminant disease with multiple strokes and global cerebral edema. The vast majority of patients make a complete functional recovery. The case fatality rate is less than 1%.

FIBROMUSCULAR DYSPLASIA

Fibromuscular dysplasia (FMD) is a noninflammatory, nonatherosclerotic arteriopathy of medium-sized vessels of unknown cause. Although it can affect any vascular bed, the renal and cervicocranial carotid and vertebral arteries are most commonly involved.

EPIDEMIOLOGY

Cervicocranial FMD is a rare condition, with one autopsy study citing an overall prevalence of 0.02%. Rates for renovascular FMD are higher, with prevalence estimates of up to 4% shown in several studies. In confirmed FMD cases, renal involvement is generally seen in up to 65% of cases, with cerebrovascular involvement in 25% to 30% of cases. In a series of 1,100 FMD patients, women were twice as frequently affected as men with Caucasians disproportionately affected. The mean age of diagnosis in patients with cerebrovascular involvement is 50 years, older than for renovascular involvement. Approximately 10% of cases are felt to be familial.

PATHOBIOLOGY

There are three types of FMD, characterized by arterial layer of involvement: intimal fibroplasia, medial dysplasia, and adventitial fibroplasia. Intimal fibroplasia occurs in up to 10% of cases and results from accumulation of abnormal subendothelial mesenchymal cells, which project into the vessel lumen. This commonly results in areas of smooth, focal stenosis or long tubular stenosis. Adventitial fibroplasia, where the fibrous adventitia is replaced by collagen, is very rare.

Medial dysplasia is the most common, with three distinct subtypes recognized: medial fibroplasia, perimedial fibroplasia, and medial hyperplasia. Medial fibroplasia is the most common and accounts for up to 80% of cases.

The main histologic hallmark is disruption of smooth muscle cells, which are replaced by fibroblasts and collagen. There is frequently secondary disruption of the internal elastic lamina, which may lead to aneurysm formation. The alternating areas of medial disruption give rise to the commonly seen “string of beads” radiographic appearance, where areas of stenosis are admixed with dilated areas that are of larger caliber than the original vessel. Perimedial fibroplasia results from abnormal collagen deposition between the media and adventitia, leading to areas of stenosis with preserved internal elastic lamina. Radiographic appearance may be similar to medial fibroplasia, but the “beads” are of smaller diameter than the original vessel.

Although the etiology is unknown, FMD is associated with a variety of diseases including alpha-1 antitrypsin deficiency, Marfan syndrome, and Alport syndrome. Given the female preponderance, hormonal links have been posited, although evidence is lacking. Ischemia at the level of the vasa vasorum has been suggested as a possible underlying factor, although this remains unproven.

CLINICAL FEATURES

Cervicocranial FMD is frequently an incidental finding and rates of neurologic symptoms vary. Neurologic complications mainly arise due to ischemic or hemorrhagic symptoms that result from stenosis, thrombosis, dissection, or aneurysmal formation. Carotid-cavernous fistulas have also been described. Severe stenosis can cause distal hypoperfusion. Thrombotic occlusion of a stenotic vessel or distal embolism can lead to hemispheric ischemic symptoms. SAH can result from intracranial aneurysm rupture. Spontaneous cervical dissection can also occur, and headache, dizziness, carotidynia, pulsatile tinnitus, and Horner syndrome are all symptoms commonly seen with cervicocranial FMD. Dissection may be more common in Asian populations.

DIAGNOSIS

The gold standard for diagnosis remains catheter-based angiography. Noninvasive imaging modalities such as Doppler ultrasound and MRA may also detect FMD, but because lesions most commonly occur in the middle to distal carotid artery near C1-C2, adequate visualization with Doppler may be limited. Based on the underlying histology, a string of beads appearance due to medial fibroplasia is most commonly seen. Aneurysmal dilatation and areas of smooth tubular stenosis may also be present (Fig. 43.4). When cervicocranial disease is discovered, intracranial vessels should be imaged to evaluate for aneurysms and renal vessels for renovascular disease that may predispose to hypertension. The main differential diagnoses to consider are vasculitis and atherosclerotic disease.

FIGURE 43.4 Angiogram of fibromuscular dysplasia in a 43-year-old female patient with multiple transient ischemic attacks. Note the multiple saccular dilatations of the internal carotid artery between the first and second cervical vertebrae.

TREATMENT

No trial data exist to guide treatment. Antiplatelet therapy is generally used when FMD is diagnosed to prevent thrombotic complications, although some practitioners institute therapy only when symptoms occur. In cases of dissection, a short course of anticoagulation is generally followed by long-term antiplatelet therapy in accordance with general practice. For patients with recurrent symptomatic ischemia refractory to medical treatment, percutaneous angioplasty is the treatment of choice, with stent placement reserved for those cases with concurrent dissection. Surgical intervention is reserved for rare, highly refractory cases. In addition to surgical dilatation, the two approaches generally used are resection with end-to-end anastomosis or carotid-middle cerebral artery (MCA) bypass. It should be emphasized that surgery is vanishingly rare in the era of percutaneous treatment. When intracranial aneurysms are present, treatment

is based on size. Both endovascular coil embolization and microsurgical clipping via craniotomy are viable definitive treatment options.

OUTCOME

Although outcome data is limited to case series, in general, the course of cervicocranial FMD is fairly benign. Many patients who are asymptomatic at the time of diagnosis remain so at follow-up several years later. Angioplasty generally has excellent results in

P.342

symptomatic patients, although true rates of recurrent ischemia are difficult to ascertain.

MOYAMOYA DISEASE

Moyamoya disease (MMD) is a chronic, progressive steno-occlusive arteriopathy of unclear etiology that affects the distal supraclinoid internal carotid artery (ICA) and/or proximal anterior and middle cerebral arteries. Chronic occlusive disease is believed to result in ischemia with subsequent neovascular proliferation of small, fragile, collateral vessels at the base of the brain. It is the hazy, fluffy angiographic appearance of this fine collateral network from which the name derives, as moyamoya means “puff of smoke” in Japanese. An essential distinction is between moyamoya disease and syndrome, where the latter refers to vessel stenosis and subsequent collateralization owing to a clearly identifiable underlying provoking condition. Commonly recognized causes of moyamoya syndrome include sickle cell disease, neurofibromatosis, advanced atherosclerosis, intracranial radiation, Down syndrome, autoimmune disease, and meningitis. The following discussion will focus on idiopathic MMD.

EPIDEMIOLOGY

Worldwide incidence and prevalence data is limited. MMD was initially described in Japan and incidence is generally felt to be highest in East Asia. Overall, worldwide incidence appears to be rising, although epidemiologic studies are limited by differences in data collection methods. Ascertainment bias due to increased disease awareness is also possible. Literature originating from East Asia reports incidence rates of 0.54 per 100,000 to 2.3 per 100,000 depending on the country, with higher rates reported in later reports and generally a higher female preponderance. There are far fewer North American and European epidemiologic studies. One that is oft quoted comes from Washington and California where the overall incidence was .086 per 100,000, again with a female majority. In terms of ethnicity-specific incidence, in this series, rates were highest in Asians and lowest in Hispanics. When patients with sickle cell disease were excluded, incidence rates in African-American and Caucasian patients were similar. General epidemiologic studies from Europe are lacking, although in a recently completed large case series from the Mayo clinic, there was significant predominance of moyamoya syndrome among women of European descent in their fourth decade of life with a significant prevalence of autoimmune diseases (notably Graves and Hashimoto disease and type 1 diabetes mellitus). A bimodal distribution of age of onset is generally demonstrated across studies, and although the average ages vary somewhat by country and study, the initial peak is generally in the first decade of life with the second in the fourth or fifth decade. Indeed, MMD is the most common cause of pediatric stroke in Asia. Clustering of MMD within families has been recognized, with rates as high as 15% in studies from Japan, consistent with an autosomal dominant trait with incomplete penetrance. Genetic heterogeneity is demonstrated by at least four documented linked loci; one site is located at 17q25.3 but no culprit gene has been identified.

PATHOBIOLOGY

The etiology of MMD remains unknown. Histopathologic studies have shown the stenotic vessels to have a severely thickened intima, primarily driven by smooth muscle proliferation, with luminal thrombosis and duplication and tortuosity of the internal elastic lamina frequently demonstrated on autopsy specimens. Signs of vascular inflammation are distinctly absent. Moyamoya vessels, the medium-sized dilated vessels originating from the distal ICA or proximal circle of Willis vessels, form complex networks, which anastomose with distal anterior cerebral artery (ACA) and/or MCA, with small, fragile, dilated vessels that penetrate the base of the brain. Pathologic evaluation has shown these dilated vessels to either have a very thin wall, prone to microaneurysm formation, or to be thick-walled with significant luminal stenosis and thrombosis.

Based on identification of a familial predisposition of 15% in Asia, recent genetic linkage studies identified the first susceptibility gene for MMD: RNF213 on chromosome 17, with the p.R4810K mutation demonstrating a high prevalence among East Asians. Although the exact etiologic role in MMD remains unknown, RNF213 is known to mediate vascular development in zebrafish, and its role in MMD is under active investigation. Interestingly, the p.R4810K mutation has not been found in European origin populations.

CLINICAL FEATURES

The main clinical manifestations relate to ischemia in the territory of the stenotic vessel, most often due to hemodynamic flow failure (rather than artery-to-artery embolus) or hemorrhage from the fragile neovascular lenticulostriate vessels that characterize the disease. Both intracerebral and subarachnoid hemorrhage can occur. Among adults, hemorrhage is more common in Asia than in North America and is infrequent in pediatric cases. When present intraparenchymally, hemorrhage is most often in the basal ganglia or thalamus with frequent intraventricular extension. This is presumably due to either rupture of microaneurysms or simply rupture of the fragile vessel wall in the setting of persistent hemodynamic stress. SAH is most commonly due to saccular aneurysm rupture at the circle of Willis frequently affecting the posterior circulation (most commonly the basilar bifurcation) because it is placed under increased stress given its role in providing collateral blood flow. Convexity SAH has also been observed in the setting of dilated pial collaterals, which are subsequently more prone to rupture.

Ischemia is the most common presentation in children and in adults in most studies. Ischemic symptoms are frequently hemispheric, with either a transient or fixed deficit depending on duration of ischemia, and are attributable to hemodynamic failure. Some patients may develop ischemic symptoms exclusively in deep hemispheric structures with relative sparing of cortical function. Cerebral infarction due to embolism or in situ thrombosis of a stenotic vessel is uncommon. In children, symptoms are frequently provoked by maneuvers that lead to hyperventilation and thus vasoconstriction, such as crying or inflating a balloon. Exercise-induced symptoms are another possible manifestation of chronic hemodynamic failure.

Other common manifestations of MMD include refractory migraine-like headache, thought to be due to dilation of meningeal and leptomeningeal vessels with subsequent activation of dural nociceptive receptors, as well as seizures. Some patients present primarily with cognitive or psychiatric symptoms from hypoperfusion, most commonly when bilateral frontal lobes are involved. Cognitive profiles of children with MMD reveal lower intelligence quotients independently of the incidence of stroke. Less common presentations include a choreiform movement disorder, particularly in children, resulting from the presence of dilated moyamoya vessels within the basal ganglia.

DIAGNOSIS

Diagnosis rests on angiographic demonstration of stenosis or occlusion of the bilateral supraclinoid ICAs and/or proximal ACA/MCAs with resulting proliferation of a small, fine network of collateral vessels

originating just distal to the site of stenosis. The determination of MMD versus syndrome is incumbent upon exclusion of underlying conditions, which could predispose to the arterial narrowing. Recently, diagnostic guidelines have acknowledged that MRI and MRA can be used in lieu of conventional angiography if bilateral distal ICA stenoses on MRA are accompanied by abnormal vascular networks within the basal ganglia, frequently described as two or more flow voids (Fig. 43.5). In children, if the collateralization is present unilaterally but bilateral ICAs are stenotic, the condition is considered “definite” MMD, but when adults present with unilateral features, they are termed *probable moyamoya disease*. In some case series, up to 50% of patients will start with unilateral involvement, although in fact, many unilateral cases at 5 years of follow-up will demonstrate bilateral involvement. Posterior circulation involvement may be present in up to 10% of patients.

Disease severity on angiography is graded using the Suzuki classification, a scheme with six phases denoting increasing disease progression (Table 43.5). Level 1 denotes bilateral ICA stenosis in the absence of lenticulostriate collaterals and level 6 denotes complete carotid occlusion in which the distal internal carotid territory is exclusively supplied by the external carotid. Intermediate levels track the gradual progression and subsequent disappearance of lenticulostriate neovascularization as the disease progresses to complete internal artery occlusion. MMD can progress to any stage without further progression; only a minority of patients progress to stage 6.

FIGURE 43.5 Internal carotid artery angiogram demonstrating moyamoya disease. (From Yomauchi T, Tada M, Houkin K, et al. Linkage of familial moyamoya disease [spontaneous occlusion of the circle of Willis] to chromosome 147q25. *Stroke*. 2000;31:930-935, with permission.)

TABLE 43.5 Suzuki Scale for Severity of Moyamoya Disease

Suzuki Stage	Angiographic Description
1	Narrowing of distal carotid No other angiographic abnormalities aside from carotid narrowing
2	Initiation of the moyamoya First signs of fine collateral networks become apparent

3	Intensification of the moyamoya	Collaterals become more pronounced, MCA and ACA may start to become obscured
4	Minimization of the moyamoya	First signs of external carotid artery (ECA) collaterals are apparent, moyamoya collaterals start to thin
5	Reduction of the moyamoya	Moyamoya collaterals further regress, carotid occlusion progresses proximally
6	Disappearance of the moyamoya	Only intracranial blood flow is via collaterals from the ECA; no angiographic evidence of distal carotid or moyamoya collaterals at the base of the brain

MCA, middle cerebral artery; ACA, anterior cerebral artery.

Adapted from Suzuki J, Takaku A. Cerebrovascular “moyamoya” disease. Disease showing abnormal net-like vessels in base of brain. *Arch Neurol.* 1969;20:288-299.

In addition to angiographic severity, assessment of hemodynamic status may provide further insight into the clinical severity of MMD. One such method is via single-photon emission computed tomography (SPECT; see [Chapter 22](#)) or computed tomography perfusion (CTP; see [Chapter 20](#)) imaging, whereby the territory of decreased cerebral blood flow (CBF) can be imaged, measured consistent with a perfusion defect. CTP also allows assessment of vascular reserve by allowing evaluation of cerebral blood volume (CBV): As the severity of stenosis progresses, the distal arteries vasodilate, producing an increase in CBV. SPECT can also be used to assess vascular reserve by measuring changes in CBF before and after administration of acetazolamide, a carbonic anhydrase inhibitor that induces a transient metabolic acidosis in the brain, resulting in vasodilation. Failure to augment CBF in an area of reduced perfusion after acetazolamide implies that the distal vascular territory is already maximally dilated and hence at greater risk for progression to infarction. Transcranial Doppler ultrasonography (see [Chapter 23](#)) can also measure cerebrovascular reserve by comparing flow velocities before and after induced hypercapnia after inhalation of 5% carbon dioxide via face mask. Failure to augment CBF velocity by 5% implies a state of maximal vasodilation and greater risk. Many centers will use degree of impaired vascular reserve to both risk stratify patients prior to surgery and to predict clinical improvement following intervention.

P.344

An additional diagnostic finding of interest in children relates to characteristic EEG changes seen in MMD. Whereas in normal children, hyperventilation leads to high-amplitude slow waves which disappear once hyperventilation ceases (so-called buildup phenomenon); in children with MMD, these slow waves reappear, an occurrence termed *re-buildup*, which is thought to be due to posthyperventilation hypoxia and decreased CBF.

TREATMENT

Treatment revolves around various revascularization strategies that promote flow to distal territories, with the ultimate goal of reducing hemodynamic stroke and abnormal angiogenesis. Bypass surgery is generally recommended in patients who have had ischemic symptoms. Alternatively, both SPECT and transcranial Doppler have been used to stratify patients such that surgery is reserved for patients without stroke or

transient ischemic attack (TIA) with evidence of hemodynamic failure and brain at risk. There are multiple revascularization strategies, generally divided into direct and indirect approaches. No randomized controlled trials have directly compared these techniques, with choice of method generally left to the discretion of the treating surgeon.

The direct approach is an anastomosis between the intracranial and extracranial circulation, which is most commonly achieved by connecting the superficial temporal artery (STA) to a branch of the MCA on the cortical surface. With this procedure, revascularization is immediate. Downsides include an increased risk of perioperative stroke or hemorrhage and the frequent occurrence (up to 25% in some studies) of the cerebral hyperperfusion syndrome, owing to the immediate revascularization in the setting of altered hemodynamics. The main symptoms of this syndrome include hemorrhage, seizures, and focal neurologic deficits from vasogenic cerebral edema.

There are two main indirect approaches: encephalomyosynangiosis (EMS) and encephaloduroarteriosynangiosis (EDAS). In the EMS procedure, a vascularized portion of the temporalis muscle is placed in direct apposition to the cortical surface, with dura closed around the muscle. In the EDAS procedure, a superficial artery, generally the STA, is placed on the cortical surface through a dural defect, sometimes with removal of intervening arachnoid (a modification termed *pial synangiosis*). Both of these techniques rely on the induced angiogenesis that naturally occurs between the underlying ischemic cortex and the apposed tissue or vessel. A third procedure is burr hole placement (with stripping of the underlying dura) in the vicinity of ischemic cortex, whereby scalp vessels grow through the burr holes to form collaterals with vessels on the cortical surface.

It is generally accepted that children achieve greater collateralization from indirect bypass than adults do, whereas direct bypass is more technically challenging in children given the smaller caliber of their vessels. An additional downside of indirect revascularization is that collateral formation may take weeks to months, a time during which repeat ischemic events may occur.

Less data exists on the prevention of hemorrhagic stroke among patients with MMD. The most exciting new development in the field of MMD is the completion of the Japanese Adult Moyamoya (JAM) trial, which offers the first prospective look at bypass as a means of reducing recurrent hemorrhage risk. This prospective randomized trial compared direct bypass to conservative management in a group of 80 patients with hemorrhage within 1 year prior to randomization. The recurrent hemorrhage rate was 11.9% in the surgical group compared with 31.6% in the conservative group (an annualized risk of 2.7% vs. 7.6% per year; $P = .04$) [Level 1].² Further trials are needed to better define population subgroups who would most benefit from surgery to reduce ischemic symptoms.

Medical management of MMD has not been formally evaluated in clinical trials, although in case series, antiplatelet therapy may be effective at significantly reducing recurrent ischemic events, presumably by preventing microthrombus generation. Aspirin 81 to 325 mg daily is the most reasonable starting dose in MMD patients with no history of bleeding events. Anticoagulation is generally avoided given the attendant increased risk of hemorrhage on the setting of fragile vessels. When patients with MMD present acutely with ischemic symptoms, the focus of management should be on maintaining cerebral perfusion by avoiding hypotension and hyperventilation and ensuring adequate intravascular volume. There is insufficient evidence to guide whether MMD patients should be treated with recombinant tissue plasminogen activator within the treatment window because there is a theoretical increased risk of hemorrhage. Induced hypertension with phenylephrine starting at 20 $\mu\text{g}/\text{min}$, titrated to clinical effect, is a treatment option in the ICU for patients with a fluctuating neurologic deficit due to perfusion failure, but care should be taken to avoid surges in blood pressure that might provoke neovascular vessel bleeding.

OUTCOME

Data on the natural course of MMD in adults is not well known. Adults are generally felt to display less progression of proximal occlusion than children with lower recurrent stroke rates. Much of the data on progression in adults is from Japan, where a 5-year rate of progression of proximal stenosis as high as 20% has been shown in the affected vessel. Other studies have shown recurrent ipsilateral stroke rates over 5 years to be as high 65% in the absence of surgery. Female sex is generally the main identified risk factor for disease progression. Even in asymptomatic patients, disease activity is apparent, as seen from a Japanese study where 20% of asymptomatic patients had imaging evidence of infarction, whereas 40% had evidence of impaired cerebral hemodynamics. The annual rate of stroke in this asymptomatic population was 3.2%.

As stated previously, no randomized data exist to support one form of surgery over another for reducing ischemic symptoms; however, results from experienced centers have been overwhelmingly excellent in terms of decreasing recurrent ischemic stroke risk following revascularization in both children and adults. This type of data is subject to reporting bias, however. Low baseline degree of disability, a small extent of existing infarction, and the presence of collaterals are some of the factors that may predict good outcome after revascularization surgery.

BINSWANGER DISEASE

Binswanger disease (BD) refers to a progressive subcortical dementia with white matter degeneration of small-vessel etiology also known as *subcortical arteriosclerotic leukoencephalopathy*. It is not a well-defined disease entity, and in fact, the clinical picture in BD is similar to the subcortical dementia seen in other small-vessel angiopathies, for example, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), which is discussed later in this chapter. In general, the term *Binswanger disease* is appropriately used when subcortical dementia is present in the setting of vascular risk factors with evidence of extensive deep and periventricular ischemic leukoencephalopathy on neuroimaging without an alternative explanatory cause.

P.345

EPIDEMIOLOGY

BD can be considered a subset of vascular dementia (VaD) (see [Chapter 53](#)). Given the extensive overlap between cerebrovascular disease and Alzheimer disease and other dementing pathologies, clinical diagnosis of “pure” VaD is fraught with challenges and prevalence estimates are highly variable. Estimating the true prevalence of BD within the context of VaD subtypes is therefore challenging. Although exact numbers are not known, BD in its classical form likely accounts for a minute portion of these “pure” VaD cases, as demonstrated by a 1987 literature review which found only 47 clinicopathologically confirmed BD cases over a period of 75 years.

PATHOBIOLOGY

The general pathologic picture is one of roughly symmetric degeneration of central white matter with myelin pallor and multiple lacunes. The term *incomplete white matter infarction* has been used to describe the pathology of BD. The degree of demyelination is heterogeneous with some areas demonstrating extensive demyelination and gliosis admixed with relatively normal-appearing white matter. Axonal loss is variable, there is no inflammatory cell infiltrate, and cortical atrophy is minimal, if not wholly absent. Although the arcuate fibers and anterior commissure are usually spared, central white matter from the periventricular region to the centrum semiovale, extending from frontal to occipital lobes, is involved to varying degrees. In addition to frequent lacunes, other hallmarks include dilated perivascular spaces, so-called *état criblé*, and moderately enlarged

lateral and third ventricles. The vascular hallmarks are small, penetrating vessels with hyalinized, thickened walls with focal fibrinoid necrosis, notably without occlusion. Generally, there is some degree of atherosclerosis in large, proximal intracerebral arteries. Interestingly, perfusion studies have shown the areas of white matter hyperintensities to have lower CBF, suggesting chronic hypoperfusion and ischemic damage due to the small-vessel changes may be the pathophysiologic mechanism of the white matter degeneration.

CLINICAL FEATURES

The clinical manifestations of BD owe mainly to the disruption of white matter tracts interconnecting primary processing areas of the brain, theorized in particular to those specifically subserving the frontal cortices. Main signs include those that tend to localize to the frontal lobe, including slowed information processing, memory disturbances, and visuospatial deficits and executive dysfunction; the latter includes impaired initiation, planning, and goal-directed activity. Behavioral disturbances are frequent. Varying degrees of pyramidal and extrapyramidal dysfunction may be present in addition to pseudobulbar signs, parkinsonism, and gait abnormalities. Focal neurologic deficits may be present at the onset or during the disease course, owing to acute lacunar infarction.

DIAGNOSIS

No consensus guidelines exist for the diagnosis for BD. In general, the diagnosis is made when subcortical dementia is found in the presence of vascular risk factors, notably hypertension, with neuroimaging evidence of white matter disease. Other causes of leukoencephalopathy such as acute disseminated encephalomyelitis (ADEM) or progressive multifocal leukoencephalopathy must be absent. In general, patients with a known small-vessel arteriopathy and associated dementia, such as CADASIL, are not considered under the umbrella term of BD.

The white matter degeneration is best seen on MRI but is also present on CT where confluent, symmetric hypodense areas throughout the central white matter are apparent. On MRI, areas of white matter degeneration appear bright on T2 (white matter hyperintensities) and are best seen on FLAIR sequences where CSF is suppressed. The lesions are generally large and rather than being isolated to the immediate periventricular region, extend throughout the corona radiata and centrum semiovale. Scattered lacunes are frequently seen, both throughout the white and deep gray matter.

TREATMENT

Given most patients with BD have evidence of lacunar infarcts, treatment is directed at secondary stroke prevention, that is, modification of vascular risk factors and introduction of antiplatelets and statins. Control of hypertension is essential, in addition to aggressive diabetes management and smoking cessation. There is no evidence that hypertension control leads to reversal of white matter changes. Supportive care for patients with severe cognitive impairment is often necessary.

OUTCOME

In one series of clinicopathologically confirmed cases, clinical course took one of three patterns: gradual progression punctuated by acute focal deficits, gradual worsening not punctuated by acute focal deficits, and multiple acute focal deficits without progression.

SUSAC SYNDROME

Susac syndrome comprises a triad of encephalopathy, branch retinal artery occlusion (BRAO), and hearing loss. It is thought to be an autoimmune microangiopathic endotheliopathy that affects brain, retina, and cochlea. The disease, which was first described in 1977 by John O. Susac after he encountered two young women with personality changes, including paranoia and hostile behavior, hearing loss, and visual disturbances, is also termed *retinocochleocerebral vasculopathy* and is frequently misdiagnosed as multiple sclerosis (MS) or ADEM.

EPIDEMIOLOGY

Susac syndrome typically begins in the third or fourth decade but may occur during childhood or after age 70 years. There is 3:1 female predominance but no racial predilection. The true incidence and prevalence of the disease are unknown. About 100 cases have been reported but diagnostic confusion abounds and the condition is likely underdiagnosed.

PATHOBIOLOGY

Susac syndrome is thought to be an immune-mediated endotheliopathy of unknown etiology. Antiendothelial cell antibodies either play a pathogenic role or arise from endothelial damage caused by other immune mechanisms. Histopathologic examination of brain biopsy samples usually reveals microinfarcts in the cerebral cortex and white matter. Areas of demyelination along with axonal and neuronal damage are also seen. Pauci-inflammatory endothelial cell injury in small arterioles, capillaries, and venules is observed.

Muscle biopsy in patients with Susac syndrome shows abnormal endothelial cells, some swollen to the point of occluding small arterioles. Muscle inflammation is subclinical, unlike dermatomyositis,

P.346

although the pathology is virtually identical, including endothelial cell degeneration and necrosis, as well as thickening, reduplication, and lamellation of the basement membrane.

FIGURE 43.6 Susac syndrome findings on MRI. Axial FLAIR image (A) shows nonspecific lesions in the cerebral hemispheres. Sagittal FLAIR (B) and T1-weighted (C) images show the characteristic central “snowball lesions” and “punched out holes,” respectively.

CLINICAL FEATURES

Encephalopathy may be manifested by psychiatric symptoms, confusion, memory loss, or simply dulling of cognitive function. BRAO, which may occur before, during, or after the encephalopathy, may cause a scotoma or photopsia. Migrainous headaches often precede other symptoms, and the association with visual symptoms may be misleading. Hearing loss may be difficult to assess, depending on the degree of encephalopathy. It frequently affects the lower tones first, which implies microinfarction of the cochlear apex, a particularly vulnerable territory. The speed and severity of hearing loss varies from profound and precipitous, with loss of hearing in one ear and the other days to weeks thereafter, to slow and insidious or fluctuating as in Ménière disease. Hearing loss may

be accompanied by nausea, vertigo, tinnitus, or gait ataxia.

DIAGNOSIS

Diagnosis requires a high index of suspicion because it is uncommon for the entire clinical triad to be present at the time of the first encounter with a physician. Furthermore, encephalopathic patients may not complain of hearing loss or visual problems. Brain MRI, dilated fundusoscopic examination, and retinal fluorescein angiography are the most useful diagnostic tests.

FIGURE 43.7 **Left:** Retinal abnormalities in Susac syndrome demonstrating hyperfluorescence of the arteriolar walls (*arrowheads*). **Right:** Retinography of the left eye shows retinal infarct (*arrow*). (Images courtesy of Zachary Grinspan, MD.)

Brain MRI reveals multiple small (typically 1 to 7 mm) white matter lesions in the cerebral hemispheres. The corpus callosum is involved in 88% to 100% of patients (Fig. 43.6). The callosal lesions that occur with acute encephalopathy are centrally located and have a “snowball” appearance. Basal ganglia, thalamic, brain stem, cerebellar, and gadolinium-enhancing lesions are common. Leptomeningeal enhancement is occasionally observed. Arteriography is typically normal because the affected arterioles are too small to be seen in angiography.

Although the MRI findings may lead to an incorrect diagnosis of MS or ADEM, the morphology and central location of the acute callosal lesions and their evolution into hypointense holes on T1-weighted imaging are characteristic findings in Susac syndrome and atypical of MS lesions, which are smaller and involve the callosal-septal interface.

Dilated fundusoscopic examination and retinal fluorescein angiography may reveal retinal infarcts and BRAO (Fig. 43.7). Audiometry may detect sensorineural hearing loss. Examination of the CSF during the acute encephalopathy typically reveals a mild lymphocytic pleocytosis. The protein content is often more than 100 mg/dL, an uncommon finding in MS. However, the occasional presence of oligoclonal bands or an elevated immunoglobulin G index may lead to further diagnostic confusion.

