Because we are dealing with practice in industrial engineering, it is important first to make the distinction between science and decision making (see Healy 1978). The statistical requirements for establishing scientific truth are much more stringent than for decision making. The manager cannot wait for the discovery of ultimate truth but must decide today. Ordinarily, the industrial engineer operates in support of that process and will serve the manager best if the decision process is supported in a timely manner. This is not to suggest carelessness or disregard for theory. It is to suggest recognition of the basic fact that the manager will make the decision with or without the potential help. A responsibly derived, yet imperfect, model can be very much better than no model at all.

Very broadly, the various goals can be put into five categories. These represent a natural evolutionary sequence of four steps, any one of which may be the intended end use.

1. *Exploration:* fishing, hypothesis finding (see Finch 1979)
2. *Specification:* hypothesis testing, confirmation of the model form (rarely an end use)
3. *Estimation:* estimating model parameters with sufficient precision (estimating future events is referred to in this chapter as ''prediction'')
4. *Prediction:* use of the model for anticipation or for ''inverse estimation'' (calibration)
5. *Control:* use of the model to prescribe change or to direct or guide policy or the behavior of a system

*A known underlying causal relationship is not a requirement for useful statistical modeling.

TABLE 1 Simple Classification of Regression Models

Class	Kind	Basis
Associative	Concomitant, precursory	Observation
Physical	Empirical	
	Causal, mechanistic	Theory

1.4. Kinds of Models

Kinds of models seem to lie more along a continuum and are therefore less easily classified. The main continuum is closeness to causality. The scale slides from loose empiricism to exact causal representation (mechanism). How far along the scale the analyst moves may depend on either the maturity of the corresponding physical discipline or the needs imposed by the goals.

There is another subset where causality is not an issue. These models might be called ''associative.'' Here the response and the predictors may both be ''caused'' by some outside force. They behave concomitantly. An example is the use of leading indicators in economic models. Another example is the precursory use of animal characteristics or behavior to predict the severity of the winter. Presumably no one would claim that the extra hair on the woolly bear caterpillar causes snow to fall (causation might be suspected in the other direction in such cases if it were not for our belief that cause must precede in time its effect).

This simple classification scheme thus takes the form shown in Table 1.

1.5. Appropriate Use of Statistics

Statistical measures and diagnostics can and do serve an essential role in regression modeling, but they must be used appropriately. Their use must be related to goals. In general, any adequate MLR computer program system will list many statistics that may not be relevant in any given situation. For example, the multiple correlation coefficient, R, is universally printed. It may be of no interest. Further, even if it is of interest, its value must be judged in the context of the problem. It depends on the question. The analyst must know what questions need to be answered and must use relevant statistical measures accordingly.

1.6. Role of Assumptions

Assumptions are, in most regression articles and texts, listed as a sort of litany to precede the analysis as if they universally apply. Moreover, they are treated as if they describe the problem setting. They are really descriptions of the mathematical model whose behavioral properties are known and that is to be used as an analog to the system under study. Assumptions (model characteristics) relate to goals just as statistics do. Those that are relevant are rarely ever exactly met by the problem system. The severity of trouble the analyst may expect because of the remaining differences (''violations of assumptions'') is a matter for judgment and experience and cannot be removed from the problem context.

Table 2 offers a skeleton relationship of assumptions to goals in a hierarchical order (for a more complete discussion, see Eisenhart 1947). Random residual variation in Y is associated with a host of small, unimportant (in context) contributions. Notice that the usual assumptions of homoscedasticity and normality are not imposed for specification and estimation. The least-squares estimates of the regression coefficients provided by MLR are the most efficient, unbiased linear estimates among all linear estimates for uniform error variance and are still unbiased for nonuniform error variance. The central limit theorem will give very good protection—just as with ordinary averaging—allowing

TABLE 2 Cumulative Relationships of Assumptions to Goals

Goals	Desirable Data Characteristics	Model and Process Characteristics
Exploration	Random Y for given X	Least-squares fitting
Specification	''Complete'' X set	''Correct'' model form
Estimation	Spread, balanced X's	b's normal by central limit theorem
Prediction and Control	Typical X space	Specified error distribution

the normal model to be used with nonnormal data for establishing confidence intervals. Stated characteristics are cumulative descending the table.

2. RELATING TWO VARIABLES

The actual use of the simple (single-predictor) model is rare (real systems are rarely that simple.) However, for examining the principles involved in regression modeling, the simple model serves well.

For illustration, hypothetical data representing steam consumption (Y) for a particular building are modeled here. This response variable was chosen because (1) energy use has universal relevance and global importance, (2) such a wide variety of goals can be authentically represented in an energy system, and (3) this same problem setting can be expanded in following sections to represent more complex modeling ventures. The structure under study might be an office complex, a factory, a warehouse, a hospital, a hotel, or even a home. For demonstration, only 20 observations are contained in the sample. Each observation represents a four-week period. Weekly data would be preferred in most cases, but to cover extremes of weather in only 20 data points, four-week periods were chosen. The goal is to establish control of steam consumption for this building. ''Excessive'' use is now dismissed as being weather related.

At first it is assumed that comfort heating in this building is the major use of steam. Its use (measured in giga-British thermal units, gBtu), should be reasonably well related to degree-days (X). This is measured relative to 65°F (degree-days F/1.8 = degree-days C) and is also reported here on a per-period basis. The 20 observations are shown in Table 3, with the periods numbered within year from 1 to 13 and years numbered 1, 2, and 3. The method of least squares will be employed to relate steam use to degree-days.

Table 3 also shows the fitted values, called *YHAT,* and the residual fitting errors, called *Y-YHAT*. The names and their symbolic forms are discussed following Eq. (3). Diagnostic attention will be given later to the values in these two columns.

2.1. Least-Squares Method

In MLR, understanding variation is the basis for problem solving. Variation in the response is made up (theoretically) of two parts:

TABLE 3 Hypothetical Data for Modeling Steam Consumption

i	Period Number	X (k degree-days)[a]	Y (gBtu)[b]	Fitted *YHAT* (gBtu)	Residual *Y-YHAT* (gBtu)
1	10-1	0.156	7.991	6.990	1.001
2	11-1	0.419	8.589	8.095	0.494
3	12-1	0.658	9.145	9.100	0.045
4	13-1	1.009	11.212	10.575	0.637
5	1-2	1.380	11.754	12.134	−0.380
6	2-2	1.103	11.469	10.970	0.499
7	3-2	1.000	10.584	10.537	0.047
8	4-2	0.703	9.509	9.289	0.220
9	5-2	0.207	7.457	7.204	0.253
10	6-2	0.086	6.989	6.696	0.293
11	7-2	0.024	6.537	6.435	0.102
12	8-2	0.005	4.938	6.355	−1.417
13	9-2	0.026	5.275	6.444	−1.169
14	10-2	0.161	7.452	7.011	0.441
15	11-2	0.307	7.962	7.625	0.337
16	12-2	0.664	8.915	9.125	−0.210
17	13-2	1.039	9.758	10.701	−0.943
18	1-3	1.275	11.183	11.693	−0.510
19	2-3	1.193	11.523	11.348	0.175
20	3-3	0.953	10.426	10.340	0.086

$n = 20$; $\Sigma X_i = 12.369$; $\Sigma Y_i = 178.67$
$\Sigma X_i^2 = 11.915$; $\Sigma Y_i^2 = 1678.7$; $\Sigma X_i Y_i = 128.42$

[a] k degree-days = 10^3 degree-days.
[b] gBtu = giga-British thermal units = 10^9 Btu.

1. The systematic variation (signal), which is associated with or is in response to changes in the predictors
2. Leftover variation (noise), which is called "residual error" or "experimental error."

The distinction is really not so sharp. The leftover error is actually associated with a great many things that, in practice, might be measured (and included in the model) if analysts had sufficient time, wisdom, patience, and money. They simply choose not to try to identify all sources of variation. They will discontinue the search when there seems to be no regular pattern of errors left over and when either all the reasonable predictors have been adequately tested or the residual error variance is small enough—again depending on goals. In terms of the true coefficients and residual error of the theoretical model, the observed response variable may be expressed as

$$Y_i = \sum_{j=0}^{P} \beta_j X_{ij} + \varepsilon_i \tag{2}$$

where ε_i is the "residual error" associated with Y and (theoretically) has variance σ_ε^2. The fitted model containing the estimates of the β_j's, then, is

$$\hat{Y}_i = \sum_{j} b_j X_{ij} \tag{3}$$

where the circumflex or "hat" on Y denotes the predicted or estimated value of the response. It is like an average (where a "bar" is used). In fact, it is the conditional average, given the location in the space defined by the X_{ij}'s. It is an estimate of the expected or true value of the response for that location or set of conditions.*

The differences between the observed and fitted values of Y are the residual errors or, simply, "residuals,"

$$e_i = Y_i - \hat{Y}_i = \hat{\varepsilon}_i \tag{4}$$

where e_i is an estimate of the "true error" ε_i. In practice, e_i may contain anything the analyst chooses to omit from the model. It has sample variance

$$s_{Y\cdot X}^2 = s_e^2 = \frac{\sum_{i=1}^{n} (Y_i - \hat{Y}_i)^2}{n - P - 1} = \frac{\sum_{i=1}^{n} e_i^2}{n - P - 1} = \hat{\sigma}_\varepsilon^2 \tag{5}$$

which, for the theoretical case, is an estimate of the "experimental" error variance. The subscript $Y \cdot X$ ("Y dot X") means "for Y, given the model containing a particular set of X's." Thus $s_{Y\cdot X}^2$ is the sample estimate of the residual variance in Y, given the model.

The least-squares method chooses values for the b_j's of Eq. (3), which are unbiased estimates of the β_j's of Eq. (2). The least-squares estimates are universally minimum variance unbiased estimates for normally distributed residual errors and are minimum variance among all linear estimates (linear combinations of the observed Y's), regardless of the residual error distribution shape (see Eisenhart 1964). The b_j's (as well as the $\hat{Y}_i$'s) are linear combinations of the observed Y_i's. The least-squares method determines the weight given to each Y value. The derivations of the least-squares solution and/or associated equations used later in this chapter are shown in other sources (see Additional Reading). In essence, the b_j's are chosen to minimize the numerator of Eq. (5)—the sum of squares of e_i's of Eq. (4)—hence "least squares."

In returning to the example problem, a geometric interpretation is presented first. Figure 1 is a plot of steam consumption vs. degree-days from Table 3. The regression coefficient, b_1 is represented by the slope of the least-squares line. It is the tangent of the angle θ. The e_i's whose squares are to be summed to a minimum are distances measured in the Y direction from the points to the line. They are illustrated by typical distances, e_4 and e_{17}.

The least-squares solutions for the simple model are

*It is important to realize that, although the model may be used for predicting future $\hat{Y}$ values, Y does not predict their individual behavior but estimates the conditional average about which those individuals are expected to vary.

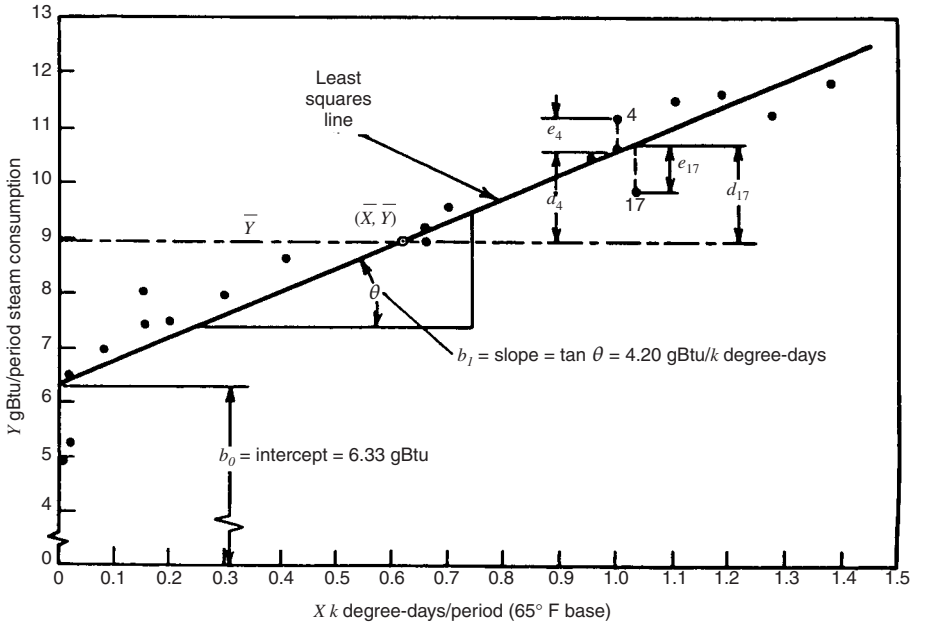

Figure 1 Relationship of Steam Use to Degree Days.

$$b_1 = \frac{\text{SPXY}}{\text{SSX}} \quad b_0 = \overline{Y} - b_1 \overline{X} \tag{6}$$

where SPXY = the (corrected) sum of products of the XY pairs
SSX = the (corrected) sum of squares of X's
$\overline{Y}$ and $\overline{X}$ = the arithmetic averages (which are also least-squares estimators) of the two variables

These averages and sums (with all sums taken for $i = 1$ to n) are

$$\begin{aligned} \overline{X} &= \sum X_i/n & \overline{Y} &= \sum Y_i/n \\ \text{SPXY}^* &= \sum (X_i - \overline{X})(Y_i - \overline{Y}) &&= \sum X_i Y_i - n\overline{XY} \\ \text{SSX} &= \sum (X_i - \overline{X})^2 &&= \sum X_i^2 - n\overline{X}^2 \end{aligned} \tag{7}$$

Equations (6) and (7) yield the following values for the example:

$$\begin{aligned} \overline{X} &= 12.369/20 = 0.618 & \overline{Y} &= 178.67/20 &&= 8.93 \\ \text{SPXY} &= 128.42 - 20(0.618)(8.93) &&&&= 17.93 \\ \text{SSX} &= 11.915 - 20(0.618)^2 &&&&= 4.23 \\ b_1 &= 17.93/4.27 = 4.20 & b_0 &= 8.93 - 4.20(0.618) &&= 6.33 \end{aligned}$$

Equation 3 then takes the form $\hat{Y}_i = 6.33 + 4.20X_i$.

2.2. Residual Variance

For $P = 1$, Eq. (5) reduces to $s^2_{Y \cdot X} = \text{SSRes}/(n - 1)$, where SSRes is the residual sum of squares given by

*These are not shown in the computationally easiest form. This form demonstrates meaning.

$$\text{SSRes} = \text{SSY} - \text{SSReg} \tag{8}$$

and where SSY is the (corrected) sum of squares of Y's and SSReg is the regression sum of squares. In Eq. 8, SSY is exactly parallel in form to SSX in Eq. (7), and when divided by its $n - 1$ DOF, it yields the Y mean square, which might be used to estimate the variance of Y. Regardless of the appropriateness of such an interpretation, the expression $\text{SSY}/(n - 1)$ is a measure of the raw variability in the response whose explanation is the goal. The contribution to SSY that is associated with X is SSReg. This is given by

$$\text{SSReg} = b_1\text{SPXY} \tag{9}$$

and is the sum of squared distances from $\overline{Y}$ to the regression line as shown by typical distances d_4 and d_{17} in Figure 1. For this example,

$$\text{SSY} = 82.55 \qquad s_Y = \left(\frac{\text{SSY}}{19}\right)^{1/2} = 2.08$$

$$\text{SSReg} = (4.20)(17.93) = 75.38$$

$$\text{SSRes} = 82.55 - 75.38 = 7.17$$

$$s_{Y\cdot X} = \left(\frac{\text{SSRes}}{18}\right)^{1/2} = 0.631$$

It can be seen that $s_{Y\cdot X}$ is only 30% of s_Y. That is, the regression equation provided a 70% reduction in variation in Y. Another way to evaluate this residual standard deviation or residual standard error is to compare it to the mean of Y. In this case it is $100\ (0.631/8.93) = 7.0\%$ of the mean and, depending on the goal, might represent a satisfactory reduction in variability. Still another way to measure the association between Y and X, and hence the residual lack of association, is to use the correlation coefficient that is developed next.

2.3. Correlation

The theoretical concept of correlation arises in conjunction with the bivariate normal distribution function. That function has five parameters. If the two variables are X and Y, the parameters are the means (μ_x, μ_y) and the variances (σ_x^2, σ_y^2) of each variate and a measure of covariation, the correlation coefficient, ρ (rho). This chapter does not deal with the theoretical bivariate (or multivariate) normal distribution. However, in practice, the sample correlation coefficient, r, is a useful measure of linear association. It is a dimensionless ratio ranging from -1.0 (perfect inverse linear agreement) through zero (orthogonal or linearly unrelated) to $+1.0$ (perfect direct linear agreement). The value can be obtained from Eq. (10) and used as an index without any assertion whatever being made about distribution form.

$$r_{XY} = \frac{\text{SPXY}}{[(\text{SSX})(\text{SSY})]^{1/2}} = \frac{s_{XY}}{s_X s_Y} \tag{10}$$

The first form of the expression for r_{XY} has the same numerator as b_1 in Eq. (6), which shows that it is just a rescaling of the same basic information. It is easily shown that $r_{XY} = b_1\, s_X/s_Y$.* In the second form in Eq. 10, s_{XY} is the sample covariance (not standard deviation). It has the same sign as SPXY and r and is $\text{SPXY}/(n - 1)$.

The square of r is called the coefficient of determination. It ranges from 0 to 1 and can be interpreted as the fraction of the variation in Y (with variation represented by SSY) that is accounted for or "explained" by variation in X. Thus and from Eq. (8):

$$r_{XY}^2 = \frac{\text{SSReg}}{\text{SSY}} = 1 - \frac{\text{SSRes}}{\text{SSY}} \tag{11}$$

Using Eq. (10) for the example data, $r_{XY} = 17.93/[(4.27)(82.55)]^{1/2} = 0.955$; $r_{XY}^2 = 0.912$. This is seen to be equal to the result of Eq. 11, where $r_{XY}^2 = 75.38/82.55 = 0.913$ (slight rounding error).

*The subscript order "XY" on r is arbitrary; $r_{XY} = r_{YX}$. But the ratio s_X/s_Y implies that b_1 is for "Y on X." With s_Y/s_{XY} b_1 would be "X on Y," with minimization of squared errors taken in the X direction, a different line except where $r = 1.0$.

So variation in X has accounted for 91% of SSY. This is approximately the same as claiming 91% reduction in the variance of Y (from s_Y^2 to $s_{Y\cdot X}^2$).

2.4. Model Specification

In other circumstances, where the physics and chemistry are not so well understood (e.g., in studying the ''cause'' of a disease), the question may focus on the statistical significance of the relationship. The analyst is attempting to decide whether the relationship seen in the sample is something real or just the result of chance association. This decision is appropriate along all goal sequences except where existing theory permits prior specification* of the model.

Model specification is the process of choosing an adequate representation of reality. To decide this question of reality, the analyst would want a test model for the behavior of the estimator, b_j, when the association is just chance. One way would be to use the t test model with the null hypothesis that $\beta_j = 0$ (or some other appropriate value). The alternative hypothesis might be $\beta_j > 0$. The t distribution is appropriate by the central limit theorem. Then

$$t_j = \frac{b_j}{s_{bj}} \tag{12}$$

with the critical value for t of $t_{n-2,\alpha}$, where α represents the specified degree of risk of rejecting a true null hypothesis (claiming a nonexistent association). The standard errors for b_0 and b_1 are given by

$$s_{b_0} = s_{Y\cdot X}\left(\frac{\Sigma X_i^2}{n\mathrm{SSX}}\right)^{1/2} \tag{13}$$

$$s_{b_1} = \frac{s_{Y\cdot X}}{(\mathrm{SSX})^{1/2}} \tag{14}$$

For the example data, $s_{b_0} = 0.236$ and $s_{b_1}, = 0.306$. The corresponding t ratios are $t_0 = 26.9$ and $t_1 = 13.8$, indicating, as was ''known'' in advance, that both constants are statistically well removed from zero (highly ''significant'' compared to a critical value of $t_{18,0.05} = 2.10$). This information is put to more appropriate use later in this section. Statgraphics (a statistical software package) output for this analysis is shown in Figure 2. An intermediate precaution should concern the analyst, that of model validation.

2.5. Model Validation

The least-squares method has permitted each of the data points to play a role in determining the constants b_0 and b_1. It is entirely possible (and nearly always true) that some observations in the data set contain errors (mistakes) in one or more of the variables or arise from unusual conditions that the model is not intended to represent. The ''back substitution'' (obtaining $Y_i - \hat{Y}_i$, values for the development data set, as shown in Table 3) may reveal suspicious points. Generally, residual errors in excess of $\pm 2s_{Y\cdot X}$ should be viewed with mild suspicion, although about 1 in 20 is expected to be in these regions. More sensitive measures will be developed in Section 5. There is an extensive literature associated with this problem of dealing with ''outliers''. One discussion that might serve as a starting point is Barnett (1978).

Perhaps the most useful graphic for examining residuals is a plot of *Y-YHAT* vs. *YHAT*. That will be illustrated later for the multiple regression model. In the simple case, one need not bother. Such a plot is equivalent to tipping Figure 1 so that the regression line is horizontal. No sophisticated techniques are required to see that the fit is poor. Ten of the first 11 points lie above the line. It may be tempting to suggest, say, a quadratic in X to achieve a better fit. However, there is no theoretical reason to expect curvature in the relationship. More properly, additional predictors might be sought, as will be shown presently. The development for the simple case is continued later, ignoring the lack of fit.

One possibility for testing the model's stability is to validate it on fresh data, that is, by back-substituting data points that were not used in developing the model.

This method of validation is called external validation. A method known as internal validation (which is arguably far superior) will be presented in Section 5.

*The distinction between specification and estimation is rarely made. See Hunter and Box (1965) for further discussion. Also see Healy (1978) regarding significance testing.

2.6. Coefficient Estimation

Suppose the model has been specified from existing theory, or by exploration, testing, and validation, and is judged adequate. Back-substitution residual errors are well behaved. Now, whether the values of the b_j's themselves are of interest or whether they are simply to be used in the equation for predicting future values of Y, the precision with which they estimate the β_j's is of concern.* Point estimates were obtained from Eq. (6), but coefficient estimation is not complete without obtaining interval estimates. It is not sufficient, where estimation is the goal (or a step on the path to the goal), just to have "significant" t ratios.

Use of the confidence interval (CI) concept helps to contrast these two steps, specification and estimation. With $\alpha = 0.05$ risk that the CI will not contain β as is claimed, the interval is

$$100(1 - \alpha)\ \text{CI} = 95\%\ \text{CI} = b_j \pm t_{n-2,0.05}\, s_{bj} \tag{15}$$

Notice that (with prescribed t) ts_b represents the maximum probable error associated with the estimate of β. This can be expressed as a percentage error (where engineers very often seek estimates that are within 5 or 10%). Using b as the base (in the absence of knowing β), let E represent the potential percentage error associated with a t value of 2, an approximate value that is never more than 2% in error for $df \geq 30$. (For $df < 30$, substitution of the correct value is advised.) Then

$$E = \frac{100ts_b}{b} = \frac{200s_b}{b} \tag{16}$$

But notice that s_b/b is just the inverse of the t ratio calculated from the sample using Eq. (12).

$$E = \frac{200}{t} \tag{17}$$

This implies the need for calculated t values of 20 or even 40 to meet our common expectation of a 10 or 5%, respectively, error of estimation!

*In general, the requirements for precision will be greatest for control, least for prediction (see Section 3.1.2).

From Eqs. (14) and (16) it can be seen that the error in estimating the slope is directly proportional to $s_{Y\cdot X}$ and inversely proportional to $(\mathrm{SSX})^{1/2}$. Thus, to achieve a prescribed value of E, either of two things must be done: (1) an improved (less noisy) model must be found to reduce residual error, or (2) a larger sample must be obtained to increase SSX (see Crocker 1985 for a more complete discussion of this issue). In general, precision will improve approximately as the square root of n.

2.7. Interval Estimation for a Point on the Line

The regression equation can be used to estimate the "true" value of the response for some specified value of the predictor. This is estimating a conditional population mean of Y and is analogous to estimating (unconditionally) the population mean in a univariate setting. The CI for this case is

$$100(1-\alpha)\ \mathrm{CI} = \hat{Y}_c \pm t_{n-2,\alpha}\, s_{\hat{Y}c}$$
$$s_{\hat{Y}c} = s_{Y\cdot X}\left[\frac{1}{n} + \frac{(X_c - \overline{X})^2}{\mathrm{SSX}}\right]^{1/2} \tag{18}$$

where the subscript c denotes the condition, the location in X, at which the estimate is to be made. Notice that the square root of n (again) determines the interval width at the mean of X and that the interval grows wider the greater distance X_c is from $\overline{X}$, the sample mean.

In most texts this CI is presented as a pair of curved lines, implying a confidence band for the entire line. Equation (18) is meant to be used for one specified location. To sustain α as the risk of not containing the true value, the entire procedure of selecting n observations, computing the coefficients, and so on would need to be followed for each X_c. Wider limits would be needed if the analyst desired limits for the entire true line. Acton (1959) gives a good discussion of this and many related concepts.

2.8. Predicting a Future Value

For predicting a future value at X_c, $\hat{Y}_c$ is obtained from the regression equation just as in the CI. Here it is the estimate of the mean about which individual values are expected to vary. The expression for prediction limits for a single future value of Y must recognize this extra source of variation associated with individuals. The interval for prediction is here abbreviated PI and called, for example, a "95% PI" for $\alpha = 0.05$.

$$100(1-\alpha)\mathrm{PI} = \hat{Y}_c \pm t_{n-2,\alpha}\, s_{Y\cdot X}\left[1 + \frac{1}{n} + \frac{(X_c - \overline{X})^2}{\mathrm{SSX}}\right]^{1/2} \tag{19}$$

The use of t in this expression implies the additional requirement that the individuals be normally distributed around the line. If this is not the case, some other constant (possibly with asymmetry) representing the actual distribution will be substituted for t. Statgraphics output for confidence intervals and predictions limits is shown in Table 4.

Again, this process applies for a single prediction. If some fraction of all future values is to be included within the limits, the limits would be called tolerance limits. (The reader is referred again to Crocker 1985 for more detailed discussion.) Table 5 offers selected values of K_c in Eq. (20) for obtaining tolerance intervals (TI) around the line at $\overline{X}(K_1)$ and at $\overline{X} \pm 2s_X(K_2)$. Linear interpolation may be employed to obtain straight-line approximations of the curved tolerance limits. The values of K were obtained by inverse interpolation of the normal distribution for 0.95 confidence of including at least 95% of all future values.

$$0.95/95\%\ \mathrm{TI} = \hat{Y}_c \pm K_c\, s_{Y\cdot X} \tag{20}$$

3. MULTIPLE LINEAR REGRESSION

The ability of today's computers and software to handle large data sets has provided the analysts with many opportunities and dangers. Many of these dangers are associated with the intercorrelations found among the predictor variables in nonexperimental data sets. The predictor matrix is said to be ''ill conditioned'' or is carelessly referred to as ''multicollinear.'' (''Multicollinear'' really means the polar condition where some of the X's enter into linear combinations, resulting in an indeterminant system. ''Intercorrelation'' is used here to describe the general case of nonorthogonality among the predictors.)

The basic relationships and computational forms, represented in matrix notation, are shown here paralleling the equations of the simple case given earlier ($v = n - P - 1$).

(''true'' Y) $$E(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta} \tag{21}$$

(observed Y) $$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon} \tag{22}$$

(b_j's) $$\mathbf{b} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Y} \tag{23}$$

(predicted or fitted Y) $$\hat{\mathbf{Y}} = \mathbf{X}\mathbf{b} \tag{24}$$

$$\mathbf{SSRes} = \mathbf{Y}'\mathbf{Y} - \mathbf{b}'\mathbf{X}'\mathbf{Y} \tag{25}$$

$$\sum_{j=1}^{p} \mathrm{SSReg}_j = \mathbf{b}'\mathbf{X}'\mathbf{Y} = \sum_{j=1}^{P} b_j \mathbf{SPX}_j\mathbf{Y} \tag{26}$$

(variance–covariance) $$\hat{V}(\mathbf{b}) = [\mathbf{X}'\mathbf{X}]^{-1}\hat{\sigma}_\varepsilon^2 \tag{27}$$

$$s_{Y\cdot X}^2 = \hat{\sigma}_\varepsilon^2 = \frac{\mathrm{SSRes}}{n - P - 1} \tag{28}$$

(joint CI for b's) $$(\boldsymbol{\beta} - \mathbf{b})'\mathbf{X}'\mathbf{X}(\boldsymbol{\beta} - \mathbf{b}) \le (P + 1)s_{Y\cdot X}^2 F_{(p+1),v,\alpha} \tag{29}$$

(CI for $\hat{Y}$) $$100(1 - \alpha)\ \mathrm{CI} = \mathbf{X}_c'\mathbf{b} \pm t_{v,\alpha}s_{Y\cdot X}[\mathbf{X}_c'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}_c]^{1/2} \tag{30}$$

(PI) $$100(1 - \alpha)\mathrm{PI} = \mathbf{X}_c'\mathbf{b} \pm t_{v,\alpha}s_{Y\cdot X}[\mathbf{X}_c'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}_c + 1]^{1/2} \tag{31}$$

3.1. Intercorrelation Effects

In regression modeling, intercorrelation affects the process in three basic ways. These three have many secondary and corollary consequences, which will be easily perceived if the basic three are understood. They are:

1. Potentially enlarged variances of the b_j's
2. Intercorrelated estimates of the b_j's
3. Ambiguity in assessing the individual contributions to the regression sums of squares

3.1.1. Potentially Enlarged Variances

In the theoretical case—with ''correct'' model and fixed residual variance—the variances of the b_j's will grow larger as intercorrelated predictors are added to the model (see Snee 1973) as a consequence

of the inverse matrix in Eq. (27). (Notice that estimates of the variances of the b_j's are obtained because an estimate of residual error variance is used. The true theoretical variances result from using σ_ε^2). In many cases in practice also, the s_b^2's will grow larger with the addition of intercorrelated predictors. This is because the increase due to the inverse matrix will more than offset the decrease due to a smaller $s_{Y\cdot X}^2$, which results from additional regression sums of squares. However, in practice, $s_{Y\cdot X}^2$ is often reduced enough by the extra predictor(s) to offset the intercorrelation effect in the inverse matrix. These considerations are at the heart of the burgeoning variety of (predictor) variables selection schemes currently appearing in the literature. A brief discussion of this topic will provided later (see Hocking 1976).

3.1.2. Intercorrelated Estimates

In the left side of Eq. (27), in addition to the diagonal variances, there are off-diagonal covariances of pairs of b_j's. Just as with correlation between variables in Eq. (10), covariance of b_j's implies correlation of b_j's. Figure 3 depicts the joint sampling distribution for a pair of positively correlated b_j's. The distribution results from repeated samplings of n values of Y for a given X matrix. For the case of $P = 2$, the correlation of the b_j's is equal in magnitude but opposite in sign to the intercorrelation of the X_j's (they tend to be equal and opposite also for $P > 2$). Notice that the unconditional sampling range of, for example, b_2 (shown by distance A) is very large compared to the conditional range of b_2 (shown by distance B), given the particular estimate of β_1. The important consequence of these two considerations is that errors in estimating the β_j's tend to be compensating among intercorrelated predictors. So intercorrelations may adversely affect the precision of estimate of the β_j's but may have little adverse effect on the use of the model for prediction. This last conclusion depends, of course, on the intercorrelations among the predictors staying about the same in prediction as they were in the sample.

3.1.3. Ambiguity in Assessing Contributions

The underlying nature of the problem is easy to comprehend (for an introductory geometric interpretation of these phenomena, see Crocker 1967, 1969). Interpreting the specific consequences in a particular problem can be extremely complicated. This is true because the ambiguity can be of up to Pth order. The problem is further complicated by the existence of two basic classes of intercorrelated ambiguity, which, for $P \geq 3$, can simultaneously be present in all sorts of hierarchical combinations. Here, the surface will only be scratched with an illustration contrasting the two classes for $P = 2$, the least complex intercorrelation situation. (See also Sections 3.9 and 6.)

In most references, ''intercorrelated'' and ''confounded'' are regarded as synonymous. Actually, confounding is only one of the two classes just mentioned. The other has not been given a name by others but is here titled ''resolving.'' This name was chosen because the separate effects of the two or more (resolving) predictors are not ''resolved'' (clearly seen) until they appear in the model together. The contrast between confounding and resolving is shown in Table 6. The circles at the bottom left represent the two predictors. Area is proportional to regression sums of squares with values as shown. The shaded area of overlap represents intercorrelation. The table shows the allocation

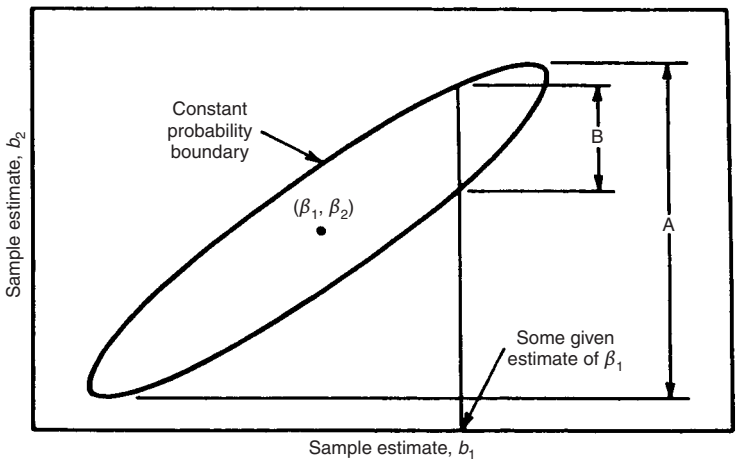

Figure 3 Correlation of Estimates of Slopes.

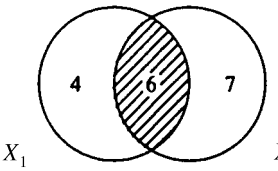
TABLE 6 Demonstration of Intercorrelation Effects[a]

	Class			
	Confounding		Resolving	
Definition	$R^2 < r_{1Y}^2 + r_{2Y}^2$		$R^2 > r_{1Y}^2 + r_{2Y}^2$	
Model order	X_1 first	X_2 first	X_1 first	X_2 first
$SSReg_1$	10	④	4	⑩
$SSReg_2$	⑦	13	⑬	7



[a]For assumed $n = 103$, SSY = 27, $F_j = 10$ $SSReg_j$.
For last predictor (circled entries), $F_j = t_j^2$.

of the 17 SSReg units to the two predictors for the two classes and for the two possible orderings of predictors in the model.

In the confounding case the ambiguous six units are allocated to the first predictor; the second predictor accounts for the balance. In resolving, the six units are available to the second predictor only after the first has clarified the picture. Notice that the total information, 17 units, is always the same. (other features of this table are discussed in subsequent sections as other diagnostic measures are presented). Relevant to this allocation process, care must be taken in interpreting Eq. (26). This equation says that the total regression sum of squares can be obtained from the sums of products of the b_j's with their corresponding SPX_jY's. It does not assert that the individual $SSReg_j$'s can be found this way. As can be seen from the foregoing discussion, the individual $SSReg_j$'s will depend on the order of appearance in the model. The total is order independent.

Extreme confounding is frequently encountered in nonexperimental data sets. It is important to recognize two quite different situations that may arise. Essentially, there is a duplication of information (i.e., a redundancy in the system). In one situation it may be that the same information is presented twice in slightly different forms (such as two different price indexes). This represents model redundancy and is dealt with by removing the redundant predictor. By contrast, it might be that two really different effects are present, but because in nature they are highly intercorrelated, their separate contributions cannot be discriminated statistically. This represents data redundancy and can clearly present a danger if one or the other predictor is arbitrarily excluded from the model, if estimation is the goal. An example is the use of R&D and capital expenditures to assess the number of technical staff needed in a business. Both effects are real, yet it would not be surprising to see them highly intercorrelated and thus inseparably confounded. This true dilemma motivates the current development of biased estimation techniques such as ridge regression (e.g., see Wichern and Churchill 1978) and will be discussed briefly later.

3.2. Detection of Intercorrelation

Several techniques have been proposed for detecting intercorrelation. These include examination of the off-diagonal elements of $\mathbf{X}'\mathbf{X}$, the examination of eigenvalues of $\mathbf{X}'\mathbf{X}$, the use of principal components, and the use of variance inflation factors (VIFs). Where VIFs are the diagonal elements of the $(\mathbf{X}'\mathbf{X})^{-1}$ matrix. Most current regression software will display these VIFs.

The VIF for each estimated coefficient b_j can be computed as $VIF_j = 1/(1 - R_j^2)$, where R_j^2 is the coefficient of determination obtained from regressing X_j on the other predictor variables. As R_j^2 approaches 1 (i.e., nearly linear dependent) the VIF for the estimated coefficient will tend to infinity. VIFs larger than 10 suggest problems with intercorrelation.

3.3. Meaning of Partial Correlation

For the two-predictor case, the (first-order) partial correlation is given by

$$r_{2Y\cdot 1} = \frac{r_{2Y} - r_{12}\, r_{1Y}}{[(1 - r_{12}^2)(1 - r_{1Y}^2)]^{1/2}} \tag{32}$$

This gives the correlation of X_2 with Y, given X_1 (or ''while holding X_1 constant '' or ''while first

removing the effect of X_1''). For a given pair of correlations of X_1 and X_2 with Y, r_{12} can influence this expression to be larger or smaller in absolute value than it would be in the orthogonal case ($r_{12} = 0$). When the partial is diminished compared to the orthogonal case, confounding exists. When the partial is increased, it is resolving. Partial correlations relating to the example in Table 6 would, in each case, be based on the circled (last-position) values. Ordinary correlations would be based on the uncircled (first-position) values. The coefficient of determination [Eq. (11)] can be used to represent these two views. The ordinary r^2 would use Eq. (11) as is. The partial coefficient of determination would place the circled value in the numerator and the net amount of SSY remaining, after removing the effect of the first predictor, in the denominator. Table 7 shows these ratios based on SSY = 27.

3.4. Multiple Correlation

The multiple correlation is represented by R. It is in fact the correlation of $\hat{Y}$ with Y, where $\hat{Y}$ a linear combination of the X's. Of course, the X's may individually have correlations with Y of either sign. Hence R is arbitrarily defined as being positive. Direct practical interpretation of R is difficult. Two transformations help to improve interpretation. One is R^2. As with the simple model, R^2 is the "coefficient of determination" and represents the fraction of SSY accounted for by the model (R^2 = SSReg/SSY). For orthogonal predictors, $R^2 = \sum_{j=1}^{P} r_{jY}^2$. For $P = 2$, if $R^2 > r_{1Y}^2$, + $r_{2Y}^2 X_1$ and X_2 represent a resolving pair, where $R^2 < r_{1Y}^2 + r_{2Y}^2$, X_1 and X_2 are confounded. These relationships were shown in Table 6 and evaluated in Table 7. A second transformation is "$\%s_Y$ removed." The percentage reduction in s_y is related to R as follows:

$$\%\ s_y \text{ removed} = 100 \left\{ 1 - \left[\frac{(1 - R^2)(n - 1)}{n - P - 1} \right]^{1/2} \right\} \tag{33}$$

For a more extensive discussion of R and a graph of Eq. 33, see Crocker 1972. Another related statistic is the "adjusted" R^2 and is used because the ordinary R^2 will never decrease when a new predictor is added to the model. The adjusted R^2, $\overline{R}^2$, is estimated by replacing SSRes and SSY with their mean squares (MS). The resulting equation is

$$\overline{R}^2 = 1 - \frac{(1 - R^2)(n - 1)}{n - P - 1} = \frac{s_Y^2 - s_{Y \cdot X}^2}{s_Y^2} \tag{34}$$

3.5. Relating t and F in Modeling

As shown in Section 2, the t ratio [Eq. (12)] gives the number of standard errors the estimated value of the coefficient is away from zero. That is still a correct interpretation in the multiple case. It is still useful in assessing the precision of the estimate as per Eq. (17). The t ratio does not, however, measure the contribution, the importance, the practical significance, or even the statistical significance of the associated term in the model! To use this statistic for assessing the contribution of a predictor, it must be carefully qualified. It answers the question "What is the impact of the unique contribution of this predictor?" "Unique" is taken here to mean "impact after resolving." Hence, it is the same as asking what the impact is for this predictor put last in the model.

For answering scientific questions about truth, this gives the t ratio a conservative interpretation. In terms of its influence in reducing $s_{Y \cdot X}^2$, $|t| = 1.0$ is the break-even value for any one predictor. With $|t| > 1.0$, $s_{Y \cdot X}^2$ is reduced by including this predictor. To have (unique) statistical significance, $|t|$ should exceed some appropriate critical value. For excellent precision in estimating β,$|t|$ should be near, say, 20 or 40 (see Section 2.6). The analyst must be wary not to exclude an important term with small t resulting from confounding. What action is appropriate depends heavily on goals (see Section 1) and upon intimate system knowledge.

The ordered F ratio for a single predictor is defined by the ratio of mean squares, regression/residual:

TABLE 7 Coefficients of Determination for Table 6 Values

	r_{1Y}^2	$r_{1Y \cdot 2}^2$	r_{2Y}^2	$r_{2Y \cdot 2}^2$	$R_{Y \cdot 12}^2$	$r_{1Y}^2 + r_{2Y}^2$
Confounding	0.370	0.286	0.481	0.412	0.630 <	0.851
Resolving	0.148	0.500	0.259	0.565	0.630 >	0.407

$$F_j = \frac{\text{MSReg}_j}{\text{MSRes}} = \frac{\text{SSReg}_j/1}{\text{SSRes}/(n - P - 1)} \tag{35}$$

It is called ''ordered'' because it contains the SSReg of the associated predictor, and this quantity is order dependent, as illustrated in Table 6. When $j = P$, $F_j = t_j^2$. Thus, the t ratios are all proportional to the square roots of the respective SSReg obtained for each predictor as if it were in last position.

For the example of Table 6, the denominator of Eq. (35) is $(27 - 17)/100 = 0.1$. Hence the ordered F values are the Table 6 entries multiplied by 10, and for the circled values these are t^2. So it is seen that t ratios are really ''partial'' t ratios and are best interpreted in terms of their relationship to last-position SSReg contributions.

3.6. Dealing with Interactions

Sometimes intercorrelation is carelessly referred to as ''interaction.'' Care should be taken to distinguish these two very different concepts. Intercorrelation is a data phenomenon and is not determined by the form of the regression equation, but rather by the particular set of observed values of the predictor variables. Interaction is a model characteristic. It is represented in the model by the product of two or more predictors. It is put there in an attempt to measure interactive behavior in the system represented by the model. Equation (36) shows an interactive model where $X_3 = X_1X_2$ represents a third predictor created from the first two (subscript i is omitted for simplicity).

$$\hat{Y} = b_0 + b_1X_1 + b_2X_2 + b_3X_3 \tag{36}$$

The meaning of ''interaction'' is this: The effect of one predictor depends on the value of another predictor. This is easily seen to be the case for Eq. (36) by factoring either X_1 or X_2. For illustration, X_1 is used.

$$\hat{Y} = b_0 + (b_1 + b_3X_2)\, X_1 + b_2X_2 \tag{37}$$

Here the coefficient of X_1 is $(b_1 + b_3X_2)$. Therefore, the effect of X_1 (its coefficient, $b_1 + b_3X_2$) depends on the value of X_2. By symmetry, the reverse is also true.

No special steps need to be taken to evaluate an interaction. Its t ratio will assess its additional contribution to SSReg, as was previously discussed. However, care is needed in interpreting the associated main effects. In general, where the X's are in their raw original forms, the interaction term will be highly confounded with the associated main effects—the predictors from which it is formed. This will tend to depress the t ratios of these main effects even where the interaction contributes a sizable SSReg (thereby reducing $s^2_{Y\cdot X}$). This should be of no concern. It is purely an arbitrary scaling problem. If desired, the interaction can be made approximately orthogonal to the main effects by subtracting their respective means before forming the product. This has no effect on the statistical assessment of the interaction.

3.7. Basics for Attribute Modeling

Regression modeling is not limited to using quantitative predictors. Any categorization, classification, or logical distinction can be represented. If there is a single class, no distinction is needed. If there are two classes, (e.g., male, female), an additional X is provided to give an attribute code to distinguish the two classes: $X = 0$ if the individual is in the first class (male), $X = 1$ for the second (female). The value chosen is arbitrary, but 0, 1 coding is easiest to interpret. This is ''differential coding,'' which means that the intercept, b_0, will represent the level in Y of the $X = 0$ group, and the coefficient for this code will estimate the difference in Y between the two classes.

To measure, for example, differences of each working day compared to Monday (arbitrarily chosen as the base of comparison), four extra predictors will be needed. Each will be given the value 1 only if the observation represents the associated day; otherwise it will be given the value 0. In general, the number of predictors added will be one less than the number of classes $(c - 1)$. In statistically evaluating the contribution of such a categorical coding scheme, a single test statistic should be used for the $c - 1$ DOF. This is because individual (single-DOF) SSReg contributions depend on the arbitrary choice of the base of comparison and the order. The total, however, is independent of the choice of base and order. The total can be evaluated using the F ratio as shown in Eq. (38), assuming that these terms are last in the model.

$$F_{c-1,n-P-1,\alpha} = \frac{\sum_{j=p-c+2}^{P} \text{SSReg}_j/(c-1)}{\text{MSRes}} \tag{38}$$

Variables selection programs that operate on individual DOF effects are clearly inappropriate for dealing with categorical structures.

Figure 4 illustrates a model with a single quantitative predictor, a two-class attribute shift, and an interaction of these two. Equation (36) applies here and implies that the slope in X_1 is different for the two classes.

3.8. Dealing with Covariates

A covariate is a source of variation contributing to SSY that may not be of particular interest but whose effect must be removed (1) in order to get unbiased estimates of other predictors of interest and (2) in order to reduce the noise level of the system so that predictors of interest can be more clearly seen. It may be that a covariate is confounded with a predictor of interest. The use of the t ratio in evaluating the reality of that predictor's contribution will then quite properly be conservative—discounting the information held in common with the covariate.

Where a categorical structure of three or more classes is involved in a covariate situation, special care must be taken. If the categorical group is the focus of interest, then it must be placed at the end of the model so that its apparent contribution, evaluated by Eq. (38), will have been reduced according to confounding with a covariate. If the categorical group is the covariate, then the term with which it is confounded will have a properly deflated t ratio independent of model position. Hence attribute code groups can always be safely placed at the end of the model.

3.9. Application to the Example

In the application of the simple model to the data of Table 3, a poor fit was obtained (see Section 2). This motivated an inquiry to find additional predictor variables. The plant engineer suggested testing steam used in production processes. He also later recalled a change in policy regarding comfort heating—a change that was coincident with the data set in hand. Table 8 extends the original data set of Table 3 by adding two more predictors. Production (X_2) is in units per period associated with a process which uses steam for heat in manufacturing. The change in policy is represented by the attribute code (variable 3), which starts at 0 when the heating level was 72°F (22°C) and goes through an adjustment (estimated by the engineer) over several periods to the new level of 65°F (18°C). The policy change should (only) affect the heating coefficient, β_1, and so is introduced as an interaction,

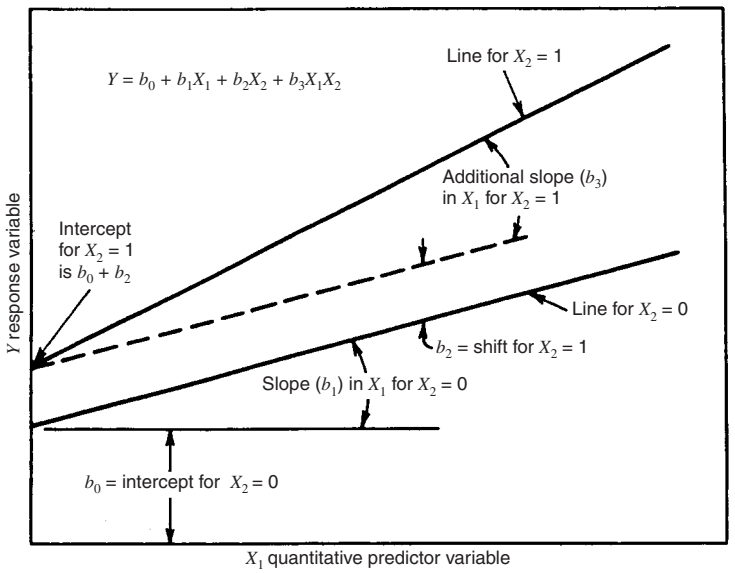


Figure 4 Illustration of an Attribute Code Shift and Slope Change (Interaction).

TABLE 8 Example Steam Consumption—Extended Data Set

i	Period Number	Heat (X_1) k degree-days	Production (X_2) Units	Policy (V_3) Attributes	$X_3 = X_1^* V_3$ k-degree-days	Steam (Y) (gBtu)

19	3-02	1.193	412	1.00	1.193	11.523
20	3-03	0.953	408	1.00	0.953	10.426

X_3 = degree-days × policy. This was suggested when the residuals from the two-predictor model displayed a slight downward trend over time. Essentially, this corrective third predictor is a covariate.

Analysis using Eq. (36) provided residual errors that were examined for pattern and excessive deviance. Figure 5 shows the residual plot (*Y-YHAT* vs. *YHAT*) produced by Statgraphics for the data of Table 8 using the $P = 3$ model and the full data set ($n = 20$). It may be noted that the residuals (*Y-YHAT*) form an arc over the range of *YHAT* and that one point (observation 4) plotted just below $P = 3$ in the title is distinctly away from the group. This fourth point was found to be at $+2.6s_{Y\cdot X}$ (Additional diagnostics relating to this are discussed in Section 6.) Further investigation revealed the malfunctioning of a steam trap in the production system. This would account for an indeterminate excess consumption of steam during the fourth period. Therefore the point was excluded.

Using the remaining 19 observations, the regression analysis was repeated for $P = 3$ [see Eq. (36)]. Statgraphics residual plot for this case is shown in Figure 6. The graph no longer displays any obvious lack of fit, outliers, or nonuniformity of variance. Additional diagnostics for this example will be displayed in Section 6 after some additional concepts have been introduced.

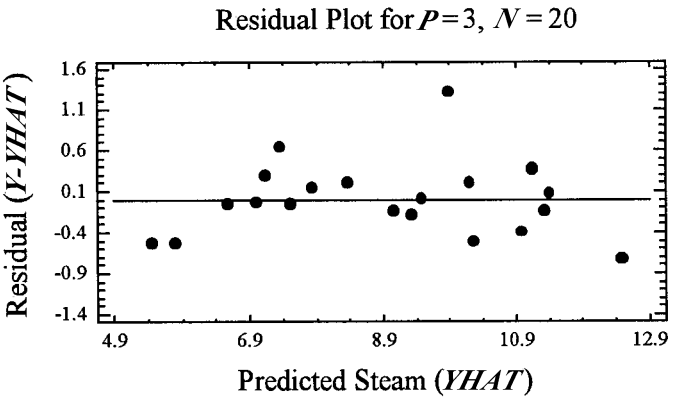

Figure 5 Representation of the Statgraphics Residual Plot.

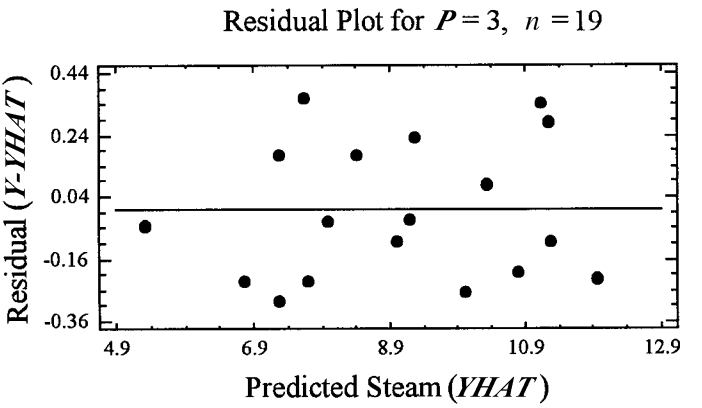

Figure 6 Representation of the Statgraphics Residual Plot.

4. RELATING DIAGNOSTIC QUESTIONS TO GOALS

4.1. Motivation

Regression analysis programs offer a great variety of analytic and diagnostic devices to assist the user. Some statistics that are automatically provided are not always relevant. Sometimes inexperienced users ask what a particular statistic is supposed to "do" or complain that it "isn't any good." Others try to discover some ritualized procedure that can be "followed" and wonder which are the key indicators belonging to such a procedure. Still others, seeking simplistic answers to complex questions, will attempt to impose rules of thumb or employ model selection algorithms. The analyst must learn to understand the complex relationships between diagnostic devices and analytic goals in order to make intelligent use of a program. Not all diagnostics need be examined just because they are there. There is no single, fixed path to follow in doing regression modeling, but rather a complicated cyclical, evolutionary behavioral process that requires simultaneous examination of many relevant diagnostics whose interpretation will frequently generate additional questions.

Space does not permit a complete display relating diagnostics and goals. It is hoped that the following summary of questions diagnostically related to goals will be helpful to the analyst in choosing (or choosing to examine) appropriate diagnostics. In addition to the five project goal-categories presented in Section 1, the analyst has two additional goals while performing regression analysis: data evaluation and model validation. They represent interconnecting analytic steps that motivate the generation of additional diagnostics.

4.2. Summary of Interrelated Diagnostic Questions

1. Are data typical, of adequate range, properly transformed, and error free (especially those of high influence)? Is the data sample large enough? Can a more balanced (less intercorrelated) sample be obtained?
2. Is there evidence of missing predictors or other lack of fit?
3. Is the residual standard deviation small enough to indicate probable model utility?
4. Are intercorrelations substantial? If so, are they reasonable and understood? What effects may they have on interpretation and decisions with respect to specific goals?
5. Do model coefficients have expected signs and reasonable magnitudes? Are they estimated with adequate precision?
6. Is there evidence of overfitting or instability?
7. Is the model to be used in regions of predictor space not seen in the development data set?

5. AN INTRODUCTION TO MODERN DIAGNOSTICS

Many modern regression diagnostics are magically intertwined—mathematically and computationally—and derive from a single germ. The germ idea can best be phrased as a question: What changes occur if a particular observation (one row of the data matrix) is deleted from the data set? Four aspects of change are of particular interest: change in the residual error of the deleted point and

changes in the regression surface, regression coefficients, and residual variance. Another closely related powerful diagnostic is the partial plot (also known as the partial-regression leverage plot). This involves deleting an X column from the data matrix. These row and column deletion constructs will be developed next after proposing some special notation.

5.1. Notation

In addition to the notation shown in Sections 2 and 3, the following conventions will be used in this development:

$\hat{Y}_i(i)$	The ith fitted response value using the regression equation derived with the ith observation row deleted ("Y − *YHAT* sub i not i")
$e_i(i)$	The deleted residual, $Y_i - \hat{Y}_i(i)$ ("e sub i not i")
$\mathbf{b}(i)$	$(P + 1) \times 1$ column vector of estimated regression coefficients derived with the ith row deleted ("**b** not i")
$\mathbf{X}_j$	$n \times 1$ column vector, jth column of **X**, one predictor
$\mathbf{X}_i$	$1 \times (P + 1)$ row vector, ith row of **X**, one observation's X's
$\mathbf{X}(i)$	$(n - 1) \times (P + 1)$ matrix of predictor variables excluding the ith observation row
$\mathbf{Y} \cdot (j)$	$n \times 1$ column vector of residuals in **Y** found when **Y** is fitted using all but the jth predictor
$\mathbf{X}_j \cdot (j)$	$n \times 1$ column vector of residuals in $\mathbf{X}_j$ found when $\mathbf{X}_j$ is fitted using all but the jth predictor
$s_{Y \cdot X}(i)$	Residual standard deviation for a model fitted to a data set excluding the ith observation row

5.2. Getting the Catcher and the Hat

Equation (23) can be rewritten in condensed notation as

$$\mathbf{b} = \mathbf{C}'\mathbf{Y} \tag{39}$$

where $\mathbf{C}'$ is called the matrix of catchers by Mosteller and Tukey (1977) and is defined as

$$\mathbf{C}' = [\mathbf{X}'\mathbf{X}]^{-1}\,\mathbf{X}' \tag{40}$$

So an individual regression coefficient can be found from

$$b_j = \sum_j c_{ij}\, Y_i = \mathbf{C}_j'\mathbf{Y} \tag{41}$$

which shows that the estimated coefficients are just linear combinations of the observed responses. Because each observation potentially contributes differently to this estimation process, each one also has a potentially different expectation for how well it will be fitted, depending on this leverage. This in turn gives an expected error variance for *Y-HAT* for each location in the sample:

$$s_{e_i}^2 = (1 - H_i)\, s_{Y \cdot X}^2 \tag{42}$$

where H_i, the leverage, is the ith diagonal of

$$\mathbf{H} = \mathbf{X}\mathbf{C}' \tag{43}$$

Substituting Eqs. (39) and (43) into Eq. (24) gives

$$\hat{\mathbf{Y}} = \mathbf{X}\mathbf{b} = \mathbf{X}\mathbf{C}'\mathbf{Y} = \mathbf{H}\mathbf{Y} \tag{44}$$

which gives **H** its name: the "hat" matrix (it puts the hat on Y). H_i sums to $P + 1$ and so represents the "consumption" of fractional DOF associated with individual observations. H_i ranges from $1/n$ at the centroid to a maximum of 1.0 for a shift parameter representing a single observation.

Equation (42) expresses the fraction of $s_{Y \cdot X}^2$ associated with the residual error around the surface. The error variance for the surface at the ith location is the complement,

$$s_{\hat{Y}_i}^2 = H_i s_{Y \cdot X}^2 \tag{45}$$

[Notice that for the simple case, H_i is just the familiar $1/n + (X_i - \overline{X}^2)/\mathrm{SSX}$ of Eq. (18)]. The estimated prediction-error variance for future observations recognizes the potential for influence on the model measured by the leverage. The consequence is the augmentation of the unit variance by H; just the reverse of Eq. (42).

$$s^2_{\text{PRED}i} = s^2_{Y\cdot X}\,(1 + H_i) \tag{46}$$

5.3. Row Deletion

One way to examine the effect of deleting the ith observation is to relate the deleted residual, $e_i(i)$, to the residual, e_i. It seems counterintuitive that this should be simply

$$e_i(i) = \frac{e_i}{1 - H_i} \tag{47}$$

because the leverage is dependent only on the X's: This relationship is unaffected by the observed value of Y. It is important to notice, however, that while the ratio of residuals, $e_i(\text{i})/e_i$, grows larger as H_i, the leverage, grows larger, both residuals may be very small. Leverage is a measure of potential influence; actual influence does indeed depend on observed Y. Unfortunately, some authors treat leverage and influence as being synonymous. By some, high-influence points are regarded as a great danger whereas correct high-influence points are to be cherished as the most informative points. (From very large data sets, leverage can be used for selection of a working subset—analogous to a designed experiment with extremes and center points.)

A proof of Eq. (47) was given by Allen (1971). Another (perhaps more accessible) path to Eq. (47) starts with the basic deletion formulas known as the Sherman–Morrison–Woodbury theorem, illustrated by Rao (1973) in an exercise.

5.4. Internal Validation

Conceptually, n regressions can be performed, each with one of the n observations deleted. From each regression the residual error for the deleted point can be calculated. This permits the validation process to be performed on all n observations while using the full available data set to estimate the regression function. How much more sensible this is than holding out some valuable data (information) for external validation! Fortunately, as seen from Eq. (47), only one regression computation need be performed to obtain all the desired information.

One useful statistic that can be derived from the $e_i(i)$ is called PRESS, an acronym for prediction sum of squares.

$$\text{PRESS} = \sum_i [Y_i - \hat{Y}_i(i)]^2 = \sum_i e_i^2(i) \tag{48}$$

It is axiomatic that the model that fits the development data set the best (minimum $s_{Y\cdot X}$) will not be the best prediction model. This is the consequence of the tendency to "overfit" to fit noise. The minimization of PRESS as a criterion for the choice of a predictive model, as suggested by Allen (1971), tends to counter this overfitting and is regarded by many as being superior to the C_P statistic (see, e.g., Mallow 1973), whose use is similarly motivated.

5.5. Examining Residual Errors and Influence

A variety of diagnostics for examining individual observations for extreme deviance and extreme influence can be derived using H_i. Four are chosen here. The following developments [except Eq. (57)] are given by or derived from the work of Belsley et al. (1980). The first diagnostic, the standardized residual for the ith observation, is

$$t_i = \frac{e_i}{s_{Y\cdot X}(1 - H_i)^{1/2}} \tag{49}$$

This statistic (sometimes called the "internalized t ratio") is often examined in screening for outliers (observations that may contain mistakes or may represent unusual conditions). Observations that generate values exceeding 2.0 in absolute value might be routinely examined.

Other analysts prefer the second of the four, the studentized residual (the "externalized t ratio"),

$$t_i(i) = \frac{e_i}{s_{Y\cdot X}(i)(1 - H_i)^{1/2}} \tag{50}$$

where

$$s_{Y\cdot X}(i) = \frac{[(n - P - 1)\, s^2_{Y\cdot X} - e_i^2/(1 - H_i)]^{1/2}}{(n - P - 2)^{1/2}} \tag{51}$$

[The original SSRes is reduced by the product of e_i and $e_i(i)$.] Here, one might usefully examine a

listing of the $s_{Y\cdot X}(i)$ as well. Here, one might also argue for the use of $e_i(i)$ in Eq. (50) with the prediction form (from Eq. (46) in the denominator. It turns out to be exactly the same thing! For the predicted point, the predictive location has $H_i(i)$ found by

$$H_i(i) = \mathbf{X}_i \, [\mathbf{X}'\mathbf{X}(i)]^{-1} \, \mathbf{X}_i' = \frac{H_i}{1 - H_i} \tag{52}$$

which provides the equivalence for the studentized residual. For Gaussian errors the distribution of $t_i(i)$ would closely follow the t distribution with $n - P - 2$ DOF.

One intuitively appealing measure of influence would be the deleted regression surface shift, $\hat{Y}_i - \hat{Y}_i(i)$. In developing a standardized form of this shift for assessment, it is discovered that the result is identical to t_i, the standardized residual of Eq. (49)! Hence, that statistic may be retained to provide this additional meaning. And in passing it is noted that the surface shift is

$$\hat{Y}_i - \hat{Y}_i(i) = \frac{e_i H_i}{1 - H_i} \tag{53}$$

An alternative scaling of this difference may be obtained by answering the question ''Compared to the uncertainty with which the position of the surface has been established at this location, how big is the shift created by this point's inclusion?'' This would use the standard error of the surface instead of the standard error of the shift in the surface. This scaling, the third measure of influence /deviance, has been labeled DFITS_i, defined as

$$\text{DFITS}_i = \frac{\hat{Y}_i - \hat{Y}_i(i)}{s_{\hat{Y}_i}(i)} \tag{54}$$

where

$$s_{\hat{Y}_i}(i) = s_{Y\cdot X}(i) \, H_i^{1/2} \tag{55}$$

Then substituting Eqs. (53) and (55) into (54), DFITS_i becomes

$$\text{DFITS}_i = \frac{H_i^{1/2}}{(1 - H_i)} \frac{e_i}{S_{Y\cdot X}(i)} \tag{56}$$

Cook (1977) developed his index of influence (the fourth examined here) in terms of the shift in the vector $\mathbf{b}$ associated with the deletion of the ith observation [see Eq. (59)]. It is structured so that the shift can be evaluated using $F(P + 1, n - P - 1, 1 - \alpha)$ with $1 - \alpha = 0.10$ giving an upper bound for ''an uncomplicated analysis,'' according to Cook. The index can be reduced to the following form:

$$\text{COOKD}_i = (t_i^2) \frac{1}{P + 1} \frac{H_i}{1 - H_i} \tag{57}$$

The third factor in this expression is the surface shift factor of Eq. (53) and is the ''deleted leverage'' of Eq. (52). It is also the ratio of the two partitioned parts of the residual variance [Eqs. (45) and (42)]:

$$\frac{s_{Y_i}^2}{s_{e_i}^2} = \frac{H_i}{1 - H_i} \tag{58}$$

This says that the larger the leverage, the larger the uncertainty of the location of the surface, the more the shrinkage of the residual. In Eq. (57), this ratio amplifies the measure of deviance given by t_i^2. Squaring DFITS and dividing by $P + 1$ gives the same measure as Eq. except that $t_i^2(i)$ is used instead of t_i^2.

It is noted in passing—for examining the deletion impact on the regression coefficients—that

$$\mathbf{b} - \mathbf{b}(i) = \frac{\mathbf{C}_i' e_i}{1 - H_i} \tag{59}$$

This result is also derived from the work of Beckman and Trussell (1974) and the basic deletion formulas discussed after Eq. (47).

5.6. Partial Regression Leverage Plots

A partial plot reveals the underlying relationship between the response and the jth predictor with the influence of all other predictors removed. That is, it plots $\mathbf{Y} \cdot (j)$ vs. $\mathbf{X} \cdot (j)$. Such a plot may reveal curvature, discontinuities, extreme influence, or other aberrations often not readily detected by plotting *Y-YHAT* or $\mathbf{Y} \cdot (j)$ vs. $\mathbf{X}_j$. This is especially true for resolving predictors. The simple regression of these residual variables gives the partial regression slope for the jth predictor in the full model—the usual multiple regression slope not always qualified as being partial. Deviations around this regression line are the full-model residuals. The correlation of these two residual variables is the $(P - 1)$st-order partial correlation of Y with X_j. One need not perform $2P$ multiple regressions to obtain the required vectors. Mosteller and Tukey (1977) and Velleman and Welsch (1981) discuss details leading to the following results. The starting point is the identity

$$\begin{aligned} \mathbf{Y} &= \sum_{(j)} b_k \mathbf{X}_k + b_j \mathbf{x}_j \cdot (j) + \mathbf{e} \\ &= \hat{\mathbf{Y}}(j) + b_j \mathbf{X}_j \cdot (j) + \mathbf{e} \end{aligned} \tag{60}$$

Then

$$\mathbf{Y} - \hat{\mathbf{Y}}(j) = \mathbf{Y} \cdot (j) = b_j \mathbf{X}_j \cdot (j) + \mathbf{e} \tag{61}$$

From Eq. (61) it is evident that the ordinate of the partial plot is simply $b_j \mathbf{X}_j \cdot (j) + \mathbf{e}$. The abscissa is $\mathbf{X}_j \cdot (j)$. Since the b_j and $\mathbf{e}$ are available from the complete multiple regression, all that is needed is $\mathbf{X}_j \cdot (j)$. This is obtained from

$$[\mathrm{X}_j \cdot (j)]_i = \frac{c_{ij}}{\sum_k c_{kj}^2} \tag{62}$$

where the denominator sums of squares of c_{kj} are just the diagonal elements of $[\mathbf{X}'\mathbf{X}]^{-1}$.

6. DIAGNOSTICS FOR THE EXAMPLE

6.1. Leverage and Influence

Available space is insufficient to permit demonstrating the partial plots for the example. However, Table 9 lists the leverages and the four influence diagnostics associated with individual observations

TABLE 9 Printing of Diagnostics for $P = 3$ $n = 20$

Row	Steam	Predicted	Residual	Studentized Residual	DFITS	COOKD	Leverage

for the example data of Table 8. Observation 4 has the highest leverage (at nearly a half a *df* "consumed" by this one point) and is also shown by all four diagnostics to have high influence. As noted earlier, the steam consumption for this observation was found to be anomalous and so the point was removed from the data set. For contrast, it is noted that observation 12 has nearly as high a leverage (at the low end of the ranges of both X_1 and X_2) but fits rather well and so has much smaller measures of influence (although COOKD_{12} at 0.365 is above the 0.10 value of F, which is 0.259). The regression analysis from which these diagnostics were obtained ($n = 20$, $P = 3$) is shown in Table 10 as produced by Statgraphics.

6.2. Final Results

With the fourth observation removed, the $P = 3$ model was repeated for the $n = 19$ remaining periods. The final results are summarized in Tables 11 and 12. The following comments deal with the main conclusions demonstrated in the table and with some diagnostics not mentioned earlier.

1. The coefficients were judged reasonable in sign and size, and the two main predictors are estimated with reasonable precision [see Eq. (17)].
2. The covariate third predictor does not show strong influence but was retained in the model to avoid biasing the estimates of the other coefficients. (The intercept represents the average consumption of all other steam uses uncorrelated with the model predictors.)
3. The final value for $s_{Y \cdot X}$ of 0.238 is the residual standard deviation for this model and data set.

4. The first predictor accounts for about 91% of the variability in Y (as measured by ordered SSReg/SSY). Therefore, it might be tempting to dismiss the use of steam for production (X_2) as unimportant. But X_2 accounts for 53% of the average steam use. That use simply does not vary as severely as weather.
5. The drop from $s_Y = 2.069$ to $s_{Y \cdot X} = 0.238$ represents an 88.5% reduction, and with $s_{Y \cdot X}$ at less than 3% of the mean, this model promises to be effective in monitoring consumption.
6. The VIF for each X is shown to help assess the intercorrelation effects.
7. The SSReg total of 76.23 is allocated among the three predictors according to model position. These SSReg_j can also be subdivided according to the effects of intercorrelations of the predictors. In this uncomplicated system the confounded portions are easily determined to be as shown in Table 12 by both the diagram and the listing to its left.

7. OTHER REGRESSION TOPICS

7.1. Variable Selection

Variable selection in regression arises when the set of variables to include into the model is not predetermined. The problem to be addressed is from the list of potential candidates to include in the model which ones should be included and in what form. The objectives here are to include as many predictors that can influence the prediction while in addition including as few as possible because the variance of the prediction increases as the number of predictors increase. Hence the goal of variable selection is to find an ''appropriate subset'' regression model.

Several criteria have been proposed to compare and evaluate the adequacy of the subset regression models. These include using R^2, adjusted R^2, MSE, Mallows' C_p, and PRESS. A brief description of the adjusted R^2 method will be provided here. Adjusted R^2 was previously defined as

$$\overline{R}^2 = 1 - \frac{(1 - R^2)(n - 1)}{n - P - 1} \tag{34}$$

The adjusted R^2 is used because the ordinary R^2 defined earlier will always increase when new terms are added to the regression model. The adjusted R^2 will not necessarily increase as new terms are added. This helps prevent over fitting the model and determining the ''appropriate subset'' regression model. Therefore one criterion associated with determining the appropriate subset model is to maximize the adjusted R^2. Note that this is equivalent to selecting the model with a minimum MSE.

7.1.1. All Possible Regressions

This procedure involves fitting all possible subset of regression models and choosing the ''best'' model based on suitable criteria. If we include the intercept in each model and there are q predictors, then there will be 2^q total equations to be fitted. Thus, if the number of predictors is 5, the total number of equations to be fitted is 32. As can be seen, the number of equations to fit grows rapidly as the number of predictors increase. In the steam example there are 3 predictor variables and thus 8 possible equations to fit. The results of fitting these 8 equations are shown in Table 13 and Figure 7. The equations have been listed by order of maximum adjusted R^2.

For cases where the number of possible equations is large, there are several procedures developed to evaluate only a small subset of these equations by adding or deleting predictors one at a time. These procedures can be classified into three groups (1) forward selection, (2) backward elimination, and (3) stepwise and are briefly described below.

7.1.2. Forward Selection

The procedure begins with the assumption that there are no predictors in the model other than the intercept. An optimal subset is determined by adding predictors into the model one at time with the first one to enter being the predictor with the largest simple correlation with the response variable. This predictor will be entered if it exceeds a predetermined F value (*Fin*). The second predictor to enter the model is then determined by the one that has the largest correlation with the response after adjusting for the effect of the first predictor (i.e., largest partial correlation). This predictor will enter the model if it exceeds *Fin*. This process continues until a predictor does not exceed the *Fin* or when all predictors have been added to the model.

TABLE 13 Statgraphics Output for Regression Model Selection for Steam

Models with Largest Adjusted R-Squared Results

MSE	R-Squared	Adjusted R-Squared	Cp	Included Variables
0.254064	95.0756	94.15220	4.00000	X_1 X_2 X_3
0.288141	94.0660	93.36790	5.28021	X_1 X_2
0.389220	91.9843	91.04130	12.04360	X_1 X_3

7.1.3. Backward Elimination

This procedure begins with the full equation fitted and successively drops one predictor out of the equation at a time. The predictor that is the first candidate to be eliminated is the one with the smallest contribution to the reduction of the error sum of squares. Based on the full model, a partial F statistic is computed for each predictor as if it were the last variable to enter the model. The predictor with the smallest partial F is eliminated if it is less then a predetermined critical F value (*Fout*). This process continues until no predictor has a partial F less than *Fout*.

7.1.4. Stepwise

The stepwise method is basically a combination of the forward selection and backward elimination methods. Thus, at each stage of the forward selection the possibility of deleting a predictor is also considered. Therefore, a variable that enters at an earlier stage may later be removed.

For all three methods the final model selected like any regression model should be evaluated to the regression diagnostics described earlier.

As an illustrative example of the method, the data for the steam example was analyzed using the forward selection method. The results are shown in Table 14. In this example the first predictor to enter was heat. Next the predictor production was added to the model. The last predictor, heat × policy, did not exceed the *Fin* value and was not included in the final model. However, as discussed earlier, the covariate third predictor was retained in the model to avoid biasing the estimates of the other coefficients.

7.2. Ridge Regression

Ridge regression is employed to combat intercorrelation between the regressors. A set of variables is exactly collinear if one of them is a linear combination of the others. The presence of intercorrelation is given by the variance inflection factors (VIF).