TREATMENT

There have been no controlled therapeutic trials in Susac syndrome, but many different approaches have been explored. Treatment recommendations are largely based on anecdotes. Although the disease often

enters spontaneous remission, treatment is recommended to try to prevent irreversible disability. Prednisone monotherapy, pulses of methylprednisolone, or a combination of corticosteroids and IV immunoglobulin appears to be beneficial in some patients. More severe cases may respond to *cyclophosphamide* or *mycophenolate* mofetil. Plasma exchange has been used in refractory cases. The use of *rituximab* in dermatomyositis, a humorally mediated autoimmune vasculopathy that shares immunopathogenic features with Susac syndrome, has raised interest in B-cell depletion as a treatment strategy for Susac syndrome. Low-dose aspirin therapy is often added in attempt to forestall microinfarcts. Although aggressive treatment is often indicated, the disease is often self-limited and may remit spontaneously after several years, so tapering of immunotherapy should be attempted judiciously.

OUTCOME

Three major clinical courses have been described: monocyclic, polycyclic, and chronic continuous. Most patients with symptomatic encephalopathy follow a monocyclic course in which the disease remits spontaneously after 1 to 2 years and does not return. The polycyclic course includes variable periods of remission separating disease activity and may persist for many years. The chronic continuous syndrome shows variations in severity of symptoms but no clear remissions, even though a slow remission may eventually occur. Case reviews suggest that those with prominent encephalopathy are more likely to have a monocyclic course, whereas those with BRAO and hearing loss may be more likely to develop prolonged polycyclic disease.

The disease usually lasts 2 to 4 years with the chronic continuous course being the least common form of the illness. Although 50% of patients are able to lead a basically normal life, most are left with varying degrees of bilateral hearing loss, and 35% to 50% have residual cognitive dysfunction, which prevents some from returning to work. Asymptomatic visual field defects are much more common than symptomatic visual loss. Treatment with immunosuppressive chemotherapy may result in infertility.

SNEDDON SYNDROME

The association between livedo reticularis, a lacy erythematous or purplish rash on the anterior legs, and ischemic stroke was first described in 1965 by Dr. Ian Sneddon, a British dermatologist, and has subsequently been termed *Sneddon syndrome*. The exact underlying pathophysiology remains unknown and whether this entity is distinct from, or lies on a spectrum with, the antiphospholipid antibody syndrome remains to be clarified.

EPIDEMIOLOGY

Two forms of Sneddon syndrome (SS) are generally recognized: those associated with the presence of antiphospholipid antibodies and those that are not, so-called seronegative cases. This is a rare disease, with the overall annual incidence estimated at 4 per million and with women predominantly affected. In general, first clinical stroke is evident by the mid-40s.

PATHOBIOLOGY

Livedo reticularis (LR) is a dermatologic condition that refers to the lacy, mesh-like appearance of blood within the cutaneous venous system. Two general forms are recognized: "physiologic" LR or *cutis marmorata*, which occurs in the setting of cold temperatures and disappears when the affected limb is warmed, and "secondary" LR due to an underlying condition. Many disease states are associated with secondary LR, where either venous stasis or significant deoxygenation of blood within the cutaneous venous plexus gives the stereotypical appearance. In SS, it is subcutaneous arteriolar occlusion leading to decreased oxygenation of venous blood

that causes LR, generally present over a large area. The trunk and limbs are usually involved, with the violaceous rings appearing irregular and broken.

Pathologic series of skin biopsy specimens of seronegative SS patients have shown that it is the small- to medium-sized arteries at the dermis-subcutaneous border that are affected. These vessels undergo four stages of involvement. Initially, there is endothelial disruption and lymphocyte infiltration, which is followed by partial vascular occlusion by stimulated monocytes that trap erythrocytes and fibrin, associated with a perivascular lymphohistiocytic infiltrate. Later stages are characterized by reorganization of this plug associated with subendothelial proliferation of smooth muscle cells and resolution of the perivascular infiltrate. The final stage is characterized by proliferation of fibroblasts and collagen, where completely occluded, shrunken vessels are apparent without inflammatory infiltrate. Following the discovery of an initial so-called endotheliitis stage, the presence of antiendothelial antibodies has been found in SS patients with one series showing up to 35% of patients harboring these antibodies. Whether they play a pathophysiologic role remains uncertain.

Unlike skin vessels, pathologic studies of cerebral vessels are limited. Stroke in SS patients most commonly affects the cortex and subcortical white matter, with some series showing frequent small, multifocal ischemic lesions within the deep white matter, a nonspecific finding that is seen in many disorders affecting small arteries including hypertension.

DIAGNOSIS

Diagnosis is made by the presence of skin biopsy-confirmed LR with the aforementioned pathologic features in the presence of focal neurologic deficit and imaging-confirmed cerebral infarction. Other conditions associated with LR should be ruled out to make the diagnosis of SS, for example, systemic lupus erythematosus and polyarteritis nodosa. The presence of antiphospholipid antibodies is not essential for the diagnosis, as up to 60% of cases are considered seronegative.

CLINICAL MANIFESTATIONS

In general, the first manifestations of SS are frequently nonspecific neurologic symptoms such as dizziness and headache. These are followed by LR, which in turn is followed by stroke. On average, symptoms evolve over 9 years. Patients seronegative for antiphospholipid antibodies generally have a wider area of LR and are less likely to have seizures compared to patients with antiphospholipid antibodies. Seropositive patients are more likely to have thrombocytopenia, in keeping with coexistent systemic lupus erythematosus and other autoimmune disease. SS is rare enough, however, that studies showing differences between seronegative and positive patients are inconsistent.

Multiple MRI patterns in patients with SS have been described. Some studies describe prominent infarcts affecting cortical-subcortical region, whereas others find FLAIR lesions in the deep periventricular

P.348

white matter, suggesting small-vessel infarct. Scattered punctate subcortical T2 hyperintensities are also commonly seen in addition to confluent areas of mild FLAIR hyperintensity within central white matter. Although the majority of lesions are supratentorial, infratentorial lesions in cerebellar and medullary white matter occasionally are present. Basal ganglia lesions are notably infrequent.

Some studies have also shown an increased incidence of hypertension and cardiac valvular abnormalities (thickening and calcification) in SS patients in keeping with comorbid autoimmune disease, but this is not consistently observed across case series.

TREATMENT

No randomized trials on treatment in SS exist. In general, seronegative patients are generally treated with antiplatelets agents such as aspirin 325 mg daily, whereas seropositive patients are anticoagulated with warfarin (5 mg daily titrated to maintain the international normalized ratio between 2.0 and 3.0), along current antiphospholipid syndrome guidelines. Immunosuppressive regimens may be used for coexistent autoimmune disease.

OUTCOME

Given its low incidence, large longitudinal studies are lacking, which make accurate predictions about outcome challenging. In one study, only one patient became functionally impaired as a consequence of neurologic disease burden, whereas in another, up to 50% of patients had some degree of disability. Some studies have shown a correlation between disability and MRI lesion burden, whereas others have not. In general, individual infarcts in SS tend to be small and thus associated with a low degree of disability.

MARANTIC ENDOCARDITIS

Nonbacterial thrombotic endocarditis (NBTE) refers to sterile valvular vegetations made up of fibrin and platelets, which are found in association with many underlying conditions. Perhaps the most prominent association is with malignancy, where NBTE is termed *marantic* (or “wasted”) *endocarditis*, and systemic lupus erythematosus (SLE), where the verrucous vegetations are termed *Libman-Sacks endocarditis* (LSE). NBTE can also be found in primary antiphospholipid syndrome (APS) and is increasingly recognized in a host of other systemic illnesses including sepsis, advanced AIDS, cirrhosis, and extensive burns. It has been hypothesized that hypercoagulability is a common link.

EPIDEMIOLOGY

The most common underlying tumors include mucin-producing adenocarcinomas of the colon, pancreas, ovary, and lung in addition to hematologic malignancies. Autopsy studies have put the incidence of NBTE in the general population at 1% with studies of SLE patients showing rates upwards of 30% and as high as 19% among cancer patients, although other series indicate lower rates among cancer patients. Specific features of SLE that predispose to LSE have not been consistent with some studies showing an increased risk in the presence of antiphospholipid antibodies, whereas others have not confirmed this association.

PATHOBIOLOGY

Despite the underlying cause, the pathology is generally the same: superficial bland vegetations affixed to a valve with preserved underlying architecture. The vegetations generally consist of a fibrin core with aggregated platelets, without any demonstrable evidence of infectious organisms or inflammatory reaction. Vegetations are generally found on left-sided valves, with the mitral valve most commonly affected. Vegetations have a predilection for the atrial side of the mitral valve and ventricular side of the aortic valve and are generally at the contact margins of the valve leaflets, perhaps due to the highest turbulence of blood at these locations with resulting microtrauma to the underlying valve. An underlying immune-mediated destructive process has also been hypothesized in addition to an underlying hypercoagulable state. NBTE vegetations span a range of sizes, from submillimeter to over 1 cm, with the lesions generally consisting of single or multiple mobile verrucae. It is thought that the lack of inflammatory reaction and attendant cellular organization makes these lesions particularly friable.

Although the underlying valve architecture is generally preserved in NBTE, one large echocardiographic study did find that a majority of patients had some degree of valvular dysfunction, most commonly regurgitation. Mitral

and aortic valves were also diffusely thickened, demonstrating frequent calcification of the mitral valve annulus and chordae.

CLINICAL MANIFESTATIONS

Although NBTE rarely causes hemodynamically significant valvular dysfunction, the consequence of importance is systemic embolism, of which stroke is the most clinically apparent. In fact, it has been estimated that up to one-third of patients with NBTE have evidence of thromboembolic ischemic stroke, with rates as high as 55% noted in autopsy studies of cancer patients and between 10% and 20% in patients with SLE. One study on the brain MRI findings of NBTE patients (all with underlying adenocarcinoma) found that all cases showed evidence of numerous small- and medium-sized (1 to 3 cm) ischemic lesions in multiple vascular territories. This was in contrast to infective endocarditis patients, where diverse diffusion-weighted imaging (DWI) findings (single lesion, multiple lesions within one vascular territory, multiple punctate disseminated lesions) were seen in addition to hemorrhage. No reliable differences in presenting neurologic symptoms have been demonstrated between NBTE and infective endocarditis patients, with both focal deficits and diffuse encephalopathy described.

DIAGNOSIS

Because the lesions are generally smaller and not associated with underlying valvular dysfunction, cardiac murmurs are infrequent. Identifying NBTE is often more difficult than infective endocarditis and requires a high index of clinical suspicion, such as multiple infarcts in the setting of systemic malignancy or autoimmune disease in the absence of other explanations. Transesophageal echocardiography (TEE) is often needed, as the small size makes transthoracic echocardiography (TTE) evaluation insensitive. Indeed, one series demonstrated over twice the diagnostic yield of TEE compared with TTE in cancer patients with NBTE. Diagnosis rests on excluding an underlying infection, thus serial blood cultures in addition to a thorough systemic infectious evaluation is necessary. The distinction from culture-negative infective endocarditis may be particularly challenging because patients with malignancy and autoimmune disease often present with fever. In general, it is reasonable to consider NBTE in cryptogenic stroke patients with embolic-appearing infarcts when there is a concern for an underlying malignancy or rheumatologic disease.

P.349

TREATMENT

Although no trial data exists on treatment for NBTE, anticoagulation is generally recommended in those with marantic endocarditis and evidence of thromboembolic stroke. Heparinoids are preferred to warfarin given the superiority of the former in preventing venous thromboembolism in cancer patients. When NBTE is identified in patients with primary or secondary APS with evidence of stroke, anticoagulation with warfarin is generally recommended per APS treatment guidelines. The case of SLE with LSE is less clear, and in general, antiplatelet agents are recommended if there is no evidence of thromboembolism, with anticoagulation considered if strokes occur. No data exists on improvement in LSE lesions with immunologic therapy.

An additional concern is the potential for NBTE lesions to get secondarily infected; thus, antibiotic prophylaxis may be warranted in certain situations, for example, prior to high-risk dental procedures or surgery. Although rare, in severe cases with multiple strokes refractory to anticoagulation, surgical mitral valve replacement has been used.

OUTCOME

The outcome of NBTE generally depends on the underlying disease process. Echocardiography-based studies of patients with LSE have shown that during follow-up between 1 and 5 years, vegetations persisted, regressed, or appeared, making the course highly unpredictable. In marantic endocarditis, prognosis often depends on the underlying malignancy, with anticoagulation somewhat effective in preventing recurrent stroke although refractory cases have been reported.

CEREBRAL AUTOSOMAL DOMINANT ARTERIOPATHY WITH SUBCORTICAL INFARCTS AND LEUKOENCEPHALOPATHY (CADASIL)

CADASIL is one of the few single-gene disorders that causes stroke as a major manifestation. Patients present with multiple subcortical infarcts, progressive dementia and gait disorder, migraine headaches with aura, and psychiatric manifestations such as depression and psychosis. Common stroke risk factors, such as hypertension and diabetes mellitus, are conspicuously absent. The median age of the first stroke is 50 years, although the strokes may occur as early as 19 years of age. MRI findings include a widespread leukoencephalopathy, and the findings are virtually pathognomonic when involvement of the anterior temporal lobes and extreme capsule is seen. A phenotypic variant of CADASIL has been identified by familial clustering of hemiplegic migraine and labeled CADASILM ("M" for migraine.)

CADASIL is a protein elimination failure angiopathy, similar to amyloid angiopathy (see [Chapter 38](#)). The genetic defect is a mutation on chromosome 19p, in the *NOTCH3* gene, a highly conserved gene regulating development. The protein is a transmembrane receptor involved in intercellular communication, and it is found on vascular smooth muscle cells. Diagnosis is made by genetic testing, which can detect 70% of the clustering mutations causing the disease, or skin biopsy, in which the presence of granular osmiophilic material (GOM) between smooth muscle cells and the basement membrane or immunostaining for the NOTCH3 protein is seen. The mechanism by which the smooth muscle cell pathology leads to vasculopathy and stroke remains uncertain, but it does not appear to be a thrombotic disorder. Apart from antiplatelet therapy with aspirin, clopidogrel, or a similar agent, there is no known treatment. The mean survival time is 20 years from onset of symptoms.

Primary and Secondary Stroke Prevention

Charles C. Esenwa

Mitchell S. V. Elkind

INTRODUCTION

Prevention of stroke can be divided into three types: (1) primordial prevention, which focuses on improving community-wide health behaviors, such as diet, exercise, and smoking; (2) primary prevention, which attempts to mitigate an individual's stroke risk factors; and (3) secondary prevention, which targets risk of stroke recurrence in those who have already suffered a stroke or transient ischemic attack (TIA).

Risk factors are generally classified as either nonmodifiable or modifiable. Nonmodifiable risk factors, although they cannot be altered, remain important in quantifying a patient's future risk of stroke. Examples include age, sex, family history, ethnicity, and race. Modifiable risk factors allow for intervention to decrease future risk of stroke.

Although primordial prevention deals with population-level risk of cardiovascular disease, individualized prevention measures require a careful history and tailored diagnostic evaluation to stratify stroke risk and guide the appropriate prevention strategy. Primary and secondary prevention methods both focus on improving the individual's risk factor profile, and secondary prevention methods further depend on the mechanism of the stroke. For ischemic stroke, these mechanisms include atherothrombotic, small vessel (or "lacunar"), cardioembolic, and cryptogenic; the last is responsible for up to 40% of strokes. Several randomized controlled trials have been conducted over the past four decades that have determined optimal therapy for stroke prevention and treatment, especially for atherothrombotic and cardioembolic stroke subtypes.

Hemorrhagic strokes account for 15% to 20% of all strokes and are further divided into subarachnoid hemorrhage (SAH) and intracerebral hemorrhage. Causes of SAH include trauma, berry or congenital aneurysms, and less often arteriovenous malformations. Intracerebral hemorrhage is most commonly caused by hypertension. Appropriate classification of a stroke and its etiology aids the clinician in determining the most effective prevention strategy.

The INTERSTROKE case-control study among 22 countries determined that 10 risk factors accounted for nearly 90% of strokes. Listed in order of significance, they are as follows: hypertension, cardiac disease, current smoking, waist-to-hip ratio, poor diet, sedentary lifestyle, excessive alcohol intake, diabetes mellitus, depression, and psychosocial stress. The highest burden of stroke in the United States falls in the so-called stroke belt located in the southeast, where high prevalences of diabetes, hypertension, and obesity remain likely important drivers of cerebrovascular disease.

PRIMORDIAL STROKE PREVENTION

DIET

The Mediterranean diet may protect against cardiovascular disease, including stroke. It is characterized by high intake of fruits, vegetables, and legumes; olive oil as the principal source of fat; moderate consumption of fish and poultry, with minimal intake of red meat and dairy; and an option of mild to moderate consumption of red wine, mostly with meals. Compared to a low-fat diet, this complex combination of nutrients decreased 5-year stroke risk by approximately 30% in a prospective study. In general, any diet aimed at promoting cardiovascular health, such as the Mediterranean diet or the Dietary Approach to Stop

Hypertension (DASH) diet, revolves around the central notions of a high intake of plant-based nutrients, low-salt intake, and a curbing of saturated fats and simple sugars.

SMOKING

Tobacco use is strongly discouraged and among smokers, cessation of smoking leads to a reduction in stroke risk to levels similar to nonsmokers by 5 years.

EXERCISE

Physical activity is associated with a reduced risk of stroke and, importantly, several studies provide evidence that only a moderate level of activity is required, and so physical activity should be encouraged even among the elderly. A sedentary lifestyle, in combination with consumption of simple carbohydrates, has contributed to one-third of Americans becoming obese and to even more becoming overweight. Obesity is an independent risk factor for stroke, even after adjusting for physical activity and diet. Obesity is comorbid with diabetes, hypertension, and heart disease, moreover.

PRIMARY STROKE PREVENTION

Like primordial stroke prevention, primary stroke prevention aims to limit the risk of first-time stroke, but instead of dealing with groups of people, the health care provider focuses on each individual separately. Specific targets for intervention are a person's major modifiable risk factors including hypertension, diabetes mellitus, hypercholesterolemia, atrial fibrillation, and medication use. Several randomized trials have demonstrated the benefits of specific interventions to prevent a first stroke among patients with certain stroke risk factors ([Table 44.1](#)).

TABLE 44.1 Evidence-Based Primary Stroke Prevention

Risk Factor	Treatment
Hypertension	Antihypertensive
Myocardial infarction	HMG-CoA reductase inhibitor
Hyperlipidemia	HMG-CoA reductase inhibitor
Atrial fibrillation	Warfarin or oral anticoagulants
DM/vascular disease	ACE inhibitor
Asymptomatic carotid stenosis (60%-99%)	Consider carotid endarterectomy.
“High-risk” populations	HMG-CoA reductase inhibitor

HMG-CoA, hydroxymethylglutaryl-coenzyme A; DM, diabetes mellitus; ACE, angiotensin-converting

HYPERTENSION

Blood pressure is the most important contributor to stroke incidence, increasing the risk of stroke in a linear fashion. High blood pressure accounts for 35% of all strokes. β -Blockers, thiazide diuretics, angiotensin-converting enzyme inhibitors (ACEIs), angiotensin II receptor blockers (ARBs), and calcium channel blockers are the most widely studied agents in stroke prevention. Although calcium channel blockers may provide the greatest neurovascular protection, they are also associated with an increased risk of heart failure. The general consensus is that protection against stroke depends on the level of blood pressure control rather than on the specific class of medication used. Blood pressure reductions of 10 mm Hg systolic or 5 mm Hg diastolic have been shown to reduce risk of first-time stroke by more than 40% [Level 1].¹ In the United States, efforts targeting hypertension have contributed to the steady decline in stroke incidence and stroke-related mortality in the last half century.

The effects of adequate blood pressure management may be more robust in those with diabetes mellitus. ACEIs and ARBs are recommended because they have been proven renoprotective and also effective in reducing cardiovascular events and specifically stroke in those with diabetes mellitus.

DIABETES MELLITUS

Epidemiologic studies show a positive relationship between hyperglycemia and stroke incidence, but aggressive management of hyperglycemia may actually be harmful. The Action to Control Cardiovascular Risk in Diabetes (ACCORD) study compared intensive glucose-lowering therapy with a goal glycated hemoglobin level below 6% versus glycated hemoglobin goals of 7% to 7.9% and found no difference in stroke incidence with a slight, but statistically significant, increase in overall mortality in the group undergoing tight control. Similarly, postprandial hyperglycemia and glycemic variability have both been associated with increased cardiovascular disease burden in epidemiologic studies, but prospective studies have not shown any benefit. Current recommendations are for a glycated hemoglobin goal of less than 7%.

The presence of diabetes also has ramifications for the management of other risk factors, specifically low-density lipoprotein (LDL) cholesterol. Diabetes is considered a cardiovascular disease equivalent and those 40 to 75 years of age with diabetes should be placed on a hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitor or statin, unless there is a contraindication.

HYPERCHOLESTEROLEMIA

Large epidemiologic studies, such as the Multiple Risk Factor Intervention Trial (MRFIT) that included over 350,000 men, have shown a positive association between death from ischemic stroke and increased cholesterol levels. There has also been evidence of a relationship between hemorrhagic strokes and low cholesterol levels. In line with the MRFIT data, trials using HMG-CoA reductase inhibitors among cardiac and other high-vascular disease risk patients have demonstrated benefits in terms of stroke risk reduction, in addition to the effects on cardiac event rates. The effect on stroke risk is more modest, however, probably reflecting the fact that stroke is more heterogeneous than heart disease and less strongly linked to elevated cholesterol levels.

In the Heart Protection Study (HPS), a randomized multicenter, placebo-controlled trial of simvastatin therapy, there was a 25% risk reduction for stroke (from 5.7% to 4.3%; $P < .0001$), without an increase in risk of hemorrhagic stroke over a 5-year period. Importantly, these benefits remained in those with LDL less than 100 mg/dL.

Evidence suggests that the optimal way to think about cholesterol goals within the context of primary stroke

prevention is to consider the individual's long-term absolute risk of combined cardiovascular events. The Pooled Cohort Risk Assessment Equations was developed by the American College of Cardiology and American Heart Association using data from several large epidemiologic studies to predict a 10-year risk of cardiovascular events and identify appropriate candidates for statin therapy. Those with a high risk of cardiovascular events (considered to be at least 7.5% over 10 years) should be placed on cholesterol-lowering therapy, independent of specific risk factors. Other high-risk groups that should receive statin therapy are individuals with an LDL greater than 190 mg/dL and those aged 40 to 75 years with comorbid diabetes mellitus [**Level 1**].²

ATRIAL FIBRILLATION

Atrial fibrillation is the most important cause of embolic stroke. Anticoagulation is effective in preventing both incident and recurrent strokes in patients with atrial fibrillation [**Level 1**].³ In the Stroke Prevention in Atrial Fibrillation (SPAF) study, anticoagulation reduced stroke recurrence substantially, even in patients older than the age of 75 years. Chance of embolization is associated with the following risk factors: age older than 75 years, previous embolization, sustained hypertension, and congestive heart failure. With one risk factor, the stroke incidence is nearly 3% per year and increases to 18% when all are present.

Warfarin, a vitamin K antagonist, is associated with a 60% to 70% relative risk reduction in stroke. More recently, two other classes of anticoagulant therapies have been employed: direct thrombin inhibitors and factor Xa inhibitors. Large randomized clinical trials that have compared warfarin to either dabigatran, rivaroxaban, or apixaban have shown similar or slightly better efficacy with the newer agents. Some of the trials also indicate a lowered risk of intracranial hemorrhage with less need for serum monitoring, although the role of serum monitoring for some agents is still under investigation. There are two deterrents to physicians routinely prescribing the newer agents, however. The first is the lack of a standardized clotting assay, such as the international normalized ratio (INR) for warfarin, that allows for rapid evaluation of level of anticoagulation, and the second is the lack of an effective antidote, such as fresh frozen plasma and vitamin K, that can be employed when major bleeding occurs. Current research is directed at addressing these concerns.

CAROTID STENOSIS

Another major source of preventable cerebral infarction is largevessel atherosclerotic disease and specifically internal carotid artery stenosis. In asymptomatic patients with greater than 60% carotid stenosis and low perioperative risk, carotid endarterectomy (CEA) should be considered with the expectation that approximately 20 procedures must be performed to prevent one stroke over a 5-year period. Men are much more likely to benefit than women, which, along with the patient-specific perioperative risk, helps the clinician decide whether or not to recommend surgery. Although CEA is the gold standard, carotid artery stenting (CAS) is an alternative and may be employed if the anatomy is unfavorable to surgical intervention. There is no benefit of either procedure in patients with less than 50% stenosis or in chronic carotid occlusion.

SECONDARY STROKE PREVENTION

Once a stroke or TIA has occurred, the goals of the clinician are to minimize long-term disability and direct management to prevent another stroke (Fig. 44.1). Secondary stroke prevention measures do not alter progression of the initial stroke, but research has shown that initiating preventive therapy in the acute setting after stroke increases the likelihood of preventive therapy being in place in the long term.

STROKE MECHANISM AND EVALUATION

Therapies aimed at limiting risk of recurrence depend in large part on the mechanism of the stroke, its severity, and the individualized modifiable risk factor profile. Because the risk of a repeat stroke is highest in the first 2 weeks after the initial event, a comprehensive evaluation must be employed as soon as possible to determine stroke mechanism and quantify the underlying risk factors. The importance of a good history and physical examination cannot be overstated and should be followed by hypothesis-driven diagnostic testing. Magnetic resonance imaging (MRI) of the brain visualizes acute ischemic injury and can aid in determining the mechanism. Although lacunar strokes, or deep punctate infarcts within the white matter, predominantly occur from small-vessel disease, for example, large wedge-shaped infarcts or multifocal infarcts are more consistent with embolism. Extracranial vessel imaging specifically looking at the patency of the carotid arteries is a crucial step in the diagnostic algorithm, whereas intracranial vessel imaging in the form of magnetic resonance angiography (MRA) or computed tomography angiography (CTA) may be useful to identify intracranial stenosis. The gold standard for carotid imaging is digital subtraction angiography, but it is impractical for screening purposes. Carotid Doppler has therefore become the main screening test for carotid atherosclerosis, whereas the widespread availability of MRA and CTA provide alternatives to be used at the clinician's discretion and to confirm the findings on ultrasound.

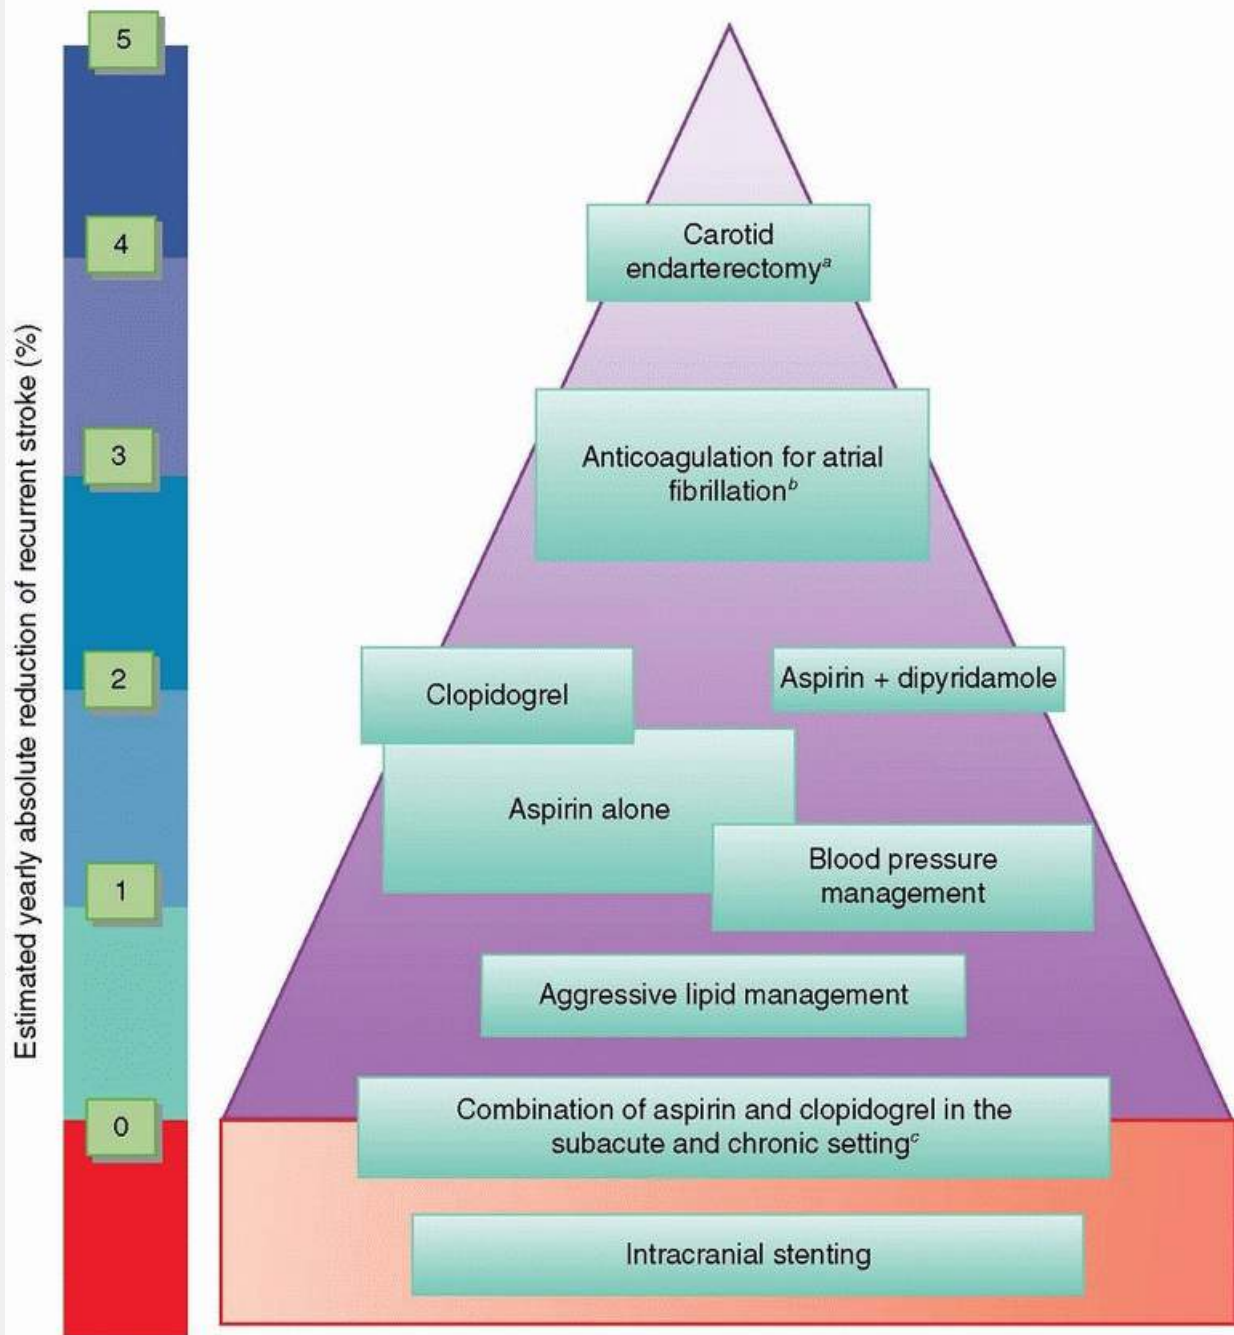

FIGURE 44.1 Effect of secondary stroke prevention measures on stroke recurrence. Estimated absolute risk reductions in stroke of various secondary stroke prevention therapies compared to placebo or in some cases, standard management. ^aRefers to symptomatic carotid stenosis of 70% to 99%. ^bWarfarin or direct oral anticoagulants. ^cCompared to single antiplatelet agent and not including dual antiplatelet therapy initiated in the acute setting after stroke.

Transthoracic echocardiography is used to assess structural cardiac abnormalities that predispose to cardioembolism. In cases with a high pretest probability of embolism, transesophageal echocardiogram can be used to better visualize the left atrium and cardiac valves, looking for intra-atrial thrombus, cardiac myxoma, or valvular vegetations. A second arm of the cardiac evaluation assesses the cardiac rhythm for evidence of atrial fibrillation. Electrocardiography and cardiac telemetry are used in screening, whereas prolonged monitoring for several weeks to months can be very helpful in capturing occult atrial fibrillation. Measuring LDL, highdensity lipoprotein, hemoglobin A1c, and in appropriate or otherwise unexplained cases, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), or rapid plasma reagin (RPR) allow for proper management and prevention of recurrent stroke.

PREVENTION EARLY AFTER ACUTE STROKE

It is important to recognize that TIAs call for the same urgency in evaluation as MRI-proven strokes.

Johnston et al. showed that

P.354

the risk of stroke after TIA is about 5% in the first 2 days and 10% within 90 days. Further, 1 in 20 individuals will suffer a fatal or disabling stroke within 90 days after TIA. Recent trials proved that urgent evaluation and directed management of TIA or minor stroke dramatically decreases the recurrence rate of stroke.

Early interventions aimed at stroke prevention revolve around mitigating high-risk situations, such as moderate to high-grade carotid stenosis and atrial fibrillation. In general, dual antiplatelet therapy in the realm of stroke prevention has been reserved for cases of atrial fibrillation in which a contraindication for anticoagulation exists, but one recent study challenged this notion. The Clopidogrel in High-risk Patients with Acute Nondisabling Cerebrovascular Events (CHANCE) trial found that a 21-day course of dual antiplatelet therapy with aspirin and clopidogrel among Chinese patients with TIA and minor stroke, given within 24 hours of symptom onset, lowered the 3-month stroke recurrence rate. A short course of aspirin and clopidogrel in the early period may therefore be considered but cannot be recommended for all patients until further studies replicate these findings. Short-term subcutaneous heparin is not effective in preventing stroke recurrence compared to aspirin, according to the International Stroke Trial (IST), which enrolled nearly 20,000 ischemic stroke patients; similar findings were seen in the Chinese Acute Stroke Trial (CAST) with nearly the same number of patients.

ANTIPLATELET THERAPY

All patients with ischemic stroke without a definite indication for anticoagulation, and in whom no contraindication is present, should receive long-term antiplatelet therapy. Aspirin monotherapy, the combination of aspirin with extended-release dipyridamole, or clopidogrel, are all acceptable options for initial therapy in the secondary prevention of noncardioembolic stroke [**Level 1**].⁴

The action of aspirin is to irreversibly acetylate and inhibit platelet cyclooxygenase-1, which stops synthesis of the powerful platelet aggregant thromboxane A₂ (TXA₂). Lower doses of aspirin have the advantage of minimizing inhibition of endothelial cell production of prostacyclin (PGI₂), the powerful platelet antiaggregant. The concept of a balance between TXA₂ and PGI₂ in the normal circulation without aggregate formation won Sir John Vane a Nobel Prize. Dipyridamole acts in conjunction with aspirin by increasing adenosine and PGI₂, two potent antiaggregants. The optimum dose of daily aspirin remains somewhat controversial, but doses as low as 30 mg daily appear effective and have less side effects such as gastrointestinal bleeding. The U.S. Food and Drug Administration (FDA) currently recommend doses between 50 and 325 mg daily for stroke prevention.

Clopidogrel, a thienopyridine derivative, is increasingly being used for secondary stroke prevention. Cilostazol is a phosphodiesterase 3 inhibitor used in peripheral arterial disease that has proven to reduce recurrence of stroke in Asian populations but is less well studied and therefore not widely used in stroke prevention in the United States. In general, the risk of adverse events with standard antiplatelet agents is very low, but a few points need to be considered: (1) treating with the combination of aspirin and dipyridamole requires twice daily dosing and is complicated by a high rate of secondary headache and gastrointestinal symptoms, thus reducing patient compliance; (2) higher doses of aspirin increase bleeding risk without providing clinical benefit; and (3) clopidogrel can cause diarrhea, thrombocytopenia, rash, and in very rare circumstances, thrombotic thrombocytopenic purpura.

As a group, antiplatelets offer an absolute risk reduction of 2% in yearly vascular events (myocardial infarction, stroke, and death), with a 0.1% to 0.2% increase in major extracranial hemorrhages (number

needed to harm is 500 to 1,000 to cause one major extracranial hemorrhage). There may also be a modest benefit of clopidogrel, or aspirin with dipyridamole, over aspirin alone for prevention of recurrent strokes, according to some meta-analyses. Aspirin with dipyridamole compared to aspirin alone produced an approximate annual absolute risk reduction of 1% in two large clinical trials. On the other hand, clopidogrel and the combination of aspirin with dipyridamole produced nearly identical results in one study. Choice of antiplatelet depends on the setting, comorbidities, and access to health care, but aspirin is the most widely studied and least expensive medication, making it ideal for large-scale use especially in developing countries where the number treated is usually determined by the cost of therapy. Clopidogrel and aspirin with dipyridamole are reasonable alternatives as first-line therapy or second-line therapy in those who have suffered a stroke while on aspirin.

More recently, dual antiplatelet therapy with clopidogrel and aspirin, compared to aspirin alone, has been investigated in secondary prevention after lacunar stroke in the Secondary Prevention of Small Subcortical Strokes (SPS3) trial. There was no evidence of a reduction in risk of stroke recurrence, despite an increase in risk of bleeding and mortality, among those treated with dual antiplatelet therapy. There are several reasons that may account for the difference in results between the CHANCE trial described earlier and SPS3: (1) CHANCE studied acute therapy, within 24 hours of stroke onset, with half of the participants randomized within 12 hours; (2) CHANCE included only patients with mild stroke and TIA, isolating a group with low risk of hemorrhagic conversion; and (3) CHANCE used dual antiplatelet agents for only 3 weeks, whereas SPS3 enrolled patients within 6 months of stroke onset and used dual antiplatelet therapy for the duration of the trial. The majority of the benefit from dual antiplatelet therapy in CHANCE occurred within the first week of treatment. This immediate reduction in recurrent vascular events is a phenomenon echoed in trials that studied dual antiplatelet agents within 24 hours of cardiac ischemia.

ANTICOAGULATION

Anticoagulation with warfarin is indicated in patients with definite cardioembolic sources of stroke such as mechanical valves or left ventricular thrombus. In patients with atrial fibrillation, anticoagulation with warfarin or one of the newer anticoagulants (described earlier) is indicated.

CAROTID ENDARTERECTOMY, ANGIOPLASTY, AND STENTING

In good surgical candidates, the treatment of choice for stroke and TIA caused by carotid stenosis of equal to, or greater than, 70% of the vessel diameter is CEA by a skilled surgeon with an acceptable complication rate (<5%) combined with optimal medical management, as demonstrated by three prospective studies: the North American Symptomatic Carotid Endarterectomy Trial (NASCET), the European Carotid Surgery Trial (ECST), and the U.S. Veterans Affairs Cooperative Study (VACS) on CEA [Level 1].⁴ The first published case of successful CEA was performed by De-Bakey in 1954, but it wasn't until 1991 that these studies confirmed its benefits. In those with high-grade carotid stenosis, CEA yields a number needed to treat of 16 to prevent one stroke over a 1-year period. There is also a benefit, albeit more modest, of CEA in symptomatic patients with moderate carotid stenosis (50% to 69%). Post hoc analysis has also demonstrated that the greatest value of CEA is within 2 weeks of the event, and contemporary literature argues for intervention as soon as is medically possible.

P.355

More recently, CAS has been compared to CEA in three large trials: Stent-Protected Angioplasty versus Carotid Endarterectomy (SPACE), International Carotid Stenting Study (ICSS), and the Carotid Revascularization Endarterectomy versus Stenting Trial (CREST). Results have been consistent in showing a slight increase in periprocedural stroke (30 days) with CAS compared to CEA. In SPACE and CREST, combined adverse outcomes over a 2-year period were similar, whereas ICSS showed that CEA was superior in combined outcomes both in the acute and long-term settings. Although CEA remains the

treatment of choice for symptomatic high-grade carotid stenosis, CAS is an alternative that can be employed in high-risk surgical patients or those with unsuitable anatomy.

There have been a number of trials looking at strategies for preventing stroke from intracranial stenotic lesions that are not readily accessible to surgeons. Stroke distal to a 50% to 99% vascular stenosis carries a recurrence rate of 15% in the first year. The comparison of Warfarin and Aspirin for Symptomatic Intracranial Stenosis (WASID) trial studied aspirin versus warfarin in patients with symptomatic intracranial stenosis 50% to 99%. The study was stopped because of a high rate of adverse events in the warfarin group, leading researchers to conclude that warfarin provides no benefit over aspirin in patients with intracranial stenosis. Despite the negative primary result, the study provided the important finding that risk was highest in patients with greater than 70% stenosis, a group that had a 25% stroke recurrence rate in the first year. The subsequent Stenting versus Aggressive Medical Therapy of Intracranial Atherosclerotic Stenosis (SAMMPRIS) trial thus targeted patients with recent stroke and high-grade intracranial stenosis (>70%), comparing percutaneous transluminal angioplasty and stenting with best medical management with aggressive risk factor control. Both groups received dual antiplatelet therapy with aspirin and clopidogrel for 3 months. There was also aggressive management of risk factors including hypertension, lipids, diabetes, and tobacco use. The primary end point of recurrent stroke or death was reached in 20% of the stenting group as opposed to 12% in the medical management group. Interestingly, the medical group had a lower than expected stroke recurrence rate compared to the 25% risk predicted by the WASID study. The results suggested that aggressive medical therapy is superior to intervention for high-grade intracranial stenosis with currently available technology.

CARDIAC ABNORMALITIES

Treatment of cardiogenic emboli depends on the offending pathology: Infected prosthetic valves need replacement, and myxomatous emboli require surgical removal of the tumor (Table 44.2). The role of anticoagulation among patients with possible paradoxical embolism through a patent foramen ovale (PFO) is unclear, and current guidelines support the use of antiplatelet agents for secondary prevention in this setting. Whether closure of PFOs using transcatheter devices can reduce secondary stroke, risk has been investigated in three large prospective trials comparing closure to medical therapy. None of them were able to show benefit of PFO closure when compared to medical therapy alone. The risk of recurrent stroke is low among patients with stroke likely due to PFO but closure may still be considered on an individualized basis.

TABLE 44.2 Cardioembolic Sources of Stroke

High-Risk	Low-Risk/Unknown Risk
Atrial fibrillation	Cardiomyopathy
Mechanical prosthetic valve	Aortic arch atheroma
Recent myocardial infarction	Patent foramen ovale
Left ventricular thrombus	Atrial septal aneurysm
Rheumatic heart disease	Mitral valve strands
Marantic endocarditis	

Atrial myxoma

Infective endocarditis

Aortic arch atheromatous plaque is another condition associated with increased risk of stroke, with retrospective case-control studies consistently showing an association. Complex plaques, defined by a protruding component greater than 4 mm, presence of a mobile component, or intraplaque ulceration, are deemed high risk for embolization. Despite the known association, a causal relationship between aortic arch atheroma and stroke has never been proven, mirroring the uncertainty in therapeutic recommendations. There is no clear evidence to support use of anticoagulation, even in complex plaques. Statins are recommended because of their potential to remodel and cause regression in atheromatous plaques, along with standard antiplatelet therapy for secondary stroke prevention.

MODIFIABLE RISK FACTOR MANAGEMENT

Hypertension

Recent studies have provided evidence for increased use of antihypertensive agents in patients with stroke and TIA. Despite evidence of the efficacy of blood pressure reduction in reducing risk of a first stroke, concerns about lowering blood pressure in patients with existing cerebrovascular disease remained due to the theoretical possibility that in patients with arterial disease of cerebral vessels, a reduction in blood pressure could worsen perfusion and precipitate clinical events or affect cognition.

Much has been made of the potential benefits of ACEIs or ARBs in stroke prevention. This has been an attractive hypothesis, but the data does not provide an entirely convincing picture regarding the privileged position of ACEIs and ARBs among antihypertensive agents, particularly after stroke. Although diabetics should probably receive these medications for prevention of progression of renal disease, it is not clear that this therapy dramatically reduces the incidence of stroke beyond what would be expected from reducing the blood pressure to a similar degree using other agents. The PROGRESS (Perindopril Protection against Recurrent Stroke Study) trial was designed and conducted in large part to address these concerns. PROGRESS was a randomized, double-blind, placebocontrolled trial of antihypertensive therapy among 6,105 patients with a history of hemorrhagic or ischemic stroke or TIA. Patients were enrolled independent of hypertension status, and 52% were nonhypertensive—considered to be systolic blood pressure 160 mm Hg or lower and diastolic blood pressure 90 mm Hg or lower—the blood pressure thresholds in use at the time the study started. Active treatment used the ACEI perindopril, with or without the thiazide diuretic indapamide. Active therapy led to a mean blood pressure reduction of 9/4 mm Hg compared with placebo, with a statistically significant 28% relative risk reduction in recurrent stroke or an absolute risk reduction of 4%. Of particular interest, the benefit of combination therapy was of a similar magnitude among hypertensive and nonhypertensive patients and was of greater benefit for those with initial hemorrhagic stroke (relative risk reduction 49%) than for those with ischemic stroke (relative

P.356

risk reduction 26%), likely reflecting the even stronger association of blood pressure with hemorrhagic stroke risk. PROGRESS has therefore been interpreted as indicating a benefit for blood pressure reduction among patients with cerebrovascular disease, independent of a history of hypertension.

The SPS3 study, aside from studying the effect of dual antiplatelet therapy, also examined the role of strict versus standard blood pressure management (systolic <130 mm Hg vs. 130 to 149 mm Hg) on the outcome of stroke recurrence and showed a trend toward benefit in stroke recurrence in the lower blood pressure group (hazard ratio 0.81, confidence interval 0.63 to 1.03). Current guidelines recommend blood pressure

lowering based on individualized targets, but it is reasonable to use a systolic blood pressure goal of less than 140 mm Hg and diastolic less than 90 mm Hg [Level 1].⁵ Reducing daily salt intake to 2 g, engaging in regular physical activity, and losing weight in overweight or obese patients may also have substantial benefits on blood pressure levels, apart from use of pharmacologic therapy.

Hyperlipidemia

Hyperlipidemia is another important modifiable risk factor for vascular disease, although its relationship to stroke is less clear than that for heart disease. The Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL) trial provides direct evidence of the benefit of statin therapy in secondary prevention of stroke among patients presenting with stroke or TIA. SPARCL enrolled 4,731 patients with stroke or TIA within the previous 6 months, and at least 30 days, after stroke. Patients were required to have baseline LDL cholesterol levels between 100 and 190 mg/dL. Those with atrial fibrillation, cardioembolism, and SAH were excluded and patients were randomized to atorvastatin 80 mg daily or to placebo. Over a median duration of follow-up of nearly 5 years, atorvastatin reduced the risk of recurrent stroke from 13.1% to 11.2%. Effects on other cardiovascular outcomes were slightly greater, but there was no effect on overall mortality.

Because lipids are not thought to contribute significantly to stroke risk, some of this benefit may derive from the anti-inflammatory or other effects of statins. Other putative mechanisms through which they exert their effects include effects on blood flow and vascular endothelial function, inflammation, free radical scavenging, hemostasis, and others.

Statin are the mainstay in lipid reduction therapy and aggressive lipid-lowering treatment should be employed after a stroke or TIA [Level 1].²

Diabetes Mellitus

Although glycemic control has been shown to reduce risks of microvascular complications, the benefit in reducing macrovascular complications, such as stroke, is less certain. In one trial, tight glycemic control of a prospective cohort of newly diagnosed diabetics was not found to significantly reduce stroke risk. Nonetheless, among sufferers of stroke who have concomitant diabetes, diet and exercise, oral hypoglycemic drugs, and insulin are recommended to obtain appropriate glycemic control.

Lifestyle Modification

Behavioral risk factors may be most difficult to control, but physicians should endeavor to educate patients about their importance. Smoking is addictive, and cessation may necessitate psychological counseling and medical aids, such as nicotine patches or varenicline. Physical activity should be encouraged, as a sedentary lifestyle is associated with elevations in blood pressure and stroke risk. Alcohol consumption in excess of two drinks daily should be discouraged, although there is evidence that moderate alcohol consumption may actually have protective effects against stroke risk. However, proof that control of these risk factors reduces stroke risk is difficult to obtain from randomized trials. Patient education regarding behavioral risk factor control is extremely important and is similar for both primary and secondary stroke prevention [Level 1].³

HEMORRHAGIC STROKE

INTRACEREBRAL HEMORRHAGE

Intracerebral hemorrhage (ICH) accounts for approximately 10% to 15% of all strokes in the United States and carries a 1-year mortality close to 60%. Other than hypertension, spontaneous ICH can be caused by cerebral amyloid angiopathy, anticoagulation therapy, vascular malformations, brain tumors, cavernous angiomas, aneurysms, cerebral vein thrombosis, illicit drugs or alcohol abuse, pathologic coagulopathy, and genetic

vasculopathies. Massive ICHs of more than 60 mL in volume are usually lethal because vital structures are irreversibly damaged, whereas smaller hemorrhages may be treated with supportive care. Given the dismal 1-year prognosis even with small- to moderate-sized hemorrhage, primary prevention of ICH is of the utmost importance.

Hypertension

As with ischemic stroke, first-time ICH can in many cases be avoided through identification and management of specific risk factors. Hypertension is the most important modifiable risk factor and doubles the risk of first-time spontaneous ICH. Blood pressure control lowers the risk of ICH recurrence by nearly 50%. Annual recurrence is high and occurs in 2% of those with a deep location and as high as 4% of those with a lobar localization. The higher risk of recurrence with lobar hemorrhage likely represents the occurrence of cerebral amyloid angiopathy in lobar vascular territories.

Cerebral Amyloid Angiopathy

Cerebral amyloid angiopathy (CAA) is not yet a modifiable risk factor but is helpful when assessing risk of recurrent ICH. CAA-associated microhemorrhages and microinfarcts are much more common than clinically evident bleeds, occurring one and eight times per year, respectively. The biggest risk factors for recurrent CAA-associated hemorrhages are age, the number of microbleeds present at baseline, and the presence of the apolipoprotein E E2 or E4 alleles.

Amyloid-depleting therapy is currently not available, limiting attempts at secondary prevention. The PROGRESS trial, discussed earlier, studied a subset of patients with recurrent ICH and determined that blood pressure lowering by systolic/diastolic of 9/4 mm Hg decreased risk of cumulative ICH by 50% and over 70% in those with presumed CAA, establishing the viability of a traditional risk prevention approach in those with CAA-related hemorrhage.

Patients with a history of symptomatic hemorrhage thought to be related to CAA carry a relative contraindication for chronic anticoagulation. Many studies reported an association of HMGCoA reductase inhibitors with an increased risk of ICH, but that was ultimately refuted by a large meta-analysis that included over 40 trials with nearly 250,000 individuals. Nonetheless, there is no benefit for statins in the prevention of ICH, although they may be used in those with previous ICH who have other indications, such as cardiovascular disease or ischemic stroke.

P.357

Arteriovenous Malformations

Bleeding from arteriovenous malformations (AVMs) is the most common cause of ICH in those younger than 45 years of age. The Medical Management with or without Interventional Therapy for Unruptured Brain Arteriovenous Malformations (ARUBA) trial evaluated interventional therapy versus medical therapy alone as management of previously unruptured AVMs. The study was stopped early because those in the medical therapy group had a lower risk of stroke or death compared to the intervention group. It is therefore prudent to manage unruptured AVMs conservatively. AVMs that have ruptured are more likely to rebleed, and surgery, embolization, or stereotactic radiotherapy may be considered when anatomically feasible.

ANEURYSMAL SUBARACHNOID HEMORRHAGE

Extirpation of the aneurysm is the definitive therapy for aneurysms causing SAH and may be accomplished surgically or with balloons, coils, or embolic material deposited in the aneurysm. When it comes to prevention of aneurysmal rupture, knowing the projected natural history of the aneurysm and risk of intervention are the two most important factors driving the decision to intervene or to watch and wait. The International Study of

Unruptured Intracranial Aneurysms (ISUIA) defined yearly risk of aneurysmal rupture by site and size of the aneurysm in question. The PHASES score was established in 2014 using a pooled analysis of six prospective trials, including over 8,000 individuals, to further help predict risk of aneurysmal rupture. It recognizes seven factors (hypertension, age, history of SAH, anatomic location, size, and geographical location of residence) as predictors of aneurysmal rupture that when combined into a single score, could more accurately quantify future risk of rupture and help determine the need for intervention. The risk of rupture must be weighed against the risks of the surgery, which are determined by the patient's comorbidities and the historical periprocedural risk of the institution.

STROKE REHABILITATION

A team approach for stroke rehabilitation, starting from a stroke recovery unit with experienced physiatrists and physical therapists, has proven beneficial for the optimum recovery of patients. This approach is particularly helpful in averting various complications from strokes, such as infections, contractures, and decubitus ulcers and in maximizing independence for patients with hemiplegia/paresis by teaching them to transfer effectively from bed to wheelchair. Activities of daily living (ADLs) may be optimized for personal hygiene, dressing, and feeding as well. Speech and occupational therapists should be consulted to help patients improve their communication skills and ADL skills.

Depression is a frequent accompaniment of stroke, partially not only because the reality of a physical disability exists but also because there is altered brain chemistry, which may respond well to selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants. One randomized trial found that escitalopram administered prophylactically to stroke patients was effective in preventing the development of depression. A Cochrane review of SSRIs in the poststroke setting showed them efficacious in improving not only depression but also stroke-related dependence as well as disability. Further studies will be needed to determine whether there is a benefit to prophylactic treatment of depression compared to treatment initiated at the time of diagnosis.

Concussion

James M. Noble

John F. Crary

INTRODUCTION

Concussion is a mild traumatic brain injury that has been recognized for centuries as an entity in accidents, battle, and sport. The visibility of higher profile cases of recurrent concussion in contact sports and growing concern of the potentially long-term impact of concussion, particularly among potentially vulnerable youth with developing brains, have brought concussion to the fore in recent years and perhaps rightfully so. In reflection of increasing concern, awareness, and research in the field, this chapter is the first version to appear into this established textbook.

DEFINITION

Concussion is a mild traumatic brain injury defined by a typically transient appearance of neurologic signs and symptoms, including headache, dizziness, imbalance, tiredness and fatigue, light and sound sensitivity, concentration difficulties, and memory impairment (often described as a brain “fog”), sleep disturbance, or mood disorder, following either a direct or indirect rapid movement in the brain causing extreme rotational or translational brain acceleration or deceleration injury. Loss of consciousness at the time of impact is not required to make a diagnosis of concussion. Additional symptoms of the time of impact may include transient visual disturbances or spontaneous visual hallucinations, commonly described to “seeing stars.”

Concussion can occur by any traumatic etiology including falls from a sufficient height, motor vehicle accidents, nonpenetrating blast injuries in the field of combat, domestic violence, or other physical traumatic events. *Sport-related concussion* (SRC) is defined as a concussion that occurs coincidentally during the play of a contact sport with a high risk of concussion (i.e., American football, soccer [European football], hockey, lacrosse, basketball, wrestling, and rugby, among others) or during combat sports, which are distinguished by having the specific goal of inducing a concussion in the opponent (boxing, mixed martial arts, and related sports). Regardless of the etiology of concussion, the symptoms are largely indistinguishable but may have differing psychosocial factors associated with recovery.

In contrast to other more advanced forms of traumatic brain injury, concussion lacks defining neuroradiologic features such as hemorrhage or other obvious abnormalities on conventional neuroimaging such as computed tomography (CT) or magnetic resonance imaging (MRI). Although several fluid-based biomarkers and electroencephalogram approaches are currently under study, none is presently used in part of standard of care practice. High-field MRI sequences including diffusion tensor imaging and functional MRI (fMRI), among others, hold promise in establishing the diagnosis of concussion or perhaps even subconcussive injuries in serially monitored individuals but these too are not part of current standard of care practice. Given substantial differences in these MRI sequences between individuals, the comparison of an individual against normative values has substantial limitations and thus currently limits the use of diffusion tensor imaging and fMRI principally to research rather than clinical practice.

EPIDEMIOLOGY

The lifetime incidence of single and repeat concussion is not well known but is thought to occur in several million

individuals annually in the United States alone. The epidemiology follows a trimodal pattern over lifetime with peaks in the first few months of life, followed by adolescence, and followed by a third peak in the elderly. Contributions to concussion etiology among the very young and very old likely principally relate to accidental falls, whereas concussions in adolescents may relate to risk-taking behaviors involving driving, exposure to violence, as well as exposure to increasingly competitive athletics. The annual incidence of SRC is at least 300,000 in the United States alone, although this is likely an underestimate given poor recognition by affected players. The epidemiology of recurrent concussion is not well described but is thought to happen in a small proportion of players previously affected by SRC.

PATHOBIOLOGY

Given that concussion patients generally have no evidence of structural brain injury using conventional neuroimaging with MRI or CT, concussion has historically been considered a physiologic alteration, but this has become a matter of some debate. Concussion may reflect substantial physiologic disturbance with significant microstructural axonal disruption, which remains difficult to detect but nonetheless occurs. These injuries may be widespread or alternatively relatively focal but involving pathways with major widespread clinical implications. Experimental models suggest metabolic changes including elevated tissue lactate, which peaks over the course of several days followed by gradual recovery of cerebral blood flow within the affected tissues, with most demonstrable changes resolving by 7 to 10 days. In response to rotational or translational shear physical stress, animal histopathologic models of concussion demonstrate disruption of the viscoelastic properties of axons with rare disruption or lysis of axons themselves (Fig. 45.1).

When considering an individual experiencing a single concussion, injury thresholds required to cause concussion are not well understood but are thought to occur following at least 60 g of

P.360

linear acceleration or at least 2,000 to 4,000 rad/s^2 rotational acceleration; these forces are seldom if ever experienced in the course of normal daily life outside of recognized physically traumatic events experienced by the affected individuals. At present, risks for concussion occurrence, severity, and recurrence are not well understood but suggest prior traumatic brain injury raises the risk of subsequent concussion. The highly variable nature of concussion expression and recovery raises the possibility of an unrecognized gene-environment risk profile.

FIGURE 45.1 A: Conceptualized diagram of a human brain in coronal plane demonstrating brain inertia and distortion typical of rotational forces applied to the brain here during blunt impact to the lateral head causing rightward translational and rotational movement (*curved arrowheads* depict rotational force applied to the brain). Among myriad circumstances of brain injury, this example could occur during a hit to the left side of the head in

the course of contact sports play. **B:** Physical simulations of intracranial brain deformation in response to linear versus rotational accelerations using 1% gelatin as a brain simulant, which has similar mechanical properties as brain. Linear accelerations cause very little deformation, whereas rotational accelerations induce marked central distortion. (Courtesy of Barclay Morrison, Associate Professor of Biomedical Engineering, Columbia University.)

DIAGNOSIS

All 50 states of the United States mandate that every individual having experienced a possible or suspected SRC must be evaluated by a licensed practitioner prior to returning to play. In contrast to SRC, in which players in conjunction with team coaches and athletic trainers bring the diagnosis to attention, concussion experienced in other contexts such as motor vehicle accidents or other causes of trauma are often diagnosed at the time that the individual is brought to attention for other matters related to bodily trauma. Although many concussion screening rubrics have been proposed, fundamentally, the diagnosis is based on a clinician's suspicion that concussion has occurred based on neurologic symptoms, which should be typically without significant focal neurologic findings on examination. Any localizing or lateralizing signs or symptoms should prompt a clinician to consider neuroimaging, such as CT if the patient is suspected of having urgently declining neurologic condition or MRI if the patient is being assessed in a nonurgent setting or experiencing unexpectedly prolonged recovery of signs or symptoms following injury.