As discussed, least squares provides unbiased estimates with minimum variance of all linear unbiased estimators without upper limit on the variance of the estimators, and if intercorrelation exists, this may produce large variance. Therefore, in the presence of intercorrelation, a penalty is paid for the unbiasness property that is usually attained via least squares. Biased estimation procedures attempt to find a biased estimator of a regression coefficient that has smaller variance than the unbiased coefficient. Ridge regression is a biased estimation procedure to address this. In ridge regression, the analyst would like to select a bias, k, such that the reduction in variance is greater than the increase in the squared bias introduced. The ridge regression estimator, b_r is given by

$$b_r = (\mathbf{X}'\mathbf{X} + kI)^{-1}\,\mathbf{X}'y \tag{63}$$

The choice of k belongs to the analyst and should be chosen where strong evidence shows more stable estimates or improved prediction. One method suggested by Hoerl and Kennard (1970) is the use of a ridge trace. The ridge trace is a plot of the b_r vs. k, usually in the interval (0, 1). For values close to $k = 0$, intercorrelation will cause rapid changes in b_r. The objective is to select a small value of k where the b_r's stabilize.

TABLE 14 Statgraphics Output of Forward Selection Method for Steam

Multiple Regression Analysis

Dependent variable: Steam

Parameter	Estimate	Standard Error	t Statistic	P-Value
CONSTANT	4.11739000	0.81425000	5.05667	0.0001
Heat	4.03422000	0.26671300	15.12570	0.0000
Production	0.00624244	0.00222214	2.80920	0.0121

Analysis of Variance

Source	Sum of Squares	Df	Mean Square	F-Ratio	P-Value
Model	77.6493	2	38.824700	134.74	0.0000
Residual	4.8984	17	0.288141		
Total (Corr.)	82.5477	19			

R-squared = 94.066 percent
R-squared (adjusted for d.f.) = 93.3679 percent
Standard Error of Est. = 0.536788
Mean absolute error = 0.34515
Durbin-Watson statistic = 1.82542

Stepwise Regression
Method: forward selection
F-to-enter: 4.0
F-to-remove: 4.0
Step 0:
0 variables in the model. 19 d.f. for error.
R-squared = 0.00% Adjusted R-squared = 0.00% MSE = 4.34462

Step 1:
Adding variable Heat with F-to-enter = 189.166
1 variables in the model. 18 d.f. for error.
R-squared = 91.31% Adjusted R-squared = 90.83% MSE = 0.398461

Step 2:
Adding variable Production with F-to-enter = 7.89159
2 variables in the model. 17 d.f. for error.
R-squared = 94.07% Adjusted R-squared = 93.37% MSE = 0.288141
Final model selected.

8. SOME PRACTICAL CONCERNS

The analyst faces a variety of dangers in practice in addition to those discussed earlier. For example, there is often pressure to ''keep it simple.'' The danger is that, by avoiding complexity, the analyst may be seriously misled or fail to develop an adequate model. Simplicity is not necessarily a virtue.

It is also easy to acquire more faith in a complex regression model than it deserves. Even a good model is at best a crude approximation of reality. Yet, by being computer born, it takes on a special aura that may encourage undeserved faith in its utility.

Another danger is the predictive use of a regression model in regions of the joint predictor space not observed in the development sample, even though within all the observed predictor ranges. Equation (52) provides one index of the presence of this condition. ''Interpolation'' seems to fit, as the result is compared to the distribution of sample leverages.

From initial questions of which variables to collect to the final checking of a suspicious residual, data management is a major constituent of any modeling venture. The collection and ''scrubbing'' process very often consumes 70% or more of project funds and elapsed time. It bears repeating that a data set will rarely ever be free of mistakes. Some process for auditing the data must be devised at the outset or much effort will be wasted on false starts.

8.1. Model Use and Maintenance

The model is a waste if it is not used. The person who will have responsibility for its use must be involved early enough to gain understanding and develop faith. The model's use must serve an ongoing function that is desired and expected by the user's superiors or it will not survive.

Provision must be made for the timely reporting of the predictors. It is of no use to develop a prediction or control model if the necessary data cannot be obtained in a timely fashion. Results must then be reported to those who can take action. Good predictions kept in a desk serve no one.

Invariably, in practice, the β's estimated are not in fact constant but are creeping and shifting overtime. Additionally, there will inevitably be other systems changes, which, for example, may require the inclusion of additional predictors. So, if the model is to continue in use, provision must be made for updating it. Failing this, the model will begin to miss until it loses credibility and its use is discontinued.

8.2. Helpful Hints in Practice

The following is a summary list of prerequisites for successful use of regression modeling techniques that an analyst should have and/or use:

1. Reasonably specific goals
2. An understanding of statistical procedures
3. Reasonable familiarity with the system modeled
4. Restraint in transforming variables
5. Facility for adequate diagnostic analysis and data scrubbing
6. A cyclical approach with documentation of decisions and choices made
7. Good judgment instead of model selection algorithms
8. Great care when excluding important predictors that were not permitted to vary
9. Great care when including ''discovered'' relationships
10. A willingness to validate the model and/or anticipate model instability
11. Recognition of the need for maintenance of the model

Economic Evaluation

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

CHAPTER 88
Product Cost Analysis and Estimating

PHILLIP F. OSTWALD
University of Colorado at Boulder

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. ESTIMATING: IT HAPPENS ALL THE TIME

Cost estimating is a popular activity within engineering. Even though the professional person may be titled a cost estimator, cost engineer, cost analyst, labor estimator, or material planner, the emphasis remains the same. He or she is required to answer a familiar question: ''How much will it cost?'' Although the purposes that underlie this question are varied, we find that businesses, government, and not-for-profit organizations desire timely and reliable measures of economic want. For it is an engineer who does the appraisal, analysis, forecasting, and compiling of a pro forma document that extends from the basic cost ingredients to the bottom line of an estimate. Using this evaluation, other management people may determine a price, make vs. buy decision, return on investment (ROI), or public fiscal-year budget. Thus the engineer finds a future value of a product that responds to a specified need.

This historical trail of the development of formal cost estimating is intimately tied to industrial engineering. The original concept of a labor ''standard'' was seminal in the development of standard cost plans found widely throughout business. The genesis of formal cost estimating is circa 1900 since it was connected closely with manufacturing and construction. Cost estimating is a long-established job and an everyday occurrence for many engineers.

2. WHY ESTIMATES OF COST ARE MADE

Every size and type of organization needs cost estimates to make intelligent decisions. Some organizations employ persons skilled in the area of cost estimating whose primary function is developing estimates. But employees in most functional areas should understand good cost-estimating techniques. With concurrent engineering practices, teamwork philosophies, and total employee involvement, more people need cost-estimating knowledge and skills.

Cost-estimating procedures must be performed quickly and accurately because of tough customer demands and global competition. Listed below are several types of cost estimates that organizations routinely make.

2.1. New Product Cost

When new product concepts or product changes are being considered, detailed estimates of cost aid management in making proper decisions. Detailed estimates include costs of material, processing of material, fabrication, assembly, labor, and purchased components. The processing, fabrication, and assembly costs include estimates for tooling, dies, fixtures, inspection instruments, and so on. Costs for capital equipment investments, space, and facilities are also major estimate areas. If a management decision is to proceed with the new product, the detailed estimate may likely become the budget for the project. This type of estimate should be detailed and cover needs and costs from cradle to grave. Today the end of the product life has been extended to include recycling and disposal of the product and components of the product. It is not uncommon for companies first to determine the market selling price and then work backwards to determine how much cost can be absorbed by different areas of the company. Within each organizational area, costs must be constrained to limits allowed.

2.2. Make or Buy

Companies should consider whether to make components or the final product ''in-house'' or purchase them from ''outside'' vendors. Price is usually the deciding factor, but other factors can affect the final decision. Some of these factors are: can production demand requirements be fulfilled, can quality expectations be met, and can delivery schedules be met? Likewise, it might be better to use a supplier because they may have been producing similar parts for years and have the expertise to produce better parts than the company making the estimate. It is always wise to develop these estimates for comparison.

2.3. Selling Price Determination

These estimates can work two ways. First, estimates are used to determine selling price. The estimate establishes the cost to produce, market, deliver, and so on. Then a profit margin can be attached to establish a selling price. If entering an existing market, the competitive selling price can be used to work backwards to determine if producing the product is appropriate.

2.4. Equipment and Technology Acquisition

Companies frequently make decisions about purchasing new equipment, software, or complete systems to replace or add to the present resources. Often this involves comparing different alternatives that comprise new technology and/or changing from manual to automated procedures. Developing accurate cost estimates for new and unfamiliar areas is not easy.

2.5. Cost Control

Some companies, especially job shop-type organizations, use cost estimates as a form of cost control. Lot sizes vary and are usually small and almost every job is different. For these and other reasons, job shops seldom develop work standards to help determine costs. If a management decision is made to proceed with the new product, the detailed estimate may likely become the budget for the project. This type of estimate is not to be considered temporary work standards, because the objective is to determine whether the job can be done profitably and less expensively than by the competition.

2.6. Temporary Work Standards

Flow shop companies producing products in high volume use estimates as temporary work standards. It is to be hoped that these temporary standards will be replaced as soon as possible with accurate time studies, work sampling, or predetermined time standards.

2.7. Vendor Quote Checks

Cost estimates are sometimes used to check vendor bid quotations on outsourced work. This estimate can be used to not only verify appropriate costs for outsourced work but also as a part of the total product cost estimate.

3. MEASURES OF ECONOMIC WANT

The task facing the engineer is to provide a fact or number that represents the economic want of the design. A ''want'' is a value exchanged between competing and selfish interests. The price a consumer is willing to pay for an item stocked on the grocery shelf, a contractor–owner agreement on the bid value of a building project, and the fiscal-year budget value for a weapons system that the U.S. Department of Defense proposes and Congress accepts are typical examples of wants exchange.

The measure of want for a product estimate is called *cost*. It usually means full cost, as all items contributing to the manufacture and purchase of material, subcontract materials, and services must be included.

4. REQUEST FOR ESTIMATE

It is not common practice for cost engineers to initiate a request for an estimate. The request is typically generated from sales and marketing sources. Another source is engineering design from a potential customer. A request for quotation (RFQ) or request for proposal (RFP) is received by engineering design or generated in sales or marketing. A customer usually does not communicate with cost engineers; usually external communication goes through another function before coming to the cost engineer. Therefore, a request for estimate (RFE) is generated internally after an RFQ, RFP, or production inquiry is received. The customary form is not intended here, but the image is a generated signal on the computer screen.

Information needed varies for each RFE, but there are general areas of information that every engineer seeks. Some of these are status of the design, quantity and production rate expectations, quality specifications, legal requirements including environmental impact, delivery requirements and location. Information necessary to the nature of the design and needed to make a complete and accurate estimate should be provided to the engineer. But it is the engineer's responsibility to request proper information to develop the estimate. As in all decision making, the cost estimate can be no better than the quality and completeness of data used to create the estimate.

Sources of estimating information are both internal and external to the organization. If the product is going to be produced within the organization, the product estimation is probably internal. Project data, which usually involve capital types of designs, are typically external sources of information. Commercial data and published and private indexes are sources of external data.

Before starting an estimate, it is essential that analysis of elements of cost be understood. Analysis of labor, material, and overhead costs must be undertaken. Once again, the estimate will not be better than the quality and thoroughness of the analysis that precedes the estimating calculations. It is also vital that timely, up-to-date information be used.

The internal elements of cost details making up the estimate are primarily obtained from the accounting department. Cost accounting is the function that collects actual cost data on the various internal elements needed to develop the estimate. Listed below are the primary elements of a cost estimate and a brief description of each.

4.1. Direct Labor

Direct labor is the labor expended to add value to the product, sometimes described as the cost related to individuals who ''touch'' the product. Process operators, assemblers, and inspectors are included in this area.

4.2. Indirect Labor

Indirect labor supports direct labor. These people are essential to the operation of an organization, but they add no value to the product being produced. Material handlers, tool room employees, shipping and receiving employees, and maintenance people are some in this category.

4.3. Direct Materials

Direct materials consist of both manufactured and purchased components that are part of the product being produced.

4.4. Indirect Materials

Indirect materials are necessary to manufacture, test, and ship the product. Indirect materials are not part of the finished product. Sand used to build a sand-cast mold is an example of indirect material. There is a cost associated with indirect material, and in some situations the indirect material can be used over.

4.5. Overhead

This is an accounting term. Included in this category are salary and management costs. Overhead also includes all costs not covered in categories above. Elements such as machinery costs, shop and office supplies, and insurance are included in this area. Often in developing estimates, overhead is expressed as a percent of direct labor cost. For information on allocating overhead cost refer to Chapter 89.

4.6. General and Administrative

Many companies list general and administrative costs as part of overhead. Other companies list these elements separately. Usually G&A are added to the estimate in the form of a percentage factor developed in the organization. As part of this category, such items as sales commissions and top executive salaries might be included. These costs are provided by the accounting department and not by the cost engineer.

4.7. Profit

Profit that must be obtained from the product must be included in the cost estimate. This margin above production cost is provided by the marketing and accounting department and by top management.

5. PRELIMINARY AND DETAILED METHODS

There are many methods used to make estimates. They range from techniques that are quick and crude, or preliminary estimates, to the comprehensive and more accurate methods, detailed estimates. Regardless of the type of design, the methods used in estimating are similar.

Preliminary methods are used in the formative stages of design, are meant to be fast, and are not expected to be as accurate as those used to prepare detailed estimates. Detailed methods, at the other extreme, are used to set prices, make competitive bids, or allow organizational decisions to be made on what type of economic action to take. As might be expected, detailed methods are much more quantitative. Arbitrary and judgmental factors are suppressed though not fully eliminated.

Quantitative estimating is desirable because it tends to provide more accurate estimates than do nonquantitative methods. The quantitative area of estimating with the use of mathematical formulas is called parametric estimating, or sometimes statistical modeling. Although parametric estimating methods have been used for many years, they are becoming more favorable for estimating because many of the calculation techniques and estimating procedures have been developed into computer software. Several methods are discussed in some detail below. They are presented in order from preliminary to detailed methods. This order also goes from nonquantitative to quantitative, or parametric. When broadly defined, these methods can be used for a variety of designs.

5.1. Judgment and Conference Method

Judgment is an important part of any estimating process. In the absence of data, and when time is of the essence, guesstimates may be the only way to find some cost components of an estimate. The best-suited engineer for the task should be the person developing the cost estimate. This means that the engineer has qualified experience, common sense, and knowledge of the design. Time, cost, and/or quantities, with regard to minor or major line elements, are chosen using the engineer's experience. The engineer must remain objective in properly measuring all the present and future factors that could affect costs. When possible, judgmental estimating should be done collectively.

If time and resources allow, the nonquantitative consensus method of estimating, called conference estimating, can be used. The more pertinent knowledge that can be obtained from various sources

about a particular detail of the estimate, the better the chance of the decision being correct. In addition to cost information, other information such as savings, potential, and marginal revenue, can be included. The conference method relies on the collective judgment of the differences between previously determined estimates and their associated relationships with the new designs being considered.

Conference estimating usually involves bringing together representatives from various departments conferring with the engineers in round table discussions. These groups of people determine costs for the features of the design for which they have been given responsibility. These conference estimates might be limited to specific areas such as direct labor, materials, and processing equipment. Overhead, distribution, selling price, and profit are later added, using the organization's various values and formulas. The engineers can add these indirect type costs to the estimate later if the various functional representatives helping develop estimate costs do not allow access to specific organization costing data.

The conference method is not typically analytical, and verifiable facts are usually lacking. When using the conference method, proper group managing techniques should be applied to ensure that the decisions are group decisions and are developed properly in the group setting.

5.2. Unit Method

The unit method, or some variation of it, is the most widely used preliminary estimating tool. This method may also be known as the order of magnitude method, lump sum method, module estimating, or flat rate method. Individuals often use the unit estimating method to estimate costs for their private needs. For example, for estimating what a new home may cost to build, the cost per square foot estimate can provide a good ballpark figure. If construction cost in a geographical area is valued at \$105/ft^2, then a family could calculate the rough cost of having a 2075 ft^2 house built = \$217,850 for the estimate of the cost of the house. Some other examples of unit estimates are:

- Cost of components per kilogram of casting
- Manufacturing cost per machine shop man-hour
- Chemical plant cost per barrel of oil capacity

All of these examples for estimating are per something. The information for these types of estimates can be obtained from the Internet, technical literature, government, banks, data files of cost engineering or accounting, and the service providers.

Contributing to the popularity of unit estimating techniques is their ease of use. Consider the manufacturing machining operation of turning. Using similar parts routings, the total time for several jobs and many part types for a lathe can be compiled. Taking averages of length of cut and time to cut, and knowing the direct labor charge, a cost per unit of length of cut can be determined.

5.3. Comparison

The comparison method is similar to the previously discussed unit method, the difference being that formal logic is applied. If an extremely difficult design is being estimated or part of the design has an unsolvable section, it is given an identifying name such as design A. A simpler design problem is then constructed so an estimate can be made. The simpler problem is given a title such as design B. The simpler design might be developed from creative and clever manipulations of the original, more difficult design. The simpler estimate may also be made up of relaxed technical constraints from the original problem. If known facts already exist about design B, the engineer can gain information useful in developing an estimate for A. The alternative design problem B must be selected to relate to the original design by the following inequality:

$$C_A(D_A) \leq C_B(D_B) \tag{1}$$

where C_A and C_B are the cost values of the estimate for designs A and B, respectively. Likewise, D_A and D_B are the designs for A and B. Obviously, estimates are better when B approximates A as closely as possible. The cost value C_A of the estimate should be something less than C_B. A conservative position may be taken initially, as can be construed from Eq. (1). It may be management's policy to estimate the cost a little high at the beginning. Once the detailed estimate of design A is thoroughly explored, it may be found that $C_A(D_A)$ is less than the original comparison estimate.

A comparison estimate can be developed where high and low bounds are placed on either side of the estimate for design A. If a similar design is known for, or approximately known for, a design A, the logic from above can be used to expand the comparison inequality to the following:

$$C_C(D_C) \leq C_A(D_A) \leq C_B(D_B) \tag{2}$$

The assumption is made that designs B and C satisfy the technical requirements and bond the economic estimate for A. In practice, many engineers use comparison logic to develop estimates. Standard

cost plans can provide ''similar-to'' approaches, and analogy plans and computer retrieval schemes use this technique.

5.4. Factor Method

The factor method is an important method used for project estimating. Methods such as ratio, percentage, and parameter are approximately the same. The factor method is an extension of the unit method discussed previously. The unit cost estimating method was limited to a single factor for calculating overall costs. A natural extension of the unit method achieves improved accuracy by using separate factors for different cost items. For example, the estimate for the house construction from the unit method could be enhanced by added factors for certain types of heating and cooling units, tiled or wood floors, landscaping costs, etc. All the various unit costs can be summed and a more accurate estimate than using the unit method can be obtained. The equation takes the form

$$C = C_e + \sum f_i C_e (I + f_I) \tag{3}$$

where C = cost of design being evaluated
C_e = cost driver or subdesign used as base
f_i = factor for estimating instruments, structures, site clearing, etc.
f_I = factor for estimating indirect expense such as engineering, contractor's profit, and contingencies
i = 1, 2, . . . , n factor index

The general idea is that C_e is chosen as the cost driver. In the example, the house would be the cost driver. Where in a community the house is desirable to be built would be a contributing factor as would the specific design chosen and the amount of land the house would sit on. These factors can all be correlated and historical data, design parameters, and indexes can be referred to for factor estimate.

5.5. Cost- and Time-Estimating Relationships

Cost estimating relationships (CERs) and time-estimating relationships (TERs) are mathematical or graphical models that estimate cost or time. CERs and TERs are formulated to give estimates in either final or line item form for a cost estimate. Rule-of-thumb estimates are not to be confused with CERs and TERs, which are analytical.

5.5.1. Learning Curve

An excellent example of a CER and TER is the learning curve. There are two types of learning curves; unit cost and average cumulative cost, shown as

$$T_U \quad \text{or} \quad T_{AC} = KN^S \tag{4}$$

where T_U = cost or time value per unit of production, such as dollars, or man-hours required to produce the Nth unit
T_{AC} = average cumulative cost, time, or value of N units.
N = unit number, 1, 2, 3, . . . N
K = constant or estimate for $N = 1$, dimensions compatible with T
S = slope parameter of the improvement rate, equal to $\log L / \log 2$, where L = learning as percent of time (S is negative)

For example, if learning improvement requires only 85% of the previous time, then $S = \log 0.85 / \log 2 = -0.2345$. The learning theory is based on the percentage of time or cost to build a quantity when doubled from the known time or cost. For example, assuming an 85% learning curve and assuming it takes 10 hours to build the first unit, then doubling that quantity, which is 2, it would require only 8.5 hours to build the second unit. Doubling the quantity again, it could be estimated that it would require only 7.225 hours to build the fourth unit, which is 85% of 8.5 hours.

Learning curves have either the unit or the cumulative average line as the linear line when drawn on a log–log graph format. In one presentation, on log–log paper, the cumulative average line is straight and the unit line curves under from unit 1 until 10 or 20 units. From then on, the unit line parallels the cumulative line. The other presentation form allows the unit line to be straight or linear when plotted on log–log paper, and the cumulative average line, though starting together with the unit line at unit 1, curves above the unit line, and at about the 10th to 20th unit the two curves will run parallel. Either way is acceptable, but it is important that the engineer understand and clarifys for the other readers of the estimate which presentation is being used. For estimating to build N number of units, the cumulative average time may be more meaningful. A company is more likely to want to know how much time it will take to build N units (N times the cumulative average time)

rather than know how long it will take to build the *N*th unit. Table 1 shows the factors for an 85% learning curve. The two approaches are shown.

Different types of manufacturing have general learning curve slopes that are peculiar to them. Electronic manufacturers, ship builders, and so on have learning curve rates that generally apply to their area of production. Each company should have historical data for various types of products to obtain data for developing cost and time estimates for any size production demand. With knowledge of these slopes, or other learning experiences, the engineer determines the appropriate factor for the job being estimated.

Ostwald (1992) is one source of information on the development and application of learning curves. Many cost-estimating and work-measurement books give information on learning curve techniques.

5.5.2. Power Law and Sizing Model

Another application of the CER is the power law technique. The power law and sizing model is frequently used when estimates for equipment or components are given as a lump sum. This concept is concerned with designs that vary in size but are similar in type. An example might be estimating the design of a new and larger size electric motor. The cost to produce a 50 hp motor can be estimated from data for manufacturing a 25 hp motor, provided both are similar in design. Anyone familiar with manufacturing cost or the law of economy of scale would not necessarily expect the larger 50 hp motor to be twice the cost of the smaller 25 hp motor. The power law and sizing model can be expressed as

$$C = C_r \left(\frac{Q_C}{Q_r}\right)^m \tag{5}$$

TABLE 1 Sample Learning Theory table for 85% for Two Methods of Learning: Unit and Average

	Learning Table $\phi = 85\%$				
N	T_U or T'_a	T_c	T_a	T'_c	T'_u
1	1.0000	1.0000	1.0000	1.0000	1.0000
2	0.8500	1.8500	0.9250	1.7000	0.7000
3	0.7729	2.6229	0.8743	2.3187	0.6187
4	0.7225	3.3454	0.8364	2.8900	0.5713
5	0.6857	4.0311	0.8062	3.4284	0.5384
6	0.6570	4.6881	0.7813	3.9419	0.5135
7	0.6337	5.3217	0.7602	4.4356	0.4937
8	0.6141	5.9358	0.7420	4.9130	0.4774
9	0.5974	6.5332	0.7259	5.3766	0.4636
10	0.5828	7.1161	0.7116	5.8282	0.4516
11	0.5699	7.6860	0.6987	6.2693	0.4411
12	0.5584	8.2444	0.6870	6.7012	0.4318
13	0.5480	8.7925	0.6763	7.1246	0.4235
14	0.5386	9.3311	0.6665	7.5405	0.4159
15	0.5300	9.8611	0.6574	7.9495	0.4090
16	0.5220	10.3831	0.6489	8.3521	0.4026
17	0.5146	10.8977	0.6410	8.7489	0.3968
18	0.5078	11.4055	0.6336	9.1402	0.3913
19	0.5014	11.9069	0.6267	9.5264	0.3863
20	0.4954	12.4023	0.6201	9.9079	0.3815
21	0.4898	12.8920	0.6139	10.2850	0.3771
22	0.4844	13.3765	0.6080	10.6579	0.3729
23	0.4794	13.8559	0.6024	11.0268	0.3689
24	0.4747	14.3306	0.5920	11.7536	0.3616
30	0.4505	17.0907	0.5697	13.5141	0.3462
40	0.4211	21.4252	0.5356	16.8435	0.3233
50	0.3996	25.5131	0.5103	19.9811	0.3066
100	0.3397	43.7539	0.4375	33.9680	0.2603
500	0.2329	151.4504	0.3029	116.4542	0.1783

where C = total cost sought for design size Q_c
C_r = known cost for a reference size Q_r
Q_C = design size expressed in engineering units
Q_r = reference design size expressed in engineering units
m = correlating exponent, $0 < m \leq 1$

An equation expressing unit cost C/Q_C can be used as

$$\frac{C}{Q_C} = \left(\frac{C_r}{Q_r}\right)\left(\frac{Q_C}{Q_r}\right)^{m-1} \tag{6}$$

As total cost varies as the mth power of capacity, C/Q_C will vary as the $(m - 1)$th power of the capacity ratio. When $m = 1$, a linear relationship exists and the law of economy of scale is ignored. For chemical processing equipment, for example, m is frequently approximately 0.6 and is sometimes called the "sixth-tenth model." The units of Q are required to be consistent since it enters only as a ratio. For situations such as inflation and deflation, the model can be altered to consider price change. A change factor C_I is placed in the equation along with index factors I_C and I_r, as follows:

$$C = C_r \left(\frac{Q_C}{Q_r}\right)^m \left(\frac{I_C}{I_r}\right) + C_1 \tag{7}$$

where C_I is the constant unassociated cost.

For estimating projects, a CER that can be used is $C = KQ^n$. K is a constant for a project that might be a processing plant, new computer system, or a highway bridge. The concept of economy of scale is derived from this CER, where capital cost per unit produced reduces as the plant size increases. The scale factor m is not constant for all project designs. General scale-up or scale-down by more than a factor of 10 should be avoided.

Multivariable CERs are also possible. For instance, where symbols have been previously supplied, an equation such as the one immediately following could be used:

$$C = KQ^m N^S \tag{8}$$

5.6. Probability and Statistical Techniques

There are a range of estimating methods that are based on applying probability and statistics. Cost is usually treated as a single-point value under conditions of uncertainty. Engineers, knowing the weakness of information and techniques applied, recognize that there are probable errors in the developed estimates. Knowing the cost determined while developing the estimate is a random variable; using probability to estimate is appropriate. In the realm of statistics, a random variable is a numerically valued function of the outcomes of a sample of data. Four probabilistic techniques are discussed below.

5.6.1. Expected Value

When an engineer can assign a probability estimate to elements of uncertainty, as represented by the economics of the design, the method of expected value can be applied. Nonnegative numerical weights associated with design elements are assigned in accordance with the likelihood of the event occurring. The probability of the occurrence must equal 1. The probabilities describe the likelihood of that the predicted event occurring. The method incorporates the effect of risk on potential outcomes by means of a weighted average. Each outcome of an alternative is multiplied by the probability that the outcome will occur. The sum of the products for each alternative becomes the expected value. It is mathematically stated as

$$C(i) = \sum_i P_i x_{ij} \tag{9}$$

where $C(i)$ = expected cost of the estimate for alternative I
p_j = probability that x takes on value x_j
x_{ij} = design event

The p_j represents the independent probabilities that their associative x_{ij} will occur with $\Sigma p_j = 1$. For example, it may be predicted that the cost of fuel for use in the design might be charged at the following discrete cost pattern: 20% probability that fuel will cost \$3.00/gallon, 30% probability that fuel will cost \$3.50/gallon, and 50% probability that fuel will cost \$3.75/gallon. Multiplying the discrete probability rates times their related fuel costs and summing gives the expected cost of \$3.525/gallon.

5.6.2. Percentile Method

Estimates reflecting uncertainty may be specified by three values representing the 10th, 50th, and 90th percentiles of an unstated probability distribution. The best value for an engineer to use is the 50th percentile. The 10th percentile cost is the best-chance scenario and represents a 1-in-10 chance that the actual cost will be lower. The 90th percentile cost is the worst-case scenario and represents a 1 in 10 chance the cost will be greater. An example is shown below.

	Percentile			Difference	
Item	10th	50th	90th	(50 − 10)	(90 − 50)
1	$25	$33	$44	$8	$11
2	9	13	15	4	2
3	3	4	7	1	3

These costs can be assumed to combine independently, that is, a low cost with a mid-cost with another low cost. After estimating, the 10th and 90th percentiles are expressed as differences from the 50th (or mid-value). The next steps are to square the differences and sum.

	(50 − 10)	Mid-value	(90 − 50)
	$64	$33	$121
	16	13	4
	1	4	9
Total	81	50	134
Square root	9		11.58

Total estimate at 10th percentile = $50 − 9 = $41
Total estimate at 50th percentile = $50
Total estimate at 90th percentile = $50 + 11.58 = $61.58

Sensitivity analysis can be applied to the percentile method in a simple way, as shown next.

Item	Contribution to Low Uncertainty	Contribution to Total Cost	Contribution to High Uncertainty
1	79% (64/81 × 100)	66% (33/50 × 100)	90.3% (121/134 x 100)
2	19.8% (16/81 × 100)	26% (13/50 × 100)	3% (4/134 × 100)
3	1.2% (1/81 × 100)	8% (4/50 × 100)	6.7% (9/134 × 100)

This simple sensitivity analysis will identify items to be monitored for possible cost reduction.

5.6.3. PERT-Based Beta Distribution

Project evaluation review technique (PERT), was developed for use in predicting the expected duration of projects and monitoring the progress of the project's activities. It is based on using the most likely cost estimate, optimistic estimate (lowest cost) and pessimistic estimate (highest cost). These estimates are assumed to correspond to the beta distribution, which can be symmetrical or skewed left or right. Using the three estimates, a mean and a variance for the cost element can be calculated as

$$E(C_i) = \frac{L + 4M + H}{6} \tag{10}$$

$$\text{var}(C_i) = \left(\frac{(H - L)}{6}\right)^2 \tag{11}$$

where $E(C_i)$ = expected cost for element I
L = lowest cost, dollars (optimistic)
M = modal value of cost distribution, dollars (most likely cost)
H = highest cost, dollars (pessimistic)

If several elements are estimated using this method, and if their costs are assumed to be inde-

pendent of each other and are summed together, the distribution of the total cost is approximately normal. This follows from the central limit theorem. Figure 1 illustrates the use of the PERT method. The example shows how to find the contingency effects for a project design. Several elements must be combined when making the estimate to satisfy the conditions of the central limit theorem.

$$E(C_T) = E(C_1) + E(C_2) + \ldots + E(C_n) \tag{12}$$

$$\text{var}(C_T) = \text{var}(C_1) + \text{var}(C_2) + \ldots + \text{var}(C_n) \tag{13}$$

$E(C_T)$ represents the expected total cost in dollars, and $\text{var}(C_T)$ is the variance of total cost in dollars.

5.6.4. Computer Simulation

Simulation techniques are more acceptable as tools for engineers developing costs of projects and systems. As computer simulation packages become more user friendly and computers' memory grow larger and computation speeds become faster, simulation as a tool for estimating is becoming more popular.

Simulation is defined as the manipulation and observation of a synthetic (logical and mathematical) model representative of a real design, that, for technical or economic reasons, is not susceptible to direct experimentation. The simulation model is developed to represent the essential characteristics of the real system, with many minor details omitted. Product estimates are not suited generally for simulation techniques, although simulation could be applied to determine costs and times for manufacturing systems being estimated to produce the product.

5.7. Standard Data

Standard data are defined as standard time values for all manual work in an estimate. Standard data provide the opportunity to be consistent when developing an estimate.

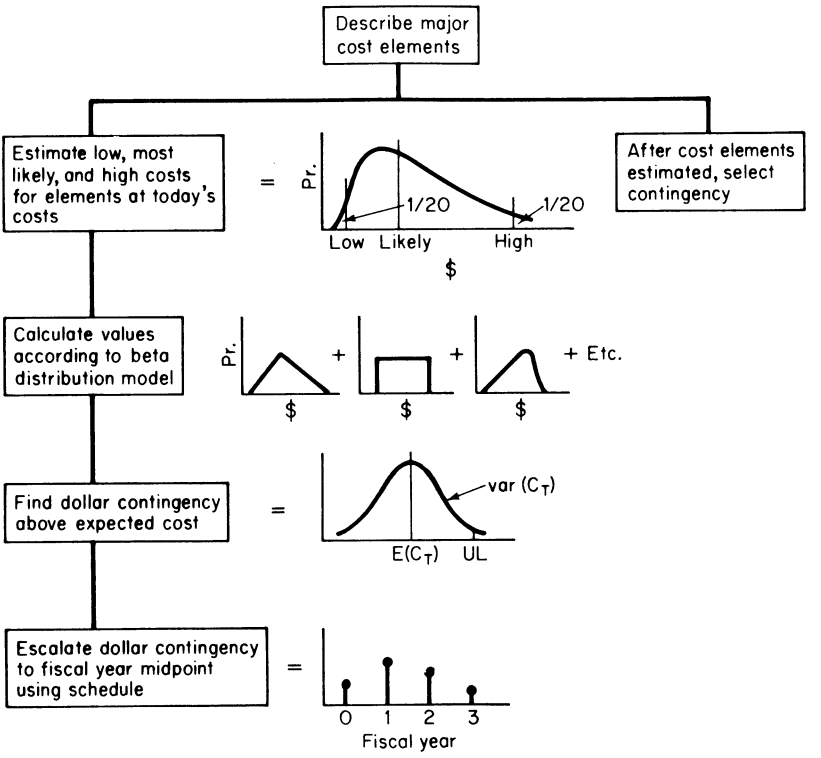

Figure 1 Flowchart of PERT-Based Estimating.

The most accurate way to estimate direct labor cost is with standard time data developed from one of the formal time-measurement techniques. (see Chapters 53 and 54). It is not the original time measurements that the engineer desires, but a set of engineering performance data or standard time data that are needed to make the estimate. Frequently, raw data or times for specific methods are incorrect because methods are altered, equipment is replaced, environmental conditions change, and so on. Industrial engineers may use regression analysis or other techniques to extend these raw data into a more usable form, such as standard data. It is easier to calculate standard time data for processes such as machining operations than fabrication processes. Most of the work content in metal removing on a machine tool is fixed machine time. In fabrication, much of the time may be manual and subject to variation depending on individuals performing work activities.

Standard time data may be divided into preliminary or detailed data. As with preliminary and detailed estimates, the engineer is more likely to be interested in preliminary standard data early in estimating, and later detailed data will become more important. Standard time data are ordinarily determined from any of the various methods of observing work.

5.7.1. Time Study

Some companies develop standard data from stopwatch time studies. Time studies are used to establish rates of production. When time studies are used to establish standard data, care must be taken in defining element content so that work content can be isolated.

5.7.2. Predetermined Time Standards

Usually, one of the commercial systems, such as MTM or MOST, will be used, but sometimes companies will develop their own system. The main advantage of predetermined time standards is the consistency of the data. The major disadvantage is the amount of time necessary to develop the data. The major commercial systems are computerized, and this allows for much faster development time.

5.7.3. Work Sampling

This technique of work measurement used the fundamentals of probability and statistics to develop work standards by making random observations on jobs over a specific period of time. This method is widely used in white-collar environments. It is a desirable technique for studying team activities and long-duration activities.

5.8. Historical Data

Past history or actual performance on jobs produced can be used to develop standard data. A disadvantage of this technique is that it rarely considers the best method of organizing work. This method is popular in smaller companies that do not have the resources to use the other work-measurement methods to develop standard time data.

In manufacturing, time study and predetermined motion time data are the major sources for obtaining standard data. In construction and white-collar environments, work sampling and man-hour reports are the principal means of information. Likewise, in certain government agencies, such as the post office and the military depots, work sampling and man-hour methods are used.

Computer databases allow for the easy and readily accessible time standard data. Often charts and tables are used in hard copy, especially when the engineer is familiar with such estimating tools. Charts and production information can be found in Ostwald (1992). When developed properly, standard time data are considered to be accurate and relatively inexpensive for labor estimating.

6. LABOR ANALYSIS

Labor constitutes one of the most important items of operation designs. Labor has received intensive study, and many recording, measuring, and controlling schemes have been developed in an effort to manage it. Labor can be classified in a number of ways, including direct–indirect, recurring–nonrecurring, designated–nondesignated, exempt–nonexempt, wage–salary, blue collar–management, and union–nonunion. Other ways in which to classify labor are according to social, political, and educational divisions and type of work. Payment of wages may be based upon attendance or performance. For cost–estimating operation designs, the direct–indirect classification is the most appropriate.

For operation designs, there is an unquestioned dependence upon the simple qualitative formula

$$\text{Labor cost} = \text{time} \times \text{wage} \tag{14}$$

The selection of time matches the requirements of the operation design. Time is expressed relative

to a unit of measure, which is denoted by terms such as *piece, bag, bundle, container, 100 units,* or *1000 board feet*. The usual ways to measure labor are by time study, predetermined motion–time systems work sampling, or man-hour reports.

Job tickets, especially for smaller organizations, are analyzed and allocated to units of work. For instance, a job ticket may state, "136 units turned of part number 8641" and list "6 person-hour." Simple analysis would show 0.044 hr/unit. The engineer would use 0.044 hr the next time this part was run. Although hardly accurate because of the nature of historical work reports, man-hour reports are used because of their simplicity. Man-hour estimating data are especially popular in construction work.

Direct observation and measurement of labor are of little use to the engineer except for guesstimates of similar work or reruns of the same work. Although the cost engineer may not be directly involved with the measurement of labor, he or she does depend on work measurement. The engineer is satisfied if such labor measurements are objective, as far as that is possible, and is willing to use the information, provided that engineering techniques were used in the determination of time. Although the time measurements are of value, it is immensely more important that work-measurement data be transformed into information that can be applied prior to the time of the operation design.

The time measurements are more valuable when expressed as standard time data (see Chapter 54) and presented in a table or computer format. The estimating data may be described in terms of elements, which are the subwork descriptors of operations, or be expressed as time-estimating relationships (TERs) for operations.

Standard data expressed at the predetermined motion–time level are too detailed for much cost-estimating work. But a typical TER is satisfactory for much cost-estimating work. A typical TER for a drill press operation of sheet metal parts is for setup 0.2 + 0.05/tool hr and for run time 0.015 + 0.003/tool + 0.001/hole hour per unit. Thus, if a sheet metal part requires two different countersinks for 22 holes, setup would be 0.3 hr and run time 0.043 hr/unit.

In some situations the estimate of time may be done from a guesstimate and be unrelated to measured, referenced, and analyzed data. A guesstimate is based on the engineer's observational experience. There are circumstances where these judgmental numbers are unavoidable.

The second part of Eq. (14), wage, is defined in the context of the operation design that is being estimated. The operation design may be for one worker and one machine, for a crew with one machine, or for a crew with several machines or processes. In the simplest case, one on one, the job description and job design are specifications available to the engineer. The number used for the wage corresponds to the time period of work and is money out of pocket. Regression methods, labor contract, and personnel planning are sources for wage trend information.

The practice of what is included in the wage amount is coordinated with the finding of the overhead. Fringe additions could include effects of paid holidays and vacations, health insurance and retirement benefits, Federal Insurance Contributions Act (FICA) benefits, workers' compensation, bonuses, gifts, uniforms, special benefits, profit sharing costs, education, and so on.

7. MATERIAL ANALYSIS

The term *direct materials* includes raw materials, purchased parts, standard commercial items and interdivisional transfers, and subcontracted items required for the design. Direct material cost is the cost of material used in the design. The cost should be significant enough to warrant the cost of estimating it as a direct cost. Some material, by virtue of the difficulty of computation and estimating, may be classified as either indirect or direct costs. The latter estimates are preferred. Paint material of irregularly shaped objects is an example of material that can be classified either way.

The engineer begins by calculating the final exact quantity or shape required for a design. To this quantity, losses for scrap, waste, and shrinkage are added. The general model for cost of direct material is

$$S_a = S_t(I + L_1 + L_2 + L_3) \tag{15}$$

where: S_a = actual shape in units of area, length, mass, volume, count, etc.
L_1 = loss due to scrap, decimal
L_2 = loss due to waste, decimal
L_3 = loss due to shrinkage, decimal

Scrap is material that is lost because of human mistakes, whereas waste is necessary because of the design. Shrinkage losses are due to theft or physical law deterioration. In estimating of foodstuffs, if direct material is not processed at the appropriate time or if it is mishandled, shrinkage of the quantity will result. It is required that these three losses be estimated and that their percentages be added to the theoretical finished requirement.

An example of material estimating is given by the 12 oz. (355 ml) beverage can, which is composed of the body, top, and pull ring. The container body is blanked from 3004 H19 aluminum coils, with the layout given in the Figure 2. An intermediate cup is formed, without any significant change in thickness. The cup is drawn in a horizontal drawing machine, and metal is squeezed to side-wall thickness of 0.0055 in. (0.140 mm), while bottom thickness remains unchanged. The can is trimmed to final height to give an even edge for later rolling to the lid. Various mensuration formulas are used to find first the volume and weight of the object. For a popular soda drink can, there is about 25% waste. These calculations eventually relate to the amount of coil aluminum stock.

8. NEED FOR ACCOUNTING DATA

Cost accounting has always been important to the performance of diverse estimating functions. As colleagues in the gathering, analysis, and reporting of business data, accountants provide overhead rates, standard costs, and budgeting data. The engineer reciprocates with labor and material estimates for the several designs. In many situations the estimate can serve as a mini-profit-and-loss statement for special products. Thus, there is interdependence between these two professions. The engineer is less interested in balance sheets, profit-and-loss statements, and the intimate details of the structure of accounts. Overhead rates are vital for the estimating functions, however, since the engineer may apply these rates in the estimate.

By definition, overhead methods would include the following:

- Indicating whether the rate includes fixed costs, as in absorption costing, or not, as in direct costing.

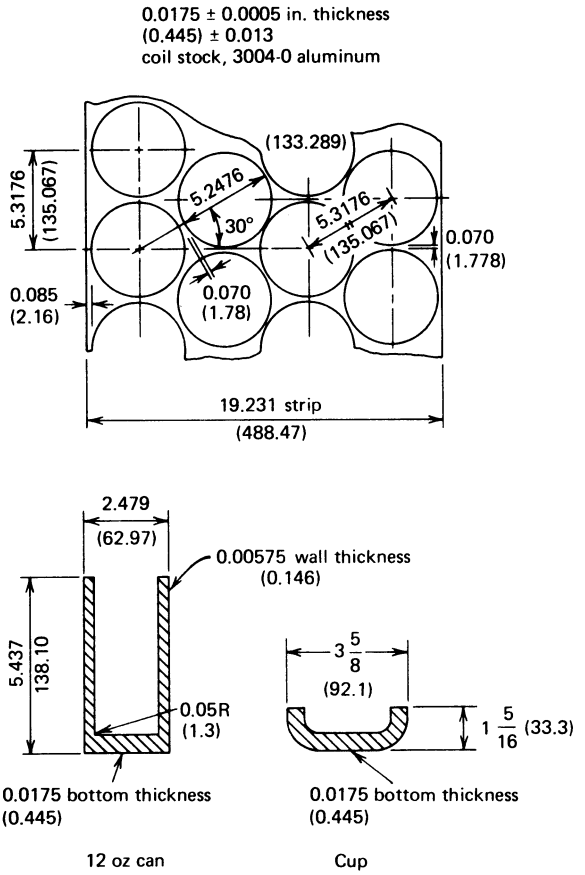

Figure 2 Simple Design for a Beverage Container, the Common 12 oz Can.

- The base used to distribute overhead, such as direct labor dollars, direct labor hours, or machine hours.
- The scope of the application of the rate, whether it is for the plant, cost center, machine, or design.
- Whether the rate applies to all designs (such as product lines) or to one line of the design.

9. FORECASTING

Many forecasting techniques have been developed to handle a variety of problems. Each has its special advantage, and care is necessary in choosing techniques for cost estimating. Selection of a method depends on the context of the forecast, availability of historical data, accuracy desired, time period to be forecast, and value to the company. The engineer should adopt a technique that makes the best use of the data. He or she should initially use the simplest technique and not expect more from the advanced technique than is justified.

For estimating requirements, we are concerned with data about labor and material overhead and their quantities and cost. The forecast should reflect those values under the proposed actions of the company and environment. It is necessary to recall that forecasting is a future prediction about line elements of the estimate. Forecasts should not deal in overall or grand average cost, time, and quantities, but should be matched to line items required by the pro forma estimate. Forecasting is not estimating, as the term is used here, since forecasting takes data and frames it in a new picture, and judgment is suppressed as much as possible.

10. INDEXES

Cost-estimating indexes are useful for a variety of purposes. Principally, they are multipliers to update an old cost to a new cost. Some examples of indexes are material, labor, material and labor, regional effects, and design type. C is the reference cost associated with a reference index I_r. The cost C to be determined is linked in terms of time to the index I.

$$C = C_r \left(\frac{I}{I_r} \right) \tag{16}$$

Indexes are prepared and published by the government, private industry, banks, consultants, associations, and trade magazines. It is important to determine one's own indexes, especially for materials or labor not charted by other groups.

A cost index is meaningful only in that it expresses a change in price level between two specific times. A cost index for steel in the year 2008 alone is meaningless. An index for material A has no relationship to the index for material B. Similarly, the cost indexes for material A in two geographical areas may not be directly comparable.

To compute a price index for a single material, a series of prices must be gathered covering a period for a specific quantity and quality of the material. Index numbers are usually computed on a periodic basis. The federal government gathers data and calculates and divulges index numbers for periods as short as a month. The prices gathered for the material may be average for the period (month, quarter, half year, or year) or may be a single observed value as found on invoice records for one purchase.

Assume that the following prices have been collected for a standardized unit of silicon laser glass material:

Period	0	1	2	3	4	5
Price	\$43.75	\$44.25	\$45.00	\$46.10	\$47.15	\$49.25
Index, %	94.9	96.0	97.6	100.0	102.3	106.8

Index numbers are computed by relating each period price to one of the prices that has been selected as the base. If period 3 is the benchmark period, because the index is 100 or 1, period 2 price divided by period 3 price = \$45.00/\$46.10 = \$0.976. When period 3 price is expressed as 100.0, period 2 price can be expressed as 97.6.

Movements of indexes from one period to another are expressed as percent changes rather than as changes in index points. Period 6, 7, and so on can be projected, and if a reference price is known, a future price can be calculated. For instance, if C_2 = \$3700, and if we want to know C_7, then projecting C_7 = \$3700 × (110.0/97.6) = \$4170.

Assume that a product called "10-cm disk aperture laser amplifier" is selected for a composite index. Although the 10-cm disk amplifier was produced only during period 0, tracing of selected cost items has continued. To worry about all amplifier components is too involved, so major items were picked for individual tracking, and spot prices have been gathered for 4 years. The quantity of each of the five materials is in proportion to the initial one-time cost of the material to the total cost. Some materials have declined in price, whereas others have increased. Prices for each material have been gathered (or imputed for periods where no information was available) and are shown in Table 2.

The prices conform to quantity and quality specifications. With the index at 100 for benchmark period 0, the following indexes are calculated as 94.1, 89.6, and 93.3. If the unit cost is $43,650 during period 0, the estimated cost is equal to $37,953 at period 5.

One may argue that cost facts, materials, quantities, and qualities are not consistent as given in Table 2. Indeed, if technology is active, a decline in the cost and index is possible. Indexes should reflect basic price movements alone. Index creep results from changes in quality, quantity, and the mix of materials or labor. Table 2 is an example of a product index. The components in this case are selected on the basis of their contribution to the product value. Selection of components could be 100%, random, or stratified in accordance with the needs of cost estimating. Quantity is determined proportional to the design requirements. Specifications provided by engineering are used to fix quality characteristics. Product indexes can be maintained by noting the changes when they occur, inputting all previous data, and recalculating the previous year's indexes. Every so often it may be necessary to reset the benchmark year whenever delicate effects are influencing the index and are not being removed.

11. OPERATIONS ESTIMATING FOR MANUFACTURING

The operations sheet is fundamental to manufacturing estimating. It is also called a route sheet, traveler, or planner. There are many styles, and each plant has its own form. The purpose of the operations sheet, however, is the same:

- To select the machine, process, or bench that is necessary for converting the material into other forms
- To provide a description of the operations and tools
- To indicate the time for the operation

The order of the operations is special too, as this sequence indicates the various steps in the manufacturing conversion.

Each operations sheet has a title block indicating the material part number, date, quantity, engineer, and other information that may be essential to the company. Following the writing of this information on the form or its entry into the computer, the instructions to the plant are provided.

TABLE 2 Simple Calculation of Index for Composite of Several Materials

			Period				
Material	Quantity	Quality	0	1	2	3	4
Laser glass	3- to 10-cm disk	Silicate	$26,117	$24,027	$22,345	$21,228	$22,713
Stainless steel tunings	18 kg	AISI 304	1,913	2,008	2,129	2,278	2,460
Aluminum extrusion	4 kg	3004	418	426	439	456	479
Fittings	3 kg	Mil Std 713	637	643	656	657	689
Harness cable	4 braid	Mil Std 503	2,103	2,124	2,134	2,305	2,466
Annular glass tubing	4 m	Tempered	$ 4,317	4,187	4,103	4,185	4,311
Total sample cost, $	12 m	3/16 in. wall PPG # 27	$35,505	$33,416	$31,808	$31,112	$33,122
Index, %			100.0	94.1	89.6	87.6	93.3

Suppose that we want to machine an aluminum casting that is on material consignment (meaning that the material is being supplied at no transfer cost). The casting is called SOHO and the part number is unknown. This casting is a consignment material and is part of a larger product. This casting will have a bored hole enlarged and deburred and it will be packaged in a carton. Your parts and assemblies are more complicated than this, but we only want to identify the process of estimating. A typical and simple operations sheet would appear as shown in Figure 3.

11.1. Preparing the Operations Sheet

The operations sheet (1) begins in the upper left-hand corner of Figure 3. The final product name (2) is often given along with the assembled product (3). The operations sheet is for a specific part name (4), which in this case is called SOHO. A part number (5) can be identified and listed if available. The part number and name are removed from the design and repeated on the operations sheet title block. The engineer will enter lot quantity (7) and material specification (8). Knowing the final amount of material required by the design, the engineer will add material to cover losses for scrap, waste, and shrinkage and multiply by the cost per pound rate of the material. Material cost, using the formula given earlier, is used to enter the value. A unit material cost is required for entry (9).

The sequence of the operation number and selection of the machine, process, or bench are made to manufacture the part. These are required at circle 10 and are shown specifically at (18) and (19). A complete operations sheet will show this column. Even though they are vital in operations planning, their importance is less in detailed estimating once that operation has been selected.

The column titled ''Table'' (12) corresponds to the equipment number for the plant. For example, ''Table 7-4'' refers to the ram milling machine class. The operations sheet column titled ''Process Description'' (13) are instructions to the shop that they will follow in making the part or subassembly. The instructions for operation number 10 to the shop are listed in Figure 3. The process description gives a listing of the elements that are pertinent to estimating the operation.

The ''Process Description'' lists the elements of the operation. These correspond to the element description listed in the estimating tables. It is an elaboration of the description given in the operations planning sheet described earlier; there is no basic difference, except that the number of lines or elements are greater for estimating than for planning. The ''Process Description'' may also indicate additional information such as length of cut, tooling used, type of NC manuscript order, and so forth.

The ''Table Time'' column (14) is a listing of the values removed from the estimating tables. These time values are posted in this column.

The ''Table Time'' column identifies the estimating table and element number. For example, if a sheet metal operation of braking were necessary, the number 3.6 would be first posted. Similarly, for a drill press operation, 9.3 would be written on the row corresponding to the machine selection. Notice, for any estimating table, that clusters of elements have a number too, starting with 1, 2, and so on. These clusters are generally related. The element ''handle'' may have many possibilities and be listed as element 1. Following the machine number, we list the element number, and it is preceded by a dash. For example, 3.6-1 is a power press brake element called ''brake.'' Also, 9.3-2 is a cluster of elements for ''clamp and unclamp'' for the upright drilling machine.

The adjustment factor (15) column operates upon the time column. Once adjusted, the time is either entered into the cycle minutes (16) or the setup hours (17) column. There is more discussion on the adjustment factor column later.

The columns titled ''Cycle Minutes'' and ''Setup Hours'' are very important, and the instructions that follow describe the methods and selection of the elements and time that are necessary to manufacture the part for that operation.

The sequence number (18) of the operation is given in the left-hand column along with the equipment (19) necessary for the operation.

The total (21) of the cycle minutes column and the total (22) of the setup hours column are summed. The lot estimate is calculated and presented (23) with the dimensions in hours. Lot time is calculated as follows:

The total of ''Lot Estimate'' is a computation that is shown on the operations sheet. The calculation is made using the setup, unit estimate, and lot quantity.

This operations sheet can be altered to consider simple assemblies or complicated products, but the approach remains the same. The purpose of estimating is to provide time or cost for the direct labor or material component of the product. The preparation of the operations sheet is important for the finding of part operational costs. Notice that the part cost is the sum of the operational costs, and this fact allows us to concentrate on the important steps that are necessary for estimating operations. Once the operational sequence, the selection of the machine, process, or bench, and a basic description of the work have been roughed out, cost estimating begins.

11.2. Setup Hours Column

Setup includes work to prepare the machine, process, or bench for product parts or the cycle. Starting with the machine, process, or bench in a neutral condition, setup includes punch in/out, paperwork,

Figure 3 Example of Process Sheet with Balloons for Instruction Sequence.

obtaining tools, positioning unprocessed materials nearby, adjusting, and inspecting. It also includes return tooling, cleanup, and tear-down of the machine, process, or bench to a neutral condition ready for the next job. Unless otherwise specified, the setup does not include the time to make parts or perform the repetitive cycle. If scrap is anticipated as a consequence of setup, the engineer may optionally increase the time allotment for unproductive material.

Setup estimating is necessary for job shops and companies whose parts or products have small to moderate quantity production. As production quantity increases, the effect of the setup value lessens its prorated unit importance, although its absolute value remains unchanged. Setup values may not be estimated for some very large quantity estimating. In these instances, setup is handled through overhead practices. Our recommendation is to estimate setup and to allocate it to the operation because it is a more accurate practice than costing by overhead methods. This recommendation applies equally to companies manufacturing their own parts or products and vendors bidding for contract work.

Some operations may not require setup. Flexible manufacturing systems, continuous production, or combined operations may not require setup time. Nonetheless, even a modest quantity may be appropriate in these circumstances. Discussion of the details regarding setup is given for each machine, process, or bench.

11.3. Cycle Minutes Column

Cycle time or run time is the work needed to complete one unit after the setup work is concluded. It does not include any element involved in setup. Besides finding a value for the operational setup, the engineer finds a unit estimate for the work from the listed elements, which is called estimating minutes.

The term *estimating minutes* implies a national norm for trained workers. These times include allowances, in addition to the work time, that take into account personal requirements, fatigue where work effort may be excessive due to job conditions and environment, and legitimate delays for operation-related interruptions. Since the allowances are included in the time for the described elements, and therefore part of the allowed time for several elements and hence several or many operations, then the allowed time is fair. The concept of fairness implies that a worker can generally perform the work throughout the day.

12. PRODUCT ESTIMATING

The cost summary (24) is for the part SOHO and the header information is repeated (see Figure 4). It is an important principle that estimating for manufacturing requires that each operation be estimated. Each operation (18) is identified and these correspond to the basic operations sheet. The table number (12) identifies the basic data set for that operation. Balloon (25) specifies the description of the machine, process, or bench necessary to perform the operation. Lot hours (28) are transferred from the operations sheet. These lot hours differentiate between quantity. For low quantity the setup becomes more important, while the cycle minute influences the lot hours if the quantity is large. Whether the part is for small or large quantity, the method is acceptable. The system is acceptable even with very large quantities that mechanization would require.

Productive hour cost (PHC) is entered as balloon (26). These company values are the costs for the labor and the machine. Overhead is included for this case. These company values are calculated by accounting.

The lot hours are multiplied by the PHC and given the total operational cost shown as column 27. For example, $3.32 \times 43.50 = \$144.27$. The PHC includes the cost of overhead, and the method can include absorption- or activity-based methods. The sum of the operation cost is given by the total operational productive hour cost, identified as column 29. The value of \$207.81, when divided by the lot quantity of 87 (7), gives the unit operational productive hour cost of \$2.39. In this case, this value is for labor and the machine process cost. Because the material is a consignment between the buyer and the manufacturer, no cost is assessed for unit material cost identified by column 31. If a unit cost exists, it is entered here. The sum of the material and the unit operational productive hour cost gives the total direct cost per unit (32). This value is multiplied by the lot quantity and the total job cost is entered as column 33.

This cost summary is used to provide information to the bill of material cost summary, which is the means of collecting all costs to obtain the full cost. Except in the case of a single part, the bill of materials is a vital and important document. For those manufacturers who only produce a single part, the cost summary is adequate since it provides the total job cost.

13. BILL OF MATERIAL EXPLOSION FOR PRODUCT ESTIMATES

The estimating of labor and material cost and its extension by overhead calculations will lead to the quantity known as full cost. This in turn will be increased for profit to give price. Before that routine

		Unit Operational Productive Hour Cost ($):			(30) 2.39
		(31) Unit Material Cost ($):			0.00
		(32) Total Direct Cost Per Unit ($):			2.39
		(33) Total Job Cost ($):			207.81

Figure 4 Example of Product Cost Summary.

is executed, it is necessary to find the total bill of material cost for several or many parts, subassemblies, and major assemblies. The bill of material explosion is unnecessary if the manufacturer only sells single-item parts, as the cost estimate serves as the principal summary document for price setting. But in the case of several or many parts and assemblies, it is necessary to organize the cost estimates effectively. A bill of material handles a scheme of this organization.

14. COMPUTERS AND ESTIMATING

Very few cost estimates are done without the aid of a computer. At least a microprocessor is used for word processing, spreadsheet calculations, database queries, and small, engineer-developed programs. At the other end of the spectrum, companies have developed their own in-house estimating software systems. Some companies with cost-estimating expertise have developed commercial cost-estimating packages for organizations wishing to use turnkey-type estimating packages.

Computer estimates are very consistent. Because of this consistency, they have an advantage of being able to be made with more accuracy. Estimates can be adjusted higher or lower as needed, or observed from previous cost estimates.

More detail concerning an estimate can be done because of computers. Details that might be tedious and time consuming if done long-hand can be done quickly and accurately on a computer. Work standard data and machining data can be accessed and inserted into an estimate easily. Also, level of detail relating to risk can easily be determined with the aid of a computer.

Cost-estimating software can provide refinements that would not be possible for an engineer to handle. For example, tool types, tool materials, material conditions, and so on. can easily and quickly be factored into cost, making the estimate more accurate and reliable.

15. CONCLUSION

Of the many paper or paperless documents a manufacturer will prepare, few are as important as the product estimate. This is the principal method for pricing that the firm will use. If the cost estimate is such that a profit will ensue, the enterprise continues the development of bringing the product to market. If the estimate gives an indication that a profit is unfeasible in the competitive market, the firm will cancel the product development or return the design to engineering for reconsideration, redesign, value engineering, or outsourcing. This chapter considers the techniques for bringing small pieces of information from data warehouses that the manufacturer will cultivate. This preparation of the cost estimates answers the question, ''What will this product cost?''

CHAPTER 89

Activity-Based Management in Manufacturing

KEITH V. SMITH
Purdue University

1. INTRODUCTION

During the last 15 years of the 20th century, the industrial sector of the United States made remarkable progress in restoring its competitiveness. The need to do so resulted from the trend toward a global economy, the increasing pace of technological innovation and development, and rapid advances in informational technology that made it possible. Progress occurred when industrial engineers and corporate managers began to *understand* the reasons why the U.S. industrial sector had slipped competitively. They began to *focus* on specific areas within the organization where things could be done more efficiently and effectively. And they began to develop a series of technological and management *improvements* in how work is planned, organized, and controlled in the modern-day organization. Improvements included material requirements planning (MRP), total quality management (TQM), computer-integrated manufacturing (CIM), just-in-time inventory (JIT), and activity-based costing (ABC).

This chapter deals with improvements in cost management systems, specifically with activity-based costing systems that are designed to provide more accurate costing of products and processes. The application of ABC systems to improve decision making within the organization is referred to as activity-based management (ABM). Included are decisions about product and process pricing, profitability of responsibility centers, capital equipment justification, and organizational performance. After reviewing the need for and development of ABC systems within the evolving manufacturing environment, we illustrate activity-based management with a case study from the automotive sector.

2. CONVENTIONAL COSTING SYSTEMS

The purpose of a cost management system is to provide management with information needed for external reporting and internal planning and control. A cost management system for a manufacturing firm includes cost accounting information for proper valuation of inventory and cost of goods sold; proper pricing of manufactured products, cash flow, and other information for proper justification of

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

capital expenditures; and performance measurements for proper assessment of how the business unit, plus its managers and employees, are doing relative to their expressed goals and objectives.

Johnson and Kaplan (1987) provide a useful historical review of the development of cost management systems in the United States. Conventional cost management systems were first developed with the advent of the industrial revolution in the 19th century. Early systems were designed for firms that manufactured one or two products using a fairly simple production process. These early systems and the information they provided were appropriately expanded with changes in manufacturing. By 1920, virtually all management accounting practices used today had been developed: cost accounts for material, labor, and overhead; budgets for cash, income, and capital; and flexible budgets, sales forecasts, standard costs, variance analyses, transfer prices, and divisional performance measures.

But as the scope and diversity of manufacturing continued to increase in the 1930s and 1940s, the state of the art of management accounting did not keep pace. The lack of new ideas for cost management was in part due to the enormous growth of audited financial reporting, plus the emergence of the public accounting profession. By their nature, public accountants were interested more in generating financial statements for external public consumption and less in generating financial information for internal use by management. Until recently, external financial statements also focused on financial activity in the aggregate, with little attention to the financial progress of profit centers and/or business units within the total organization. Unfortunately, there was not enough pressure by management to develop a second accounting system for internal use.

When companies did attempt to account for individual profit centers, the procedure was straightforward. Costs of material and direct labor were relatively easy to track. The difficulty was in how to assign corporate overhead costs to each profit center. Because direct labor tended to be the largest expense category for most businesses, the easiest practice was just to allocate overhead expenses based on direct labor hours. In other words, the profit center with the largest amount of direct labor would thus have the largest overhead assignment. In essence, allocation of overhead to profit centers was a single-stage process based on direct labor. And because direct labor did not necessarily correlate with the way in which corporate overhead expenses were actually incurred, the single-stage allocation system was also an *arbitrary* costing system.

3. THE EVOLVING MANUFACTURING ENVIRONMENT

During the 1980s, U.S. manufacturers faced increasing competition, largely from abroad. They allowed themselves to fall behind by failing to recognize shifts in consumer demand. They compounded the difficulty by continuing to utilize manufacturing processes and costing systems that were developed in a different time under a different competitive environment. Better news was that many U.S. manufacturers began to understand these developments and began to take steps to improve their competitive posture during the decade of the 1990s. By emphasizing product quality, building flexibility into production processes, reducing inventory, shifting factors of production from direct labor to machinery and equipment, and reorganizing product lines toward less centralized service departments, U.S. manufacturers fought back. A pivotal ingredient was the use of newer and improved information technologies. Of interest in this chapter is the role that cost accounting played in enabling improved information for improved decision making by management.

In addition to the pioneering work of Johnson and Kaplan (1987), important contributions to the literature on cost management systems were provided by Berliner and Brimson (1988), Kaplan (1990), Brimson (1991), and Hicks (1992). An earlier source on the emerging literature on manufacturing management is Hayes et al. (1988). These sources collectively acknowledged the need for improved cost management systems and provided tangible examples of how improved systems could be used to help in improved management decision making.

At the beginning of the 1990s, a comprehensive survey of cost management systems in the United States was conducted by Sullivan and Smith (1993a, b). They investigated the extent and processes by which corporate managers adapted their costing systems to the evolving manufacturing environment. They analyzed responses from 289 manufacturing firms (with a wide range of firm size) to discover linkages between changes in cost management systems and changes in production processes, competitive market conditions, and key elements of manufacturing strategies. They found that while cost management systems were changing, it was more likely to be the fine-tuning of existing systems and less likely to be bold innovation in changing costing systems that would allow management to better understand the economics of their internal managed transactions.

Sullivan and Smith concluded that the evolution in costing systems was really just beginning because plant managers were not yet satisfied that they had the proper information for effective decision making within the organization. An example of bold innovation in cost management systems at that time was activity-based costing, but only 15% of the responding firms reported that they had developed an ABC system. We turn now to a closer look at how ABC developed during the 1990s, and especially how ABC was useful in improving activity-based management.

4. ACTIVITY-BASED COSTING SYSTEMS

Broadly defined, an *activity-based accounting system* is one that attempts to identify the primary activities that allow each cost category to be allocated to all business unit products as reasonably and accurately as possible. Unfortunately, activity-based information is rarely obtainable from the financial accounts that comprise a conventional cost accounting system. Why is it important to have accurate costs? Because managers in a competitive manufacturing environment need to know the true costs in order to decide what to produce and distribute. Decisions involving product design, new product introductions, and the amount of effort expended on trying to market a new product will be influenced by anticipated costs as well as anticipated revenues. Product costs also play an important role in setting prices for products, especially those customized products where there are no comparable market prices.

As mentioned before, direct labor is the basis for overhead allocations in conventional costing systems. But in a manufacturing environment that features technological development and automation, direct labor has become less and less important. Profitability no longer results from just reducing direct labor costs. For example, quality and flexibility play important roles in determining the profitability of the manufacturing firm.

How does a manufacturing firm design and develop an activity-based costing system that provides more accurate information on product costs? As explained by Hilton (1997), management must continue to collect accurate data on direct labor and material costs. But management must also analyze the demands that various products make on the overhead resources of the firm. In so doing, it is useful to give greater attention to more expensive overhead activities, as well as those overhead activities whose consumption varies dramatically across products or product groups.

Another difference between conventional and ABC costing systems is that conventional costing is a single-stage allocation system, while ABC is a two-stage system of allocation. In conventional costing, overhead costs are allocated to profit centers or business units based on direct labor. In ABC, overhead costs are first allocated to *cost pools* of activity. Examples of cost pools in a manufacturing firm are machinery, engineering, purchasing, receiving, inspection, materials handling, quality assurance, packaging, and shipping. For each cost pool, the key activity or *cost driver* is identified. Examples of cost drivers are purchase orders, units produced, inspections, and shipments. In the second stage of allocation, costs in each overhead pool are allocated to profit centers based on the cost driver that is unique to that cost pool.

As a result of a two-stage process of cost allocation, activity-based costing is apt to reflect different costs than in a conventional costing system. For example, costs associated with ordering parts, keeping track of parts, inspecting parts, and setting up to produce parts as input to larger assemblies make up a large fraction of what normally might be classified as purchasing, as just one segment of total manufacturing overhead. However, there are two cost categories that should *not* be included in an activity-based costing system. Research and development costs for new products are more appropriately treated as a capital expenditure. And cost of excess capacity should be separated from product costs so as not to penalize products unfairly during periods of slack demand.

While there is a need for improved cost information, establishing an activity-based cost management system is not easy. And it becomes more difficult as the business firm becomes larger and more complicated. Many corporate managers have been reluctant to abandon a single conventional costing system. But the increased availability of computational power over time has enabled firms to develop and install an improved, second accounting system that provides useful information for internal decision making. Armed with more accurate product cost information, managers can contemplate improved strategic decisions on product lines, product prices, capital expenditures, and organizational performance. That is why the application of ABC is referred to as activity-based management

Activity-based costing represents a distinct improvement over conventional costing. But according to Kaplan and Cooper (1998), most U.S. firms are only at the third of four possible stages of development. Their first stage includes many firms that a decade or more ago had a conventional accounting system that simply did not provide accurate information. The second stage includes firms having an adequate accounting system for external reporting, but nothing that would help with internal management decisions. Kaplan and Cooper believe that many firms are now in the third stage because they have realized the need for improved information for managerial decision making and have developed a second and alternative accounting system for measuring and monitoring costs internally that leads toward improved decision making. The authors suggest a fourth stage in which firms develop a comprehensive accounting system that provides for both external financial reporting and internal decision making. It also should have the capacity to integrate financial reporting of the past and management decision making in the future.

5. CASE STUDY OF AN AUTOMOTIVE MANUFACTURER

To illustrate activity-based costing systems and how they can be used to make improved management decisions, we examine the case of the Titantic Auto Production Company (TAP). An earlier version

TABLE 1 Titatic Auto Production Company Balance Sheet as of December 31, 1999 (in millions)

Cash et al.	$3.1	Current liabilities	$18.1
Receivables	9.4	Long-term debt	13.3

Total	$56.0	Total	$56.0

of the case study was presented in Smith and Leksan (1991). Henry Hankinson, president and chief executive officer of TAP has decided that his firm must do something rather drastic to improve their cost management system. Two years ago, Mr. Hankinson attended a seminar in Boston entitled "Manufacturing Strategies for the Future." The seminar was attended by about 70 CEOs of medium-sized manufacturing firms. In addition to making interesting new contacts, Hankinson found the presentations excellent and the ensuing discussions both intense and useful.

Among the topics covered at the seminar, Hankinson was particularly interested in one session on cost management. The featured speaker at that session, a well-regarded professor from an eastern university, discussed management's critical need for better financial information. The thesis of his presentation was that for many manufacturing firms, today's financial information is based on antiquated cost-accounting systems that do not reflect the reality of the increasingly competitive environment for manufacturing.

That single presentation, together with the lively discussion that followed, convinced Hankinson that he and the TAP board of directors were just not getting the information needed to make important decisions at this critical time in the history of their firm. Among those questions were the pricing of one particular auto model, the relative profitability of TAP's three product lines, the possibility of further automation, and the overall ability of TAP management to control the business. As a result, Henry Hankinson has decided to look beyond the monthly reports that he now receives.

Last month at the TAP annual meeting, CEO Henry Hankinson presented the financial statements for 1999. As seen in Tables 1 and 2, TAP had total sales revenue of $66.5 million on assets of $56 million at year end. After-tax income of $4.9 million (up from $4.6 million in 1998) amounted to 7.4% of sales, 8.8% of assets, and a return on equity of 19.9%. These profitability numbers were well received at the annual meeting, but Hankinson is not sure how TAP compares with other firms in the automotive industry. He also is not sure what changes, if any, should be made in the TAP product line and marketing strategy so as to remain competitive in the years ahead. In order to answer these questions, as well as to learn more about TAP's cost management system, Mr. Hankinson requests a meeting with corporate comptroller Bradley Bartlett.

Bradley Bartlett is well prepared for his meeting with Henry Hankinson. Breakdowns of sales and profitability for each of the three automobiles produced by TAP—compact, midsize, and luxury—are shown in Tables 3 and 4, respectively. In Table 3, we see that total sales volume reached 10,000 autos in 1999, an increase of almost 650 vehicles from the prior year. Although sales volume increased for all three models, compacts accounted for most of that. Management has been pleased with the results of the vigorous advertising program for compacts that led to that increase. For purposes of this illustration, we assume that TAP is operating nearly at maximum capacity.

TABLE 2 Titantic Auto Production Company Income Statement for the Year Ended December 31, 1999 (in millions)

Gross revenues	66.5
Operating expenses	−58.3
Gross margin	8.2
Corporate overhead	− 1.2
Before-tax income	7.0
Federal taxes (30%)	− 2.1
After-tax income	$4.9

TABLE 3 Schedule of Sales Revenues by Model for the Year Ended December 1999

Model	Volume	Price	Revenue
Compact	7,000	$ 5,000	$35.0 million
Midsize	2,900	10,000	29.0 million
Luxury	100	25,000	2.5 million
Totals	10,000		$66.5 million

Profitability by model is analyzed in Table 4, and we see a quite different picture, with compacts actually losing almost $2.3 million. In Table 4, manufacturing overhead totaling $25.0 million is allocated by the conventional method on the basis of direct labor hours at the rate of $25 per hour. By far the largest contributor to TAP's gross margin in 1999 was the midsize product line. Bartlett explains that TAP's corporate overhead of $1.2 million must be subtracted from the gross margin of $8.2 million (Table 4) in order to obtain the firm's before-tax income of $7.0 million (Table 2). Profitability of an individual vehicle is presented in Table 5. Under a conventional cost management system, we see that TAP loses $325 on each compact sold. In contrast, TAP makes $3,150 on each midsize and $13,400 on each luxury automobile.

Despite the favorable aggregate results of TAP for 1999, Hankinson and Bartlett agree that they need to reconsider the emphasis on particular models within the total product line. In particular, should TAP continue its aggressive advertising for compact automobiles when that particular product apparently is losing money? Mr. Hankinson shares his notes and experiences from the seminar that he attended, and he asks Mr. Bartlett to see if he can apply some of the newer thinking to their firm—especially the concept of ''activity-based'' cost accounting.

Two weeks later, Messrs. Hankinson and Bartlett have a second meeting to continue their discussion of the relative profitability of the TAP automotive products. Because Mr. Hankinson is scheduled to attend a local meeting of financial analysts to discuss the latest earnings prognosis for TAP, he has time for only a summary of Bradley's work during the last few days. Mr. Bartlett thus decides to present only the comparison in Table 6.