A number of devices and tools have been suggested to comprise concussion monitoring strategies, including questionnaires, complemented by a range of tests from simple reaction time to automated neuropsychological testing to more formal/conventional neuropsychological testing.

With the exception of formal neuropsychological testing, which has a significant disadvantage as a screening tool given its cost and time required, most if not all, other tests in this field were developed as a tool to assist in sideline assessments by nonmedical staff, with the intention of screening to limit the risk of prematurely returning a player to contact sport. However, they must be interpreted with substantial caution because they cannot supplant formal neurologic evaluation, which may capture subtleties not otherwise recognized on these screening assessments. Current consensus guidelines advocate the use of a standardized screening assessment, such as the Sideline Concussion Assessment Tool (third version) in the context of game play, but the validity of this and other screening tools in clinical contexts remain uncertain, and a comprehensive neurologic assessment should be pursued whenever concussion is suspected. Moreover, some screening assessments are considered normal within a relatively large range of values, are prone to retest bias, and may have limited generalizability beyond a relatively small reference population. Finally, most tests used in serial concussion monitoring programs are susceptible to “gaming” or “sandbagging” by a player eager to return to play, with baseline assessments purposefully performed poorly such that postconcussion assessments may not substantially differ.

TREATMENT

At present, there are no rigorously studied or U.S. Food and Drug Administration-approved medical therapies or physical therapy treatments, which have been clearly proven to hasten recovery following a single concussion or improve lingering postconcussion symptoms. Empiric approaches to concussion treatment among non-sport-related concussion are based on approaches developed for SRC recovery. For SRC, current empirically based guidelines recommend at least 24 hours removal from contact sport following any suspected concussion. Thereafter, players experience a graduated, patient-centered return to play protocol beginning with

slow introduction of aerobic, followed by anaerobic exercise leading into full contact drills. Although some practitioners previously advocated for prolonged rest and removal from any potentially cognitively or physically engaging scenarios, such an approach may be more harmful from a psychosocial perspective for young individuals. A return-to-play protocol typically takes place over the course of at least a week following a suspected concussion, predicated on a player not reexperiencing symptoms of concussion as each threshold of activity is gradually approached. Only when a player is symptom-free and off all medications potentially providing a clinical advantage or benefit (including those used for pain relief) is the player considered to have recovered from a concussion.

In addition to strategies to reengage the athlete to playing the sport, a significant amount of attention is placed on young individuals attempting to reengage with the academic and other scholarly activities. This often involves a multimodal treatment approach involving the players, school, and parents in a process referred to as *return to learn*. At each point of contact with a young individual having experienced concussion, clinicians should attempt to assess the player's current level of stamina for athletic and/or cognitively stimulating activities as well as potentially aggravating symptoms such as screen time in the course of computer or cellular telephone use typically used in social and academic settings. These guidelines provide a tool to monitor progress and encourage the individual to be an active participant in the recovery. Approaches to patients affected by concussion in nonsport contexts should follow similar threshold-based, gradual, patient-centered approaches to return to work, social, and professional life.

Retirement from sport or a risky behavior associated with recurrent concussions in an individual patient may be considered in some scenarios; in the context of SRC, this concept is called *medical retirement*. Such a discussion is done in a highly individualized and often challenging manner, balancing factors of patient and family motivation, potential scholarship, or other fiscal incentive to continue playing against an uncertain and highly variable neurologic prognosis. However, this may be an appropriate decision among players who demonstrate progressively lower thresholds of injury required to express concussion, progressively longer neurologic recovery periods following successive concussions, and declining scholarly, neuropsychological, or athletic performance.

OUTCOME

The natural history of a single uncomplicated concussion is not well understood. Based on SRC studies of high school and collegiate athletes involved in contact sports, approximately 80% to 90% of all persons with single uncomplicated concussions will fully recover within several days to 2 weeks. In the short term, approximately 10% to 20% of individuals with concussion will have a prolonged recovery—longer than 1 to 2 weeks and occasionally up to several months. Symptoms lingering beyond this time frame raise the possibility of a preexistent or superimposed neuropsychological condition including a mood disorder or premonitory migraine headaches. Some studies have suggested that recurrent concussions portend to a more prolonged recovery, with decreasing threshold of injury in some being associated with subsequent concussion.

Following head trauma of any kind, including concussion, patients may be more likely to express migraine headaches, mood disorders, or benign paroxysmal positional vertigo, given likely contribution of the impact to canalithiasis. At present, no evidence exists to treat these individuals any differently than would a patient be treated with these diagnoses as primary or nontraumatic disorders. However, some patients experiencing several lingering symptoms or syndromes may be best served by using therapies which offer treatment impact in multiple modalities through a relatively simple regimen.

The long-term risks and outcomes associated with single uncomplicated concussion are not well known but are thought to be associated with an increased risk of dementia if concussion is associated with loss of consciousness, particularly among apolipoprotein E4 carriers. Studies of apolipoprotein E4 are limited but have not identified differences in concussion risk or recovery based on carrier status. Although single uncomplicated concussion is considered a mild traumatic brain injury, recurrent concussions have been associated with significantly increased likelihood of developing major neuropsychiatric disorders associated with aging, including depression, dementia, Parkinson disease, amyotrophic lateral sclerosis, and erratic psychosocial behaviors including drug abuse and suicide, thus significantly impacting the quality of life of many affected individuals and their families.

One reason for the mandatory removal from play for a suspected concussion and graduated return to play thereafter is based on concern for a rare yet clearly defined neurologic syndrome called *second impact syndrome*. The disease has been identified exclusively among individuals who have returned to sports or had a second concussion prior to complete recovery from the first concussion, even if the two events are separated by days. The pathophysiology of second impact syndrome is not well understood but appears to involve severe, aggressive, and often medically refractory focal or whole brain edema following the second concussion.

CHRONIC TRAUMATIC ENCEPHALOPATHY

Chronic traumatic encephalopathy (CTE) is a term used to describe the long-term neurodegenerative syndrome that arises following mild yet repetitive traumatic brain injury. CTE was initially called *punch drunk* and later *dementia pugilistica* in light of its long established association with boxing. CTE can arise in any individual with repetitive concussive or subconcussive injuries (e.g., victims of domestic violence and psychiatric patients exhibiting headbanging behavior), but athletes who have participated in contact and/or combat sports have received the most attention. Military veterans represent another at risk population that has been increasingly studied. Furthermore, some veterans with a clinical diagnosis of posttraumatic stress disorder have been found to have CTE at autopsy, suggesting a potential overlap between these conditions.

CTE is associated with a spectrum of personality and behavioral changes, depression, increased suicidal behavior, memory loss, and cognitive dysfunction. The clinical spectrum of CTE is broad, and the full extent of the symptomatology awaits larger autopsy series, but recent research suggests that CTE has two clinical variants. The first is a *behavioral/mood variant* with features that develop at a younger age. The other is a *cognitive variant* that arises at an older age. Movement disorders, including parkinsonism, are also common. Further, it is not uncommon to observe motor neuron disease in CTE patients; this is referred to as *chronic traumatic encephalomyelopathy*. Dementia, parkinsonism, and motor neuron disease can occur singly or collectively in a single patient. Cognitive decline may be similar clinically to Alzheimer disease or frontotemporal dementia. Suicide has emerged as a cause of death among several former elite athletes, including in a period prior to recently increased CTE awareness, yet its epidemiology is not well understood.

P.362

Most CTE cases are thought to progress over decades. Manifestations of neurologic decline typically begin years after cessation of exposure to high-risk sports or recognized head injury, although some athletes have quit after developing chronic cognitive problems in the context of ongoing competitive play. Whether these changes signal active clinical manifestations of CTE is of great debate because no validated in vivo biomarkers currently exist.

The epidemiology of chronic traumatic encephalopathy is not well established given the lack for formalized diagnostic criteria and the similarities with other sporadic neurodegenerative diseases. This is even so in known

high-risk combat sports such as boxing where to date, only case series have been published, followed by more recent series involving participants in contact sports such as football, hockey, baseball, and soccer as well as combat military veterans. Case reports also exist among domestic violence victims. A recent case series of professional football players from a highly selected population of families and individuals concerned about major neurobehavioral changes identified CTE in the vast majority of subjects. Despite potential for bias, for all known professional American football brain autopsies in 2011, all 12 exhibited neuropathologic signatures of CTE. Thus, among a total of 321 professional football player deaths in the same year, most presumably without dementia, a minimum of 3.7% had neuropathologic defined CTE at death. Several young football players with neuropathologically defined early-stage CTE, who died for unrelated causes, have had no recognizable neurologic or psychiatric symptoms. However, a growing concern is that it may have substantial clinical sequelae when advanced neuropathologic changes are present. To date, the disease has not been recognized in the absence of head trauma, although the threshold of risk (how much and how severe injury is required to cause CTE) remains uncertain. Also, whether a single traumatic brain injury can trigger CTE is not known.

The pathogenesis of CTE is currently under investigation. Physical trauma is thought to lead to mechanical stress in the acute setting, shearing cellular structures (e.g., axons, dendrites, synaptic connections, glial processes, and blood vessels), resulting in cognitive impairment, or postconcussive syndrome. Associated molecular changes with acute trauma include elevation of amyloid precursor protein and other proteins. Repetitive injury may progress to neurodegeneration, sometimes many years later. Gross brain changes are nonspecific but include brain atrophy and a cavum septum pellucidum. Microscopically, CTE patients exhibit massive accumulation of abnormal aggregates containing hyperphosphorylated forms of the microtubule-associated protein tau. Tau pathology is present in neurons and glia. As many as 85% of CTE patients also exhibit accumulation of 43 kDa TAR DNA-binding protein, the primary disease protein in amyotrophic lateral sclerosis. Amyloid plaques that are characteristic of Alzheimer disease and α -synuclein-positive inclusions of Parkinson disease can also be observed but are not prominent. The abnormal tau inclusions develop in a distinctive pattern that reflects the biomechanical characteristics of the injury, including focally in perivascular spaces and at the recess of sulci, a region that can display injury acutely in traumatic brain injury (Fig. 45.2). Additional findings include subcortical axonal varicosities and axonal loss.

Finally, given the distinctly known and highly preventable risk factor of head injury leading to concussion and presumably CTE in combat sports and perhaps also in contact sports, a substantial ethical and moral dilemma is raised by this spectrum of disease. Although many professional groups, including neurologists, have advocated for banning boxing, most likely public interest in these sports will persist. Historical accounts suggest an increased risk of death during time periods when sports like these are banned yet persist in an underground or unsanctioned manner without the involvement of neurologists or colleagues in supervision or consultation. Until such time that the appetite of the general public wanes to the point of self-discontinuation of these sports, neurologists will continue to have an important role in combat sports and high-risk contact sports in helping shape public knowledge and better understanding near and long-term personalized risks for the individual athlete.

Traumatic Brain Injury

Neeraj Badjatia

Gunjan Y. Parikh

Stephan A. Mayer

EPIDEMIOLOGY

Traumatic brain injury (TBI) is a modern scourge of industrialized society. It is a major cause of death, especially in young adults, and a major cause of disability. The costs in human misery and dollars are exceeded by few other conditions.

More than 2 million patients with head injuries are seen annually in U.S. emergency rooms, and 25% of these patients are admitted to a hospital. In general, total combined rates for TBI-related emergency department (ED) visits, hospitalizations, and deaths have increased over the past decade. Almost 10% of all deaths in the United States are caused by injury, and about half of the traumatic deaths involve the brain. In the United States, a head injury occurs every 7 seconds and a death every 5 minutes. About 200,000 people are killed or permanently disabled annually as a result.

Brain injuries occur at all ages, but the peak is in young adults between the ages of 15 and 24 years. Head injury is the leading cause of death among people younger than the age of 24 years. There is, however, a trend toward an increase of mortality rates from TBI among populations aged older than 65 years over the past decade. It is anticipated that this trend will continue as the overall population ages. Men are affected three or four times as often as women. The major causes of brain injury differ in different parts of the United States; in all areas, motor vehicle accidents are prominent, and in metropolitan areas, personal violence is prevalent.

PATHOBIOLOGY

SKULL FRACTURES

Skull fractures may be divided into linear, depressed, or comminuted types. If the scalp is lacerated over the fracture, it is considered an open or *compound fracture*. Skull fractures are important markers of a possibly serious injury but rarely cause problems by themselves; prognosis depends more on the nature and severity of injury to the brain than on the severity of injury to the skull.

About 80% of fractures are linear. They occur most commonly in the temporoparietal region, where the skull is thinnest. Detection of a linear fracture often raises the suspicion of serious brain injury, but computed tomography (CT) in most patients is otherwise normal. Nondisplaced, linear skull fractures generally do not require surgery and can be managed conservatively.

In *depressed fracture* of the skull, one or more fragments of bone are displaced inward, compressing the underlying brain. In comminuted fracture, there are multiple, shattered bone fragments, which may or may not be displaced. In 85% of cases, depressed fractures are open (or "compound") and liable to become infected or leak cerebrospinal fluid (CSF). Even when closed, most depressed or comminuted fractures require surgical exploration for debridement, elevation of bone fragments, and repair of dural lacerations. The underlying brain is injured in many cases. In some patients, depressed skull fractures are associated with tearing, compression, or thrombosis of underlying venous dural sinuses.

Basilar skull fractures may be linear, depressed, or comminuted. They are frequently missed by standard skull x-rays and are best identified by CT bone windows. There may be associated cranial nerve injury or a dural tear

adjacent to the fracture site, which may lead to delayed meningitis if bacteria enter the subarachnoid space. Signs that lead the physician to suspect a fracture of the petrous portion of the temporal bone include hemotympanum or tympanic perforation, hearing loss, CSF otorrhea, peripheral facial nerve weakness, or ecchymosis of the scalp overlying the mastoid process (Battle sign). Anosmia, bilateral periorbital ecchymosis, and CSF rhinorrhea suggest possible fracture of the sphenoid, frontal, or ethmoid bones.

CEREBRAL CONCUSSION AND AXONAL-SHEARING INJURY

Loss of consciousness at the moment of impact is caused by acceleration-deceleration movements of the head, which result in the stretching and shearing of axons. When the alteration of consciousness is brief (e.g., <6 hours), the term *concussion* is used. These patients may be completely unconscious or remain awake but appear dazed; most recover within seconds or minutes, rather than hours, and some have retrograde or anterograde amnesia surrounding the event.

The mechanism by which concussion leads to loss of consciousness is believed to be transient functional disruption of the reticular activating system caused by rotational forces on the upper brain stem. Experimentally, sudden and violent head rotation may produce concussion without impact to the head. Most patients with concussion have normal CT or magnetic resonance imaging (MRI) findings because concussion results from physiologic, rather than structural, injury to the brain. Only 5% of patients who have sustained a concussion and are otherwise intact have an intracranial hemorrhage on CT.

The term *diffuse axonal injury* (DAI) is applied to traumatic coma lasting more than 6 hours. In these cases, when no other cause of coma is identified by CT or MRI, it is presumed that widespread microscopic and macroscopic axonal-shearing injury has occurred. Coma of 6 to 24 hours duration is deemed mild DAI; coma lasting more than 24 hours is considered moderate or severe DAI, depending on the absence or presence of brain stem signs, such as decorticate or decerebrate posturing (Table 46.1).

Autonomic dysfunction (e.g., hypertension, hyperhidrosis, hyperpyrexia) is common in patients with acute severe DAI and may reflect brain stem or hypothalamic injury. Patients may remain unconscious for days, months, or years, and those who recover may be left with severe cognitive and motor impairment, including spasticity and ataxia. DAI is considered the single most important cause of persistent disability after traumatic brain damage.

P.365

TABLE 46.1 Clinical Characteristics and Outcome of Diffuse Brain Injuries

	Mild Concussion	Cerebral Contusion	Diffuse Axonal Injury		
			Mild	Moderate	Severe
Loss of consciousness	None	Immediate	Immediate	Immediate	Immediate
Length of unconsciousness	None	<6 h	6-24 h	>24 h	Days to weeks
Decerebrate posturing	None	None	Rare	Occasionally	Present

Posttraumatic amnesia	Minutes	Minutes to hours	Hours	Days	Weeks
Memory deficit	None	Mild	Mild to moderate	Mild to moderate	Severe
Motor deficits	None	None	None	Mild	Severe
Outcome at 3 mo (%)					
Good recovery	100	95	63	38	15
Moderate deficit	0	5	15	21	13
Severe deficit	0	0	6	12	14
Vegetative	0	0	1	5	7
Death	0	0	15	24	51

Adapted from Gennarelli TA. Cerebral concussion and diffuse brain injuries. In: Cooper PR, ed. *Head Injury*. 3rd ed. Baltimore: Williams & Wilkins; 1993:140.

Axonal-shearing injury tends to be most severe in specific brain regions that are anatomically predisposed to maximal stress from rotational forces. Macroscopic tissue tears, best visualized by MRI, tend to occur in midline structures, including the dorsolateral midbrain and pons, posterior corpus callosum, parasagittal white matter, periventricular regions, and internal capsule. Microscopic damage occurs more diffusely, as manifested by axonal retraction bulbs throughout the white matter of the cerebral hemispheres. Prolonged loss of consciousness from DAI tends to be associated with bilateral, asymmetric, focal lesions of the midbrain tegmentum, a region densely populated with reticular activating system neurons. Small hemorrhages, known as *gliding contusions*, are sometimes associated with focal-shearing lesions (Fig. 46.1).

Axonal shearing is thought to initiate a dynamic sequence of pathologic events that evolve over days to weeks. Initially, injury causes physical transection of some neurons and internal axonal damage to many others. In both cases, the process of axoplasmic transport continues, and materials flow from the cell body to the site of damage. These materials accumulate and may lead to secondary axonal transection, with formation of a “retraction ball” from 12 hours to several days after the injury. Membrane channels may open to admit toxic levels of calcium. If the patient survives, MRI may demonstrate chronic atrophy of involved white matter tracts (wallerian degeneration) and gliosis.

BRAIN SWELLING AND CEREBRAL EDEMA

Brain swelling after head injury is a poorly understood phenomenon that may result from several different mechanisms. Posttraumatic brain swelling may result from *cerebral edema* (e.g., an increase in the content of extravascular brain water), an increase in cerebral blood volume (CBV) resulting from abnormal vasodilatation, or both. Cerebral edema may be further classified as cytotoxic, vasogenic, or interstitial (see Chapter 107). The

swelling may be diffuse or focal, adjacent to a parenchymal or extradural hemorrhage, or related to contusion or infarction.

Brain swelling may follow any type of head injury. Curiously, the magnitude of swelling does not always correlate well with the severity of injury. In some cases, particularly in young people, severe diffuse brain swelling that may be fatal occurs minutes to hours after a minor concussion. Abnormal dilation of the cerebral blood vessels is thought to lead to increased CBV, hyperperfusion, and increased vascular permeability, resulting in secondary leakage of plasma and vasogenic cerebral edema. Cerebral blood flow studies indicate that after an initial period of hypoperfusion within the first 24 hours, hyperemia occurs in nearly all patients 1 to 3 days after severe head injury, followed less commonly by arterial vasospasm between days 4 and 7. Severe brain swelling may be related to local endothelial and microcirculatory dysfunction or from damage to cerebral vasomotor regulatory centers in the brain stem.

PARENCHYMAL CONTUSION AND HEMORRHAGE

Cerebral *contusions* are focal parenchymal hemorrhages that result from scraping and bruising of the brain as it moves across the inner surface of the skull. The inferior frontal and temporal lobes, where brain tissue comes in contact with irregular protuberances at the base of the skull, are the most common sites of traumatic contusion (Fig. 46.2). Linear tears of the meninges or cerebral tissue, usually a result of cuts from the sharp edges of depressed skull fragments, are called *lacerations*.

Hemorrhagic contusions may occur at the site of a skull fracture but more often occur without a fracture and with the overlying pia and arachnoid left intact. In most patients, contusions are small and multiple. With lateral forces, contusions may occur at the site of the blow to the head (coup lesions) or at the opposite pole as the brain impacts on the inner table of the skull (contrecoup lesions). Contusions frequently enlarge over 12 to 24 hours, especially in the setting of coagulopathy. In some cases, contusions appear in delayed fashion 1 or more days after injury.

When rotational forces lead to tearing of small- or medium-sized vessels within the parenchyma, an intracerebral *hematoma* may occur (Fig. 46.3). Hematomas are focal collections of blood clots that displace the brain, in contrast to contusions, which resemble bruised and bloodied brain tissue (Fig. 46.4). Most

P.366

parenchymal hematomas are located in the deep white matter, in contrast to contusions, which tend to be cortical.

FIGURE 46.1 Focal MRI findings characteristic of diffuse axonal shearing injury after neurotrauma. **Top:** Gradient echo (T2*) images demonstrating hemorrhagic lesions (gliding contusions) of the right dorsolateral midbrain and splenium of the corpus callosum. **Bottom:** FLAIR images showing edema in these regions.

P.367

FIGURE 46.4 Pathologic specimen demonstrating traumatic contusions in the temporal lobes.

If there is no DAI, brain swelling, or secondary hemorrhage, recovery from one or more small contusions may be excellent. Healed contusions are often found at autopsy of people with no clinical evidence of permanent brain damage. Large, parenchymal hematomas with mass effect may require surgical evacuation.

Contusions are often managed conservatively unless they lead to significant symptomatic mass effect because they often consist of hemorrhagic or ecchymotic (but potentially viable) brain tissue.

SUBDURAL HEMATOMA

Subdural hematomas usually arise from a venous source, with blood filling the potential space between the dural and arachnoid membranes. In most cases, the bleeding is caused by movements of the brain within the skull that leads to stretching and tearing of “bridging” veins that drain from the surface of the brain to the dural sinuses.

Most subdural hematomas are located over the lateral cerebral convexities, but subdural blood may also collect along the medial surface of the hemisphere, between the tentorium and occipital lobe, between the temporal lobe and the base of the skull, or in the posterior fossa. CT usually reveals a high-density, crescentic collection across the entire hemispheric convexity (Fig. 46.5).

Elderly or alcoholic patients with cerebral atrophy are particularly prone to subdural bleeding; in these patients, large hematomas may result from trivial impact or even from pure acceleration-deceleration injuries, such as whiplash. Coagulopathy, including the use of oral anticoagulants, is another important risk factor for subdural

hematoma and is associated with increased mortality.

Acute subdural hematomas, by definition, are symptomatic within 72 hours of injury, but most patients have neurologic symptoms from the moment of impact. They may occur after any type of head injury but seem to be less common after vehicular trauma and relatively more common after falls or assaults. Half of all patients with an acute subdural hematoma lose consciousness at the time of injury; 25% are in coma when they arrive at the hospital, and half of those who awaken lose consciousness for a second time after a “lucid interval” of minutes to hours as the subdural hematoma grows in size. Hemiparesis and pupillary abnormalities are the most common focal neurologic signs, each occurring in one-half to two-thirds of patients. The usual picture is ipsilateral pupillary dilation and contralateral hemiparesis. However, so-called false localizing signs are common with acute subdural hematoma because uncal herniation may lead to compression of the contralateral cerebral peduncle or third cranial nerve against the tentorial edge (*Kernohan notch*).

Chronic subdural hematomas become symptomatic after 21 days. They are more likely to occur in patients after age 50 years. In 25% to 50% of cases, there is no recognized episode of head injury. Risk factors for chronic subdural hematomas include cerebral atrophy, alcoholism, bleeding disorders or use of anticoagulant medication, and overdrainage of a ventriculoperitoneal shunt.

FIGURE 46.5 Acute subdural hematoma. Noncontrast axial CT demonstrates a hyperdense, crescent-shaped, extraaxial collection showing mass effect (sulcal and ventricular effacement) and midline shift from left to right. (Courtesy of Drs. J. A. Bello and S. K. Hilal.)

FIGURE 46.6 Bilateral chronic subdural hematoma. **A:** Noncontrast axial CT shows bilateral isodense extra-axial collections, larger on the left. **B:** These are better demonstrated on the postcontrast scan, in which enhancing membranes, typical of the subacute phase, may be seen. (Courtesy of Drs. J. A. Bello and S. K. Hilal.)

In many cases of chronic subdural hematoma, bleeding results from trivial trauma, and symptoms are minimal because the brain accommodates the gradual buildup of mass effect. After 1 week, fibroblasts on the inner surface of the dura form a thick outer membrane; after 2 weeks, a thin inner membrane develops, resulting in encapsulation of the clot, which eventually liquefies into a *hygroma*. Enlargement of the hematoma may then result from recurrent bleeding (acute-on-chronic subdural hematoma) or because of osmotic effects related to a high-protein content of the fluid. Symptoms may be restricted to altered mental status, a syndrome sometimes mistaken for dementia. CT typically shows an isodense or hypodense, crescent-shaped mass that deforms the surface of the brain, and the membranes may enhance with intravenous (IV) contrast (Fig. 46.6).

Symptomatic acute and chronic subdural hematomas with significant mass effect should be evacuated. Surgical evacuation of the thick, clotted blood that constitutes an acute subdural hematoma usually requires a large-window craniotomy. Outcome after surgical evacuation depends primarily on the severity of the initial deficit and the interval from injury to surgery. Liquefied chronic subdural hematomas are usually evacuated with drainage of the collections via a series of burr holes. Reoperations for acute and chronic subdural hematomas are required in about 15% of cases. Steroids have no role in the conservative management of smaller, minimally symptomatic, subdural hematomas.

EPIDURAL HEMATOMA

Epidural hematoma is a rare complication of head injury. It occurs in less than 1% of all cases but is found in 5% to 15% of autopsy series, attesting to the potential seriousness of this complication.

Bleeding into the epidural space is generally caused by a tear in the wall of one of the meningeal arteries, usually the middle meningeal artery, but in 15% of patients, the bleeding arises from a dural sinus. Seventy-five percent of patients are associated with a skull fracture. The dura is separated from the skull by the extravasated blood, and the size of the clot increases until the ruptured vessel is compressed or occluded by the hematoma.

Most epidural hematomas are located over the convexity of the hemisphere in the middle cranial fossa, but

occasionally, hemorrhages may be confined to the anterior fossa, possibly as a result of tearing of anterior meningeal arteries. Extradural hemorrhage in the posterior fossa may occur when the torcular herophili is torn. In most cases, the hematoma is ipsilateral to the site of impact.

Epidural hematoma is primarily a problem of young adults; it is rarely seen in the elderly because the dura becomes increasingly adherent to the skull with advanced age. The clinical course, in one-third of patients, proceeds from an immediate loss of consciousness caused by concussion to a lucid interval and then to a relapse into coma, with hemiplegia as the epidural hematoma expands. The ipsilateral pupil loses reactivity to light because the third cranial nerve is stretched as the midbrain is displaced contralaterally. Later, it becomes fixed and dilated as the third nerve is compressed by the hippocampal gyrus as it herniates over the free edge of the tentorium.

As with acute subdural hematomas, false localizing signs may occur. The presence of cerebellar signs, nuchal rigidity, and drowsiness, together with a fracture of the occipital bone, should prompt suspicion of a clot in the posterior fossa.

Epidural blood takes on a bulging convex pattern on CT (Fig. 46.7) because the collection is limited by firm attachments from the dura to the cranial sutures. Progression to herniation and death may occur rapidly because the bleeding is arterial. The mortality rate approaches 100% in untreated patients and ranges from 5% to 30% in treated patients. As the interval between injury and surgical intervention decreases, survival improves. If there is little coexisting brain damage, functional recovery may be excellent.

TRAUMATIC SUBARACHNOID HEMORRHAGE

Some extravasation of blood into the subarachnoid spaces is to be expected in any patient with head injury. In most cases, subarachnoid blood is detected only by CSF examination and is of little clinical importance. With more serious injuries, when larger vessels traversing the subarachnoid space are torn, focal or diffuse

P.369

subarachnoid hemorrhage may be detected by CT. In most cases, traumatic subarachnoid hemorrhage is distributed over the convexities. By contrast, spontaneous aneurysmal rupture results in bleeding into the basal cisterns. Although the presence of a large amount of subarachnoid blood is a poor prognostic sign, delayed complications of aneurysmal subarachnoid hemorrhage, such as hydrocephalus and ischemia from vasospasm, are unusual after traumatic subarachnoid hemorrhage.

FIGURE 46.7 **A:** Epidural hematoma is evident on CT. **B:** CT with bone windows shows two adjacent fractures (*arrows*); the anterior fracture is at the site of the groove for the middle meningeal artery.

INITIAL ASSESSMENT AND STABILIZATION

On admission to the emergency room, resuscitation measures, history taking, and examination should begin simultaneously. The immediate goals of management are to assess and stabilize the airway, breathing, circulation, and disability (ABCD). The immediate goals of the initial neurologic assessment are to (1) perform a rapid screening neurologic examination; (2) classify the severity of the head injury as low, moderate, or high risk; (3) stabilize and rule out a fracture of the cervical spine; (4) begin empiric treatment for increased intracranial pressure (ICP) if it is suspected; and (5) perform an emergency CT scan of the head and neck to rule out bony fractures or intracranial bleeding. Careful screening at this time is also required to identify significant extracranial injuries.

CARDIOPULMONARY RESUSCITATION

Hypoxia and *hypotension* have a devastating effect on head-injured patients. If the patient is hypoxic (arterial oxygen saturation level <90%), in respiratory distress, or comatose and unable to protect his or her airway, endotracheal intubation should be performed urgently to be certain that the spine is immobilized during the procedure. Two doses of peri-intubation cefuroxime (1.5 g) may reduce the risk of subsequent pneumonia. Minute ventilation should initially be set to maintain a tidal volume of 6 mL/kg and rate of 8 to 12 breaths per minute, with the goal of maintaining the PCO₂ between 30 and 40 mm Hg. The fraction of inspired oxygen can be quickly reduced from 100% to 40% as long as oxygen saturation levels are above 95%. Prophylactic aggressive hyperventilation (PCO₂ <25 mm Hg) during the acute stage of injury may cause excessive vasoconstriction and aggravation of ischemic injury and is contraindicated.