The comparison between conventional and activity-based cost accounting systems is striking. We see that the results have reversed. Namely, compacts made money, while luxuries lost money. Meanwhile, midsized automobiles continued to generate the largest part of gross margin. Both Hankinson and Bartlett are surprised at these results. Henry Hankinson asks for further explanation at their next

TABLE 4 Schedule of Profitability by Model—Conventional Cost Management System—for the Year Ended December 31, 1999 (in millions)

Model	Sales Revenue	Material	Direct Labor	Overhead	Total Cost	Gross Margin
Compact	$35.0	$14.0	$6.65	$16.62	$37.27	($2.27)
Midsize	29.0	8.7	3.19	7.98	19.87	9.13
Luxury	2.5	0.6	0.16	0.40	1.16	1.34
Totals	$66.5	$23.3	$10.00	$25.00	$58.30	$8.20

TABLE 5 Schedule of Profitability by Vehicle—Conventional Cost Management System—for the Year Ended December 31, 1999 (in millions)

Model	Sales Revenue	Material	Direct Labor*	Overhead	Total Cost	Gross Margin
Compact	$5,000	$2,000	$950	$2,375	$5,325	($325)
Midsize	10,000	3,000	1,100	2,750	6,850	3,150
Luxury	25,000	6,000	1,600	4,000	11,600	13,400

*Direct labor is charged at $10/hr.

TABLE 6 Comparison of Accounting Systems on Gross Margin for the Year Ended December 31, 1999 (in millions)

Model	Sales Revenue	Gross Margin	
		Conventional-Cost	Activity-Based
Compact	$35.0	($2.27)	$2.00
Midsize	29.0	9.13	8.79
Luxury	2.5	1.34	(2.59)
Totals	$66.5	$8.20	$8.20

meeting as to why activity-based cost accounting leads to such different results. Bradley Bartlett agrees to try to provide the requested information.

6. IMPROVED PRODUCT PRICING AND PROFITABILITY

Ten days later, Bradley Bartlett provides the necessary backup information to justify the comparison in Table 6. He explains that TAP has four distinct overhead functions, and thus it is necessary to examine each function individually. The four overhead departments are purchasing, production planning and control, quality control and inspection, and inventory control. The respective analyses are presented as Tables 7–10.

For each overhead department, it is necessary to define the particular activities that drive the functions within that department. For example, in 1999 the purchasing department (see panel A of Table 7) incurred total costs of $5 million. Cost drivers were the purchasing of raw materials, the purchasing of components, and vendor relations. Appropriate allocation measures for these activities are the number of orders for purchasing, and the number of vendors for vendor relations. Levels of those activities for each auto model are indicated in panel B. In turn, these levels lead to the total allocated costs for each auto model in panel C.

TABLE 7 Activities and Costs for Purchasing for the Year Ended December 31, 1999

Panel A: Analysis

Activity	Number of Employees	Total Cost	Allocation Measure	Unit Cost
Purchasing materials	20	$2.0 million	Number of orders	$2,000
Purchasing components	5	1.0 million	Number of orders	250
Vendor relations	10	2.0 million	Number of vendors	20,000
Totals		$5.0 million		

Panel B: Activities

Model	Number of Purchase Orders		Number of Vendors
	Materials	Components	
Compact	500	2000	25
Midsize	300	1500	30
Luxury	200	500	45
Totals	1000	4000	100

Panel C: Costs (in millions)

Model	Purchasing Materials	Purchasing Components	Vendor Relations	Total Cost
Compact	$1.00	$0.50	$0.50	$2.00
Midsize	0.60	0.38	0.60	1.58
Luxury	0.40	0.13	0.90	1.43
Totals	$2.00	$1.00	$2.00	$5.00

TABLE 8 Activities and Costs for Production Planning and Control for the Year Ended December 31, 1999

Panel A: Analysis

Activity	Number of Employees	Total Cost	Allocation Measure	Unit Cost
Developing manufacturing plan	10	$1.0 million	Number of units produced	$100
Controlling manufacturing plan	10	1.0 million	Number of units produced	100
Expediting manufacturing plan	10	1.0 million	Number of units expedited	500
Totals		$3.0 million		

Panel B: Activities

Model	Number of Units Produced	Expedited
Compact	7,000	1,500
Midsize	2,900	450
Luxury	100	50
Totals	10,000	2,000

Panel C: Costs (in millions)

Model	Developing Manufacturing Plan	Controlling Manufacturing Plan	Expediting Manufacturing Plan	Total Cost
Compact	$0.70	$0.70	$0.750	$2.150
Midsize	0.29	0.29	0.225	0.805
Luxury	0.01	0.01	0.025	0.045
Totals	$1.00	$1.00	$1.000	$3.000

The other overhead departments for TAP are production planning and control ($3 million), inventory control ($10 million), and quality control and inspection ($7 million). Similar activity and cost analyses for the other overhead departments (see Tables 8–10) provide improved overhead allocations that can be used to better understand the relative profitability of each of the TAP auto models. The results are included in a revised profitability schedule in Table 11. It shows how a conventional costing system can lead to incorrect decisions by management.

For example, Simon Starling, senior manager of the TAP compact product line, recently suggested that the price of compacts should be increased by 10% in the next model year from $5000 to $5500. According to Starling, if sales remained at the current level of 7000 vehicles, revenues and costs would increase, but gross margin would improve from a loss of $2.27 million to a profit of $1.2 million. Such an improvement certainly would be welcomed. But, more realistically, a price increase of 10% may well affect sales volume for compacts, especially since the compact model competes in a price-sensitive segment of the market. Mr. Starling forecasts an *expected* sales volume of only 5500 vehicles as a result of the 10% price increase. At the same time, Starling's colleagues believe that sales of midsize and luxury automobiles are likely to remain the same during the next model year.

A comparison of direct labor utilization is shown in Table 12. Total overhead costs of $25 million remain the same, at least in the short run, and per hour costs thus increase from $25 per hour (before the price increase) to $25 million/857,500 hr = $29.15/hr (after the price increase). Recomputation of overhead allocations on model profitability via a conventional cost system is presented in Table 13.

Comptroller Bradley Bartlett notes that sales revenue for compacts would be expected to decrease from $35 million to $30.2 million as a result of the lower volume. The gross margin for compacts improves from a loss of $2.27 million (before price increase) to a loss of $1.28 million (after price increase). Gross margins of both midsize and luxury models decrease because they are penalized by having to absorb more of the total corporate overhead. Under the conventional cost management system, management might also look at the decreased gross margins for the midsize and luxury models and thus propose price increases for those products as well. In other words, conventional cost management systems give incorrect signals that are not in the best interest of the firm and its owners.

TABLE 9 Activities and Costs for Inventory Control for the Year Ended December 31, 1999

Panel A: Analysis

Activity	Number of Employees	Total Cost	Allocation Measure	Unit Cost
Receiving parts	25.0	$5.0 million	Number of shipments	$1,250
Receiving materials	12.5	2.5 million	Number of shipments	2,500
Disbursing materials	12.5	2.5 million	Number of production runs	50,000
Totals		$10.0 million		

Panel B: Activities

Model	Number of Shipments		Number of Production Runs
	Parts	Materials	
Compact	2000	500	10
Midsize	1500	300	15
Luxury	500	200	25
Totals	4000	1000	50

Panel C: Costs (in millions)

Model	Receiving Parts	Receiving Materials	Disbursing Materials	Total Costs
Compact	$2.500	$1.250	$0.500	$4.250
Midsize	1.875	0.750	0.750	3.375
Luxury	0.625	0.500	1.255	2.375
Totals	$5.000	$2.500	$2.500	$10.000

If TAP instead were to utilize an activity-based costing system, Simon Starling probably would not have proposed a price increase, since compacts already were making a positive contribution (see Table 11) to the overall profitability of TAP. Under the activity-based costing system, the difficulty caused by lower volume would be avoided by treating the cost of idle capacity as a *period cost,* rather than attributing it to individual products. This is illustrated in Tables 14 and 15. The Starling proposal would cause the gross margin of compacts to increase from $2 million (in Table 11) to $4.01 million (in Table 15). However, that improvement would be more than offset by the $2.39 million cost of idle capacity, so the project should be rejected. However, note that the activity-based costing system suggests that TAP's problem is not with the compacts, but with the luxury line of automobiles. Specifically, either the price of the luxury line should be increased substantially, and/or costs for luxury vehicles should be decreased if possible. Alternatively, TAP should consider abandoning that segment of the market.

7. IMPROVED CAPITAL INVESTMENT JUSTIFICATION

Two months ago, the TAP board of directors heard a presentation from the president of a foreign firm that manufactures high-technology industrial equipment. The firm has a new machine that performs a variety of inspection activities with great precision and considerable flexibility. The president of the foreign firm argues that their new machine is ideally suited for relatively low volume, high-quality manufacturing, such as TAP's midsize automobiles. The new machine costs $2.2 million, has an expected useful lifetime of six years and an estimated salvage value of $400,000, and is expected to reduce by two-thirds the manual inspection of midsize automobiles.

The TAP board was impressed by the presentation, and some members believe that the proposed new machine will add to the profitability of the midsize line. As a result, Henry Hankinson asks Bradley Bartlett to run the numbers, factor in other relevant considerations, and make a recommendation. Bartlett wonders if his new data, using activity-based cost analysis, will have any impact on his eventual recommendation.

Bradley Bartlett has worked hard on trying to understand the full implications of the proposed new machine for automated inspection of midsize automobiles. He wonders what incentive there

TABLE 10 Activities and Costs for Quality Control and Inspection for the Year Ended December 31, 1999

TABLE 16 Allocation of Overhead on All Product Lines—Proposed Inspection Equipment for Mid-Sized Automobiles—Conventional Cost Management System

Model	Before	After	Savings
Compact	$4,655,000	$3,990,000	665,000
Midsize	2,233,000	1,914,000	319,000
Luxury	112,000	96,000	16,000
Totals	$7,000,000	$6,000,000	$1,000,000

might be for management of the midsize line to adopt such a cost-savings device, since under the conventional cost management system the savings would reduce that portion of total overhead attributable to quality control and inspection, which in turn is then allocated to all three TAP product lines. The midsize product line thus would not receive the full benefit of the new inspection equipment. To understand the implication of this, he decides to prepare an analysis of the potential savings from the proposed foreign equipment under both cost management systems.

The conventional cost management system cannot even tell TAP management how many hours currently go into inspection. In a sense, this isn't important to the conventional system, since total

overhead expenses are allocated on the basis of direct labor hours. Bartlett proceeds as follows for his analysis of the midsize product line:

20 employees × 32 effective hr per week × 50 weeks = 32,000 hr/yr.

320,000 inspection points/32,000 hr/yr = 10 inspection points/hr.

Each midsize auto has 41 inspection points, hence 4.1 hr of inspection time per auto.

2,900 autos × 4.1 hr = 12,000 hr of inspection.

Reduced by two-thirds from 12,000 to 4,000 hours, hence savings = 8,000 hr, or 5 employees.

5 employees × ($10 wages/hr + $2 benefits/hr) × 40 hours/wk × 52 weeks = $125,000/yr.

Since this is a permanent reduction in number of employees, the fixed overhead attributed to each employee is also eliminated, for a savings of $1 million.

Assuming overhead percentage among the three product lines remains the same, under conventional costing, the midsize line would have an overhead reduction of $1 million × 31.9% (see Table 12) = $319,000.

Total quality control and inspection overhead of $7 million is reduced by $125,000 in labor saved and $875,000 of fixed overhead to become $6 million. The savings by product line is shown in Table 16.

Bradley Bartlett is puzzled by this result. Under the conventional cost management system, the primary beneficiary of the proposed inspection equipment for midsized automobiles is the compact line, even though that part of the business has nothing to do with the proposed new equipment. Management of the midsize product line would have little incentive to even propose the project, since they would be charged the entire $2.2 million cost of the new machine and yet receive credit for only part of the potential savings. In fact, under conventional costing, the project would actually reduce the return on investment of the midsize line, even though the project would help the corporation overall.

Bartlett next proceeds to analyze of how the proposed new equipment for midsized inspection would look under an ABC system. His calculations are shown in Table 17. The results are striking. Under an activity-based system, the $1 million savings per year is fully attributed to the midsized product line. If TAP has a tax rate of 30% and an annual after-tax cost of capital (i.e., required rate of return) of 15%, then the net present value of the six year investment would be as follows:

Present value:		
Savings	(3.784)(1,000,000)	$3,784,000
Tax shield	(3.784)(2,200,000 − 400,000)/6 yr	340,560
Salvage	(0.432)(400,000)	172,800
		$4,297,360
Cost of the inspection equipment		−2,200,000
Net present value		$2,097,360

This, of course, looks very good for TAP, and it is directly a result of a proposal appropriately attributable to the midsize product line.

8. IMPROVED PERFORMANCE MEASUREMENT

Bradley Bartlett had just completed his analysis of the inspection equipment when he received another proposal from the compact division. Their top management proposes a $2 million automation project that is expected to reduce direct labor from 95 hr to 90 hr per automobile. Again, he wonders how this proposal will look under different cost management systems. He also feels that he should be careful to include all relevant considerations in his analysis.

Mr. Bartlett proceeds to analyze the new proposal from the compact division. The automation project will result in the reduction of direct labor from 95 hours to 90 hours per auto. That would represent an annual savings of:

$$5 \text{ hr} \times 7{,}000 \text{ autos} \times \$12/\text{hr} = \$420{,}000$$

The new automated process costs $2 million and has an expected lifetime of five years and an estimated salvage value of $300,000. The annual tax shield would be:

TABLE 17 Activities and Costs for Quality Control and Inspection for the Year Ended December 31, 1999

Panel A: Analysis

Activity	Number of Employees	Total Cost	Allocation Measure	Unit Cost
Inspecting materials	15	$3 million	Number of shipments	$600
Inspecting	15	3 million	Number of inspection points × number of autos	12.50
Totals		$6 million		

Panel B: Activities

Model	Number of Shipments	Number of Inspection Points/Auto	Total Number of Points
Compact	2500	28	196,000
Midsize	1800	⅓ × 41 = 14	40,600
Luxury	700	51	5,100
Totals	5000		241,700

Panel C: Costs (in millions)

Model	Inspecting Materials	Inspecting Autos	Total Cost
Compact	$1.500	$2.450	$3.950
Midsize	1.080	0.500	1.580
Luxury	0.420	0.064	0.484
Totals	$3.000	$3.000	$6.000

$$30\% \times (\$2 \text{ million} - \$300{,}000)/5 \text{ years} = \$102{,}000$$

The present value calculation, again using a 15% cost of capital, would be as follows:

Present value:

Savings	(3.353)(350,000)	$1,408,260
Tax shield	(3.353)(102,000)	342,000
Salvage	(0.497)(300,000)	149,100
		$1,899,360
Cost of investment		−2,000,000
Net present value		($100,640)

Because net present value is negative, the proposal would not be accepted using the conventional costing system.

Suppose, however, that the new equipment will also improve the flexibility of TAP to offer additional options of the component whose production is being automated. The machine can perform certain manufacturing steps in very short times that were economically infeasible to perform under the current production process.

This ability to offer additional variations of the component is expected to be valued by consumers, and TAP will be able to charge more for compacts that have these option variations. It is anticipated that 2000 compacts per year would be sold with the more expensive option at a price of $5,070 (i.e., $70 higher). Added material cost for the option is $10, and hence TAP would benefit each year by the after-tax amount of:

$$2{,}000 \text{ autos} \times (\$70 - \$10) \times (1 - 30\%) = \$84{,}000$$

The present value of this is:

$$\$84{,}000 \times 3.353 = \$281{,}650$$

The net present value of the proposal becomes $181,010, and the project should now be accepted. Once again, activity-based costing leads to an improved management decision.

Henry Hankinson and Bradley Bartlett are preparing for the next monthly meeting of the TAP board of directors. As part of his CEO report, Hankinson has decided to make a presentation to the board on the firm's improved cost management system. He asks Mr. Bartlett to prepare illustrations for some recent management proposals where the older cost management system would have led to incorrect or myopic decisions. More work needs to be done to improve their cost management system further, but Henry Hankinson is pleased with the progress as TAP strives to be more competitive in the automobile industry. Mr. Hankinson also decides that he must confront the issue of whether the Titantic Auto Production Company should consider moving into the next stage of development, namely an integrated accounting system that would provide accurate information both externally and internally.

9. SUMMARY

As suggested by the TAP case study, it is likely that much of the information generated by conventional costing systems is inadequate in the evolving manufacturing environment. Focusing on the key costs of a bygone competitive era, conventional costing systems cannot adequately explain the rise of key costs today, namely, overhead. Making matters worse, conventional costing systems allocate overhead on the basis of direct labor, which in many operations is a relatively minor expense. This is where product cost distortions occur. Finally, the standard approaches toward pricing and investment decision making may well not reflect all of the relevant factors that have an impact on the firm.

Managers need to know what their products cost in order to make appropriate decisions concerning the products that they manufacture. This has become critical in the evolving manufacturing environment in which U.S. firms find themselves. However, product-costing decisions cannot be made in a vacuum. In and of itself, this does not increase the competitive advantage of a company. Company management must analyze its entire manufacturing strategy and make necessary changes that will lead to a competitive advantage in its operating activities.

The cost management system of a successful firm needs to be developed to handle two functions. First, it must generate nonfinancial indicators of operating results on a timely basis so that management can control the manufacturing process. Second, it must cost products on the basis of the underlying activities and their costs, rather than on just the purely financial numbers that are utilized for product costing in their conventional systems. In sum, the focus of their cost management system much be changed from its current role of inventory costing for financial statement purposes to a role that involves the effective control of operating activities, the accurate pricing of a company's products, and correct decisions about proposed capital investments and how the organization is appraised overall. Only when the cost management system reaches the third stage can it be used as a competitive weapon in the evolving manufacturing environment of the 20th century. The fourth stage of development for cost management systems is even more promising for firms in the 20th century as they explore the possibility of developing an integration of their external and internal accounting systems.

CHAPTER 90
Discounted Cash Flow Methods

RAYMOND P. LUTZ
The University of Texas at Dallas

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. DEFINING ALTERNATIVE CAPITAL EXPENDITURE PROPOSALS

Expenditures are made with the anticipation that more will be gained in benefits from expenditures than they will cost. If those benefits were to accrue over more than one year, then they would be called *capital expenditures*. Buildings, machinery, equipment, software, or research and development would be typical capital expenditures. When evaluating an expenditure proposal, the primary question is whether or not the money invested will generate a worthwhile annual flow of benefits.

To determine the economic feasibility of a proposed expenditure, it is necessary to define and relate four variables:

1. The economic life of the proposed alternative
2. The amount and pattern of the expenditures and the time period over which they will occur
3. The amount and pattern of the benefits and the time period over which they will occur
4. The interest rate that will appropriately represent the capital structure of the firm and the risk involved

The recognition of risk is especially important because all estimates and actual outcomes are subject to variability.

1.1. Determining the Economic Life of an Asset

The economic life of a capital expenditure is the number of years that this asset will make a positive economic contribution to the firm. The equipment used for a project will be retired when management observes (1) unsatisfactory functional characteristics, such as wear and deterioration; (2) unsatisfactory economic characteristics: it costs more than it earns; (3) termination of need: no one wants to pay for its output anymore; or (4) obsolescence due to changes in policy regulations or technology. The economic life is estimated by considering when the preceding conditions will occur. Such estimations can be facilitated by using data from historical service records of comparable assets, either within the firm or from other sources required to keep accurate records. Utilities or government agencies will often make such data available. Economic service lives can vary significantly. Telecommunications and computer equipment can be obsolete in 18 months, while aircraft and power generators can have life cycles of 30 years. Estimation of economic service lives can be complicated by the potential of legislative or regulatory action terminating or significantly modifying the use of an asset. Finally, economic service lives are not the same as tax lives, which are established for tax strategies, not operational plans.

1.2. Developing Cash Flow Profiles

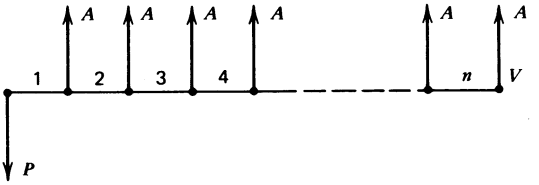
The cash flow profile should include all cash items anticipated to flow into or out of a project. Each cash flow item must be identified specifically according to the time at which this flow occurs. The major items included in an engineering economy study are:

1. First cost, P, is the sum of the costs of engineering, construction, purchasing, installation, and so on, to bring the asset into service. This cost is considered to occur at the installation of the project, $t = 0$. However, if the project requires a number of years to construct, then the major expenditures to be made each year during construction should be identified at the time the cash flow occurs.
2. Salvage, V, is the net sum realized from the disposal of the project or asset at the termination of its useful economic life.
3. Income (revenues), other benefits, and expenses are identified according to their type of flow over time.
   - **(a)** Periodic cash flow items occur at specific times, such as an overhaul of an engine every three years.
   - **(b)** Uniform series revenues or expenses are equal periodic amounts such as property taxes, leasing costs, interest on debt, etc.
   - **(c)** Continuous flow of revenues or expenses occur continuously and uniformly over the life of the project, such as the savings realized from a new assembly technique or the revenue stream from evenly divided alphabetical billing.

1.2.1. Traditional Engineering Economy Cash Flow Profiles

To ensure that all positive and negative cash flow items are included in the analysis and to better visualize these cash flows, it is useful to construct a *cash flow diagram* or *table.* A generalized illustration of a cash flow diagram for n periods of time is shown below. In the diagram, P is the present value of the first cost; A is the value of an annuity, a uniform series of equal cash savings

occurring at the end of each period; and V is the salvage value received for the asset upon the termination of the project.



Convention in engineering economy studies dictates that all discrete cash flows are considered to occur at the end of the period, which is normally at the end of each year. However, the period may be quarterly, monthly, or even daily.

To describe a specific cash flow, consider the following discrete items, with the cash flow developed using a tabular format.

End of Year	Receipts	Disbursements	F_{jt}
0	\$ 0	\$−6000	\$6000
1	2000	−500	1500
2	3500	−1000	2500
3	5000	−2000	3000
4	5000	−1000	4000

In this table F_{jt} = net cash flow for investment j at time t. If $F_{jt} < 0$, then F_{jt} represents a net cash disbursement of expense. If $F_{jt} > 0$, then F_{jt} represents a net gain or revenue.

1.2.2. Computer Spreadsheet Cash Flow Profiles

Spreadsheets, such as Microsoft Excel, have largely replaced the traditional tabular cash flow profiles and calculators for setting up and solving cash flow problems. The spreadsheet format has become the business standard for collecting, analyzing, and displaying data. Entering the previous data into an Excel format would result in the following table.

	A	B	C	D
1	End of	Receipts	Disbursements	Fjt
2	Year	\$	\$	\$
3	0	—	(6,000)	(6,000)
4	1	2,000	(500)	1,500
5	2	3,500	(1,000)	2,500
6	3	5,000	(2,000)	3,000
7	4	5,000	(1,000)	4,000

The calculation of F_{j0} would be accomplished as before, using the Excel commands = B3 + C3. Then the remaining F_{jt} values would be found by duplicating the formula for all subsequent F_{jt} cells.

The principal value of spreadsheets, other than their universal acceptance and use over the past decade, is the ability to display efficiently and use individual estimates of costs and benefits for each period over the life of the project, reflecting anticipated variability rather than a uniform average value or an approximate mathematical series. This will be discussed as each discounted cash flow method is presented. The principal disadvantage of a spreadsheet is that computational errors are hidden, even though an ''audit tool'' exists. However, the problem of quality assurance is not a new one, and the engineer must always be alert to the prevention and elimination of errors.

1.3. Selecting the Interest Rate

When analyzing the feasibility of any investment, two principles must be observed. First, the value of a sum of money is a function of the time span between the base point of reference and the date

an expenditure or the receipt of revenue will occur. For example, the value of $100 one year from today is not the same as that of $100 today. Consequently, money has a time value, which is measured by the interest rate. Second, because of this time value of money, all comparisons of receipts and disbursements must be made at a common specific point of time. Compound interest factors provide the means of shifting cash flows to this common time.

1.3.1. Weighted Average Cost of Capital

The minimum interest rate a company should earn on its invested capital is determined by the capital structure of the firm. The firm must earn an adequate return both to support the long-term debt and to compensate the stockholders adequately for their equity investment. This minimum interest rate, C_C, is calculated using the capital asset pricing model and is often referred to as the weighted cost of capital.

$$C_C = C_D + C_E$$

where C_C = weighted cost of capital, %
C_D = weighted cost of long-term debt, %
C_E = weighted cost of equity, %

The weighted cost of long-term debt, C_D, can be determined by

$$C_D = k_D \times W_{LTD}$$

where k_D is the return necessary to support debt, stated as a percentage and W_{LTD} is the percentage of the firm's capital structure represented by long-term debt. The values of k_D and W_{LTD} are determined by examining the financial statements of the firm. The value of k_D would represent the average interest rate charged on the firm's long-term obligations.

$$W_{\text{LTD}} = \frac{\text{long-term debt}}{\text{long-term debt + equity}} = \frac{\text{LTD}}{\text{LTD} + E}$$

The weighted cost of equity, C_E, can be determined by

$$C_E = k_E \times W_E$$

where k_E is the return necessary to support the firm's equity stated as a percentage and W_E is the percentage of the firm's capital structure represented by equity. As would be expected, W_E is the complement of W_{LTD} and would be calculated by

$$W_E = \frac{\text{equity}}{\text{long-term debt + equity}} = \frac{E}{\text{LTD} + E}$$

The before-tax rate of return required to support the firm's equity structure would reflect both the risk attributable to equity instruments and the volatility associated with the firm's stock price relative to the equity market average. The rate of return, k_E, required to support the equity portion of the firm's capital structure is

$$k_E = \frac{\text{(risk-free rate) + (risk premium)}}{1 - \text{tax rate}}$$

$$\text{k}_E = \frac{r^* + \beta(R_m - r^*)}{1 - t}$$

where r^* = risk-free rate of return
R_m = risk attributable to the general equity market
t = effective tax rate
β = systematic risk of a stock due to underlying movements in security prices

The value of the risk-free rate of return, r^*, can be estimated as being equal to the interest rate paid on U.S. Treasury Bills or other guaranteed savings instruments, approximately 6% in mid-2000. The interest rate equivalent to the general equity market, R_m, was found to be approximately 9% by Fisher and Lorie (1968). Over the past 30 years this figure has risen to 11%. The effective tax rate, t, can

be calculated from data obtained from the annual consolidated statement of earnings in the firm's annual report. Values for the systematic risk of a stock due to underlying movements in security prices, β, can be obtained for the majority of firms traded on major stock exchanges from references such as *Value Line Investment Survey.*

As an example of determining the minimum rate of return that must be earned to maintain the capital structure of the firm, consider the following calculation for Johnson & Johnson using the data contained in its*1999 Annual Report.* The data are in $million.

$$t = \frac{\text{taxes paid}}{\text{profit before taxes}} = \frac{\$\ 1{,}586}{\$\ 5{,}753} = 27.6\%$$

$$k_E = \frac{r^* + \beta(R_M - r^*)}{1 - t} = \frac{6 + 0.8(11 - 6)}{1 - 0.276} = 13.8\%$$

$$W_E = \frac{E}{\text{LTD} + E} = \frac{\$16{,}231}{\$18{,}689} = 0.8675$$

Cost of equity

$$C_E = W_E \times k_E = .8675 \text{ x } 13.8 = 11.97\%$$

$$W_D = \frac{\text{LTD}}{\text{LTD} + E} = \frac{\$\ 2{,}476}{\$18{,}689} = 0.1325$$

Cost of long-term debt

$$C_D = W_D \times k_D = 0.1325 \times 6.42 = 0.85\%$$

Weighted cost of capital

$$C_C = C_D + C_E = 11.97\% + 0.85\% = 12.82\%$$

1.3.2. Factors Impacting the Selection of an Interest Rate

The preceding calculation will determine the *minimum* interest rate a company should earn on its invested capital to preserve its capital structure. Any lesser rate would erode the firm's reserves. Most companies use a ''hurdle rate'' of approximately two times the weighted cost of capital. Since research has shown that the average project returns approximately half of the original estimate, using a higher rate of return is a good policy. However, a firm may adopt differing interest rates in order to establish strategic investment guidelines for different types of business or functions within the business. For example, an energy company might require quite different interest rate hurdles between marketing and exploration and production, or a technology firm could encourage research and development expenditures by using a rate in a feasibility study which would be a fraction of that applied to a ''cash cow'' operation. For example, consider projects for:

1. *Safety, quality, or legal requirement:* A specific rate of return is usually not required. The immediate need for the project or the lack of an alternative solution may preclude an earnings test for such an expenditure.
2. *Increased profit:*
   - **(a)** *Cost reduction:* Projects with a rate of return of at least 25% would qualify for consideration.
   - **(b)** *Existing product:* Projects to increase the production capacity, flexibility, or delivery speed for an existing product would be considered if the return were at least 25%.
   - **(c)** *New product line:* Because of the greater risk of demand, technology, and life cycle, the rate of return should be at least 50% over the projected life of the project.
3. *Country risk:* When operating offshore, the stability of a country's government, labor force, and infrastructure operations can vary the risk to the firm. The hurdle rate should be varied accordingly.

The interest rate used to evaluate capital investment alternatives should be greater than the weighted cost of capital. However, the specific rate to be used in capital budgeting and project

feasibility analysis must be a management decision, depending on the type of activity, the risk, and the opportunity costs.

2. USING INTEREST FACTORS TO FIND EQUIVALENT MONETARY AMOUNTS

Equivalence is equating monetary values occurring at different points in time. Comparisons of financial alternatives must be made among equivalent units. The Interest rate provides the mechanism for converting a cash flow at one specific time into an equivalent cash flow at another time. This conversion is facilitated by using either the Excel spreadsheet functions in Table 1 or the interest tables at the end of the chapter.

2.1. Simple Interest

The simple interest payment each year, i_n, is found by multiplying the interest rate, i, times the invested capital, or principal, P. Thus, $i_n = Pi$. After any n time periods, the accumulated value of money owed under simple interest, F_n, would be

$$F_n = P(1 + i_n)$$

For example, \$100 invested now at 9% simple interest for eight years would yield

$$F_8 = \$100[1 + 0.09(8)] = \$172$$

Simple interest forgoes the money earned by annual compounding and is rarely used in engineering economy analyses.

2.2. Compound Interest

The interest payment each year, or each period, is found by multiplying the interest rate by the accumulated value of money, both principal and interest.

TABLE 1 Compound Interest Factors: Discrete Cash Flow, Discrete Compounding

To Find	Given	Name of Factor	Algebraic	Format	
				Functional	Excel
F	P	Compound amount factor (single payment)	$(1 + i)^n$	$(F/P, i\%, N)$	FV (rate, nper, pmt, pv, type)
P	F	Present worth factor (single payment)	$(1 + i)^{-n}$	$(P/F, i\%, N)$	PV(rate, nper, pmt, fv, type)
F	A	Compound amount factor (uniform series)	$\frac{(1 + i)^n - 1}{i}$	$(F/A, i\%, N)$	FV(rate, nper, pmt, pv, type)
A	F	Sinking fund factor	$\frac{i}{(1 + i)^n - 1}$	$(A/F, i\%, N)$	PMT(rate, nper, pv, fv, type)
A	P	Capital recovery factor	$\frac{i(1 + i)^n}{(1 + i)^n - 1}$	$(A/P, i\%, N)$	PMT(rate, nper, pv, fv, type)
P	A	Present worth factor (uniform series)	$\frac{(1 + i)^n - 1}{i(1 + i)^n}$	$(P/A, i\%, N)$	PV(ratte, nper, pmt, fv, type)
A	G	Arithmetic gradient conversion factor to uniform series	$\frac{(1 + i)^n - (1 + ni)}{(1 + i)^n - 1}$	$(A/G, i\%, N)$	
P	G	Arithmetic gradient conversion factor to present value	$\frac{1 - (1 + ni)(1 + i)^{-n}}{i^2}$	$(P/G, i\%, N)$	

End of Period (EOP)	Accumulated BOP Value of Amount Owed (1)	Interest for Period (2)	Amount Owed or Value Accumulated End of Period (3) = (1) + (2)
0	0		P
1	P	Pi	$P + Pi = P(1 + i)^2$
2	$P(1 + i)^1$	$[P(1 + i)^1]i$	$P(1 + i)^1 + P(1 + i) = P(1 + i)^2$
3	$P(1 + i)^2$	$[P(1 + i)^2]i$	$P(1 + i)^2 + P(1 + i)^2\, i = P(1 + i)^3$
. . .	. . .	. . .	. . .

Consequently, the value for an amount P invested for n periods at i rate of interest would be

$$F_n = P(1 + i)^n$$

For example, \$100 invested now at 9% compound interest for eight years would yield

$$F_8 = \$100(1 + 0.09)^8 = 100(1.9926) = \$199.26$$

2.3. Nominal and Effective Interest Rates

For many financial feasibility studies it is appropriate to consider interest periods of one year. However, financial agreements may call for interest to be compounded or paid more frequently, say quarterly, monthly, or even daily. Interest rates associated with more frequent compounding, say of quarterly interest periods, are usually stated as "8% compounded quarterly."

The nominal interest rate, r, is expressed as an annual rate, without considering the impact of any compounding per period during the year. It is obtained by multiplying the periodic interest rate, i, by the number of periods per year, m.

$$r = im$$

For example, the nominal annual rate would be 8% with a 2% quarterly rate.

The effective annual interest rate is the true or actual annual interest rate, taking into account the monetary gain obtained by compounding the invested capital each period during the year. The effective interest rate per year, i_a, is

$$i_a = (1 + i)^m - 1 \text{ when } m < \infty$$

For example when the effective interest rate is 2% per month, the nominal interest rate per year is

$$r = (0.02)(12) = 24\%$$

and the effective interest rate per year is

$$i_a = (1 + 0.02)^{12} = 26.8\%$$

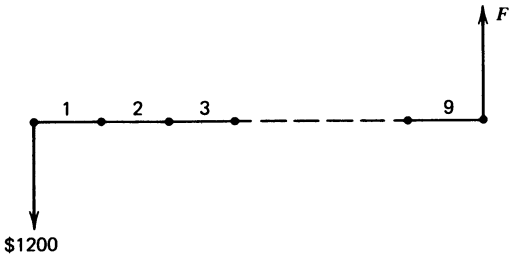
2.4. Compound Interest Factors: Discrete Cash Flow, Discrete Compounding

The compound interest factors described in this section are used for discrete cash flows compounded discretely at the end of each interest period. All of these factors can be found in Table 1, including algebraic and functional formats and the Excel functions. The numerical values for each factor for selected interest rates can be found in the tables at the end of this chapter. Complete tables can be found in the Additional Reading at the end of the chapter. The notation used in this chapter is

i = effective interest rate.
n = number of compounding periods.
A = end-of-period cash flows (or equivalent end-of-period vales) in a uniform series continuing for a specified number of periods (the letter A implies annual or an annuity).
F = future sum of money (the letter F implies future or equivalent future value).
P = present sum of money (the letter P implies present or equivalent present value).

2.4.1. Compound Amount Factor (Single Payment)

This factor finds the equivalent future worth, F, of a present investment, P, held for n periods at a rate of i interest. For example, what is the value in nine years of \$1200 invested now at 10% interest?



Algebraic format

$$\begin{aligned} F &= P(1 + i)^n \\ &= \$1200(1 + 0.10)^9 \\ &= \$1200(2.3579) \\ F &= \$2829 \end{aligned}$$

Functional format (note that throughout this chapter only the functional format will be used)

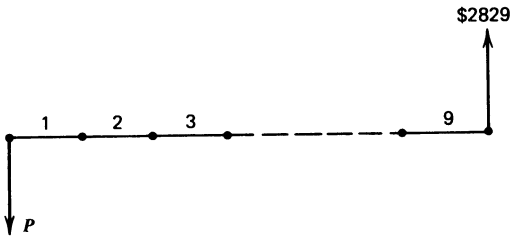
$$\begin{aligned} F &= P(F/P, i\%, N) \\ &= P(F/P, 10\%, 9) \\ &= \$1200(2.3579) \\ F &= \$2,829 \end{aligned}$$

Excel format
Highlight the location where you want the solution. Click on the f_x button on the Standard Tool Bar. Follow the Excel instructions to enter the appropriate variables.

F = FV (rate, nper, pmt, pv, type)
= FV (0.10, 9, 0, A1, 0)
pmt = no intervening payments
pv = A1, location of the present value payment of \$1,200 in the spreadsheet. Note that from the cash flow diagram, pv should be negative if F is to be positive.
Type = 0 for end of the period payments. Excel default. 0 for beginning of the period payments
F = \$2830

2.4.2. Present Worth Factor (Single Payment)

This factor finds the equivalent present value, P, of a single future cash flow, F, occurring at n periods in the future when the interest rate is $i\%$ per period. Note that this factor is the reciprocal of the compound amount factor (single payment). For example, what amount would you have to invest now to yield \$2829 in nine years if the interest rate were 10%?



$$\begin{aligned} P &= F(P/F, 10\%, 9) \\ &= \$2829\ (0.4241) \\ &= \$1200 \end{aligned}$$

Functional format

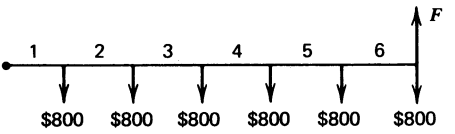
$$\begin{aligned} P &= F(P/F, \text{i}\%, N) \\ &= F(P/F, 10\%, 9) \\ &= \$2839(0.4241) \\ &= \$1200. \end{aligned}$$

Excel format

$$\begin{aligned} P &= \text{PV(rate, nper, pmt, pv, type)} \\ &= \text{FV}(0.10, 9, 0, \$1200, 0) \\ &= \$(1200) \end{aligned}$$

2.4.3. Compound Amount Factor (Uniform Series)

This factor finds the equivalent future value, F, of the accumulation of a uniform series of equal annual payments, A, occurring over n periods at i rate of interest per period. For example, what would be the future worth of an annual year-end cash flow of \$800 for six years at 12% interest per year?



$$\begin{aligned} F &= A(F/A, 12\%, 6) \\ &= \$800\ (12.2997) \\ &= \$9840 \end{aligned}$$

Functional format

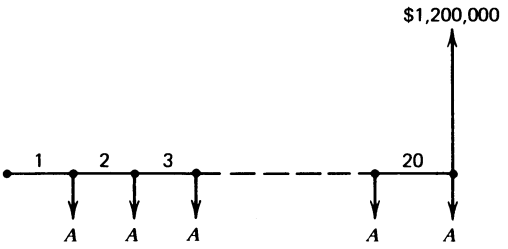
$$\begin{aligned} F &= A(F/A, \text{i}\%, N) \\ &= A(F/A, 12\%, 6) \\ &= \$800(8.1152) \\ &= \$6492 \end{aligned}$$

Excel format

$$\begin{aligned} F &= \text{FV(rate, nper, pmt, pv, type)} \\ &= \text{FV}(0.10, 6, -800, 0, 0) \\ &= \$6492 \end{aligned}$$

2.4.4. Sinking Fund Factor

This factor determines how much must be deposited each period in a uniform series, A, occurring over n periods at i rate of interest per period to yield *a specified* future sum, F. For example, if a \$1.2 million bond issue is to be retired at the end of 20 years, how much must be deposited annually into a sinking fund at 10% interest per year?



$$A = F(A/F, 7\%, 20)$$
$$= \$1{,}200{,}000\ (0.0244)$$
$$= \$29{,}280$$

Functional format

$$A = F(A/F, \text{i}\%, N)$$
$$= F(A/F, 10\%, 20)$$
$$= \$1{,}200{,}000(0.01746)$$
$$= \$20{,}952$$

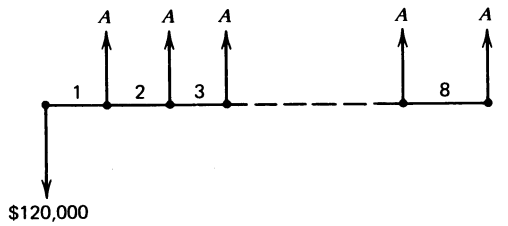
Excel format

$$A = \text{PMT(rate, nper, pv, fv, type)}$$
$$= \text{PMT(0.10, 20, 0, \$1,200,000, 0)}$$
$$= \$20{,}952$$

This factor was historically used to find the required annual payments that must be made into a "sinking fund" to retire a bond issue by a particular date.

2.4.5. Capital Recovery Factor

This factor finds an annuity, or uniform series of payments, over n periods at $i\%$ interest per period that is equivalent to a present value, P. For example, what savings in annual manufacturing costs over an eight-year period would justify the purchase of a $120,000 machine if a firm's minimum attractive rate of return (MARR) were 20%?



$$A = P(A/P, 25\%, 8)$$
$$= \$120{,}000\ (0.3004)$$
$$= \$36{,}048$$

Functional format

$$\begin{aligned} A &= P(A/P, \text{i}\%, N) \\ &= P(A/P, 20\%, 8) \\ &= \$120{,}000(0.2606) \\ &= \$31{,}272 \end{aligned}$$

Excel format

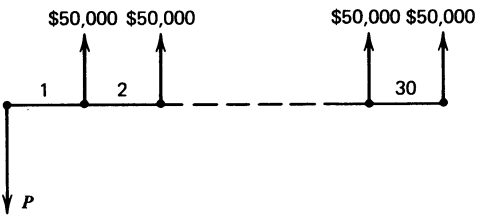
$$\begin{aligned} A &= \text{PMT(rate, nper, pv, fv, type)} \\ &= \text{PMT(0.20, 8, \$120,000, 0)} \\ &= \$31{,}273 \end{aligned}$$

This problem of finding the revenue that must be generated each period to justify a capital expenditure is one of the most common facing the engineer. The analyst should be reminded that there are two elements of the capital recovery factor. The first is the recovery of the \$120,000 original investment, and the second is the necessity of earning 20% on the capital invested over the life of the project. In this case,

$$\begin{aligned} 8 \text{ payments} \times \$31{,}273 &= \$250{,}184 \text{ cash flow} \\ &= \underline{(\$120{,}000)} \text{ return of original investment} \\ &= \$130{,}184 \text{ interest paid on invested capital} \end{aligned}$$

2.4.6. Present Worth Factor (Uniform Series)

This factor finds the equivalent present value, P, of a series of end-of-period payments, a, for n periods at $i\%$ interest per period. For example, a donor has offered to give the Hospital Authority a new wing for treatment of allergies. However, since the operation and maintenance of the existing facility requires all of the funds available under the authority's taxing limits, how much additional endowment would be required to provide \$50,000/year over the 30-year economic life of the structure. The endowment is expected to earn 10% on its invested capital.



$$\begin{aligned} P &= \$50{,}000\ (P/A, 7\%, 30) \\ &= \$50{,}000\ (12{,}409) \\ &= \$620{,}450 \end{aligned}$$

Functional format

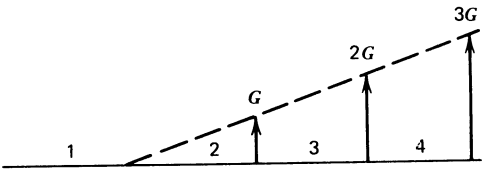
$$\begin{aligned} P &= A(P/A, i\%, N) \\ &= \$50{,}000(P/A, 10\%, 30) \\ &= \$50{,}000(9.4269) \\ &= \$471{,}345 \end{aligned}$$

Excel format

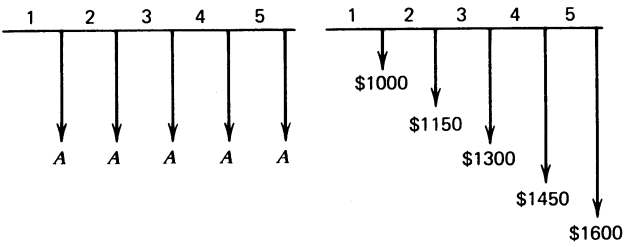
$$\begin{aligned} P &= \text{PV(rate, nper, pmt, fv, type)} \\ &= \text{PV(0.10, 30, } -50000\text{, 0, 0)} \\ &= \$471{,}345 \end{aligned}$$

2.4.7. Arithmetic Gradient Conversion Factor (to a Uniform Series)

Many times annual payments do not occur in equal amounts. Inflation causes annual increases in operating costs, and maintenance costs often increase with the age of the equipment. If a series of payments increases by an equal amount or gradient, G, each year, then a special compound interest factor can be used to reduce the gradient series to an equivalent equal-payment series. The following illustration shows a four-period gradient series that increases by G each period.



The arithmetic gradient conversion factor (to uniform series) is used when it is necessary to convert a gradient series into a uniform series of equal payments. For example, what would be the equal annual series, A, that would have the same net present value (i.e., be equivalent) at 20% interest per year to a five-year gradient series that started at \$1000 for the first year and increased \$150 every year thereafter?



$$A = A_g + G(A/G, 20\%, 5)$$
$$= \$1000 + \$150\ (1.6405)$$
$$= \$1246$$

Functional format

$$A = A_g + G(A/G, i\%, N)$$
$$= A_g + G(A/G, 20\%, 5)$$
$$= \$1000 + \$150(1.6405)$$
$$= \$1246$$

where A_g is the uniform base value of the gradient series. In the previous four-period gradient series illustration, $A_g = 0$.

Excel format

It is necessary to solve this problem in two steps

1. Net present value of the series of cash flows:

$$\text{NPV} = (\text{rate, value 1, value 2, value 3, value 4, value 5})$$
$$= (0.20, 1000, 1150, 1300, 1450, 1600)$$
$$= \$3762$$

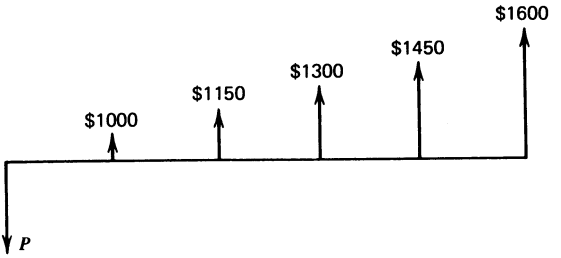
2. Equal annual cash flows equivalent to the series of cash flows:

$$A = \text{PMT (rate, nper, pv, fv, type)}$$
$$= \text{PMT (0.20, 5, 3726, 0, 0)}$$
$$= \$1246$$

Excel Spreadsheet can calculate equivalent values from a series of cash flows regardless of whether they follow a particular gradient series, such as in this example, or are just best estimates of the cash flows for each period. This is a powerful feature eclipsing the requirement of uniform cash flow series necessary in traditional engineering economy models.

2.4.8. Arithmetic Gradient Conversion Factor (to a Present Value)

This factor converts a series of cash amounts increasing by a gradient value, G, each period to an equivalent present value at $i\%$ interest per period. For example a machine will require \$1000 maintenance in the first year of its five-year operating life. Further, the cost of maintenance will increase by \$150 each year. What is the present worth of this series of maintenance costs if the firm's minimum attractive rate of return (MARR) is 20%?



$$P = A(P/A, 20\%, 5) + G(P/G, 20\%, 5)$$
$$= \$1000\ (2.9906) + \$150\ (4.9061)$$
$$= \$3727$$

Functional format

$$P = A(P/A, i\%, N) + G(P/G, i\%, N)$$
$$= A(P/A, 20\%, 5) + \$150(P/G, 20\%, 5)$$
$$= \$1000(2.9906) + \$150(4.9061)$$
$$= \$3727$$

Excel format—referring to the previous example

$$\text{NPV} = \text{(rate, value 1, value 2, value 3, value 4, value 5)}$$
$$= \text{(0.20, 1000, 1150, 1300, 1450, 1600)}$$
$$= \$3726$$

2.5. Compound Interest Factors: Discrete Cash Flow, Continuous Compounding

Monetary institutions and industrial firms alike strive to keep their funds working at all times. Techniques of cash management, such as electronic funds transfer, provide the potential to put to work cash receipts immediately. This has shortened the compounding periods to the point where the use of continuous compounding is the most appropriate cash flow model. In the concept of discrete cash flows with continuous compounding, it is assumed that the cash flows occur once per year but that compounding is continuous throughout the year. Thus, if

r = nominal interest rate per year
M = number of compounding periods per year
N = number of years

then at the end of one year one unit of principal will equal

$$\left[1 + \left(\frac{r}{n}\right)\right]^M \tag{1}$$

Letting $k = M/r$, Eq. (1) becomes

$$\left[1 + \frac{1}{k}\right]^{rk} = \left[\left(1 + \frac{1}{k}\right)^k\right]^r \tag{2}$$

The limit of $(1 + 1/k)^k$ as k approaches infinity is e. Thus, Eq. (2) can be written as e^r, and the single-payment continuous compounding amount factor at $r\%$ nominal annual interest rate for N years is e^{rN}. Also, since e^{rN} (for continuous compounding) corresponds to $(1 + i)^N$ for discrete compounding,

$$e^r = 1 + i$$

or

$$i = e^r - 1$$

By the use of this relationship, the compound interest factors for discrete cash flows compound continuously shown in Table 1 can be derived from the discrete compounding factors in Table 2.

TABLE 2 Compound Interest Factors: Discrete Cash Flow, Continuous Compounding

To Find	Given	Name of Factor	Format: Algebraic	Format: Functional
F	P	Continuous compounding Compound amount factor (single payment)	e^{rn}	$(F/P, r\%, N)$
P	F	Continuous compounding Present worth factor (single payment)	e^{-rn}	$(P/F, r\%, N)$
F	A	Continuous compounding Compound amount factor (uniform series)	$\dfrac{e^{rn} - 1}{e^r - 1}$	$(F/A, r\%, N)$
A	F	Continuous compounding Sinking fund factor	$\dfrac{e^r - 1}{e^{rn} - 1}$	$(A/F, r\%, N)$
A	P	Continuous compounding Capital recovery factor	$\dfrac{e^{rn}(e^r - 1)}{e^{rn} - 1}$	$(A/P, r\%, N)$
P	A	Continuous compounding Present worth factor (uniform series)	$\dfrac{e^{rn} - 1}{e^{rn}\,(e^r - 1)}$	$(P/A, r\%, N)$
A	G	Continuous compounding Arithmetic gradient conversion factor (to uniform series)	$\dfrac{1}{e^r - 1} - \dfrac{n}{e^{rn} - 1}$	$(A/G, r\%, N)$
P	G	Continuous compounding Arithmetic gradient conversion factor (to present value)	$\dfrac{e^{rn} - 1 - n(e^r - 1)}{e^{rn}(e^r - 1)^2}$	$(P/G, r\%, N)$
P	A_1, c	Continuous compounding Geometric gradient Conversion fctor (to present value)	$\dfrac{1 - e^{(C-r)n}}{e^r - e^c}$	$(P/A, r\%, c\%, N)$ $r \neq c$
F	A_1, c	Continuous compounding Geometric gradient Conversion factor (to uniform series)	$\dfrac{e^{rn} - e^{cn}}{e^r - e^c}$	$(F/A, r\%, c\%, N)$ $r \neq c$

2.5.1. *Continuous Compounding Compound Amount Factor (Single Payment)*

This factor is used to find the equivalent future worth, F, of a present value, P, when the interest is continuously compounded at the nominal annual rate of $r\%$. For example, consider the problem of finding the future worth in six years of \$5,000 invested now at 9% nominal interest rate compounded continuously.

$$F = Pe^{rn}$$

Functional format

$$\begin{aligned} F &= P(F/P, r\%, N) \\ &= P(F/P, 9\%, 6) \\ &= \$5000(1.7160) \\ &= \$8580 \end{aligned}$$

Note that the only difference between continuous compounding and discrete compounding in finding equivalent values of F, P, A, and G is the interest factor used (r, the nominal annual interest rate). Consequently, to solve discrete cash flow continuous compounding problems, use the same procedures illustrated for discrete compounding with the functional format.

2.5.2. *Continuous Compounding Geometric Conversion Factor (to Present Value)*

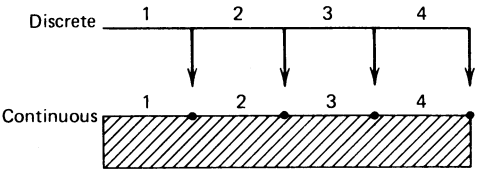
When conditions such as inflation cause a gradient that increases at a fixed percent per period, c, then geometric conversion factors should be used. For example, find the present worth of a series of costs that increase 10% per year from the initial first-year cost of \$1000 for five years when the firm's MARR is 15%.

Functional format

$$\begin{aligned} P &= A(P/A, r\%, c\%, N) \\ &= A(P/A, 15\%, 10\%, 5) \\ &= \$1000\ (3.9037) \\ &= \$3904 \end{aligned}$$

2.6. Compound Interest Factors: Continuous Uniform Cash Flows, Continuous Compounding

Many cash flows that engineers must consider can be assumed to occur continuously, such as accounts receivable, the cost savings resulting from productivity improvements, or the costs of carrying inventories. The following cash flow diagrams serve to illustrate the differences between discrete and continuous cash flows.



Again, as with discrete cash flows, to solve for one variable given another, it is only necessary to select the proper interest factor for continuous cash flow, continuous compounding. A listing of these factors can be found in Table 3.

As an example, consider the equivalent future worth of a uniform series of continuous cash flows totaling \$2000 per year for 10 years compounded continuously at 15% nominal annual rate of interest.

$$\begin{aligned} F &= \overline{\mathbf{A}}(F/\overline{\mathbf{A}}, r\%, N) \\ &= \$2000\ (F/\overline{\mathbf{A}}, 15\%, 10) \\ &= \$2000\ (23.2113) \\ &= \$46{,}423 \end{aligned}$$

TABLE 3 Compound Interest Factors: Continuous, Uniform Cash Flow, Continuous Compounding

To Find	Given	Name of Factor	Format	
			Algebraic	Functional
F	$\overline{A}$	Continuous compounding Compound amount factor (continuous, uniform payments)	$\frac{e^{rn} - 1}{r}$	$(F/\overline{A}, r\%, N)$
$\overline{A}$	F	Continuous compounding Sinking fund factor (continuous, uniform payments)	$\frac{r}{e^{rn} - 1}$	$(\overline{A}/F, r\%, N)$
$\overline{A}$	P	Continuous compounding Capital recovery factor (continuous, uniform payments)	$\frac{re^{rn}}{e^{rn} - 1}$	$(\overline{A}/P, r\%, N)$
P	$\overline{A}$	Continuous compounding Present worth factor (continuous, uniform payments)	$\frac{e^{rn} - 1}{re^{rn}}$	$(P/\overline{A}, r\%, N)$

3. COMPARING ALTERNATIVES

In comparing alternatives to meet a need or an objective, plans (1) should provide the same quality and quantity (or level) of service and (2) should provide that service over the same period of time. Competing plans should be alternative ways to accomplish the same end. Any differences in expected revenue or other benefits must be credited to the plan providing the additional services. The analysis is concerned only with the *differences* in the cash flows between the alternatives.

3.1. Present Worth

The present worth method compares all of a project's estimated expenditures to all of its estimated revenues and other benefits at a reference time called the "present" ($t = 0$). For a particular interest rate, if the present value of the revenues and other benefits exceeds the present value of the expenses, the project is considered acceptable. The present worth of alternative j with cash flows that last of n periods of time at $i\%$ interest per period is

$$\text{PW } (i)_j = \sum_{t=1}^{N} F_{jt} \, (P/F, i\%, t)$$

If two or more alternatives are being compared, the alternative with the greatest present worth or net present value is recommended. To compare alternatives fairly using the present worth method, it is necessary that all alternatives have a common retirement date.

For example, two pieces of equipment are being considered by a hospital to perform a particular service. Brand A will cost \$30,000 and will have an annual operating and maintenance cost of \$5000 over its eight-year economic life with a salvage value of \$3000. Brand B will cost \$15,000, will have an annual operating and maintenance cost of \$8000 over the first three years and \$10,000 over the last three years of its economic life, and will have a negligible salvage value. Which brand of equipment would you recommend, using the present worth comparison with an interest rate of 10%/year?

Cash Flow Item	Brand A	Brand B
First cost	\$(30,000)	\$(15,000)
Operating and maintenance		
A: = \$(5,000) $(P/A,10\%,6)$		
= \$(5,000) (4.3553)	(21,776)	
B: = \$(8,000)$(P/A,10\%,3)$		
= \$(8,000)(2.4869)	(19,895)	

Cash Flow Item	Brand A	Brand B
= \$(10,000)[(*P*/*A*,10%,3)(*P*/*F*,10%,3)]		
= \$(10,000)[(2.4869)(0.7531)]	\$(18,684)	
Salvage value		
A: = \$3,000(*P*/*F*,10%,6)		
= \$3,000(0.5645)	1,694	
B:		0
Present worth	\$(50,082)	\$(53,579)

Brand A would be the recommended alternative since the present worth of its total cost is smaller or its present worth is greater.

3.2. Annual Worth

The annual worth method converts all cash flows to an equivalent uniform series of equal annual payments. As in the present worth method, if the annual worth of the revenues is greater than the annual worth of the costs for the specified interest rate, then the project is acceptable. The annual worth of alternative j and i percent rate of interest per period, which lasts for n periods, is

$$\mathrm{AW}(i)_j = \mathrm{PW}(i)_j(A/P, i\%, N)$$

It is usually necessary to calculate the present worth of all cash flows, PW(i), first since these cash flows are rarely a uniform series that can be summed directly to find AW(i).

If two or more alternatives are being compared, the alternative with the greatest annual worth (cash receipts are positive and disbursements are negative) is the recommended alternative.

If you must compare alternatives with differing economic lives, the annual worth method is preferred when the ''repeatability assumption'' is valid for the analysis. (See Section 4 for a detailed discussion of the comparison of alternatives with unequal service lives.) If this assumption is valid, then the annual worth at the time of renewal of the asset is exactly the same as before. Therefore, you are actually comparing the annual worth of two infinite series.

Using the preceding example, the following calculations are made.

Cash Flow Item	Brand A	Brand B
First cost		
A: = \$(30,000) (*P*/*A*, 10%, 6)		
= \$(30,000)(0.2296)	\$ (6,888)	
A: = \$(15,000) (*P*/*A*, 10%, 6)		
= \$(15,000) (0.2296)		\$ (3,444)
Operating and maintenance		
A: =	\$ (5,000)	
B: = \$(8,000)(*P*/*A*, 10%, 3) (*A*/*P*, 10%, 6)		
= \$(8,000)(2.4869)(0.2296)		\$ (4,568)
= \$(10,000)[(*P*/*A*, 10%, 3)(*P*/*F*, 10%, 3) (*A*/*P*, 10%, 6)]		
= \$(10,000)[(2.4869)(0.7531)(0.2296)]		\$ (4,290)
Salvage value		
A: = \$3,000(*A*/*F*, 10%, 6)		
= \$3,000(0.1296)	389	
B:		0
Annual worth	\$(11,499)	\$(12,302)

Brand A is the recommended alternative since it has the greatest annual worth.
Note that either of these methods of comparison recommends the same alternative because they are dealing with equivalent monetary amounts.

A common method of finding the annual worth of an alternative is

$$\mathrm{AW}(i)_j = R_j - \mathrm{FC}(A/P, i\%, N) - (\mathrm{O\&M}) + V(A/F, i\%, N)$$

where R = revenues per year (uniform series)
FC = first cost
V = salvage value
O&M = operating and maintenance cost (uniform series)

This is simply an equation form of the preceding tabular format.

3.3. Future Worth

The future worth (FW) method is comparable to the present worth method except that the comparison between the project's estimated expenditures and benefits occurs at a reference time called the "future" ($t = F$). As in present worth analysis, in future worth analysis a project is acceptable at a particular interest rate if the future value of the revenues and other benefits exceeds the future value of the expenses. Likewise, the preferred alternative, given equal future benefits, would be the alternative with the lowest future costs.

For example, if the estimated future worth of a stream of revenues and other benefits from proposed materials handling equipment at the end of 10 years is \$1,200,000, should the new equipment be purchased? The firm's MARR before taxes is 25%. The initial cost would be \$125,000, and the annual maintenance cost would be \$750/year for the 10-year life.

$$\begin{aligned} \text{FW}(25\%) &= \$125{,}000\ (F/P, 25\%, 10) + \$750\ (F/A, 25\%, 10) \\ &= \$125{,}000\ (9.313) + \$750\ (33.253) \\ &= \$1{,}164{,}125 + \$25{,}940 \\ &= \$1{,}189{,}065 \end{aligned}$$

Since the future worth of the benefits exceed the future worth of the costs, the purchase of the equipment would be justified.

3.4. Rate of Return

The rate of return method finds the interest rate that equates the cash flows of receipts and disbursements. That is an alternative's rate of return is the interest rate at which the present worth of the cash flows is equal to 0.

$$0 = \sum_{t=0}^{N} F_{jt}\,(1 + i)^{-k}$$

Thus, for alternative j the rate of return is the break-even interest rate between incomes and expenses.

For example, what rate of return would be earned from a \$64,000 investment in a testing device if the savings were to be \$16,000/year for 8 years?

Functional format

$$-\$64{,}000 = \$16{,}000\ (P/A, i\%, 8)$$

Solving for (P/A) and interpolating from the interest tables

$$i = 18.62\%$$

Excel format
IRR calculates the rate of return for a series of cash flows. Assume the data were located in an Excel spreadsheet with −64,000 in cell A1 and 16,000 in each of cells A2 through A9. Going to the function button and then to the financial micros,

$$i = \text{IRR(values, guess)}$$

Enter the location of the data array, A1:A9, in the value command box. The "Formula Result" then indicates the internal rate of return,

$$i = 0.1862$$

A more complex example would consider the investment yielding the four-year stream of cash flows illustrated in the discussion on cash flow profiles. What rate of return would equate the −\$6000

disbursement at $t = 0$ with the positive cash flows of \$1500, \$2500, \$3000, and \$4000 at the end of years 1, 2, 3, and 4, respectively?

$$0 = -5000 + \$1500\ (P/F, i\%, 1) + \$2500\ (P/F, i\%, 2) + \$3000\ (P/F, i\%, 3) + \$4000\ (P/F, i\%, 4)$$

Functional format
The rate of return for this set of cash flows is approximately 34%/year and would be determined using an iterative trial-and-error solution method, guessing values of i until a zero solution is obtained.

Excel format
From an array of values of cash flow on the spreadsheet arranged from $n = 0$ to $n = 4$, enter A1: a5 into the values box.

$$i = \text{IRR(values, guess)}$$
$$i = 33.99\% \text{ by the formula}$$

The Excel solution is far faster and less error prone than an iterative method in the functional format.

3.5. Payback Period

The payback period method determines the length of time required to recover the initial investment, or first cost, at a zero rate of interest. The payback period (PP) for alternative j is

$$\text{PP}_j = \frac{\text{first cost of the project}}{\text{uniform } \textit{net} \text{ benefits per period}}$$
$$\text{PP}_j = \frac{\text{FC}_j}{R - D}$$

where R equals the equivalent uniform benefits per period and D equals the equivalent uniform costs per period. For example, find the payback period for a \$10,000 investment that will return net uniform benefits of \$1,250/year.

$$\text{PP} = \frac{\$\ 10{,}000}{\$\ 1{,}250} = 8 \text{ years}$$

The alternative with the shortest payback period would be the preferred alternative.

The payback period method is an approximate measure of preference. First, it does not consider the timing of cash flows prior to payback, ignoring the time value of money. It weighs cash flows 10 years from now the same as cash flows occurring today. Second, it ignores the duration of the cash flows. Cash flows after the payback period, such as major overhauls, are not included in the calculation. These weaknesses in the payback period method render it less desirable than the other measures of merit presented in this section.

Payback period is still widely used for comparing alternatives. Its use precludes the necessity of specifying an interest rate or performing interest rate calculations. However, its widest use is as a surrogate measure of risk. The faster the cash is returned from the project, the less the likelihood of unforeseen risks harming the outcome.

3.6. Benefit–Cost Analysis

The benefit–cost method is often utilized to determine the feasibility of public sector expenditures. The benefit–cost criterion for the jth alternative, B/C_j, can be expressed as

$$B/C_j = \frac{\sum_{t=1}^{Nt} B_{jt}\,(1 + i)^{-t}}{\sum_{t=1}^{tN} C_{jt}\,(1 + i)^{-t}}$$

where B_{jt} equals the public benefits accruing to alternative project j during year t and C_{jt} equals the governmental costs associated with the alternative project j during year t. A project is deemed to be acceptable if $B/C_j \geq 1.0$, that is, if the project's benefits equal or exceed its costs.

The calculation of the benefit–cost ratio is not different in principle from the other methods of comparing alternatives. However, determining the monetary value of the costs and benefits associated with projects in the public sector is difficult. This difficulty arises because of the often subjective nature of the costs and benefits and because they often occur far into the future. A detailed discussion of the problems of defining public costs and benefits and of their use in calculating the benefit–cost ratio can be found in other sources, such as Smith (1987) or White et al. (1998).

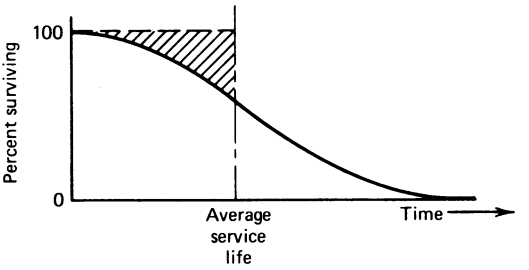
An example of the use of the benefit–cost method is as follows: A government bridge project requires an initial investment of $10 million and operation and maintenance costs of $250,000/year for the 20-year life of the project. The annual user benefits of $1,950,000/year are estimated to arise from savings in travel distance and time. At an annual interest rate of 7%, the benefit–cost ratio is

$$
\begin{aligned}
B/C &= \frac{\$1{,}950{,}000\ (\text{P/A},7\%,20)}{\$10{,}000{,}000 + \$250{,}000\ (\text{P/A},7\%,20)} \\
&= \frac{\$1{,}950{,}000\ (10.5940)}{\$10{,}000{,}000 + \$250{,}000\ (10.5940)} \\
&= \frac{\$20{,}658{,}300}{\$10{,}000{,}000 + \$2{,}648{,}500} \\
&= 1.63
\end{aligned}
$$

Thus, the project benefits would exceed its costs.

4. NONUNIFORM SERVICE LIVES

Engineers are often required to purchase or install a number of items at one time in order to provide a service or manufacture a product. The group of such items is called a vintage group. For example, you may install 2000 telephone poles or 50 automobiles. Assuming that all these items must be in working order in order to provide the required level of service, whenever an item fails, it must be replaced. Thus, if 10 poles are destroyed or fail during the first year of service, they must be replace in order to maintain the desired level of service. The result of having to replace items to maintain the desired level of service means that the true cost will always be higher than the estimated by conventional interest factors. Therefore, the error is always one of *underestimation*. The following figure illustrates the effect of assuming the rectangular distribution as opposed to a survival distribution, representing the true failure rate of the items in question. The shaded portion of the distribution indicates the items that must be replaced to maintain a given level of service.



It is the cost of these replacement items that provides the error of underestimation. See Smith (1987) for details on how to correct for this error in group properties that is due to nonuniform service lives.

5. PERPETUITIES AND CAPITALIZED COSTS

In some major public works projects, such as dams, locks, or bridges, the life of the investment is considered to be infinite. In the case of an infinite life asset, the amount needed to construct or acquire that asset initially plus the amount to provide for the perpetual maintenance and replacement of that asset is referred to as the capitalized cost. A ''perpetuity'' is a uniform series of payments that continues indefinitely, such as one would find from the conversion of a capitalized cost to an annuity.

For example, what would be the capitalized cost of an irrigation dam at a 5% rate of interest per year if the initial construction cost were $5 million/year for three years and there was a $50,000 maintenance cost/year forever after the completion of the construction?

$$
\begin{aligned}
P &= \$5{,}000{,}000\ (P/A,\ 5\%,\ 3) + \$50{,}000\ (P/A,\ 5\%,\ \infty)\ (P/F,\ 5\%,\ 3) \\
&= \$5{,}000{,}000\ (2.7233) + \$50{,}000\ (20.00)(0.8638) \\
&= \$13{,}616{,}500 + \$863{,}800 \\
&= \$14{,}480{,}300
\end{aligned}
$$

Note that in this example the present worth factor of the annuity is the reciprocal of the interest rate.

$$(P/A,\ i\%,\ \infty) = 1/i$$

CHAPTER 91

Economic Risk Analysis*

G. A. FLEISCHER
University of Southern California

*Portions of this chapter are adopted substantially unchanged from the *Handbook of Industrial Engineering,* 2nd ed., Chapter 52. That material, in turn, was based in large part on the *Handbook of Industrial Engineering,* 1st ed., Chapter 9.5, by James R. Buck and Jose M. Tanchoco, as well as other material adopted, by permission of the publisher, from G. A. Fleischer, *Engineering Economy,* Chapter 8, PWS-Kent Publishing Company, Boston, 1984.

1. INTRODUCTION

Various methods of analysis for economic justification are shown in Chapter 90 based on the assumption that all of the component cash flows for the proposed investment are known and certain. However, in most cases the amount and timing of these cash flows are estimated, and uncertainties exist in the estimation process. Furthermore, there is usually more uncertainty with some component cash flows than others, and some of these component flows affect the economic criteria more than others. Thus, additional methodologies and concepts are needed for economic analysis when explicit information on the effects of uncertainties in the timing and amounts of the cash flows is important. These methodologies and concepts are the focus of this chapter.

Numerous factors contribute to the uncertainties in the estimates of the amount and timing of component cash flows. Delivery or construction delays, unexpected bottlenecks in new projects, inflationary or recessionary pressures, labor negotiations, and problems in R&D are but a few examples of changes that can and do occur to alter the amounts and timing of disbursements and receipts of monies. Although these possibilities are usually recognized during the early planning phases of a project, the actual cash flows are uncertain, and there is a risk associated with the resulting project's present worth, benefit–cost ratio, or other measure of economic merit being used. Since this economic risk is as important to the decision maker as the other aspects of economic analysis, explicit information regarding the risk should be developed as part of the analysis. Approaches to this form of analysis and some of the relevant techniques are described in this chapter.

A variety of measures have been proposed for dealing with a noncertain operating environment, that is, where the relevant parameters of the analytical model cannot be assumed with certainty. The relevant literature is very extensive, and an encyclopedic treatment is beyond the scope of this chapter. Our discussion will be limited, therefore, to a limited number of concepts related for their popularity among practitioners and because they are representative of the spectrum of possible approaches to this issue. We begin with *sensitivity analysis,* that technique which, surveys show, appears to be most commonly used in industry.

2. SENSITIVITY ANALYSIS

Sensitivity analysis is the process whereby one or more system input variables are changed and corresponding changes in the system output, or figure of merit, are observed. If a decision is changed as a certain input is varied over a reasonable range of possible values, the decision is said to be *sensitive* to that input; otherwise it is *insensitive.*

The term *break-even analysis* is often used to express the same concept for a single input variable. Here, the value of the input variable at which the decision is changed is determined. If the break-even point lies within the range of expected values, the decision is said to be sensitive to that point. Thus, sensitivity and the break-even point are directly related.

2.1. Numerical Example: Certainty Analysis

A manufacturing firm is considering the introduction of a new product to be produced and sold over a 15-year period. The initial cost of capital facilities is $100,000; the anticipated net salvage value at the end of 15 years is $20,000. It is expected that 7000 units will be produced each year at a cost

of \$10 per unit and sold at \$12 per unit. The firm's minimum attractive rate of return (MARR) is 10% per year.

The anticipated "profitability" of this proposed investment can be measured by present worth (PW) as follows.

$$\text{PW} = Q(r - c)(P/A, i, N) - P + S(P/F, i, N) \tag{1}$$

where Q = quantity sold per year
r = revenue per unit
c = cost per unit
P = initial cost of capital facilities
S = net salvage value of capital facilities
N = project life, in years
i = MARR, the discount rate per year

[Note the factor $(P/A, i, N)$ is the *functional* form of the uniform series present worth factor, the *algebraic* form of which is $((1 + i)^N - 1)/(i(1 + i)^N)$. Similarly, the functional form of the single payment present worth factor, $(P/F, i, N)$, represents the algebraic form $(1 + i)^{-N}$. See Chapter 90 for additional discussion.]

Assuming the "certainty estimates" for these seven parameters as described in the preceding paragraph, the solution is

$$\begin{aligned}\text{PW} &= 7000(\$12 - \$10)(P/A, 10\%, 15) - \$100{,}000 + \$20{,}000(P/F, 10\%, 15)\\ &= \$14{,}000(7.606) - \$100{,}000 + \$20{,}000(0.2394)\\ &= \$11{,}273\end{aligned}$$

Since the PW is positive, we conclude that the proposal appears to be economically attractive. This result, of course, is based on the presumption that all of the parameter values assumed for the analysis will in fact occur as anticipated.

2.2. Classical Sensitivity Analysis: Single Variable

2.2.1. Algebraic Solution

Suppose there is some reason to question the validity of the assumption concerning the number of units produced and sold annually. Additional investigation, for example, may suggest that the "certainty estimate" of 7,000 units per year is questionable; it now appears that this parameter value could occur anywhere over the range of 6,000 to 7,500 units. With this new information the resulting range of values for the present worth is

$$\begin{aligned}\text{Min PW} &= 6000(\$2)(7.606) - \$95{,}212 = -\$3{,}940\\ \text{Max PW} &= 7500(\$2)(7.606) - \$95{,}212 = \$18{,}878\end{aligned}$$

The break-even point can be determined by determining that value of $Q = Q_0$ such that PW = 0:

$$\text{PW} \equiv 0 = Q_0(\$2)(7.606) - \$95{,}212$$

Solving,

$$Q_0 = \$95{,}212/\$15.212 = 6259 \text{ units}$$

Since the break-even point lies within the range $(6000 < 6259 < 7500)$, the decision *is* sensitive to the estimate for Q.

2.2.2. Graphical Presentation

Sensitivity analyses are usually presented in graphical format. Indeed, it is this "power of pictures" that probably accounts for its widespread popularity. The graphical portrayal of sensitivity of PW to the variable Q in our example is illustrated in Figure 1. The linear function in the figure is the graph of

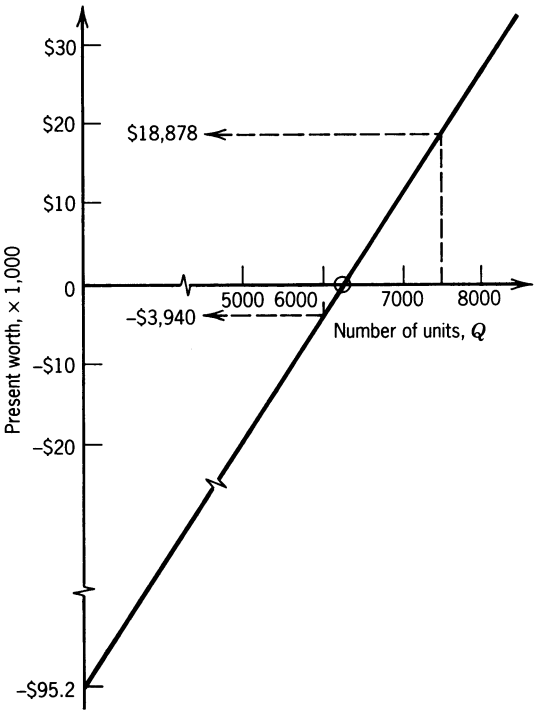

Figure 1 Present Worth as a Function of Number of Units Produced and Sold Annually. (Break-even = 6259 units)

$$\text{PW} = \$15.212Q - \$95{,}212 \qquad 0 \le Q \le 9{,}000$$

Note the break-even point at $Q_0 = 6259$. Also note that the range for Q is highlighted at $Q(\text{min}) = 6000$ and $Q(\text{max}) = 7500$.

2.2.3. Percent Deviation Graph

An alternative approach is a plot of the figure of merit—here, the present worth (PW)—as a function of the *percent deviation* of the variable of interest In the example let p_Q = the percent deviation of Q such that

$$\begin{aligned}\text{PW} &= \$15.212(7000)(1 - p_Q) - \$95{,}212 \\ &= \$11{,}272 - \$106{,}485p_Q \end{aligned} \tag{2}$$

The function is graphed in Figure 2. Also shown in the figure are similar graphs for percent deviation for revenue per unit (p_r), cost per unit (p_c), and the number of units produced and sold annually (p_Q).

Although percent deviation graphs for one or more variables may be shown in a single illustration, it should be emphasized that sensitivity to only one variable at a time is being examined. The graph of PW as a function of p_Q, for example, is based on the assumptions that *all* other variables (r, c, P, S, N, i) are held constant at their "certainty estimates." When sensitivity to p_r is being examined, we set $Q = 7000$. And so on.

One notable advantage of the percent deviation graph is that it makes apparent the relative degree of sensitivity for the various parameters. The greater the slope (steepness of the function) the more likely is the decision to be sensitive to that parameter, that is, the break-even point for percent deviation will be relatively small. In Figure 2 it is apparent that the decision is somewhat more sensitive to per unit revenue (r) and cost (c) and is relatively insensitive to number of years of service (N). This conclusion may be misleading, however, because it is based on the presumption of equal

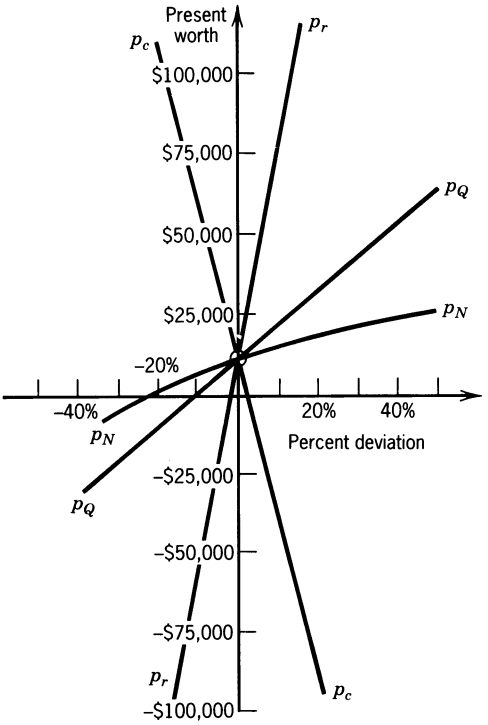

Figure 2 Present Worth as Function of Percent Deviation in Estimates for r, c, Q, and N.

likelihoods of deviation for the various parameters. To illustrate, we found that the break-even percent deviations are about -23% for p_N and -11% for p_Q. But suppose that there is evidence to suggest that:

Parameter	Certainty Estimate	Range	Deviation
Quantity	7000 units	6000 to 7500	-14 to $+7\%$
Life	15 years	l0 to 18	-33 to $+20\%$

Thus, it would appear that the decision maker would be well advised to give careful attention to the assumption concerning service life (N) as well as quantity produced (Q). The point here is that the *range* of interest for percent deviation may be different for different parameters.

2.3. Sensitivity to Two Parameters Considered Simultaneously

Suppose that our decision maker in this example is concerned about the sensitivity to the revenue per unit (r) as well as the number of units produced and sold (Q). Considering these two parameters, now variables, simultaneously,

$$\text{PW} = Q(r - \$10)(7.606) - \$95{,}212 \tag{3}$$

As before, assume $6000 \leq Q \leq 7500$, and assume further that $\$11.25 \leq r \leq \$12.50$.

One approach to sensitivity analysis for two variables considered simultaneously is to construct a three-dimensional graph with the x and y axes representing the two variables and the z axis serving as the figure of merit. The combined function is now a *surface* and we now have a break-even *line.* But three-dimensional graphs are difficult to construct and generally harder to interpret. A useful

alternative is a variant of the two-dimensional graph as illustrated in Figure 3. One of the two variables is represented along the x axis. The second variable is reflected by a family of curves, specifically, curves based on the maximum and minimum values of the variable.

The two functions plotted in Figure 3 are

$$\text{PW} = Q(\$12.50 - \$10)(7.606) - \$95{,}212$$

and

$$\text{PW} = Q(\$11.25 - \$10)(7.606) - \$95{,}212$$

These represent the upper and lower bounds of the r variable, respectively. Two additional vertical lines are drawn at the lower and upper bounds of the Q variable, at 6000 and 7500 units. The polygon thus formed contains all possible combinations of r and Q, and the maximum and minimum values of the figure of merit (PW) can be readily determined. The decision is insensitive if the polygon lies either wholly above the x axis (PW = \$0) or wholly below the x axis.

One problem in the interpretation of sensitivity graphs can be illustrated by this numerical example. It would appear from Figure 3 that, since the area of the polygon lying above the x axis is roughly the same as the area lying below the line, the likelihood of making money on this project (PW > \$0) is about the same as the likelihood of losing money. Implicit in this conclusion is the assumption that all points in the polygon are equally probable. But this is not necessarily the case. Indeed, it would be reasonable to assume that there is an inverse relationship between price per unit and quantity sold, so that Q would decrease as r increases. This dependency is not reflected in the graph.

The simultaneous consideration of sensitivity to two variables can also be displayed in a percent deviation format. In Figure 4, the percent deviations for each of the variables are shown on the x and y axes. The function plotted is

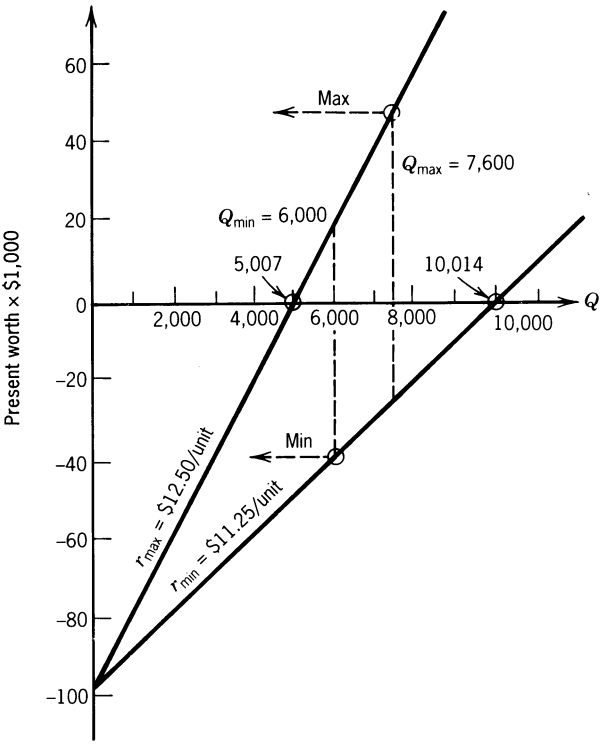

Figure 3 Present Worth as a Function of Units Produced (Q) and Revenue per Unit (r).

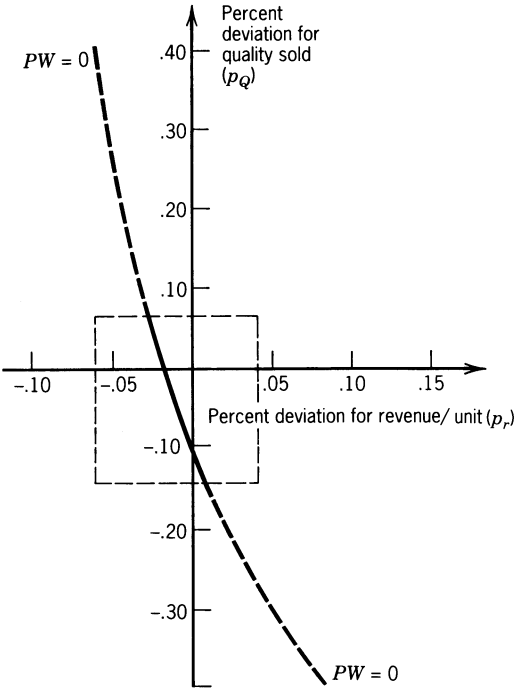

Figure 4 Percent Deviation Graph for Two Variables: Quantity Sold and Revenue per Unit.

$$\text{PW} = 7000(1 + p_Q)[\$12(1 + p_r) - \$10](7.606) - \$95{,}212 = 0$$

This is an *indifference curve,* the locus of all points (p_r, p_Q) such that PW = \$0, which is in fact the *break-even line.* The solid portion of the line represents the set of possible outcomes: $(-6\% \leq p_r \leq +4\%)$ and $(-14\% \leq p_Q \leq +7\%)$.

2.4. Sensitivity to More Than Two Parameters

Using the previous example, suppose that, in addition to uncertainty about quantity sold (Q) and revenue per unit (r), there is also uncertainty as to the cost per unit (c). Suppose that the following range of values is possible:

Parameter	Minimum	Most likely	Maximum
Quantity	6000	7000	7500
Revenue/unit	\$11.25	\$12.00	\$12.50
Cost/unit	\$ 9.00	\$10.00	\$11.00

As mentioned previously, a percent deviation graph, as in Figure 2, permits the plotting of the figure of merit (PW) as a function of the percent deviation from the most likely value for any number of parameters. However, the *interactive* effects of the parameter are ignored.

It is possible, of course, to reduce the original problem to a series for two-dimensional graphs. Here, for example, consider: (1) PW as a function of quantity, assuming C = \$9.00, and a family of curves for r = \$11.25 and \$12.50; and (2) PW as a function of quantity assuming C = \$11.00, and a family of curves for r = \$11.25 and \$12.50. This approach suffers from two defects. First, although a series of smaller problems is solved, we are not testing for the sensitivity of *all* parameters *simultaneously.* Second, the number of graphs required grows exponentially as the number of uncertain parameters increases arithmetically.

A second approach is based on the *a fortiori* (''strength of the argument'') principle. If it can be shown that a certain course of action is indicated regardless of the input assumptions, then it has been proven, *a fortiori,* that there can be no other possible outcome. To illustrate, the following is a computation of both the minimum and maximum possible values for PW, given the ranges for the input assumptions:

$$\text{Min PW} = 6000(\$11.25 - \$11.00)(7.606) - \$95{,}212 = -\$83{,}803$$
$$\text{Max PW} = 7500(\$12.50 - \$9.00)(7.606) - \$95{,}212 = \$104{,}446$$

If both present worths had been negative, we would have proven, *a fortiori,* that the proposal should be rejected on economic grounds. Conversely, if both PW values had been positive, an ''accept'' decision would have been indicated.

Unfortunately, this test of extreme values rarely yields a clear result, and the *a fortiori* argument cannot be used. Nevertheless, analysts would be well advised to try this approach before proceeding further. The calculations can be completed relatively easily, and the few cases for which a clear signal *is* indicated more than justify the time involved.

3. RISK ANALYSIS

3.1. Alternative Risk Measures

A number of different statistics have been proposed for the measure of ''riskiness'' of proposed plans, programs, and projects. Perhaps the most widely used measure is the *variance* (*or standard deviation*) *of the prospective return,* where return is generally the present worth, internal rate of return, and so forth. The variance (σ^2) of the distribution for a continuous random variable x is given by

$$\sigma^2 = \int_{-\infty}^{\infty} (x - \mu)^2 f(x)dx \tag{4}$$

Large variance signifies large risk; relatively small variance indicates relatively small risk. In general, everything else being equal, risk is to be minimized.

An alternative view is that the *semivariance* is a preferred statistic as it focuses on the variability in negative return, that is, on the reduction of losses. The semivariance (S_h) of a distribution for a random variable X is given by

$$S_h = \int_{-\infty}^{h} (h - x)^2 f(x)dx \tag{5}$$

Still another measure of risk is the *probability of loss,* a statistic that measures the probability that the return will lie below some predetermined critical level, h. The probability of loss (L) for a continuous random variable is given by

$$L = \int_{-\infty}^{h} f(x)dx \tag{6}$$

Limited space precludes a full discussion of these (and other) risk measures. Therefore, in the remainder of this section we will limit our remarks to the variance, a statistic that has proven most popular in use as well as in the literature of engineering economy.

3.2. Determining the Probability Distribution for Present Worth

3.2.1. Expected Present Worth

Consider an uncertain stream of cash flows, A_j, occurring at the end of periods 1, 2, . . . j, . . . , N. If the project life, N, the discount rate, i, and the amounts and timing of the cash flows are known with certainty, then

$$\text{PW} = \sum_{j=0}^{N} A_j(1 + i)^{-j} \tag{7}$$

Now suppose that the cash flows are random variables with associated probability or density functions $f(A_j)$. The PW is a function of random variables, so it is itself a random variable with mean, μ_p,

$$\mu_p = \text{Exp[PW]} = \sum_{j=0}^{N} \mu_j(1 + i)^{-j} \tag{8}$$

where $\mu_j = \text{Exp}[A_j]$ for $j = 0, 1, \ldots, N$.

3.2.2. Variance of Present Worth

The variance of the PW distribution depends upon the degree of correlation between the individual cash flows. In general

$$\sigma_p^2 = \text{Var[PW]} = \sum_{j=0}^{N} \sigma_j^2(1 + i)^{-2j} + 2 \sum_{j=0}^{N-1} \sum_{k=j+1}^{N} \rho_{jk}\sigma_j\sigma_k(1 + i)^{j+k} \tag{9}$$

where ρ_{jk} is the correlation coefficient between cash flows, A_j and A_k and σ_j and σ_k are the standard deviations of the distribution of A_j and A_k, respectively. This formulation is intractable in practice because of the difficulty, if not impossibility, in estimating the correlation coefficients. However, formulations of the variance under the two extreme cases—independent cash flows ($\rho_{jk} = 0$) and perfectly correlated cash flows ($\rho_{jk} = 1$)—is helpful, as will be shown.

3.2.2.1. Independent Cash Flows If there is no causative or consequential relationship between the cash flows, they are said to be independent and

$$\sigma_p^2 = \sum_{j=0}^{N} \sigma_j^2(1 + i)^{-2j} \tag{10}$$

A numerical example, summarized in Table 1, illustrates Eqs. (9) and (10). This is a five-period project life with means (μ_j) and variances (σ_j^2) of the cash flows as shown. The results: $\mu_p = \$69.44$ and $\sigma_p = \sqrt{\$802.9325} = \$28.34$.

3.2.2.2. Perfectly Correlated Cash Flows Cash flows in any two periods, x and y, are perfectly correlated if, given that A_x is the actual value of $\mu_x + d\sigma_x$, then

$$A_y = \mu_y + d\sigma_y$$

In words, if random factors cause A_x to deviate from its mean value by d standard deviations, the same factors will cause A_y to deviate from its mean in the same direction by d standard deviations. Under these conditions

$$\sigma_p = \sum_{j=0}^{N} \sigma_j(1 + i)^{-j} \tag{11}$$

To illustrate, consider the example summarized in Table 2. Assuming a 10% discount rate, the expected value of the PW of the five cash flows is \$625.92, and the standard deviation of the PW is \$75.82. Note that the expected value of PW is given by Eq. (8) and is independent of the degree of correlation.

TABLE 1 Numerical Example: Determining the Mean and Variance of PW Given Probabilistic Cash Flows and 10% Discount Rate—Independent Cash Flows

End of Period j	Cash Flow Estimates: Mean μ_j	Cash Flow Estimates: Variance σ_j^2		Present Worth at 10%: $\mu^j(1.10)^{-j}$	Present Worth at 10%: $\sigma_j^2(1.10)^{-2j}$
0	−\$400	\$\$ 0^2		−\$400.00	\$\$ 0.0000
1	100	10^2		90.91	82.6446

5	100	20^2		62.09	154.2173
			Totals	\$ 69.44	\$\$802.9325

TABLE 2 Numerical Example: Determining the Mean and Standard Deviation of PW Given Probabilistic Cash Flows and 10% Discount Rate—Perfectly Correlated Cash Flows

End of Period j	Cash Flows: Mean μ_j	Cash Flows: Standard Deviation σ_j		Present Worth at 10%: $\mu_j(1.0)^{-j}$	Present Worth at 10%: $\sigma_j(1.10)^{-j}$
1	\$100	20		\$ 90.91	\$18.18
2	150	20		123.97	16.53
3	200	20		150.26	15.03
4	200	20		136.60	13.66
5	200	20		124.18	12.42
			Totals	\$625.92	\$75.82

3.2.2.3. Combining Independent and Perfectly Correlated Cash Flows Suppose that it is feasible, in a given problem situation, to identify two types of cash flows: those that are statistically independent and those that are perfectly correlated. In this case the variance of the PW distribution is the sum of (a) the sum of the variances of the independent cash flows, discounted, and (b) the sum of the variances of each of the subsets of perfectly correlated cash flows, where the variance of each subset is the square of the sum of the standard deviations of the cash flows in that subset. That is,

$$\sigma_p^2 = \sum_{j=0}^{N} \sigma_j^2(1 + i)^{-2j} + \sum_{k-1}^{M} \left\{ \sum_{j=0}^{N} [\sigma_{jk}(1 + i)^{-j}] \right\}^2 \tag{12}$$

where σ_j^2 = variance of the distribution of the independent A_j's
σ_{jk} = standard deviation of the distribution of the perfect correlated cash flows in subset k, $k = 1, 2, \ldots, M$

Returning to the previous example (Table 2), suppose that there is a cash flow A_0 such that $\mu_0 = -\$500$ and $\sigma_0 = \$10$, and A_0 is independent of the positive cash flows in periods 1 through 5. All cash flows for the proposal are now completely specified, and

$$\mu_p = \sum_{j=0}^{5} \mu_j(1.10)^{-j} = -\$500 + \$625.93 = \$125.93$$

$$\sigma_p = \$10 + \$75.82 = \$85.82$$

Note in this example that $M = 1$; there is only one subset of perfectly correlated cash flows.

3.3. Cash Flows with Uncertain Timing

3.3.1. Single Cash Flow

Consider a single (impulse) cash flow, F, occurring at time t. If both t and F are deterministic, and assuming that interest is compounded/discounted continuously at nominal rate r per period, then the present worth is given by

$$\text{PW} = Fe^{-n} \tag{13}$$

If the timing, t, is a random variable with probability density function $f(t)$, then

$$\mu_p = \text{Exp[PW]} = F \int_0^{\infty} f(t)e^{-n}\, dt \tag{14}$$

and

$$\sigma_p^2 = \text{Var[PW]} = F^2 \int_0^{\infty} f(t)e^{-n}\, dt - \{F[\text{Exp}(e^{-n})]\}^2 \tag{15}$$

When the cash flow, F, is also a random variable with known μ_F and σ_F^2, then the PW is the product

of two random variables. Determination of μ_p and σ_p^2 results from a straightforward application of probability theory with respect to products of random variables.

3.3.2. Uncertain Initiation and Duration

Consider a uniform continuous cash flow, A, which begins at time m and continues for an uncertain duration t. Assume that m and t are statistically independent random variables with known probability functions $f(m)$ and $f(t)$. It may be shown that

$$\mu_p = (\overline{A}/r)[\text{Exp}(e^{-rm})][1 - \text{Exp}(e^{-n})]$$

and

$$\sigma_p^2 = (\overline{A}/r)^2[\text{Var}(e^{-rm}) + \text{Var}(e^{-r(m+t)})] \tag{16}$$

To illustrate, consider a uniform cash flow of \$1000 per year beginning at some uncertain time m and continuing for a duration of t years. The delay to initiation is *uniformly* distributed between 6 months and 1 year. The project duration is *gamma* distributed with mean of 3 years and standard deviation of 1 year; the parameters of the gamma distribution yielding these statistics are $a = 3$ and $b = 9$. The nominal interest rate is 10% compounded continuously. It is assumed that the initiation time and project duration are independent random variables. Our problem is to determine the equivalent present value of these cash flows. (This problem is taken from Park and Sharp-Bette (1990, p. 411)

This problem may be solved by use of integral calculus in connection with Eq. (16). However, it may be instructive to use *Laplace transform* methodology to evaluate μ_p and σ_p^2. If a function $f(x)$ is considered to be piecewise continuous, then the Laplace transform of the function, written $\mathcal{L}\{f(x)\}$, is defined as a function $F(s)$ of the variable r by the integral

$$\mathcal{L}\{f(x)\} = F(r) = \int_0^\infty f(x)e^{-rx}\,dx = \text{Exp}(e^{-rx})$$

over the range of values of r for which the integral exists. For the *uniform* distribution

$$F(x) = \frac{e^{-ra} - e^{-rb}}{r(b - a)}$$

and for the *gamma* distribution

$$F(r) = \left[1 + \left(\frac{r}{a}\right)\right]^{-b}$$

Returning to our example, for the uniformly distributed delay time, m,

$$\text{Exp}(e^{-rm}) = \mathcal{L}(r)_m = \frac{e^{-0.10(0.5)} - e^{-0.10(1.0)}}{0.10(1.0 - 0.5)} = 0.92784$$

and

$$\begin{aligned}\text{Var}(e^{-rm}) &= \mathcal{L}(2r) - \mathcal{L}(r)^2 \\ &= \frac{e^{-0.2(0.5)} - e^{-0.2(1.0)}}{0.2(1.0 - 0.5)} - (0.92784)^2 \\ &= 0.86107 - 0.86089 = 0.00018\end{aligned}$$

Similarly, considering the gamma-distributed random variable, t,

$$\text{Exp}(e^{-n}) = \mathcal{L}(r)_t = [1 + (0.10/3)]^{-9} = 0.74445$$

and

$$\begin{aligned}\text{Var}(e^{-n}) &= [1 + (0.20/3)]^{-9} - (0.74445)^2 \\ &= 0.559425 - 0.554206 = 0.00522\end{aligned}$$

Next, we must determine

$$\begin{aligned}\mathrm{Var}(e^{-r(m+t)}) &= \mathrm{Var}(e^{-rm}e^{-rt})\\ &= \mathscr{E}(r)_m^2[\mathrm{Var}(e^{-n}) + \mathscr{E}(r)_t^2[\mathrm{Var}(e^{-rm})] + [\mathrm{Var}(e^{-rm})][\mathrm{Var}(e^{-n})]\\ &= (0.92784)^2(0.00522) + (0.74445)^2(0.00018) + (0.0018)(0.00522)\\ &= 0.00459\end{aligned}$$

Finally, using Eq. (16),

$$\begin{aligned}\mu_p &= (\$1{,}000/0.10)(0.92784)(1 - 0.74455)\\ &= \$2{,}371\end{aligned}$$

and

$$\begin{aligned}\sigma_p^2 &= (\$1{,}000/0.10)^2(0.00018 + 0.00459)\\ &= \$477{,}000\end{aligned}$$

or

$$\sigma_p = \$691$$

3.4. Uncertain Project Life and Uncertain Cash Flow

Consider the case in which the amounts and timing of cash flows are random variables with known means and variances, and the project life, also, is a random variable, N. Here, N must be integer valued and, of course, must be positive. If cash flows are statistically independent,

$$\mu_p = \mathrm{Exp}[\mathrm{PW}] = \sum_{N=1}^{\infty}\left[\sum_{j=1}^{N}\mu_j(1+i)^{-j}\right]p_N \tag{17}$$

where p_N is the probability mass function for N. Moreover,

$$\sigma_p^2 = \mathrm{Var}[\mathrm{PW}] = \sum_{k=1}^{N}\left\{\sum_{j=0}^{k}\mathrm{Var}(X_j) + \left[\sum_{j=0}^{k}\mathrm{Exp}(x_j)\right]^2\right\}P_k - \mu_p^2 \tag{18}$$

where

$$\mathrm{Exp}(X_j) = \mu_j(1+i)^{-j} \tag{19a}$$

$$\mathrm{Var}(X_j) = \sigma_j^2(1+i)^{-2j} \tag{19b}$$

To illustrate, consider the problem summarized in Table 3. There are three risky, independent, end-of-year cash flows; the means and variances of their respective probability functions are given in columns (2) and (3) of Table 3. Project life, N, is also a random variable, with probability mass function as shown in columns (6) and (7) of the table. A 10% discount rate is assumed. Determination of the expected present worth, μ_p, based on Eq. 17, is summarized in the table. Here, $\mu_p = -\$82.64$. The variance of present worth, σ_p^2, based on Eqs. 18 and 19, may be shown to be

$$\sigma_p^2 = \$121{,}687 \qquad \text{or} \qquad \sigma_p = \$349$$

3.5. Other Models

There are a variety of other analytical models for assessing risky investments. The randomness (''riskiness'') of cash flow amounts, timing, project life, and discount rate are considered singly and/or in combination. The complexity of the analytical procedure is roughly a function of the number of variables considered as well as the assumptions concerning mutual independence between random variables. In almost all cases the *mean* and *variance* of the distribution of the figure of merit are of primary concern. In some instances it is also possible to approximate the statistical *distribution* as well. Space limitations preclude an exhaustive review of the extant literature. For further readings consult the bibliography at the end of this chapter.

3.6. Analysis Based on the Probability Distribution for Present Worth

As before, the mean and variance of the probability distribution for the present worth statistic (PW) are denoted by μ_p and σ_p^2, respectively. These are measures of central tendency and variability, or

TABLE 3 Numerical Example: Both Cash Flows (A_j) and Project Life (N) Are Random Variables

End of Year j (1)	Mean μ_j (2)	Variance σ_j^2 (3)	Present Worth at 10% $\mu_j(1.10)^{-j}$ (4)	Present Worth at 10% $\sigma_j^2(1.10)^{-2j}$ (5)
0	−$1,000	$ 50^2	−$1,000.00	$ 2,500.00
1	500	100^2	454.55	8,264.46
2	800	200^2	661.16	27,320.54

Project Life N (6)	Probability p_N (7)	$\sum_{j=0}^{N}\mu_j(1.10)^{-j}$ (8)	$p_N\sum_{j=0}^{N}\mu_j(1.10)^{-j}$ (9)
0	0.00	−$1,000.00	$ 0
1	0.30	− 545.45	− 163.64
2	0.70	115.71	81.00
Totals	1.00		−$ 82.64

From Park and Sharp-Bette 1990, p. 416.

dispersion, of the PW distribution. Under certain conditions the underlying probability distribution may be fully or partially characterized. When such is the case, it may be useful to describe the riskiness of the figure of merit in terms other than the variance of the distribution; for example, the probability that the PW will exceed some specified critical level.

3.6.1. Discrete Distribution for Present Worth

Consider a two-period problem as summarized in Figure 5. A cash outlay of $100 occurs at the start of period 1 ($j = 0$). There are two possible discrete cash flows at end of period 1: $A_1 = \$50$ with probability 0.5 or $A_1 = \$70$ with probability 0.5. *If* $A_1 = \$50$, there are two possibilities for the cash flow at end of period 2: either $A_2 = \$60$ with probability 0.3 or $A_2 = \$80$ with probability 0.7. *If* $A_1 = \$70$, then either $A_2 = \$44$ with probability 0.4 or $A_2 = \$90$ with probability 0.6. The diagram of the possible outcomes shown in Figure 5 is sometimes known as a *probability tree.*

There are four possible present worths (outcomes), each with an associated joint probability. Assuming a 10% discount rate:

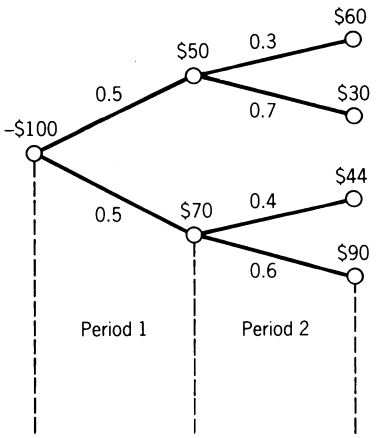

Figure 5 Cash Rows and Their Probabilities. Example problem from Park and Sharpe-Bette 1990, p. 419.

Outcome	A_0	A_1	A_2	$\sum_{j=0}^{2} A_j(1.10)^{-j}$	Joint Probability
1	−$100	$50	$60	−$4.96	0.5 × 0.3 = 0.15
2	−100	50	80	11.57	0.5 × 0.7 = 0.35
3	−100	70	44	0	0.5 × 0.4 = 0.20
4	−100	70	90	38.02	0.5 × 0.6 = 0.30

The remainder of the analysis is summarized in Table 4. Note that column (4) reflects the calculation of Exp[PW] and column (5) reflects the calculation of Exp[$(PW)^2$]. Moreover

$$\sigma_p^2 = \text{Exp}[(\text{PW})^2] - [\text{Exp}(\text{PW})]^2 \tag{20}$$

as discussed previously.

Now, suppose that it is of interest to determine the probability that this investment will be profitable, that is, PW > $0. Only two of the possible outcomes, 2 and 4, meet this requirement, and, as they are independent events, the sum of their probabilities is

$$\begin{aligned}\text{Prob}[\text{PW} > \$0] &= \text{Prob}[\text{PW} = \$11.57] + \text{Prob}[\text{PW} = \$38.02] \\ &= 0.35 + 0.30 = 0.65\end{aligned}$$

3.6.2. Using Only the Mean and Variance of the PW Distribution

Tchebycheff's (sometimes written Chebyshev's) *inequality* states that

$$\text{Prob}[\mu - k\sigma < X < \mu + k\sigma] \geq 1 - 1/k^2 \tag{21}$$

where X is any random variable having mean μ and variance σ^2 and k is a positive constant. This is a useful relationship when only the mean and variance of the distribution are known. In terms of an unknown PW distribution with known mean μ_p and variance σ_p^2,

$$\text{Prob}[\mu_p - k\sigma_p < \text{PW} < \mu_p + k\sigma_p] \geq 1 - 1/k^2 \tag{22}$$

To illustrate, suppose that the mean and variance of the PW distribution have been determined to be $800 and ($50)^2, respectively. The analyst has been asked to determine the probability that the PW lies between two values, say, between $600 and $1000. Note here that

$$\mu_p - k\sigma_p = \$800 - k(\$50) = \$600$$

and

TABLE 4 Determining the Expected Present Worth

Outcome (1)	PW at 10% (2)	Joint Probability (3)	(4) = (2) × (3)	(5) = $(2)^2$ × (3)
1	−$ 4.96	0.15	−$ 0.744	$$ 3.690
2	11.57	0.35	4.050	46.853
3	0	0.20	0	0
4	38.02	0.30	11.406	433.656
	Totals	1.00	$14.712	$$484.199

Exp[PW] = $14.712

Var[PW] = $$484.199 − ($14.712)^2 = $$267.756

$\sigma_P = \sqrt{\text{Var}[\text{PW}]}$ = $16.363

$$\mu_p + k\sigma_p = \$800 + k(\$50) = \$1000$$

from which it is apparent that $k = 4$. Thus

$$\text{Prob}[\$600 < \text{PW} < \$1000] \geq 1 - 1/16 \quad \text{or} \quad 0.9375$$

Put somewhat differently, in the absence of any knowledge as to the *shape* of the distribution, the probability is *at least* 0.9375 that the random variable lies with $\pm 2\sigma$ of the mean.

3.6.3. When the Normal Distribution Can Be Assumed

Consider a stream of risky cash flows A_j occurring at the ends of periods 1, 2, . . . j, . . . N. The project life N and the discount rate i are known with certainty. The only stochastic variable here is the amount of the cash flow. The resulting PW is a random variable with mean given by Eq. (8) and, assuming independent cash flows, with variance given by Eq. (10). Under some general conditions application of the central limit theorem leads to the result that

$$Z_N = \frac{\text{PW} - \Sigma_{j=0}^{N} \mu_j (1 + i)^{-j}}{\sqrt{\Sigma_{j=0}^{N} \sigma_j^2}} \tag{23}$$

is approximately normally distributed, with $\mu = 0$ and $\sigma = 1$, as N approaches infinity. The "general condition" may be summarized as follows: the terms A_j, taken individually, contribute a negligible amount to the variance of the sum, and it is unlikely that any single A_j makes a relatively large contribution to the sum.

The terms A_j may have essentially any distribution. As a general rule of thumb, if the A_j's are approximately normally distributed, then the central limit theorem is a very good approximation when $N \geq 4$. If the distribution of the A_j's has no prominent mode(s), that is, approximately uniformly distributed, then $N \geq 12$ is a reasonable rule of thumb for applicability of the central limit theorem.

To illustrate the application of Eq. (23), consider the numerical example given in Table 1. It was determined that $\mu_p = \$69.44$ and $\sigma_p = \sqrt{\$\$802.9325} = \$28.34$. The probability distribution for PW is shown in part (*a*) of Figure 6; the equivalent standardized normal distribution is shown in part (*b*).

Consider the question: What is the probability that this proposal will result in a present worth greater than \$50?

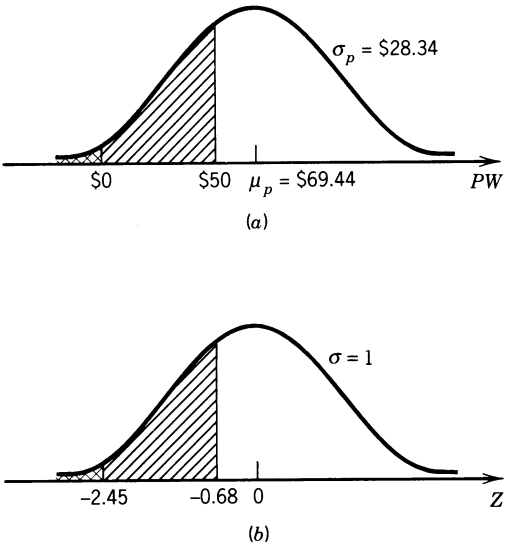

Figure 6 Probability Distribution for Present Worth.

$$\begin{aligned}\text{Prob}[\text{PW} > \$50] &= 1 - \text{Prob}[\text{PW} < \$50] \\ &= 1 - \text{Prob}\left[Z < \frac{\$50.00 - \$69.44}{\$28.34}\right] \\ &= 1 - \text{Prob}[Z < -0.686] \simeq 1 - 0.75 = 0.25\end{aligned}$$

An abbreviated version is included here in Table 5.

Consider a second question: What is the probability that this proposal will result in a loss?

$$\begin{aligned}\text{Prob}[\text{PW} < \$0] &= \text{Prob}\left[Z < \frac{\$0 - \$69.44}{\$28.34}\right] \\ &= \text{Prob}[Z < -2.45] \simeq 0.01\end{aligned}$$

Note that the probability of a loss is identical here to the probability that the proposal's internal rate of return will be less than the minimum attractive rate of return.

3.7. Comparing Risky Proposals

As indicated previously, decision makers are generally risk avoiders. Additional risk, as measured by the variance of the figure of merit, is to be avoided whenever possible. Thus there are two criteria to be considered simultaneously: the figure of merit, for example, present worth, as measured by the expected value (mean, μ) of the distribution; and the riskiness of the outcome as measured by the variance (σ^2) of the distribution. The former is to be maximized, and the latter is to be minimized.

Consider two mutually exclusive alternations. Let (μ_1, σ_1^2) and (μ_2, σ_2^2) represent the mean and variance of alternatives I and II, respectively. The appropriate decision rules are as follows:

Case A:	If $\mu_1 = \mu_2$ and $\sigma_1 < \sigma_2$ or $\mu_1 > \mu_2$ and $\sigma_1 \leq \sigma_2$	Choose I over II
Case B:	If $\mu_1 = \mu_2$ and $\sigma_1 > \sigma_2$ or $\mu_1 < \mu_2$ and $\sigma_1 \geq \sigma_2$	Choose II over I
Case C:	If $\mu_1 < \mu_2$ and $\sigma_1 < \sigma_2$ or $\mu_1 > \mu_2$ and $\sigma_1 > \sigma_2$	Conclusion ambiguous

There is no clear conclusion in case C because the riskier alternative is also the one with the larger expected return. When this situation arises, trade-offs must be made between risk and return. There is little theoretical guidance short of converting to utility theory (discussed later). Additional discussion is beyond the scope of this chapter.

4. DECISION THEORY APPLICATIONS

The approach to risk analysis outlined in the previous section is based on the premise that the decision maker desires to (a) maximize expected return and (b) minimize risk. This section presents some additional principles of choice that may be appealing under certain conditions. A simple numerical example is used as a basis for the discussion.

4.1. Problem Statement

The International Manufacturing Company (IMC) is considering five mutually exclusive alternatives for constructing a new manufacturing plant in a certain Asian country. The cost of each alternative, stated in terms of present worth (or net present value) of cost, depend on the outcome of negotiations that are currently under way between IMC, lending agencies, and the government of the host country. IMC analysts have concluded that four specific mutually exclusive outcomes are possible, and they have computed the present worth (cost) for each alternative—outcome combination. These are shown as cell values in the *cost matrix* in Table 6.

If the future is known with certainty, then the least costly alternative may be selected by any of the methods presented in Chapter 91. For example, if it is known that outcome s_3 will definitely occur, then a_3 should be selected because it will result in the lowest present worth (cost). On the other hand, if a_3 is selected and s_4 perversely occurs, choosing a_3 will have resulted in the most costly event.

Assume that sufficient information exists to warrant statements about the relative probabilities of the possible future outcomes. Specifically, these probabilities (expected relative frequencies) are

TABLE 6 Cost Matrix for Illustrative Problem (Cell entries are multiples of $1,000,000)

		Possible Outcomes			
		s_1	s_2	s_3	s_4
Alternatives	a_1	18	11	10	10
	a_2	16	16	16	16
	a_3	14	14	8	20
	a_4	9	12	17	16
	a_5	10	13	17	18

$$P[s_1] = 0.3 \qquad P[s_3] = 0.2$$
$$P[s_2] = 0.4 \qquad P[s_4] = 0.1$$

Given this additional information, which alternative should be selected? A number of principles that may be applied in this situation are discussed later.

A problem statement of this type is known as a *decision under risk* because the underlying probability distribution for the future scenarios, or *states of nature,* is known or can be assumed. ''Risk,'' in the previous section, was used in a more general sense to characterize the absence of certainty. The term was used analogously to ''randomness'' or uncertainty. Here, in a more limited sense, a problem statement in which the underlying distribution for the s_j's is *not* known or assumed is a *decision under uncertainty*.

4.2. Dominance

Before applying *any* of the principles of choice, it is first desirable (although not absolutely necessary) to apply the *dominance principle* to determine which alternatives, if any, are dominated. If, of two alternatives, one would never be preferred no matter what future occurs, it is said to be dominated and may be removed from any further consideration. From the example, consider a_4 and a_5:

	s_1	s_2	s_3	s_4	
a_4	9	12	17	16	(in $ million)
a_5	10	13	17	18	

Since a_5 is always at least as costly as a_4, irrespective of which future outcome occurs, a_5 may be ignored in the remaining discussion.

If one alternative dominates all others, it is said to be *globally dominant,* and the decision maker need look no further; the optimal solution has been found. Unfortunately, globally dominant alternatives are rare. But in any event, the dominance principle is frequently effective in reducing the number of alternatives to be considered.

4.3. Principles for Decisions under Risk

4.3.1. The Principle of Expectation

The *principle of expectation* states that the alternative to be selected is the one that has the minimum expected cost (or maximum expected profit or revenue). In general,

$$\text{Min } E[C(a_i)] = \sum_j C(a_i|s_j)p_j \tag{24a}$$

or

$$\text{Max } E[R(a_i)] = \sum_j R(a_i|s_j)p_j \tag{24b}$$

where $C(a_i|s_j)$ = total cost of alternative a_i given that states of nature s_j occurs
$R(a_i|s_j)$ = total net return of alternative a_i given that state of nature s_j occurs
p_j = probability that state s_j will occur

From the example it may be shown that

$$E[C(a_1)] = \$12{,}800{,}000 \qquad E(C(a_3)) = \$13{,}400{,}000$$
$$E[C(a_2)] = \$16{,}000{,}000 \qquad E[C(a_4)] = \$12{,}500{,}000$$

Here, a_4 should be selected because it yields the minimum expected cost.

Principles that depend on determination of expected values by the mathematics of probability theory are frequently criticized on the grounds that the theory holds only when trials are repeated many times. It is argued that, for certain types of decisions—for example, whether to finance a major expansion—expectation is meaningless since this type of decision is not made very often. According to the counterargument, even if the firm is not faced with a large number of repetitive decisions, it should apply the principle to many different decisions and thus realize the long-run effects. Moreover, even if the decision is unique, the only way to approach decisions for which probabilities are known is to behave as if the decision were a repetitive one and thus minimize expected cost or maximize expected revenue or profit.

4.3.2. The Principle of Most Probable Future

Assume that the future event to expect is the most likely event. Thus, observing that s_2 has the highest probability of occurring, assume that it will in fact occur. In this case a_1 (with present worth (cost) = \$11,000,000 is the least costly of the four available alternatives.

This principle is particularly appealing in cases in which one future is significantly more probable than all other possibilities.

4.3.3. The Aspiration Level Principle

The *aspiration level principle* requires the establishment of a goal, or "level of aspiration." Thus the alternative that maximizes the probability that the goal will be met or exceeded should be selected. To illustrate, suppose that the management of IMC wishes to minimize the probability that present worth (cost) will exceed \$15,000,000. (This is identical to the requirement that it maximize the probability that costs will *not* exceed \$15,000,000.) The probabilities are

$$\text{Prob}[C(a_1) > \$15{,}000{,}000] = 0.3$$
$$\text{Prob}[C(a_2) > \$15{,}000{,}000] = 0.3 + 0.4 + 0.2 + 0.1 = 1.0$$
$$\text{Prob}[C(a_3) > \$15{,}000{,}000] = 0.1$$
$$\text{Prob}[C(a_4) > \$15{,}000{,}000] = +0.2 + 0.1 = 0.3$$

Thus, the aspiration level will be met if a_1 is selected.

Clearly, the selection from mutually exclusive alternatives is a matter of which principle is used to guide the decision.

4.4. Principles for Decisions under Uncertainty

This section examines a number of principles of choice that may be used when the relative likelihoods of future states of nature *cannot* be estimated. These principles will be demonstrated by using the example problem introduced earlier.

4.4.1. The Minimax (or Maximin) Principle

The *minimax principle* is pessimistic in the extreme. It assumes that, if any alternative is selected, the worst possible outcome will occur. The maximum cost associated with each alternative is examined, and the alternative that *minimizes* the *maximum* cost is selected. In general, the mathematical formulation of the minimax principle is

$$\min_i [\max_j (C_{ij})] \tag{25a}$$

where C_{ij} is the cost that results when alternative i is selected and state of nature j occurs. From the example

Alternative (a_j)	$\max_j C_{ij}$
a_1	18 (in $ million)
a_2	16 (in $ million)
a_3	20 (in $ million)
a_4	17 (in $ million)

If the minimax principle is adopted, a_2 is indicated because it results in minimum costs, assuming the worst possible conditions.

The mirror image of the minimax principle, the *maximin principle,* may be applied when the matrix contains *profits* or *revenue* measures. In this case the most pessimistic view suggests that the alternative to select is the one that *maximizes* the *minimum* profit or revenue associated with each alternative. The mathematical formulation of the maximin principle is

$$\max_i [\min_j (R_{ij})] \tag{25b}$$

where R_{ij} is the revenue or profit resulting from the combination of a_i and s_j.

4.4.2. The Minimin (or Maximax) Principle

The *minimin principle* is based on the view that the best possible outcome will occur when a given alternative is selected. It is optimistic in the extreme. The minimum cost associated with each alternative is examined, and the alternative that *minimizes* the *minimum* cost is selected. The mathematical formulation is

$$\min_i [\min_j (C_{ij})] \tag{26a}$$

From the example

Alternative (a_1)	$\min_j C_{ij}$
a_1	10 (in $ million)
a_2	16 (in $ million)
a_3	8 (in $ million)
a_4	9 (in $ million)

Alternative a_3 minimizes the minimum cost.

As a corollary to the minimin principle, the *maximax principle* is appropriate when the decision maker is extremely optimistic and the matrix contains measures of profit or revenue. The maximum profit (or revenue) associated with each alternative is examined, and the alternative that *maximizes* the *maximum* profit (or revenue) is selected. The mathematical formulation is

$$\max_i [\max_j (R_{ij})] \tag{26b}$$

4.4.3. The Hurwicz Principle

It may be argued that decision makers need not be either completely optimistic or pessimistic, in which case the *Hurwicz principle* permits selection of a position between the two extremes. When evaluating costs, C_{ij} the *Hurwicz criterion* for alternative a_i is given by

$$\min_j H(a_j) = \alpha[\min_j (C_{ij})] + (1 - \alpha)[\max_j (C_{ij})] \tag{27a}$$

where α is the ''index of optimism'' such that $0 \leq \alpha \leq 1$. Extreme pessimism is defined by $\alpha = 0$; extreme optimism is defined by $\alpha = 1$. The value of α used in any particular analysis is selected by the decision maker based on subjective judgment. The alternative that *minimizes* the quantity $H(a_i)$ is the alternative to select.

When evaluating profits or revenues, R_{ij}, the expression for the Hurwicz criterion is

$$\text{Max } H(a_i) = \alpha[\underset{j}{\text{Max}}(R_{ij})] + (1 - \alpha)[\underset{j}{\text{Min}}(R_{ij})] \tag{27b}$$

The values of $H(\alpha_j)$ are plotted in Figure 7 for the sample problem. We may determine, either graphically or algebraically, that a_2 will be chosen for $0 \leq \alpha \leq 0.125$, a_4 will be selected for $0.125 \leq \alpha \leq 0.75$, and a_3 is least costly for $0.75 \leq \alpha \leq 1.00$.

4.4.4. The Laplace Principle (Insufficient Reason)

The *Laplace principle,* sometimes known as the *principle of insufficient reason,* assumes that the probabilities of future events occurring are equal. That is, in the absence of any information to the contrary, it is assumed that all future outcomes are equally likely to occur. The expected cost (or profit/revenue) of each alternative is then computed, and the alternative that yields the minimum expected cost (or maximum expected profit/revenue) is selected. The mathematical expression for this principle is

$$\underset{i}{\text{Min}} \left\{ \left(\frac{1}{k} \right) \sum_{j=1}^{k} C_{ij} \right\} \tag{28a}$$

when the figure of merit is expressed as a cost or as

$$\underset{i}{\text{Max}} \left\{ \left(\frac{1}{k} \right) \sum_{j=1}^{k} R_{ij} \right\} \tag{28b}$$

when the figure of merit is expressed as revenue or profit.

Returning to our example, the insufficient reason assumption yields $p_1 = p_2 = p_3 = p_4 = 0.25$. With these probabilities:

$$E[C(a_1)] = \$12{,}250{,}000 \qquad E[C(a_3)] = \$14{,}000{,}000$$
$$E[C(a_2)] = \$16{,}000{,}000 \qquad E[C(a_4)] = \$13{,}500{,}000$$

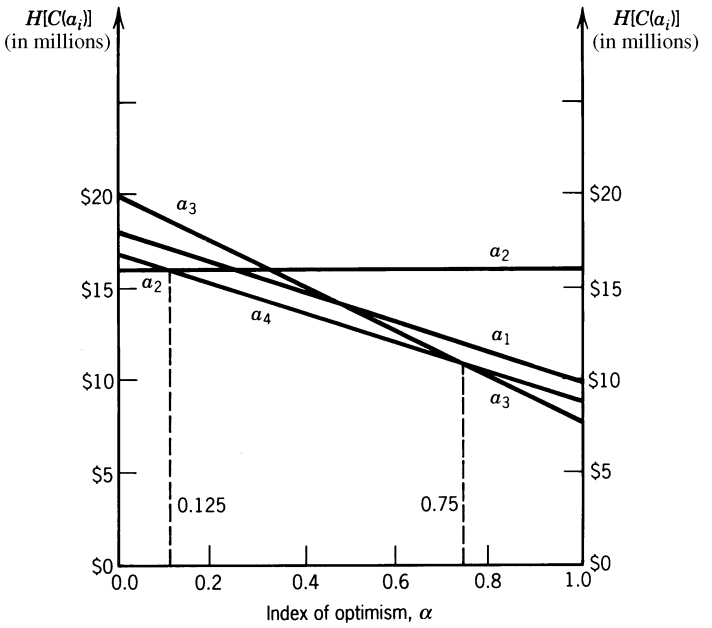

Figure 7 Sample Problem—Hurwicz Criterion as Function of Index of Optimism.

Alternative a_1 should therefore be selected because it results in the minimum expected present worth (cost).

4.4.5. The Savage Principle (Minimax Regret)

The *Savage principle,* or *principle of minimax regret,* is based on the assumption that the decision maker's primary interest is the *difference* between the actual outcome and the outcome that would have occurred had it been possible to accurately predict the future. Given these difference, or *regrets,* the decision maker then adopts a conservative position and selects the alternative that minimizes the maximum potential regret for each alternative.

A *regret matrix* is constructed, having for its cell values either

$$C_{ij} - [\underset{i}{\text{Min}}(C_{ij})] \tag{29a}$$

for cost data or

$$[\underset{i}{\text{Max}}(R_{ij})] - R_{ij} \tag{29b}$$

for revenue or profit data. In either case these cell values, or regrets, represent the differences between (a) the outcome if alternative a_j is selected and state of nature s_j subsequently occurs and (b) the outcome that would have been achieved had it been known in advance which state of nature would occur, so that the best alternative could have been selected. To illustrate, consider alternative a_1 and state of nature s_1: C_{11} = \$18,000,000. However, if we had known *a priori* that state s_1 would in fact occur, we would have selected a_4, incurring a cost of only \$9,000,000. The difference (\$18,000,000 − \$9,000,000) is a measure of "regret" about selecting a_1 when we could have selected a_4 (had we known the state of nature in advance). The complete regret matrix for the example is given in Table 7.

The alternative that *minimizes* the *maximum* regret is preferred. That is, for cost data,

$$\underset{i}{\text{Min}}\ \underset{j}{\text{Max}}\{C_{ij} - [\text{Min}(C_{ij})]\} \tag{30a}$$

or, when the cell values are based on revenue or profit data,

$$\underset{i}{\text{Min}}\ \underset{j}{\text{Max}}\{[\underset{i}{\text{Max}}(R_{ij})] - R_{ij}\} \tag{30b}$$

Equation (30a) is applicable for the sample problem, yielding the following:

Alternative	Maximum Regret
a_1	9 (in \$ millions)
a_2	8 (in \$ millions)
a_3	10 (in \$ millions)
a_4	9 (in \$ million)

Thus, according to this principle of choice, a_2 should be preferred.

TABLE 7 Regret Matrix for Sample Problem (Cell values are multiples of \$1,000,000)

		Possible Outcomes			
		s_1	s_2	s_3	s_4
Alternatives	a_1	18 − 9 = 9	11 − 11 = 0	10 − 8 = 2	10 − 10 = 0
	a_2	16 − 9 = 7	16 − 11 = 5	16 − 8 = 8	16 − 10 = 6
	a_3	14 − 9 = 5	14 − 11 = 3	8 − 8 = 0	20 − 10 = 10
	a_4	9 − 9 = 0	12 − 11 = 1	17 − 8 = 9	16 − 10 = 6

4.5. Summary of Results

There is no special reason why the principles of choice discussed in the preceding sections should yield the same solution. Indeed, each of the alternatives in this example problem were selected at least once.

Decision Under Risk	
Principle	Solution
Expectation	a_4
Most probable future	a_1
Aspiration level	a_3

Decisions Under Uncertainty	
Principle	Solution
Minimax	a_2
Minimin	a_3
Hurwicz ($0.1215 < \alpha < 0.75$)	a_4
Laplace (insufficient reason)	a_1
Savage (minimax regret)	a_2

Is one principle more ''correct'' than any other? There is no simple answer to this question—the choice of principle largely depends on the predisposition of the decision maker and the specific decision situation. Each principle has certain obvious advantages, and each is deficient in one or more desirable characteristics. Nevertheless, the principles in this section are useful because they shed some light on the subjective decision process and make the available information explicit to the decision process.

5. DECISION TREES

Decision tree methodology is useful for the evaluation of problems characterized by *sequential* decisions, each of which involves a variety of outcomes. The pictorial representation of this problem is suggestive of a tree lying on its side, with the branches in the tree representing successions of outcomes. The graphic portrayal of the problem structure is both its primary asset as well as its principal disadvantage. The ability to communicate complex dependencies is of great value, of course. However, the number of sequential decisions and outcomes (branches) is necessarily limited by the graphic medium (CRT screen, 8½ × 11 in. paper, etc.). These features will be apparent from the following discussion of deterministic and stochastic decision trees.

5.1. Deterministic Decision Trees

Consider a problem of retirement and replacement over a three-year planning horizon. The existing equipment, the defender, is now two years old. Replacement decisions are to be made now, one year hence, and two years hence. Whichever equipment is in service three years from now will be removed from service and sold in any event. Initial costs, salvage values, and operating costs for each of the 3 years are summarized in Table 8. Note that the first row of the table represents the defender: It has a current salvage value of \$50, \$40 after one year, \$30 after two years, and \$20 if sold at the end of the third year.

TABLE 8 Input Data for Deterministic Example (All cash flows have been discounted—they are shown as their PW equivalents)

Year j	Initial Cost if Purchased at Start of Year j	Salvage Value if Sold at End of Year			Operating Cost in Year		
		1	2	3	1	2	3
1	\$50[a]	\$40	\$ 30	\$ 20	\$90	\$95	\$100
1	100[b]	80	65	55	50	60	70
2	120[b]		100	85		45	55
3	130[b]			110			40

[a] Current salvage value of defender.
[b] Challengers at start of years 1, 2, and 3.

The decision tree for this problem is shown in Figure 8. The three decision points are represented by squares, the branches are the decisions, and the economic consequence of each branch is shown at that line. The solution begins at the end of the tree, that is, at the latest decision point, which is decision 3 in this case.

Decision Point	Alternative	Monetary Outcome, 3rd Year	Choice
3*a*	Keep	−$100 + $20 = −$80	
	Replace	$30 − $130 − $40 + $110 = −$30	Replace
3*b*	Keep	−$55 + $85 = $30	
	Replace	$100 − $130 − $40 + $110 = $40	Replace
3*c*	Keep	−$70 + $55 = −$15	
	Replace	$65 − $130 − $40 + $110 = $5	Replace
3*d*	Keep	−$55 + $85 = $30	
	Replace	$100 − $130 − $40 + $110 = $40	Replace

Next, the procedure rolls back to the preceding decision point, the beginning of the second year. The monetary outcomes are cumulative, that is, the economic consequences in year 2 are added to those of the optimal decisions at the beginning of year 3.

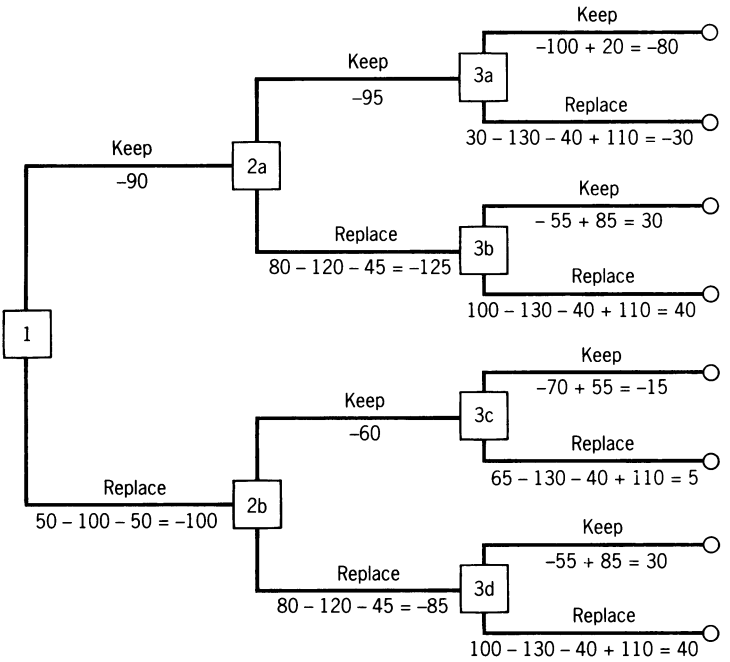

Figure 8 Decision Tree for Deterministic Example.

Decision Point	Alternative	Monetary Outcome, 2nd + 3rd Year	Choice
2*a*	Keep	(−$95) + (−$30) = −$125	
	Replace	($40 − $120 − $45) + ($40) = −$85	Replace
2*b*	Keep	(−$60) + ($5) = −$55	
	Replace	($80 − $120 − $45) + ($40) = −$45	Replace

The process continues until the first decision point. Here:

Decision Point	Alternative	Monetary Outcome, 1st, 2nd, 3rd Year	Choice
1	Keep Replace	(−$90) + (−$85) = −$175	
		($50 − $100 − $50) + (−$45) = −$145	Replace

The optimal solution is now complete. The optimal path through the tree is determined by beginning at the first decision point and continuing through subsequent decisions in accordance with the indicated decisions. In this example the optimal solution is *replace, replace,* and *replace* at the start of years 1, 2, and 3, respectively.

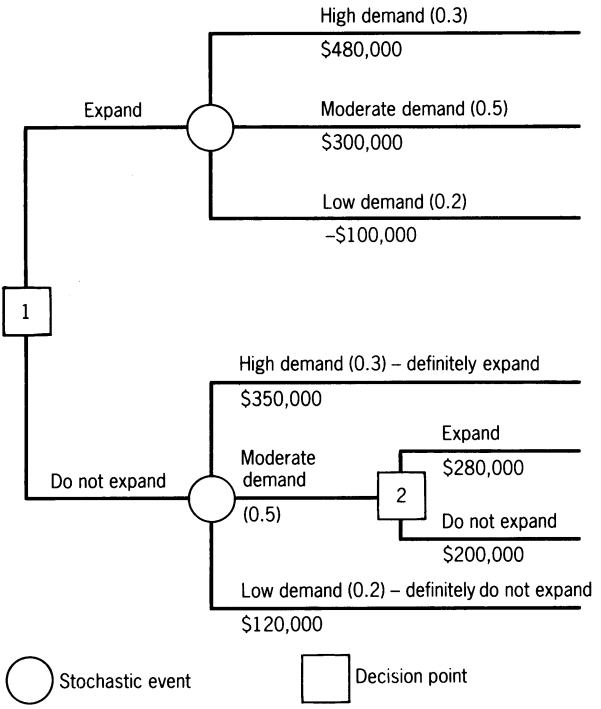

Figure 9 Decision Tree for Stochastic Example. (All cash flows have been discounted. They are shown here in their PW equivalents.)

5.2. Stochastic Decision Trees

One of the most useful features of decision trees is their ability to illustrate variable outcomes when their probabilities of occurrence can be estimated. To be effective in a graphic format, the outcomes must be characterized as discrete random variables with a relatively small number of possibilities.

A very simple example of a stochastic decision tree is illustrated in Figure 9. The firm is considering expansion of a production line for the manufacture of a certain product. If the decision is made to forgo expansion at the present time, a subsequent opportunity will arise in about a year from now. The delay, perhaps, might be warranted based on the demand experienced over the next year. All dollar values shown in the tree are present value equivalents. There are three possible demand outcomes as shown—high, moderate, and low, with probabilities 0.3, 0.5, and 0.2, respectively.

At decision point 2 it is clear that plant expansion is preferred as PW(expand) = \$280,000 and PW(do not expand) = \$200,000. Rolling back to decision point 1, it is now necessary to evaluate the *expected* present worth through each of the branches emanating from that point.

$$\begin{aligned}\text{Exp[PW, expand now]} &= 0.3(\$480{,}000) + 0.5(\$300{,}000) + 0.2(-\$100{,}000)\\ &= \$274{,}000\\ \text{Exp[PW, do not expand]} &= 0.3(\$230{,}000) + 0.5(\$280{,}000) + 0.2(\$120{,}000)\\ &= \$233{,}000\end{aligned}$$

Thus, based on this analysis, it would appear that expansion at the present time is warranted.

The solution can be effected, of course, without reference to the decision tree. It is the graphic character of the tree that permits the analyst to articulate the sequential and stochastic nature of events and outcomes and to communicate these interrelationships to decision makers.

6. DIGITAL COMPUTER (MONTE CARLO) SIMULATION

The statistical procedures related to risk analysis suffer from at least one important drawback: The analytical techniques necessary to derive the mean, variance, and possibly the probability distribution of the figure of merit may be extremely difficult to implement. Indeed, the complexity of many real-world problems precludes the use of these computational techniques altogether; computations may be intractable, or the necessary underlying assumptions may not be met. Under these conditions analysts may find *digital computer* (*Monte Carlo*) *simulation* especially useful. (Strictly speaking, *Monte Carlo* simulation and *digital computer* simulation are not synonymous. Monte Carlo simulation is a sampling technique used in the digital computer simulation of systems behavior. However, in recent years, practitioners have tended to blur this semantic distinction, using the terms interchangeably.)

The objective of digital computer simulation is to generate a probability distribution for the figure of merit, generally present worth or rate of return, given the probability distributions for the various components of the analysis. The decision maker can thus compare expected returns as well as the variability of returns for two or more alternatives. Moreover, probability statements can be made, in this form: The probability is x that project y will result in a profit in excess of z.

6.1. Sampling from a Discrete Distribution

Suppose that "annual operating savings," A, is a discrete random variable with probabilities as given in Table 9. The associated *cumulative distribution function* (CDF), also given in the table, represents the probability that the annual operating savings will be less than or equal to some given value.

Our problem now is one of sampling from this distribution, using either the probability function or its associated CDF in order to preserve precisely all the characteristics of the original distribution. We can do this by obtaining, say, 100 perfectly matched balls, numbered from 00 to 99. We want to label four of the balls "\$2400," eight of the balls "\$2500," and so on. The number of balls labeled with a particular amount is proportional to their relative probability in the original distribution:

Ball Numbers	Number of Balls	Labels	Ball Numbers	Number of Balls	Label
01–04	4	\$2400	49–64	16	\$2900
05–12	8	2500	65–80	16	3000
13–22	10	2600	81–90	10	3100
23–34	12	2700	91–98	8	3200
35–48	14	2800	99–00	2	3300

TABLE 9 Probabilities and Cumulative Distribution Function for Sample Problem

Event i	Annual Savings A_i	Probability of Occurrence[a] $P(A_i)$	Cumulative Distribution Function (CDF) P(Ann. Savings $\leq A_i$)
1	$2400	0.04	0.04
2	2500	0.08	0.12
3	2600	0.10	0.22
4	2700	0.12	0.34
5	2800	0.14	0.48
6	2900	0.16	0.64
7	3000	0.16	0.80
8	3100	0.10	0.90
9	3200	0.08	0.98
10	3300	0.02	1.00

[a] The probability function for a *discrete* random variable is sometimes known as a *probability mass function.* The equivalent function for a *continuous* random variable is a *probability density function* (pdf).

Now we can put all the balls into a large jar, shake it thoroughly so that the balls are completely mixed, and then draw out a single ball. Then, the result of this "random sample" is recorded and the ball is placed back in the jar to select our next sample. As we continue this process through a large number of samples, or trials, we can expect the resulting frequency distribution to approximate that of the original population.

Of course, in practical applications, the sampling process does not consist of drawing balls from a jar. There are a variety of more elegant procedures, generally based on successive iterations of a predetermined formula. An alternative approach that is useful when the number of samples to be drawn is relatively small is to reference a *table of random numbers*. Such tables have been developed and the results recorded in tabular format. (A table of three-digit random numbers appears in Table 10.) Inasmuch as the numbers in the table are randomly generated, users may enter the table at any point and proceed in any direction.

6.2. Sampling from a Normal Distribution

The *normal distribution* is frequently used to describe the probabilities of certain continuous random variables. The probability density function is given by

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} \left\{ \exp\left[\frac{-1}{2} \left(\frac{x - \mu}{\sigma} \right) \right] \right\} \tag{31}$$

where μ = mean and σ = standard deviation of the distribution and x is the particular value of the random variable. A particular normal distribution is fully described by the parameter μ and σ, where μ is a measure of central tendency and σ is a measure of dispersion.

The *standard normal distribution* results from the special case wherein $\mu = 0$ and $\sigma = 1$. The area under the curve from $-\infty$ to $+\infty$ is exactly 1.0. If one can develop a table of random numbers for a uniform distribution over the interval 0–1, it is possible to map a set of equivalent values for the standard normal distribution, as in Figure 10. The value along the ordinate represents the probability that the random variable X lies in the interval $-\infty$ to x. For any random number we can compute the equivalent value x. This latter value is called the *random normal deviate*.

Tables of random normal deviates exist that contain values from which one may generate a random sample for *any* normal distribution with known parameters μ and σ. (See Table 11.) The simulated event, then, is given by

$$\{\text{Simulated event (Sample)}\} = \mu + \{\text{Random normal deviate}\}\sigma \tag{32}$$

6.3. General Framework

The previous sections discussed the process whereby random samples are drawn from an underlying probability distribution. The general procedure can be described in four steps:

Step 1: Determine the probability distribution(s) for the significant factors, as illustrated in Figure 11.

TABLE 10 Random Numbers[a]

[a]This table was prepared by Mr. Ken Molay using a PDP 22 computer with a TOPS 10 operating system. To produce these random numbers, a congruential multiplicative generator was used, based on a seed of system time in milliseconds.

Step 2: Using Monte Carlo simulation, select random samples from these factors according to their relative probabilities of occurring in the future. (See Figure 12.) Note that the selection of one factor (price, for example) may determine the probability distribution of another factor (total amount demanded, for example).

Step 3: Determine the figure of merit (rate of return or present worth, for example) for each combination of factors. One trial consists of one calculation of the figure of merit.

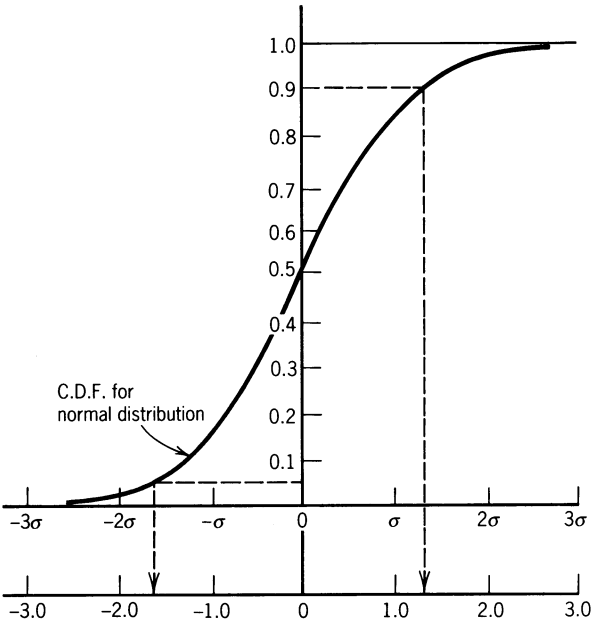

Figure 10 Sampling from a Normal Distribution.

Step 4: Repeat the process, that is, conduct a series of trials, building a frequency histogram with the results, as in Figure 13. Continue until you are reasonably satisfied that the histogram yields a clear portrayal of the investment risk. (There is no universally accepted rule for determining the optimum number of trials. It is clearly less expensive to produce a smaller number of trials, yet a larger number of trials yields more information. Substantial literature is addressed to this interesting problem, but additional discussion is not warranted here.)

6.4. Numerical Example

A certain investment, if purchased, will result in annual operating savings described by the probability distribution shown in column (b) of Table 12. The project life is described by the probability distribution shown in column (e), and the initial cost is a normally distributed random variable with μ = \$25,000 and σ = \$1000. The discount rate to be used in the analysis, a certainty estimate, is 0.10. It is assumed that the annual savings, project life, and initial cost are independent random variables. If there are no other relevant consequences of the proposed investment, the expected net present value is given by the equation

$$\text{PW} = \overline{A}(\text{P}/\overline{A},\ 10\%,\ N) - P \tag{33}$$

where $\overline{A}$ = annual operating savings, N = project life, and P = initial cost.

Columns (c) and (f) of Table 12 contain the random numbers corresponding to the relative probabilities in columns (b) and (e), respectively. Note that two-digit random numbers are used. Inasmuch as the specified accuracy of the probability distributions is two significant digits, the corresponding random numbers must be specified by *at least* two digits. (A three-digit random number, say 843, could be rounded to 84 or simply truncated after the first two digits.) For the first variable, annual operating savings ($\overline{A}$), there are 100 random numbers, the first four of which correspond to the event $\overline{A}$ = \$2400. The next eight numbers, 05 through 12, correspond to the event $\overline{A}$ = \$2500, and so on.

The results of 10 simulated trials are shown in Table 13. Consider the first trial, for example: a random number, 09, is drawn from the table of random numbers in Table 10. As shown in Table 12, this corresponds to the event $\overline{A}$ = \$2500. Next, a new random number, 52, is drawn, which corresponds to the event N = 30. Note that *the same random number cannot be used for both random variables because they are independent.* The third random variable, P, is normally distributed, so a random normal deviate (RND) is drawn from Table 11. This number, 0.464, indicates a simulated value for

[a] This table was prepared by Mr. Shay Bao Lai using an Apple II computer. The algorithm for producing these random normal deviates is from A. M. Law and W. D. Kelton, *Simulation Modeling and Analysis,* McGraw-Hill, New York, 1982, pp. 258–259.

$$P = \mu + (\text{RND})\sigma$$
$$= \$25{,}000 + (0.464)(\$1000) = \$25{,}464$$

The present worth for the first trial can now be computed:

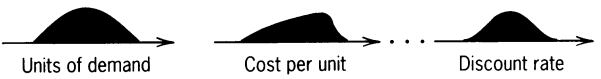

Figure 11 Probability Functions for Inputs.

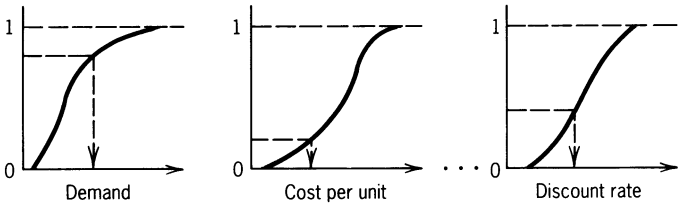

Figure 12 Cumulative Distribution Functions.

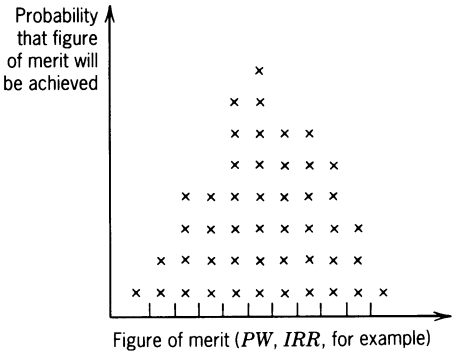

Figure 13 Frequency Histogram for Figure of Merit.

$$\text{PW} = \$2500(P/\overline{A}, 10\%, 30) - \$25{,}464 = -\$737$$

A frequency distribution can be developed from the resulting PW values, and relevant statistics can be computed. In this example the cumulative average PW after 10 trials is \$2023; 40% of the trials result in a negative PW. The minimum value simulated was −\$737; the maximum value simulated was \$6761. Of course, if this were an actual application, the number of trials would be much larger, perhaps several thousand or more, and we would have considerably greater confidence in the resulting statistics.

In this particular example there are relatively few random variables, the relationships are not complex, and the variables are independent. Hence it is possible to compute the *theoretical expected value* for the net present value. That is

$$E[\text{PW}] = \text{E}[\overline{A}](P/\overline{A}, 10\%, E[N]) - E[P] \tag{34}$$

where

$$\begin{aligned} E[\overline{A} &= 0.04(\$2400) + 0.08(\$2500) + \ldots + 0.02(\$3300) \\ &= \$2848 \\ E[N] &= 0.05(25) + 0.10(26) + \ldots + 0.05(35) \\ &= 30 \\ E[P] &= \$25{,}000 \end{aligned}$$

Thus,

$$E[\text{PW}] = \$2848(P/A, 10\%, 30) - \$25{,}000 = \$3170$$

We can expect, therefore, that the cumulative average PW will approach \$3170 as the number of trials increases. Although we can compute the theoretical *mean,* it is not possible in this case to compute the theoretical *distribution* for the PW. However, an approximate distribution can be developed through simulation.