Hypotension (systolic blood pressure [BP] <90 mm Hg) should be corrected with large-volume IV infusions of isotonic fluids such as normal saline or lactated Ringer solution (10 to 40 mL/kg) and blood transfusions or vasopressors as needed. Systolic BP during the stabilization phase should be maintained above 90 mm Hg to

ensure adequate cerebral blood flow. If the patient is hypotensive, bleeding into the abdomen, thorax, retroperitoneal space, or tissues surrounding a long-bone fracture should be excluded by CT. Hypotension may also reflect *spinal shock* related to a coexisting spinal cord injury (see [Chapter 47](#)). Hypertension associated with wide pulse pressure and bradycardia (Cushing reflex) may reflect increased ICP or focal brain stem injury.

INITIAL NEUROLOGIC ASSESSMENT AND STABILIZATION

A baseline neurologic evaluation should be performed immediately while airway, respiration, and circulation are assessed. Injuries may be ranked as low, moderate, or high risk according to risk factors and a rapid initial neurologic assessment ([Table 46.2](#)). The skull should be palpated for fractures, hematomas, and lacerations. A step-off or palpable bony shelf is presumed to be a depressed skull fracture. A hard neck collar should be in place for all patients with any history of concussion, whiplash, or trauma above the level of the clavicles.

The Glasgow Coma Scale (GCS; [Table 46.3](#)) is based on eye opening and the patient's best verbal and motor responses; these three individual scores should be recorded separately. The GCS is widely used as a semiquantitative clinical measure of the severity of brain injury; it also provides a guide to prognosis ([Table 46.4](#)). Patients who are comatose (GCS score ≤ 8), or

P.370

who show clinical signs of herniation, require emergency interventions to reduce ICP, including 30 degrees of head elevation, hyperventilation to a target arterial PCO_2 of 30 mm Hg, and 20% mannitol solution at a dose of 0.5 to 1.0 g/kg via rapid IV infusion ([Table 46.5](#)).

TABLE 46.2 Risk Stratification of Patients with Head Injury

Risk Category	Characteristics
Mild	<ul style="list-style-type: none"> • Normal neurologic examination • No concussion • No drug or alcohol intoxication • May complain of headache and dizziness • May have scalp abrasion, laceration, or hematoma • Absence of moderate or severe injury criteria
Moderate	<ul style="list-style-type: none"> • Glasgow Coma Scale score of 9-14 (confused, lethargic, stuporous) • Concussion • Posttraumatic amnesia • Vomiting • Seizure • Signs of possible basilar or depressed skull fracture or serious facial injury • Alcohol or drug intoxication • Unreliable or no history of injury • Age younger than 2, older than 65
Severe	<ul style="list-style-type: none"> • Glasgow Coma Scale score of 3-8 (comatose) • Progressive decline in level of consciousness ("talked and deteriorated") • Focal neurologic signs • Penetrating skull injury or palpable depressed skull fracture

Adapted from Masters SJ, McClean PM, Arcarese JS, et al. Skull x-ray examinations after head trauma. Recommendations by a multidisciplinary panel and validation study. *N Engl J Med.* 1987;316(2):84-91.

HISTORY

The circumstances of the accident and the clinical condition of the patient before admission to the emergency room should be ascertained from records of the emergency medical services, the patient (if possible), and eyewitnesses. The force and location of head impact should be determined as precisely as possible. Specific inquiry should be made about concussion; because patients are amnesic during the concussion, only an eyewitness may accurately gauge the duration of loss of consciousness.

Patients who have “talked and deteriorated” should be assumed to have an expanding intracranial hematoma until proven otherwise. Reports of headache, nausea, vomiting, confusion, or seizure activity must be noted. A medical history, including medications and drug and alcohol use, should be obtained. Recent drug and alcohol use occurs in many trauma patients.

RADIOGRAPHY AND IMAGING

CT is the emergency imaging method of choice for head and cervical spine injury. CT is more informative than standard skull radiographic films for detecting skull or neck fractures and provides unsurpassed sensitivity for detecting intracranial blood. In general, all patients with a head injury should have CT, except for those who are classified as low risk (e.g., without concussion; with no neurologic abnormalities on examination; and with no evidence or suspicion of a skull fracture, alcohol or drug intoxication, or other moderate-risk criteria) (see [Table 46.2](#)). The likelihood of detecting intracranial hemorrhage by CT in these patients is only 1 in 10,000. MRI is better for detecting subtle injury to the brain, particularly for focal lesions related to DAI, but is generally not used for emergency evaluations unless it is rapidly and readily available.

CT images of the head should be assessed for evidence of the presence of epidural or subdural hematoma, subarachnoid or intraventricular blood, parenchymal contusions and hemorrhages, cerebral edema, and gliding contusions related to DAI. With bone window settings, fractures, sinus opacification, and pneumocephalus may be identified. Axial CT images of the entire cervical spine should also be obtained in all patients. If traumatic arterial dissection is possible, CT angiography of the head and neck is indicated.

SECONDARY NEUROLOGIC EVALUATION

On arrival at the intensive care unit (ICU), more detailed physical and neurologic examinations should be performed (the “secondary survey”). The patient should again be examined for external signs of trauma to the neck, chest, back, abdomen, and limbs. A bloody

P.371

discharge from the nose or ear may indicate leakage of CSF; bloody CSF may be differentiated from blood by a positive halo test (i.e., a halo of CSF forms around the blood when dropped on a white cloth sheet). If there is no admixture of blood, CSF may be distinguished from nasal secretions because the CSF glucose concentration is 30 mg/dL or more, whereas lacrimal secretions and nasal mucus usually contain less than 5 mg/dL glucose.

TABLE 46.4 Estimated Mortality Based on Various Features of Head Injury

After determining the patient's level of consciousness (e.g., alert, lethargic, stuporous, or comatose), a focused mental status examination should be performed if the patient is conversant. Particular attention should be paid to attention capabilities, concentration (e.g., counting backward from 20 to 1 or reciting the months in reverse), orientation, and memory, including assessment for retrograde and anterograde amnesia.

Eye movements, pupillary size and shape, and reactivity to light should be noted. A sluggishly reactive or dilated pupil suggests transtentorial herniation with compression of the third cranial nerve. A mid position, poorly reactive, irregular pupil may result from injury to the oculomotor nucleus in the midbrain tegmentum. Nystagmus often follows a concussion. In comatose patients, the oculocephalic and oculovestibular reflexes should be tested (see [Chapter 18](#)).

Motor examination should focus on identifying asymmetric weakness or posturing. Spontaneous movements should be assessed for preferential use of the limbs on one side. If the patient is not fully cooperative, lateralized weakness may be detected by assessment of an asymmetry in tone or tendon reflexes or by the presence of an arm drift, preferential localizing response to sternal rub, or extensor plantar reflex. Noxious stimuli, such as pinching the medial arm or applying nail bed pressure, may reveal subtle motor posturing in a limb that otherwise moves purposefully. *Decorticate posturing* (i.e., flexion of arms, extension of legs) results from injury to the corticospinal pathways at the level of the diencephalon or upper midbrain. *Decerebrate posturing* (i.e., extension of legs and arms) implies injury to the motor pathways at the level of the lower midbrain, pons, or medulla.

Gait is particularly important to check in low-risk patients who are treated and scheduled for release without CT. Balance and equilibrium, tested by tandem heel-to-toe walking, are frequently impaired after a concussion.

TREATMENT

ADMISSION TO THE HOSPITAL

Low-risk Group

Low-risk patients who meet all criteria described in [Table 46.2](#), generally, may be discharged from the emergency room without CT, so long as a responsible person is available to observe the patient for the next 24 hours. In general, these are patients who

P.372

did not sustain a concussion and have normal findings on neurologic examination. Patients are given a checklist of symptoms (e.g., headache, vomiting, confusion) and instructed to return immediately to the emergency room if any occur.

TABLE 46.6 Criteria for Hospital Admission after Head Injury

- Intracranial blood or fracture identified on head CT

- Confusion, agitation, or depressed level of consciousness

- Focal neurologic signs or symptoms

- Posttraumatic seizure

- Alcohol or drug intoxication

- Significant comorbid medical illness

-
- Lack of a reliable home environment for observation

CT, computed tomography.

Moderate-risk Group

Among patients who have had a concussion, a normal GCS score of 15 (e.g., alert, fully oriented, and following commands) and normal CT eliminate the need for hospital admission. These patients may be discharged to home for observation with a warning card, even in the presence of headache, nausea, vomiting, dizziness, or retrograde amnesia, because the risk of a significant intracranial lesion developing thereafter is minimal. Criteria for hospital admission for patients with head injury are listed in [Table 46.6](#).

Patients with mild to moderate neurologic deficits (generally corresponding to GCS scores of 9 to 14) and CT findings that do not require neurosurgical intervention should be admitted to an intermediate care unit or ICU for observation. Follow-up CT at 24 hours is often helpful to check for progression of bleeding.

High-risk Group

All patients with a serious head injury are admitted to the hospital. An early neurosurgical consultation is crucial because once the patient has been stabilized, assessed, and imaged, the immediate consideration is whether emergency surgery is indicated. If the decision is made to operate, surgery should proceed immediately because delays only increase the likelihood of further brain damage during the waiting period. Medical management of severe-injury patients should take place in an ICU. Although little may be done about the brain damage that occurs on impact, ICU care may play a major role in reducing secondary brain injury that develops over hours or days.

SURGICAL INTERVENTION

Simple wounds of the scalp should be thoroughly cleaned and sutured. Compound fractures of the skull should be completely debrided. Operative treatment of compound fractures should be performed as soon as possible but may be delayed for 24 hours until the patient is transported to a hospital equipped for this purpose or until the patient is hemodynamically stable. Elevation of small, depressed fractures need not be performed immediately, but the depressed fragments should be elevated before the patient is discharged from the hospital, particularly if the inner table of the skull is involved.

The treatment of massive acute subdural, epidural, or parenchymal hematomas with mass effect is *craniotomy* and surgical removal of the clot. Results from a large randomized clinical trial indicate that decompressive *craniectomy*—removal of a large lateral portion of the skull—is not indicated emergently [**Level 1**].¹ The bleeding point should be identified and either ligated or clipped. The operative results depend to a great extent on the degree of associated brain damage. In the absence of coexisting brain injury, remarkable improvement may occur after evacuation of a subdural or epidural hematoma, with disappearance of the hemiplegia or other focal neurologic signs.

Burr-hole or *twist-drill* evacuation is insufficient for acute, large, subdural, and epidural hematomas, but for liquefied, chronic, subdural hematomas, it is associated with better outcomes than craniotomy. A plastic catheter (e.g., Jackson-Pratt drain) is usually placed in the subdural space for several days until the drainage subsides.

INTRACRANIAL PRESSURE MANAGEMENT

As a general rule, an ICP monitor should be placed in all head-injured patients who are comatose (i.e., GCS score of 8) after resuscitation. Intracranial hypertension occurs in more than 50% of comatose patients with CT evidence of mass effect from intracranial hemorrhage or cerebral edema and in 10% to 15% of patients with normal imaging. A ventricular catheter or fiberoptic parenchymal monitor may be used. Ventriculostomy has the advantage of allowing CSF drainage to reduce ICP but has a high risk of infection (approximately 12%). The risk of infection or hemorrhage is substantially lower with parenchymal ICP monitors (approximately 1% to 2%).

Normal ICP is less than 15 mm Hg, or 20 cm H₂O. Cerebral perfusion pressure (CPP) is routinely monitored in conjunction with ICP because it is an important determinant of cerebral blood flow; CPP is defined as mean arterial BP minus ICP. The goal of ICP management after head injury is to maintain ICP less than 20 mm Hg and CPP greater than 60 mm Hg. The magnitude and duration of derangements beyond these targets is highly correlated with poor outcome after severe TBI.

Treatment of elevated ICP is most successful when a preestablished protocol is used. The Columbia University Medical Center stepwise management protocol for treating ICP elevations in monitored ICU patients is shown in [Table 46.7](#) (see also [Chapter 107](#)).

An acute, severe increase in ICP always prompts a repeat CT to assess the need for a definitive neurosurgical procedure. If the

P.373

patient is agitated or appears to be fighting the ventilator, a shortacting IV sedative agent, such as propofol, or analgesic, such as fentanyl, should be given alone or in combination to attain a quiet, motionless state. Thereafter, if CPP is less than 60 mm Hg, vasopressors may lead to reduction of ICP by decreasing cerebral vasodilation that occurs in response to inadequate perfusion. Alternately, if CPP exceeds 120 mm Hg, BP reduction with IV labetalol or nicardipine may sometimes lead to a parallel decrease of ICP. The relationship between extremes of CPP and ICP in states of reduced intracranial compliance is shown in [Figure 46.8](#).

TABLE 46.7 Stepwise Treatment Protocol for Elevated Intracranial Pressure (>20 mm Hg for >10 min) in a Monitored Patient

1. Consider repeat CT and surgical intervention (ventricular drainage, craniotomy, or hemicraniectomy).

2. IV sedation to attain a motionless quiet state

3. Pressor infusion if CPP <60 mm Hg or reduction of blood pressure if CPP remains >110 mm Hg

4. Mannitol 0.25-1.5 g/kg IV every 2-6 h as needed

5. Hyperventilation to PCO₂ levels of 28-32 mm Hg

6. Systemic hypothermia (T = 33°C)

7. High-dose pentobarbital therapy (load with 5-20 mg/kg, maintain with 1-4 mg/kg/h)

See text for details.

CT, computed tomography; IV, intravenous; CPP, cerebral perfusion pressure.

Adapted from Mayer SA, Chong J. Critical care management of increased intracranial pressure. *J Intensive Care Med.* 2002;17:55-67.

FIGURE 46.8 Relationship between extremes of CPP and ICP in states of reduced intracranial compliance. In the vasodilatory cascade zone, CPP insufficiency and intact pressure autoregulation leads to reflex cerebral vasodilation and increased ICP; the treatment is to raise CPP. In the autoregulation breakthrough zone, pressure and volume overload, which overwhelms the brain's capacity to autoregulate, leads to increased CBV and ICP; the treatment is to lower CPP. (Adapted from Rose JA, Mayer SA. Optimizing BP in neurological emergencies. *Neurocrit Care.* 2004;1:287-299, with permission.)

Mannitol and hypertonic saline are used only after all surgical options have been exhausted and sedation and CPP optimization fail to normalize ICP. Mannitol, an osmotic diuretic, lowers ICP via its cerebral dehydrating effects. The initial dose of mannitol 20% solution is 0.5 to 1.0 g/kg, followed by doses of 0.25 to 1.0 g/kg as needed. Further doses should be given individually based on ICP measurements rather than on a standing basis. Mannitol boluses may also be used to reverse acute herniation syndromes (i.e., a blown pupil) resulting from compartmental mass effect and ICP gradients. The effect of mannitol is maximal when given rapidly; ICP reduction occurs within 10 to 20 minutes and may last for 2 to 6 hours. Serum osmolality should be monitored closely and the osmolar gap calculated by subtracting the measured osmolality from the calculated osmolality. Should the osmolar gap increase to greater than 15 mOsm/L, then there is a greater likelihood of mannitol leading to renal failure. Urinary losses should be compensated for with IV normal saline to avoid secondary hypovolemia. Assessment of intravascular volume status with a combination of invasive monitoring and ultrasound is generally recommended. More recently, hypertonic saline in the form of a 3% sodium chloride/acetate continuous infusion, or 10% or 23.4% NaCl as an alternative to mannitol bolus therapy, has been advocated for the treatment of intracranial hypertension and herniation syndromes. Studies evaluating equiosmolar doses of mannitol and hypertonic saline indicate that in most cases, hypertonic saline is at least equivalent, if not superior, to mannitol for lowering ICP in terms

of the rapidity, extent, and duration of ICP reduction. The exception is in the prehospital setting where empiric administration with hypertonic saline failed to improve outcomes after TBI [Level 1].² As a general rule in the critical care setting, hypertonic saline is generally preferred in patients who are hypotensive or hypovolemic, whereas mannitol is preferable for patients who are volume overloaded or who have congestive heart failure (CHF).

Hyperventilation lowers ICP by inducing cerebral alkalosis and reflex vasoconstriction, with a concomitant reduction of CBV. Hyperventilation to PCO₂ levels of 28 to 32 mm Hg may lower ICP within minutes, although the effect gradually diminishes over as little as 1 to 3 hours, as acid-base buffering mechanisms correct the alkalosis within the CNS. Additionally, prophylactic hyperventilation has been shown to lead to detrimental outcomes [Level 1],³ and overly aggressive hyperventilation to PCO₂ levels less than 26 mm Hg may potentially exacerbate cerebral ischemia and, in general, should be avoided unless jugular venous oxygen saturation or brain tissue oxygen monitoring is available to ensure that cerebral hypoxia does not occur.

High-dose barbiturate therapy with pentobarbital given in doses equivalent to those used for general anesthesia (5 to 20 mg/kg as a loading dose, followed by 1 to 4 mg/kg/h) effectively lowers ICP in most patients who are refractory to the steps outlined earlier. It can be dosed as either a continuous infusion or given as bolus injection as needed for ICP control (50 to 200 mg every 15 minutes). The effect of pentobarbital is multifactorial but most likely stems from a coupled reduction in cerebral metabolism, blood flow, and blood volume. Pentobarbital may cause profound hypotension and usually requires the use of vasopressors to maintain CPP of at least 60 mm Hg. The other major side effect of pentobarbital

P.374

is prolonged immobilization and ventilator dependence, which increases the risk of nosocomial infection and exposure to other iatrogenic complications. In a clinical trial, the prophylactic use of pentobarbital was associated with poor outcome, and its use currently is reserved for cases of refractory raised ICP [Level 1].⁴

Mild to moderate systemic hypothermia (33°C) has been shown to reduce ICP in patients with refractory intracranial hypertension. The application of hypothermia is complex and requires a management protocol that emphasizes the use of agents such as meperidine, fentanyl, or dexmedetomidine and neuromuscular blocking agents, if necessary, to prevent shivering that increases cerebral and metabolic stress and fights the cooling process. The routine application of mild to moderate hypothermia within 8 hours of TBI, as a form of neuroprotection, was tested in a large clinical trial and was shown not to be of benefit [Level 1].^{5,6} For this reason, its use should be limited to the management of refractory intracranial hypertension.

INTENSIVE CARE UNIT MANAGEMENT OF SEVERE HEAD INJURY

Patients with severe head injuries are best treated in an ICU. In some hospitals, patients with head injuries are treated in a special neurologic or neurosurgical ICU. A time-coded flow sheet is helpful to allow for meticulous, continuous updating of the patient's clinical, neurologic, and physiologic status.

Serial Neurologic Evaluation

The patient should be examined repeatedly to evaluate level of consciousness and the presence or absence of signs of injury to the brain or cranial nerves. Variations in level of consciousness, reflected by changes in the GCS score or the appearance of hemiplegia or other focal neurologic signs, should prompt repeat CT.

Airway and Ventilation

In general, patients who are unable to protect their airways because of depressed levels of consciousness should be intubated with an endotracheal tube. Routine hyperventilation is not recommended; in the

absence of increased ICP, ventilatory parameters should be set to maintain PCO₂ at 30 to 40 mm Hg and PO₂ at 90 to 100 mm Hg.

Blood Pressure Management

If the patient shows signs of hemodynamic instability, a radial artery catheter should be placed to monitor BP. Because cerebral blood flow autoregulation is frequently impaired in acute head injury, mean BP (or CPP if ICP is being monitored) must be carefully regulated to avoid hypotension that may lead to cerebral ischemia or hypertension that may exacerbate cerebral edema. Continuous infusion, short-acting vasopressors (e.g., phenylephrine and norepinephrine), and antihypertensive agents (e.g., labetalol and nicardipine) are preferable because of their abilities to stabilize BP within a narrow therapeutic range. Sodium nitroprusside should be avoided because it may dilate cerebral vessels and raise ICP.

Fluid Management

Only isotonic fluids, such as 0.9% (i.e., normal) saline or plasmalyte solution, should be administered to head-injured patients because the extra free water in half-normal saline or D5W may exacerbate cerebral edema. Hypertonic saline (i.e., 3% sodium chloride/acetate solution) with a target osmolality of 300 to 320 mOsm/L may be used as an alternative in patients with significant brain edema, and may reduce the number of ICP elevations, at the risk of causing fluid overload and pulmonary edema if volume status and oxygenation are not carefully monitored. CVP monitoring is helpful to guide fluid management in hypotensive or hypovolemic patients. Negative fluid balance is associated with poor outcome after TBI and should be avoided.

Nutrition

Severe head injury leads to a generalized hypermetabolic and catabolic response, with caloric requirements that are 50% to 100% higher than normal. Enteral feedings via a nasogastric or nasoduodenal tube should be instituted as soon as possible (e.g., usually after 24 to 48 hours). Early enteral feeding on day 1 after injury is generally well tolerated and has been shown to improve outcome compared with delayed feeding. Parenteral nutrition carries significant risks, primarily those of infection and electrolyte derangements, and should be used only if enteral feeding may not be tolerated.

Analgosedation

Patients may be agitated or delirious, which may lead to self-injury, forcible removal of monitoring devices, systemic and cerebral hypermetabolism, and increased ICP. Intubated patients may be sedated using a continuous IV infusion of a rapid-acting sedative agent, such as propofol, fentanyl, or remifentanyl, that may be turned off periodically to allow neurologic assessments. Pain control should always be the first consideration when using analgosedation. Daily interruption of sedation in mechanically intubated patients allows for improved sensitivity to changes in neurologic status, more appropriate titration of sedation, and reduced duration of mechanical ventilation. Nonintubated patients with delirium may be treated with haloperidol 2 to 10 mg every 4 hours as needed, quetiapine 25 to 50 mg orally every 6 to 8 hours, or a similar agent.

Temperature Management

Fever (>38.3°C) is common after TBI and may be the result of infection or of central fever. Even small temperature elevations may exacerbate TBI and ischemic brain injury and should be aggressively treated. Newer cooling devices using adhesive cooling pads or intravascular heat-exchange catheters are superior to standard water-circulating cooling blankets for maintaining normothermia in comatose brain-injured patients.

Anticonvulsants

Phenytoin or fosphenytoin (15 to 20 mg/kg loading dose, then 300 mg/day) reduced the frequency of early

(i.e., first week) posttraumatic seizures from 14% to 4% in a clinical trial of patients with intracranial hemorrhage but did not prevent later seizures [Level 1].⁷ IV valproic acid or levetiracetam is an acceptable alternative for patients with phenytoin allergy. If the patient has not had a seizure, prophylactic anticonvulsants should be discontinued after 7 days. Anticonvulsant serum levels of head-injured patients should be monitored closely because subtherapeutic levels frequently result from drug hypermetabolism, particularly in younger men. Nonconvulsive seizures and status epilepticus, which are diagnosable only with continuous electroencephalogram (EEG) monitoring, occur in over 10% to 20% of comatose TBI patients, are associated with poor outcome, and generally warrant aggressive treatment with continuous infusion midazolam or similar agents.

P.375

Intensive Insulin Therapy

Continuous insulin infusion therapy to control blood glucose to between 100 and 180 mg/dL in hyperglycemic patients reduces mortality in critically ill surgical patients and is increasingly being adopted as a practice option in the ICU management of severe TBI. Meticulous attention, including hourly blood glucose monitoring, must be paid to avoid excessive hypoglycemia with continuous insulin infusion.

Steroids

Glucocorticoids have been used to treat cerebral edema for years but have not been shown to favorably alter outcomes or lower ICP in head-injured patients. A large randomized controlled trial demonstrated an increased rate of death in patients given high-dose steroids during the first week after TBI [Level 1].⁸ This was probably attributable to increased risk of infection, hyperglycemia, or other complications. For these reasons, dexamethasone and other steroids are absolutely contraindicated for use in patients with head injury.

Deep Vein Thrombosis Prophylaxis

Patients with head injury who are immobilized are at high risk for deep vein thrombosis in the legs and pulmonary thromboembolism. Pneumatic compression boots should be used routinely to protect against this risk, and patients should also be given subcutaneous heparin 5,000 units every 8 hours or enoxaparin 40 mg daily. Low-dose anticoagulants to prevent thromboembolic disease can safely be added within 48 hours after injury, even in the presence of intracranial hemorrhage, so long as hematoma expansion is not noted on serial imaging.

Gastric Stress Ulcer Prophylaxis

Patients on mechanical ventilation or with coagulopathy are at increased risk of gastric stress ulceration and should receive pantoprazole 40 mg daily intravenously; famotidine 20 mg intravenously, every 12 hours; or sucralfate 1 g, orally, every 6 hours.

Antibiotics

The routine use of prophylactic antibiotics in patients with open skull injuries is controversial, and opinions are sharply divided. Prophylactic antibiotics with gram-positive activity, such as oxacillin, are often used to reduce the risk of meningitis in patients with CSF otorrhea, rhinorrhea, or intracranial air; however, these agents may increase the risk of infection with more virulent or resistant organisms. A single dose of an antibiotic with activity against gram-positive bacteria such as oxacillin or cefazolin should be administered immediately prior to the insertion of an intracranial monitor.

ACUTE COMPLICATIONS OF HEAD INJURY

CEREBROSPINAL FLUID FISTULA

CSF fistulas result from tearing of the dura and arachnoid membranes. They occur in 3% of patients with closed head injury and in 5% to 10% of those with basilar skull fractures. They are usually associated with fractures of the ethmoid, sphenoid, or orbital plate of the frontal bone.

CT may demonstrate *pneumocephalus* (air in the subarachnoid space). Clinical manifestations include obvious leakage of CSF from a scalp laceration, the nose, or the ear. CSF leakage ceases after head elevation alone for a few days in 85% of cases. If it persists, the insertion of a lumbar drain may lower CSF pressure, reduce flow through the fistula, and hasten spontaneous closure of the dural tear. Patients with dural leaks are at increased risk for meningitis, and although the use of prophylactic antibiotics is controversial, most physicians use them. Persistent CSF otorrhea or rhinorrhea for more than 2 weeks calls for surgical repair, as does recurrent meningitis. If there is a leak and the site of the fracture is not evident, a metrizamide CT study is the diagnostic method of choice.

CAROTID-CAVERNOUS FISTULA

Carotid-cavernous fistulae are characterized by the clinical triad of pulsating exophthalmos, ocular chemosis, and orbital bruit. They result from traumatic laceration of the internal carotid artery as it passes through the cavernous sinus; approximately 20% of cases are nontraumatic, and most of these are related to spontaneous rupture of an intracavernous internal carotid artery aneurysm. Other symptoms may include distended orbital and periorbital veins and paralysis of the cranial nerves (e.g., III, IV, V, and VI) that pass through or within the wall of the cavernous sinus.

Traumatic carotid-cavernous fistulae may develop immediately or within days after injury. Angiography is required to confirm the diagnosis (see [Fig. 46.7](#)). Endovascular treatment, with a balloon placed through the defect in the arterial wall into the venous side of the fistula, is the most effective means of repair and may prevent permanent visual loss caused by venous retinal infarction if performed as soon as possible after injury.

TRAUMATIC ARTERIAL DISSECTION AND VASCULAR INJURIES

Traumatic injuries may be associated with dissections of the extracranial or intracranial internal carotid or vertebral arteries, which may lead to thrombosis at the site of the intimal flap and stroke resulting from distal thromboembolism. The gold standard for diagnosis is conventional angiography, but CT and magnetic resonance (MR) angiography are often used to screen for arterial dissections. Anticoagulation with unfractionated heparin is the primary strategy to prevent intravascular thrombosis and thromboembolism. However, anticoagulation poses risks when there is evident intracranial hemorrhage or coexisting intracranial dissection with pseudoaneurysm formation. Treatment decisions must be individualized.

Basilar skull fractures are sometimes associated with thrombosis of adjacent dural sinuses; the sphenoid and transverse sinuses are most commonly involved. Symptoms are related to increased ICP or associated venous infarction. The diagnosis is established by angiography or MR venography, and anticoagulation is the treatment of choice (see [Chapter 43](#)).

In patients with large epidural or subdural hematomas and subfalcine herniation, secondary cerebral infarction may sometimes result from compression of the ipsilateral anterior cerebral artery against the falx or posterior cerebral artery against the tentorium. Urgent neurosurgical decompression to prevent these infarcts is the only effective management strategy.

CRANIAL NERVE INJURY

Injury to the cranial nerves can occur with basilar skull fractures (see [Chapter 48](#)). The facial nerve is the most commonly injured nerve in these cases, complicating 0.3% to 5% of all head injuries.

Occasionally, the paralysis may not develop until several days after the injury. Partial or complete recovery of function is the rule with traumatic injuries to the cranial nerves, with the exception of injury to the first or second cranial nerve.

INFECTIONS

Infections within the intracranial cavity after head injury may be extradural (e.g., osteomyelitis), subdural (e.g., empyema), subarachnoid (e.g., meningitis), or intracerebral (e.g., abscess). These infections usually develop in the first few weeks after injury but may be delayed. Diagnosis is suggested by CT or MRI and confirmed by culture of the infected tissue. Treatment includes surgical debridement and administration of antibiotics.

Meningitis may follow any type of open fracture associated with tearing of the dura, including compound skull fractures, penetrating missile injury, or linear fractures that extend into the nasal sinuses or the middle ear. Meningitis occurs in as few as 2% and as many as 22% of patients with basilar skull fractures. Cases of meningitis that develop within a few days after injury are almost always caused by pneumococcus or other gram-positive bacteria, but any pathogenic organism may be the cause. Diagnosis depends on the CSF findings after lumbar puncture. The principles of treatment are those recommended for meningitis in general (Chapter 61). The presence of a persistent CSF fistula with rhinorrhea or otorrhea favors the recurrence of meningitis; as many as seven or eight attacks have been reported. Treatment in such cases may require surgical closure of the fistula.