7. OTHER APPROACHES FOR DEALING WITH THE UNCERTAIN/RISKY FUTURE

As indicated at the beginning of this chapter, risk and uncertainty are inherent in the general problem of resource allocation because all decisions depend on estimates about the noncertain future. Thus, risk and uncertainty have occupied the attention of a great many theoreticians and practitioners. A substantial number of approaches have been proposed, several of which were summarized earlier. Now four additional approaches are briefly identified. The first three are widely used in industry, despite certain important shortcomings; the fourth requires detailed discussion beyond the scope of this text.

7.1. Increasing the Minimum Attractive Rate of Return

Some analysts advocate adjusting the minimum attractive rate of return to compensate for risky investments, suggesting that, since the future is uncertain, stipulation of a minimum attractive rate of return of, say, $i + \Delta i$ will ensure that i will be earned in the long run. Since some investments will not turn out as well as expected, they will be compensated for by the incremental "safety margin," Δi. This approach, however, fails to come to grips with the risk or uncertainty associated with estimates for specific alternatives, and thus an element Δi in the minimum attractive rate of return penalizes all alternatives equally.

7.2. Differentiating Rates of Return by Risk Class

Rather than building a safety margin into a single minimum attractive rate of return, some firms establish several risk classes with separate standards for each class. For example, a firm may require low-risk investments to yield at least 15% and medium-risk investments to yield at least 20%, and it may define a minimum attractive rate of return of 25% for high-risk proposals. The analyst then

judges which class a specific proposal belongs in, and the relevant minimum attractive rate of return is used in the analysis. Although this approach is a step away from treating all alternatives equally, it is less than satisfactory in that it fails to focus attention on the uncertainty associated with the individual proposals. No two proposals have precisely the same degree of risk, and grouping alternatives by class obscures this point. Moreover, the attention of the decision maker should be directed to the causes of uncertainty, that is, to the individual estimates.

7.3. Decreasing the Expected Project Life

Still another procedure frequently employed to compensate for uncertainty is to decrease the expected project life. It is argued that estimates become less and less reliable as they occur further and further into the future; thus shortening project life is equivalent to ignoring those distant, unreliable estimates. Furthermore, distant consequences are more likely to be favorable than unfavorable; that is, distant estimated cash flows are generally positive (resulting from net revenues) and estimated cash flows near date zero are more likely to be negative (resulting from startup costs). Reducing expected project life, however, has the effect of penalizing the proposal by precluding possible future benefits, thereby allowing for risk in much the same way that increasing the minimum attractive rate of return penalizes marginally attractive proposals. Again, this procedure is to be criticized on the basis that it obscures uncertain estimates.

7.4. Utility Models

In essence, utility is a single metric on the unit interval denoting the degree of desirability of an item or a quantity of items with respect to a completely defined collection of such items. Thus an item or group of items with the greatest desirability would have a utility of, say, 100, and at a least desirable item, a zero utility. All items and groups within the collection range between these extremes in an ordered fashion. Amounts of monetary receipts and disbursements would provide a utility function from 0 to 100. A monetary gamble would be reviewed in this theory as a linear combination of the amount won and lost in the gamble, with the expected utility associated with winning. Once a person's utility function is derived, the theory of utility denotes how one should act in order to remain consistent with his or her denoted goals. Accordingly, utility theory is a description of normative economic behavior based on several stated axioms.

A number of advocates of this theory have therefore recommended that utility functions be established and economic risk analysis conducted with respect to this theory. That is, projects with the greatest expected utility should be selected by rational economic decision makers. There are many compelling features to this approach. However, it also involves the required development of the utility function, which is not a simple task; the question of whose utility function should represent the firm; and other perplexing problems. Also, it has been shown that current methods of risk cash flow analysis do represent a reasonable and rational approximation of the utility theory approach. There are also challenges to the axioms of existing theories of utility. Because of these and other detractions, the utility theory approach has not enjoyed popularity among many practitioners.

CHAPTER 92

Inflation and Price Change in Economic Analysis

JOSEPH C. HARTMAN
Lehigh University

1. INTRODUCTION TO INFLATION AND DEFLATION

The economic analysis of investment alternatives generally entails the estimation of cash flows and the application of some measure of worth, such as net present value or the internal rate of return, in order to make a decision. The estimation of these cash flows requires the estimation of prices, whether they be the price of goods sold to forecast revenues or the estimation of wages to forecast labor costs. Over time these prices change. An increase in price is known as inflation, while a decrease in price is termed deflation. These concepts and their measurement are explained in this chapter. Cash flow analysis methods are revisited under the assumption of price changes, as their effects can be significant (Fleischer 1994). This is especially true when one considers after-tax cash flow analysis, as the effects of depreciation and taxes represent one of the most important aspects of investment analysis (Park and Sharp-Bette 1990).

1.1. Inflation, Deflation, and Purchasing Power

Consider the price of something as simple as a stamp. In 1967, a typical first class postage stamp cost just 5 cents in the United States (Park 1997). In 1999, that same stamp (in that it provided the same service as in 1967) cost 33 cents. So if you had tucked away a nickel in 1967 to buy a stamp in 1999, you would be out of luck. This is not the case with all commodities, as competition and improved manufacturing efficiencies may actually lead to decreases in the price of a good or commodity over time. Consider the average price of a one-minute long distance (interstate) call. In 1970, it cost roughly \$0.25 cents per minute to place a call between states in the United States. Now, prices average in the neighborhood of \$0.08 per minute (Festa 1999). This effect is known as deflation.

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

Although it is rare, it has happened with numerous commodities in the last decade, mainly due to deregulation and increased competition.

Changes in price affect one's purchasing power. When inflation occurs, the worth or value of money decreases in that one cannot buy as much commodity with the same amount of money as earlier. This is known as a decrease in purchasing power. In the case of deflation, the same amount of money purchases more commodity than previously possible and thus results in an increase in purchasing power.

Because investment alternatives are generally modeled as cash flows over some time horizon, it is important to include the effects of inflation in economic equivalence calculations (Thuesen and Fabrycky 1994). This chapter illustrates measures of inflation and how to include it in cash flow analysis calculations. For the remainder of this chapter, the term *inflation* is utilized exclusively and *deflation* refers to negative inflation.

1.2. Measures of Inflation

The movement of prices is tracked in a variety of ways for a variety of products, generally with the use of a price index. A price index is merely a measure of the change in price of a commodity relative to some baseline. This is generally taken as a ratio of the price at some point in time to a price at some earlier point in time. In the United States, the Consumer Price Index (CPI) is a popular method to measure inflation associated with the cost of living. The CPI tracks the movement in price of a variety of commodities and services, including food and beverages, housing, apparel, transportation, medical care, recreation, education and communication, and energy (Bureau of Labor Statistics 1999b). While the CPI tracks this bundle of commodities and services, indexes also exist for the individual commodities and services that comprise the CPI. For example, there is a conglomerate index for transportation that is composed of indexes for private transportation and public transportation. Private transportation is composed of indexes for new and used motor vehicles, gasoline, motor vehicle parts and equipment, and motor vehicle maintenance and repair. These indexes are generally available on a regional basis and/or seasonally adjusted.

For the CPI, the baseline is given at 100 for the year 1967. The CPI for the end of 1998 was 491.0, and at the end of November 1999 the index stood at 504.1 (Bureau of Labor Statistics 1999a).

While the CPI is very popular, it is not the only price index available to those in need of estimating inflation for a specific service or commodity. The Bureau of Labor Statistics publishes a number of price indexes that may or may not influence the CPI (Standard & Poor's Statistical Service 1999). To provide some semblance of the range of available data, the Bureau of Labor Statistics provides producer price indexes for selected lumber, including hardwoods, southern pine, oak, softwoods, and Douglas fir. Breakdowns to such fine detail are available for a variety of commodities. Indexes are also available for industry trade groups to provide information for specific estimates, such as construction costs and machinery.

1.3. Computing Periodic and Average Inflation

Price indexes provide a measure of the relative change in prices from year to year. Thus, the inflation rate for one period (generally a month or a year) may be computed from the relative change in the index over the corresponding period. We will use the CPI in the following calculations, but the relationships hold for any price index. We follow notation similar to (Thuesen and Fabrycky 1994).

Define the inflation for period n as f_n. This value is calculated as:

$$f_n = \frac{CPI_n - CPI_{n-1}}{CPI_{n-1}}$$

In the one-period case, the previous period $(n - 1)$ represents the base period. This calculation is valid only for single period price changes. For changes over multiple periods, an average inflation rate may be calculated.

Define the average inflation rate over n periods (period t to period $t + n$), $\overline{f}$, as:

$$CPI_t(1 + \overline{f})^n = CPI_{t+n}$$

such that:

$$\overline{f} = \left[\frac{CPI_{t+n}}{CPI_t}\right]^{1/n} - 1$$

In this calculation, time t refers to the base period for calculations. Generally, the bar is dropped and this rate is referred to as f. Note that this interest rate includes the effects of compounding and is not merely an arithmetic average of CPI values.

Consider the change in the CPI from 1967. Given an index value of 100 at the end of 1967, rising to 491.0 at the end of 1998, the average annual inflation rate over those 31 years is calculated as:

$$f = \left[\frac{491.0}{100.0}\right]^{1/31} - 1 = 0.0527 = 5.27\%$$

Again, this is an average annual rate over the respective 31 years. While this may seem like a high annual rate when one considers the recent years of low inflation, one must consider the double-digit percentage inflation rates of the 1970s in the United States.

Consider the postage stamp example presented earlier. The two prices from 1967 and 1999 can be used to determine the average inflation rate for the postage stamp over the past 31 years as follows:

$$f = \left[\frac{0.33}{0.05}\right]^{1/31} - 1 = .0628 = 6.28\%$$

Thus, it can be concluded that the average annual increases in price for a postage stamp have outpaced the average increases in the cost of living over the past 31 years in the United States. This further illustrates the need to utilize specialized indexes to achieve more accurate inflation estimates.

2. INCORPORATING INFLATION INTO ECONOMIC ANALYSIS

The role of economic analysis in engineering is to determine whether engineering projects are economically viable. This generally entails determining whether a single project should be accepted or rejected, or choosing the best project from a set of feasible projects. The analysis may take on the form of cost minimization or profit maximization. Regardless of the application or situation, the procedure generally requires the estimation of relevant cash flows and their conversion to some common denominator, such as the net present value, in order to make a decision. In this section, we consider this decision process under the assumption that the cash flows are subject to inflation. After terminology is introduced, an analytic approach is outlined to handle these types of analyses, with or without inflation. Generalizations are made for cases where the inflation rate varies according to different cash flows and over time.

2.1. Inflation-Free and Market Interest Rates

The inflation rate has been defined which allows one to predict price changes. However, economic analysis requires the use of an interest rate for discounting or compounding procedures in order to reduce a set of cash flows to a common measure for analysis, such as net present value. Because cash flows may or may not be inflated, two interest rates must be defined for use in analysis.

Define the market interest rate i as the rate of interest that can be expected to be earned on investments in the marketplace. It is a function of the investments available on the market and their associated risks. Additionally, this rate includes the effect of inflation such that if there is an upward movement in prices (inflation), there is an upward movement in the market interest rate. Other terms that may be commonly used to refer to the market rate include the minimum attractive rate of return (MARR), nominal MARR, actual interest rate, effective rate, and inflated interest rate.

Define the inflation-free interest rate i' as the market interest rate with the effects of inflation removed. While this rate is fictitious on the market, because any interest rate available on the market includes the effects of inflation, it is useful in economic analysis. This rate is also termed the real interest rate.

In the previous section, we defined the inflation rate f as the periodic increase in the price of some good or service. This rate provides the link between inflation-free and market rates because the first rate excludes inflation while the latter rate includes the effects of inflation.

To convert from an inflation-free interest rate to a market interest rate, one must add inflation. This is accomplished as follows:

$$(1 + i) = (1 + i')(1 + f)$$

such that:

$$i = i' + f + i'f$$

Similarly, to convert a market interest rate to an inflation-free rate, one must remove inflation, as:

$$i' = \frac{(1 + i)}{(1 + f)} - 1$$

Thus, the periodic inflation rate provides the link between the inflation-free interest rate and the market rate.

2.2. Actual and Constant Dollar Cash Flows

As noted earlier, economic analysis may be performed on cash flows that are either inflated or not. Thus, two interest rates were defined. The market rate includes the effects of inflation, while these effects are removed from the real interest rate. Here, the corresponding cash flows are defined.

Define actual dollars as cash flows that incorporate the effects of inflation. These may be viewed as out-of-pocket dollars because they are the true expenses paid or revenues received in business transactions at any point in time. Unfortunately, a common terminology does not exist for differentiating dollars, as actual dollars are often referred to as current, nominal, future, or inflated dollars.

Constant dollar cash flows do not include the effects of inflation. As with the inflation-free interest rate, constant dollars are a fictitious concept that represents the change in purchasing power through inflation according to some baseline in time. Constant dollars are often referred to as real, deflated, or today's dollars.

The relationship between constant dollars and actual dollars lies in the inflation rate, as with the relationship between the market and inflation-free interest rates. Because constant dollars do not include the effects of inflation, they may be converted to actual dollars by adding inflation. To show this mathematically, define the actual dollar cash flow at time n as F_n and the constant dollar cash flow at time n as F'_n. To convert constant to actual dollars at the same time period, one must incorporate the effects of inflation, or:

$$F_n = F'_n(1 + f)^n$$

Similarly, to convert actual dollars to constant dollars, one must remove inflation, as follows:

$$F'_n = \frac{F_n}{(1 + f)^n}$$

Figure 1 illustrates the two realms of cash flows: actual dollars and constant dollars. As illustrated in the figure, discounting with actual dollars requires use of the market interest rate, while the

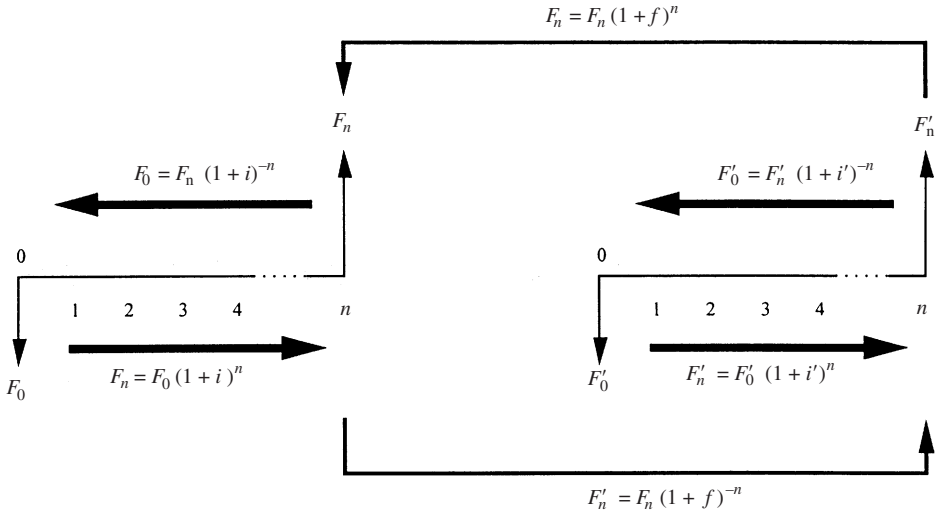

Figure 1 Time Value of Money Calculations for Actual and Constant Dollar Cash Flows and Conversions between the Two with the Inflation Rate.

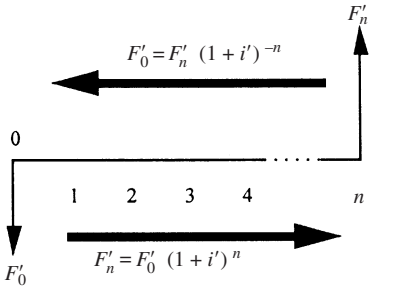

Figure 2 Time Value of Money Calculations for Constant Dolllar Cash Flows with the Inflation-free Interest Rate.

inflation-free rate is utilized with constant dollars. To convert between the interest rates or the dollar domains, the inflation rate is utilized. This is shown with the arrows that cross the domain boundaries.

2.3. Economic Equivalence Calculations with Inflation

Because there are two types of cash flows and two types of interest rates, one may perform economic analyses in one of two domains: (1) constant dollar cash flows with the inflation free interest rate or (2) actual dollar cash flows with the market interest rate. Figure 1 can be broken into the two different domains of cash flows for analysis. Figure 2 illustrates the computations in the constant-dollar domain. These calculations require the use of i'.

Similarly, Figure 3 breaks out the calculations in the actual dollar domain. As noted earlier and illustrated in Figure 1, the inflation rate provides the mathematical link between these environments because it allows one to transform constant-dollar cash flows to actual dollar-cash flows and inflation-free interest rates to market interest rates.

For a decision maker, it is critical that analysis with actual dollars be conducted with the market interest rate and analysis with constant dollars be evaluated at the inflation-free interest rate. If one is provided with constant dollars and a market interest rate or actual dollars and an inflation-free interest rate, the inflation rate must be used to convert either the dollars (from actual to constant or vice versa) or the interest rate (from market to inflation free or vice versa) to the appropriate combination for the ensuing analysis.

Example

Due to deterioration, an industrial firm replaces a piece of its machinery every year. The time zero price of the asset is $25,000. The purchase price is expected to rise at a rate of 4.35% each year. What is the present value of the capital costs incurred by the firm over the next three years? Assume purchases occur at time zero and at the end of each of the three years and a market interest rate of 20%.

Constant Dollar Analysis Because inflationary effects on the cash flows can be ignored, the constant dollar cash flow diagram consists of four expenditures of $25,000 each. The one caveat in

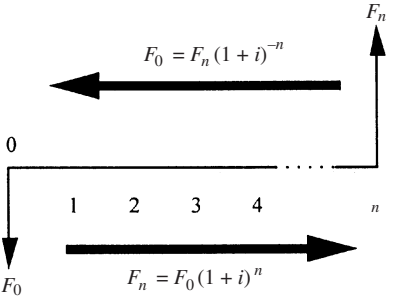

Figure 3 Time Value of Money Calculations for Actual Cash Flows with the Market Interest Rate.

this problem is that the discount rate is the market rate, not the inflation-free rate. Convert the rate as follows:

$$i' = \frac{(1 + i)}{(1 + f)} - 1 = \frac{(1 + 0.20)}{(1 + 0.0435)} - 1 = 0.14997 \simeq 15\%$$

With the inflation-free rate, the net present value (NPV) of the three expenditures in periods one through three can be brought back to time zero using the equal-payment series present-worth factor (Thuesen and Fabrycky 1994) and added to the time zero expenditure, as follows:

$$\begin{aligned} \text{NPV} &= \$25{,}000 + \$25{,}000(P/A, 15\%, 3) \\ &= \$25{,}000 + \$25{,}000 \left[\frac{(1 + 0.15)^3 - 1}{0.15(1 + 0.15)^3}\right] = \$82{,}080.63 \end{aligned}$$

An equivalent analysis can be conducted with actual dollar cash flows.

Actual Dollar Analysis The actual cash flows must be calculated in each period. To convert the constant dollar flows, the inflation rate must be utilized as follows:

$$F_n = F'_n(1 + f)^n$$

For time zero, the cash flows are the same, but for time period one:

$$F_1 = \$25{,}000(1 + .0435) = \$26{,}087.50$$

The cash flows have been calculated for each period and are listed in Table 1.

The NPV of the actual cash flows is found using the market interest rate of 20%. Because there is no pattern, each cash flow must be brought back to time zero individually as follows:

$$\text{NPV} = \$25{,}000 + \frac{\$26{,}087.50}{(1 + 0.20)} + \frac{\$27{,}222.31}{(1 + 0.20)^2} + \frac{\$28{,}406.48}{(1 + 0.20)^3} = \$82{,}082.90$$

Note that the constant dollar and actual dollar analysis lead to the same net present value of costs (within an acceptable rounding error of $2.27). To illustrate that this holds in general, the NPV value for the actual dollar cash flow can be rewritten as follows:

$$\begin{aligned} \text{NPV} &= F_0 + \frac{F_1}{(1 + i)} + \frac{F_2}{(1 + i)^2} + \frac{F_3}{(1 + i)^3} \\ &= \$25{,}000 + \frac{\$26{,}087.50}{(1 + 0.20)} + \frac{\$27{,}222.31}{(1 + 0.20)^2} + \frac{\$28{,}406.48}{(1 + 0.20)^3} \\ &= \$25{,}000 + \frac{\$25{,}000(1 + 0.0435)}{(1 + 0.20)} + \frac{\$25{,}000(1 + 0.0435)^2}{(1 + 0.20)^2} + \frac{\$25{,}000(1 + 0.0435)^3}{(1 + 0.20)^3} \\ &= F'_0 + \frac{F'_1(1 + f)}{(1 + i)} + \frac{F'_2(1 + f)^2}{(1 + i)^2} + \frac{F'_3(1 + f)^3}{(1 + i)^3} \\ &= F'_0 + \frac{F'_1}{(1 + i')} + \frac{F'_2}{(1 + i')^2} + \frac{F'_3}{(1 + i')^3} \end{aligned}$$

Therefore, if one inflation rate is assumed for all cash flows, then actual and constant dollar analyses are equivalent. This allows one to choose the more straightforward analysis for calculations. In the

TABLE 1 Constant and Actual Dollar Cash Flows for Example

Year	Constant-Dollar Cash Flow	Actual Dollar Cash Flow
0	$25,000.00	$25,000.00
1	$25,000.00	$26,087.50
2	$25,000.00	$27,222.31
3	$25,000.00	$28,406.48

previous example, the constant dollar cash flow was straightforward because the cash flows resulted in an equal payment series while the actual dollar cash flows had no pattern. Unfortunately, most applications do not allow for the decision maker to select the analysis, as inflation rates may differ by the cash flow or time period or inflation may not affect certain cash flows, such as loan payments and the cash flow effects of depreciation (in the United States). These cases are examined in the following sections.

2.4. Differing Inflation Rates for Component Cash Flows

As noted earlier, numerous price indexes exist for estimating inflation rates for various commodities. Thus, for a given analysis, one may compute a variety of inflation rates for use in a single analysis. Unless a single inflation rate affects all the cash flows involved in calculations, each component cash flow must be converted individually at the appropriate rate for proper analysis (Oakford and Salazar 1982).

Define f_k as the inflation rate for cash flow component k. If the net cash flow at time n, F_n, is made up of a number (K) of component cash flows $F_{k,n}$, then the actual net cash flow is equivalent to the sum of the actual component cash flows:

$$F_n = \sum_{k=1}^{K} F_{k,n}$$

To convert constant dollar component cash flows to a net actual dollar cash flow, one sums the individually converted cash flows as follows:

$$F_n = \sum_{k=1}^{K} F'_{k,n} (1 + f_k)^n$$

This is illustrated in the following example.

Example. Labor costs are estimated at \$10,000 at time zero and are assumed to increase at a rate of 3.2% per year. Time zero material costs are estimated at \$20,000 and are assumed to increase at a rate of 5%. Finally, fuel and energy costs are expected to increase at a rate of 4.5% from a time zero value of \$12,000. What are the total expected costs at the end of period 3?

Constant Dollar Analysis As all costs are given in time zero dollars, a straightforward solution would be that the total costs are:

$$\$10{,}000 + \$20{,}000 + \$12{,}000 = \$42{,}000$$

in constant dollars (with time zero serving as the baseline).

Actual Dollar Analysis The individual component inflation rates must be used to convert this to an actual dollar cash flow at the end of period 3. This is accomplished as follows:

$$\$10{,}000(1 + 0.032)^3 + \$20{,}000(1 + 0.05)^3 + \$12{,}000(1 + 0.045)^3 = \$47{,}837.54$$

This represents the expected net expenses at the end of time period 3 in actual dollars.

2.5. Differing Inflation Rates per Time Period

An additional complication is an inflation rate that changes over time. This is generally more realistic, as inflation is not a constant, which is assumed when using the average rate f defined earlier. Examining various price indexes, such as the CPI, it is clear that the inflation rate changes periodically. To perform precise economic analysis, the inflation rate must also change periodically. This is not difficult, but it complicates the analysis as calculations must be repeated.

Consider the conversion of a constant dollar cash flow at time n, F'_n, to an actual dollar cash flow F_n at the same time period:

$$F_n = F'_n(1 + f)^n$$

Because there are n periods of inflation, we may generalize this to n different periodic inflation rates. Define f_t as the inflation rate for period t. The conversion can now be written as:

$$f_n = F'_n(1 + f_1)(1 + f_2) \ldots (1 + f_n)$$

We revisit the example of the previous section to illustrate the calculation.

Example. Labor costs are estimated at $10,000 at time zero and are assumed to increase at a rate of 2.0% the first year, 2.4% the second year, and 3.5% the third year. Time zero material costs are estimated at $20,000 and are assumed to increase at rates of 3.0, 4.0, and 5.5% for each of the three years, respectively. Finally, fuel and energy costs are expected to increase at rates of 4.5, 4.1, and 5.2%, respectively, from a time zero value of $12,000. What are the total expected costs at the end of period 3?

Constant Dollar Analysis As before, the constant dollar solution is as follows:

$$\$10{,}000 + \$20{,}000 + \$12{,}000 = \$42{,}000$$

in constant dollars (with time zero serving as the baseline).

Actual Dollar Analysis Again, the component inflation rates, with considerations for the change over time, must be used to convert this to an actual dollar cash flow at the end of period 3. This is accomplished as follows:

$$\$10{,}000(1 + 0.02)(1 + 0.024)(1 + 0.035) + \$20{,}000(1 + 0.03)(1 + 0.04)(1 + 0.055) + \$12{,}000(1 + 0.045)(1 + 0.041)(1 + 0.052) = \$47{,}145.64$$

As before, this represents the expected net expenses at the end of time period three in actual dollars.

2.6. Relationship between Inflation and Exchange Rates

Inflation is a general term that refers to changes in price. As illustrated in this chapter, it allows one to convert a constant dollar cash flow, which does not incorporate the effects of inflation, into an actual dollar cash flow. An exchange rate, which allows for the conversion from one form of currency to another, acts in a similar manner. Exchange rates allow one to convert dollars in a given currency to another currency. Furthermore, changes in the exchange rate between two currencies over time are analogous to changes in the general inflation rate because the relative purchasing power between the two currencies changes with the exchange rate (DeGarmo et al. 1997). We examine this with the following investment example.

Example. A multinational firm based in the United States is considering an investment in Mexico. The exchange rate is currently 10 Mexican pesos to 1 U.S. dollar. (There are a variety of sources available with exchange rate data, e.g., Tukiainen 1999.) Assume an investment cost of 10 million pesos with an expected annual return of 500,000 pesos per year over a five-year horizon.

Assuming a constant exchange rate over the five-year horizon, the analysis is straightforward. In pesos, a 10 million-peso investment at time zero results in five equal annual payments of 500,000 pesos. The exchange rate converts this to U.S. dollars, in which it is equivalent to a 1 million-dollar investment at time zero with annual profits of $50,000 per year. Because these are assumed to be constant dollars, the net present value can be computed given the appropriate inflation-free interest rate.

A more interesting question that is more directly related to the issue of inflation is whether the currency exchange rate is expected to change over time. For example, assume that the exchange rate between the U.S. and Mexico is expected to decline at 1% per year over the next five years. As the exchange rate is merely an index to convert currencies, the change in the rate corresponds to inflation. See DeGarmo et al. (1997) and Lee and Sullivan (1995) for more on this matter.

3. THE EFFECTS OF INFLATION IN ECONOMIC ANALYSIS

This section examines more complicated investment scenarios from both before-tax and after-tax cash flow perspectives. It is important to analyze these cases because inflation has a much more drastic impact on after-tax analysis due to the necessary inclusion of depreciation charges. Specifically, examples that include taxes and loans are examined to illustrate the different effects of inflation.

3.1. Before-Tax Cash Flow Analysis

The following example illustrates the effects of inflation on borrowing funds. This analysis is similar to any contract signed for future services because the cash flows are agreed upon and therefore represent out-of-pocket expenses. Thus, by definition, these expenses are actual dollar cash flows. The following example illustrates the required calculations to determine the net present value or rate of return for a project.

Example. A firm purchases a piece of machinery for $50,000. Half of the purchase price is borrowed at an interest rate of 7% per year. Two equal payments are made at the end of years 1 and 2 to pay off the loan. The asset is expected to generate revenues of $75,000 per year for three years,

TABLE 2 Actual Cash Flows for Investment Example

Year	0	1	2	3
Revenues		\$78,750.00	\$82,687.50	\$86,821.88
O&M expenses		(\$15,750.00)	(\$16,537.50)	(\$17,364.38)
Interest expenses		(\$1,750.00)	(\$904.59)	
Capital cost	(\$50,000)			\$11,576.25
Loan principal	\$25,000	(\$12,077.30)	(\$12,922.70)	
Before-tax cash flow	(\$25,000)	\$49,172.70	\$52,322.71	\$81,033.75

at which time it is sold for a salvage value of \$10,000. Operating and maintenance (O&M) expenses are assumed to be \$15,000 per year. All costs here are given in time zero dollars. Determine the net present value of the transaction assuming a market interest rate of 20%.

Because loan interest and principal payments are defined by a contractual agreement, they are actual dollar cash flows. Thus, we first analyze this problem from the perspective of the actual dollar domain.

Actual Dollar Analysis (1) In this first actual dollar analysis, we assume one (general) annual inflation rate of 5% for the revenues and expenses and the salvage value of the asset at the end of period 3. All of the actual dollar cash flows are given in Table 2. Negative cash flows are denoted in parentheses. Note that the interest and principal payments are unaffected by the inflation rate becasue they are dependent on a prior agreement.

The present value of the actual dollar before-tax cash flow is calculated using the market interest rate, as follows:

$$\text{NPV} = -\$25{,}000 + \frac{\$49{,}172.70}{(1 + 0.20)} + \frac{\$52{,}322.71}{(1 + 0.20)^2} + \frac{\$81{,}033.75}{(1 + 0.20)^3} = \$99{,}207.00$$

Constant Dollar Analysis In the original problem statement, all cash flows were presented in constant dollars. Thus, revenues, operating and maintenance expenses, and capital costs are straightforward. However, the loan principal and interest expenses are actual dollar cash flows, which means they include the effects of inflation. Thus, these cash flows must be deflated with the inflation rate of 5%. These calculated cash flows, along with the other constant cash flows, are provided in Table 3.

The present value of the constant dollar before-tax cash flow is calculated using the inflation free interest rate. The inflation-free rate is calculated from the market and inflation rates, as follows:

$$i' = \frac{1 + 0.20}{1 + 0.05} - 1 = 0.1429 = 14.29\%$$

This rate is then used to calculate the net present value with the constant dollar before-tax cash flow:

$$\text{NPV} = -\$25{,}000 + \frac{\$46{,}831.14}{(1 + 0.1429)} + \frac{\$47{,}458.24}{(1 + 0.1429)^2} + \frac{\$70{,}000.00}{(1 + 0.1429)^3} = \$99{,}197.46$$

As expected, the net present value is equivalent (within rounding error) of the actual dollar analysis.

TABLE 3 Constant Cash Flows for Investment Example

Year	0	1	2	3
Revenues		\$75,000.00	\$75,000.00	\$75,000.00
O&M expenses		(\$15,000.00)	(\$15,000.00)	(\$15,000.00)
Interest expenses		(\$1,666.67)	(\$820.49)	
Capital costs	(\$50,000)			\$10,000.00
Loan principal	\$25,000	(\$11,502.19)	(\$11,721.27)	
Before-tax cash flow	(\$25,000)	\$46,831.14	\$47,458.24	\$70,000.00

TABLE 4 Actual Cash Flows with Varying Inflation Rates for Investment Example

Year	0	1	2	3
Revenues		$78,750.00	$82,687.50	$86,821.88
O&M expenses		($15,450.00)	($15,913.50)	($16,390.91)
Interest expenses		($1,750.00)	($904.59)	
Capital costs	($50,000)			$12,597.12
Loan principal	$25,000	($12,077.30)	($12,922.70)	
Before-tax cash flow	($25,000)	$49,472.70	$52,946.71	$83,028.09

Actual Dollar Analysis (*2*) Because it is more realistic to assume inflation rates that vary for each cash flow component, we revisit the actual dollar analysis. Assume that the revenues grow at a rate of 5% per period, O&M expenses increase at a rate of 3% and the salvage value grows at a rate of 8% per period. The revised actual dollar cash flows for this example are given in Table 4. As before, interest expenses, the initial purchase cost, and the loan principal payments are unaffected.

Using the market interest rate of 20%, the net present value of the actual dollar before-tax cash flows is $101,044.46. Because O&M costs were projected lower and the salvage value higher than in the previous actual dollar cash flow analysis, this higher net present value was expected.

The calculations are not repeated here for the corresponding constant dollar analysis, as the cash flows are the same as before. However, there is one final point that must be addressed. In this problem instance, the market rate was provided. This allows for the discounting of actual dollar cash flows. Generally, with the use of an inflation rate, the market rate can be converted to an inflation-free rate. However, in this final example with component cash flows having different inflation rates, this analysis is not straightforward. In this case, a *general* inflation rate (Park 1997) is generally specified such that the inflation free rate can be calculated. This rate would generally correspond to a broader index, such as the CPI, whereas the component inflation rates would be derived from more specific indexes. If an inflation-free rate had been specified in the problem, then a general inflation rate would have also had to be specified to determine a single market interest rate for discounting.

3.2. After-Tax Cash Flow Analysis

As shown in the previous section, loans and agreed-upon prices can complicate analyses because not all cash flows are defined as either constant or actual dollars, but rather a mix. Performing after-tax analysis presents further complicating issues. However, it is generally recognized that after-tax analyses should be performed when economically validating engineering projects (Park and Sharp-Bette 1990).

When considering after-tax cash flows, some form of actual dollar analysis must be performed because taxes are paid on profits from actual revenues. This is not to say that constant dollar analyses cannot be performed, but the actual dollars must generally be estimated before conversion to constant dollars can take place.

The following after-tax analyses revisit the before-tax transaction from the previous section. It should be noted that the goal of this section is not to present current tax law, which is forever changing and in which rules are different according to the location where the asset is in use and the time the asset is both placed in and removed from service. Rather, the point here is to illustrate the effect of inflation on differing components of cash flows common to after-tax analysis.

Example. The example analyzed as a before-tax transaction is again examined here. It is assumed that the asset is depreciated using the straight-line method over three years. For simplicity, no adjustments to the amount of depreciation are made at the time of sale.

Because taxes are paid on actual revenues and expenses, the actual dollar cash flow is analyzed first. A market interest rate of 15% is assumed.

Actual Dollar Analysis Assume a single annual inflation rate of 5% for the revenues, expenses, and salvage value of the asset at the end of period 3. As before, the interest and principal payments are not affected by inflation. Table 5 provides the actual cash flows for this example. Note that depreciation expenses are provided in order to calculate taxes although they are not cash flows. For the sake of simplicity, we assume a marginal tax rate of 40%, which is also applied to capital gains.

The after-tax cash flow, which is generally found on a cash flow statement, adds the after-tax profit, purchase costs, and loan principal payments and also adds back in the depreciation expenses because depreciation is not a cash flow. The net present value of the actual dollar after-tax cash flow is then computed at the market rate of 15%. The NPV for this example is $63,474.15.

TABLE 5 Actual Cash Flows for After-Tax Investment Example

Year	0	1	2	3
Revenues		$78,750.00	$82,687.50	$86,821.88
O&M expenses		($15,750.00)	($16,537.50)	($17,364.38)
Interest expenses		($1,750.00)	($904.59)	
Depreciation expenses		($16,666.67)	($16,666.67)	($16,666.67)
Before-tax operating profit		$44,583.33	$48,578.74	$52,790.83
Salvage values				$11,576.25
Tax on capital gain				($4,630.50)
Total taxes		($17,833.33)	($19,431.50)	($25,746.83)
After-tax profit		$26,750.00	$29,147.24	$38,620.25
Purchase cost	($50,000)			
Loan principal	$25,000	($12,077.30)	($12,922.70)	
After-tax cash flow	($25,000)	$31,339.37	$32,891.21	$55,286.92

Constant Dollar Analysis Unlike previous examples presented in this chapter, the constant dollar analysis for after-tax cash flows requires the computation of actual dollar cash flows because taxes are actual dollar cash flows. Although the net actual dollar after-tax cash flow can be converted to a net constant dollar cash flow for analysis, we explicitly show each of the component cash flows in Table 6 because if the component inflation rates differ, each component cash flow must be analyzed with the appropriate rate. The cash flows given in Table 5 as depreciation expenses are no longer needed as the taxes have been calculated. The general 5% inflation rate is used here to deflate all actual dollar cash flows.

With a market interest rate of 15% and a general inflation rate of 5%, the inflation-free rate is 9.52%. This leads to a net present value of $63,480.63, which is equivalent to the actual dollar analysis (within rounding error). This is expected because all of the component cash flows were inflated at the same rate. As noted in the before-tax analysis, if the component inflation rates differ, then there may be a discrepancy in the final net present value analysis because the conversion from a market rate to an inflation-free rate (or vice versa) requires a single inflation rate.

This may lead one to ask the question of which analysis should be performed. There is no correct answer. However, as these examples illustrated, more complicated cash flow scenarios generally lead to actual dollar cash flow analysis. This is because the computation of one's tax liability is based on actual dollar cash flows. Also, contracted prices, such as loans and lease agreements, are based on actual dollar cash flows. In these situations, actual dollar cash flow analysis may be more straightforward because most of the data are also in the correct form.

Regardless of the method chosen, it is important to include inflation in analysis because it may have drastic effects. Consider the after-tax example analyzed in this section. Table 7 provides the cash flows ignoring inflation. Note that these flows are not equivalent to constant dollar cash flows, as the interest and principal payments remain as actual dollar flows. The present value, at the 15% market rate, is $54,765.84. In this example, ignoring inflation leads to a lower net present value and thus may lead to a different decision. Inflation can have various effects on project cash flows and thus greatly influence decisions. In general, inflation results in overstated income and higher taxes. This is sometimes referred to as tax bracket creep because inflation may push a company's revenues, and thus profits, into a higher tax bracket. Similarly, inflated salvage values result in larger capital gains and resulting taxes. As shown in the above example, inflation can actually reduce the cost of

TABLE 6 Constant Cash Flows for After-Tax Investment Example

Year	0	1	2	3
Revenues		$75,000.00	$75,000.00	$75,000.00
O&M expenses		($15,000.00)	($15,000.00)	($15,000.00)
Interest expenses		($1,666.67)	($820.49)	
Salvage values				$10,000.00
Total taxes		($16,984.12)	($17,624.94)	($22,241.08)
Purchase cost	($50,000)			
Loan principal	$25,000	($11,502.19)	($11,721.27)	
After-tax cash flow	($25,000)	$29,847.02	$29,833.30	$47,758.92

TABLE 7 Cash Flows Ignoring Inflation for After-Tax Investment Example

Year	0	1	2	3
Revenues		$75,000.00	$75,000.00	$75,000.00
O&M expenses		($15,000.00)	($15,000.00)	($15,000.00)
Interest expenses		($1,750.00)	($904.59)	
Salvage values				$10,000.00
Total taxes		($16,633.33)	($16,971.50)	($21,333.33)
Purchase cost	($50,000)			
Loan principal	$25,000	($12,077.30)	($12,922.70)	
After-tax cash flow	($25,000)	$29,539.37	$29,201.21	$48,666.67

financing because that cost is fixed at the agreed upon rate. In summary, the effects of inflation can alter cash flows significantly and thus strongly influence the decision to accept or reject a project. Therefore, they should not be ignored in any economic analysis.

1. INTRODUCTION

Over the past few decades, human factors and ergonomics practitioners have increasingly been called upon early in the system design and development process. Early input from all disciplines results in better and more integrated designs as well as lower costs than if one or more disciplines finds that changes are required later. Our goal as human factors and ergonomics practitioners should be to provide substantive and well-supported input regarding the human(s), his or her interaction(s) with the system, and the resulting total performance. Furthermore, we should be prepared to provide this input from the earliest stages of system concept development and then throughout the entire system or product life cycle.

To meet this challenge, many human factors and ergonomics tools and technologies have evolved over the years to support early analysis and design. Two specific types of technologies are design guidance (e.g., O'Hara et al. 1995; Boff et al. 1986) and high-fidelity rapid prototyping of user interfaces (e.g., Dahl et al. 1995). Design guidance technologies, in the form of either handbooks or computerized decision support systems, put selected portions of the human factors and ergonomics knowledge base at the fingertips of the designer, often in a form tailored to a particular problem such as nuclear power plant design or UNIX computer interface design. However, design guides have the shortcoming that they do not often provide methods for making quantitative trade-offs in *system* performance as a function of design. For example, design guides may tell us that a high-resolution color display will be better than a black-and-white display, and they may even tell us the value in terms of increased response time and reduced error rates. However, this type of guidance will rarely provide good insight into the value of this improved element of the human's performance to the *overall system's* performance. As such, design guidance has limited value for providing concrete input to system-level performance prediction.

Rapid prototyping, on the other hand, supports analysis of how a specific design and task allocation will affect human and system-level performance. The disadvantage of prototyping, as with all human-subjects experimentation, is that it can be costly. In particular, prototypes of hardware-based systems, such as aircraft and machinery, are very expensive to develop, particularly at early design stages when there are many widely divergent design concepts. In spite of the expense, hardware and software prototyping are important tools for the human factors practitioner, and their use is growing in virtually every application area.

While these technologies are valuable to the human factors practitioner, what is often needed is an integrating methodology that can extrapolate from the base of human factors and ergonomics data, as reflected in design guides and the literature, in order to support system-level performance predictions as a function of design alternatives. This methodology should also bind with rapid prototyping and experimentation in a mutually supportive and iterative way. As has become the case in many engineering disciplines, a prime candidate for this integrating methodology is computer modeling and simulation.

Computer modeling of human behavior and performance is not a new endeavor. Computer models of complex cognitive behavior have been around for over 20 years (e.g., Newell and Simon 1972) and tools for computer modeling of task-level performance have been available since the 1970s (e.g., Wortman et al. 1978). However, two things have changed appreciably in the past decade that promote the use of computer modeling and simulation of human performance as a standard tool for the practitioner. First is the rapid increase in computer power and the associated development of easier-to-use modeling tools. Individuals with an interest in predicting human performance through simulation can select from a variety of computer-based tools (for a comprehensive list of these tools, see McMillan et al. 1989). Second is the increased focus by the research community on the development of *predictive* models of human performance rather than simply descriptive models. For example, the GOMS model (Gray et al. 1993) represents the integration of research into a model for making predictions of how humans will perform in a realistic task environment. Another example is the research in cognitive workload that has been represented as computer algorithms (e.g., McCracken and Aldrich 1984; Farmer et al. 1995). Given a description of the tasks and equipment with which humans are engaged, these algorithms support assessment of when workload-related performance problems are likely to occur and often include identification of the quantitative impact of those problems on overall system performance (Hahler et al. 1991). These algorithms are particularly useful when embedded as key components in computer simulation models of the tasks and the environment.

Perhaps the most powerful aspect of computer modeling and simulation is that it provides a method through which the human factors and ergonomics team can step up to the table with the

other engineering disciplines that also rely increasingly on quantitative computer models. What we will discuss in this chapter are the methods through which the human factors and ergonomics community can contribute early to system design tradeoff decisions.

2. OBJECTIVES OF THIS CHAPTER

This chapter will discuss some existing computer tools for modeling and simulating human/system performance. It is intended to provide the reader with:

1. An understanding of the types of human factors and ergonomics issues that can be addressed with modeling and simulation
2. An understanding of some of the tools that are now available to assist the human factors and ergonomics specialist in conducting model-based analyses
3. An appreciation of the level of expertise and effort that will be required to use these technologies

We begin this chapter with two caveats. First, we are not yet at a point where computer modeling of human behavior allows sufficiently accurate predictions that no other analysis method (e.g., prototyping) is likely to be needed. In early stages of system concept development, high-level modeling of human–system interaction may be all that is possible. As the system moves through the design process, human factors and ergonomics designers will often want to augment modeling and simulation predictions with prototyping and experimentation. In addition to providing high-fidelity system performance data, these data can be used to enhance and refine the models. This concept of human performance modeling supporting and being supported by experimentation with human subjects is represented in Figure 1. In essence, simulation provides the human factors and ergonomics practitioner with a means of extending the knowledge base of human factors and of amplifying the effectiveness of limited experimentation.

Second, the technologies discussed here are evolving rapidly. We can be certain that (1) every tool discussed is undergoing constant change and (2) new modeling tools are being developed. We are discussing computer-based tools, and we expect the pace of change in these tools to mirror the pace in other computer tools such as word processors and spreadsheets. These detailed discussions of several of the modeling tools are included to facilitate a better understanding of human performance modeling tools. We encourage the reader to contact citations in this chapter to assess the state of any tool at that time.

3. THE TYPES OF QUESTIONS THAT ARE BEING ADDRESSED BY HUMAN PERFORMANCE MODELS

Below are a few classes of problems to which human/system modeling has been applied:

- How long will it take a human or team of humans to perform a set of tasks as a function of system design, task allocation, and individual capabilities?
- What are the trade-offs in performance for different combinations of design, task allocation, and individual capability selections?
- What are the workload demands on the human as a function of system design and automation? How will human performance and resulting system performance change as the demands of the environment change? How many individuals are required on a team to ensure safe, successful performance? How should tasks be allocated to optimize performance?
- How will environmental stressors such as heat, cold, and the use of drugs affect human–system performance?

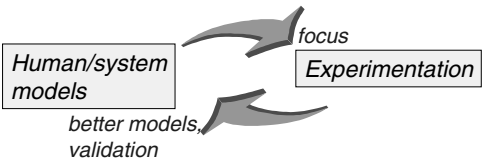

Figure 1 The Synergy between Modeling and Experimentation.

The above is a sampling rather than an exhaustive list. The tools we discuss in this chapter are inherently flexible, and we consistently discover that these tools can be used to solve problems that the tool developers never conceived.

To assess the potential of simulation to answer questions, every potential human performance modeling project should first determine the specific questions that the project is trying to answer. Then conduct a critical assessment of what is important in the human–machine system being modeled. This will define the required content and fidelity of the model. The questions that should be considered about the system include:

- *Human performance representation:* What time or duration of performance is important? How is human performance initiated and what resolution of behavior is required? What aspects of human performance, including task management, load management, and goal management, are expected?
- *Equipment representation:* What equipment is used to accomplish the tasks? To what level of functional and physical description can and should the equipment be represented? Is it operable by more than one human or system component?
- *Interface requirements:* What information needs to be conveyed to the humans and when? Is transformation of information required?
- *Control requirements:* What processes need to be controlled by the human and to what level of resolution?
- *Logical and physical constraints:* How is performance supported through equipment operability and procedural sequences? What alarms and alerts should be represented?
- *Simulation driver:* What makes the system function—the occurrence of well-defined events (e.g., a procedure), the movement of time (e.g., the control of a vehicle), or a hybrid of both?

By defining the purpose of the model and then answering the above questions, the human factors practitioner will get a sense of what is important in the system and therefore what may need to be represented in a model. In using human performance models, perhaps the most significant task of the human factors practitioner will be to determine what aspects of the human/machine system to include in the model and what to leave out. Many modeling studies have failed because of the inclusion of too many factors that, while a part of human–system performance, were not system performance drivers. Consequently, the models become overly complex and expensive to develop. In our experience, it is better to begin with a model with too few aspects of the system represented and then add to it than to begin a modeling project by trying to model everything. The first approach may succeed, while the second is often doomed.

Second, the human factors practitioner should consider the measures of effectiveness of the system that the model should be designed to predict. In building the model, it is important to remember that the goal of the model will be to predict measures of human performance that will impact system performance. Therefore, a clear definition of what is important to performance is necessary. The following aspects of performance measures should be considered:

- *Success criteria:* What operational success measures are important to the system? Can these be stated in relative terms, or must they be measured in absolute terms?
- *Range of performance to be studied:* What are the experimental variables that are to be explored by the model? How important is it to establish a range of performance for each experimental condition as a function of the stochastic (i.e., random) behavior of the system?

By asking the above questions prior to beginning a modeling project, the human factors practitioner can develop a better sense of what is important in the system in terms of both aspects that drive system performance as well as the measures of effectiveness that are truly of interest. Then and only then can a human performance modeling project begin with a reasonable hope of success.

The remainder of this chapter will discuss two classes of modeling tools for human performance simulation. After discussing each class of modeling tool, we will provide specific examples of a modeling tool and then provide case studies about how these tools have been used in answering real human performance questions.

4. THE TWO CLASSES OF SIMULATION MODELS OF HUMAN–SYSTEM PERFORMANCE

Human performance can be highly complex and involve many types of processes and behavior. Over the years, many models have been developed that predict sensory processes (e.g., Gawron et al. 1983), aspects of human cognition (e.g., Newell 1990), and human motor response (e.g., Fitts's law).

The current literature in the areas of cognitive engineering, error analysis, and human–computer interaction contains many models, descriptions, methodologies, metaphors, and functional analogies. However, in this chapter we are not focusing on the models of these individual elements of human behavior but rather on models that can be used to describe human performance in systems. These human/system performance models typically include some of these elemental behavioral models as components but provide a structural framework that allows them to be put in the context of human performance of tasks in systems.

We separate the world of human–system performance models into two general categories: *reductionist* models and *first principle* models. Reductionist models use human/system task sequences as the primary organizing structure, as shown in Figure 2. The individual models of human behavior for each task or task element are connected to this task-sequencing structure. We refer to it as reductionist because the process of modeling human behavior involves taking the larger aspects of human/system behavior (e.g., ''perform the mission'') and then successively reducing them to smaller elements of behavior (e.g., ''perform the function,'' ''perform the tasks''). This continues until a level of decomposition is reached at which reasonable estimates of human performance for the task elements can be made. One can also think of this as a top-down approach to modeling human/system performance. The example of this type of modeling that we will use in this chapter will be task network modeling, where the basis of the human–system model is a task analysis.

First-principle models of human behavior are structured around an organizing framework that represents the underlying goals and principles of human performance. Tools that support first-principle modeling of human behavior have structures embedded in them that represent elemental aspects of the human. For example, these models might directly represent processes such as goal-seeking behavior, task scheduling, sensation and perception, cognition, and motor output. To use tools that support first-principle modeling, one must describe how the system and environment interact with the modeled human processes. An example of a very simple structure that supports this type of modeling environment is presented in Figure 3. The example we will use of a tool designed to support this type of modeling is the Man–Machine Integrated Design and Analysis System (MIDAS).

It is worth noting that these two modeling strategies are not mutually exclusive and, in fact, can be mutually supportive in any given modeling project. Often, when one is modeling using a reductionist approach, one needs models of basic human behavior to represent behavioral phenomena accurately and therefore must draw on elements of first-principle models. Alternatively, when one is modeling human–system performance using a first-principled approach, some aspects of human–system performance and interrelationships between tasks may be more easily defined using a reductionist approach. Either class of model has been used to model individual and team performance. It is also worth noting that recent advances in human performance modeling tool development are blurring the distinctions between these two classes (e.g., Hoagland et al. 2001; LaVine 2000). Increased emphasis on interoperability between models has caused researchers and developers to focus on integrating reductionist and first-principle models.

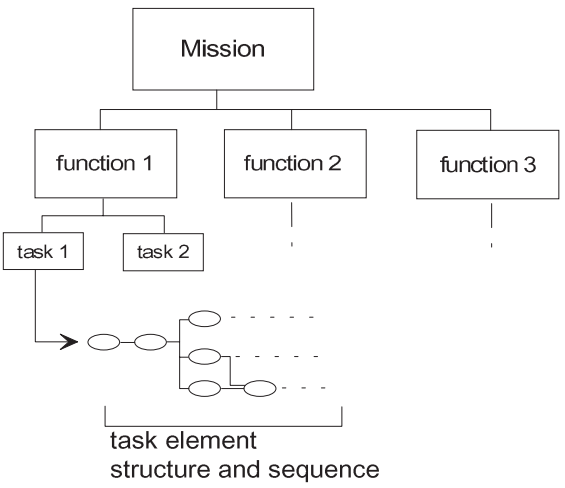

Figure 2 The Concept of Reductionist Models of Human Performance.

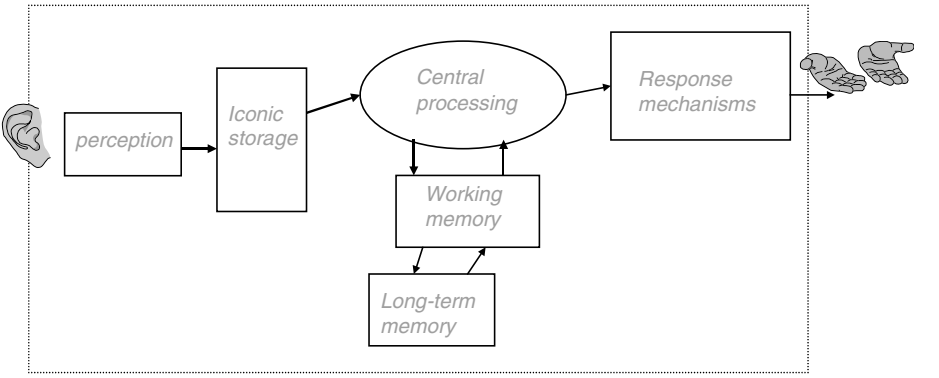

Figure 3 An Example of the Concept of First-Principle Models of Human Performance.

5. AN EXAMPLE OF A REDUCTIONIST APPROACH: TASK NETWORK MODELING

One technology that has proven useful for predicting human-system performance is task network modeling. In a task network model, human performance is decomposed into tasks. The fidelity of this decomposition can be selective, with some functions being decomposed several levels and others just one or two. This is, in human factors engineering terms, the task analysis. The sequence of tasks is defined by constructing a task network. This concept is illustrated in Figure 4, which presents a sample task network for dialing a telephone.

Task network modeling is an approach to modeling human performance in complex systems that has evolved for several reasons. First, it is a reasonable means for extending the human factors staple—the task analysis. Task analyses organized by task sequence are the basis for the task network model. Second, task network models can include sophisticated submodels of the system hardware and software to create a closed-loop representation of relevant aspects of the human/machine system. Third, task network modeling is relatively easy to use and understand. Recent advancements in task network modeling technology have made this technology more accessible to human factors practitioners. Finally, task network modeling can provide efficient, valid, and useful input to many types of issues. With a task network model, the human factors engineer can examine a design (e.g., control panel redesign) and address questions such as ''How much longer will it take to perform this procedure?'' and ''Will there be an increase in the error rate?'' Generally, task network models can be developed in less time and with substantially less effort than would be required if a prototype were developed and human subjects used. However, as stated before, for revolutionary designs, modeling may not alleviate the need for empirical data collection.

Task network models of human performance have been subjected to validation studies with favorable results (e.g., Lawless et al. 1995; However, as with any modeling approach, the real level at which validation must be considered is with respect to a particular model, not with respect to the general approach.

5.1. What Goes into a Task Network Model?

To represent complex, dynamic human/system behavior, many aspects of the system may need to be modeled in addition to simply task lists and sequence. In this subsection, we will use the task network modeling tool Micro Saint as an example.

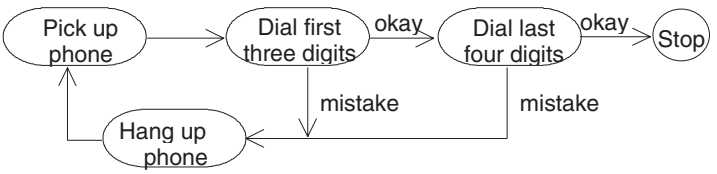

Figure 4 An Example of a Task Network Model Representing a Human Dialing a Telephone.

The basic ingredient of a Micro Saint task network model is the task analysis as represented by a network or series of networks. The level of system decomposition (i.e., how finely we decompose the tasks) and the amount of the system that is simulated depends on the particular problem. For example, in a power plant model, one can create separate networks for each of the operators and one for the power plant itself. While the networks may be independent, performance of the tasks can be interrelated through shared variables. The relationships among different components of the system, represented by different segments of the network, can then communicate through changes in these shared variables. For example, when an operator manipulates a control, this may initiate an open valve task in a network representing the plant. This could ripple through to a network representing other operators and subsystems and their response to the open valve.

This basic task network is built in Micro Saint via a point-and-click drawing palette. Through this environment, the user creates a network as shown in Figure 5. Networks can be embedded within networks, allowing for hierarchical construction. In addition, the shape of the nodes on the diagram can be chosen in order to represent specific types of activity.

To reflect complex task behavior and interrelationships, more detailed characteristics of the tasks need to be defined. By double clicking on a task, the user opens up the task description window, as shown in Figure 6. Below are descriptions of each of the items on this window.

Task number: An arbitrary number for task referencing.

Task name: any name used to identify the task.

Time distribution: Micro Saint will conduct Monte Carlo simulations with task performance times sampled from a distribution as defined by this option (e.g., normal, beta, exponential).

Mean time: This parameter defines average task performance time for this task. This can be a number, equation, or algorithm, as can all values in the fields described below.

Standard deviation: Standard deviation of task performance time.

Release condition: Data in this field will determine when a task begins executing. For example, a condition stating that this task will not start before an operator is available might be represented by a release condition such as the following:

$$\text{operator} >= 1$$

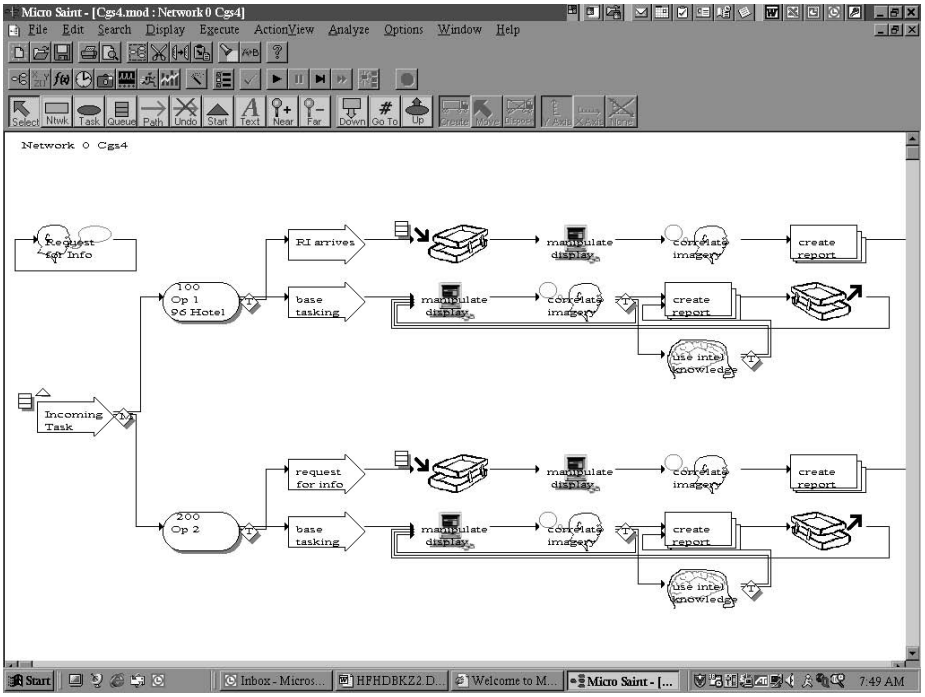

Figure 5 The Main Window in Micro Saint for Task Network Construction and Viewing.

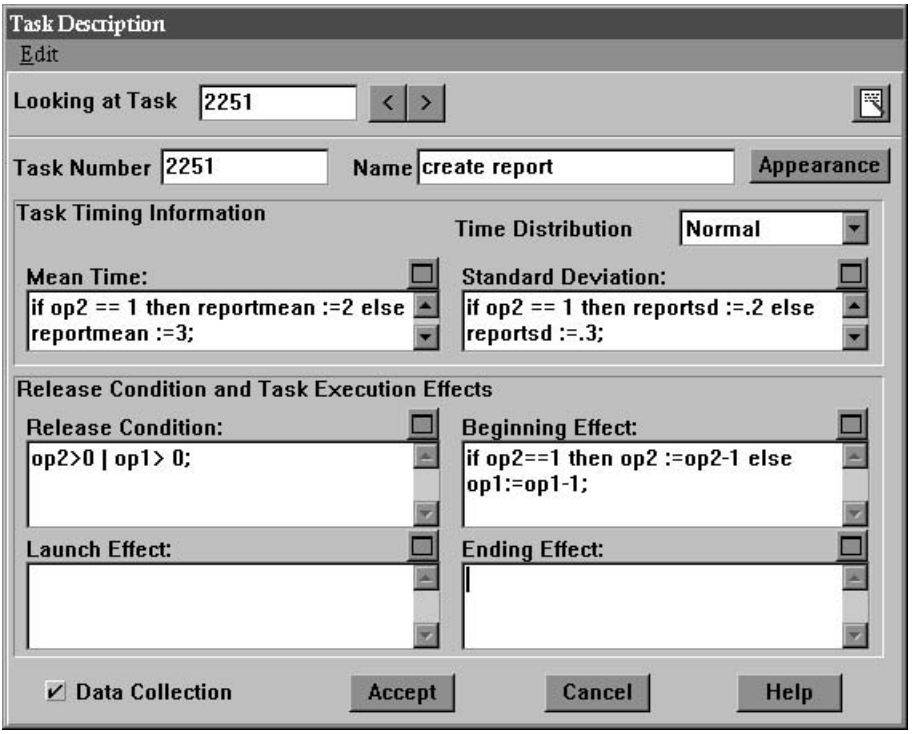

Figure 6 The User Interface in Micro Saint for Providing Input on a Task.

In other words, there must be at least one operator available for the task to commence. If all operators were busy, the value of the variable operator would equal zero until a task is completed, at which time an operator becomes available. This task would wait until the condition was true before beginning execution, which would probably occur as a result of the operator completing the task he or she is currently performing.

Beginning effect: This field permits the user to define how the system will change as a result of the commencement of this task. For example, if this task used an operator that other tasks might need, we could set the following condition to show that the operator is unavailable while he performed this task:

$$\text{operator} := \text{operator} - 1$$

Assignment and modification of variables in beginning effects are one key way in which tasks are interrelated.

Launch effect: Similar to a task beginning effect but used to launch high-resolution animation of the task.

Ending effect: This field permits the definition of how the system will change as a result of the completion of this task. From the previous example, when this task was complete and the operator became available, we could set the ending effect as follows

$$\text{operator} := \text{operator} + 1$$

at which point another task waiting for an operator to become available could begin. Ending effects are another key way in which tasks can be interrelated through the assignment and modification of variables.

Another notable aspect of the task network diagram window shown in Figure 5 is the diamond-shaped icons that follow some tasks. These are present every time more than one path out of a task

is drawn. In a task network model, this means that several tasks might commence at the completion of this task. Often this represents a human decision-making process. In that case, the branches align to potential courses of action that the modeled human could select. To define the decision logic, the user of Micro Saint would double-click on the diamond to open up a window, as shown in Figure 7.

There are only three general types of decisions to model:

- *Probabilistic:* In probabilistic decisions, the human will begin one of several tasks based on a random draw weighted by the probabilistic branch value. These weightings can be dynamically calculated to represent the current context of the decision. For example, this decision type might be used to represent human error likelihoods and would be connected to the subsequent tasks that would be performed.
- *Tactical:* In tactical decisions, the human will begin one of several tasks based on the branch with the highest "value." This could be used to model the many types of rule-based decisions that humans make, as illustrated in Figure 7.
- *Multiple:* This would be used to begin several tasks at the completion of this task, such as when one human issues a command that begins other crew members' activities.

The fields in Figure 7 labeled "Routing Condition" represent the values associated with each branch. The values can be numbers, expressions, or complicated algorithms defining the probability (for probabilistic branches) or the desirability (for tactical and multiple branches) of taking a particular branch in the network. Again, any value on this screen can not simply be numbers but also include variables, algebraic expressions, logical expressions, or groups of algebraic and logical expressions that would essentially form a subroutine. As the model executes, Micro Saint includes a parser that evaluates the expressions included in the branching logic when it is encountered in the task network flow. This results in a dynamic network in which the flow through the tasks can be controlled with variables that represent equipment state, scenario context, or the task loading of the humans in the

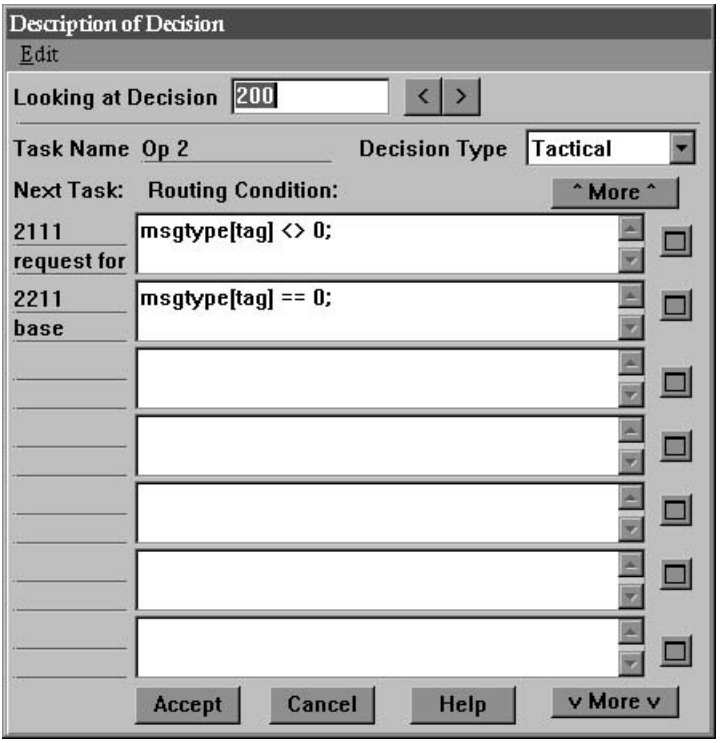

Figure 7 The User Interface in Micro Saint for Defining Task Branching Decision Logic.

system, to name a few examples. It is the power of this parser that provides many task network models the ability to address complex problems.

There are other aspects of task network model development. Some items are defining a simulation scenario, defining continuous processes within the model, and defining queues in front of tasks. Further details of these features can be obtained from the Micro Saint User's Guide (Micro Analysis and Design 1999).

As a model is being developed and debugged, the user can execute the model to test it and collect data. There are several display modes, reflecting differing levels of information provided to the user during execution. In the most detailed mode, the simulation pauses after every simulated task. Another mode shows the user nothing about the simulation except when it is completed. There is also a model animation mode in which the task network is drawn on the screen and tasks that are currently executing are highlighted. In the model animation mode, the analyst can get a very clear picture of what events are occurring in what sequence in the model. Figure 8 presents a sample display during model animation.

Once a model is executed and data are collected, the analyst has a number of alternatives for data analysis. The data created during a model execution can be reviewed in the model analysis environment or exported to statistical and graphics packages.

The above discussion should indicate that task network modeling is a relatively straightforward concept that is a logical extension of task and systems analysis. Task network modeling is an evolution, not a revolution, to the human factors practitioner. As stated before, the basis for task network models of human performance is the mainstay of human engineering analysis—the task analysis. Much of the information discussed is generally included in the task analysis. Task network modeling, however, greatly increases the power of task analysis since the ability to simulate a task network with a computer permits prediction of human performance, rather than simply the description of human performance that a task analysis provides. What may not be as apparent, however, is the power of task network modeling as a means for modeling human performance in systems. Simply describing the systems activities in this step-by-step manner allows complex models of the system to be developed where the human's interaction with the system can be represented in a closed-loop manner.

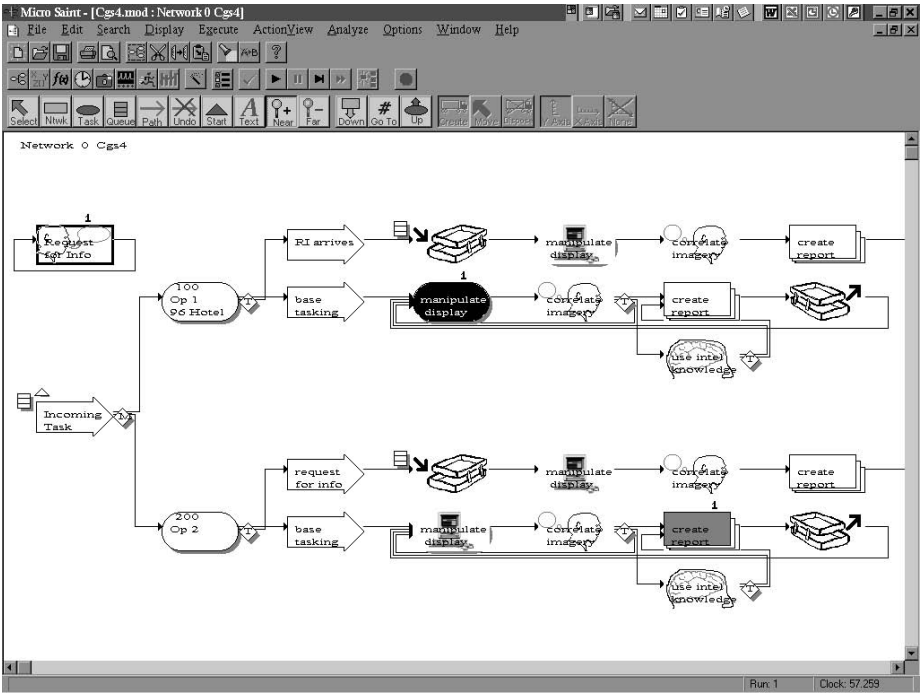

Figure 8 An Example of a Task Network Animation during Model Execution in Micro Saint.

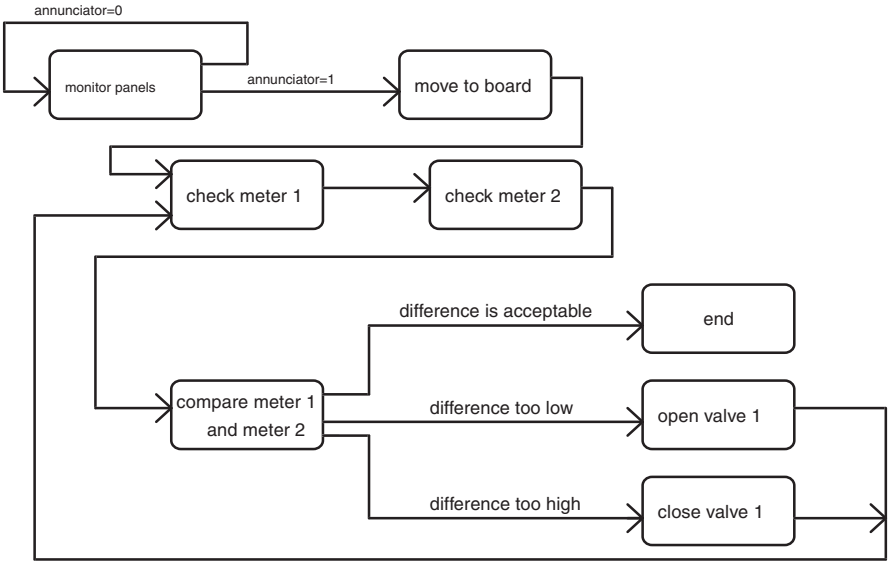

Figure 9 Sample Task Network Model of a Process Control Operator Responding to an Annunciator.

The above discussion, in addition to being an introduction to the concepts, is also intended to support the argument that task network modeling is a mature technology ready for application in a wide range of problem domains.

5.2. An Example of a Task Network Model of a Process Control Operator

This simple hypothetical example illustrates how many of the basic concepts of task network modeling can be applied to studying human performance in a process control environment. It is intended to illustrate many of the concepts described above.

The simple human task that we want to model is of an operator responding to an annunciator. The procedure requires that the operator compare readings on two meters. Based on the relative values of these readings, the operator must either open or close a valve until the values on the two meters are nearly the same. The task network in Figure 9 represents the operator activities for this model. Also, to allow the study of the effects of different plant dynamics (e.g., control lags), a simple one-node model of the line in which the valve is being opened is included in Figure 10.

The operator portion of the model will run the monitor panels task until the values of the variables meter1 and meter2 are different. The simulation could begin with these values being equal and then precipitate a change in values based on what is referred to as a scenario event (e.g., an event representing the effects of a line break on plant state). This event could be as simple as:

$$\text{meter1} := \text{meter1} + 2.0$$

or as complex as an expression defining the change in the meter as a function of line break size,

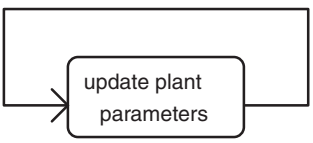

Figure 10 A Simple One-Node Model of the Plant That Is Integrated with the Detailed Operator Model.

flow rates, and so on. An issue that consistently arises in model construction is how complex the plant system model should be. If the problem under study is purely operator performance, simple models will usually suffice. However, if overall plant behavior is of interest, then the models of plant dynamics, such as meter values, are more important. Again, we recommend the "start simple" approach whenever possible.

When the transient occurs and the values of meter1 and meter2 start to diverge, the annunciator signal will trigger. This annunciator would be triggered in the plant portion of the model by a task-ending effect such as:

$$\text{if meter1} <> \text{meter2 then annunciator} := 1$$

Once the plant model sets the value of the variable annunciator to 1, the operator will begin to move to the appropriate board. Then the operator will continue through a loop to check the values for meter1 and meter2 and either open valve1, close valve1, or make no change. The determination of whether to make a control input is determined by the difference in values between the two meters. If the value is less than the acceptable threshold, then the operator would open the valve further. If the value is greater than the threshold, then the operator would close the valve. This opening and closing of the valve would be represented by changes in the value of the variable valve1 as a task-ending effect of the tasks open valve1 and close valve1. In this simple model, operators do not consider rates of change in values for meter1 and therefore would get into an operator-induced oscillation if there were any response lag. A more sophisticated operator model could use rates of change in the value for meter1 in deciding whether to open or close valves.

Again, this is a very small model reflecting simple operator activity on one control via a review of two displays. However, it illustrates how large models of operator teams looking at numerous controls and manipulating many displays could be built via the same building blocks used in this model. The central concepts of a task network and shared variable reflecting human–system dynamics remain the same.