OUTCOMES

Outcomes that may be expected after head injury are often matters of great concern, particularly in those with serious injuries. *Depth of coma*, *CT findings*, and *age* of the patient are the variables most predictive of late outcome. Other factors of prognostic importance include the absence of pupillary responses, hypotension or hypoxemia on admission, specific patterns of injury noted on admission CT scan, persistently elevated ICP, hyperthermia, and critically reduced (< 10 mm Hg) brain tissue oxygen levels. Functional outcomes from severe TBI have improved markedly over the past 20 years, although mortality remains constant at approximately 30%.

Severity of coma may be quantified using the admission GCS score (see [Table 46.3](#)), which has substantial prognostic value. Historically, patients scoring 3 or 4 (deep coma) have an 85% chance of dying or remaining vegetative, whereas these outcomes occur in only 5% to 10% of patients scoring 12 or more. In general, elderly patients do very poorly. In one series of comatose patients older than 65 years of age, only 10% survived, and only 4% regained functional independence. Death may result from progression to brain death or refractory medical complications but most often is the consequence of decisions to limit life support because poor functional recovery is anticipated. It is increasingly recognized, however, that caregivers tend to underestimate capacity for recovery from severe brain injury, and some fatal outcomes may be the result of self-fulfilling prophecy. Attempts to make a firm prognosis in severe head injuries, especially in the early stages, are hazardous because the outcome depends on so many variables. Some indices, however, are valuable as prognostic indicators (see [Table 46.4](#)).

In general, the prospects of recovery from trauma-induced coma are better than recovery from coma by other causes. Fifty percent of adults and 60% of children who experience trauma-induced coma for 30 days will recover consciousness within 1 year compared with 15% of patients in coma from nontraumatic causes. Recovery of consciousness is operationally defined as the ability to follow verbal commands convincingly and consistently. *Unresponsive wakefulness*, rather than the former used term *persistent vegetative state*, refers to a state of eyes open coma with no external signs of consciousness. The *minimally conscious state* refers to a transitional state between coma and full consciousness. Patients exhibit the capacity to understand and obey commands and make some purposeful behaviors but otherwise demonstrate a paucity

of spontaneous thought and activity.

Cognitive impairment is by far the most common and disabling problem among survivors of head injury. During the acute phase, disorientation and agitation are particularly common. In addition to cognitive and motor deficits, headache, dizziness, vomiting, or vertigo may be present in the immediate posttraumatic period. These symptoms usually disappear in a few weeks but may persist for months. Common chronic cognitive problems include impaired short- and long-term memory, attention, and concentration; slowing of psychomotor speed and mental processing; and changes in personality. There may be loss of memory for the events that occurred in the immediate period after recovery of consciousness (i.e., *posttraumatic amnesia*) and a similar amnesia for the events immediately preceding the injury (i.e., *pretraumatic amnesia*). These periods of amnesia may encompass days, weeks, or years. Depression occurs in up to 40% of TBI survivors during the first year of recovery and is highly amenable to medical therapy. With time, there is usually considerable improvement in the signs and symptoms of brain damage, but permanent sequelae are common.

Early cognitive, physical, and occupational therapy is an important part of optimizing recovery after TBI. Physical therapy, including range-of-motion exercises to prevent limb contractures, may begin even while patients are still in the ICU. Once the patients are stabilized, they can be transferred to an acute or subacute rehabilitation facility. Whether cognitive rehabilitative measures truly improve neuropsychological outcome remains to be established.

In a study of patients with moderate or severe injuries, only 46% returned to work 2 years later, and most of those who did return to work did not go back to their original work. Only 18% were financially independent, inducing considerable stress on the family. Vocational training may play a key role in helping patients reintegrate into the workforce.

POSTCONCUSSION SYNDROME

About 40% of patients who have sustained minor or severe injuries to the head complain of dizziness, fatigue, insomnia, irritability, restlessness, and inability to concentrate. Often, there is overlap with anxiety and depression. This group of symptoms, which may be present for only a few weeks or may persist for years, is known as *postconcussion syndrome* (see also [Chapter 45](#)).

Postconcussion syndrome is somewhat misleadingly named because affected individuals need not have suffered loss of consciousness. There are no criteria to define the role of either physiologic or psychological factors in the etiology of postconcussion syndrome. Patients may be severely disabled yet have normal findings on neurologic examination and no MR evidence of brain injury. The correlation between the severity of the original injury and the severity and duration of later symptoms is poor. For instance, the incidence of postconcussion syndrome is not related to the duration of retrograde amnesia, coma, or posttraumatic amnesia. In some patients, symptoms may be related to the brain damage; in others,

P.377

they seem to be entirely psychogenic. In practice, it is often difficult to sort out the complicated origins of this disorder.

Posttraumatic symptoms may develop in patients who had previously shown normal adjustment but are more likely to occur in patients who had psychiatric symptoms before the injury. Factors such as domestic or financial difficulties, unrewarding occupations, and the desire to obtain compensation, financial or otherwise, tend to produce and may prolong the symptoms once they have developed.

The prognosis of the postconcussion syndrome is uncertain. In general, progressive improvement may be expected. The duration of symptoms is not related to the severity of the injury. In some patients with only mild injuries, symptoms continue for long periods, whereas patients with severe injuries may have only mild or transient symptoms. By and large, however, it is a matter of 2 to 6 months before the headache and

dizziness, and the more definite mental changes, show much improvement. Treatment for postconcussion syndrome is based on psychotherapy, cognitive and occupational therapy, vocational rehabilitation, and treatment with antidepressant or anti-anxiety agents.

SEIZURES AND POSTTRAUMATIC EPILEPSY

Posttraumatic seizures may be immediate (i.e., within 24 hours), early (i.e., within the first week), or late (i.e., occurring after the first week).

The exact incidence of seizures after head injury is unknown, but figures in the literature vary from 2.5% to 40%. As a rule, the more severe the injury, the greater the likelihood that seizures will develop. The overall incidence of seizures is about 25% in those with brain contusion or hematoma and as high as 50% in those with penetrating head injury.

Immediate seizures are infrequent; they are risk factors for further early seizures but not for late seizures. Early seizures occur in 3% to 14% of patients with head injury who are admitted to the hospital. Risk factors include depressed skull fracture, penetrating head injury, intracranial hemorrhage (i.e., epidural, subdural, or intraparenchymal), prolonged unconsciousness (i.e., more than 24 hours), coma, and immediate seizures; the risk of early seizures in patients with any of these risk factors is 20% to 30%. Children are more likely to develop early posttraumatic seizures than are adults. Patients who experience early seizures remain at risk for late seizures and should be maintained on anticonvulsants after discharge from the hospital.

The overall incidence of late seizures (e.g., posttraumatic epilepsy) after closed-head injury is 5%, but the risk is as high as 30% among patients with intracranial hemorrhage or a depressed skull fracture and 50% among patients who have experienced early seizures. About 60% of patients experience their initial seizures during the first year, but the risk of seizures remains increased for up to 15 years after a severe head injury. Because 25% of patients have only a single late seizure, many practitioners begin anticonvulsants only after a second seizure occurs. Therapy of posttraumatic epilepsy is discussed further in Chapter 58.

POSTTRAUMATIC MOVEMENT DISORDERS

Movement disorders are rare sequelae of head injury. Action tremor is most common, although its pathogenesis remains obscure. Cerebellar ataxia, rubral tremor, and palatal myoclonus have been described in patients with focal shearing injuries of the superior cerebellar peduncle, midbrain, and dentato-rubro-olivary triangle, respectively. Parkinsonism and other basal ganglia syndromes have been reported after a single episode of head trauma.

PEDIATRIC TRAUMA

Injuries are the leading cause of death in children, and brain injury is the most common cause of pediatric traumatic death. Motor vehicle accidents account for the largest number of severe injuries in children, but children are also prone to unique forms of injury, such as birth injury and child abuse. Children are more likely than adults to experience brain swelling and seizures after head injury and, in general, make better recoveries than do adults.

MISSILE-RELATED CEREBRAL BLAST INJURY

Historically, penetrating military missile and blast injuries to the brain have led to a uniformly fatal outcome. With improvements in body armor and helmet construction, however, a previously unrecognized syndrome of cerebral *blast injury* has been described in soldiers injured in the United States-Iraq conflict. The syndrome is produced by explosive devices that propel a blast wave and a shower of metallic fragments. In addition to producing concussion, DAI, and the typically encountered forms of acute intracranial bleeding, cerebral blast injury is

manifest as massive brain swelling and diffuse arterial vasospasm that begins within several days and resolves on average of 2 weeks after the injury. The syndrome is attributed to diffuse high-frequency shock wave-mediated tissue injury at the time of impact. Hemicraniectomy is often used as a lifesaving procedure because standard measures to reduce brain edema and control ICP often fail despite absence of data regarding its efficacy. Arterial vasospasm, which can result in delayed cerebral infarction, can be treated successfully with balloon angioplasty.

Traumatic Spinal Cord Injury

Christopher E. Mandigo

Michael G. Kaiser

Peter D. Angevine

INTRODUCTION

Traumatic spinal cord injury (SCI) is a sudden event with possibly catastrophic effects that may create a medical, financial, and social burden for the individual and society. Adequate management of these patients requires knowledge of SCI, including epidemiology and pathophysiology, acute and chronic medical complications, and long-term rehabilitation and social needs.

ETIOLOGY AND EPIDEMIOLOGY

Epidemiologic data can guide the use of resources for treating and preventing SCI. The best source of this information for the United States is the National Spinal Cord Injury Database (NSCID), which has been collecting information from facilities that have participated in the Model Spinal Cord Injury System (MSCIS) since 1973. This database includes data from an estimated 13% of new SCI cases each year and has information on over 25,000 people with SCI. SCI occurs in the United States in approximately 40 per 1 million people per year, which results in about 12,000 new cases annually. This figure does not include injuries that result in fatality before hospital arrival, which may double the number of injuries. Currently, 225,000 to 300,000 people are living with SCI.

SCI primarily affects young adults aged between 16 and 30 years, but the average is increasing. The average age in the 1970s was 28.7 years; in the period 2005 to 2008, it was 39.5 years. The median age is 27 years, and 65% of SCI patients are younger than 35 years. The highest incidence occurs between ages 20 and 24 years. The most significant changes between the 1970s and 2005 to 2008 have occurred at the extremes of age. The proportion of patients older than 65 years has increased from 5% to 11%, and the proportion of children from birth to 15 years has decreased from 6% to 2%. The increasing age could arise from data collection bias, improved survival of older patients in the acute period of SCI, or in age-specific incidence rates. That is, the larger population of elderly patients requires special consideration for medical, surgical, and rehabilitative care.

TABLE 47.1 Life Expectancy after Spinal Cord Injury

Age at Injury (yr)	For Persons Who Survive the First 24 h						For Persons Surviving at Least 1 yr Postinjury				
	No SCI	Motor Functional at Any Level	Para	Low Tetra (C5-C8)	High Tetra (C1-C4)	Ventilator Dependent at Any Level	Motor Functional at Any Level	Para	Low Tetra (C5-C8)	High Tetra (C1-C4)	Ventilator Dependent at Any Level
20	58	53	45	40	36	17	53	46	41	37	24
40	40	34	28	23	20	7	35	28	24	21	11
60	22	18	13	10	8	2	18	13	10	9	3

Life expectancy in years based on age and injury severity.
SCI, spinal cord injury.

Seventy-eight percent of SCI patients are male. Among those injured after 2000, 63% were white, 23% were African-American, 12% were Hispanic, and 2% were from other racial or ethnic groups.

Motor vehicle accidents account for approximately 42% of cases, a relatively steady figure for 30 years. Falls account for 27% of all and are the most common cause in patients older than age 65 years. Work-related injury (10%), sports (7%), and violence, typically gunshot wounds (15%), account for most of the remaining causes of SCI. Most injuries occur on the weekends and during the summer months.

Since 2000, the most frequent neurologic category at discharge is incomplete tetraplegia (34%), followed by complete paraplegia (23%), complete tetraplegia (18%), and incomplete paraplegia (19%). Less than 1% of persons experienced complete neurologic recovery by hospital discharge. The average length of hospital stay for a patient with SCI was 15 days in 2005, and the length of rehabilitation stay was 36 days. As one might expect, length of stay for patients with neurologically complete injuries is significantly longer. The Life expectancy for patients with SCI is significantly less than those for uninjured people. Mortality rates are significantly higher during the first year after injury than during

subsequent years. As shown in [Table 47.1](#), adapted from the NSCID Web site, life expectancy rates for SCI are directly related to the severity of injury.

There are profound sociologic and economic effects from SCI. About 57% of people with SCI were employed at the time of their injury. Ten years after injury, only 32% of persons with paraplegia and 24% with tetraplegia are employed. About 80% to 90% of patients with SCI are eventually discharged to a private residence, and only 6% are discharged to nursing homes. The rest are discharged to hospitals, group living situations, or other destinations.

P.381

Most SCI patients (53%) are single at the time of injury, and those who are married, or become married, are slightly more likely to become divorced than uninjured individuals. The average yearly and lifetime costs of SCI patients are directly related to the severity and level of injury. For example, patient with high tetraplegia (injury at C1-C4) is estimated to have expenses totaling \$775,000 in the first year and \$140,000 for each subsequent year. A 25-year-old with a C1-C4 injury will have a lifetime expense of \$3 million, and a 50-year-old will have an expense of \$1.8 million. A patient with low tetraplegia (injury at C5-C8) will have expenses of \$500,000 in the first year and about \$55,000 for each subsequent year. Paraplegics and incomplete motor injuries cost from \$225,000 to \$300,000 for the first year and \$15,000 to \$30,000 for each subsequent year. These numbers do not reflect the additional indirect costs that relate to unemployment and loss in productivity, which average another \$60,000 per year per patient.

Nontraumatic SCI affects a large number of people and can result from a number of etiologies (see [Chapter 111](#)). These include multiple sclerosis (MS), neoplastic diseases, vascular disease, inflammatory disease, infections, and degenerative spinal stenosis. This population of patients more commonly presents with incomplete lesions and over a subacute or chronic period. The extent of injury at presentation, the response to treatment, and the prognosis of the underlying disease process will guide medical therapy and the ultimate rehabilitation goals.

MECHANISM OF INJURY

It is generally accepted that acute SCI is a two-step process that involves primary and secondary mechanisms. The primary mechanism results from the initial mechanical injury due to local deformation and energy transformation, whereas the secondary mechanisms encompass a cascade of biochemical and cellular processes that are initiated by the primary process and cause ongoing cellular damage and death.

Primary SCI is most commonly a combination of the initial impact as well as subsequent persisting compression. The most frequent primary mechanism of SCI is impact of bone and ligament against the spinal cord from high translational forces, such as that generated by flexion, extension, axial rotation, or vertebral compression. These motions may result in a variety of vertebral column injuries, which can be identified through imaging studies such as plain radiographs, computed tomography (CT) scans, or magnetic resonance imaging (MRI) scans. The spinal cord may consequently be compressed, stretched, or crushed by fracture or dislocations, burst fractures of the vertebral body, or acutely ruptured intervertebral disks. Injury can result from only the initial impact without ongoing compression. These may occur from severe ligamentous injuries in which the spinal column dislocates and then spontaneously reduces or when there is preexisting cervical spondylosis or spinal stenosis. In this circumstance, a trivial injury may cause major neurologic damage even without obvious fracture or dislocation after the event.

Similarly, SCI from sharp bone fragments or stabbing or missile injuries can produce a mixture of spinal cord laceration, concussion, contusion, and/or compression. Direct injuries, like indirect injuries, may be partial or complete in their destruction of the cord.

An understanding of the mechanism of injury and the radiographic findings can provide insight into the biomechanical stability of the vertebral column after SCI. For example, flexion injuries, particularly in the cervical and thoracic regions, may cause anterior compression fractures of vertebral bodies and unilateral or bilateral facet joint dislocation, which can cause spinal cord compression and spinal instability. Severe axial loading can cause complete fracture of the vertebral body with displacement of bony fragments and disk material into the spinal canal and SCI. Any combination of forces may occur in a single case. Understanding the mechanism of injury permits a more complete assessment of the underlying cord injury and the instability of the spinal column.

Secondary mechanisms that result from biochemical cascades that occur after the initial event are a source of ongoing SCI and neurologic deterioration. These cause damage to neural tissue on the cellular level and include the pathologic effects of microvascular changes, excitatory amino acids, cell membrane destabilization, free radicals, inflammatory mediators, and neuroglia apoptosis.

PATHOBIOLOGY

GROSS PATHOLOGY

The pathology of SCI has been divided into four relatively simple groups based on gross findings: solid cord injury, contusion/cavity, laceration, and massive compression. Solid cord injury refers to a cord that grossly appears normal without evidence of softening, discoloration, or cavity formation. However, damage to the cord can be clearly seen on histologic examination. Contusion or cavity injuries have no breach or disruption in the surface anatomy, and there are no dural adhesions. Areas of hemorrhage and necrosis (eventually evolving into cysts) are readily identified in the cord parenchyma. In many instances, these lesions taper rostrally and caudally in a cone-like fashion along the ventral regions of the posterior columns. Lacerations result in clear-cut disruption of the surface anatomy. This type of injury is most often caused by penetrating missiles or sharp fragments of bone. The lesions are characterized by a break in the glia limitans, with damage to the underlying cord parenchyma. The epicenter of the injury generally shows minimal to no evidence of cavity formation; rather, the lesion is dominated by the deposition of a variable amount of collagenous connective tissue that, in most cases, is adherent to the overlying

meninges. With massive compression injury, the cord is macerated or pulpified to a varying degree. This lesion is often accompanied by severe vertebral body fractures or dislocations. In many instances, the epicenter of this lesion is replaced by connective tissue scar and fragments of nerve roots. The tissue response is similar to that seen with laceration injuries where extensive fibrous scarring occurs over time.

There are additional anatomic characteristics of SCI worth noting. The lesion may be surprisingly small and may involve no more than a single spinal cord segment. There may be multiple lesions, especially with gunshot wounds. It is also rare to observe a complete transection of the spinal cord; on close examination, there is almost always a small amount of residual tissue traversing the cord.

HISTOPATHOLOGY

The histologic changes in SCI can be divided into immediate, acute, intermediate, and late phases.

Immediate Phase (Initial 1 to 2 Hours)

The immediate event, presumably arising from the primary injury, consists of the actual mechanical disruption of tissue that occurs at the time of injury, such as tears, compression, and distortions.

P.382

Vascular changes are commonly found and are characterized by vasodilatation, congestion (hyperemia), and petechial hemorrhages. In many cases, however, no abnormalities are observed during this early time period, particularly in the absence of a massive compression or laceration injury. This lack of pathologic changes in the early period reflects the observation that the pathology of SCI is also due to secondary phenomena, which include progressive edema, ischemia, hemorrhage, inflammation, hyperthermia, as well as calcium-, free radical-, nitric oxide-, and glutamate-mediated cell injury.

Acute Phase (Hours to 1 to 2 Days)

Vascular changes, edema, hemorrhage, inflammation, and neuronal and myelin changes characterize this phase. Edema may be vasogenic or cytotoxic. Vasogenic edema is leakage of plasma fluid into the extracellular space from breakdown of the blood-brain barrier (BBB). Cytotoxic edema results from intracellular swelling after cell death. Edema from either mechanism may result in pressure-induced ischemia caused by diminished blood flow to the injured region. Edema is seen from 3 hours to 3 days after injury. In addition to creating pressure effects, cell swelling may also alter astroglial functions.

Injury to vessels may lead to hemorrhage, which occurs primarily in the gray matter following contusion injury. Hemorrhages are primarily due to rupture of postcapillary venules or sulcal arterioles, either from mechanical disruption by the trauma or from intravascular coagulation leading to venous stasis and distention.

The inflammatory response that follows early after injury is a complex process involving vascular changes, cellular responses, and chemical mediators. There is a mild influx of neutrophils within 1 day, a peak at 2 days, and most are gone by 3 days. It is likely that the neutrophilic response is neurotoxic in nature, as these cells normally act to eradicate infection through the release of free radicals.

Neurons are very vulnerable to injury following SCI. Most neurons die from necrosis, but neuronal apoptosis also has been observed. Acute injury is characterized by axonal swelling, manifested as retraction balls or spheroids. Myelin breakdown occurs early following SCI. It is characterized initially by swelling of myelin sheaths and ultimately by its fragmentation and phagocytosis by macrophages. The loss of myelin occurs with the destructive process and is almost always associated with axonal pathology. Oligodendrocytes, like neurons, are exquisitely sensitive to SCI and undergo necrosis and apoptosis. It is likely that the death of oligodendrocytes contributes significantly to the process of wallerian degeneration.

Intermediate Phase (Days to Weeks)

Over the ensuing days and weeks, there are prominent glial responses with the elimination of necrotic debris, the beginning of astroglial scarring, the resolution of edema, the revascularization of tissue, and restoration of the BBB.

Late Phase (Weeks to Months/Years)

The later phases of SCI are characterized by wallerian degeneration, astroglial and mesenchymal scar formation, development of cysts and syrinx, and schwannosis.

Wallerian degeneration is the anterograde disintegration of axons and their myelin sheaths that have been transected following injury. It is characterized by distorted and fragmented myelin sheaths with absent or malformed axons. An astroglial "scar," which comprises tightly interwoven astrocyte processes and extracellular matrix, eventually replaces the destroyed myelinated axon. Wallerian degeneration is a protracted process and may take more than a year to complete. The spinal cord may also be replaced by fibrous connective tissue and collagen. This occurs particularly after lacerating-type injuries and is stimulated by violation of the glia limitans. This abnormal healing coupled with astroglial scarring are thought to create physical and biochemical barriers to axonal migration and spinal cord healing.

Another late finding is the formation of cysts and syrinxes, which may be single, multiple, or multiloculated. Cysts and syrinxes are surrounded by an astroglial wall and represent the final "healing" phase of the necrotic process. These cavities are filled with extracellular fluid and commonly contain residual macrophages, small bands of connective tissue, and blood vessels. These cavities typically do not create a clinical problem, except that they do not provide a good substrate for regeneration.

Schwannosis is an aberrant intra- and extramedullary proliferation of Schwann cells with associated axons. It is similar, if not identical, to

traumatic neuromas that occur in injured peripheral nerves. Varying amounts of spinal cord tissue may be replaced by schwannosis. The Schwann cells are introduced into the spinal cord after penetrating injuries. The incidence of schwannosis in human SCI is very high and directly correlates with time after injury, suggesting an ongoing mechanism. Its clinical significance is unclear. The prolific schwannosis may be a physical barrier to spinal cord healing. The aberrant axons that are part of this process may have untoward physiologic consequences and potentially contribute to pain, spasticity, and other abnormal responses observed in the chronically injured patient with SCI.

In general, the morphologic responses in human SCI are stereotyped and follow discernible patterns. Early glial (astrocytic and microglial) responses may greatly influence the outcome of SCI.

DIAGNOSIS, NEUROLOGIC ASSESSMENT, AND CLASSIFICATION

CLINICAL EVALUATION

The diagnosis and initial management in patients with SCI often are intertwined, as a large percentage of patients present acutely, often with multisystem trauma, and require rapid assessment and medical intervention.

Prehospital trauma protocols are critical to prevent further injury to the spinal cord, particularly by modifying factors that contribute to secondary spinal cord damage. *Any patient with suspected SCI should be immobilized with a hard cervical collar and/or a rigid head-strap/backboard until definitive neurosurgical assessment can take place.* Treatment of hypoxia and hypotension, proper monitoring of vital signs, and transfer to an appropriate trauma center will affect ultimate outcomes positively.

On arrival to the trauma center, a rapid assessment should be undertaken to assess the status of the airway, respiratory, and circulatory (ABC) systems. In addition, a cursory assessment of the neurologic status (“disability”) and removal of all clothing with attention to possible injuries missed on the primary survey (“exposure”) are now included in the initial steps of trauma protocols. Clinical signs of shock and hypoxia require immediate attention and appropriate therapy.

Specific diagnosis of SCI requires a more comprehensive neurologic exam as outlined later in the text with the steps necessary to determine the exact spinal cord impairment. Concomitant with the

P.383

physical exam, complete and accurate imaging studies of the spinal column are necessary if SCI is suspected. These can enhance the accuracy of diagnosis and determine the extent of spinal column injury, especially in a comatose, confused, or uncooperative patient. Imaging studies are not necessary when patients are awake, are alert and cooperative without evidence of intoxication, do not have evidence of neurologic injury, and have no pain or tenderness along the spine to palpation and no associated injuries distracting from the general evaluation.

TABLE 47.2 High-Risk Criteria for Patients Who Clearly Need C-Spine Imaging

- Altered mental status (GCS <15)
- Neurologic deficit (i.e., limb weakness or paralysis, numbness, tingling)
- Distracting injuries present
- Neck pain or tenderness present
- Decreased range of motion of the cervical spine

GCS, Glasgow Coma Scale.

IMAGING STUDIES

Risk Stratification

Trauma patients typically arrive with neck collars. Some patients are clearly at high risk, whereas other can be cleared clinically in the emergency department or intensive care unit (ICU) without imaging. The cervical collar and spinal precautions should remain in place, and cervical spine imaging is clearly necessary; when clear symptoms, neck pain, or distracting conditions exist, clinical conditions are met (Table 47.2). National Emergency X-Radiography Utilization Study (NEXUS) criteria (Table 47.3) address the question of who does not require imaging after presenting with head or neck trauma. *A patient who meets all five NEXUS criteria is deemed to have a low probability of injury to the cervical spine and can be cleared clinically without imaging because the risk of significant injury is miniscule [Level 1].*¹ The Canadian C-spine rule offers even slightly better sensitivity and specificity for identifying low-risk patients but is a bit more complicated to use.

Cervical X-rays

Anteroposterior (AP) and lateral x-rays can be taken of the appropriate spinal region as directed by the clinical evaluation. AP and lateral x-rays of the cervical spine, visualizing the superior part of the first thoracic vertebral body, and open-mouth, odontoid radiographic views can form part of the initial radiologic survey. However, due to its ease of use and superior sensitivity, most centers go directly to cervical spine CT as the initial imaging study of choice. When CT scanning is available, plain x-rays contribute no additional information and need not be obtained.

TABLE 47.3 NEXUS Criteria for Low-Risk Patients Who Do Not Require Imaging after Head or Neck Injury^a

1. No tenderness at the posterior midline of the cervical spine

2. No focal neurologic deficit

3. Normal level of alertness

4. No evidence of intoxication

5. No clinically apparent, painful injury that might distract the patient from the pain of a cervical spine injury

^aIn these patients, the neck collar can be removed and the patient cleared clinically after demonstrating full range of motion with no neck pain or point tenderness.

NEXUS, National Emergency X-Radiography Utilization Study.

Upright flexion and extension films, when appropriate, are useful for assessing biomechanical instability due to ligamentous injury. In suspected thoracic and lumbar injuries, AP, lateral, oblique, upright, and dynamic (flexion/extension) views may be necessary. Indications for thoracolumbar x-rays include falls greater than 6 ft, expulsion from motor vehicles, complaints of back pain, associated injuries, and altered mental status with an unknown mechanism of injury.

Cervical Computed Tomography

High-resolution CT scanning (see [Chapter 20](#)) with sagittal and coronal reconstruction is the best procedure for evaluating uncertain findings seen on x-rays as well as for detecting bone pathology ([Fig. 47.1](#)). The study should be performed from the occiput to T1 with three-dimensional sagittal and coronal reformats. Threedimensional reconstructions allow for visualization in the coronal, sagittal, and axial planes and provide superior injury detection compared with plain x-ray. The main limitation of CT rests in its relative inability to detect changes in soft tissues including the spinal cord and ligamentous structures.

Whether it is safe to remove a neck collar in a comatose or obtunded patient with a normal neck CT has long remained a vexing clinical conundrum. In the past, it was felt that it was necessary to obtain a cervical MRI within 72 hours in order to rule out possible ligamentous injury, which appears as swelling or thickening of the interspinous ligaments. More recent data indicates that in obtunded or intubated patients, the use of modern CT alone is sufficient to exclude unstable cervical spine injuries. The complete absence of any sign of fracture or misalignment of the bony structures indicates a less than 0.1% chance of the patient harboring a clinically significant unstable cervical spine injury [[Level 1](#)].²

MRI (see [Chapter 21](#)) is the best technique for imaging the spinal cord itself. Specific indications for MRI scanning include a neurologic deficit with normal x-rays, lack of correlation between a neurologic deficit and x-ray findings, deterioration following closed reduction, and failed attempts at closed reduction. Multiplanar, high-resolution MRI with T1-weighted and gradient echo or T2-weighted imaging is the most specific and sensitive technique for assessing soft-tissue paraspinal lesions, disk herniation, spinal cord hemorrhage, spinal cord edema, and intra- or extradural hemorrhage ([Fig. 47.2](#)). The ability to adequately monitor the critically injured must be a priority when MRI is considered. If MRI is not available or possible, CT myelography is the current best alternative.

NEUROLOGIC ASSESSMENT AND CLASSIFICATION

The most widely accepted, standardized method of classifying SCI is the *International Standards for Neurological and Functional Classification of Spinal Cord Injury* published jointly by the American Spinal Injury Association (ASIA) and the International Medical Society of Paraplegia (IMSOP). It is more commonly known as the ASIA Impairment Scale. This is an excellent guide for clinical

evaluation and neurologic assessment and allows uniform comparisons among clinicians and researchers.