Given a task network model of a process control operator in a current control room, how might the model be modified to address human-centered design questions? Some examples are:

1. Modifying task times based on changes in the time required to access a new display
2. Modifying task times and accuracies based upon changes in the content and format of displays
3. Changing task sequence, eliminating tasks, and/or adding tasks based upon changes in plant procedures
4. Changing allocation of tasks and ensuing task sequence based upon reallocation of tasks among operators
5. Changing task times and accuracies based upon stressors such as sleep loss or the effects of circadian rhythm

The above is not intended as a definitive list of all the ways that these models may be used to study design or operations concepts, but it should illustrate how these models can be used to address design and operational issues.

5.3. Case Studies in the Use of Task Network Modeling to Address Specific Design Issues

In this section, we will examine two case studies in the use of task network simulation for studying human performance issues. The first case study explores how task network modeling can be used to assess task allocation issues in a cognitively demanding environment. The second example explores how task network modeling has been used to extend laboratory and field research on human performance under stress to new task environments.

We should state clearly that these examples are intended to be representative of the types of issues that task network modeling can address, as well as approaches to modeling human performance with respect to these issues. *They are not intended to be comprehensive with respect to either the issues that might be addressed or the possible techniques that the human factors practitioner might apply.* Simulation modeling is a technology whose application leaves much room for creativity on the part of the human factors practitioner with respect to application areas and methods. These two case studies are representative.

5.4. Using Task Network Modeling to Evaluate Crew Workload

Perhaps the greatest contributor to human error in many systems is the extensive workload placed upon the human operator. The inability of the operator to cope effectively with all of his or her

information and responsibilities contributes to many accidents and inefficiencies. In recognition of this problem, new automation technologies have been introduced to reduce workload during periods of high stress. Some of these technologies are in the form of enhanced controls and displays, some are in the form of tools that push information to the operator and alert the operator in order to focus attention, and still others consist of adaptive tools that take over tasks when they sense that the operator is overloaded. Unfortunately, these technical solutions often introduce new tasks to be performed that affect the visual, auditory, and/or psychomotor workload of the operators.

Recently, new concepts in crew coordination have focused on better management of human workload. This area shows tremendous promise and is benefiting from efforts of human factors researchers. However, their efforts are hindered because there are limited opportunities to examine empirically the performance of different combinations of equipment and crew composition in a realistic scenario or context. Additionally, high workload is not typically caused by a single task but by situations in which multiple tasks must be performed or managed simultaneously. It is not simply the quantity of tasks that can lead to overload, but also the composition of those tasks. For example, two cognitive tasks being performed in parallel are much more effortful than a simple motor task and an oral communication task being performed together. The occurrence of these situations will not typically be discovered through normal human engineering task analysis or subjective workload analysis until there is a system to be tested. That is often too late to influence design.

To rectify this problem, there has been a significant amount of recent research and development aimed at human workload *prediction* models. Predictive models allow the designers of a system to estimate operator workload *without human subjects experimentation*. From this and other research, a solid theoretical basis for human workload prediction has evolved, as is described in Wickens (1989).

This section discusses a study using task network modeling to predict the impact of task allocation on human workload. While these examples are posed in the context of the design of a military system, the same techniques have been used in nonmilitary applications such as process control and user–computer interface design.

5.4.1. Modeling the Workload of a Future Command and Control Process

The Army command and control (C2) community is concerned with how new information, technology, and organizational changes projected for tomorrow's battlefield will impact soldier tasks and workload. To address this concern, an initiative was taken to model soldier performance under current and future operational conditions. In this way, the impact of performance differences could be quantitatively assessed so that equipment and doctrine design could be influenced in a timely and effective manner.

In one C2 project, the primary concern was to determine how tasks should be allocated and automated such that a C2 team could evaluate all the relevant data and make decisions within an environment with particularly high time pressure. Specifically, the effort was to address the following key questions:

- How many crew members do you need?
- How do you divide tasks among jobs?
- How does decision authority flow?
- Can the crew meet decision time line requirements?
- Is needed information usable and accessible?

We used task network modeling to study crew member, task and scenario combinations in order to examine these questions.

Figure 11 shows the top level diagram of the task network. Essentially, the crew members receive and monitor information about the system and the environment until an event occurs that pushes them out of the 10000 and 20000 networks into either a series of planning tasks, and/or a series of evaluation, decision, direction, and execution tasks. The purpose of the planning task is to update tactical battle plans based on new information received from the system or the environment. Receipt of new intelligence data about the enemy's intention or capability is an example of an event that would cause the crew members to undertake planning tasks. Similarly, receipt of information from the system about resource limitations might trigger the crew members to proceed down the alternative path (through evaluate to execute). Specifically, limited resources might cause the crew members to evaluate whether the engagement is proceeding appropriately (30000), decide how to adjust system parameters (40000), direct the appropriate response to the correct level of command (50000), and then execute the order (60000). Upon completion, the crew members would return to monitoring the system and situation.

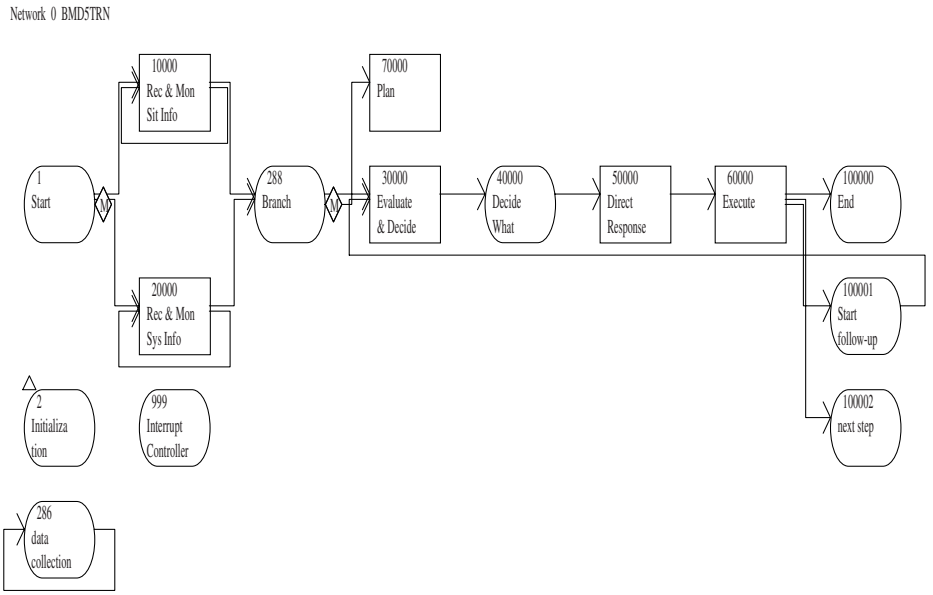

Figure 11 Upper-Level Task Network.

Each of the rectangles in the task network shown in Figure 11 actually consists of a network of tasks. An example of the tasks that belong to Network 10000, receive and monitor situation information, is shown in Figure 12. As described under Figure 7 of this chapter, the tasks in Network 10000 are linked by probabilistic and tactical decisions.

Each of the tasks in the C2 task network is associated with several items of human performance data. These include:

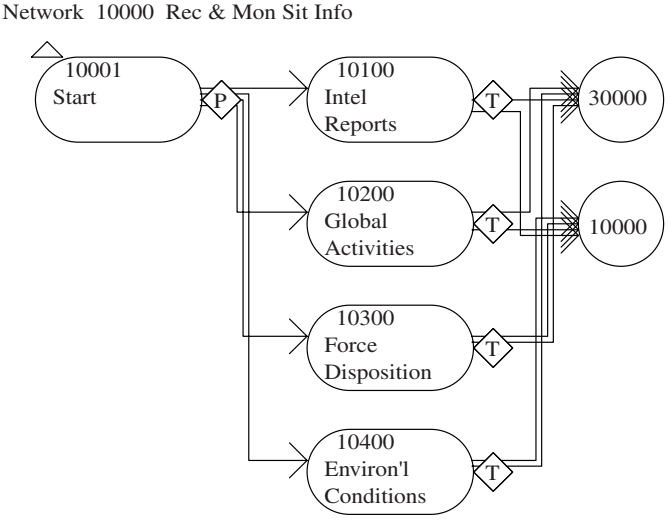

Figure 12 Second- Level Task Network.

- *Task performance time:* These data consist of a mean, standard deviation, and distribution. The data were collected from a combination of three sources: (1) human factors literature (e.g., Fitts's Law); (2) empirical studies during operator-in-the-loop simulator exercises; and (3) subject matter experts.
- *Branching logic:* While the task network indicates a general process flow, this particular model was designed to respond to scenario events. Because of that design decision, each task includes logic to determine the following task. For example, if the scenario is very intense and multiple target tracks are available, the crew members will follow a different task flow than if they were performing routine system checks.
- *Release rules:* Logic controlling the number and types of parallel tasks each crew member can perform are contained in each task's release condition.

Since one purpose of the model was to examine various task-allocation strategies, the model was designed to incorporate several measures of crew member workload. The basis of this technique is an assumption that excessive human workload is not usually caused by one particular task required of the operator. Rather, the human having to perform several tasks simultaneously leads to overload. Since the factors that cause this type of workload are intricately linked to these dynamic aspects of the human's task requirements, task network modeling provides a good basis for studying how task allocation and sequencing can affect operator workload.

However, task network modeling is not inherently a model of human workload. The only relevant output common to all task network models is the time required to perform a set of tasks and the sequence in which the tasks are performed. Time information alone would suffice for some workload-evaluation techniques, such as Siegel and Wolf (1969), whereby workload is estimated by comparing the time available to perform a group of tasks to the time required to perform the tasks. Time available is driven by system performance needs, and time required can be computed with a task network model. However, it has long been recognized that this simplistic analysis misses many aspects of the human's tasks that influence both perceived workload as well as ensuing performance. At the very least, this approach misses the fact that some pairs of tasks can be performed in combination better than other pairs of tasks.

One of the most promising theories of operator workload, which is consistent with task network modeling, is the multiple resource theory proposed by Wickens (e.g., Wickens et al. 1983). Simply stated, the multiple-resource theory suggests that humans have several different resources that can be tapped simultaneously. Depending upon the nature of the information-processing tasks required of a human, these resources would have to process information sequentially (if different tasks require the same types of resources) or possibly in parallel (if different tasks required different types of resources). There are many versions of this multiple-resource theory in workload literature (e.g., McCracken and Aldrich: Bierbaum et al. 1989; North and Riley 1989; Little et al. 1993; Knapp et al. 1999). In this chapter, we will provide a discussion of the underlying methodology of the basic theory.

Multiple-resource workload theory is implemented in a task model in a fairly straightforward manner. First, each task in the task network is characterized by the workload demand required in each human resource, often referred to as a workload channel. Examples of commonly used channels include auditory, visual, cognitive, and psychomotor. Particular implementations of the theory vary in the channels that are included and the fidelity with which each channel is measured (high, medium, low vs. seven-point scale). In fact, Bierbaum et al. 1989 present reliable benchmark scales for determining demand for each channel. As an example, the scale for visual demand is presented in Figure 13.

Similar scales have been developed for the auditory, cognitive, and psychomotor channels. With this approach, each operator task can be characterized as requiring some amount of each of the four kinds of resources, as represented by a value between one and seven. All operator tasks can be analyzed with respect to these demands and values assigned accordingly.

In performing a set of tasks pursuant to a common goal (e.g., engage an enemy target), crew members frequently must perform several tasks simultaneously, or at least nearly so. For example, they may be required to monitor a communication network while visually searching a display for target track. Given this, the workload literature indicates that the crew member may either accept the increased workload (with some risk of performance degrading) or begin dumping tasks perceived as less important. To factor these two issues into task network simulations, two approaches can be incorporated: (1) evaluate combined operator workload demands for tasks that are being performed concurrently, and/or (2) determine when the operator would begin dumping tasks due to overload.

During a task network simulation, the model of the crew may indicate they are required to perform several tasks simultaneously. The task network model evaluates total attentional demands for each human resource (e.g., visual, auditory, psychomotor, and cognitive) by combining the attentional demands across all tasks that are being performed simultaneously. This combination leads to an overall workload demand score for each crewmember.

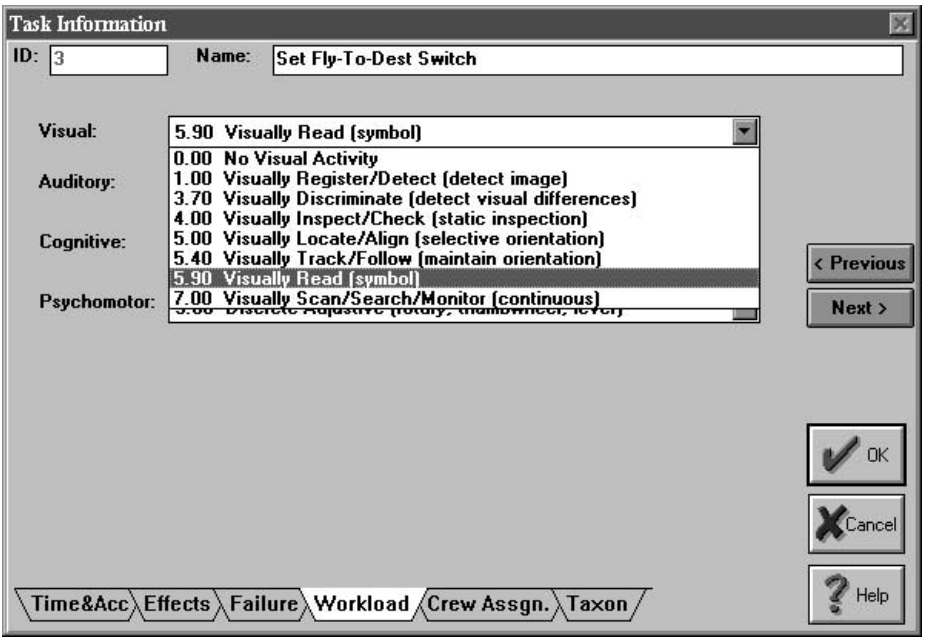

Figure 13 An Example of a Visual Workload Scale.

To implement this approach in Micro Saint, the task beginning effect can be used to increment variables that represent the current workload score in each resource. Then, while the tasks are being performed, these variables track attentional demands. When the tasks are completed, the task ending effects can decrement the values of these variables accordingly. Therefore, if these workload variables were recorded and then plotted as the model runs, the output would look something like what is shown in Figure 14. This result can be used to identify points of high workload throughout the scenario being modeled. The human factors practitioner can then review the tasks that led to the points of high workload and determine whether they should be reallocated or redesigned in order to alleviate the peak. This is a common approach to modeling workload.

Once the task networks were verified with knowledgeable crewmembers, they became part of the human factors team's analytical test bed. Figure 15 shows the overall method that we used to examine aspects of crew member performance across a wide variety of operational scenarios and crew configuration concepts.

The center of this diagram, labeled task network, represents the tasks that the crew performs as we just described them. The network itself, representing the flow of the tasks, does not change between model runs. Rather, the model has been parameterized so that an event scenario stimulates the network. The left side of the diagram illustrates the types of data that are used to drive the task network model. In this case, those data include crew configurations, or allocations of tasks to different crew members and automation devices, as well as scenario events. The scenario events represent an externally generated time-ordered list of the events that trigger the crew members to perform tasks in the task network. The right side of Figure 15 represents the types of outputs that can be produced from this task network model. One of the primary outputs is a crew member workload graph, such as that shown in Figure 14.

5.4.2. Extensions of This Approach to Simulating Crew Mental Workload to Other Environments

The workload-analysis methodology described above has recently been developed into a stand-alone task network modeling tool by the Army Research Laboratory (ARL) Human Research and Engineering Directorate (HRED), as part of the Improved Performance Research Integration Tool (IMPRINT) (Allender et al. 1994; Archer and Adkins 1999). IMPRINT integrates task network modeling software with features to support specifically the multiple-resource theory of workload discussed

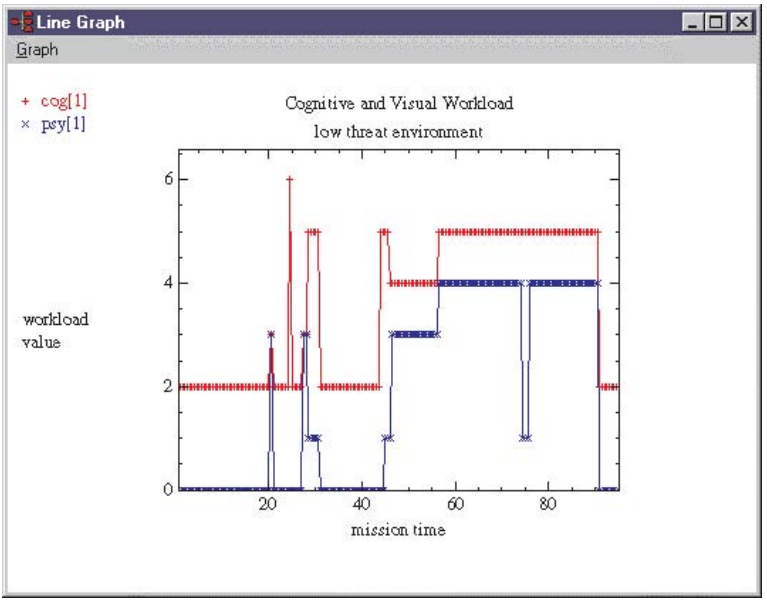

Figure 14 An Example Workload Output from a Task Network Model.

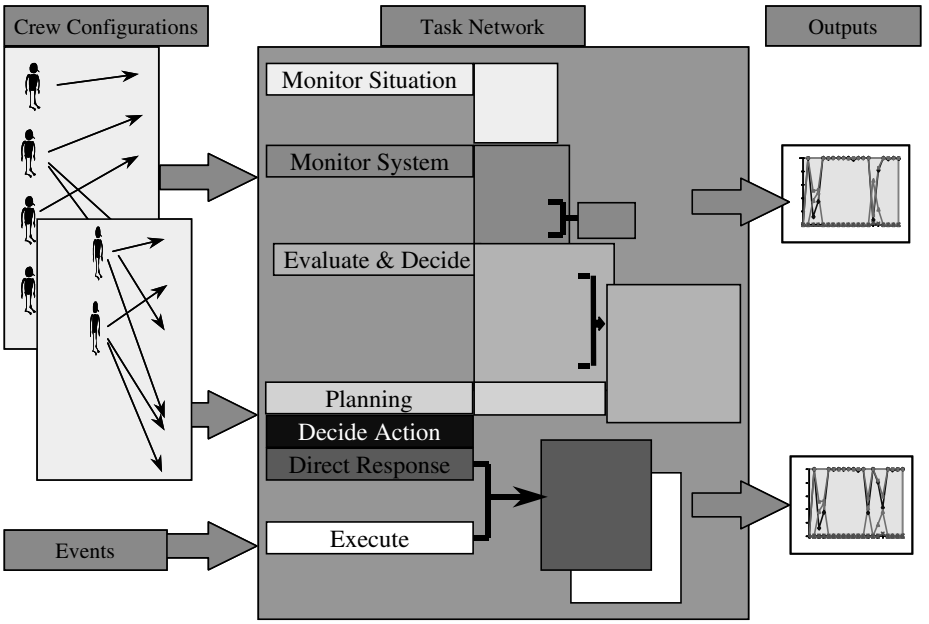

Figure 15 Overall Method for Examining Workload in a Complex System.

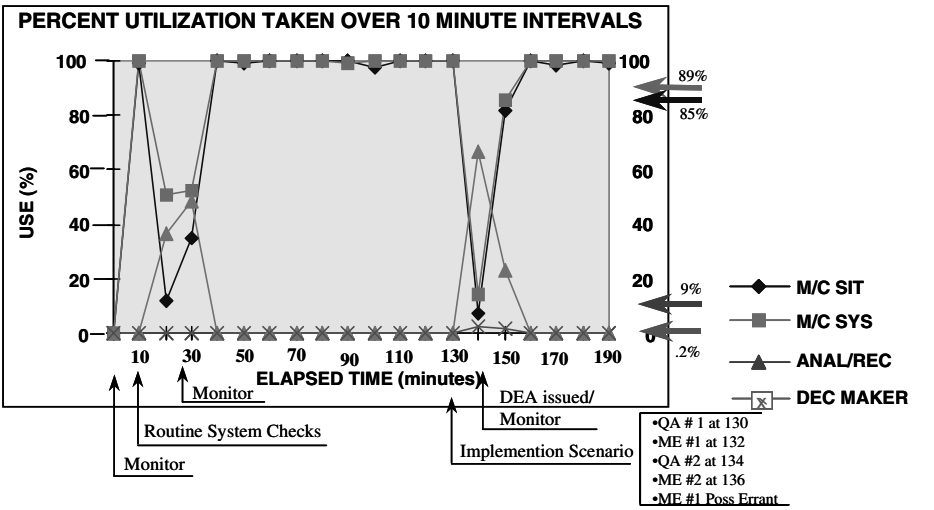

Figure 16 Example of Model Predictions of Operator Utilization over Time.

above. It provides the human factors practitioner with an environment that supports the analysis of task assignment to crewmembers based on four factors:

1. *Workload of crew members:* Tasks should be assigned to minimize the amount of time crew members will spend in situations of excessive workload.
2. *Time performance requirements:* Tasks must be assigned and/or sequenced so that they are completed within the available time. This consideration is essential because time constraints often will drive the need to perform several tasks simultaneously.
3. *Likelihood of successful performance and consequences of failure:* Tasks must be assigned and/or sequenced so that they can be completed within a specified accuracy measure.
4. *Access to controls and displays:* Tasks cannot be assigned to crew members who do not have access to the necessary controls and displays.

Of course, there are numerous theoretical questions regarding this simplistic approach to assessing workload in an operational environment. However, even the use of this simple approach has been shown to provide useful insight during design. For example, in a study conducted by the Army (Allender 1995), a three-man crew design was evaluated using a task network model. The three-man model was constructed using data from a prototype four-man system. From this model-based analysis, the three-man design was found to be unworkable . Later, human subjects experimentation verified that the model's workload predictions were sufficiently accurate to point the design team in a valid direction.

Finally, ARL HRED has developed another custom software package named WinCrew (Plott 1995). It includes capabilities, also available in an advanced version of IMPRINT, to implement more refined methods of predicting workload. WinCrew overlays the W/INDEX manifestation of the multiple resource theory of workload (Boettcher et al. 1989) into a task network-based environment. In addition to a better estimate of workload, WinCrew is unique in that it has built-in constructs for simulating workload management strategies that operators would employ to accommodate points of high operator workload. The ultimate result of simulating the workload management strategies is that the operator task network being modeled is dynamic. In other words, the task sequence, assignments to operators, and individual task performance may change in response to excessive operator workload as the task network model executes. These changes may be as simple as one operator handing tasks off to another operator to reduce workload to an acceptable level or as complex as the operator beginning to time share tasks in order to complete all the assigned tasks, potentially task time and/or accuracy. Ultimately, the tool provides an estimate of system-level performance as a result of these realistic workload management strategies. This innovation in modeling provides greater fidelity in

efforts that model human behavior in the context of system performance, particularly in high-workload environments such as complex system control and management.

5.5. Using Task Network Modeling as a Means of Extending Research Findings on Human Performance under Stress to New Task Environments

Task network modeling was used by LaVine et al. (1995) to extend laboratory data and field data collected on one set of human tasks to predicting performance on similar tasks. The problem of extending laboratory or field human performance data to other tasks has plagued the human engineering community for years. We intuitively know that human performance data can be used to predict performance for similar tasks. However, often the task whose performance we want to predict is similar in some ways but different in others. The approach described below uses a skill taxonomy to quantify task similarity and therefore provides a means for determining how other tasks will be affected when exposed to a common stressor on human performance. Once functional relationships are defined between a skill type and a stressor, task network modeling is used to determine the effect of the stressor on performance of a complex task that simultaneously uses many of these skills.

The specific approach below is being used by the U.S. Army to predict crew performance degradation as a function of a variety of stressors. It not intended to represent a universally acceptable taxonomy for simulating human response to stress. The selection of the best taxonomy would depend upon the particular tasks and stressors being studied. What this example is intended to illustrate is another way that task network modeling can be used to predict human performance by making a series of reasonable assumptions that can be played together in a model for the purpose of making predictions that would be impossible to make otherwise.

The methodology for predicting human performance degradation as a function of stressors consists of three parts: (1) a *taxonomy* for classifying tasks according to basic human skills, (2) *degradation functions* for each skill type for each stressor, and (3) *task network models* for the human-based system whose performance is being predicted. Conceptually, either laboratory or field data can be used to develop links between a human performance stressor (e.g., heat, fatigue) and basic human skills. By selecting a skills taxonomy that is sufficiently discriminating to make this assumption reasonable, one can assume that the effects of the stressor on all tasks involving the skill will be approximately the same. The links between the level of a stressor (e.g., fatigue) and resulting skill performance (e.g., the expected task time increase from fatigue) are defined mathematically as the degradation function. The task network model is the means for linking these back to complex human/system performance.

5.5.1. The Taxonomy

The basic premise behind the taxonomy is that the tasks that humans perform can be broken down into basic human skills or atomic tasks (Roth 1992). The taxonomy used by Roth consists of five skill types: attention, perception, psychomotor, physical, and cognitive skills. These taxonomic skills are described by Roth as follows:

1. *Attention:* The ability to attend actively to a stimulus complex for extended periods of time in order to detect specified changes or classes of changes that indicate the occurrence of some phenomenon that is critical to task performance.
2. *Perception:* The ability to detect and categorize specific stimulus patterns embedded in a stimulus complex.
3. *Psychomotor:* The ability to maintain one or more characteristics of a situation within a set of defined conditions over a period of time, either by direct manipulation or by manipulation of controls that cause changes in the characteristics.
4. *Physical:* The ability to accomplish sustained, effortful muscular work.
5. *Cognitive:* The ability to apply concepts and rules to information from the environment and from memory in order to select or generate a course of action or a plan. This includes communicating the course of action or plan to others.

These five skills covered most of the tasks that were of interest to the Army for this study and still provided a manageable number of categories for an analyst to use.

5.5.2. Degradation Functions

The degradation functions quantitatively link skill performance to the level of a stressor. The degradation functions can be developed from any data source, including standard test batteries or actual human tasks. Through statistical analysis, one can build skill-degradation functions for each taxon. These functions map the performance decrement expected on a skill based on the parameters of the

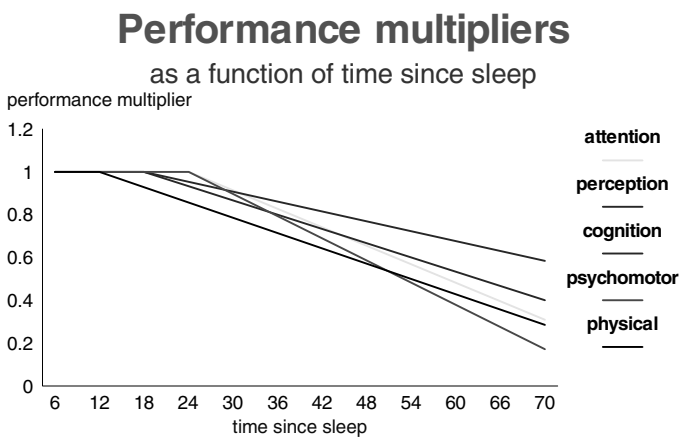

Figure 17 An Example of the Performance Degradation Functions Associated with each of the Human Skills from the Taxonomy.

performance-shaping factor (e.g., time since sleep). An example of these functions is presented in Figure 17.

5.5.2.1. Incorporating the Degradation Functions into Task Network Models to Predict Overall Human/System Performance Degradation The key to making this approach useful to predicting complex human performance is the task network model of the new task. In the task network model of the human's activities, all tasks are defined with respect to the percentage of each skill required from the taxonomy. For example, the following are ratings for tasks faced by a console operator responding to telephone contacts:

- Detect ring—50% attention, 50% perception
- Select menu item using a mouse—40% attention, 60% psychomotor
- Interpret customer's request for information—100% cognitive

In building the task network model, one can build functions to degrade a specific task's performance through an arithmetic weighting of skill-degradation multipliers that are derived from the degradation functions. For example, if the fatigue parameter was time since sleep and the value of that parameter was 36 hours since sleep, the task time performance multipliers would be as follows in the example above:

- Attention performance multiplier = 0.82
- Perception performance multiplier = 0.808
- Cognition performance multiplier = 0.856
- Psychomotor performance multiplier = 0.784
- Physical performance multiplier = 0.727

Based upon these multipliers and the above task weightings, the specific task effects would be:

- Detect ring—50% attention, 50% perception

$$\text{Task multiplier} = 0.5 \times 0.82 + 0.5 \times 0.808 = 0.814$$

- Select menu item using a mouse—40% attention, 60% psychomotor

$$\text{Task multiplier} = 0.4 \times 0.82 + 0.6 \times 0.784 = 0.7984$$

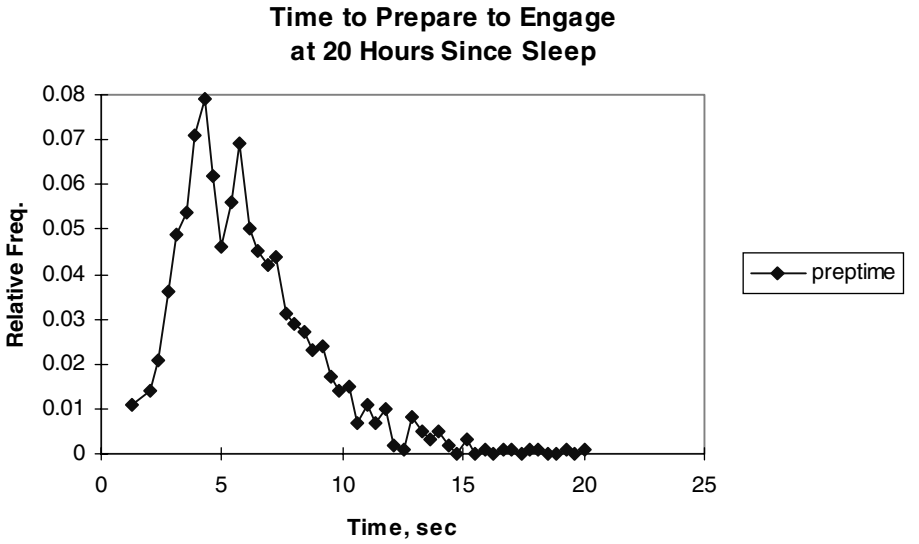

Figure 18 Frequency Distribution of Expected Human Performance as a Function of Time Since Sleep That Was Derived Using Task Network Modeling.

In a model of the complex tasks examined by LaVine et al. (1995), the task networks consisted of several dozen or even several hundred tasks. Through the approach described above, each task in a model exhibited a unique response to a stressor depending upon the particular skills that it required. The task network model then provided the means for relating the individual task performance to overall human/system performance as a function of stressor level (e.g., the time to perform a complex series of tasks involving decision making and error correction). Through this type of analysis, LaVine et al. were able to develop curves such as that shown in Figure 18 relating human performance to a stressor. These relationships would have been virtually impossible to develop experimentally.

Again, there were a number of simplifying assumptions that were made in this research. However, by being willing to accept these assumptions, LaVine et al. were able to characterize how complex human/system performance would be affected by a variety of stressors over a wide range in a relatively short time. They were thus able to estimate the effects of stressors that would have otherwise been pure guesswork.

5.6. Summary of Examples of Task Network Modeling of Human–System Performance

Once again, the above are intended to serve as examples, not as a catalogue of problems or approaches that are appropriate for task network modeling. Task network modeling is an approach to extend task and systems analysis to make predictions of human system performance. The creative human factors and ergonomics practitioner will find many other useful applications and approaches.

6. AN EXAMPLE OF A FIRST-PRINCIPLED APPROACH TO HUMAN/SYSTEM PERFORMANCE MODELING: THE MAN MACHINE INTEGRATED DESIGN SYSTEM (MIDAS)

The other fundamental approach to modeling human performance is based upon the mechanisms that underlie and cause human behavior. Since this approach is based on fundamental principles of the human and his or her interaction with the system and environment, we have designated them first-principle models. By integrating these models with models of the system and environment, the human factors specialist can predict the full behavior of large-scale interactive human–machine systems. The Man–Machine Integrated Design and Analysis System (MIDAS) follows in the tradition of integrated, first-principled models of human performance such as PROCRU (Baron et al. (1980) in that the modeling framework provides models of emergent human behavior based on elementary models of human behaviors such as perception, attention, working memory, and decision making. In the operation of these elementary models, MIDAS shares some of the characteristics of the task network approach. However, MIDAS is focused around an integrated architecture where micromodels of

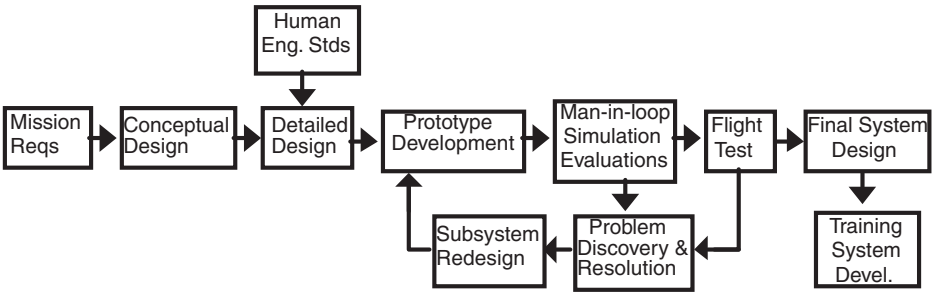

Figure 19 Current Crew-Station and Human–Computer Interaction Development Process.

human performance feed forward and feedback to the other constituent models in the human system rather than being linked primarily to the human's activities as in task network models.

6.1. Background

The A^{3}I Program was initiated in 1985 to support exploration of computational representations of human–machine performance to aid designers of crew systems. The major product of this effort was a human factors computer-aided engineering system called MIDAS (Man–Machine Integration Design and Analysis System). MIDAS is intended to revise the system design process in order to place more accurate information into the hands of the designers early in the process of human engineering design so that the impact and cost of changes are minimal. It is also intended to identify and model human–automation interactions with flexible representations of human–machine function. The crew station development process, as it is currently undertaken, is illustrated in Figure 19. The design proceeds from requirements and capabilities in conceptual design through increasing specification to hardware and software prototypes and simulation tests. Human performance evaluation occurs after prototype design and development. Results from testing the prototype are then used to guide prototype redesign.

MIDAS integrates the design process by using human performance models in the conceptual design phases of system development. Human–system integration and development enabled by the computational human performance models methodology are illustrated in Figure 20.

In this revised process, human performance considerations are accounted for early in the designs and played out for evaluation in the simulation mode. Iteration in this mode is flexible and timely. The flow then proceeds with a refined design into the standard design and prototype development phases. MIDAS provides a prototyping test bench, based on human performance models. Designers can work with computational representations of the crew station and human operators rather than relying solely on hardware simulators and man-in-the-loop studies, to discover problems and ask ''what-if'' questions regarding the projected mission, equipment, and environment.

In addition to its use in development and design, MIDAS offers a structure or framework in which to test and implement models of human cognition. The MIDAS framework systematizes and unifies the interaction of human performance representations in a common structure and with a common

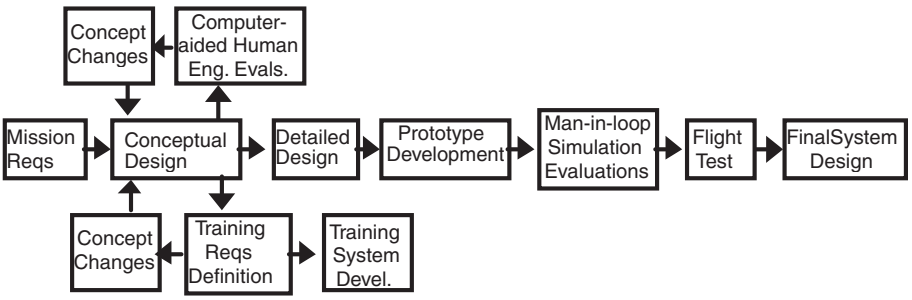

Figure 20 Design Methodology Made Possible through Modeling and MIDAS.

language for interaction. The representation is a tightly linked set of computational descriptions of the elemental aspects of human performance. Models of human performance from perception through cognition and action are implemented within this framework. The interplay of the models produces simulations of behavior.

In developing MIDAS, three challenges were considered. First, the level of representation of human behavior has to be sufficiently detailed to predict individual performance and guide design for individual aiding and support systems. At the same time, that behavioral representation must be able to provide input into large-scale analyses to predict global consequences of system modification. Second, the models of human–system performance have to be sufficiently computational to support design specification in control theoretic terms but also sufficiently flexible and robust to account for a range of human behavior influenced by cultural (corporate, professional, and national) and environmental context. Third, the human performance model has to represent individuals and teams of human operators. This requires control of not only single cognitive behavior but also the cognitive activities associated with group and organizational behavior. Such applications require representation of many intelligent agents sharing world models, and coordinating action/intention with cooperative scheduling of goals and actions in a potentially unpredictable world of operations. The simulated operators' activity structures must provide for anticipation (knowledge of the intention and action of remote operators) and respond to failures of the system and other operators in the system in context-sensitive processes.

MIDAS is intended to meet these challenges by including the following characteristics:

- *Modifiability and manipulability:* The basic mode of operation for MIDAS users is to explore the impact of changes to the baseline design. Thus, the capability for systematic change is critical. Of equal importance is system extensibility. To be generally useful, the modeling environment should be applicable to many types of design changes, and to many operational domains. The MIDAS architecture is designed to allow extensions of this type with minimal disruption to the existing core MIDAS system.
- *Transparency:* The analysis system must provide designers with explicit and transparent reference to the rules, decision-making strategies, heuristics, and assumptions under which the human–machine system is assumed to be operating, as well as predicted performance. For example, at any point in the simulation, a designer should be able to examine the cognitive state of the human operators, the rules that are being used to guide their behavior, and their nominal workload. The designer should also be able to perform sensitivity analyses on critical parameters of the human–machine system. Similarly, the state of equipment or mission progress should be able to be probed in order to relate the system state to the operator's performance.
- *Dynamic analysis capability:* The simulation system must produce a stream of behavior in the form of dynamic timelines describing not only its state and structure, but also sequences of action over time and contingent responses of the human/system behavior. The system must support testable hypotheses. Designers must be able to analyze the events occurring in a simulation scenario and relate this performance to man-in-the-loop simulation data. In MIDAS, each action taken, decision made, and communication event is logged by the analysis system.

6.2. System Architecture

There are two perspectives on the MIDAS system architecture that describe the system to support these modes of analysis: the functional architecture and structural bases of the system. Each is discussed below.

6.2.1. MIDAS Functional Architecture

The MIDAS system has evolved over a period of 15 years of development (Corker and Smith 1992). The basic structure of the core system presented here is based on the work of Tyler et al. (1998). This architectural version of MIDAS has throughout its development been used to evaluate helicopter crew stations, short-haul civil tiltrotor emergency handling operations, and the impact of MOPP flight gear on crew performance (Atencio et al. 1996, 1998; Shively et al. 1995). The specific development for analysis of air traffic management systems will be provided below.

The user enters the system through the graphical user interface (GUI), which provides the main interaction between the designer and the MIDAS system. The user selects among four functions in the system:

1. Create and/or edit a domain model that includes establishment and selection of the parameters of performance for the human operator model(s) in the simulation
2. Select the graphical animation or view to support that simulation or a set of simulations

3. Specify in the simulation module the parameters of execution and display for a given simulation set
4. Specify in the results analysis system the data to be collected and analyzed as a result of running the simulation.

The results-analysis system also provides for archival processes for various simulation sessions. The overall functional architecture is provided in Figure 21.

The user would typically use all of the top-level features to support a new simulation. If a user were exploring, for instance, the assignment of function between a human operator and an automated assistant, the user could maintain the majority of the extant domain, graphical, and analytic models and make modification through the domain model to the human operator model, the equipment model, and the simulation scenario.

6.2.1.1. Domain Model The domain model consists of descriptors and libraries supporting the creation of:

- *Vehicle characteristics:* Location space, aerodynamic models of arbitrarily detailed fidelity, and guidance models for vehicle (automatic) control.
- *Environment characteristics:* This provides the external interactions, including terrain from selected databases at varied levels of resolution, weather features insofar as they affect vehicle performance or operator sensory performance, and cultural features (towns, towers, wires, etc.). In short, the analyst here specifies the world of action of the experiment/simulation.
- *Crew Station/equipment characteristics:* The crew station design module and library is a critical component in the MIDAS operation. Descriptions of discrete and continuous control operation of the equipment simulations are provided at several levels of functional detail. The system can provide discrete equipment operation in a stimulus–response (black box) format, a time-scripted/ event driven format, or a full discrete-space model of the transition among equipment states. Similarly, the simulated operator's knowledge of the system can be at the same varied levels of representation or can be systematically modified to simulate various states of misunderstanding the equipment function.
- *The human operator model* (*HO*): The human performance model in MIDAS allows for the production of behavior and response for single and multiple operators in the scenarios. The

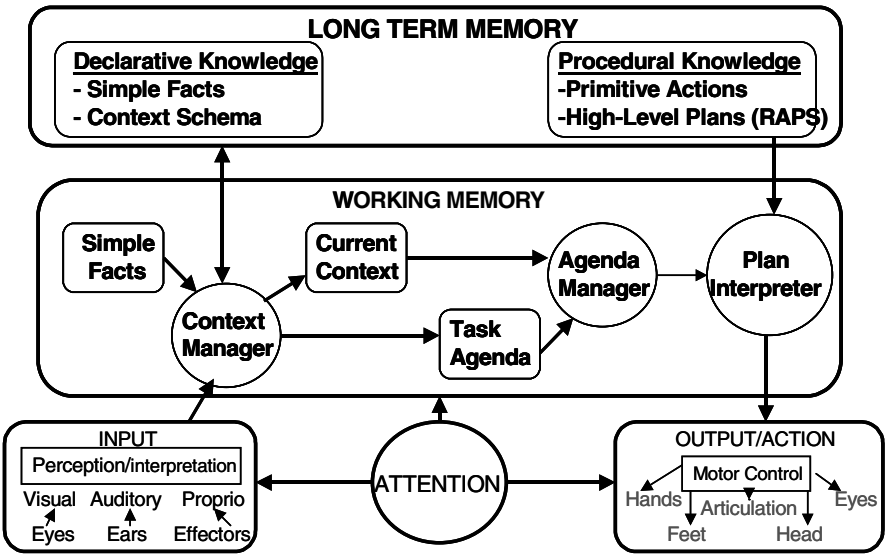

Figure 21 Illustration of the Overall Functional Architecture of the Human Operator Model in MIDAS. The functional architecture is repeated because multiple operators need to be represented in larger team simulations.

human operator model is the key to the MIDAS function as a predictive design aid. The human operator performance model is a combination of a series of functionally integrated micromodels of specific cognitive capabilities within a human operator. The human operator model functions as a closed-loop control model with inputs coming from the world and action being taken in the world. The model provides psychological plausibility through the explicit representation of cognitive constructs (detailed in Section 6.3).

- *Mission and activity models:* describe in a hierarchic structure the goals and the available recovery activities from missions-not-as-planned that make up the human operators' high-level behavioral repertoire in the mission. The next level of decomposition of the action of the mission is a set of high-level procedures (that can be stored as a fairly generic set of routines, e.g., look at or fixate). Finally, there are the specific activities in "active action packets" RAPS, which are the process by which the human operator affects the simulation.

6.2.1.2. Graphical Simulation Model MIDAS provides the user with a set of CAD development tools for both the design and modification of the simulation domain elements. The system also provides for the selection of a set of views or graphical simulation windows. These windows can provide various perspectives into the ongoing simulation, from that of a God's-eye view of the vehicles, environment and operators to views from the eyes of a particular human agent in the simulation.

In addition to the standard physical views, MIDAS supports a number of analytic views. The user can select views into the activity performance over time or views into the cognitive activities of any of the operators of the simulation. In addition, these views can be linked to the overall simulation view so that the user can view the cognitive activities and their effect in the real world at the same time. The time synching also allows for retrospective reply after a particular simulation has been performed. Figure 22 illustrates a standard set of views that might be selected during a simulation.

6.2.1.3. Analytic Tools After the simulation trials have been run, MIDAS provides the user with an editor to aid in the specification of analyses to be performed on the data generated. A set of analyses can be undertaken in the MIDAS model environment, which will allow the analyst views

into the task timeline and load levels for the operators simulated in the scenario. MIDAS supports packaging and exportation of specific data associated with the simulation entities to external statistical packages as well.

6.3. MIDAS Structural Architecture

The structural architecture of MIDAS is that of a federated set of models organized into groupings that represent the various agents in the simulation. We will concentrate here on the structural integration of the models that compose the human operator(s) in the MIDAS modeling system. These models have been developed in a structure that represents an empirically based human information-processing model. This structural integration has been termed a first-principles model, based on its intentional integration of cognitive models that represent separable elements of the cognitive process.

The first-principles models of human performance are based on the mechanisms that underlie and cause human behavior. First-principles models integrate human perceptual and cognitive systems and human motor systems, thus incorporating the higher-level behaviors that are characteristic of human performance. This incorporation supports emergent human behavior based on elementary model function. The representational models and the research upon which these models have been based can be seen in Table 1.

Figure 23 presents a schematic of the way that the models can be structured for many human performance-modeling applications.

The cognitive submodels function as follows.

6.3.1. Working and Long-Term Memory Stores

Working memory is the store that is susceptible to interference and loss in the ongoing task context. Long-term memory loss would represent, for instance, a loss of skills or deep procedural memory

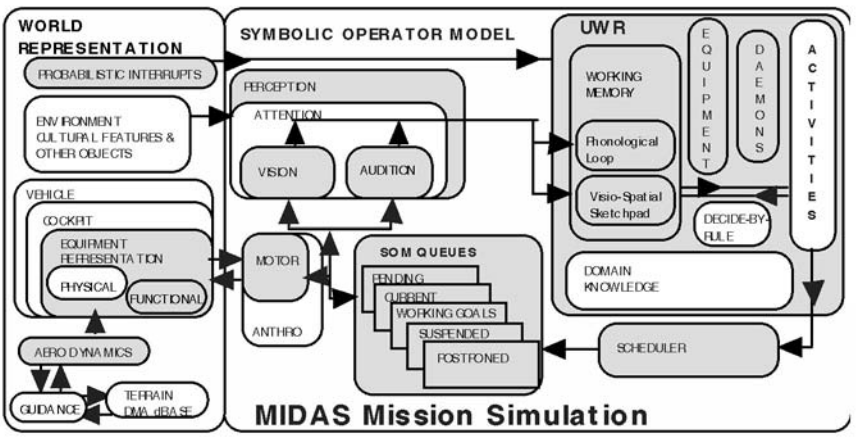

Figure 23 Structure of Cogntive Models.

of how to perform tasks. Neither the process of loss nor development of long-term memory, learning, is explicitly represented as a MIDAS function. We have modeled human memory structures as divided into long-term (knowledge) and working memory (short-term store). We have implemented working memory, described by Baddeley and Hitch (1974) as composed of a central control processor (of some limited capacity), an ''articulatory loop'' (temporary storage of speech-based information), and a ''visuo-spatial scratch pad'' (temporary storage of spatial information). The point of transference of information from the flight deck and ATC displays to the operators' working memory is the critical juncture in the subsequent use of the information that is exchanged.

Long-term memory structure is provided via a semantic net. The interaction of procedure with memory is provided by a goal decomposition method implemented as a form of cognitive schema. In order to capture the central role of schema and internal representation, we have an elaborate representation of both declarative and procedural information in the MIDAS model. In MIDAS, the internal updatable world representation (UWR) provides a structure whereby simulated operators access their own tailored or personalized information about the operational world. The structure and use of the UWR are akin to human long-term memory and are one of the aspects of MIDAS unique from most human–system modeling tools. UWR contents are defined by presimulation loading of required mission, procedural, and equipment information. Data are then updated in each operator's UWR as a function of the mediating perceptual and attentional mechanisms previously described. These mechanisms function as activation filters, allowing more or less of the stimuli in the modeled environment to enter the simulated operator's memory. Knowledge of what is on each operator's mind is a key modeling feature that allows MIDAS to examine decision making and the information exchange that is critical to decision making.

6.3.2. Attentional Control

Representation of human–automation integration requires functions of attentional control and concurrent task performance. Distributed attention and attention switching refer to an operator's ability to perform multiple tasks simultaneously. In many cases, a second task can be added to the performance of a primary task with little or no impact to the performance of the first task. In other cases, the performance of two tasks simultaneously has a disastrous interaction. Such context-and order-sensitive effects are determined in the scheduling and agenda management function provided in the MIDAS model. Attention capture functions are represented through a preattentive filter mechanism that responds to physical characteristics of environmental stimuli (e.g., color, blinking, auditory characteristics).

6.3.3. Activity Representation

Tasks or activities available to an operator are contained in that operator's UWR and generate a majority of the simulation behavior. Within MIDAS, a hierarchical representation is used (similar to, but more flexible than, the mission–phase–segment–function–task decomposition employed by many task-analysis systems). Each activity contains slots for attribute values, describing, for example, preconditions, temporal or logical execution constraints, satisfaction conditions, estimated duration, priority, and resource requirements. A continuum of contingent or decision-making behavior is also represented in MIDAS, following the skill, rule, knowledge-based distinction reported by Rasmussen (1983). The activity structures in MIDAS are currently being implemented as sketchy plans in the reactive action packets paradigm (RAPS) of Firby (1989). This structure of activities will interact with resource and context mangers to structure an agenda.

6.3.4. Task Agenda

The agenda structure stores instantiated RAPS as goals with subnetworks and logical control flags, object bindings, and history of state and completion. This network represents the current set of tasks to be performed by the operators of the simulation given the current goals and context. The network can complete successfully, be interrupted by other task networks, or be aborted. The relationship among the actions in terms of logic of performance (e.g. sequential or concurrent tasks) is also specified in the agenda structure. Whether, in fact, tasks can be performed concurrently is a function of resource relations in the cognitive model (sensation/reception, central/attentional/effectors). Work is currently underway to unify the representation of action and resources in the various version of the MIDAS system.

6.3.5. Decision Making

Quick, skill-based, low-effort responses to changes in values of information held in the UWR are captured by ''daemons'' when a triggering state or threshold value, sensed by perception, is reached. Daemons represent well-trained behaviors such as picking up a ringing phone or extinguishing a caution light. Classic production rule-based behavior is also available and is used when conditions in the simulation world match user-defined rule antecedent clauses active for the scenario modeled. Finally, more complex or optimization-oriented decision making is represented via a set of six pre-

scriptive algorithms (e.g., weighted additive, elimination by aspect, etc.), as reported by Payne et al. (1988). Each of these algorithms uses a different combination of attribute values, weights, and cut-off values for calculating the ''goodness'' of the options.

6.3.6. Higher-Level Functions

The cognitive submodel architecture allows for the development of higher-order functions of cognition. For example, Shiveley et al. 1995 has developed and demonstrated a ''situation awareness'' function that combines characteristics of working memory, long-term memory search, and perceptual models to develop an abstraction termed situation, which can then be used to guide behavior or to serve as a measure of adequacy of information in the environment and in the crew's knowledge store to meet task demands.

Context is a combination of declarative memory structures and incoming world information that is mapped to the agenda manager who is taking the plan (overall mission). This, combined with the plan interpreter, provides a series of actions to be performed in order to meet mission goals and handle contingent activities (such as interruption or plan repair). Verma (2000) has explored the extension of situation to ''contextual control'' (Hollnagel 1993) by using the elements of rule-based behavior, number of goals in working memory, and decision horizon in the MIDAS planning module.

6.4. Case Studies in MIDAS Applications to Aviation

The world community of aviation operations is engaged in a vast, system-wide evolution in human–system integration. The nature of this change is to relax restrictions in air transport operations wherever it is feasible. The relaxation includes schedule control, route control, and, potentially, separation authority in some phases of flight, such as aircraft self-separation in en route and oceanic operations. The consistent result of the relaxation of system constraints is to change and challenge human performance in that system in two dimensions. First, the decision-making process becomes distributed. This distributed decision differs from current operation and has a direct impact on crew and team resource management processes. Second, the dynamic concept of operations provides a new challenge to the human operators of that system. The human operators (pilots, air traffic controllers, and airline operations personnel) must monitor and predict any change in the distribution of authority and control that might result as a function of the airspace configuration, aircraft state or equipage, and other operational constraints. The operators are making decisions and sharing information not only about the management of the airspace, but also about the operating state of that airspace. In order to support collaborative and distributed control between air and ground for separation assurance, modifications to the roles and decision authority must be explored. The evolution of the air transportation system, therefore, profoundly challenges human performance prediction and the cognitive sciences. Previous models of human performance linked to machine performance have had distinct boundaries in the human–machine elements to be modeled. Current system design requires models of human, machine/automation, aircraft, airline operations, air traffic management, and National Airspace (NAS) management to be tightly coupled in order to guide design, evaluate the effectiveness, and ensure the safe operation of the system.

6.4.1. MIDAS Case Study 1: Predicting Flight Crew Performance in the Advanced Air Traffic Management System

We have focused our early investigation on critical issues in air ground coordination in relation to aircraft self-separation. The interaction among aircraft and controllers is proposed to occur at points in space around each aircraft called *alert* and *protected zones*.

These zones are to be used by an alerting system to monitor and advise the flight crew on conflicting traffic flying within these areas. In a cockpit-based system, the alerting system would warn the flight crew of any aircraft entering the alert zone. The crew could evaluate the situation and choose or negotiate a preferred deviation. If the intruding aircraft continued into the smaller warning zone, the crew would be advised to take evasive action.

Much discussion and debate has gone into the further definition of the warning and alert zones, including their description as complex surfaces that take into account the speed, performance, and turning radius of the aircraft. Up to this time, the process of definition lacked data for inclusion of human performance in the size and shape of these areas. Figure 6 proposes a redefinition of these zones based on a human–machine system performance. Built upon the well-defined physical aerodynamic response of the aircraft are the more varying machine (sensing, communication, computation) and human (perception, communication, decision, action) responses to any alert. These zones might also differ, depending on the speed of the aircraft, configuration of the conflict, and procedures used to process the conflict.

6.4.1.1. Study 1: Model Analysis The goal of this study was to develop a better understanding of the impact of joint and distributed decision making among flight crews and air traffic control on

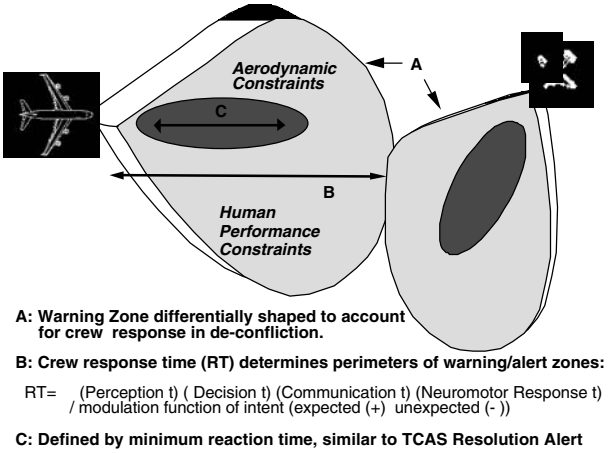

Figure 24 Alert and Protected Zones Calibrated to Human Performance Parameters, Aircraft Performance Parameters, and Communication Systems Parameters.

the size and shape of the alert zones. This was accomplished by first analyzing and modeling the cognitive and procedural requirements of several candidate encounter scenarios. These models were then populated with performance data derived from human-in-the-loop experiments. The specified scenarios were then represented within the MIDAS computational modeling and simulation system.

With Monte Carlo simulation techniques, each scenario could be exercised many times, eventually establishing a statistical distribution for the human–machine performance of that configuration. Combining this with the aerodynamic performance of the system (in this case the closing speed of conflicting aircraft at differing encounter angles) meant that the differences in warning requirements between the different scenarios should have emerged. All encounters were assumed to be two-ship interactions.

- *Scenario 1:* In this scenario, both aircraft are equipped with some type of CDTI detection equipment. Here a single aircraft can detect and avoid the conflicting aircraft by acting on its own (no communications are necessary). This might describe a situation where one aircraft is slowly closing on another from behind.
- *Scenario 2:* Both aircraft are again equipped. However, because of the geometry of the encounter and conflicting goals, both aircraft must be involved and negotiate to resolve the problem. The solution would be arrived at though communication and negotiation between the two flight crews.
- *Scenario 3:* This scenario describes an encounter where communications with ATC are required to resolve the problem. This is necessary because one aircraft is equipped with the required suite of equipment while the other is not. Such encounters might be common early in the implementation of free flight or when encountering older, nonupgraded aircraft.

6.4.1.2. High-Level Activity Definition in the MIDAS Model An initial cognitive and physical task analysis was performed for each of the three scenario cases. The result was a sequential model identifying the high-level processes (or activities) performed by the operators. In scenarios 2 and 3, the activities that were to be performed in parallel by the other flight crew and ATC were also defined. Falling out of this analysis was a recognizable cycle of alert, recognition, communication, decision, then communication and action by the crews. This process was replicated throughout the scenarios for each flight crew interaction.

6.4.1.3. Lower-Level Activity Specification Using these sequences as a guide, the lower, or leaf-level, activities (corresponding to the physical or cognitive tasks actually performed by the operators) were defined for each high level task. Columns 2 and 3 of Figure 7 show the high- and lower (leaf)-level activities defined for scenario 1. The remaining columns show the interrupt recovery, duration, and VACM (visual, auditory, cognitive, and motor channel capacity requirements) specifications assigned to those activities. Where possible, the activities were chosen to correspond to research that had been performed in previous studies (Corker and Pisanich 1995). This provided access to fully

defined activity specifications. New activities, along with their specifications, were developed by interpolating prior results.

The MIDAS model can contain activities that may interrupt the flight crew from the normal activities (for example, a question in the cockpit may interrupt a flight crew member from a CDU entry task). The interrupt resumption specifications define how an activity is resumed after being suspended. Resumption methods are individually defined based on the characteristics of the activity and the sequence in which it operates. The resumption methods used on this simulation include not-interruptible (cannot be interrupted); resume (resume activity where interrupted); and restart (restart the activity from its beginning). Interruptions and the way that an activity is resumed directly affect the duration of the activity sequence.

6.4.1.4. Experimental Runs After specification and testing, each scenario was loaded into Air-MIDAS and 50 Monte Carlo runs were gathered for that simulation. The data recorded for each run included the activity sequence along with the individual activities and their duration for that sequence (including any interrupt activities). These data were written to a file for analysis in Microsoft Excel format. This data was postprocessed using the rules described earlier to extract a proper time for the parallel activity sets. This allowed the establishment of a total duration (time required for all operators to complete their tasks) for each scenario run. This was the dependent variable in this study.

6.4.1.5. Results A standard set of descriptive statistics was generated for each scenario based on the set of 50 Monte Carlo runs. The temporal performance data were also plotted as a histogram using a bin size of 10 seconds, illustrated in Figure 25.

The performance observed in each scenario above was applied to a 90° crossing conflict. In this geometry, the initial traffic alert was proposed to be signaled at 40 miles from the crossing point and assumed a typical commercial aircraft cruise speed (Mach 0.82). The measure in this case was the closing distance (straight-line distance between the aircraft). The minimum, maximum, and average human–machine performance times are illustrated in Figure 25. This calculation also allowed the determination of a closing distance for each performance time (potentially from 56 down to 0 miles). Using this geometry, an idea of the initial warning distance could be inferred using the worst-case performance criteria. Although the average clearing distances in scenarios 1 and 3 differ significantly, given a warning at 40 miles, the worst-case time in both scenarios would allow an avoidance maneuver to begin well before the aircraft were 20 miles from each other. In scenario 3, however, the

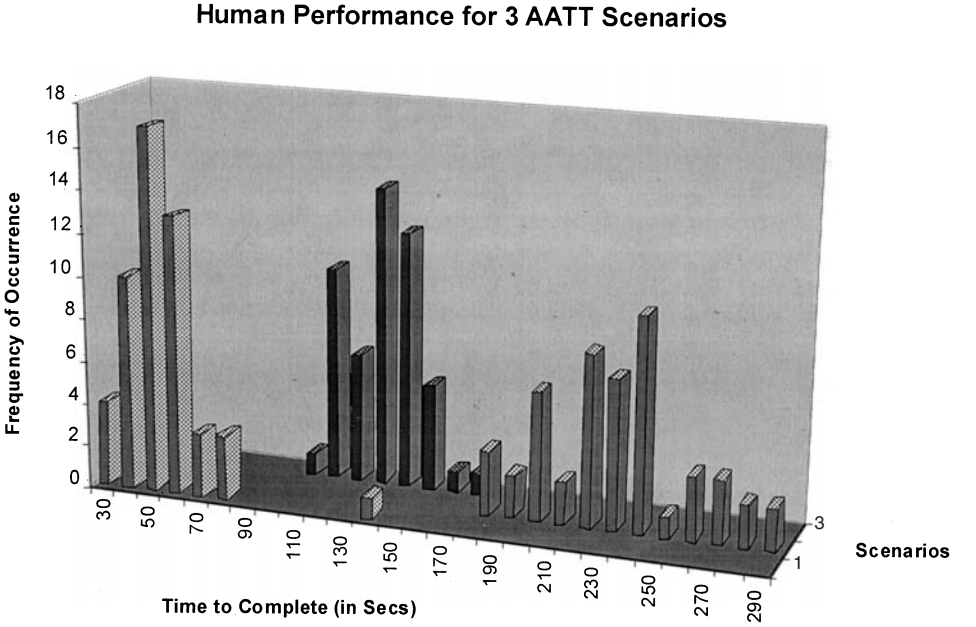

Figure 25 Response Times for an Air-to-Air Encounter at 90° Intercept.

worst, and even average, clearing distances observed would indicate that the alert point for that type of interaction should be initiated well beyond 40 miles.

To investigate this idea further, a second application of the human performance data was performed. Calculations were again made with both aircraft maintaining a speed of Mach 0.82. For each 15° angle around the aircraft, the resulting closing speed was calculated. Combining that speed and the performance distribution of each scenario resulted in a distance traveled for that angle. In this case, two standard deviations above and below the average were used as the minimum and maximum points respectively. Five miles were added to these distances to account for the warning zone. When plotted, these points create the heart-shaped rosettes shown in Figure 26.

In addition to showing the difference in warning distance needed to maintain the same performance at differing closing angles, these plots are interesting because they also illustrate a difference in performance area (size of the area between minimum and maximum performance) between the three scenarios. Given the performance observed, the higher closing speeds actually exacerbate the differences between the scenarios. Although scenarios 1 and 3 looked comparable in the 90° closure shown earlier, at shallower angles scenario 3 actually requires a significantly earlier warning point to maintain the five mile alert zone.

6.4.2. Extension of Model to Air Traffic Control

The second example of MIDAS use concentrates on the air traffic controller operations in response to free-flight self-maneuvering aircraft. In this study, the human operator's performance measures in the distributed air/ground air traffic management (ATM) that characterizes the multiple-controller, multiple-aircraft system include visual monitoring, perception, spatial reasoning, planning, decision making, communication, procedure selection, and execution. Two scenarios will be created in the current modeling effort. The first scenario will be operated consistent with the air traffic control rules of flight. The second scenario will be operated consistent with free flight rules of operation established by RTCA. Each scenario involves a response to a scripted conflict situation in a number of conditions.

The MIDAS model of the controller was developed using the rules of current and free-flight operation. Estimates and measured times for controllers performance on these tasks was input into the task descriptions. Here the interest was in how stable the system was to emergency conditions under current and free-flight conditions. The control scenario was focused on the handoff between

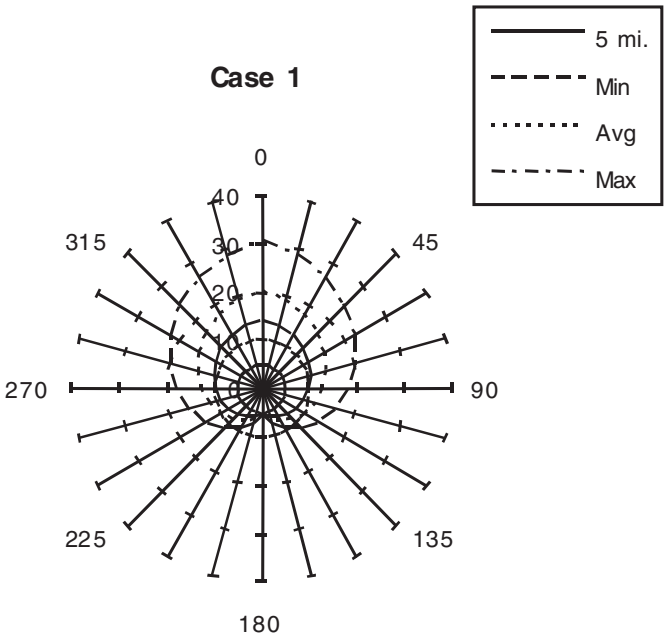

Figure 26 Cartoid Shape of Minimum Safe Distance to Alert Calculated as a Function of Model-Generated Crew Response Times.

sectors in an enroute segment of flight. This scenario then required the development and interaction of several MIDAS human performance models. There were two controllers modeled that interacted with a single aircraft flight crew. The scenario is illustrated in Figure 27.

Results were compiled for various conditions of weather and emergency management under the two flight regimes and controllers' performance profiles for workload were developed. In addition, operational measures, such as aircraft maneuvers and points of closest approach, were also calculated. The details of these analyses can be found in Gore (1999).

6.5. Other Modeling Strategies That Have Demonstrated Utility in Modeling Human Performance in Systems

There has been a flurry of interest over the past decade in the use of object-oriented tools that focus on the representation of human knowledge and how humans use that knowledge in real situations to make decisions and act. An example of this approach is the Distributed Operator Model Architecture (DOMAR), developed by Dr. Michael Young of the Wright Patterson Air Force Research Laboratories and Mr. Stephen Deutsch of BBN Inc. (Young and Deutsch 1999). The system is composed of a framework of software languages and model-development tools. As with the other models discussed in this section, the intention is to provide the analyst with the necessary components to develop models that simulate both the human operators and the systems with which they interact.

DOMAR is unique in its intention to allow these models to interact not only to allow with other entities in the model environment, that is, with simulations, but to allow the human performance models developed in OMAR to interact with live human operators and real systems in a hybrid human–simulation modeling capability.

The component software tools that are part of DOMAR allow the developers to construct their own unique cognitive architecture for the operators simulated in DOMAR.

DOMAR is made up of tools to support the development of appropriate cognitive models of human operators interacting with systems. The following description is provided by Young and Deutsch (1999):

- The Simple Frame Language (SFL) is used to represent knowledge about objects, their attributes, and the relationships among objects. It provides an object-oriented substrate for the entire simulation environment. One of the most important classes of objects is an agent—the special type of object that can execute procedures and thereby run in the DOMAR simulator. The Rule Definition Language (RDL) provides computational primitives for representing rules (i.e., condition action pairs of the form if-then). Rules are developed as rule packets, which specify when and how the rules are to be applied to a specific situation. The Simulation Core Language

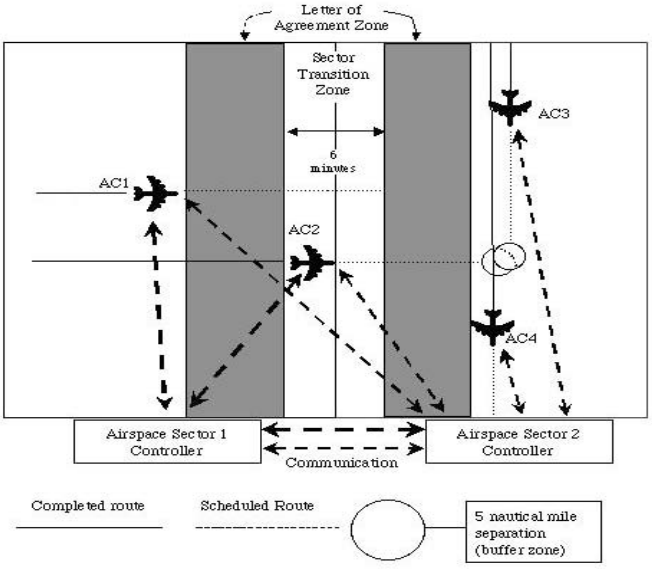

Figure 27 Cross-Sector Handoff Scenario

(SCORE) is a procedure definition language that provides a set of computational primitives for modeling the priority-based serial or parallel execution of goals, plans, and tasks.

- The DOMAR publish–subscribe protocol, implemented in a set of SCORE forms, plays a central role in several important aspects of model building. Within the human performance models themselves, it is used to coordinate the concurrent operation of related procedures. It is frequently employed in the modeling of person-to-person communication, and it is the basis for the distributed execution, in real time or fast time, that DOMAR supports. Very large agent-based simulations may be developed in a distributed computing environment.
- Knowledge engineering: DOMAR provides graphical tools to support knowledge acquisition, the development and management of large bodies of code, and data-analysis tools to support model development and experiment evaluation. SFL objects and agents are defined using the graphical concept editor, which provides an interactive graphical display of the hierarchical relationship among object definitions as a directed network of connected nodes. It provides a table window for displaying and editing slots associated with objects. SCORE procedures are created with a text editor (e.g., EMACS). They can then be viewed with the procedure browser, which provides several different graphical views of the programmatic interrelationships among the procedures.
- Analysis capabilities: DOMAR provides tools for monitoring events as reported by the simulator during a model run. Events that can be monitored include goal events, procedure events, stimulus-and-response events, and user-defined events such as communication events. Using a menu, the DOMAR user chooses the events to be displayed before the start of a simulation or at any point during a run. Finally, DOMAR has two post-run analysis displays. The event timeline window displays a listing of time-tagged events for one or more simulation agents. Individual agents have their own timelines within the display. The task timeline window displays the set of concurrently running tasks for one or more agents over a specific period of time. It provides the start and end time for a task and the task's status and priority. All of the displays are written in the Java language and can be connected to any DOMAR image that may be running on a local or remote computer.

6.5.1. Sample Applications

DOMAR was created to support the development of human performance models. DOMAR's sophisticated agent framework has recently been used by other researchers to develop a variety of agent-based systems. DOMAR is being used by AFRL in its Human Interaction with Software Agents (HISA) project to create human–computer interfaces incorporating intelligent agents; by the Defense Advanced Research Project Agency (DARPA) in its Collaborating Agent Based Systems (CoABS) program to demonstrate a collaborating agent communication framework and in its Joint Forces Air Component Commander (JFACC) program to create a business enterprise model of the JFACC process; and by the Navy in its Conning Officer Virtual Environment (COVE) program to create an intelligent training system.

7. SUMMARY

This chapter has provided the need for simulating performance of complex human-based systems as an integral part of system design, development, testing, and life-cycle support. It has also defined two fundamentally different approaches to modeling human performance: a reductionist approach and a first-principled approach. Additionally, we have provided detailed examples of two modeling environments that typify these two approaches, along with representative case studies.

As we have stated and demonstrated repeatedly throughout this chapter, the technology for modeling human performance in systems is evolving rapidly. Furthermore, the breadth of questions being addressed by models is constantly expanding. We encourage the human factors practitioner with a little creativity and computer savvy to consider how computer simulation can provide a better and more cost-effective basis for human factors analysis.

CHAPTER 94
Simulation Packages

ABE NISANCI
Bradley University

ROBERT E. SCHWAB
Caterpillar Inc.

1. INTRODUCTION

The increased complexity and cost of modern service and manufacturing systems, coupled with the advances in computer and simulation technologies, have led to an extensive use of simulation. Parallel

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

to this development, simulation languages, and products have also proliferated. In the early 1970s, there were only a few special-purpose languages such as SIMSCRIPT, Q-GERT, GASP, GPSS, and DYNAMO, and general-purpose languages such as ALGOL, PL/1, and FORTRAN (Nance 1996; Schwab and Nisanci 1992). Initially, the most significant use of simulation was by the military. Currently, simulation plays a significant role in almost every major service and manufacturing industry throughout the world. The *Directory of Simulation Software* published by the Society for Computer Simulation (Rodrigues 1994), lists 174 simulation products that are available in the marketplace. The annual Buyer's Guide of simulation software (Institute of Industrial Engineers 1999) lists 27 companies providing 40 simulation software products. Twenty-eight simulation products are listed under the categories of general purpose simulation software, manufacturing-oriented software, business process engineering, simulation-based scheduling, animators, simulation support software, and optimization (Banks 1998a). The simulation software market is very dynamic, resulting in many mergers and new companies replacing the existing ones. There are many more products that are in various states of development and use at companies and universities. Most major companies employ at least one simulation specialist on staff or have developed a close relationship with a consulting firm that offers simulation service. Major manufacturers started requiring simulation analysis prior to approving significant capital expenditures as early as the 1980s (Krepchin 1988; Schwab 1987). This soaring interest in simulation and the simultaneous availability of PCs have produced a corresponding growth in simulation companies and products. Simulation products can be divided into two distinct categories: simulation tools and associated/complementary products. Traditionally, simulation tools include languages and simulation packages (sometimes called simulators). However, the difference between languages and packages seems to disappear over time. A simulation package may have all the power of a simulation language. Complementary products are used to support simulation serving as front and back ends.

1.1. Simulation Languages

Simulation languages allow the user to mathematically describe a process using constructs and syntax specifically designed for the analysis of dynamic and stochastic systems (Smith 1987). Early simulation models were coded in general-purpose procedural languages such as FORTRAN. This approach resulted in spending a large percentage of time developing, debugging, and verifying the model. The new languages alleviated most of these problems by significantly eliminating the need for programming. Most modern languages have an internal simulation clock, entity tracking, some form of statistical output, and animation capability. Typically, modern simulation languages have the ability to handle a broad range of problems and are flexible enough to handle complex decision rules.