FIGURE 47.1 Type 2 acute dens fracture (*blue arrow* and *green arrow*) on sagittal T1- (**left**) and T2 (**center**)-weighted MRI and a CT sagittal reconstruction (*red arrow*) (**right**). (Images courtesy of Dr. Alexander Khandji.)

FIGURE 47.2 **Left:** Non-fat-saturated T2 image showing anterior subluxation of C7 on T1 (with anterior tear drop fracture of T1 *blue arrow*) and widened interspinous space C7-T1 posteriorly (*green arrow*). **Right:** Sagittal CT reconstruction demonstrating anterior teardrop fracture of T1 (*red arrow*). (Images courtesy of Dr. Alexander Khandji.)

TABLE 47.4 American Spinal Injury Association (ASIA) Impairment Scale

A	Complete	No sensory or motor function preserved in the lowest sacral segments (S4/S5)
B	Sensory incomplete	Sensory but no motor function preserved below the neurologic level, including the sacral segments
C	Motor	Motor function is preserved below the neurologic level, and more than half of the key muscles below the level

	incomplete	have a grade <3, and there is some sacral sensory and/or motor sparing.
D	Motor incomplete	Motor function is preserved below the neurologic level, and more than half of the key muscles below the level have a grade ≥ 3 , and there is some sacral sensory and/or motor sparing.
E	Normal	Sensory and motor functions are normal. There can be reflex abnormalities.

The ASIA Impairment Scale is scored from A to E and is detailed in [Table 47.4](#). The steps to classify injury severity in a patient with SCI are described in [Table 47.5](#). There are some terms that require clear definitions for categorizing impairments within the ASIA scoring system. The motor level is the most caudal key muscle group that is graded 3/5 or greater, with the segments cephalad to that level graded normal strength (5/5). The sensory level is the most caudal dermatome to have normal light touch and pinprick sensation on both sides. The neurologic level of injury is the most caudal level at which both motor and sensory modalities are intact. A complete injury is the absence of motor and sensory function in the lowest sacral segments. An incomplete injury has preservation of motor or sensory function below the neurologic level of injury that includes the lowest sacral segments. A zone of partial preservation describes all segments below the neurologic level of injury that have preserved motor or sensory findings; this is used only in complete injuries.

TABLE 47.5 Physical Examination Steps for Classifying Spinal Cord Injury

1. Perform sensory examination in 28 dermatomes bilaterally for pinprick and light touch, including the S4/S5 dermatome, and test for anal sensation.
 2. Determine sensory level (right and left).
 3. Perform motor examination in the 10 key muscle groups, including anal contraction.
 4. Determine motor level (right and left).
 5. Determine neurologic level of injury.
 6. Classify injury as complete or incomplete.
 7. Categorize ASIA Impairment Scale (A-E).
 8. Determine zone of partial preservation if ASIA A.
- ASIA, American Spinal Injury Association.

A subset of SCIs has been grouped by their specific clinical features into six clinical syndromes: Brown-Séquard, central cord, anterior cord, posterior cord, conus medullaris, and cauda equina.

Brown-Séquard Syndrome

This syndrome is characterized anatomically by a hemicord injury with ipsilateral proprioceptive and motor loss and contralateral pain and temperature sensation loss below the level of the lesion. The pattern of neurologic deficits observed in Brown-Séquard injuries result from the local spinal cord anatomy. Pain and temperature fibers cross to the opposite side of the spinal cord at the level of nerve root entry, whereas the proprioception and motor fibers decussate at the level of the brain stem. Brown-Séquard accounts for 1% to 5% of all traumatic SCIs. The most common presentation is the Brown-Séquard plus syndrome, which refers to a relative ipsilateral hemiplegia with a relative contralateral hemianalgesia. Although Brown-Séquard traditionally has been associated with stab or missile injuries, a variety of etiologies may cause this syndrome. Brown-Séquard has the best prognosis for ambulation of the SCI clinical syndromes, as 75% to 90% of patients ambulate independently in long-term follow-up.

Central Cord Syndrome

This lesion is characterized by disproportionately more motor impairment of the upper than the lower extremities, bladder dysfunction, and varying degrees of sensory loss below the level of the lesion. The most common presentation occurs in older patients with preexisting cervical spondylosis who experience hyperextension injuries of the cervical spine. Cord compression occurs between osteophyte-disk complexes anteriorly and infolded ligamenta flava posteriorly. Studies have reported falls as the most common etiology, followed by motor vehicle accidents. Recent evidence from clinical-pathologic studies using MRI scans has demonstrated that this clinical pattern likely results from

injury to the corticospinal tract in the cervical spine, which affects the distal, more than proximal, limb musculature and not the specific somatotopic representation within the corticospinal tract. It is considered the most common of the SCI syndromes, accounting for approximately 9% of all traumatic SCIs. Central cord syndrome generally has a favorable prognosis for functional recovery, especially in younger patients with good hand function, evidence of early motor recovery, and absence of lower extremity impairment.

Anterior Cord Syndrome

This syndrome results from a lesion that affects the anterior two-thirds of the spinal cord with preservation of the posterior columns. It is characterized by complete paralysis and loss of pain and temperature sensation below the level of the lesion, accompanied by preservation of touch and proprioception. It occurs in 3% of all traumatic SCIs. It can result from flexion injuries, direct damage from bony fragments or disk compression, or secondary to occlusion of the anterior spinal artery. This syndrome carries a poor prognosis for functional improvement.

Posterior Cord Syndrome

This is the least common of the clinical syndromes and has an incidence of less than 1%. It is a lesion of the posterior columns with resultant loss of touch and proprioception below the level of injury and preservation of pain and temperature sensation and

P.386

motor strength. It can be caused by hyperextension, posterior spinal artery occlusion, or nontraumatic etiologies such as tumors or vitamin B₁₂ deficiency.

Conus Medullaris and Cauda Equina Syndromes

Conus medullaris syndrome is an injury of the caudal spinal cord (conus) and its associated sacral nerve roots within the spinal canal. The conus typically sits at the level between the first and second lumbar vertebrae. This condition is characterized by a combination of upper and lower motor neuron signs. Findings include saddle anesthesia, areflexic bladder and bowel, and variable degrees of lower extremity weakness and sensory loss.

Cauda equina syndrome results from an injury to the lumbosacral nerve roots within the neural canal below the conus medullaris and presents with saddle anesthesia, bladder and bowel dysfunction, and variable lower extremity involvement. The difference from the conus medullaris syndrome is the absence of upper motor neuron signs, and it is usually characterized by asymmetric lower extremity weakness and reflex changes. It is believed to have a better prognosis for neurologic recovery than SCI because nerve roots have the ability to regenerate. Important predictors for favorable outcome from cauda equina are early diagnosis and surgical decompression.

ACUTE MEDICAL MANAGEMENT

The acute management of patients with SCI is primarily directed at medical stabilization to prevent secondary injury and to permit the accurate clinical and radiographic diagnosis of spinal cord and column pathology. The specifics of initial management have been detailed to some degree in the earlier section covering diagnosis of SCI, as the acute management and evaluation of SCI are intertwined.

GENERAL TRAUMA CARE

In general, patients should be managed at a trauma center, preferably level 1, with SCI experience. If an appropriate trauma center is not immediately available, transfer to a trauma center as soon as possible is advocated. Emergency medical services in urban areas should preferentially take patients to level 1 centers, potentially bypassing nearer hospitals. Level 1 centers are required to have in-house neurosurgical consultation for rapid evaluation. The patient should be immobilized with a cervical collar and backboard/head-strap as soon as possible. The backboard can be removed after radiographic studies are completed and interpreted. The cervical collar should be maintained until the cervical spine has been clinically and/or radiographically cleared. Neurosurgical evaluation should happen as soon as possible; neural element decompression and spinal stabilization within 24 hours may improve neurologic recovery in patients with deficits and spinal cord compression, but the clinical data are inadequate to advocate this as a standard of care. It is important to note that there has been no demonstrated increased risk of neurologic deterioration from early surgery.

STEROIDS

High-dose methylprednisolone has long been considered a potential neuroprotective agent in SCI, with the potential of reducing tissue injury by inhibiting lipid peroxidase and free radical production. Methylprednisolone therapy was evaluated in 487 SCI patients in the National Acute Spinal Cord Injury Study II (NASCIS II), trial in 1990. Patients were given a bolus of 30 mg/kg of methylprednisolone over 15 minutes, followed by a 5.4-mg/kg infusion over 23 hours. The authors reported a mean improvement of 5 points in motor score (total possible score = 50) and 4 points in sensory scores (total possible score = 58) for patients treated with methylprednisolone compared to controls at 6 months, but only if they received the drug within 8 hours of injury. Although NASCIS II was initially reported as a positive trial, re-analysis has shown that the strength of the evidence generated is weakened by omission of data from publication, the arbitrary assignment of an 8-hour therapeutic window, the inconsistency of reported benefit, and the absence of functional outcome measures. Accordingly, the beneficial results of NASCIS II have been downgraded to Class III medical evidence. Due to a trend towards more serious complications associated with steroid use, current guidelines do not recommend administration of methylprednisolone (MP) for the treatment of acute SCI [Level 1].³

AUTONOMIC DYSFUNCTION AND BLOOD PRESSURE MANAGEMENT

Autonomic dysfunction with hypotension can occur acutely in SCI, especially in patients with cervical injuries. Autonomic dysfunction may

result from a variety of reasons including the following: spinal shock, neurogenic shock, hypovolemia, bradycardia, sepsis, and cardiogenic shock. Hypotension is a common contributor to secondary neurologic injury and should be avoided; its treatment can involve careful volume resuscitation, vasopressors, and diagnostic maneuvers such as an arterial line, a central venous catheter, and noninvasive continuous cardiac output assessment. *Current SCI guidelines recommend maintenance of mean arterial pressure at a minimum value of 85 to 90 mm Hg for the first 7 days after injury.* This has limited supporting clinical data, but hypotension clearly should be avoided. Occasionally, intravenous (IV) atropine sulfate may be necessary to counter unopposed parasympathetic activity. Vasomotor paralysis may also cause loss of thermal control and lead to poikilothermy, which usually may be treated by the appropriate use of warming blankets. Acute cervical SCI is also associated with a risk of cardiac arrhythmia due to excess vagal tone, as well as complicating hypoxia, hypotension, and fluid and electrolyte imbalances.

CRITICAL CARE

After complete medical stabilization, neurologic assessment, and spinal column stabilization and/or bracing within the initial 24 to 48 hours, attention is paid to the prevention of common medical problems in patients with acute SCI. Prophylactic treatment for deep venous thrombosis should begin no later than 72 hours after SCI. The first-line therapy is subcutaneous injection of low molecular weight heparin (enoxaparin 40 mg SC QD), and second-line therapy is subcutaneous injection of unfractionated heparin (5000 U SC BID or TID). In patients with contraindications to anticoagulation, an inferior vena cava filter should be placed to prevent pulmonary embolism. Lower extremity sequential compression devices should also be employed when feasible. Stress ulceration should be prevented with proton pump inhibitors or H2 blockers with a minimum of 4 weeks of therapy after SCI. Nutritional support, via feeding tubes or parental nutrition if appropriate, is suggested to begin with 72 hours after SCI. Pressure ulcers of the occiput, sacrum, and heels should be prevented through manual or automatic turning every 2 hours without lateral

P.387

sliding to prevent sacral shearing. Rehabilitation maneuvers should begin as soon as possible and should include passive and active range-of-motion (ROM) activities, bowel and bladder programs (e.g., chronic intermittent catheterizations), pulmonary programs (mechanical ventilation, manually assisted cough), and dysphagia evaluations.

SURGICAL TREATMENT

After control of the acute medical issues and accurate neurologic and radiographic diagnosis of SCI, attention is directed toward treating instability of the vertebral column and neural element compression, if present. This is directed by neurosurgical or orthopedic caregivers. There are currently no standards and no evidencebased guidelines regarding the role and method of decompression in acute SCI. In a recent prospective randomized trial, decompression of cervical spinal cord injuries within 24 hours of injury was found to be safe and associated with improved neurologic outcome at 6 months follow-up when compared to more delayed surgical intervention [Level 1].⁴ The management of cervical, thoracic, and lumbar spine and spinal cord injuries depends mainly on the particular injury but also on a surgeon's personal experience and practice norms in his or her center. The options include closed reduction via traction and open surgical procedures. The overall goals are to decompress the spinal cord and nerve roots, to restore the spinal alignment, and to prevent progressive deformity.

Cervical spine fracture or dislocations may be treated with closed reduction through the use of traction. Thoracic and lumbar fractures cannot be corrected with this treatment. Traction uses skull tongs or the headpiece of a halo attached to a system to apply rostral force, usually with rope, a pulley, and weights. An initial weight of 5 to 15 lb is applied and a lateral x-ray is obtained. Weight can be increased at 5-lb increments, and a neurologic exam and lateral x-ray should be obtained after each adjustment. The maximum weight applied relates to the level of injury. A general rule of 3 to 5 lb per vertebral level is used. We suggest that after 35 lb is applied, patients be observed for at least an hour with repeat cervical spine x-rays before the weight is cautiously increased further. Muscle relaxants and analgesics may help facilitate reduction.

Cervical spine surgery is indicated for injuries that are not amenable or do not respond to closed reduction. These include unstable cervical fractures and cord compression with an incomplete neurologic deficit. Patients without neurologic deficits are often treated nonoperatively with bracing unless there is evidence of instability. Some penetrating injuries may require surgical exploration to ensure that there are no foreign bodies imbedded in the tissue and also to clean the wound to prevent infection.

Thoracolumbar injuries do not lend themselves to external traction, and accordingly, surgical repair is typically achieved through open reduction followed by stabilization. There are a variety of anterior and posterior approaches that employ metallic implants such as interbody cages, pedicle screws, laminar wires or hooks, and connecting rods.

In clinical studies, surgery has little effect on the neurologic outcome of the primary injury. When cord compression is evident, or the initial neurologic deficit progresses, immediate decompression (i.e., 1 to 2 hours after injury) may halt or reverse the process. There are no set rules for determining appropriate selection of early or late surgical intervention. Individual patient factors and clinical judgment continue to direct the surgical timing in each case.

CHRONIC MEDICAL MANAGEMENT

Chronic medical therapy is directed at preventing and treating the common, and often severe, medical complications of SCI. SCI produces a wide variety of changes in systemic physiology that can lead to a number of complications, which rival the impact of neurologic deficits on function and quality of life. In the MSCI database, rehospitalizations occurred in 55% of patients in the first year after SCI and continued at a

stable rate of about 37% per year over the next 20 years. Factors contributing to the risk of rehospitalization included increased age and severity of SCI. Genitourinary problems, respiratory complications, and pressure ulcers were the most common reasons for hospitalization. As mentioned earlier, life expectancy is reduced among patients with SCI. The mortality rates are highest during the first year. Higher injury levels, more severe injury, and older age correlate with higher mortality. The most common causes of death are respiratory diseases and cardiovascular events.

AUTONOMIC DYSREFLEXIA

Injuries above T6 may be complicated by autonomic dysreflexia, which results from the loss of coordinated autonomic responses to physiologic stimuli. Uninhibited or exaggerated sympathetic responses to noxious stimuli can lead to extreme hypertension through vasoconstriction. The parasympathetic system will respond with vasodilation and bradycardia above the level of the lesion, but it is not sufficient to correct the elevated blood pressure (BP). SCIs below T6 do not produce dramatic effects as the intact splanchnic innervation allows for compensatory dilatation of the splanchnic vascular bed.

Typical stimuli producing autonomic dysreflexia include bladder distention, bowel impaction, pressure sores, bone fractures, or occult visceral disturbances.

Common clinical manifestations are hypertension, bradycardia, headache, and sweating. Attacks have a range of severity from asymptomatic hypertension to hypertensive crisis with possible cardiac arrest from bradycardia and intracranial hemorrhage. The severity of attacks correlates with the severity of the SCI. The management of acute autonomic dysreflexia involves monitoring BP, removing tight-fitting garments, and searching for sources of noxious stimuli, including bladder distension and fecal impaction. Reduction of elevated BP can be achieved with sitting the patient upright and with rapid-acting antihypertensives with short half-lives. Sublingual or oral nitrates and IV β -blockers, calcium channel blockers, or angiotensin-converting enzyme (ACE) inhibitors are often used. Recognition and avoidance of inciting stimuli are important in preventing attacks.

Orthostatic hypotension can also affect patients with SCI. Treatment involves the implementation of temporary maneuvers, such as gradual position changes, compression stockings, and abdominal binders until the body adapts to the loss of peripheral tone. Medical therapy, if necessary, can include salt tablets to increase blood volume, α -adrenergic agonists, such as midodrine, or mineralocorticoid supplements, such as fludrocortisone.

CORONARY ARTERY DISEASE

Coronary artery disease (CAD) is a prominent complication of SCI with long-term survivors. Patients with SCI are more likely to acquire CAD risk factors than the average population secondary to loss of muscle mass, inactivity, and increased body fat. CAD is

P.388

3 to 10 times more likely in patients with chronic SCI, and SCI patients have higher mortality rates with CAD-related events. This is partly explained by abnormal presentations that occur in patients with lesions higher than T5 and the higher likelihood of episodic autonomic dysreflexia.

PULMONARY DISEASE

Cervical and high thoracic SCI will affect respiration. The severity of respiratory failure and need for assisted ventilation is directly related to the level and severity of SCI. Patients have impaired cough strength and difficulty mobilizing lung secretions and are at increased risk for pneumonia, especially during the first year following injury (see also [Chapter 116](#)). Prevention of pneumonia includes chest physiotherapy and pneumococcal vaccination. Deep venous thrombosis and pulmonary embolism are common early complications of SCI. Prophylactic use of low molecular weight heparin is the treatment of choice for most patients with SCI; treatment should be continued for at least 3 months after SCI, after which the risk appears to approximate that of the general population.

GENITOURINARY COMPLICATIONS

SCI produces bladder dysfunction, often referred to as the *neurogenic bladder* (see also [Chapter 121](#)). Other complications can result from this, including infections, vesicoureteral reflux, renal failure, and nephrocalculi. Urologic evaluation with regular follow-up is recommended for patients after SCI. Genitourinary complications may not produce symptoms and, if untreated, can have serious consequences. The frequency and specific testing involved (serum creatinine, cystoscopy, urodynamic studies, renal ultrasound) are not well defined but depend in part on the nature of the patient's urologic problems and other risk factors.

After SCI, the sensation for bladder fullness as well as motor control of bladder and sphincter function can be impaired. Depending on the timing, the level, and the severity of injury, one of several types of bladder dysfunction can occur. These include bladder hyperactivity with reflexive bladder emptying, sphincter hyperactivity with impaired emptying of the bladder, detrusor-sphincter dyssynergia leading to uncoordinated bladder contractions, bladder flaccidity with urinary retention, and over-flow incontinence.

Clean intermittent catheterization (CIC) programs achieve the goal of preserving renal function while eliminating urine at regular and socially acceptable times. This avoids high bladder pressures, retention, incontinence, and infection. This should be initiated as early as possible after SCI. Catheterization is performed approximately every 4 hours and is adjusted as necessary. Often, patients have a fluid intake restriction of 2 L to prevent bladder overdistention.

After ruling out an infection and adjusting the frequency of CIC and fluid intake, medications targeting the sympathetic and

parasympathetic receptors are employed depending on the specific bladder condition.

Urinary tract infections (UTIs) are common in SCI and are the most frequent source of septicemia in SCI patients. Asymptomatic UTIs are not generally treated, and prophylactic antibiotics are not used for prevention.

Sexual dysfunction has a high prevalence in SCI; dysfunction in males can exceed 75% and is related to the severity of injury. There are a variety of treatment options for men with SCI, which include medicines for erectile dysfunction and surgically implanted prosthetics. Sexual responses in women may also be impaired after SCI, but ovulation and fertility are generally unaffected. Pregnancy with SCI is considered high risk because of the high rate of complications secondary to infections and autonomic dysreflexia.

GASTROINTESTINAL DYSFUNCTION

Bowel dysfunction is very common after SCI and can significantly affect quality of life. There are no evidence-based recommendations for clinical management of this problem. A structured bowel regimen employing a regular diet, 2 to 3 L of fluid/day, 30 g of fiber, and chemical and mechanical stimulation is often employed to achieve predictable bowel evacuation to avoid fecal incontinence and impaction.

ABNORMAL BONE METABOLISM

Osteoporosis can affect the bones below the level of SCI, most likely secondary to disuse, and may predispose to fractures. Bone resorption in the first few months after SCI can lead to symptomatic hypercalcemia. Treatment can involve the use of hydration with IV fluids, loop diuretics, and IV bisphosphonate therapy.

Heterotopic ossification, the deposition of bone within the soft tissue around peripheral joints, can also occur in SCI. This occurs in up to half of SCI patients but is symptomatic, as evidenced by pain and inflammation in the affected joints, in 10% to 20% of patients. Treatment involves passive ROM exercise, oral bisphosphonates, nonsteroidal anti-inflammatory drugs (NSAIDs), and, in some cases, delayed surgery.

SPASTICITY

Spasticity results from the disruption of the descending inhibitory pathways, with a concomitant increase in the excitability of spinal reflexes and resting muscle tone. Spasticity can negatively affect quality of life through pain, decreased mobility, muscle spasms, and ultimately, contractures. Prevention of contractures involves proper positioning, passive ROM exercises, appropriate splinting, and treatment of spasticity. However, the increased tone can also make some activities easier, such as standing and transfers. Treatment can include physical therapy, passive ROM exercises, oral medications (baclofen, tizanidine, valium, etc.), and surgical interventions (intrathecal baclofen pumps, rhizotomies, etc.).

PSYCHIATRIC COMPLICATIONS

Psychiatric disorders associated with SCI include depression, suicide, and drug addiction. Approximately a third of patients with SCI will be depressed within the first year after SCI; this is not closely associated with severity of injury. Suicide occurs at a rate four to five times higher in patients with SCI and is the leading cause of death in patients with SCI younger than the age of 55 years. Patients should be regularly screened for symptoms of depression, and symptoms should be treated immediately.

CONCLUSION

SCI remains a difficult medical, social, and financial problem. A more clear understanding of the pathophysiology and resultant medical complications has resulted in improved long-term survival and functional status. However, the unsolved problem of SCI repair remains. It is worth remembering that the best treatment is prevention. Nationwide educational programs should be concerned with combating the causes of SCI: motor vehicle safety, water and occupational safety, eliminating drunk driving, adhering to speed limits, and mandatory use of seatbelts and other protective gear.

Traumatic Cranial and Peripheral Nerve Injuries

Jennifer F. Russo

Charles B. Mikell

Christopher J. Winfree

INTRODUCTION

Traumatic injury to peripheral nerves is associated with significant disability and decreased quality of life. In this chapter, we discuss the classification, pathophysiology, evaluation, and treatment of peripheral nerve injuries, as well as the clinical manifestations of common peripheral and cranial nerve lesions. Understanding of the principles described in this chapter, by clinicians, is important for timely diagnosis and treatment of these common clinical entities.

EPIDEMIOLOGY

It has been estimated that approximately 3% to 10% of all patients presenting to a level 1 trauma center present with injury to a peripheral nerve. Motor vehicle accidents are most commonly cited as the leading cause, whereas industrial accidents, recreational vehicle use, falls, gunshot and stab wounds, as well as iatrogenic injuries also contribute. The potential economic and social impact of these injuries is compounded by the fact that they occur most commonly within the productive age range, with highest incidence reported between 20 and 40 years of age. Males are affected more often than females, and injury to the nerves of the upper extremity occur more commonly than do those to the nerves of the lower extremity. Peripheral nerve injuries are also commonly comorbid with traumatic injury to the brain, which can result in delayed diagnosis and intervention.

PATHOBIOLOGY

ANATOMY AND PHYSIOLOGY

Evaluation of traumatic peripheral nerve injury requires understanding of nerve structure. Peripheral nerves consist of a mixture of myelinated and unmyelinated, somatic and autonomic, nerve fibers. Each fiber is surrounded by an endoneurial sheath, which provides some tensile strength. Multiple fibers, of various types, are grouped together into fascicles and surrounded by the perineurium, a specialized structure composed of perineurial cells and collagen that serves to maintain homeostasis of the endoneurial fluid that surrounds individual fibers. This perineurial sheath provides most of the tensile strength and elasticity of the nerve and provides a diffusion barrier that resists and maintains intrafascicular pressure. Multiple fasciculi, in turn, are embedded in a connective tissue matrix called the *epineurium*, which protects the nerve from compression. The most superficial layer of the epineurium condenses to form an external epineurial sheath, which gives the nerve a cord-like appearance on gross examination.

Both within and between nerve fibers, the number, size, and organization of fascicles varies significantly. As fascicles branch, split, and rejoin continuously along their course, sections through the nerve may alternatively reveal plexiform and cable-like structure, which has implications for both clinical presentation of nerve injuries, as well as surgical repair and functional regeneration. Further, variability in internal organization is partially responsible for observed differences in the prevalence of particular nerve injuries. That is, peripheral nerves with a higher proportion of epineurial tissue to fasciculi may be more resistant to compression injuries, whereas peripheral nerves with greater numbers of fasciculi have greater tensile strength.

MECHANISMS OF INJURY

Traumatic nerve injuries may be acute or chronic and iatrogenic or idiopathic. They result from the application of kinetic energy to a nerve, which is transformed into damaging compressive or tensile forces. Chronic traumatic nerve injuries most often result from anatomic nerve entrapment leading to well-described clinical entities, such as carpal tunnel syndrome. These chronic syndromes, requiring unique medical and surgical treatment approaches, are discussed more thoroughly in Chapter 87.

Acute traumatic nerve injuries occur, most commonly, from traction/stretch, compression, contusion, laceration, or ischemia. Injury is derived primarily from direct application of mechanical forces and secondarily from vascular compromise. Multiple mechanisms of injury may be present, particularly when the lesion occurs during a catastrophic event, such as a motor vehicle accident. Identifying the type of insult incurred, when possible, is important for treatment planning, as various types of forces result in different patterns of injury.

INJURY CLASSIFICATION

Two major classification systems are used most commonly to describe peripheral nerve injuries. The injury categories defined by these systems each have unique diagnostic characteristics, prognoses, and therapeutic approaches.

The classification system used most commonly in clinical settings was proposed by Seddon in 1942. Seddon's system divides injuries into three main categories delineated by the extent of disruption to the structure of the nerve. The three categories are *neurapraxia*, *axonotmesis*, and *neurotmesis* (Table 48.1).

Neurapraxia is the least severe of the three injury types. It most commonly is caused by a mild insult resulting in focal demyelination with no associated axonal degeneration. It is characterized by transient focal conduction block across the lesion. The axon distal to the site of injury remains intact and the nerve remains in continuity. Clinically, this class of injury may manifest as weakness or sensory loss in the anatomic distribution of the affected nerve. Prognosis for this type of injury is excellent, with spontaneous recovery occurring within hours to, in the most severe cases, a few months. No specific therapeutic intervention is required.

Axonotmesis occurs most commonly during crush, stretch, or percussive injuries, such as gunshot wounds where injury is most commonly caused by indirect heat and shock wave from the bullet rather than transection. These injuries result in irreversible damage to axonal elements including the myelin sheath, leading to distal degeneration. Supporting structures such as the epineurium, perineurium, and, at times, the endoneurium remain intact.

P.391

TABLE 48.1 Seddon's Nerve Injury Classifications and Prognosis

Class	Pathology	Mechanism	Treatment	Prognosis	Time Course
Neurapraxia	Demyelination	Compression Ischemia	Medical Physical therapy	Excellent	Hours to 3 mo
Axonotmesis	Axonal disruption Distal degeneration	Crush Stretch Percussion	Variable: may require surgery	Variable: good to poor	Weeks to years

	Epineurium intact				
Neurotmesis	Complete loss of continuity Transection Distal degeneration	Sharp injuries Traction	Surgical: end-to-end neurorrhaphy, grafting or neurotization	Poor/nil without repair	Months to years with surgery No spontaneous recovery

Prognosis for axonotmetic injuries depends on several factors. These factors include the degree of disruption of the internal structure of the nerve, as well as distance from the end organ and the particular characteristics of the injured nerve. Spontaneous recovery is possible after axonotmetic injury, but the time course is considerably greater than that of neurapraxic lesions. Recovery is more commonly partial than complete.

Neurotmesis is defined by complete loss of continuity of the nerve. All connective tissue layers, the axon, and the myelin sheath are irreversibly damaged. Surgical intervention is required, as no spontaneous recovery is possible. The timing of surgery is dependent on the mechanism of injury, as blunt injuries continue to evolve through an inflammatory process over a period of weeks. Prognosis after surgery is variable but is generally poorer than that of spontaneous recovery.

A second important peripheral nerve injury classification system was proposed by Sunderland in 1951 ([Table 48.2](#)). Expanding on the work of Seddon, he described five classes of nerve injury, with class I describing neurapraxic lesions and class V equivalent to neurotmesis. For classes II to IV, Sunderland subdivided axonotmesis into three levels, of increasing severity and worsening prognosis, based on the extent of internal disruption, from axon only in class II to endoneurial sheath in class III and perineurium in class IV. Although this additional level of detail is helpful in a research setting, the clinical use is more limited, as all classes II to IV will require the same initial therapeutic approach. Nevertheless, this classification scheme highlights the importance of internal nerve structure for spontaneous recovery and functional regeneration.