1.2. Simulation Packages

Simulation packages have been in development for the last 15 years. They are a product of simulation companies' and simulation users' desire for the benefits of simulation and a belief that the simulation process should be accomplished more easily and results produced more quickly. All packages use some programming language as the base language, but some packages use a specific simulation language (e.g., Arena uses SIMAN, and AweSim uses Visual SLAM). All packages are designed to make the model-development phase much easier by limiting the number of constructs, providing a menu-driven format, presenting fill-in menus, and tying simulation and animation together. Today, all simulation packages are designed for specific industries such as manufacturing, communication, supply chain management, and business process improvement.

1.3. Complementary Products

Complementary products include all simulation support software, which are usually developed independently and later incorporated into a package as a front or end use. Some examples consist of curve-fitting programs, input data generators, scenario builders, programs for file management and data handling, graphics and animation builders, and optimization programs. The vendor of the package or the users of the package develop some upon a perceived need, such as specific material-handling extensions or applications. Some of the popular complementary simulation products are (Banks 1998a; Institute of Industrial Engineers 1999):

- ExpertFit (Averill M. Law & Associates): Automatically determines which of 39 probability distributions best represents a data set. It puts the selected distribution into the proper format for 30 simulation products. ExpertFit provides goodness-of-fit tests, more than 30 graphical plots, a distribution viewer, and batch mode operation.
- StatFit (Geer Mountain Software): Fits input data to one of 21 theoretical continuous and discrete distributions and provides relative comparisons between distribution types.
- Proof Animation (Wolverine Software Corporation): Provides animation for discrete event simulation software.

- OptQuest (OptTek Systems): An optimization tool that guides the process of selection of system inputs and then executes the model by running alternative scenarios for each set of inputs in order to enhance system performance (Laguna 1997; Glover and Kelly 1999). OptQuest is available with ARENA, Micro Saint, and Taylor ED.
- SimRunner: Given the input factor levels and system performance measures, SimRunner is employed in two stages. The first stage involves determining the important input factors, and the second stage involves determining the best factor levels to improve the system performance. It is included in ProModel's optimization module (Heflin and Harrel 1998).

2. SELECTION STRATEGY

Even with the tremendous increase in the number of simulation products and simulation companies, the selection of simulation tools need not be difficult if an organized approach is developed. This includes two key elements: the development of a strategy for the use of the products and the knowledge of the characteristics required in the products (Schwab 1987). The strategy has an impact on the features of the tool that is chosen. The features of the tool should be tailored for the people and uses of that tool. Strategy development for the use of the product is essential for the product's benefits to be fully exploited. A good strategy addresses how the tool will be used, who will use the tool, how the users will be trained, and how the users will be supported. In developing such a strategy, it would be useful to establish a team consisting of those who will use, maintain, and provide support for the product.

2.1. Establish the Uses of the Tool

First, the type of application for the tool should be specified. Types of application include:

- One product for one application
- One product for multiple applications
- Multiple products for multiple applications

Typically, individuals charged with investigating simulation tools start by selecting one product for one application. This allows for a fair evaluation of the specific simulation product in an application for which it was designed. This approach also minimizes start-up and training costs.

The one-product-for-multiple-applications approach is particularly helpful in integrating operations separated by distance or function. Selecting one product allows for a common communication tool that can be understood by everyone trained in the tool. In selecting only one tool for all applications, some sacrifice may be made in terms of modeling efficiency. Each product has features that make specific model development easy. As an example, CACI offers a product (COMNET) to design communication systems, and AutoSimulations (AutoMod) makes automatic guided vehicle systems design easy. Selecting only one product allows for standardization, model sharing, and communication but risks some inefficiency in model development.

The multiple-products-for-multiple-projects approach has the opposite advantages and disadvantages of the previous approach. It always allows for the selection of the most appropriate tool for the application. This approach is essential for consulting firms offering simulation services to diverse companies. A broad range of products and abilities is necessary to meet the diverse needs of clients. The disadvantage to this approach is a dilution of simulation personnel. If people must be trained on a number of products, then specialization in any one tool is sacrificed. As more people are cross-trained on various products, training costs increase. However, more flexibility and diversification is achieved.

Second, it is important to have an understanding of the specific use to which the tool will be put. The tool may be used for evaluation purposes such as the analysis of different layout alternatives for a manufacturing system. It may then be used for detailed design to define and fully describe the operational characteristics of the system. The tool may also be used in narrow application such as the design of communication systems or automatic guided vehicle systems. The product itself, however, may be used in broad applications from preliminary design to detailed design.

2.2. Select the Users of the Tool

Users of the simulation tool play an important part in its success. Matching the wrong people to the right tool is just as dangerous as matching the wrong tool to the project. Users of simulation may have a broad educational background and work experience. A flexible approach to the education and experience of the simulation user must be considered in the selection of a product. This also influences training requirements, which are discussed later. If personnel options are limited, then the training program for these individuals must be flexible enough to compensate for their varied backgrounds. On the other hand, if no time or money is available for training, then individuals must be chosen

with enough previous training and experience to begin work on simulation projects immediately. Personnel selected for simulation projects should meet several criteria:

- Familiarity with the general process
- Analytical and computer skills
- Knowledge of probability, statistics, and design of experiments

Simulation is not just computer programming. A simulation analyst must be proficient in all of the above areas. Simulation tools are statistical tools; therefore, an understanding of statistics is essential to make effective use of any simulation product.

2.3. Design the Training Program

Even if the software supplier is to be the primary source of training, it is important to establish a comprehensive training plan as an integral part of an overall simulation strategy. The training plan should include the following major areas:

- *Fundamentals:* The fundamental issues related to the use of simulation tools might include training in the simulation process, data collection and preparation, model building, experimentation, and input and output data analysis. All of these areas can be taught by linking them to a specific simulation tool.
- *Tool training:* Training in the use of the tool is critical. Ideally, the training is accomplished over a number of days and includes an exposure to all the features of the tools. Instructors need to provide a wide range of examples and have extensive simulation experience in order to answer the questions of trainees effectively. Trainees should attend simulation classes with specific work-related projects and should begin working on them immediately after training. This helps cement the concepts of the class firmly in the minds of the trainees. Professional training and frequent use represent the only way to become proficient with any simulation tool.
- *Application training:* Many users of simulation products find it difficult to begin to use the product for a specific task even after they have received training in how to manipulate it. It may be necessary to show users how to use the product as it specifically applies to their work. An example of this would be a warehouse engineer who takes simulation training where most examples in the class are from manufacturing. The engineer may find it difficult to return to the job and immediately make application to the warehouse. This difficulty may be overcome by allowing the new simulation person to work with and be quided by an experienced simulation person. Another alternative might be to retain a consulting firm to develop the first model and allow the new simulation person to follow and assist in the entire model-development process. All new users should be taught the use of gradual complexity in the model-building process. They need to start with a simple representation of the process and get the model running. Then they can gradually add more and more complexity until the process has been modeled completely.
- *Programming:* Within the framework of modern simulation tools, what the users need to program today is more like programming an Excel spreadsheet than programming per se. However, some simulation tools provide use of an underlying language such as FORTRAN, Pascal, or C in addition to the syntax for the simulation language. This feature enables the user to program complex decision rules and other logic not capable of being handled by the simulation language itself.
- *Hardware and operating system:* New users may be unfamiliar with the hardware on which the simulation software runs, as well as the operating system utilized on the computer. A short course covering these topics enhances productivity.

2.4. Assess Support Needs

Care should be taken to determine in what manner the users will be supported. Obviously, if there is only one user, then the only reasonable approach is to depend on customer support from the software supplier. However, a site with multiple users presents some opportunities for self-support. As an example, one person at the site could be designated as the simulation support for everyone and could spend a certain number of hours each week learning more details about the simulation tool. This may result in faster problem resolution. Responsiveness to support needs, means of providing support, and geographical proximity of the support services need to be considered in selecting vendors

3. EVALUATING SIMULATION TOOL CHARACTERISTICS

Number of studies exist related to simulation software evaluation criteria and methodologies (Tumay and Harrington 2000; Banks 1998a; Nikoukaran et al. 1998; Hlupic 1997; Hlupic and Paul 1995; Pritsker 1995; Davis and Wiliams 1994; Law and Kelton 1991). The characteristics listed below should not be considered as all-inclusive but should be used as an aid in assembling a list for the software evaluation process. As an example, if the strategy calls for purchasing one package for only one computer, then portability is not a consideration. For a given set of criteria, there may be additional items that should appear on the list. The characteristics of any simulation tool can be divided into six major areas: language, operational, input, output, hardware, and vendor.

3.1. Language Characteristics

Language characteristics include the features used in writing code and providing useful external support tools. Some simulation tools allow the user to write complex rules. All the features in this section deal with writing simulation instructions.

- *Portability:* If the computing environment is made up of different hardware platforms, then the software should be usable on a wide variety of machines, from mainframes to PCs, and operating systems such as OS/2, Windows, and UNIX. Also important are factors such as special graphics card or driver requirements, ability to run on a network, special compiler needs, and memory (RAM) requirements.
- *Readability:* If the system generates or uses some type of computer code, it should be understandable and easily read by people as well as computers. Commands should be "English-like" statements to assist the writer and reviewer in debugging the model. The language should permit the use of comment statements within the code.
- *Documentation:* The documentation, consisting of installation instructions, test models, and user manual, must provide the user with all the information required to run and debug the models. It must also provide a thorough understanding of all aspects of the software and a large number of example problems and their detailed solutions. An extensive and well-organized index to all documents is a necessity.
- *Data requirements:* The software must allow for both deterministic and stochastic input. Sampling from system-supplied distribution functions should include theoretical statistical distributions such as exponential, normal, triangular, uniform, Poisson, beta, gama, erlang, and log-normal. In addition to these, user-defined distribution functions should be permitted.
- *Capability to support different worldviews:* Depending on the characteristics studied, a discrete or continuous change model may be suitable. In discrete change models, the variables of interest may change in a discrete fashion at any point in time or at certain points in time. In continuous change models, the variable of interest changes continuously at any point in time or at certain points in time (Pritsker and O'Reilly 1999). A project may need both discrete and continuous modeling. If so, they must be supported by the same software, or two different pieces of software must be purchased. Continuous modeling can be used with chemical-related processes such as tank filling and emptying and in discrete processes that can be modeled as continuous processes, such as high-speed canning.
- *Algorithms and modeling features:* A library of available algorithms can potentially save a significant amount of time in the model-building process. For example, automatic guided vehicles and automatic storage and retrieval systems modules are extremely useful. Additional features such as cost modeling, scheduling and schedule generation, breakdown generation, and maintenance planning also enhance modeling productivity.
- *Capability to have user-written interface:* The ability to interface with user-written routines permits the development of industry specific routines or decision logic, which can be filed in a library and reused. This allows flexibility and avoids duplication.
- *Compatibility with other software packages:* Integration is becoming more important with software packages. The ability to access other software packages allows the simulation person to work more efficiently and effectively. Interface to spreadsheet products is helpful in the collection and organization of data. An interface with computer-aided design software can be helpful to reduce the layout development time of animation. If a database package has already been chosen, the ability to integrate the simulation software with that package is extremely useful. An ability to interface as well with statistical analysis software adds additional powers and enhances user productivity.
- *Ability to communicate with other applications on a dynamic basis:* The concept of distributed interactive simulation that includes the ability to exchange data with other applications, including

other simulations, is becoming widely popular. For example, Micro Saint and Arena are both using Microsoft COM features that allow their tools to work with other applications that may even reside on different computers.

- *Ease of error recovery:* The software must be able to handle user-generated errors, especially in the interactive mode, and continue to function after receiving such an error.

3.2. Operational Characteristics

Operational characteristics involve the features in which the software interfaces with the user, except for code writing, which was considered above. These characteristics can make a significant contribution to the productivity of the modeler.

- *Applicability:* Ideally, a single piece of software should allow the novice to use the tool with a minimum amount of training and an absence of frustration. It should also allow the expert to use the tool to perform difficult, complicated simulations of a wide spectrum of systems.
- *Availability and use of debugging features:* The software must contain error diagnostics and debugging features, which help the modeler rapidly check out the model code. An interactive debugger with the ability to set stopping points and step through the model is useful in debugging complicated simulations. An important feature in model debugging is the ability to generate a detailed standard or customized trace to determine whether the model operates properly.
- *Ease of use and intuitiveness:* The software should have features to help automate the model-building process. Desirable features might include menu-driven operation, fill-in menus, and prompting for omitted values. The casual user requires online, context-sensitive help in the model-building process. The software should be accessible in an interactive mode.

  The software needs intuitive icons, menu arrangements, and keystroke sequences. Software that requires the user to enter obscure keystrokes to bring up the help screen prevents the user from making intuitive guesses about forgotten operations. Significant amounts of time are then wasted looking through a user's manual. Since most software programs use the F1 key to bring up the help screen, an intuitive system would have some form of help available by pressing the F1 key.
- *Ease of parameter variation:* The software should allow automatic parameter variation over a specified range of values and hence allow the running of multiple replications without requiring user interface. This feature can also aid in performing sensitivity analyses.
- *Ease of model revisions:* The software must allow changes to be made to the existing model quickly and easily. The best solution is rarely chosen first. The ability to change the model, the routing of the entities, and the parameters, and change them quickly, is important.
- *Interactive:* The software should allow changes in the model during the simulation run. Such changes are vital for doing ''what-if'' analysis with the model, although they invalidate the statistics collected during the run.
- *Availability of checkpoints:* The software should be able to print out data about the model, in tabular or graphical form, at specified intervals before the end of the simulation. This allows a look at intermediate results at critical times such as shift change.
- *Optimization:* The software should also have an optimization feature to guide the user in selecting system inputs and executing the model to enhance system performance.

3.3. Input Characteristics

The simulation model may require input from different sources. The following features may save significant time and effort in preparing the necessary input:

- Ability to read from external files, databases
- Ability to interact with popular spreadsheet, computer-aided design, and process-planning software
- Ability to trigger input functions throughout the simulation process
- Features to define, analyze, and display input in terms of statistical distributions
- Automated definition of model entities, their attributes, and rules for their interaction
- Ability to interact dynamically with other software applications

3.4. Output Characteristics

The results of simulation form the foundation for many conclusions regarding a process under consideration. Therefore, the availability and presentation of output results is important.

- *Reports:* The reports generated by the software must be clear and easy to interpret. The report format should provide graphical output such as simple bar charts and histograms as well as the standard statistical listing. Because all applications of simulation have some differences, the software must enable the user to generate special reports and control the amount, format, and type of output. A list of the standard statistics that may be included in an output report may consist of:
  1. Activity statistics: Average, minimum and maximum duration, standard deviation, entity count, current status
  2. Waiting statistics: Average, minimum and maximum length and wait time, standard deviation, queue current status
  3. Resource statistics: Average and maximum utilization, standard deviation, current status
- *Graphics:* The graphics should display a wide variety of graphs and charts (bar, pie, histogram) in a user-designated format. The ability to relate data across different scenarios helps during the analysis phase.
- *Animation:* Animation allows the user to represent the physical process graphically and describe and visualize the system being modeled. The animation portion should have a standard library of symbols and icons to assist the user in developing a picture of the process. Furthermore, an icon builder helps design shapes that are not included in the standard library. Animation can be helpful in the verification and validation of the model, as a selling tool to management or others not closely involved with the project as an operator-training tool, and as a technique to solicit ideas from experienced workers. Although experienced workers might never have used a computer product and might even feel intimidated if asked to do so, they could be drawn quickly into a discussion about the viability of a process change if they were shown an animated picture.
- *Output analysis assistance:* Automation of output analysis is certainly a characteristic of the new generation of simulation systems. Features that compare or relate data from replications or probable scenarios provide significant support to the user in reaching conclusions. Assistance in steady state analysis, confidence interval estimation, automatic stopping rules, sample size determination, and so on is very desirable.

3.5. Hardware Characteristics

Most organizations have hardware requirements that must be followed when selecting software. Therefore, the purchase of any software must be influenced by the hardware requirements of the organization and the flexibility and limitations of the simulation software. The compatibility of the software with the hardware already in place, file sharing capability between machines and facilities, and the capability to support the output devices already in place need to be considered.

3.6. Vendor Characteristics

The websites of the vendors are important sources of information. Many useful information about the companies and their products can be obtained from these sites. A critical examination of the company that develops the product requires significant attention. The process of acquiring a simulation tool, however, should not be viewed as a simple exchange of product for money. The company developing the product plays an important part in the successful use of the simulation product. Therefore, attention must be paid to certain features of the supplier. These features include:

- *Presence of ongoing software-development efforts:* The company should have an ongoing program of software development for both existing products and new applications. Otherwise, the user risks product obsolescence.
- *Training:* The company supplying the software must provide high-quality training programs that include both onsite and offsite classes. For large installations, training for systems personnel should also be available.
- *User support:* The company must have qualified technical personnel available during working hours to answer software questions. A functional user group with regular meetings is a good source of contacts and information. The user group can provide an avenue to influence the software-development priorities of the simulation company.
- *Company performance:* It is important that the company be established in the modeling and simulation business with an extensively field-tested software package that is in use by a significant number of corporate and academic clients. Nothing can be more frustrating than to have a supplier of simulation software go out of business and leave no one to call for support.
- *Cost/value relationship:* The price must be consistent with the job expected of the software, the features offered, and the training and support supplied with the software. In addition to

licensing, costs related to maintenance and upgrades, training, support, consultancy, and run times also need to be considered.

- *Business history:* Information such as the number of employees, the business focus (products vs. consultancy), experience, the customer base, the financial status, and references provide insight about the success and continuity of the vendor.

3.7. Evaluation Methodology

The abundance of simulation tools and the need to evaluate their numerous characteristics have turned tool selection into a major issue. Based on the May 1998 *IIE Solutions* "Last Word" reader survey on simulation (Garnett 1999), the capabilities of a simulation tool have been ranked in order of importance by 41 participants as follows:

1. Supply chain modeling
2. Ability to import CAD files
3. Customizable programming language
4. Cost modeling and analysis
5. Input distribution fitting and design of experiments

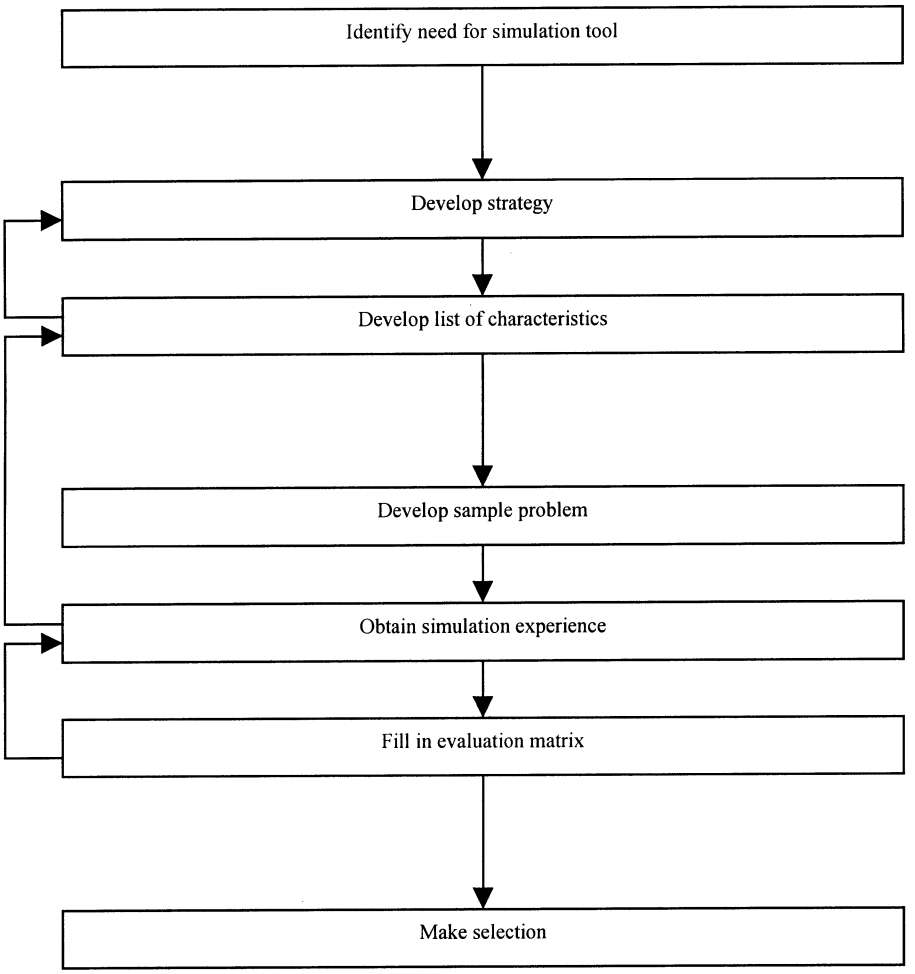

Figure 1 Simulation Software-Selection Flowchart.

6. Process plan modeling
7. Output analysis systems
8. Graphical and programmable model-building capabilities

Based on the same survey, attributes of a simulation tool have been ranked in order of importance as follows:

1. Quality of graphics and animation
2. Availability of training and consulting
3. Price

TABLE 1 Software Evaluation Matrix

		Software 1		Software 2	
Importance (1)	Desired Features	Rank (2)	Score (1 × 2)	Rank (3)	Score (1 × 3)
	Language				
	Portability				
	Readability				
	Documentation				
	Data requirements				
	World views				
	Library of algorithms

	Cost/value relationship				
Total Score			Score 1		Score 2

4. Speed of execution
5. Flexibility
6. Ease of use

References cited in Section 3 also propose methodologies for evaluating simulation tools. The proposed methodology to select the appropriate software is outlined in Figure 1. Once the need for simulation software is identified, a strategy needs to be developed (Section 2).

Given the company objectives and constraints, a list of desired characteristics needs to be formulated. These characteristics are listed in Table 1. A simple yet realistic sample problem must be constructed to evaluate the software. Simulation experience must be gained either by using the software over a period of time or by participating in simulation activities with trained individuals. The software can be compared using an evaluation matrix like the one presented in Table 1. The decision maker must decide on the desired characteristics to be included in the study and the importance of these characteristics. During the experimentation with the sample problem, ranks can be assigned to the characteristics of the software subjected to evaluation. Once all the software is evaluated, the total score for each software can be calculated. The selection can be made comparing the total scores and the costs of each alternative. Since the assignment of importance factors and ranks is subjective, including more people in the evaluation process will strengthen the decision.

4. SIMULATION TOOLS

This section is prepared using the user's manuals/guides, demo software, articles, books, and promotional material obtained from simulation software vendors. The websites of the vendors were also very useful.

4.1. Languages

Once the simulation model is formulated, it needs to be translated into a computer language for execution. In the early days of simulation, general-purpose computer languages were the only alternatives. Regardless of the language used, simulation modelers have been burdened with the task of writing procedures and functions for creating and deleting entities (transactions), creating random numbers and variates, updating simulation time and system status, and recording and analyzing data for output (Schwab and Nisanci 1992). This inefficiency in the model translation stage has led to the development of powerful special purpose simulation languages. These languages are capable of supporting discrete, continuous, and combined modeling world views. Furthermore, discrete change simulation languages offer event scheduling, activity scanning, or process orientations in modeling systems. Uses of software engineering has led to reduced software development costs and improved flexibility. Significant advances have been made in the field of model translation.

The following section reviews some of the most popular simulation languages and their features.

AweSim is a descendant of SLAM II (O'Reilly and Lilegdon 1999a; Pritsker and O'Reilly 1998, 1999; Symix Systems/Pritsker Division 1999) that supports a wide range of tasks necessary to execute a simulation project. It is a general-purpose simulation system that is distributed by Symix Systems, Inc., formerly Pritsker Corporation. It takes advantage of the latest Windows technology and includes the Visual SLAM simulation language. AweSim provides the user with three frameworks (network, discrete, and continuous) that can be used independently or combined depending on the problem. This feature of AweSim enables virtually modeling any system or process. Programming is not needed for network models, yet flexibility is provided through allowing user coded inserts in C or Visual Basic. Network models can be combined with continuous and discrete-event models that can be developed using the object-oriented technology of Visual Basic, C, or Visual C++. AweSim's architecture has the openness and interconnectivity to store, retrieve, browse, and communicate with externally written software applications such as databases, spreadsheets, and word-processing programs.

A simulation project with AweSim consists of scenarios that represent alternative system configurations. Scenarios consist of component parts that are created by software programs, referred to as builders, that are provided by AweSim. Through an executive window, project, scenarios, components (network, subnetwork, control and user data, etc.), simulate, and report options are defined. Component builders are accessed through the Components menu. The project maintainer, which examines changes made to the current scenario, determines a model translation or compilation requirement. Based on the prompt from the project maintainer, the user initiates a translation task. AweSim allows multiple tasks to be performed in parallel while a simulation is executed as well as switching between tasks. Some of the features of AweSim are:

- *Building models:* A network is a basic component that graphically displays the flow of entities through the system being modeled. A network consists of nodes (processing locations) that are connected by activities that describe routing and operation time requirements. Nodes are used

for functions such as removing or entering entities, seizing or freeing resources, changing variable values, etc. Entities may also be described by assigning attribute values such as weight, arrival time, etc. A network is built interactively in AweSim by selecting symbols from a graphical palette and dragging them to the desired location on a screen. Required informations about the symbols are specified by filling out a form that is supported by online error checking. Context-sensitive help and search capabilities are also provided.

- *Subnetworks:* These are reusable network objects that are provided for hierarchical models and are invoked from a calling network. This feature enables creating some form of a model depository that can be used by different modelers in different projects. Hence, it enables saving modeling time and sharing modeling expertise. Subnetwork builder works like the network builder but contains slightly different nodes.
- *Model output:* Output from various scenarios can be compared both graphically (in the form of bar charts, histograms, plots) and textually through a report browser. Multiple windows of graphical output, and side-by-side comparison of textual output are also provided. Information in the AweSim database can be exported to other Windows packages, such as Excel and Word.
- *Animation:* Multiple scenarios can be developed for a single scenario using ''point and click.'' The animator manipulates graphical items one wants to move and the background on which they appear. Storing the symbols in standard Windows bitmap format allows them to be exchanged between programs using the Windows clipboard.
- *Interactive execution environment* (*IEE*)*:* Enables the modeler to examine, modify, save, or load the current system status. This feature facilitates debugging and verifying the model.
- *Scenario selector:* Allows screening a set of scenarios or selecting the best scenario.
- *Integration with other software:* AweSim is built on a relational database that can be accessed with tools such as Dbase, Access, FoxPro, and Excel. AweSim provides the capability to exchange data between its input and output files and these tools. Graphical elements produced by CAD, drawing, or paint programs can also be loaded into AweSim.

GPSS (General Purpose Simulation System) is a process-oriented special purpose simulation language (Crain 1998; Schriber and Brunner 1998; Banks et al. 1995, 1996; Pritsker 1995; Schriber 1991). Geoffrey Gordon developed GPSS about 1960. It is a language to model discrete systems. GPSS consists of a well-defined vocabulary (set of blocks) and a grammar. Each block carries information related to its location, operation, and operands. Operation descriptions define the tasks the blocks perform. Operands specify how these tasks need to be performed. A block may not have a location name and operands. Each block is represented by a differently shaped figure. A GPSS model consists of a selection of blocks connected with lines that describe the operation of the system model. GPSS defines dynamic and static model entities. Dynamic entities represent the units of traffic and are referred to as transactions. Static entities represent system resources. As the simulation runs, transactions enter the model and start moving over as many blocks as possible until they encounter a user-defined delay, are removed from the system, or are denied entry by the next block. The procedure summarized above describes the flow of entities in a GPSS model and the interactions between different types of model entities. Ease of learning the language and reduction of the modeling time have made GPSS one of the popular discrete-event simulation languages. Various versions of GPSS exist, such as GPSS/H (Wolverine Software Corporation) and GPSS/PC and GPSS World for Windows (both by Minuteman Software). GPSS World includes drag-and-drop modeling, a high-performance model translator, point-and-shoot debugging, an embedded programming language, built-in probability distributions, programmable experiments, interactive operation of all commands, and interactive graphical text views of running simulations.

SIMAN is the simulation language within Arena. First introduced in 1983 by Systems Modeling Corporation (Pegden et al. 1995; Kelton et al. 1998; Schriber and Brunner 1998), SIMAN provides the use with three distinct but fully integrated modeling frameworks. Each framework is divided into two sections: a system model framework and an experimental framework. The system model permits the user to describe the process, while the experimental frame permits the user to supply the parameters and characteristics describing the system operation. SIMAN provides modeling blocks for describing the system model and experimental elements for use in the experimental frame, including several blocks and elements that provide SIMAN with materials-handling modeling capabilities as part of the basic package. In the discrete-event framework, SIMAN provides a complement of user-definable and user-callable functions and subroutines to be used alone or in conjunction with the block framework. These subprograms allow the user to manipulate entity attributes and files easily and provide for complex decision rules. In the continuous framework, system state equations can be integrated over time while simultaneously integrating with the blocks and discrete-event frameworks.

CACI Products Company provides SIMSCRIPT II.5. Developed by Kiviat, Villanueva, and Markowitz, it is an event-oriented discrete-event simulation language (Kiviat et al. 1969; Russell 1983). SIMSCRIPT II.5 consists of features for developing time-driven simulation models. It includes both

event- and process-oriented simulation constructs, multiple random-number generators, range of random distribution functions, automatic statistics collection, an integrated continuous simulation capability, and built-in graphics support for model input and output. Its world view facilitates the mapping of real-world modeling requirements directly onto its language features. Its general-purpose programming constructs, such as arithmetic operators, text manipulation, arrays, and subroutines, and the other features are accessed using English-like programming syntax that supports the self-documenting nature of the code. It provides extensive error checking through entity referencing, array bounds, and memory use. It contains a rich library of simulation objects that is designed to fulfill common simulation requirements, activity scheduling, and constrained resource modeling. Compilation and linking of all parts of a program are done automatically. Its graphic editor helps in creating and editing graphic images and charts and user interface objects such as menus and dialog boxes. Images and graphics are importable, and graphics library elements are fully portable. The debugger feature provides detection of programming and simulation errors, and a detailed trace reporting. SIMSCRIPT II.5 also provides integrated graphics and animation with scaling, rotating, and positioning capabilities. Using its graphics editor, presentation graphics such as pie charts, level meters, and bar graphs can be produced. The supported platforms consist of Windows 95/NT, SPARC, HP9000/700, SGI, DECAlpha, and IBM AIX.

4.2. Packages

Early offerings were no-programming products. Many were not versatile enough to handle complex decision-making rules. The biggest growth of simulation packages has been in the manufacturing area with products for PCs. Figure 2 lists the major components and functions of simulation packages. Some of the packages and their features are described below.

Arena (Sadowski et al. 1998; Kelton et al. 1998; Snowdon et al. 1998) is a graphical modeling and animation system. It is a product of Systems Modeling Corporation. Arena consists of a complementary family of products (Arena Product Suite) to meet the various needs for simulation in an enterprise through a common software interface and compatible features. These products share a common software foundation. The Business Edition (Arena BE) targets business and other systems. Arena Standard Edition (SE) targets detailed modeling of discrete and continuous systems and provides more flexibility. Arena Professional Edition enhances Arena SE with the capability to build custom simulation objects. Call$im targets call-center analysis, and HiSpeed$im targets high-speed production line modeling. Arena provides a hierarchical structure consisting of alternative and interchangeable templates of graphical simulation modeling and analysis modules. The user combines these modules in building a simulation model. Modules are grouped into a panel to compose a template. Different modeling constructs and capabilities are obtained by switching templates and bringing modules from different panels and templates. For example, modules from the SIMAN template can be pulled and SIMAN constructs can be mixed with the higher-level modules from another template. Complex decision rules can be coded using Visual Basic, FORTRAN, or C/C++. Each level in the hierarchical structure is managed with a single graphical user interface. Arena's application solution templates (collection of modules for an area, e.g., Call$im) provide applications for modeling specific areas. Arena is compatible with Microsoft Windows and Microsoft Office. It also enables integration with other technologies and applications such as databases, drawing/modeling (AutoCAD) products, and spread sheets such as Visio, Oracle, and Microsoft Office. Arena provides user interface features such as drag-and-drop, context-sensitive click menus, and customizable tool bar. It also provides a project bar for accessing modeling constructs and navigating through model hierarchy. Using Arena (Business Edition), process dynamics is represented in a hierarchical flowchart with system information stored in data spreadsheets. It also has a built-in activity-based costing and system performance data that enables analyzing business, manufacturing, service, and other systems. Arena also provides input and output analyzer for entering, analyzing and reviewing data. OptQuest for Arena is also provided for simulation optimization.

AutoMod version 8.7 (AutoSimulations 1999; Banks 1998a; Phillips 1998a, b) is an industrial-oriented simulation system provided by AutoSimulations Inc. It uses CAD-like graphics to define the physical components of a system. A procedural language is used to define the logical elements. This language is based on action statements that combine the power of a structured language with the ease of English-like syntax. If needed, the user may define C functions. The communications module allows communications between two or more models and third-party applications such as spreadsheets or Visual Basic programs. All graphics are represented in 3D space, and complex motion (kinematics and velocity) of equipment can be simulated. The kinematics module allows simulating the robots and other equipment containing moving parts and integrating them into a simulation model. AutoMod's CAD features are used to define layout and material-handling and storage systems by maintaining distance, space, and size characteristics in 3D. All graphics created can be viewed with unlimited control with respect to translation, rotation, scale, perspective, and so on. The animation runs in real time with the simulation. The model execution is interactive, which enables the user to

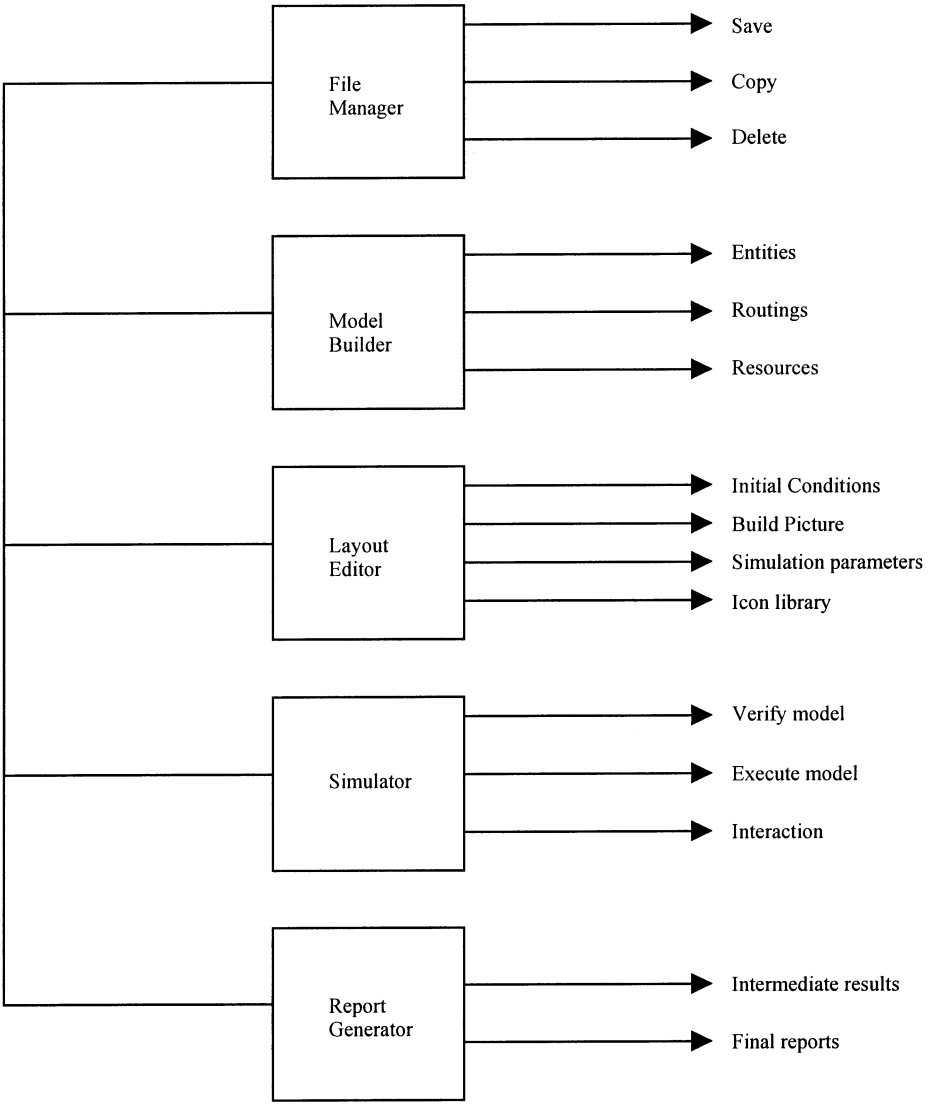

Figure 2 Major Components and Functions of Simulation Packages.

stop and resume the simulation, cancel animation, and select objects for detailed statistics. AutoMod has a material-handling orientation. Entities moving around the system are called loads, and loads are worked on by processes. The software features a well-developed array of predefined material-handling systems, including conveyors, automatic guided vehicle systems (AGVs), automated storage and retrieval systems (ASRS), bridge cranes, and power and free conveyors.

AutoMod also has support tools: AutoStat, Simulator, and AutoView. AutoStat provides enhanced analysis of output such as calculating confidence intervals, design of experiments capability, optimization, and steady-state analysis. The user defines the desired analysis through a point-and-click Windows interface. AutoView, a postprocess package, allows the creation of a directed walk-through of the output. It allows panning, zooming, and moving back and forth in time and space. The animation view can be attached to a moving model entity to get an inside view of the system. Simulator, which is shared with AutoSched AP (ASAP), provides a template for capacity planning. ASAP is a simulation-based, finite capacity planning and scheduling tool. It is used to increase

throughput, reduce in-process inventory, and increase resource utilization. ASAP takes into consideration constraints such as shift schedules, work setup rules, batching, preventive maintenance, machine efficiency, and operator skill classes. Its built-in task-selection rules enable the modeling of selection of machines and personnel to enhance performance. Its output consists of reports, Gantt charts, and utilization graphs. In addition to scheduling, ASAP is also used as a planing tool for capacity analysis.

FACTOR/AIM (AIM) (Pritsker 1995; Symix Systems/Pritsker Division 1997; O'Reilly and Lilegdon 1999b) is a special-purpose simulation system for use in manufacturing decision support in areas such as engineering design, scheduling, and planning. A product of Symix Systems, Pritsker Division, it is used to build, simulate, and animate models and analyze graphically and statistically the simulation results obtained from various scenarios. AIM uses the language of manufacturing, which eliminates the need to learn a language-based syntax and abstract a system to fit syntax. AIM components, which have both operational and graphical characteristics, consist of machines, operators, materials, parts (loads), batches (group of loads), process plans or routings, conveyors, and so on. It also has nongraphical components such as work calendar, orders, shifts, and breakdowns. These components, coupled with a comprehensive set of predefined manufacturing rules, provide a powerful framework for modeling and simulation analysis of manufacturing systems. The modeler has the option of coding customized rules in C language if the built-in rules do not represent the desired logic.

The current version of AIM (8.1) supports user code with the latest version of Visual C++. AIM uses the Windows platform, where the model and the data are stored in a Microsoft Access database. This feature enables importing and exporting data and preparing customized reports. Access application wizards can be used in developing decision support applications with dialog boxes and menus. AIM consists of five modules: Executive, which triggers other modules, controls data collection, and supports database and scenario management; Simulator, which builds and runs simulation with animation; Batch Simulator, which supports experimentation through replications and multiple runs; Reporter, which provides textual reports; and Gantts, which provides detailed schedule information. A model is created through interactive point-and-click operations to select and locate graphical components that can be further refined using dialog boxes. Next, parts and their routings are defined. A model can also be prepared using automatic loading if the existing information is in electronic form. Animation of an AIM model is created automatically. An interactive run process provides support for verification and validation through automatic animation, reports and graphs summarizing system status, detailed information on each model component, and the ability to view all scheduled events. Multiple replicate and scenario runs can be made through the Batch Simulator module.

AIM provides an extensive set of standard output reports and graphs in addition to customized reports and graphs that can be created using Access report wizards. Furthermore, output can be moved to Excel Spreadsheet for additional processing. Schedule reports can be created and communicated using the GANTT chart module. AIM also has cost-modeling capability. Product costs in four groups, operating, overhead, inventory, and lateness, can be defined using fill-in-the-blank forms. For example, operating costs resulting from part production and flow, such as machining, fixture, operator, and consumables, can be tracked. Using the cost-modeling feature of AIM, cost-simulation and output reports can be generated. Cost reports such as average operating expense per part, value of inventory, and total expense incurred can be prepared. Cost reporting can be customized to generate cash flow reports and pro forma income statements. The user also has the option of selecting cost reports for the entire system, by part or resource type.

Mast Simulation Environment is a product of CMS Research Inc. (1999). It is an integrated software tool for addressing manufacturing system design and evaluation problems. It provides a single environment to aid decisions on design, acquisition, and operation of manufacturing systems. MAST offers a pull-down menu toolbar to access commonly used features, can launch multiple results, and has a cost modeling option. It utilizes CAD graphics for layout and animation and allows importing CAD layout as background. It has features such as exporting and importing data to and from spreadsheets and databases. It provides station worktable and animation libraries with zoom, scroll, scale, and speed adjustment options. Launching multiple results at one time is also an option. Mast is available for Windows 95/98/NT.

Micro Saint version 3.0 (Laughery 1999; Plott et al. 1999; Ernst et al. 1999; and Barnes and Laughery 1998) is a PC-based discrete-event simulation software program available from Micro Analysis & Design. With Micro Saint, any process can be modeled as a network of tasks that can be represented in a flow diagram. Sets of decision rules and algorithms consisting of algebraic and logical expressions specific to a process can be developed using Micro Saint's own C-like language. The user defines the terms that are used. A graphical user interface is used for model development and testing. The icons and background for the Action View animation and the flowcharting symbols are customizable. Drawings from other graphics programs can be imported through the clipboard. Micro Saint symbolically animates the network diagram as it executes the model, using the routing choices and random number seed to generate task times that are supplied by the user. The user also

selects statistics charts or graphical representations to analyze the data collected during the simulation run. Queue, resource, and task statistics are collected automatically as well as the snapshots of user-defined variables at user-defined triggers. Micro Saint also has a resource wizard that can be used to create new resources quickly and allocate them to tasks in the process. The syntax checker searches the model for automatic detection and display of errors. OptQuest, included with Micro Saint, automatically searches for and finds optimal or near-optimal solutions to simulation problems and fine-tunes simulation parameters. Micro Saint has built-in features using Microsoft COM services that allow it to communicate dynamically (i.e., as the model runs) with other applications such as Visual Basic, C++ applications, and even other simulations. Micro Saint is available for Windows 95, 98, and NT, and a Unix/Linux version variant is available under the title of Integrated Performance Modeling environment.

MODSIM III is a product of CACI Products Company (Tumay and Wood 1999; Goble and Wood 1998; and Lewellen and Tumay 1998). MODSIM III is an object-oriented discrete-event simulation language that provides a complete development environment (built on top of Microsoft's Visual Studio environment) for developing models that are visual, interactive, and hierarchical. Its features include run-time libraries, graphical user interface and results presentation tools, database access, and hooks to HLA. Its components, such as Simulation Layer, Graphics Editor, Compilation Manager, and Interactive Debugger, support the development of advanced simulation models. Seamless interoperability with other tools is achieved through its ability to generate C++, which compiles using the platform's native compiler. Objects are defined in two separate blocks of code. The definition block defines the object type through its variables (everything the object knows) and methods (everything the object can do) which is used for interface specification. The implementation block defines the logic of what the objects do (their behaviors) and their affect on their state variables. MODSIM III sequences the execution of the methods of object instances to ensure correct sequences for the events. Its features to manage the scheduling, interaction, and synchronization of behaviors provide increased readability and consistency. Its features for modeling concurrent and interacting behaviors qualify it as a development tool.

MODSIM III provides a library of tested objects that can be customized. For example, objects may compete and queue for resources based on a priority while accumulating statistics on resource utilization, waiting time, and so on. Inheritance, which is a benefit of object-oriented software construction, provides object libraries that can be customized. New objects evolve through inheritance with additional capabilities resulting in enhanced software-development productivity. Inheritance also enriches the graphical properties of objects and facilitates the creation of interactive and graphically managed models. The graphical editor supports creation and configuration of icons, menus, dialog boxes, and presentation charts. Through interactive graphical editing, scenarios are defined on screen and animation and plots can be viewed while the simulation is running. The graphics environment allows easy access to animation, dynamic presentation graphics, and user interface toolkits using SIMDRAW graphics editor. Its DatabaseMod module enables access to ODBC-compliant databases and retrieving and committing data to databases. HLA is supported through run-time interface (RTI), which can be called from languages such as C++, Java, and Ada. RTI supports both local intranets and the global Internet. MODSIM III with SimGraphics is available on Windows 95/98/NT and Unix platforms. This enables load-balancing a simulation model through a network or displaying the user interface and animated graphical output on different and remote computers.

ProModel is a product of ProModel Corporation (Heflin and Harrell 1998; ProModel Corporation 1999). It is a menu-driven, mouse-activated discrete-event simulation and animation tool. The model development is graphical and object oriented. Modeling is done by selecting from a set of modeling elements such as resources, downtimes, and shifts and modifying the appropriate elements. All input is provided graphically, with information being grouped by object type and presented in a format similar to a spreadsheet. User coding in C, Pascal, or Basic can be linked to the models and called during the simulation. Its top-level menu allows the user to select model editor, run simulation, view output, or quit. The model editor permits full model definition, routing, scheduling, resource description, and transportation. All standard statistical distributions are available, and StatFit is provided to aid the user in selecting the proper distribution. The model editor also allows full control over the graphical presentation. A standard set of icons is provided and presented for selection by number. An icon editor is also provided to create special symbols. ProModel provides an automated model builder that prompts the user for all information required for modeling the process. It is organized logically and guides the user from creation of the model name to part and routing definition and finally to layout definition for the animation.

A pop-up menu is provided to prompt the user in defining a statement or expression. Its graphics editor allows scaling, rotating, copying, and so on, and drawings from other packages can be imported. Animation development is integrated with the model definition. Run simulation permits viewing of the animation while the simulation is running. The user retains full control over the animation. The simulation may be paused at any time to allow intermediate statistics to be viewed. ProModel is interactive during the run time, enabling model parameters to be changed and thus facilitating the

"what-if" analysis. Basic statistics such as utilization and throughput are available, as well as cost statistics. It provides features to select reports and provides tabular and graphical reports on all system performance measures. Output reports from different simulation runs can be compared on the same graph. ProModel also provides model-merging capabilities. It can exchange data with external files and application programs such as Excel. SimRunner optimization capability is also provided.

QUEST is a product of Deneb Robotics, Inc. (Donald 1998). It is a discrete-event simulation package used to simulate discrete flow processes. QUEST uses 3D geometry and combines a graphical user interface with material-flow logic grouped in modules consisting of labor, conveyors, AGVs, kinematics, power and free conveyors, and ASRSs. For unique flow logic problems, QUEST's Simulation Control Language (SCL) can be used. It also provides a value-added costing module for activity-based costing analysis. Results can be viewed with graphical and numerical analysis capabilities. It consists of features to create a 3D virtual factory environment. Its other features consist of the ability to import and export 2D or 3D CAD geometry and data (e.g., spreadsheets, MRP systems), a graphical user interface and a programming language, and the ability to provide integrated solutions through interaction with other Deneb software. Quest also provides a virtual collaborative engineering (VCE) environment that enables modelers in remote locations to interact with the same model. QUEST integrates virtual reality (VR) devices such as head-mounted displays, stereo glasses, and cyber gloves to immerse the modelers within the factory simulation.

SDI Industry is a product of Simulation Dynamics (Siprelle et al. 1998). It is a discrete-event simulation package designed specifically for the process-oriented industries, such as chemicals, foods, consumer goods, and pharmaceuticals. SDI industry uses discrete rate technology to simulate processes in these industries. It adds an embedded database and specially designed functions to Extend for simulating high-speed and high-volume processes. Extend is the underlying simulation engine, developed by Imagine That Inc. SDI industry is a graphical interactive program that provides a hierarchical framework of model templates, flow blocks to model material flows, control blocks to manage flow, and an integrated database to store management information. A model is developed through four hierarchical levels, consisting of equipment (process), operations, systems, and plant. Each level is provided with a template and with a process management block to control the process at that level and interface with the other levels. A relational database is used to store and manage data centrally. Data requirements for the control blocks at each level are provided by standardized tables such as "materials and brands," and "shift schedule." A database viewer is provided to view and edit table data in Extend. Simulation Dynamics provides two more products: SDI Industry Pro provides scheduling and control tools, and SDI Supply Chain is used to model the dynamics of a supply chain from source to user.

SimEngine is a product of Industrial Modeling Corporation (1999). It is a 3D simulation tool that incorporates object-oriented programming. SimEngine builds on Delphi and C++ object-oriented languages, which feature inheritance, polymorphism, and encapsulation. Every SimEngine entity is an object with exposed properties, methods and events. Models are built by manipulating the objects in visual environment and in code. SimEngine also works with C++ Builder, which incorporates an ANSI standard version of C++. Delphi and C++ Builder share a development environment that is similar to Visual Basic. The environment features visual design tools, an object browser, code window, and debugging tools. SimEngine builds on these development tools by adding simulation objects such as orders, routings, resources, and vehicles. The basic model building is done via visually manipulating these objects in 3D simulation explorer. Objects are created and moved using drag-and-drop techniques, and their properties are set in the object inspector. Code writing becomes necessary only when implementing complex routing logic. Database components enable reading information directly from company databases. It has native links available to SQL databases. Its ActiveX feature enables posting of the models to a website.

SIMUL8 is a product of Visual Thinking International Inc. (1999). It is a discrete-event simulation package to simulate a business or a manufacturing process. SIMUL8 provides objects such as work centers, storage bins, conveyors, entry/exit points, resources, variables (including spreadsheets), labels (attributes), and work items. Objects are linked automatically. Models are built on the screen via point-and-click operations and by drawing them with the mouse. The drawings are detailed by using intuitively organized options. After dragging and dropping the parts of the process onto the screen, clicking on "run" shows the full animation of the products flowing through the system. All animation is automatic with full zoom and pan options and distance on the screen relates to distance and time in the model. By clicking on resources, entities, and so on, their parameters (speeds, setups, constraints, etc.) can be modified and status updates through counts and reports can be obtained. These capabilities are extended using Excel or VBA. SIMUL8 can also import Visio flowcharts to begin the simulation process. SIMUL8 also conforms to the SDX (simulation definition exchange) file standard, which allows interchange of structure and detailed data between simulation and other packages (e.g., CAD) that contain information related to simulations.

Taylor ED (Enterprise Dynamics) is the product of F&H Simulations (Hullinger 1999). It replaces the Taylor II (Nordgren 1998) software, which is being phased out. Taylor ED is an object-oriented software system for modeling, simulating, visualizing, and monitoring dynamic (discrete) flow pro-

cess activities and systems. It uses an atom concept. An atom is defined as a four-dimensional object that has a location and speed (x, y, z) and a dynamic behavior (time). Atoms can inherit behavior, contain other atoms, and be created, destroyed, and moved onto one another. Atoms also communicate with each other. Within Taylor ED, everything, such as resources, products, a model, and a record, is referred to as an atom. Through its open architecture, it allows users to access standard libraries of atoms (logistics suite) to build models or create their own atoms. 4DScript language (atom editor) is used to create the atoms and to control atom's behavior, the user interface, and model visualization. A model is built by selecting, dragging, and dropping atoms from the library onto the screen. This is followed by connecting the atoms and defining routings of entities/atoms. Routing is defined by linking the output channels of an atom to the input channels of another one. Complex routing rules can be assigned using a pull-down menu. Finally, each atom is assigned a logic through defining atom's parameters, that is, its behavior and functionality. Clicking on the atom opens editing windows. Taylor ED includes experiment and optimizer (OptQuest) modules through which experimental and run conditions and performance measures can be defined. Results consisting of animation, predefined, and user-defined reports, and graphs can be viewed in 2D or 3D concurrently with simulation. Results can also be exported to external software programs. Taylor ED also monitors real-time systems by linking external programs to read and write information. Run time and real time can be synchronized, enabling the model to monitor the system in real time.

Call Center MAESTRO (Model Builders) is a decision support tool that is composed of a discrete-event simulation engine and is used to effectively staff and configure a call center. COMNET III (CACI) is a network simulation tool to predict LAN, WAN, and enterprise network performance. Its add-on modules consist of application profiler to predict the impact of a new client application, satellite and mobile module, and circuit-switched traffic module. SIMPROCESS (CACI) is a hierarchical and integrated simulation tool to enhance productivity for business process modeling and analysis. Packages such as ASSEMBLY, ERGO, and TELEGRIP are also offered by Deneb. These products are directed towards more specific applications and can be integrated with QUEST. Visual Simulation Environment (VSE) is a product of ORCA Computer, Inc. (Balci 1996). VSE is a discrete-event, general purpose, object-oriented, picture- and component-based visual simulation model development and execution product that can be used in solving complex problems such as air traffic control and communications networks.

4.3. Applications

Over 170 simulation products listed in the Directory of Simulation Software (Rodrigues 1994) published by the Society for Computer Simulation cover a wide range of application areas, such as aerospace, AI/Expert systems, business, communications, education, manufacturing, military, and networks. The annual Buyer's Guide of simulation software (Institute of Industrial Engineers 1999) lists 27 companies providing 40 simulation software products. In this list, the application areas are classified as general purpose, manufacturing, construction, service, health care, material handling, warehousing and distribution, and enterprise and business planning. Banks (1998a) classifies and gives examples of 27 simulation software products as general-purpose, manufacturing-oriented, and business process reengineering products. Simulation has also been used to study areas such as urban systems, economic systems, biological systems, environmental and ecological studies, computer and communication systems, project planning and control, and financial planning (Pritsker and O'Reilly 1999). Within each of these areas, a multitude of topics has been subjected to simulation analysis. For example, under transportation systems, topics include railroad system performance, truck scheduling and routing, air traffic control, terminal and depot operations, and issues related to supply chain management. The accelerated rate of change in simulation technology and the increasing complexity of problems associated with modern systems will undoubtedly widen the areas and the topics necessitating simulation studies (Nisanci 1997, 1998, 1999).

5. PITFALLS INHERENT IN THE USE OF SIMULATION TOOLS

Although there are many dangers inherent in the use of simulation products, only the major ones are addressed here (see Musselman 1998; Norman and Banks 1998; Rohrer and Banks 1998; Banks and Gibson 1996, 1998; Harrel and Tumay 1994; Pritsker Corporation 1993). Careful use of simulation will always be rewarded, while a disregard for the dangers may have disastrous consequences.

5.1. General Pitfalls

The general pitfalls consist of:

5.1.1. Having the Tool and Not Using It

Strange as this may seem, this is a real danger. Sooner or later, most project engineers will feel some pressure to reduce the time or expenditures required to complete a project. Simulation analysis is an easy target for elimination because the impact of its elimination is not noticed immediately. Cutting

manpower or reducing the project scope has immediate and noticeable impact on the project. The project can move ahead, detailed design can be done, and equipment can be purchased and installed, all without any felt loss of simulation analysis. Usually the first time the lack of simulation analysis is experienced is during start-up when design flaws and oversights typically caught by simulation are revealed. When an inadequate design is revealed, the solution is usually expensive in redesign time and equipment cost. These costs, however significant, may still be dwarfed by the loss in revenue due to the failure to deliver the goods or services on time.

Complex systems often defy the intuition and the traditional simplified analysis (including rules of thumb) that have been faithfully passed down through the engineering generations. Complex systems with complex interactions demand detailed analysis using simulation tools. The project engineer assumes a large and unnecessary risk in not using available simulation tools when the project calls for them.

5.1.2. Failure to Establish and Adhere to Project Objectives

A clear and specific set of objectives must be established at the beginning of every simulation project. These objectives should address the questions to be answered by the project engineer using the simulation tool. Issues to consider include:

1. Configuration, quantity, utilization of nonconsumable resources
2. Quantity of consumable resources required
3. Total time to provide goods or services to the customer
4. Critical processes and bottlenecks
5. Process capability (throughput)

Once management personnel have agreed upon the objectives, they need to direct the project to its conclusion. Every new idea or suggested change to the project needs to be tested against the approved objectives. Value-adding changes should be incorporated into the objectives and reapproved. Suggested changes that add nothing to the project or do not support the objectives should be rejected. Periodically during the course of the project, the objectives should be reviewed to make certain that the project would answer all questions raised at the beginning. Failure to monitor the project in relation to the objectives may allow project personnel to pursue information and solutions that do not contribute to the objectives. This results in delays of the project's completion.

5.1.3. No Review or Inadequate Review

One of the greatest mistakes made by project engineers who have committed time and money to perform a simulation is neglecting to take the additional time to properly review the model. A review should take place after the completion of data collection and before the beginning of model building. A review of the anticipated modeling assumptions should be done in addition to a discussion of any problems with data collection. A process flowchart, providing a thorough description of the process being modeled and the method of modeling, should be developed and presented to all involved. As the project develops, additional interim progress reviews should be held as often as needed.

The final review should take place after completion of all the experimentation but before the submission of the project report. The final review process should include at least the four following key elements:

1. Thorough understanding of the assumptions. Particularly important would be a review of the elements of the process which were not modeled and why they were excluded from the analysis.
2. Review of all parameter values. Care should be taken to ensure that data used in the analysis is correct and up to date.
3. Line-by-line review of all code, including model input values. This is essential, especially if others do the modeling, e.g., simulation department or consultant.
4. Review of all conclusions and the supporting data. Careful review of the data that lead to the conclusions ensures that they are properly supported. The results and conclusions should also make reasonable sense.

At this point, simulation plays a key role in the development of the design parameters. Therefore, a thorough review is necessary to make certain that the model and the values used as a basis for the design are indeed correct. The engineer who depends on others to do simulation takes an enormous risk if the final product is not thoroughly reviewed. To assume that correct work is done by an internal simulation expert or a consultant is risky. Conceivably, one piece of information improperly translated, one parameter off by a factor of two, or one part of the process not modeled as it will

operate can invalidate the results of the simulation. A thorough review of the model and the results is critical to the overall success of the project.

5.1.4. Not Having the Proper View of the Tool

The proper view of the simulation tool leads to proper expectations regarding what the tool can do and what results should be obtained.

5.1.5. Not Viewing Simulation as a Statistical Tool

Simulation is a statistical tool and must be used as such if reliable results are to be obtained. Its basic task is to collect data about how a system changes with time.

5.1.6. Thinking of Simulation as an Optimization Tool

Because simulation is a data-collection tool only, it should not be thought of as an optimization tool. Parameters are put into the tool and data are generated about the system (e.g., throughput, resource utilizations, congestion) and the components in their relationship as it was entered. Enhancement of any design only takes place as the engineer reviews the output from a simulation run and adjustments are made to the model and the model parameters. Improvement is therefore an external, manual process. However, incorporation of automated scenario-generation capabilities and optimization packages into simulation tools significantly enhances this process.

5.2. Pitfalls Related to Methodology

5.2.1. Failure to Establish Appropriate Model Boundaries and Parameters

Model boundaries become important in modeling because equipment and items not modeled are considered to be unlimited. Unlimited resources are not a problem if the cost of the resource is relatively low. However, resources having a significant impact on the process (e.g., fixtures that cost $50,000 and computer hardware) should all be modeled. Modeling can also be used to describe restrictions on the flow through the model. Not describing a restriction would mean that there is no restriction and therefore that flow is unlimited.

5.2.2. Improper Data Collection

In the simulation process, data collection may be the biggest problem faced by the project team. Critical data may not be available. If data are available, they may not be in a useful form.

5.2.3. Not Verifying Data

It is important to know the source of the data and how good they are. Downtime data carefully gathered over several years of maintenance are certainly more significant than a wild guess by a maintenance foreman.

5.2.4. Not Collecting the Proper Data

Because data collection is often a difficult task, data gatherers are often tempted to shortcut the process, especially if they do not understand the statistical implications. It is possible to believe that an average time for a transaction might be just as good (and of course easier to obtain) than the raw data reduced to a distribution. The use of average time leads to a deterministic solution and can invalidate the simulation study.

5.2.5. Avoidance of the Proper Level of Analysis

Because simulation is a statistical tool that collects statistical data about a system or process, statistical techniques must be used to examine and analyze the data. As an example, since each run of the simulation produces one sample point and since this process involves sampling for a distribution, it is impossible to determine the relationship of a single point to the true mean. Multiple runs are required to generate enough points to determine a calculated mean, standard deviation, and confidence intervals. Then and only then should the design proceed. Knowledge and use of statistical techniques with simulation is essential to produce reliable results.

5.2.6. Validation Problems

A successful simulation study must produce a solution credible enough to be used by the decision makers (Balci 1998). Validation may take more time than building the model.

6. CURRENT STATUS AND TRENDS

There have been continuous efforts to use computers in all stages of simulation besides model execution. These efforts have been significantly enhanced by the development in various technologies

such as computer technology, animation, expert systems and artificial intelligence, optimization, and experimentation. Considering the stages of simulation, significant advances have been made in designing the simulation tools that have the following features:

- Assisting the modeler in problem and system definition. Intelligent user interfaces guide the user in producing a quicker and more complete definition of the problem. Complex manufacturing systems are defined quickly with the selection and placement of icons and computer-guided interrogation.
- Model building features in the form of interactive flow charting (block or network diagrams) with a one-to-one correspondence to the simulation program. These features also include a knowledge base consisting of a generic model that can be tailored to a specific model or submodels that can be combined to form the required model using object-oriented programming. Model building features tailored to specific industries allow access to simulation by nonsimulation personnel.
- Evaluation of data requirements based on problem and system definition and objectives. Automatic data-acquisition capability to prepare the data directly from an external company database.
- Model translation feature to provide automatic computer code generation using either program generators or data-driven simulators and thus eliminating the need to teach users a simulation language.
- Model verification features consisting of expert diagnosis programs for debugging models. Output and system animation features to evaluate the logical consistency of a model.
- Features to assist strategic and tactical planning. Automatic detection of steady-state and rundown periods, testing for autocorrelation, and checking for sample size sufficiency.
- Experimentation and automatic search features to find the best combination of resource configurations and levels and operating strategies.
- Automatic documentation of experimental conditions in graphical or tabular form in addition to standard simulation output.
- Highly developed graphical user interfaces that integrate the entire modeling process.

Successful new-generation simulation systems will be expected not only to automate the stages of simulation but to integrate them as well. The following developments are expected to impact future simulation software:

- The significant increase in research, development and application of object-oriented simulation. This technology is becoming the choice for modeling large, complex, and distributed systems. Modeling and simulation using an object-oriented language will increase due to its advantages in compilation, execution, and extensibility (Roberts and Dessouky 1998; Keller and Tchernev 1997).
- With high level architecture (HLA), an individual simulation or set of simulations that was developed for one purpose can be applied to another application. The HLA will provide a structure that will support reuse capabilities available in different simulations that will reduce the cost and time required. Through HLA, simulations can exchange data dynamically and interact with each other as they run. HLA will facilitate interoperability, software interface, and data exchanges. Simulation software will incorporate these developments, as is the case with MODSIM III and Micro Saint (Yu et al. 1998).
- Artificial intelligence and simulation have mutually beneficial connections. Model-based expert systems, simulations built out of neural networks, and smart interfaces to simulation tools are commonplace. It is expected that AI and simulation will join forces to model and simulate intelligent behavior (Wildberger 1999).
- Advances in parallel and distributed simulation are increasingly being applied to complex systems that require significant run times (George et al. 1999; Low et al. 1999; Fujimoto 1998).
- Web-based simulation to exploit Web technology is expected to grow. The number of languages such as Simjava (a discrete-event simulation library for Java) is expected to increase (Triadi and Barta 1999; Narayanan et al. 1997).
- Online simulation efforts for real-time management and control of complex systems will also grow (Gonzales and Davis 1997).
- More specialized products for specific environments will be developed, e.g., TRANSIM by Los Alamos Research Laboratories to simulate transportation and urban traffic.

- Links between virtual reality and simulation will grow stronger.
- Developments in Internet applications, enterprise resource planning applications, and embedded simulations will also impact the development of simulation tools (Banks 1998b).

CHAPTER 95

Statistical Analysis of Simulation Results

BARRY L. NELSON
Northwestern University

1. INTRODUCTION

The design and control of many industrial and service systems requires the industrial engineer to account for uncertainty: uncertainty about the demand for products, the reliability of a machine, the arrival of customers, or the availability of components, for example. The language of probability is the primary tool for modeling uncertain or *stochastic* systems. Mathematical analysis, numerical analysis and computer simulation are techniques for analyzing stochastic models. Chapter 83 of the Handbook covers mathematical analysis of stochastic models. Chapters 93 and 94 describe the process of modeling a stochastic system and translating that model into a simulation program, respectively. This chapter provides guidelines for the design and analysis of computer simulation experiments. For a more extensive textbook treatment of these topics see Banks et al. (2000).

Compared to the other techniques, simulation is a brute force approach: using pseudorandom numbers to reproduce the uncertainty in the model, sample model behavior is generated and analyzed,

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

much in the same way that sample behavior of the physical system might be collected and analyzed. Simulation is perhaps the most general analysis technique, but the price of generality is that simulations provide only *estimates* of model performance parameters. The best that can be guaranteed is that these estimates converge to the true performance parameters as the simulation becomes infinitely long.

The emphasis in this chapter is on problems that are common in, or unique to, computer simulation relative to statistical experiments as a whole. The reader should refer to Chapters 83 to 87 of the Handbook for basic statistical methods. No specific computer hardware or software is assumed other than a language for programming the simulation experiment and possibly a statistical-analysis package capable of standard procedures such as least-squares regression.

Where possible, algorithms and procedures are provided rather than referenced. In that sense the chapter is self-contained. When references are provided, textbooks are often cited rather than original research papers, since they are more accessible.

Due to space constraints, only one or two methods are included for any problem, which does not imply that they are necessarily the best methods for any particular problem. The methods chosen are theoretically sound, empirically tested, but often conservative. The chapter is up to date, but it is not a guide to current research or emerging techniques.

One omission is the use of animation for simulation output analysis. Animation can be extremely helpful for developing a simulation model, verifying and validating the model, communicating results, and studying unusual model behavior in detail. However, it is not a substitute for a thorough numerical and graphical analysis that encompasses a much longer, and more representative, simulation run than anyone can reasonably view as animation.

The chapter is organized around three examples that are described below. The examples are simple enough that they can be presented in detail (except for the computer code).

2. OVERVIEW

This section is an annotated index to the chapter so that, if desired, the user can find the information of critical interest directly. However, all users should read Section 3, which introduces the three examples that are used as illustrations throughout the chapter, and most users should read Section 4 and Section 5, which describe the source of randomness and the standard statistics available in many simulation languages. A brief description of the other sections in this chapter is given below:

- Section 6 describes estimators for means, probabilities, and quantiles.
- Section 7 describes methods for detecting and reducing the effect of the initial conditions in a simulation experiment that estimates long-run performance.
- Section 8 describes ways to evaluate the goodness of estimates, including standard-error and confidence-interval procedures.
- Section 9 describes methods for evaluating alternative systems.
- Section 10 describes a way to improve the precision of simulation estimators.

Many of the sections contain programming-language-independent algorithms for design and analysis procedures. To understand the algorithms, it is useful to know the following:

The symbol $\leftarrow$ indicates assignment; for example, $a \leftarrow 5$ assigns the value 5 to the variable a.

The scope of *for* and *if* are delimited by *endfor* and *endif,* respectively.

The notation $\lfloor x \rfloor$ means the greatest integer less than or equal to x.

The subscripts on variables that are vectors or arrays are indicated by square brackets; e.g., $y[i,j]$ for y_{ij}.

Addition, subtraction, multiplication and division are indicated by $+$, $-$, $*$ and $/$, respectively.

3. EXAMPLES

Three examples that will be used throughout the chapter to illustrate simulation design and analysis techniques are introduced in this section. Appropriate design and analysis depends on characteristics of the model and on the questions being asked, so these three examples have been chosen to illustrate important classes of problems. Although they are simpler than many practical models—in fact, they are so simple that simulation is not actually needed—the techniques are no more difficult to apply in complex models.

3.1. Static Simulation: Acceptance Sampling

Acceptance sampling is a widely used technique for economically assessing the quality of a "lot" of items. A single-sampling attributes plan of the form (n, c) specifies that n items will be sampled and the lot will be accepted if no more than $c < n$ defective items are discovered. The values of n and c are chosen based on the operating characteristic (OC) curve they imply. The OC curve is the probability of accepting a lot as a function of the lot quality, where quality is usually stated in terms of the probability of a defective item (see Chapter 69 of the Handbook).

OC curves for standard acceptance-sampling plans are derived under the assumption that the quality of items can be modeled as independent and identically distributed (i.i.d.) Bernoulli random variables. Although this model is often plausible, the quality of items produced by some processes exhibit statistical dependence. The goal of this simulation experiment is to estimate the OC curve for sampling plan (10, 1) when item quality is dependent.

Let $X_1, X_2, \ldots, X_n$ represent a sample of n items, where $X_i = 1$ if the ith item is defective and $X_i = 0$ if the ith item is acceptable. The probability that an item is defective is p, and the quality of any item may be dependent on the other items. Specifically, the items are assumed to have a joint Pólya distribution with pairwise correlation $\rho = 0.08$. Standard tables of sampling plans are not appropriate for this situation.

Let $Y = \Sigma_{i=1}^{n} X_i$ be the number of defective items in the sample. The performance parameter of interest is $\theta(p) = \Pr\{Y \leq c|p\}$, the probability that there are c or fewer defective items (i.e., that the lot is accepted) as a function of p.

This simulation experiment is called a *static simulation* because there is no explicit modeling of the passage of time ($X_1, X_2, \ldots, X_n$ need not even be arranged by order of selection). Although static simulations are conceptually the easiest to design and analyze, they nevertheless present important design and analysis problems. In addition, this example illustrates estimating a probability, $\theta(p)$.

3.2. Terminating Simulation: License Plate Renewal

A small city will allow auto owners to renew their license plates by mail, with each owner's renewal taking place during the month of his or her birth. The mail-in renewal applications will be processed by a clerk. It is anticipated that the rate of receipt of applications will increase steadily throughout the month, but that the load during all months is about the same. Mail-in renewals that are postmarked after the 27th day of the month are returned to the applicant without being processed. The city is interested in determining the performance level the clerk must attain, in terms of renewals processed per day, to prevent excessive delays or carryover from month to month.

The arrival of mail-in renewals is modeled as a Poisson process with time-dependent arrival rate $\lambda(t) = t$ renewals per day, where time $0 \leq t \leq 27$ is measured in days. In other words, on the first day of the month applications arrive at a rate of 1 per day, but by the end of the month they are arriving at a rate of 27 per day. The time to process an application is modeled as an exponentially distributed random variable with mean $1/\mu$ days, so that μ is the processing rate in applications per day.

Let Y_i be the delay in processing the ith application received during the month, and let N be the number of applications received during the month. A performance parameter of interest is

$$\theta(\mu) = E_\mu \left[\frac{1}{N} \sum_{i=1}^{N} Y_i \right]$$

the expected average delay for mail-in renewals as a function of the processing rate, μ.

This simulation experiment is called a *terminating simulation* because the parameter of interest is defined with respect to a finite time horizon, the time to process one month of renewal applications in this case. The example illustrates estimating transient or time-dependent performance, and also examining the effect of a continuous design variable, the processing rate μ.

3.3. Steady-State Simulation: Inventory Model

An (s,S) inventory system involves the periodic review of the level of inventory of some discrete unit. If the inventory position (units in inventory plus units on order minus units backordered) at a review is found to be below s units, then enough additional units are ordered to bring the inventory position up to S units. When the inventory position at a review is found to be above s units, no additional units are ordered. One possible goal is to select the values of s and S that minimize inventory cost. The third example is the (s, S) inventory model in Koenig and Law (1985) and Law and Kelton (2000).

TABLE 1 Inventory Policies

ℓ	s	S
1	20	40
2	20	80
3	40	60
4	40	100
5	60	100

Let $\{I_t; t = 1, 2, \ldots\}$ represent the inventory position just after a review at period t, and let $\{X_t; t = 1, 2, \ldots\}$ represent the demand for units of inventory in period t. The inventory position I_t changes in the following way:

$$I_{t+1} = \begin{cases} S, & \text{if } I_t - X_t < s \\ I_t - X_t, & \text{if } I_t - X_t \geq s \end{cases}$$

For convenience, the initial inventory position is taken to be $I_1 = S$; that is, the inventory position is initially at its maximum. The demand $\{X_t; t = 1, 2, \ldots\}$ is modeled as a sequence of i.i.d. Poisson random variables with mean 25 units.

In each period there are costs associated with the inventory position. If $I_t - X_t < s$, then in period $t + 1$ a cost of $32 + 3[S - (I_t - X_t)]$ is incurred, which is a fixed cost plus a per-unit cost of bringing the inventory position up to S. In period $t + 1$, if $I_{t+1} \leq X_{t+1}$, then a holding cost of $(I_{t+1} - X_{t+1})$ dollars is incurred; otherwise a shortage cost of $5(X_{t+1} - I_{t+1})$ dollars is incurred.

Let $Y_t^{(\ell)}$ be the cost incurred in period t under inventory policy ℓ; the inventory policies under consideration are given in Table 1. The performance parameters of interest are the long-run expected cost per period of each inventory policy, with a smaller expected cost being preferred. The assumption behind such a long-run analysis is that $Y_t^{(\ell)}$ converges in distribution to $Y^{(\ell)}$ as $t \to \infty$, which means that the cost per period converges to a limiting random variable whose distribution does not depend on time (period) t. The parameter of interest is $\theta^{\ell} = \mathrm{E}[Y^{(\ell)}]$, the long-run expected cost per period for policy ℓ.