TABLE 48.2 Sunderland's Classification of Peripheral Nerve Injuries

Class	Pathology	Mechanism	Treatment	Prognosis	Time Course
I	Demyelination	Compression Ischemia	Medical Physical therapy	Excellent	Hours to 3 mo
II	Axonal disruption Distal degeneration	Crush Stretch Percussion	Variable	Good	Months to years
III	II + endoneurial disruption	Crush Stretch Percussion	Variable	Moderate	Months to years
IV	III + perineurial	Crush	Variable	Poor without	Months to years

	disruption	Stretch Percussion Traction		repair	
V	Complete transection	Sharp injury Traction	Surgery	Poor/nil without repair	Months to years with surgery No spontaneous recovery

REPAIR AND REGENERATION

Characteristic pathologic changes in the nerve occur as a result of traumatic insult. In the mildest form, demyelination is observed at the injury site. When trauma results in axonal disruption, the distal nerve undergoes a process of degeneration that extends to the end organ. The duration of the degenerative process is dependent on the distance of the injury from the end organ. Morphologic and functional changes also take place within the proximal stump adjacent to the injury site.

In the initial period immediately following injury, acute axonal degeneration, extending approximately 300 mm proximally and distally from the lesion site, is triggered by an influx of extracellular calcium. On electron microscopy, vacuoles resembling autophagosomes accumulate in the axon ends. Swelling and disruption of neurofilaments is observed.

These immediate changes are followed by fragmentation and phagocytosis of the myelin sheath. Within 2 days, whorls of myelin debris and small lipid droplets may be observed within the Schwann cells. Circulating macrophages are recruited and enter

P.392

the distal stump. Loss of axonal contact and the presence of macrophages stimulate Schwann cell proliferation and dedifferentiation. These dedifferentiated Schwann cells line up along the basal lamina to form bands of Büngner, which will act as guides to regenerating nerve axons.

Reinnervation occurs via two main mechanisms: collateral axonal sprouting from uninjured axons and axonal regeneration, which occurs spontaneously from the proximal stump following degeneration. Collateral sprouting is an early mechanism of functional motor recovery. It occurs with incomplete lesions, in which some of the axons remain intact. New axonal outgrowths are noted to arise from both nearby nodes and terminal branches. These fine axonal extensions travel along the remaining nerve structures to provide partial reinnervation to nearby motor targets. Generally, collateral sprouting is not sufficient to restore full power to the muscle but may be responsible for some early functional recovery.

Axonal regeneration is the primary mechanism by which reinnervation occurs, following distal degeneration, in axonotmetic and neurotmetic lesions. Regeneration begins from the proximal stump and extends along intact basal lamina toward the end organ at a variable rate of approximately 1 to 2 mm/day. Once the target organ has been reached, a process of maturation occurs to reestablish functional connection. The appearance of clinical evidence of reinnervation reflects both the distance from injury site to the end organ and the maturation process. Rate of regeneration appears to be slower for transected lesions than for crush injuries.

Successful regeneration and functional recovery rely on a number of factors. Inflammation and scar tissue provide major barriers to axonal growth. Gap lengths that are too long result in disorganized and highly tortuous axonal paths, which may coalesce within scar tissue to form a nonfunctional and potentially painful bulb referred to as a *neuroma*.

Even when regeneration does occur successfully, functional recovery is not guaranteed. Regenerating sprouts

must be able to form mature connections with appropriate motor or sensory targets in order for recovery to occur. In highly mixed nerves, with an approximately equal amount of sensory and motor fibers, some regenerating motor fibers may be lost to sensory targets or vice versa. Nerves that contain one predominant modality generally have a better prognosis for functional recovery.

Finally, sensory targets maintain viability for a much longer period of time than does muscle tissue. Within 12 to 18 months, fibrotic changes take place in denervated muscle that make successful reinnervation unlikely. Sensory targets, on the other hand, maintain viability for up to 2 to 3 years. Therefore, patients may continue to experience recovery of sensation well beyond the period of motor recovery.

CLINICAL FEATURES

The clinical manifestation of traumatic peripheral nerve injury depends on the mode, location, and extent of the injury sustained. Signs and symptoms reflect both the location and severity of the lesion, as well as the composition of the injured nerve. Injury to a nerve that consists predominantly of motor fibers will manifest as weakness or paralysis and atrophy in the corresponding myotomal distribution. Injury to a predominantly sensory nerve, on the other hand, will present with sensory alteration or loss in the corresponding dermatomes. Autonomic and trophic function may also be affected resulting in decreased sweating, hair loss, and skin changes in the affected region. Partial lesions and faulty regeneration may result in the development of difficult to treat pain, often described as “pins and needles,” stabbing or burning in character. For some patients, a debilitating symptom complex called *complex regional pain syndrome II*, also referred to as *causalgia*, may develop, which is characterized by allodynia, autonomic dysregulation, and maladaptive neuroplastic changes in central nervous system (CNS) response to and processing of pain signals. This syndrome often does not respond well to conventional pain management strategies.

Some common associations are seen between various injury mechanisms and specific peripheral nerves. Awareness by clinicians, of these associations, may contribute to the earlier identification and treatment of potentially disabling injuries. Some of these common associations and their clinical presentations are discussed in the following section.

CRANIAL NERVE LESIONS

Acute injury to cranial nerves often accompanies trauma to the head and neck. Significant injury may occur even with mild head trauma. One study by Coello and colleagues that evaluated cranial nerve function in 16,440 mild head trauma patients, defined by a Glasgow Coma Scale score of 14 or 15 at the time of presentation, over a period of 6 years, found a prevalence of associated cranial nerve injury of 0.3%, with the olfactory nerve being the most commonly affected, followed by the facial nerves and the nerves responsible for ocular movement. Injury to the lower cranial nerves (IX to XII) was noted to occur less frequently as a consequence of head trauma but to be more closely associated with iatrogenic injury during various medical and surgical interventions. The prevalence, location, and type of cranial nerve injuries observed most frequently result from the specific anatomic vulnerabilities of the affected nerve.

Cranial Nerve I: The Olfactory Nerve

The olfactory nerve, responsible for our ability to detect and distinguish smells, is one of the most commonly cited cranial nerves to be injured as a result of head trauma. Olfactory dysfunction has been reported to occur in up to 4% to 7% of all cases of head trauma. Injury may occur at multiple sites along the olfactory pathway. It is most often associated with acceleration-deceleration forces, such as those generated during motor vehicle accidents. Common injury sites include the olfactory nerve filaments as they cross the cribriform plate and are subject to shearing forces; the olfactory bulb, which may be contused against the frontal bone; and the cortical olfactory tracts, which may be damaged by edema, hemorrhage, or ischemic injury of the orbitofrontal and

temporal lobes. *Anosmia*, the complete loss of odor detection, is the most common clinical finding, but *parosmia*, a decrease in olfaction acuity, is also observed, particularly with injury to the temporal lobe. The perception of taste, which is reliant on olfaction, is also commonly impaired in patients with injury to the olfactory nerve, and it is this symptom for treatment of which most patients present.

Despite the relative frequency with which injury to the olfactory nerve occurs following head trauma, deficits are rarely identified in the acute period. This may be because of the fact that trauma patients present with multiple injuries of varying severity and immediacy that require disproportionate allocation of resources. Nevertheless, loss of olfaction may have significant impact on quality of life, resulting in diminishment of enjoyment of food and other sensual experiences reliant on smell; loss of employment, when dependent on the sense of smell or taste; and decreased ability to detect environmental cues that may signal danger, such as the odor of volatile gas or fire. Awareness by clinicians of the association of head trauma with cranial nerve I dysfunction is important for early detection and diagnosis.

P.393

Cranial Nerve II: The Optic Nerve

Traumatic optic neuropathy, which may result in complete or partial loss of visual acuity in the affected eye, has been reported to occur in 1.4% to 5% of head trauma cases. Injury may be *direct*, resulting from anatomic disruption of nerve fibers by fracture fragments, penetrating trauma, or hematoma within the nerve sheath, or *indirect*, reflecting the transmission of forces to the optic canal during blunt head trauma. Early decompressive surgery may be required to prevent irreversible vision loss.

Additionally, injury to the optic nerve is recognized as a potential complication of facial fracture repair in patients with maxillofacial trauma, with a reported incidence of 0.3%. Mechanisms include direct intraoperative nerve injury, retinal vascular occlusion from orbital edema, and increased intraorbital pressure in the optic canal resulting in indirect injury to the nerve. This complication is most often reported after surgical intervention of the orbital floor, and ischemia is the most common final pathway leading to injury.

Unlike skeletal tissues, the optic nerve and retinal tissues are extremely sensitive to hypoxia and pressure, with irreversible ischemic damage occurring within 60 minutes to 2 hours. Because of this sensitivity, prompt identification of even subtle changes in visual acuity by the clinician is essential to provide potentially vision-sparing interventions in a timely manner.

Cranial Nerve III, IV, VI: The Oculomotor, Trochlear, and Abducens Nerve

Together, the oculomotor, trochlear, and abducens nerves innervate the muscles responsible for ocular movements. Damage to these nerves is a common complication of closed head injury. It may result in diplopia, impairments in eye movement, and ocular deviation. Injury to the nerves may occur at the nuclei in the brain stem, as the nerve exits the brain stem, and at the point where it pierces the dura mater. The site of injury reflects both the injury mechanism and the anatomic characteristics of the nerve. One or all of the nerves for oculomotor control may be affected, and clinical presentation will vary accordingly.

Cranial nerve III, the oculomotor nerve, innervates many of the muscles responsible for eye movement, including the medial rectus, superior rectus, inferior rectus, inferior oblique, levator palpebrae superior, and the pupillary constrictor. Additionally, the oculomotor nerve carries parasympathetic fibers to the eye. Complete lesion of this nerve results in a “down and out” deviation of the eye, ptosis, dilation of the pupil, and loss of pupillary constriction to light but not accommodation. Partial lesions may result in any combination of these findings, depending on the specific nerve fibers affected. Because the parasympathetic fibers run along the outside of the nerve, compressive lesions, such as an expanding hematoma or progressive uncal herniation secondary to intracranial hemorrhage or edema, tend to present with pupillary changes first, which may progress to

oculomotor palsy with increasing pressure. Aneurysms of the posterior communicating artery may also compress the third cranial nerve and should be considered when evaluating a patient with oculomotor nerve palsy. Injuries that cause third nerve ischemia, on the other hand, are more likely to affect the motor fibers before disrupting the parasympathetic components. This distinction may help the clinician to identify the etiology of idiopathic third nerve palsy.

The trochlear nerve provides innervation to the superior oblique muscle. Lesion of this nerve results in an inability to move the eye medially and inferiorly. The resulting diplopia may be resolved by inclining the head toward the unaffected eye. Trochlear nerve palsies occurring in isolation have been observed following dorsal midbrain hemorrhage and as a complication of dental anesthesia during upper molar surgery but are extremely rare. Generally, injury to the fourth cranial nerve is accompanied by other oculomotor and neurologic deficits.

The abducens nerve innervates the lateral rectus muscle, which is responsible for abduction of the eye. Injury to this nerve results in severe double vision in almost all gaze directions and medial deviation. Traumatic injury to the sixth cranial nerve has been associated with cranial base fracture and the development of clival epidural hematoma, as well as cervical hyperextension, atlantooccipital dislocation, and hyperflexion. The sixth cranial nerve vulnerability to injury is thought to be a result of its long and delicate intracranial source. After exiting the pons, it ascends vertically within the subarachnoid space for 15 mm before piercing the dura mater. From there, the nerve travels over the ridge of the petrous bone, change directions abruptly at a 120-degree angle to enter Dorello canal, a triangular space defined by the apex of the petrous bone, the posterior clinoidal process, and a thickened portion of the dura mater, which connects the two, referred to as *Gruber ligament*. The nerve is tethered by the dura on either side of the canal. From Dorello canal, the nerve passes through the cavernous sinus and the superior orbital fissure to reach the lateral rectus muscle. Traumatic injury to the abducens nerve is thought to occur most commonly by downward displacement against the petrous ridge at the point at which it turns to enter the canal.

Cranial Nerve V: The Trigeminal Nerve

The trigeminal nerve supplies sensation to the face through three major peripheral branches, the ophthalmic (V1), maxillary (V2), and mandibular (V3) nerves. V1 and V2 are purely sensory, whereas V3 also carries motor fibers to the muscles of mastication. V1 is also responsible for the corneal reflex. Traumatic injury to the branches of the trigeminal nerve is uncommon but may result from dental or cranial trauma or as a side effect of dental and surgical procedures in the region. Several cases of damage to the lingual nerve, which is a branch of the mandibular division, which provides sensation to the anterior two-thirds of the tongue, and which is joined by the chorda tympani from cranial nerve VII, have been reported with the use of supraglottic airway devices. Compression of the nerve branch by the device results in temporary loss of sensation and taste (from the gustatory fibers of cranial nerve VII) in the anterior tongue, which, although potentially upsetting to the patient, generally resolves spontaneously within 6 to 9 weeks. The patient experiencing these symptoms postoperatively should be reassured regarding chance of recovery.

Cranial Nerve VII: The Facial Nerve

The facial nerve provides most of the motor innervation for the muscles of expression in the face. It also, via the nervus intermedius, relays afferent taste sensation from the anterior two-thirds of the tongue and carries sympathetic fibers to the lacrimal and salivary glands. Depending on the location of the injury, motor, autonomic, and gustatory deficits may be seen. Lesions of the intracranial portion of the nerve near the origin or close to the geniculate ganglion by the internal acoustic meatus, may affect all three components, whereas those in the facial canal of the temporal bone between the geniculate ganglion and the origin of the chorda tympani near the stylomastoid foramen may spare lacrimation. Lesions occurring after the stylomastoid process in the extracranial portion of the nerve result primarily in motor deficits. Symptoms may be mild to severe depending on the severity

Injury to the facial nerve may present as complete paralysis of the facial muscles, with flattening of the facial folds around the nose, lips, and forehead; widening of palpebral fissures; and incomplete closure of the eyelid on the affected side, which can result in corneal scarring from desiccation particularly if the injury also affects lacrimation. Decreased salivation and loss of taste in the anterior two-thirds of the tongue may also be present if the chorda tympani is affected. Less commonly, patients with seventh nerve injuries may experience sensitivity to loud sounds, or hyperacusis, as the facial nerve supplies motor input to the stapedius muscle, which has a dampening effect on the tympanic membrane. During regeneration, *synkinesis* may develop, which is the movement of unrelated facial muscles during attempts at isolated muscle movements, such as lip twitch with blinking, if aberrant reinnervation occurs. Importantly, lesions of the peripheral facial nerve can be distinguished from central motor pathway lesions by assessing involvement of the forehead. Central lesions spare forehead motion due to bilateral representation in the CNS, whereas peripheral lesions do not.

Traumatic injury to the facial nerve may result from temporal bone fracture, penetrating injuries, such as knife or gunshot wounds, as a result of surgery for other indications, including resection of acoustic neuroma, or in the neonate at the time of delivery by the application of forceps. The superficial peripheral branches are particularly vulnerable to injury. Studies suggest that approximately 7% to 10% of temporal bone fractures result in facial nerve dysfunction. Trauma to the temporal bone may result in both an initial direct injury to the nerve followed by a secondary ischemic injury, as edema causes increased pressure in the fallopian canal containing the nerve. Decompressive surgery may be necessary to prevent progression of injury and should be undertaken as early as possible. Likewise, penetrating injuries most often result in nerve transection and early surgical exploration is desirable. Surgical approach is dependent on the location of the injury.

Cranial Nerve IX: The Glossopharyngeal Nerve

Trauma to cranial nerves IX, X, XI, and XII is most often iatrogenic. The glossopharyngeal nerve carries both sensory and motor fibers. The sensory fibers transmit information from the upper part of the pharynx and taste from the posterior one-third of the tongue. The motor component innervates the constrictor muscles of the pharynx and the stylopharyngeus as well as secretory glands in the pharyngeal mucosa. Traumatic injury to the nerve occurs most commonly with fractures through the jugular foramen where it exits the skull together with the vagus and accessory nerves. Lesions resulting from trauma are rarely isolated and occur most commonly with injuries of the X and XI cranial nerves. Clinically, glossopharyngeal dysfunction presents with diminished taste in the posterior one-third of the tongue and loss of gag reflex on the side of the lesion. The presence of dysphagia or dysarthria may signal concomitant injury to the vagus nerve, as these symptoms are rarely present in isolated glossopharyngeal injuries.

Cranial Nerve X: The Vagus Nerve

The vagus nerve provides motor, sensory, and autonomic innervation to a wide variety of targets. Motor fibers originating in the nucleus ambiguus in the brain stem innervate the somatic muscles of the pharynx and larynx, which coordinate the initial phase of swallowing. Autonomic fibers from the dorsal motor nucleus provide innervation to the heart, lungs, esophagus, and stomach. Sensory fibers from the upper gastrointestinal tract and oropharynx travel within the vagus nerve to the spinal nucleus, and sensation from the thoracic and abdominal organs is transmitted to the tractus solitarius. Dysarthria and dysphagia may occur with injury, and the palate on the affected side will be low at rest. Deviation of the uvula toward the unaffected side with phonation may be observed as the unopposed contralateral muscles contract.

Individual branches of the vagus nerve may be injured during surgical intervention on the head and neck. Careful physical examination aids injury localization, as clinical presentation varies with site of lesion. Injury to the

pharyngeal branches of the vagus nerve will present with dysphagia, which may be mild or severe. The superior laryngeal nerve, which carries sensory fibers from the larynx and provides motor innervation to the cricothyroid muscle, will present with anesthesia of the larynx and paralysis of the cricothyroid muscle. Injury to the recurrent laryngeal nerve leads to vocal cord paralysis, resulting in hoarseness and dysphonia. The voice may sound breathy or harsh during speech production. Bilateral injury results in complete vocal cord paralysis, which can be distinguished by the presence of dyspnea, inspiratory stridor, and an inability to phonate, *aphonia*. Lesions of the pharyngeal and superior laryngeal nerves may also produce vocal abnormalities, resulting in a voice that is weak and easily fatigable.

Cranial Nerve XI: The Spinal Accessory Nerve

The spinal accessory nerve, unlike the other cranial nerves, originates from the C2, C3, and C4 in the upper cervical spinal cord. It enters the skull through the foramen magnum and then travels back out through the jugular foramen with cranial nerves IX and X. Like the glossopharyngeal and vagus nerves, the spinal accessory nerve may be damaged by trauma that results in fracture through the jugular foramen. Iatrogenic injury has also been observed during lymph node biopsy, internal jugular central venous line placement, and carotid endarterectomy. In these instances, injury generally occurs extracranially as the nerve passes through the posterior triangle in the neck.

The spinal accessory nerve carries motor fibers to the sternocleidomastoid muscle and the upper portion of the trapezius. Lesions of this nerve result in atrophy of the upper trapezius, inability to shrug the affected shoulder, and impairment in rotation of head to the contralateral side. Winging of the scapula at rest, which is worsened by abduction, may be present. The scapular winging that results from upper trapezius weakness may be distinguished from that associated with long thoracic nerve injury and anterior serratus weakness by the position of the scapula at rest. When the anterior serratus is affected, winging will be minimal at rest and increase with shoulder flexion.

Cranial Nerve XII: The Hypoglossal Nerve

The hypoglossal nerve originates from the medulla and exits the skull through the hypoglossal foramen in the posterior fossa. It carries motor fibers to the muscles of the tongue and is particularly important for articulation. Injury to this nerve produces dysarthria and atrophy with deviation of the tongue on protrusion toward the side of the lesion due to the action of the unopposed contralateral muscles. Trauma to the hypoglossal nerve has been reported with many surgical interventions including carotid endarterectomy, endotracheal intubation, and supraglottic airway device usage. Cranial nerve XII compression during head turning has also been observed to result from medially oriented, elongated, styloid processes with associated ossification of the stylohyoid ligament. During acute head trauma, hypoglossal nerve injury may

P.395

be associated with fracture of the occipital condyle. Presence of a 12th nerve palsy after trauma should prompt a magnetic resonance imaging (MRI) of the cervical spine to assess spinal stability. Urgent decompression may be necessary to prevent irreversible injury to the spinal cord.

UPPER EXTREMITY NERVE LESIONS

The peripheral nerves of the upper extremity are vulnerable to traumatic injury by compression and stretch, lacerating and penetrating wounds, fracture and dislocation of nearby bones and joints, and ischemic and iatrogenic insults of various etiologies. Trauma, resulting in injury, may be either acute or chronic. Carpal tunnel syndrome and cubital tunnel syndrome are two examples of chronic entrapment syndromes, in which the application of chronic traumatic compressive forces result in impaired nerve function. These and other common entrapment syndromes will be discussed in detail in subsequent chapters. This section will focus on common

acute upper extremity traumatic peripheral nerve injuries and their mechanisms.

Brachial Plexus Injuries

Injury to the brachial plexus, which supplies much of the motor, sensory, and vasomotor innervation of the upper limb and shoulder, can be severely disabling, particularly as traumatic injury to the brachial plexus tends to occur most frequently within the productive age groups. Recovery is often incomplete, resulting in lasting disability, which may negatively affect quality of life. The superficial location, large size, and position between two highly mobile structures (the neck and the arm) make the brachial plexus vulnerable to traumatic injury. Although brachial plexopathies will be discussed in greater detail elsewhere in this book, it is important for the clinician to be aware of common traumatic mechanisms and presentations of brachial plexus injury.

The brachial plexus, which travels from the spinal cord to the axilla, is derived from the nerve roots of C5-T1. It is progressively divided into five roots, three trunks (upper, middle, lower), six divisions (three anterior, three posterior), three cords (lateral, posterior, and medial), and several terminal branches which provide motor, sensory, and sympathetic innervation to the upper limb. C5 and C6 contain the largest number of motor fibers, whereas C7 and T1 contain the least. C7 contains the largest amount of sensory fibers followed in descending order by C6, C8, T1, and C5. These relative sensory and motor distributions have implications for both injury presentation and chance of spontaneous functional recovery, as nerves with greater proportion of either sensory or motor fibers have a greater likelihood of having regenerating axons make appropriate end-organ connections, as compared to mixed nerves.

Injury to the plexus occurs commonly with stretch from extreme positioning associated with falls, direct lacerating or penetrating trauma, dislocation of the shoulder, traction during birth, and stretch or compression during surgical positioning. Injury may be classified as *supraclavicular* (affecting roots and trunks), *retroclavicular* (divisions), or *infraclavicular* (trunks and terminal nerves) with deficit pattern reflecting the site of injury. Supraclavicular lesions result in motor and sensory loss in myotomal and dermatomal distributions associated with the affected roots, whereas infraclavicular injuries tend to have deficits limited to the territories of the terminal branches. Infraclavicular injuries are more commonly seen with penetrating injuries, whereas high-velocity injuries, as occur with motor vehicle accidents, are more likely to result in closed traction supraclavicular injury patterns.

Additionally, injuries may be classified as *upper* (C5-C6), *lower* (C8-T1), or *panplexal* (C5-T1) with implications for both presentation and prognosis. The presence of Horner syndrome or involvement of proximal branches such as the dorsal scapular, which provides motor innervation to the rhomboids, or latissimus dorsi dysfunction due to long thoracic nerve injury, indicates a proximal injury and carries a poorer prognosis. Dysautonomic features such as vasomotor abnormalities or skin changes may be observed in the affected limb. Severe pain in an anesthetic limb may be suggestive of root avulsion, in which the nerve roots are torn from their attachment to the spinal cord by the force of the injury. Avulsion generally requires a different surgical approach than more distal nerve injuries and may carry a worse prognosis. In acute trauma, the position of the arm at time of impact, as well as the associated injuries, may provide clues to the clinician about possible plexus injuries.

The upper plexus is the most common site of injury. Injury to this region results from closed traction, which occurs when the shoulder is forcibly separated from the head. This injury pattern is common in contact sports, as well as postoperatively as a result of prolonged positioning with contralateral rotation of the head or upper extremity abduction greater than 90 degrees. It may also result from the application of excessive traction to the plexus during delivery and is referred to as *Erb palsy* (C5-C6) or *Erb palsy plus* (C5-C7), depending on the roots involved. Weakness or paralysis of the deltoid, biceps, brachioradialis, pectoralis major, supraspinatus, infraspinatus, subscapularis, and teres major results in the classic “waiter’s tip” position, with internal rotation of the arm, extension and pronation of the forearm, and flexion of the wrists and fingers. The biceps reflex is absent

and sensory loss incomplete, with hypesthesia on the outer surface of the arm and forearm. Contracture may result if passive range-of-motion exercises are not undertaken early. Prognosis for upper plexus injuries associated with birth trauma is generally very good, with 90% chance of spontaneous recovery reported most often in the literature, although controversy remains regarding the optimal timing of surgical intervention in these patients. Generally, the watchful waiting period of 3 to 6 months in adults with closed nerve injuries is extended to 9 months in children.

Traumatic lower plexopathies, affecting C8-T1 nerve roots, are less common than upper plexus injuries but have been associated with thoracic surgery requiring median sternotomy, cervical rib and band syndrome, obstetrical trauma, and the presence of a Pancoast tumor by compression or direct tumor invasion. The resulting syndrome is referred to as *Klumpke palsy*. It presents with isolated hand paralysis and ipsilateral Horner syndrome. This clinical presentation mimics that of a combined median and ulnar lesion. Sensory loss is observed on the medial arm and forearm and the ulnar side of the hand. Atrophy of the intrinsic hand muscles occurs and the triceps reflex is lost. The anatomic particularities of the C8 and T1 nerve roots make the lower plexus more susceptible to avulsion than the upper and middle plexus. The greater vulnerability to avulsion results in a poorer prognosis for lower plexus injuries.

Isolated middle plexus injury, affecting nerve root C7 or the middle trunk, is the least common form of traumatic brachial plexopathy. These lesions cause paralysis in a primarily radial distribution with sparing of the brachioradialis. Due to extensive dual innervation, sensory loss is minimal and may be limited hypesthesia over the dorsal surface of the hand and forearm.

A complete lesion of the brachial plexus results in a flail arm with or without ipsilateral Horner syndrome. Complete plexus injuries carry the worst prognosis and extensive surgical intervention,

P.396

including amputation, may be required to restore function and alleviate pain.

Proximal Nerve Injuries

The *long thoracic nerve* is a purely motor nerve that arises from the ventral rami of C5-C7. It provides motor innervation to the serratus anterior muscle which stabilizes, protracts, and upwardly rotates the scapula to abduct the arm over the head. Weakness or paralysis of this nerve results in winging of the scapula, which is particularly notable during abduction and forward flexion. Very little winging is observed at rest, which distinguishes long thoracic palsy from injury to the spinal accessory nerve. Abduction between 90 and 180 degrees may be limited.

Injury to this nerve is usually isolated and may result from blunt trauma to the thorax or forceful depression of the shoulder girdle, as may occur during a fall. It commonly occurs during participation in contact sports. Iatrogenic injury has been associated with first rib resection and radical mastectomy. Long thoracic nerve palsy may also result from carrying heavy loads on the shoulder. Fortunately, as most injuries to the long thoracic nerve are neurapraxic, spontaneous recovery is expected and prognosis is good.

The *suprascapular nerve* branches from the upper trunk and is derived of fibers mostly from C5. It provides motor innervation to the supraspinatus and the infraspinatus muscles, as well as sensory and sympathetic innervation to two-thirds of the shoulder capsule, the glenohumeral, and the acromioclavicular joints. Weakness of the supraspinatus muscle results in difficulty in initiating shoulder abduction, particularly through the first 15 to 30 degrees, after which the deltoid takes over. The infraspinatus externally rotates the shoulder, and weakness may be observed with external rotation as a result of suprascapular nerve injury. Isolated injury is rare with shoulder trauma, although chronic trauma from entrapment by the suprascapular ligament has been reported. Compression by tumors and ganglion cysts may also occur.

Median Nerve

The median nerve derives from the C6-T1 nerve roots. In the forearm, it provides motor innervation to the pronator teres, the flexor carpi radialis, palmaris longus, and flexor digitorum superficialis muscles before branching into the purely motor anterior interosseous nerve and the main branch. The main branch passes through the carpal tunnel and then gives off the recurrent thenar nerve to provide innervation to the abductor and lateral flexor pollicis brevis and the opponens brevis. It terminates in the palm where it supplies innervation to lumbricals I and II. The median nerve is therefore involved with pronation of the forearm, wrist flexion, thumb, index and middle finger flexion, and opposition of the thumb.

Additionally, the median nerve provides sensation to the radial palm, ventral thumb, index, middle fingers, and the radial half of the ring finger. The dorsal surfaces of the distal phalanx of the thumb and the terminal phalanges of the index and middle fingers are also supplied by the median nerve.

Injury to the median nerve may occur at multiple points along its course as a result of trauma. Median nerve palsy has been associated with stabbing injuries to the brachial plexus, crush injury from prolonged crutch or tourniquet usage, fracture of the distal humerus, anterior shoulder dislocation, and Colles fracture of the wrist, although chronic trauma due to entrapment is the most common median nerve injury observed clinically. The nerve may become entrapped within the carpal tunnel or between the heads of the pronator teres in the forearm. Chronic entrapment within the carpal tunnel results in pain and sensory loss in the distal median distribution with wasting and weakness of the thenar muscles and lumbricals I and II. Direct traumatic injury to the median nerve has also been reported secondary to poorly placed steroid injections for treatment of carpal tunnel syndrome. Histologic examination in several cases revealed the presence of white crystals with the median nerve sheath suggesting that aberrant injection directly into the nerve was the likely mechanism of injury. Carpal tunnel syndrome is discussed more thoroughly in subsequent chapters.

Radial Nerve

The radial nerve arises from the posterior cord and contains elements from C5-T1 nerve roots. It is composed of primarily motor fibers and provides innervation to the wrist, forearm, and finger extensors. It passes through the axilla to supply the triceps and then winds around the posterior humerus, descending in the spiral groove. The nerve innervates the brachioradialis and extensor carpi radialis longus muscles before branching into the superficial radial nerve, which carries sensory information from the dorsoradial aspect of the distal forearm and the dorsal surface of the hand and the posterior interosseous nerve, which supplies motor innervation to the remaining forearm, wrist, and finger extensors as well as the supinator.