This simulation experiment is called a *steady-state simulation* because the parameter of interest is associated with a limiting random variable. This example illustrates estimating a limiting quantity from a simulation experiment that is (necessarily) finite, and also comparing alternative systems (inventory policies) with the goal of selecting the best system.

4. RANDOMNESS IN SIMULATIONS

Modern simulation languages contain *pseudorandom number generators* that produce sequences of numbers—typically numbers in the interval (0,1)—that are difficult to distinguish from independent and identically distributed (i.i.d.) random numbers. In other words, an analyst subjecting a sequence of pseudorandom numbers to a battery of statistical tests would be unlikely to recognize that they were produced by a deterministic algorithm rather than by a random process. However, if the same simulation program is executed on the same computer at any time, identical results are obtained. This is a useful property because debugging programs would be difficult if results changed randomly.

This method of incorporating randomness into computer simulations has a profound impact on the design and analysis of simulation experiments. Most importantly, it means that different simulation runs will be dependent if they employ the same pseudorandom numbers. This can be good, yielding sharper comparisons between alternative systems, or bad, invalidating the assumptions behind statistical procedures that assume independent observations.

An important feature of most simulation languages is that they permit control of the pseudorandom numbers through random number *streams* or *seeds,* which permit the user to access different, and thus apparently independent, portions of the pseudorandom number sequence. Such control allows the user to induce dependence where desired or obtain independence where necessary.

To be more precise, suppose that a simulation language includes one pseudorandom number generator that produces an ordered sequence of pseudorandom numbers $u_1, u_2, \ldots, u_g$. The length of this sequence is necessarily finite; for many pseudorandom number generators $g < 2^{31} \approx 2$ billion, although generators that produce much longer sequences are becoming common.

Let the seeds or streams be denoted by $s_1, s_2, \ldots, s_h$. The seeds or streams are nothing more than reference points within the sequence $u_1, u_2, \ldots, u_g$. For instance, s_1 might correspond to starting the sequence at u_{2137}. Thus, the number of seeds $h \leq g$, and is typically much less than g with the reference points spaced widely apart. Note that some simulation languages allow the user to specify the *offset* between seeds, rather than having to specify the seeds themselves. In any event, since the

entire sequence $u_1, u_2, \ldots, u_g$ appears to be a sequence of i.i.d. random numbers, the subsequences between seeds also appear to be independent of each other. This property implies an important design and analysis principle:

Design and Analysis Principle 1. The assignment of random number streams or seeds is part of the design of a simulation experiment. Assigning the same streams or seeds to different simulations induces dependence, while assigning different seeds or streams to different simulations induces independence between simulation results.

The simulation-language user seldom works directly with the pseudorandom numbers $u_1, u_2, \ldots, u_g$, but rather specifies the probability distributions of the simulation *inputs*. A convention in this chapter is that input random variables are denoted generically by X. Examples of simulation inputs are:

- The item quality random variables $X_1, X_2, \ldots, X_n$ in the acceptance-sampling model, which have a joint Pólya distribution
- The arrival and processing times of renewal applications in the license-renewal model, which have time-dependent Poisson and exponential distributions, respectively
- The demand for inventory in period t, X_t, in the inventory model, which has a Poisson distribution

Observations or realizations of the inputs are obtained by transforming the pseudorandom numbers. One or more pseudorandom numbers may be required to produce each input, depending on what transformation is used. The inputs, X, are functions of the pseudorandom numbers, u, so they are completely determined by the seed or stream, s, say $X = X(s)$.

The purpose of performing a simulation experiment is to observe model performance. The observed model performance, called the *output,* is derived from realizations of the inputs and the (often complex) logic of the model. A convention in this chapter is that output random variables are denoted generically by Y. Since the outputs are functions of the inputs, they are also functions of the seeds or streams, say $Y = Y[X(s)]$. Examples of simulation outputs are:

- The number of defective items discovered in a sample, Y, in the acceptance-sampling model
- The delay experienced by the ith renewal application, Y_i, in the license-renewal model
- The cost in period t for inventory policy ℓ, $Y_t^{(\ell)}$, in the inventory model

In most simulation experiments a large number of outputs are generated. They are summarized by a *statistic,* which is often a sample average of the outputs, denoted $\overline{Y}$. The value of the statistic is used to estimate system performance, so statistics are also called *estimators*. The statistics are functions of the outputs, so they are also completely determined by the random number seeds or streams.

Perhaps it seems strange that statistical methods are employed to analyze a completely deterministic process, which a simulation is after the seeds are specified (particularly since many users accept the default seeds or streams). However, if the pseudorandom numbers cannot easily be distinguished from random numbers, then treating functions of these numbers—the inputs, outputs and statistics—as random variables will not be misleading.

The role of the pseudorandom number streams or seeds is important. This method of representing randomness, and the corresponding control it permits, is the primary difference between simulation experiments and classical statistical experiments.

5. SIMULATION STATISTICS

Many simulation languages compute statistics and generate reports automatically. To understand these statistics it is necessary to distinguish between within- and across-replication statistics (some simulation languages refer to a replication as a ''run''). To make the difference concrete, consider the license-renewal simulation. One replication or run of this simulation represents one month and generates outputs $Y_1, Y_2, \ldots, Y_N$, which are processing delays for the N applications received during the month. The sample average of these delays is

$$\overline{Y} = \frac{1}{N} \sum_{i=1}^{N} Y_i$$

which is a *within-replication statistic,* meaning a summary of the outputs within one replication or run.

If k months are simulated, then each month yields a sample average delay, say $\overline{Y}_1, \overline{Y}_2, \ldots, \overline{Y}_k$. The sample average of these sample averages is

$$\overline{\overline{Y}} = \frac{1}{k}\sum_{j=1}^{k} \overline{Y}_i$$

which is an *across-replication statistic,* meaning a summary of the statistics across several replications.

Nearly all simulation languages compute within-replication statistics automatically. Many compute across-replication statistics. The standard statistics provided are sample averages, variances (or standard deviations), maximum and minimum observed values, and number of observations.

Some care must be exercised when interpreting the within-replication statistics because the outputs within a replication *are typically neither independent nor identically distributed,* and ''i.i.d. data'' is a common assumption behind many statistical procedures.

For example, in the license-renewal simulation, the within-replication sample variance of the processing delays, $Y_1, Y_2, \ldots, Y_N$, would be calculated by many simulation languages as

$$S^2 = \frac{\Sigma_{i=1}^{N}(Y_i - \overline{Y})^2}{N - 1}$$

Familiarity with classical statistics might lead one to use S^2 as an estimator of $\text{Var}[Y_i]$, the (assumed) common variance of the processing delays, and S^2/N as an estimator of $\text{Var}[\overline{Y}]$, the variance of the average delay.

However, the observed delays within a replication are not identically distributed, since applications received later in the month tend to be delayed longer than applications received earlier in the month. Thus, there is no common variance of the delays within a replication.

Also, the observed delays within a replication are not independent, since applications that experience long (short) delays tend to be followed by applications that experience long (short) delays. The validity of S^2/N as an estimator of $\text{Var}[\overline{Y}]$ rests on the assumption of i.i.d. data, and the estimator can be significantly biased when this assumption is violated. Unfortunately, the estimator is often biased low, which means that $\overline{Y}$ appears to be more precise than it actually is and confidence intervals based on S^2/N are inappropriately narrow.

Finally, the number of applications received during the month, N, is a random variable, so S^2 is a ratio of the random variables $\Sigma_{i=1}^{N}(Y_i - \overline{Y})^2$ and N. The properties of ratio estimators are not straightforward or easy to summarize, and they are typically different from the corresponding estimator when the denominator is not a random variable.

In summary, the within-replication sample variance S^2 is not a useful measure in this example, but there is no way for the simulation language to know that and notify the user.

On the other hand, most simulation languages ensure that statistics across replications are i.i.d. because by default they initialize each replication in the same way, implying identically distributed outputs, but they use different random numbers (by continuing in the same pseudorandom number sequence), implying independent outputs. In the license-renewal simulation the replication averages $\overline{Y}_1, \overline{Y}_2, \ldots, \overline{Y}_k$ are i.i.d., so applying classical statistical analysis is appropriate.

Design and Analysis Principle 2. Outputs within a replication may be neither independent nor identically distributed, and the number of observations may be random. Statistical analysis should therefore typically be based on multiple replications, with each replication supplying one observation of the performance measure of interest.

Rather than using automatically generated statistics, the author favors saving the raw data from a simulation experiment and performing the statistical analysis a posteriori using a general-purpose analysis package that may be separate from, or integrated into, the simulation language. There are three reasons for this preference. First, statistical-analysis packages can perform more procedures than most simulation languages; regression analysis, for instance. Second, using a package on the raw data facilitates exploratory analysis that may suggest what additional analysis is appropriate. For example, the normality of the output data can be empirically checked to see if an inference based on the normal distribution is reasonable. Finally, the raw data may be reanalyzed if new questions arise for which the necessary statistics were not computed during the simulation runs. For example, in a service system, the mean customer delay may be estimated from the individual customer delays. If it is later determined that the probability of a customer being delayed beyond some threshold value is of interest, then this can be estimated without rerunning the simulation if the raw data are available.

The primary arguments against saving all of the data are the storage requirement, which can be excessive, the decrease in simulation execution speed due to electronically writing all of the output data, and the difficulty of transforming the simulation data into a form suitable for an analysis

package. Language designers have addressed these problems by developing integrated database and analysis software and exporting data in standard formats that can be imported by spreadsheet or statistical-analysis software.

6. POINT ESTIMATORS

The decisions resulting from simulation studies are often based on point estimates of system performance parameters. The term *point estimate* means a single number that serves as a best candidate for the unknown performance parameter. Although the point estimates are important, they should always be accompanied by a measure of the error; error estimation is covered in Section 8.

This section describes estimating θ, a parameter of a probability distribution, F. Although F is usually not known, it is assumed that simulation outputs Y can be generated from F. The three cases considered are:

1. When θ is the *mean* of Y; i.e., $\theta = \mathrm{E}[Y] = \int_{-\infty}^{\infty} y dF(y)$
2. When θ is a *probability* associated with Y; e.g., $\theta = \Pr\{a < Y \leq b\} = F(b) - F(a)$ for given values $a < b$
3. When θ is a *quantile* of Y; i.e., $q = \Pr\{Y \leq \theta\} = \int_{-\infty}^{\theta} dF(y)$ for a given probability q

These cases arise in static and terminating simulation experiments. In steady-state simulation, outputs from F cannot be observed directly (because the distribution of interest is a limiting distribution), which introduces bias into the estimators. Estimation of parameters of a steady-state distribution is treated in Section 7.

6.1. Mean Estimation

Perhaps the most commonly reported performance parameter is the mean (expected value) of a system performance measure. The term *expected value,* which defines a parameter, will be used rather than the synonym *mean,* because *mean* may be confused with the *sample mean,* which is an estimator of a parameter.

In the license-renewal simulation, the parameter

$$\theta(\mu) = \mathrm{E}_{\mu}\left[\frac{1}{N}\sum_{i=1}^{N} Y_i\right] \tag{1}$$

is an expected value: the expected average delay for all applications received during one month when the processing rate is μ.

To estimate $\theta(\mu)$ the simulation is designed to generate k i.i.d. replications of one month of renewal processing. Each replication yields a within-replication average

$$\overline{Y} = \frac{1}{N}\sum_{i=1}^{N} Y_i$$

Let $\overline{Y}_j$ be the within-replication average from the jth replication. Since $\theta = \mathrm{E}[\overline{Y}_j]$ for each j by definition, an unbiased estimator of θ is the across-replication average

$$\overline{\overline{Y}} = \frac{1}{k}\sum_{j=1}^{k} \overline{Y}_j$$

Within- and across-replication averages for $k = 5$ replications when $\mu = 20$ applications per day are given in the second column of Table 2.

The standard error of $\overline{\overline{Y}}$ as an estimator of $\theta(\mu)$ is $\sigma/\sqrt{k}$, where σ^2 is the common variance of the replication averages $\overline{Y}_j$. Estimating measures of error is covered in Section 8. The important concept is that the error decreases as the number of replications increases.

Design and Analysis Principle 3. The sample average of i.i.d. outputs is an unbiased estimator of their common expectation. The standard error of the estimate decreases at rate $1/\sqrt{k}$, where k is the number of replications.

Given i.i.d. outputs with a common expectation, mean estimation is straightforward, as illustrated above. However, as discussed in Section 5 some care must be exercised when defining the expected value of interest in terminating simulations because performance parameters may be time dependent.

TABLE 2 Simulation Results for Five Replications of the License-Renewal Simulation with $\mu = 20$ (units are days)

Replication j	$\overline{Y}_j$	Y_{Nj}
1	0.34	1.25
2	0.72	2.20
3	0.32	1.04
4	0.46	1.68
5	0.42	1.08
$\overline{\overline{Y}}$	0.45	1.45

For example, the expected delay of an individual renewal application is not well defined because applications have different expected delays, depending on their order of arrival during the month. The parameter $\theta(\mu)$ in (1) circumvents this problem by averaging all the delays during a month and defining $\theta(\mu)$ to be the expectation of this average. However, $\theta(\mu)$ masks the time-dependent behavior of the delays, which may be important.

A time-dependent parameter that is well defined is $\theta_N(\mu) = \mathrm{E}[Y_N]$, the expected delay of the last application received during the month. To estimate $\theta_N(\mu)$, which is also an expected value, the delay for the last application, Y_N, is the within-replication statistic, and the across-replication average of these delays is an estimator of $\nu_N(\mu)$. The third column of Table 2 gives the delay for the last application received in each of the five replications and the across-replication average of these delays.

6.2. Probability Estimation

Probabilities can be represented as expected values, so the discussion in Subsection 6.1 is applicable to estimating probabilities as well. However, probability estimation is required so frequently that it is worth treating as a separate topic.

In the acceptance-sampling simulation, the parameter of interest is $\theta(p) = \Pr\{Y \leq c|p\}$, where Y is the number of defective items in a sample of n items and the quality of the items has a joint Pólya distribution with marginal probability p of a defective. As a function of p, $\theta(p)$ is the OC curve for sampling plan (n, c).

The key to estimating probabilities is the following principle:

Design and Analysis Principle 4. A probability θ can be represented as the expected value of an indicator (0, 1) random variable, where the value 1 corresponds to occurrence of the event of interest. The variance of an indicator random variable is $\sigma^2 = \theta(1 - \theta)$.

For the acceptance-sampling simulation, define an indicator random variable I as follows:

$$I = \begin{cases} 1, & \text{if } Y \leq c \\ 0, & \text{otherwise} \end{cases}$$

Then $\theta(p) = \mathrm{E}[I]$, and all of the principles of mean estimation can be applied to the indicator random variable, I.

Figure 1 shows an estimate of the OC curve for sampling plan $(n, c) = (10, 1)$ that was obtained by estimating $\theta(p)$ at points $p = 0.01, 0.05, 0.1, 0.15$ and $0.2, 0.3, \ldots, 0.9$. Each point estimate is the average of 10,000 replications of I. Since $\theta(p) = \mathrm{E}[I]$, the point estimators are unbiased, and the standard error of the estimators is $\sqrt{\theta(p)[1 - \theta(p)]/10000}$.

6.3. Quantile Estimation

Quantiles are points on the distribution of a random variable. The most familiar quantile is the *median,* which is the 0.5 quantile. The 0.25 and 0.75 quantiles are also called the *quartiles*. Extreme quantiles, such as the 0.9, 0.95, and 0.99 quantiles, are one way to characterize the tail of a distribution.

Subsection 6.1 described estimating the expected value of $\overline{Y}$, the average delay of renewal applications received during a month. The 0.9 quantile of $\overline{Y}$, denoted $\theta_{0.9}$, is the value such that $\Pr\{\overline{Y} \leq \theta_{0.9}\} = 0.9$. In other words, the average delay in 9 out of 10 months is less than or equal to $\mu_{0.9}$.

The procedure below, called *algorithm quantile estimation,* estimates the q quantile of a random variable given k i.i.d. replications:

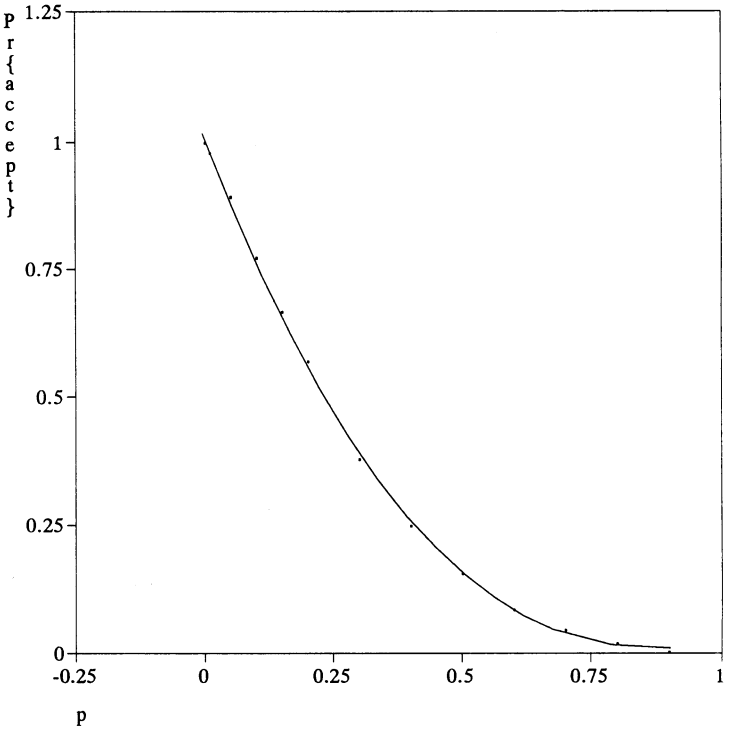

Figure 1 Plot of Estimated OC Curve for Sampling Plans (10, 1) Derived from $k = 10{,}000$ Replications.

1. *Initialization:* Number of replications, k; quantile probability, $0 < q < 1$.
2. *Data:* $y[j]$, output from the jth replication.
3. *Compute order statistics:* sort $y[j]$ from smallest to largest so that $y[1] \leq y[2] \leq \ldots \leq y[k]$ (comment: these sorted values are called the *order statistics* of the sample).
4. $i \leftarrow \lfloor (k + 1)*q \rfloor$.
   if $i < 1$ output $y[1]$
   if $i \geq k$ output $y[k]$
   otherwise $f \leftarrow (k + 1)*q - i$; output $(1 - f)*y[i] + f*y[i + 1]$

Quantile estimators are biased in general, but the bias (as well as the variance) of the estimator decreases as the number of replications increases. The procedure *algorithm quantile estimation* interpolates between order statistics to reduce bias.

For the license-renewal simulation the data are $\overline{Y}_1, \overline{Y}_2, \ldots, \overline{Y}_k$, the average delays from k replications. For $k = 200$ replications and $\mu = 20$ applications per day, an estimate of $\theta_{0.9}$ is $(0.1)*y[180] + (0.9)*y[181] = 0.88$ days.

7. INITIAL-CONDITION BIAS

Performing a steady-state simulation experiment implies that the analyst is interested in long-run performance of the model that is independent of the initial conditions of the simulation replication or run. In the inventory simulation the parameter of interest is $\theta^{(\ell)}$, the long-run expected cost per period of inventory policy ℓ, which does not depend on the inventory position in period 1.

The length of a simulation run is necessarily finite, so residual effects of the initial conditions will often be present in the outputs. These residual effects manifest themselves as *bias* in the statistics, meaning that the expectation of the statistic is not equal to the value of the performance parameter of interest. In some simulations, the effect of the initial conditions can be so overwhelming that the

results are meaningless unless appropriate remedial measures are taken. This section covers mean estimation for steady-state simulation. For more general estimation problems, see Law and Kelton (2000), Schruben (1981), and the comments at the end of this section.

Consider (s, S) inventory policy 1—which is (20, 40)—and let $Y_1^{(1)}, Y_2^{(1)}, \ldots, Y_{200}^{(1)}$ be the observed inventory costs in the first 200 periods of a replication of this policy. An estimator of the long-run expected cost per period, $\theta^{(1)}$, is the sample average

$$\overline{Y}^{(1)} = \frac{1}{200} \sum_{t=1}^{200} Y_t^{(1)}$$

The effect of the initial condition $I_1 = S$ is to cause the expected value of $\overline{Y}^{(1)}$ to be less than $\theta^{(1)}$ because little or no ordering and setup cost is incurred until the inventory has been depleted somewhat. This means that, on average, the estimate will indicate that policy 1 is less costly than it actually is.

The appropriate remedial measure depends on whether it is feasible to perform some preliminary or pilot analysis of the model prior to making the final runs. When a large number of similar systems are to be investigated (e.g., different inventory policies for the same inventory system), then preliminary analysis of one system may be worthwhile since the results can be extrapolated to the other systems. However, if only one system is to be investigated, or if each run is very expensive, then it may be desirable to use the same experiment to remedy the initial-condition bias and estimate the parameters of interest. This section describes both approaches and two remedial measures, data deletion and intelligent initialization.

7.1. Remedial Measures

For most estimation and inference problems, increasing the number of replications is beneficial. The initial-condition bias problem is an exception.

Design and Analysis Principle 5. Increasing the number of independent replications does not decrease the bias of the sample average. If the number of replications is increased at the expense of decreasing the length of each replication, then increasing the number of replications may even increase the bias.

This principle suggests that in the presence of initial-condition bias and a tight budget, the number of replications should be small and the length of each replication should be long. When bias is severe, making only one very long replication may be advantageous. Experiment designs that call for only one replication require more sophisticated strategies for computing a measure of error, as discussed in Section 8.

Even with only a few long replications, remedial measures may be needed. Two of the many remedial measures, which can be used together, are described below.

7.1.1. Data Deletion

If there is a standard remedial measure, it is to delete or discard some of the outputs from the beginning of each replication where the effects of the initial conditions are most pronounced. Returning to the inventory simulation, if $Y_1^{(1)}, Y_2^{(1)}, \ldots, Y_{200}^{(1)}$ are the observed inventory costs in the first 200 periods, then another estimator of $\theta^{(1)}$ is the truncated sample average

$$\overline{Y}^{(1)}(d) = \frac{1}{200 - d} \sum_{t=d+1}^{200} Y_t^{(1)}$$

where d, the number of outputs deleted, could be 0, 1, . . . , 199. Typically, the bias of the truncated sample average decreases as d increases, which is good, but its variance increases with d, which is bad. Methods for choosing d are discussed in a later subsection.

Many simulation languages make it convenient to delete all outputs up to a fixed point in simulated time or up to an event time rather than deleting a fixed number of outputs, d. This makes d a random variable but does not significantly change the properties of the estimators, provided the runs are not too short.

7.1.2. Intelligent Initialization

The initial conditions for a simulation experiment are the starting values assigned to the variables in the model and the events scheduled at the beginning of each run or replication. Since the parameters of interest in a steady-state simulation do not depend on the initial conditions, initial conditions are often chosen for programming convenience. In the inventory simulation the initial inventory position is $I_1 = S$, for example. Some care in setting the initial conditions can greatly reduce the bias they cause.

Any model that has a steady-state distribution has a ''correct'' initialization procedure so that there is no initial-condition bias. This result is of more theoretical interest than practical importance because knowing the correct procedure typically implies already knowing the values of the parameters of interest. However, setting initial conditions close to steady-state mean or mode conditions, while not correct, can be very effective in reducing bias. There are at least two ways to approximate steady-state conditions:

1. *Approximate models:* Steady-state distributions and parameters are known for many stochastic processes; e.g., queueing, inventory, Markov chains. These results can be used to approximate the simulation model. For example, a service system can be approximated by a Markovian queue to determine the expected number of customers in the system. This value can be used to set the initial number of customers in the system for the simulation, rather than using the (convenient) initial condition of an empty system. Chapter 81 of the *Handbook* is a good source of approximations. Even cruder approximations, such as replacing a random quantity by its expectation, can also be used.
2. *Pilot runs:* The debugging runs or preliminary pilot runs of the simulation can provide information for setting initial conditions more intelligently. For instance, printing out the average inventory position during debugging runs of the inventory simulation showed that taking $I_1 = 36$ is closer to steady-state conditions than $I_1 = 40$ for inventory policy 1.

The problem of setting optimal initial conditions has been studied, but there is no single recommendation. Significant improvement is possible even if the initial conditions are not optimal, especially when the convenient initial conditions are far from optimal. The point is to use all available knowledge about the model, including knowledge gained from experimentation, to refine the initial conditions.

7.2. Detection of Initial-Condition Bias

The methods described in this subsection can be used to detect the presence of initial-condition bias and to determine the amount of data to delete.

7.2.1. Mean Plot

Let $\theta_t^{(1)} = \mathrm{E}[Y_t^{(1)}]$ be the expected cost of inventory policy 1 *in period t.* The assumption behind steady-state simulation is that $\theta_t^{(1)} \to \theta^{(1)}$ as t increases. The mean plot estimates $\theta_t^{(1)}$ as a function of t so that the rate of convergence can be determined. This method is appropriate when some preliminary study of the bias is possible.

An estimate of $\theta_t^{(1)}$ can be obtained by making a number of replications of the experiment, averaging across replications, and plotting the resulting values. To be specific, suppose that 30 replications of 200 periods each were generated for inventory policy 1. Let $Y_{tj}^{(1)}$ be the cost in period t for replication j, $t = 1, 2, \ldots, 200$ and $j = 1, 2, \ldots, 30$. Then the across-replication averages

$$\overline{Y}_t^{(1)} = \frac{1}{30} \sum_{j=1}^{30} Y_{tj}^{(1)}$$

are estimates of $\theta_t^{(1)}$, since $\overline{Y}_t^{(1)}$ is the average cost in period t across 30 replications. A plot of these averages as a function of t is given in Figure 2. Since the data are still quite variable, a smoothing curve was fitted to make the mean function more apparent (a smoothing spline was used in Figure 2; Welch 1983 recommends a moving average). Another way to smooth the plot is to increase the number of replications. The procedure below, called *algorithm mean-plot,* calculates the across-replication averages needed for the plot:

1. *Initialization:* number of replications, k; length of each replication, m; array $a[t]$ of length m; array $s[t] \leftarrow 0$ for $t \leftarrow 1, 2, \ldots, m$
   (comment: k and m are problem dependent and require experimentation)
2. *Data:* $y[t, j]$, the tth observation from replication j
3. *Calculate averages:*
   (a) for $t \leftarrow 1$ to m:
   for $j \leftarrow 1$ to k: $s[t] \leftarrow s[t] + y[t, j]$, endfor
   endfor
   (b) for $t \leftarrow 1$ to m: $a[t] \leftarrow s[t]/k$, endfor
4. *Output:* plot $a[t]$ vs. t, smoothing the plot if necessary

The mean plot in Figure 2 shows that bias is clearly present—although it dissipates rapidly in this example—and the early cost values have a negative bias (biased low). A deletion point d can

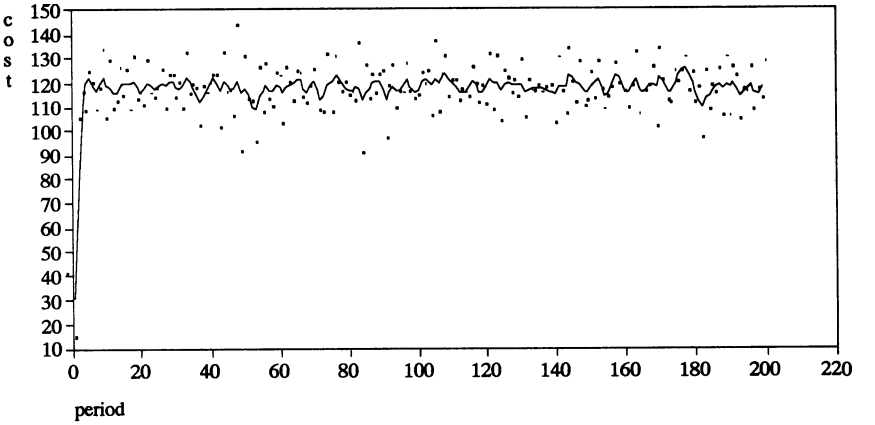

Figure 2 Mean Plot for Inventory Example.

be obtained by looking for a point where the curve seems to become nearly horizontal, perhaps at $d = 20$ periods in this example. The selection of d using the mean plot is subjective.

7.2.2. Cusum Plot

Schruben derived a plot that can be formed from a single, long replication and that is particularly sensitive to the presence of initial-condition bias (Barton and Schruben 1989). In terms of the inventory simulation, define $S_0 = 0$, and let

$$S_j = \sum_{t=1}^{j} (\bar{Y}^{(1)} - Y_t^{(1)})$$

for $j = 1, 2, \ldots, m$, where m is the number of periods simulated. The *cusum plot* is a graph of S_j vs. j.

Notice that $S_0 = S_m = 0$. If there is no initial-condition bias, then $E[S_j] = 0$ for all values of j in between, so the plot of S_j will tend to cross zero several times. However, when bias is present the values of S_j will all tend to be on one side of zero, depending on whether the bias is positive or negative.

Figure 3 shows such a plot for $m = 200$ periods of the inventory simulation before and after 20 periods of output were deleted (this plot was formed after averaging across several replications to make the characteristic behavior even more pronounced). In the first case the plot tends to be above zero, indicating negative bias, while after deletion no bias appears to be present.

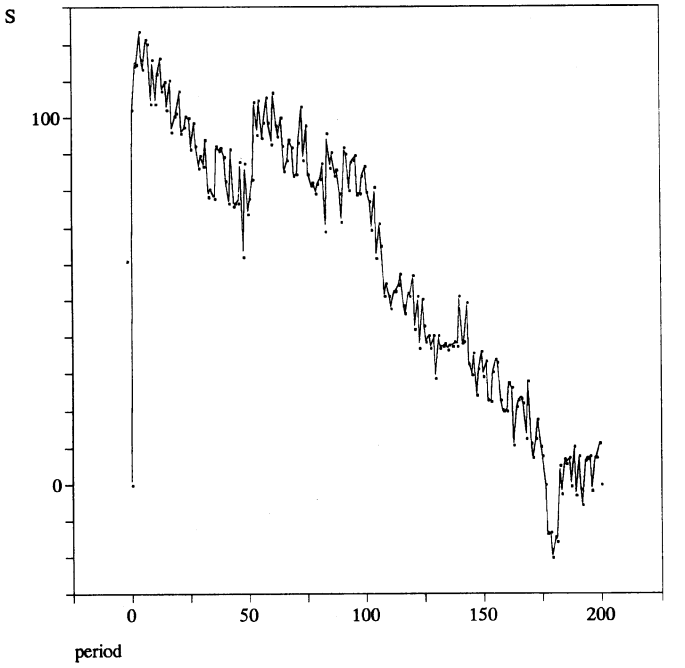
To smooth the plot, batching can be used. This is done in *algorithm cusum:*

1. *Initialization:* length of the replication, m; batch size b; number of batches $k \leftarrow \lfloor m/b \rfloor$; $a \leftarrow 0$; array $s[j] \leftarrow 0$ for $j \leftarrow 0, 1, \ldots, k$
(comment: m is problem dependent but should be large; Schruben recommends $b \leftarrow 5$)

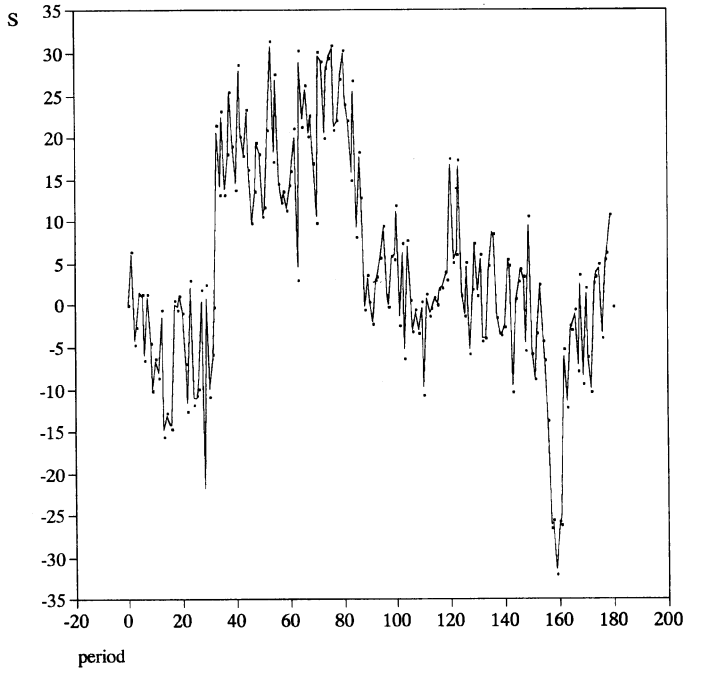
2. *Data:* $y[t]$, the tth observation from a single replication

3. *Batch the outputs:*
(a) for $j \leftarrow 1$ to k:
$y[j] \leftarrow y[(j-1)*b + 1]$
for $t \leftarrow 2$ to b: $y[j] \leftarrow y[j] + y[(j-1)*b + t]$, endfor
endfor
(b) for $j \leftarrow 1$ to k: $y[j] \leftarrow y[j]/b$, endfor
(comment: batch averages are now stored in $y[1], y[2], \ldots, y[k]$; if the original data must be saved then a separate array should be used)

4. *Compute overall average:*
for $j \leftarrow 1$ to k: $a \leftarrow a + y[j]$, endfor
$a \leftarrow a/k$



(*a*)



(*b*)

Figure 3 Cusum Plot for Inventory Model before and after Deleting Outputs.

5. *Generate cusum plot:* for $j \leftarrow 1$ to k: $s[j] \leftarrow s[j-1] + a - y[j]$, endfor

6. *Output:* plot $s[j]$ vs. j

The procedure *algorithm cusum* assumes that all of the outputs $y[t]$ are available before generating the plot. If an additional batch average, $y[k+1]$, is generated, then the plot values can be updated using the following steps:

$s[j] \leftarrow s[j] + j*(y[k+1] - a)/(k+1)$ for $j \leftarrow 1, 2, \ldots, k$
$s[k+1] \leftarrow 0$
$a \leftarrow (k * a + y[k+1])/(k+1)$

In the next subsection a test for initial-condition bias based on the characteristic behavior of the cusum plot is given.

7.2.3. Initial-Condition-Bias Test

Schruben (1982) used the characteristic behavior of the cusum plot to derive a statistical test for the presence of initial-condition bias. The test would typically be performed on an output process after remedial measures, such as data deletion, have been applied. The null hypothesis of the test is that there is no negative initial-condition bias (biased low) in the mean of the output process.

Loosely speaking, the test works as follows. The output of a single replication is divided in half. If the run is long enough, then any bias is most prevalent in the first half. The cusum values from each half are compared in terms of the location and magnitude of their maximum deviation from zero. If the behavior of the first half is significantly different from the second half, then the hypothesis of no initial-condition bias is rejected.

There are several versions of this test that have power against specific alternatives (Schruben et al. 1983; Goldsman et al. 1989). The version given in *algorithm bias test* is conservative in the sense that it tries to ensure that all of the asymptotic assumptions behind the test will be valid:

1. *Initialization:* length of the replication, m; batch size b; number of batches $k \leftarrow \lfloor m/b \rfloor$; arrays $a[j] \leftarrow 0$, $s[j] \leftarrow 0$, $smax[j] \leftarrow 0$ and $\ell[j] \leftarrow 0$ for $j = 1, 2$
(comment: m is problem dependent but should be large; Schruben recommends $b \leftarrow 5$)

2. *Data:* $y[t]$, the tth observation from a single replication
(comment: test assumes negative bias; if positive bias, modify step 6 as indicated; both tests can be performed if the direction of bias is uncertain)

3. *Batch the outputs:*
(a) for $j \leftarrow 1$ to k:
$y[j] \leftarrow y[(j-1)*b + 1]$
for $t \leftarrow 2$ to b: $y[j] \leftarrow y[j] + y[(j-1)*b + t]$, endfor
endfor
(b) for $j \leftarrow 1$ to k: $y[j] \leftarrow y[j]/b$, endfor
(comment: batch means are now stored in $y[1], y[2], \ldots, y[k]$; if the original data must be saved, then a separate array should be used)

4. $n \leftarrow \lfloor k/2 \rfloor$
(comment: n is half the batched process; the algorithm ignores the last batch if k is odd)

5. *Calculate sample mean of each half:*
for $i \leftarrow 1$ to n:
$a[1] \leftarrow a[1] + y[i]$
$a[2] \leftarrow a[2] + y[n+i]$
endfor
for $i \leftarrow 1$ to 2: $a[i] \leftarrow a[i]/n$, endfor

6. Locate maximum from each half:
(comment: if positive bias is suspected, replace all $>$'s with $<$'s in this step)
for $i \leftarrow 1$ to n:
$s[1] \leftarrow s[1] + a[1] - y[i]$
if $s[1] > smax[1]$
$\ell[1] \leftarrow i$ and $smax[1] \leftarrow s[1]$
endif
$s[2] \leftarrow s[2] + a[2] - y[n+i]$
if $s[2] > smax[2]$
$\ell[2] \leftarrow i$ and $smax[2] \leftarrow s[2]$
endif
endfor

7. Calculate test statistic:
(comment: if $\ell[1] = 0$ test for bias of the opposite sign; if $smax[2] = 0$ then m is too small)
$f \leftarrow \ell[2] * (n - \ell[2]) * smax[1] * smax[1] / ((\ell[1] * (n - \ell[1]) * smax[2] * smax[2])$
8. If $f > 9.28$, then reject the hypothesis of no initial-condition bias
(comment: 9.28 is the critical value for a 5% significance level; use 5.39 or 29.5 for 10% or 1% significance levels, respectively; to obtain other significance levels use the F distribution with (3,3) DOF).

Applying the test to the output process in Figure 3 before data deletion yields an f value of 88.66, which is significant even at the 1% level. However, after deleting the first 20 outputs from the process the f value is only 2.93, which is not significant.

7.3. A Comment on Probabilities and Quantiles

Long-run probabilities and quantiles of an output process can be estimated from a single replication of a steady-state simulation using the estimators given in Section 6. However, the convergence of probabilities and quantiles to their limiting values is often much slower than convergence of the mean. Thus, approximate convergence of the mean cannot be used as a substitute for establishing the convergence of probabilities and quantiles if they are the parameters of primary interest.

8. MEASURES OF ERROR

Design and Analysis Principle 6. A point estimator should be accompanied by a measure of its potential error.

A simple example illustrates why this principle is so important: Measures of error can be interpreted as the number of meaningful digits in a point estimate. If the estimated expected cost of an inventory policy is 1.1 million, it probably matters whether or not the second digit is meaningful. Without a measure of error, however, the analyst cannot even be sure if the *first* digit has meaning! A true expected cost of 2.7 million may mean the company is out of business.

This section describes measures of error for estimates of a performance parameter, θ, that can be represented as a mean (expected value), probability or quantile; point estimators for such parameters are covered in Section 6.

Two measures of error are the *standard error* and *confidence interval*. Whether or not it is difficult to derive a measure of error is related to whether or not the experiment design calls for i.i.d. replications: static and terminating experiments always specify replications, but steady-state simulations may not, depending on the severity of the initial-condition bias (see Section 7).

8.1. Standard Error

The *standard error* of a point estimator is an average error, where the average is with respect to repeated experiments of the same type. More precisely, it is the standard deviation of the point estimator. This subsection begins with a basic result for estimating the standard error of a mean or probability estimate and then illustrates it using the examples.

Let $Y_1, Y_2, \ldots, Y_k$ be i.i.d. output random variables with mean (expected value) θ, and let $\overline{Y}$ be their average as defined in Section 6. Then the standard error of $\overline{Y}$ as an estimator of θ is $\sigma/\sqrt{k}$, where σ^2 is the common $\mathrm{Var}[Y_i]$. An estimator of $\sigma/\sqrt{k}$ is

$$\frac{S}{\sqrt{k}} = \sqrt{\frac{\sum_{i=1}^{k} (Y_i - \overline{Y})^2}{k(k-1)}} = \sqrt{\frac{\sum_{i=1}^{k} Y_i^2 - (\sum_{i=1}^{k} Y_i)^2/k}{k(k-1)}} \tag{2}$$

where $S^2 = (k-1)^{-1} \sum_{i=1}^{k} (Y_i - \overline{Y})^2$ is the sample variance, an estimator of σ^2.

The estimator $S/\sqrt{k}$ is also valid when θ is a probability and the outputs are indicator variables I_i (as defined in Section 6), in which case (2) reduces to

$$\frac{S}{\sqrt{k}} = \sqrt{\frac{\overline{I}(1-\overline{I})}{k-1}}$$

For example, in the acceptance-sampling simulation I_i could be an indicator of whether or not the ith sample of size 10 was accepted (had 1 or fewer defectives), so that $\overline{I}$ estimates $\theta(p)$, the probability of accepting the sample. Table 3 gives the estimated standard errors for estimates of $\theta(p)$, where each estimate is based on $k = 10{,}000$ i.i.d. replications as described in Section 6.

TABLE 3 Estimated Points on OC Curve and Associated Standard Error of the Estimate

p	$\bar{I}$	$S/\sqrt{10000}$
0.00	1.00	0.000
0.01	0.98	0.001
0.05	0.89	0.003
0.10	0.77	0.004
0.15	0.67	0.005
0.20	0.57	0.005
0.30	0.38	0.005
0.40	0.25	0.004
0.50	0.16	0.004
0.60	0.09	0.003
0.70	0.05	0.002
0.80	0.02	0.001
0.90	0.01	0.001

Design and Analysis Principle 7. The first nonzero digit in the standard error indicates an uncertain digit in the corresponding decimal place of the point estimator.

This principle is conservative; it does not imply that the first uncertain digit in the point estimator has no meaning, but only that it may not be correct. Table 3 displays two decimal places for each $\bar{I}$ because the first nonzero digit of the standard error is in the third decimal place; however, the third decimal place of $\bar{I}$ was used for rounding.

Formula (2) is applicable when the point estimator is an average across k i.i.d. replications. As discussed in Section 5, it is seldom applicable to outputs within a single replication because they may be neither independent nor identically distributed. This causes no problem in static or terminating simulations because the natural experiment design is to generate independent replications.

Replications can also be generated in steady-state simulations, although remedial measures (such as deletion, see Section 7) must be applied to each replication. When initial-condition bias is not severe, replications are recommended and formula (2) can be applied to the across-replication statistics.

When only a single replication is generated from a steady-state simulation, an estimator of the standard error can be derived using the method of *batch means*. To illustrate the discussion, let $Y_1^{(1)}, Y_2^{(1)}, \ldots, Y_m^{(1)}$ be the output from a single replication of the inventory simulation for policy 1 *after* the first 20 periods have been deleted; thus, $Y_t^{(1)}$ is the observed cost in period $t + 20$. The sample average, $\bar{Y}^{(1)}$, is used to estimate $\theta^{(1)}$, the long-run expected cost per period for inventory policy 1. An estimate of the standard error of $\bar{Y}^{(1)}$ is required. For convenience, drop the superscript (1) and let the output and statistic be simply Y_t and $\bar{Y}$, respectively.

Let $k \leq m$ be the *number of batches,* $b = \lfloor m/k \rfloor$ the *batch size,* and define the jth batch mean (average) to be

$$\bar{Y}_j(k) = \frac{1}{b} \sum_{t=1}^{b} Y_{(j-1)b+t}$$

for $j = 1, 2, \ldots, k$. The principle behind batch means is that $\bar{Y}_1(k), \bar{Y}_2(k), \ldots, \bar{Y}_k(k)$ are more nearly independent than the original outputs, $Y_1, Y_2, \ldots, Y_m$, for most simulation output processes. If the remedial measures for initial-condition bias have been effective, then the batch means are also nearly identically distributed. Thus, the batch means are (approximately) i.i.d. statistics, even though they are within-replication statistics, and formula (2) applies. The batch means are written as functions of k because selecting the number of batches is a decision that the analyst must make.

The procedure below, called *algorithm batch_means,* computes an estimate of the standard error of a within-replication average $\bar{Y}$. It can be used to compute the standard error for the across-replication average of k replications (formula (2)) by omitting step 3(a) and setting $m = k$:

1. *Initialization:* length of the replication, m; number of batches k; batch size $b \leftarrow \lfloor m/k \rfloor$; *sum* $\leftarrow 0$; and *sumsq* $\leftarrow 0$.
   (comment: m is problem dependent but should be large; choosing k is discussed below)
2. *Data:* $y[t]$, the tth observation from a single replication *after* applying remedial measures.

3. *Batch the outputs:*
(a) for $j \leftarrow 1$ to k:
$y[j] \leftarrow y[(j-1)*b+1]$
for $t \leftarrow 2$ to b: $y[j] \leftarrow y[j] + y[(j-1)*b+t]$, endfor
endfor
(b) *Compute the standard error:*
for $j \leftarrow 1$ to k:
$y[j] \leftarrow y[j]/b$
$sum \leftarrow sum + y[j]$
$sumsq \leftarrow sumsq + y[j]*y[j]$
endfor
(comment: batch means are now stored in $y[1], y[2], \ldots, y[k]$; if the original data must be saved, then a separate array should be used)

4. *Output:* sqrt{$(sumsq - sum*sum/k)/(k(k-1))$}.

To illustrate the effect of batching, 2020 periods of the inventory simulation were generated and the first 20 periods of data were deleted, leaving $m = 2000$ outputs. The sample mean of the outputs was $\overline{Y} = 118.48$ dollars per period. The estimated sample correlation between successive periods, $\text{Corr}[Y_t, Y_{t+1}]$, was -0.51, clearly showing dependence. After batching the cost data into $k = 20$ batches of size $b = 100$, the estimated correlation between successive batch means, $\text{Corr}[\overline{Y}_j(20), \overline{Y}_{j+1}(20)]$, was -0.09, which appears less correlated. The standard error of $\overline{Y}$ calculated by *algorithm batch means* was 0.29, an average error of 29 cents.

The most difficult design decision when using the method of batch means is choosing k, the number of batches. Several studies have concluded that no matter how long the replication is, it should be divided into a relatively small number of batches, say $10 \leq k \leq 30$. Diagnostic tests, such as computing the correlation between successive observations, can be employed to verify that batching has been effective. Formal batching algorithms are also available (Bratley et al. 1987; Fishman 1978; Fishman and Yarberry 1997; Law and Kelton 2000).

8.2. Confidence Intervals

Confidence intervals are constructed in hopes that they contain the unknown performance parameter of interest, θ. The ''confidence'' associated with a confidence interval is, strictly speaking, a statement about the *procedure* used to construct the interval, not the interval itself. The confidence interval either contains θ or it does not. The width of the confidence interval is a measure of error.

There are many confidence-interval procedures based on a variety of different assumptions, too many to describe here (see Chapter 86 of the Handbook or any introductory statistics text). This subsection contains some general comments regarding the use of confidence-interval procedures for estimating means, and a specific confidence-interval procedure for quantile estimation.

8.2.1. Confidence Intervals for Means

The validity of a confidence-interval procedure frequently depends on a number of conditions. One such condition is that the output data are i.i.d. As discussed in Subsection 8.1, i.i.d. outputs can be obtained by generating replications, or, in steady-state simulation, by using the method of batch means.

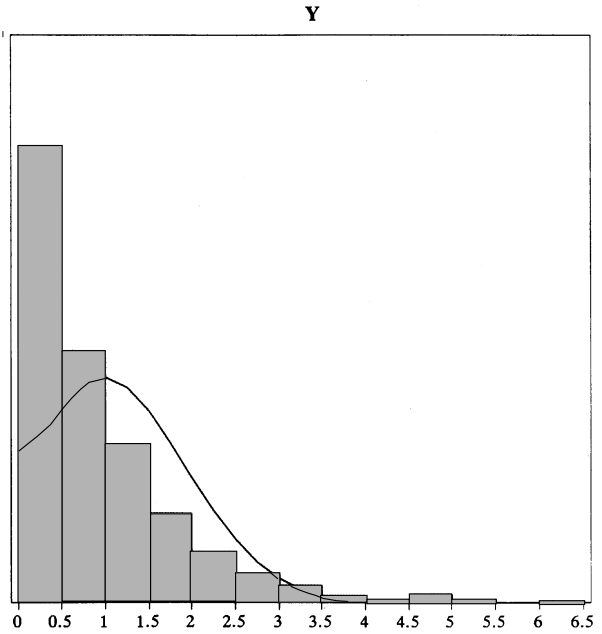
A second common condition is that the simulation outputs have a normal distribution. The assumption of normality can be severely violated in simulations. Diagnostic checks using histograms, quantile plots, or hypothesis tests are recommended to verify the normality of the output data.

The normality of the output data can be improved by using the method of batch means, even if the data are already i.i.d. This is because averages tend to be normally distributed, as shown in the central limit theorem. For example, Figure 4 shows two histograms for the same 500 i.i.d. simulation outputs. The first histogram shows raw data, while the second displays the same data after batching them into $k = 100$ batch means (batch size $b = 5$). In both cases a normal curve is superimposed over the histogram. Clearly the sample distribution of the batch means is more nearly normal.

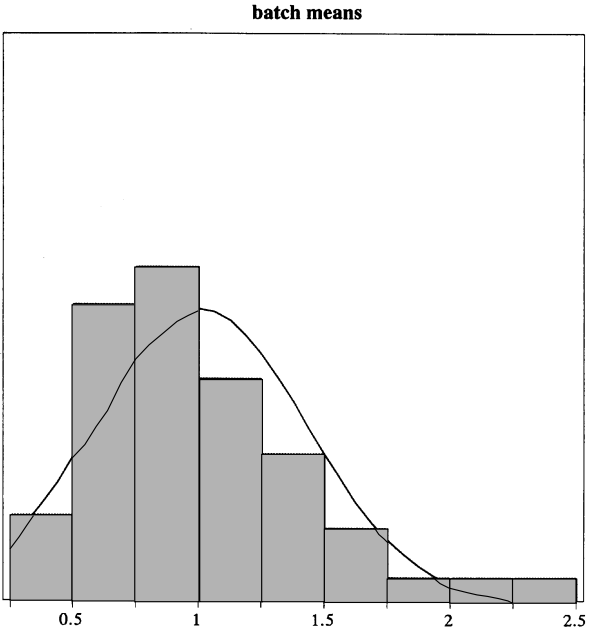
Although batching reduces the number of degrees of freedom for the confidence-interval procedure—since there are fewer batch means than total outputs—the penalty is slight provided that the number of batch means is not too small. Schmeiser (1982) showed that, for the standard t confidence-interval procedure, batching to $10 \leq k \leq 30$ batch means does not degrade the performance of the procedure substantially *even if the original data are precisely i.i.d. normal.* On the other hand, when the data are not normal, batching can improve the performance of the procedure in terms of delivering the requested level of confidence.

8.2.2. A Confidence Interval for Quantiles

A point estimator for the q quantile, θ_q, of a random variable Y was given in Section 6. The point estimator and the confidence-interval procedure given here assume that k i.i.d. replications of Y are



(*a*)



(*b*)

Figure 4 Simulation Outputs before and after Batching.

TABLE 4 Standard Normal Quantiles

$1 - \alpha$	$z_{1-\alpha/2}$
0.90	1.6449
0.95	1.9600
0.99	2.5758

available, denoted generically by $Y_1, Y_2, \ldots, Y_k$. Let the sorted values of Y, called the order statistics, be denoted $Y_{(1)} \le Y_{(2)} \le \ldots \le Y_{(k)}$.

Although a standard error estimate is difficult to derive, deriving a confidence interval for θ_q is relatively easy. In addition, this confidence-interval procedure is nonparametric, meaning that the distribution of Y is not a factor.

A $(1 - \alpha)100\%$ confidence interval for θ_q is $(Y_{(\ell)}, Y_{(u)})$, where $1 \le \ell < u \le k$ are integers such that the binomial probability

$$\sum_{j=\ell}^{u-1} \binom{k}{j} q^j (1-q)^{k-j} \approx 1 - \alpha$$

The confidence interval is nonparametric since the constants ℓ and u depend only on k and q. Determining ℓ and u is difficult when the number of replications, k, is large (and k should be large for quantile estimation), but large k allows a normal approximation to the binomial distribution. The approximation leads to setting

$$\ell = \lfloor kq - z_{1-\alpha/2}\sqrt{kq(1-q)} + 1/2 \rfloor \text{ and} \tag{3}$$

$$u = \lfloor kq + z_{1-\alpha/2}\sqrt{kq(1-q)} + 1/2 \rfloor + 1 \tag{4}$$

where $z_{1-\alpha/2}$ is the $1 - \alpha/2$ quantile of the standard normal distribution. The standard normal quantiles for 90%, 95%, and 99% confidence intervals are given in Table 4.

Section 6 illustrated estimating the 0.9 quantile, $\theta_{0.9}$, of Y, the average delay for renewal applications received during a month in the license-renewal simulation. Based on 200 replications, the point estimate was 0.88 days. Substituting $k = 200$ and $q = 0.9$ into (3) and (4) gives $\ell = 172$ and $u = 189$ for a 95% confidence interval. The corresponding interval is $(Y_{(172)}, Y_{(189)}) = (0.82, 0.98)$.

8.3. A Note on Experiment Planning

The discussion above assumes that the analyst is interested in computing a measure of error *after* completing the simulation replications or runs. Experiment planning includes determining the number of replications required to achieve a prespecified level of error.

Consider the standard error. If the process variance σ^2 is known, then it is easy to determine the number of replications (or batch means) required to achieve a standard error less than or equal to, say, δ, by solving

$$\frac{\sigma}{\sqrt{k}} \le \delta \tag{5}$$

for k. Typically, σ^2 is not known, but it may be estimated during debugging or preliminary pilot runs and the estimate can be substituted into (5).

Law and Kelton (2000) contains a discussion of methods for determining k sequentially (while the simulation is in progress) to guarantee a prespecified level of error.

9. OPTIMIZATION AND SENSITIVITY

Industrial engineers frequently use simulation experiments to compare the performance of alternative systems and, ideally, to optimize system performance. When a system is modeled as a stochastic process, the objective is often to optimize expected performance, where "expected" means the mathematical expectation of a random variable. This section describes methods for optimization via simulation, using the problem of selecting the inventory policy that minimizes long-run expected cost per period as an illustration.

Even if optimization is not desired or feasible, the analyst may be interested in the sensitivity of system performance to certain controllable factors. This section also discusses sensitivity analysis, using the sensitivity of the expected average delay $\theta(\mu)$ to the processing rate μ in the license-renewal simulation as an illustration.

The scope of this section is limited because methods for optimization and sensitivity analysis are still evolving. See Andradóttir (1998).

9.1. Multiple Comparisons

A common optimization problem is to choose the system with maximum or minimum expected performance from among a small number of systems, say 2 to 10. Assuming that estimates of expected performance are available from simulation experiments, the question of which system to select is easily answered: all else being equal, select the system with the sample best performance. A more relevant question is whether the observed ranking of the systems is due to estimation error or actual differences in performance. Thus, optimization is an extension of the problem of estimating and controlling error, as discussed in Section 8.

The case of comparing two systems is covered in standard statistics texts. For three or more systems, two classes of statistical procedures are widely used: ranking-and-selection procedures and multiple-comparison procedures.

Ranking-and-selection procedures treat the optimization problem as a decision problem, typically either deciding which system is the best (indifference-zone ranking) or on a subset of systems that contains the best system (subset selection). The decisions are guaranteed to be correct with a prespecified probability. Achieving this goal often requires two-stage sampling, which means restarting simulation experiments after initial runs of all systems. A summary of the many ranking and selection procedures is given by Bechhofer et al. (1995), Gupta and Panchapakesan (1979), and Law and Kelton (2000). Extensions of these procedures have been made specifically to stochastic simulation (Koenig and Law 1985; Clark and Yang 1986; Goldsman 1985; Goldsman and Nelson 1998; Iglehart 1977; Sullivan and Wilson 1989).

Multiple-comparison procedures, on the other hand, treat the optimization problem as an inference problem on the performance parameters of interest. An important property of multiple-comparison procedures is that inference about the relative performance of all systems is provided. In addition, multiple-comparison procedures can be implemented in a single-stage of sampling. This subsection describes a multiple-comparison procedure that is useful for optimization.

In the inventory simulation smaller $\theta^{(\ell)}$ is preferred, where $\theta^{(\ell)}$ denotes the long-run expected cost per period for policy ℓ, $\ell = 1, 2, \ldots, 5$. For policy ℓ, the parameter $\theta^{(\ell)} - \min_{i \neq \ell} \theta^{(i)}$ is policy ℓ cost minus the minimum of the other policies' costs. The parameters $\theta^{(\ell)} - \min_{i \neq \ell} \theta^{(i)}$, for $\ell = 1, \ldots, 5$, are the appropriate parameters to estimate for optimization. If $\theta^{(\ell)} - \min_{i \neq \ell} \theta^{(i)} < 0$, then policy ℓ is the best because all other policies have larger expected cost. On the other hand, if $\theta^{(\ell)} - \min_{i \neq \ell} \theta^{(i)} > 0$, then policy ℓ is not the best, since there is another policy with smaller expected cost. Even when $\theta^{(\ell)} - \min_{i \neq \ell} \theta^{(i)} > 0$, if $\theta^{(\ell)} - \min_{i \neq \ell} \theta^{(i)} < \Delta$, where Δ is a positive number, then policy ℓ is within Δ of the best. Simultaneous statistical inference on $\theta^{(\ell)} - \min_{i \neq \ell} \theta^{(i)}$, for $\ell = 1, \ldots, 5$, is termed *multiple comparisons with the best* (MCB). In problems where larger expected performance is preferred, the parameter of interest is $\theta^{(\ell)} - \max_{i \neq \ell} \theta^{(i)}$, so that $\theta^{(\ell)} - \max_{i \neq \ell} \theta^{(i)} > 0$ indicates the best system.

For the general case of r systems, Hsu (1984) derived simultaneous $(1 - \alpha)100\%$ confidence intervals for $\theta^{(\ell)} - \max_{i \neq \ell} \theta^{(i)}$ (equivalently $\theta^{(\ell)} - \min_{i \neq \ell} \theta^{(i)}$) for $\ell = 1, 2, \ldots, r$. The form of the intervals is

$$\left[(\overline{Y}^{(\ell)} - \max_{i \neq \ell} \overline{Y}^{(i)} - H)^-, (\overline{Y}^{(\ell)} - \max_{i \neq \ell} \overline{Y}^{(i)} + H)^+ \right]$$

where $\overline{Y}^{(\ell)}$ is the sample average of the outputs from system ℓ, $x^- = \min\{0, x\}$, $x^+ = \max\{0, x\}$ and H is a quantity that depends on r, k and the sample standard error.

The assumptions behind these confidence intervals, and their interpretation in simulation experiments, are listed below. To aid the explanation let $Y_j^{(\ell)}$ be generic for the jth output from system ℓ.

- For each system ℓ, the output data consist of k i.i.d. outputs $Y_1^{(\ell)}, Y_2^{(\ell)}, \ldots, Y_k^{(\ell)}$ with common expected value $\theta^{(\ell)}$. This will be true if the outputs are from across replications, or approximately true if they are batch means from within a single replication (see Section 8).
- The outputs from different systems $\ell = 1, 2, \ldots, r$ are independent of each other. This will be true if different random number streams or seeds are specified for the simulation of each system (see Section 4).
- All the outputs $Y_j^{(\ell)}$ $j = 1, 2, \ldots, k$ and $\ell = 1, 2, \ldots, r$ are normally distributed. This may be approximately true if $Y_j^{(\ell)}$ is an average of many outputs, but it should be verified through graphical or statistical analysis.
- $\mathrm{Var}[Y_j^{(\ell)}]$ is the same for all j and ℓ. This may be true if the different systems are similar, but it should be verified through graphical or statistical analysis. If the variances across systems are widely different then variance-stabilizing transformations can be applied.

The procedure below, called *algorithm mcb*, calculates MCB intervals for the maximization case; to obtain results for the minimization case replace all the >'s with <'s in step 6 of the algorithm as indicated.

1. *Initialization:* number of independent observations, k; number of systems, r; arrays $sum[\ell] \leftarrow 0$ and $sumsq[\ell] \leftarrow 0$ for $\ell = 1, 2, \ldots, r$; $s \leftarrow 0$; array $ybar[\ell]$ of length r; critical value $d \leftarrow d^{\alpha}_{r(k-1),r}$ (see Table 5)
2. *Data:* $y[\ell, j]$, the jth independent observation from system ℓ
3. *Compute sums and sums of squares:*
   for $\ell \leftarrow 1$ to r:
      for $j \leftarrow 1$ to k:
         $sum[\ell] \leftarrow sum[\ell] + y[\ell, j]$
         $sumsq[\ell] \leftarrow sumsq[\ell] + y[\ell, j]*y[\ell, j]$
      endfor
   endfor
4. *Compute sample averages and pooled standard error estimate:*
   for $\ell \leftarrow 1$ to r:
      $ybar[\ell] \leftarrow sum[\ell]/k$
      $s \leftarrow s + sumsq[\ell] - sum[\ell]*sum[\ell]/k$
   endfor
   $s \leftarrow \text{sqrt}\{s/(r(k-1))\}$
5. *Confidence interval halfwidth:* $h \leftarrow d * s * \text{sqrt}(2/k)$
6. Find first- and second-best sample performance:
   (comment: for minimization problems replace all >'s by <'s in this step)
   $findex \leftarrow 1$; $first \leftarrow ybar[1]$
   $sindex \leftarrow 2$; $second \leftarrow ybar[2]$
   if $ybar[2] > ybar[1]$
      $findex \leftarrow 2$; $first \leftarrow ybar[2]$
      $sindex \leftarrow 1$; $second \leftarrow ybar[1]$

[a]These values were calculated using a program provided by Jason C. Hsu

```
    endif
    for ℓ ← 3 to r:
      if ybar[ℓ] > first
        sindex ← findex; second ← first
        findex ← ℓ; first ← ybar[ℓ]
      else
        if ybar[ℓ] > second
          sindex ← ℓ; second ← ybar[ℓ]
        endif
      endif
    endfor
```

7. *Output:* For system ℓ, the lower endpoint, point estimate, and upper endpoint for $\theta^{(\ell)} - \max_{i \neq \ell} \theta^{(i)}$ (or $\theta^{(\ell)} - \min_{i \neq \ell} \theta^{(i)}$)

```
    for ℓ ← 1 to r:
      point ← ybar[ℓ] − first
    if ℓ = findex then point ← ybar[ℓ] − second
      lower ← min{point − h , 0}
      upper ← max{point + h, 0}
      output ℓ, lower, point, upper
    endfor
```

The critical values $d^{\alpha}_{r(k-1),r}$ for 95% confidence intervals ($\alpha = 0.05$) are given in Table 5. Critical values for other confidence levels can be found in Table 4 of Appendix 3 in Hochberg and Tamhane (1987).

MCB intervals are constrained intervals, meaning that they either contain 0 or one of their endpoints is 0. In a maximization problem, if the confidence interval for $\theta^{(\ell)} - \max_{i \neq \ell} \theta^{(i)}$ contains 0 it means that system ℓ is not significantly different from the best system, and may be the best. If the upper endpoint of the interval is 0, then system ℓ is not the best system. However, if the lower endpoint is 0, then system ℓ is the best system; at most one system will have lower endpoint 0. These statements are made with confidence level $1 - \alpha$.

The minimization case is illustrated by the inventory example. For each inventory policy a single replication of 2020 periods was generated and the first 20 periods of data were deleted to reduce initial-condition bias (see Section 7). A different random number stream was used to generate demands for each policy so that the results across policies are independent. To obtain approximately i.i.d. outputs from within each replication, the 2000 outputs were batched into $k = 20$ batch means, and the batch means were used as the basic data for each inventory policy (see Section 8). Thus, the critical value from Table 5 is $d^{0.05}_{5(19),5} = 2.189$, which comes from the $k = 20$ row and $r = 5$ column. The 95% simultaneous confidence intervals for $\theta^{(\ell)} - \min_{i \neq \ell} \theta^{(i)}$ computed by *algorithm mcb* are given in Table 6.

Since the lower endpoints for policies 3, 4, and 5 are 0, they are significantly more expensive than the least-cost policy; in other words, the difference between the cost of any one of these policies and the minimum cost of the other policies is greater than 0. Policy 2 is the sample best policy, but it is not statistically significantly different from policy 1 since the intervals for both policies 1 and 2 contain 0. However, if policy 2 is not the best, the upper endpoint of its interval indicates that it is no more than 1.836 per period more expensive than the best. Similarly, policy 1 is no more than 2.526 from the best. If these differences are practically insignificant, then policy 2 should be selected. If more precision is required, then additional replications or batches will sharpen the comparison.

9.2. Metamodels

In some simulation studies, the analyst is interested in determining the effects of controllable system factors, perhaps to optimize system performance with respect to the controllable factors or to examine

TABLE 6 MCB Intervals for $\theta^{(\ell)} - \min_{i \neq \ell} \theta^{(i)}$ in the Inventory Simulation

ℓ	Policy	Lower Endpoint	Point Estimate	Upper Endpoint
1	(20,40)	−1.836	0.345	2.526
2	(20,80)	−2.526	−0.345	1.836
3	(40,60)	0	15.409	17.590
4	(40,100)	0	18.574	20.755
5	(60,100)	0	34.064	36.245

their relative impact. For example, in the license-renewal simulation, the application processing rate, μ, may be controllable through the equipment and staff available to the clerk, and the analyst may be interested in its effect on the average processing delay for applications.

The sample performance of a simulated system can be viewed as a complicated function of the controllable factors, which include the random number seeds or streams assigned to the experiment. A *metamodel* is a simpler function that approximates the relationship between system performance and the controllable factors. The primary benefit of a metamodel is that it can be studied using straightforward mathematical analysis.

One approach that is often used to derive a metamodel is to propose a function that has some unknown parameters and then estimate the parameters via least-squares regression. For example, the following metamodel might be postulated to describe the relationship between the average monthly delay for renewal applications, $\overline{Y}$, and the processing rate, μ:

$$\overline{Y} = \beta_0 + \beta_1\mu + \beta_2\mu^2 + \epsilon(s) \tag{6}$$

where β_0, β_1, and β_2 are unknown parameters and $\epsilon(s)$ is a mean 0 random variable that represents the variability in the system. Notice that $\epsilon(s)$ is a function of s, the random number stream or seed assigned to the simulation experiment. Metamodel (6) implies that $\theta(\mu)$, the expected average delay when the processing rate is μ, can be approximated by the function

$$\theta(\mu) = \mathrm{E}_\mu[\overline{Y}] \approx \beta_0 + \beta_1\mu + \beta_2\mu^2$$

Metamodels, such as (6), become useful when appropriate values are assigned to the unknown parameters. Experimental design—choosing the levels of the controllable factors at which simulation experiments will be performed—is needed to ensure good parameter estimates; see Chapter 85 of the Handbook for guidance. Once the experiments have been performed, least-squares regression is a standard procedure for estimating the parameters; see Chapter 87 of the Handbook.

The methods and procedures discussed in Chapters 85 and 87 are as relevant to simulation experiments as they are to statistical experiments in general. There is one experiment design and analysis issue that is unique to simulation, however:

Design and Analysis Principle 8. Statistical inference on a metamodel is typically based on the assumption that outputs from different design points (factor settings), and the replications at a single design point, are statistically independent. Thus, different random number streams or seeds should be assigned to each design point unless the analyst plans to account directly for the dependence induced by using common streams.

Although there are potential advantages from using common streams or seeds across design points, methods for statistical analysis under such designs are still evolving (Hussey, et al. 1987a, b; Kleijnen 1988; Nozari, et al. 1987; Schruben and Margolin 1978). See also Section 10.

Table 7 shows the experiment design used to fit (6). Ten independent replications were made at each design point, and the parameters were estimated via least-squares regression. The resulting metamodel for the expected average delay is

$$\theta(\mu) \approx 12.01 - 0.97\mu + 0.02\mu^2 \tag{7}$$

Because each design point was simulated independently, standard tests for significance of the parameters and lack of fit could be used to validate the fitted model.

The derivative of (7) with respect to μ gives the approximation

TABLE 7 Experiment Design for Fitting License-Renewal Processing Metamodel

Design Point	Processing Rate, μ	Random Number Stream
1	15	3
2	20	1
3	25	4

$$\frac{d\theta(\mu)}{d\mu} \approx -0.97 + 0.04\mu$$

The derivative of a metamodel is one way to examine the sensitivity of the expected average delay to the processing rate. For example, at $\mu = 20$ the derivative is -0.17, implying that an increase of one application per day in the processing rate should result in a decrease of 0.17 days in the expected average delay.

The extent to which a metamodel is valid is necessarily limited. Extrapolating a metamodel beyond the factor settings used to fit the model should always be done with caution. For instance, the metamodel (7) predicts that the expected average delay will begin to increase if the processing rate exceeds 25 applications per day!

Many methods, in addition to metamodel estimation, have been proposed for examining the sensitivity of system performance to controllable factors. For recent surveys see Andradóttir (1998), Glynn (1989), and Jacobson and Schruben (1989) and the references therein.

10. VARIANCE REDUCTION

The goal of variance reduction is to decrease the error of a point estimate, which should lead to a smaller estimated standard error or a narrower confidence interval (see Section 8 for a discussion of measures of error). This section describes the variance reduction technique known as *common random numbers* (CRN), which is useful for reducing the error in comparing the expected performance of two or more systems. The presentation is based on Nelson (1987).

For simplicity, suppose that there are two competing systems, and let $\theta^{(1)}$ and $\theta^{(2)}$ be the (unknown) expected performance of system 1 and system 2, respectively. If there are more than two systems, then the methods described below can be applied to each pair of systems. When comparing the performance of two systems, the single parameter $\theta^{(1)} - \theta^{(2)}$ often captures the essential information about their relative performance.

For example, consider comparing the expected cost per period of inventory policies 1 and 2 of the inventory example. Since a smaller expected cost is preferred, $\theta^{(1)} - \theta^{(2)} < 0$ implies that inventory policy 1 is superior, while $\theta^{(1)} - \theta^{(2)} > 0$ implies that inventory policy 2 is better. The absolute value of $\theta^{(1)} - \theta^{(2)}$ is the amount by which one of the policies is better than the other.

Generically, let $Y_1^{(\ell)}, Y_2^{(\ell)}, \ldots, Y_k^{(\ell)}$ be outputs from k i.i.d. replications (or possibly batch means, see Section 8) from system ℓ, for $\ell = 1, 2$, so that $\theta^{(\ell)} = \mathrm{E}[Y_j^{(\ell)}]$; that is, $Y_j^{(\ell)}$ is the sample performance of system ℓ on replication j. Let $D_j = Y_j^{(1)} - Y_j^{(2)}$ for $j = 1, 2, \ldots, k$, the difference between the sample performance of the two systems on the jth replication. A point estimator of $\theta^{(1)} - \theta^{(2)}$ is

$$\overline{D} = \frac{1}{k}\sum_{j=1}^{k} D_j = \overline{Y}^{(1)} - \overline{Y}^{(2)}$$

An estimator of the standard error of $\overline{D}$ is $S_D/\sqrt{k}$, and an approximate $(1 - \alpha)100\%$ confidence interval for $\theta^{(1)} - \theta^{(2)}$ is

$$\overline{D} \pm t_{1-\alpha/2,k-1} S_D/k$$

where

$$S_D^2 = \frac{1}{k-1}\sum_{j=1}^{k} (D_j - \overline{D})^2$$

is the sample variance of the differences and $t_{1-\alpha/2,k-1}$ is the $1 - \alpha/2$ quantile of the t distribution with $k - 1$ degrees of freedom (a table of t-distribution quantiles can be found in any statistics text; if no such text is available, the normal distribution quantiles $z_{1-\alpha/2}$ from Table 4 can be used provided $k \geq 30$). The condition that makes this confidence interval valid is that the D_j are i.i.d. normally distributed random variables. If the $Y_j^{(\ell)}$ are actually within-replication averages or batch means, then this condition may be approximately satisfied.

The size of the estimated standard error or width of the confidence interval determines whether or not a difference in system performance can be detected in the presence of the random variation in the simulation results. To be able to detect a difference, it is necessary that the potential error in the point estimate $\overline{D}$ be small with respect to the difference $\theta^{(1)} - \theta^{(2)}$.

The true standard error of $\overline{D}$ can be written as $\sigma_D/\sqrt{k}$, where $\sigma_D^2 = \mathrm{Var}[D_j]$, the common variance of the differences. Thus, the size of the estimated standard error and the width of the confidence interval depend on the underlying variance σ_D^2. The variance of the difference is

$$\sigma_D^2 = \text{Var}\,[Y_j^{(1)}] + \text{Var}\,[Y_j^{(2)}] - 2\text{Cov}[Y_j^{(1)}, Y_j^{(2)}]$$
$$= \sigma_1^2 + \sigma_2^2 - 2\rho\sigma_1\sigma_2 \quad (8)$$

where $\sigma_\ell^2 = \text{Var}\,[Y_j^{(\ell)}]$ and ρ is the correlation between pairs of observations from the two systems on the same replication, $Y_j^{(1)}$ and $Y_j^{(2)}$. Typically, the variances σ_1^2 and σ_2^2 are properties of the systems being simulated and are not easily altered. However, the correlation ρ may be controlled, and Eq. (8) shows that making $\rho > 0$ will result in a variance reduction. The following design and analysis principle describes how to accomplish this:

Design and Analysis Principle 9. Positive correlation between the sample performance of two systems can often be induced by assigning the same ("common") random number streams or seeds to the simulation of each system (see Section 4 for a description of random number streams and seeds). The magnitude of the correlation can be increased further by synchronizing the pseudorandom numbers, as described below.

The intuition behind the use of CRN is straightforward: a fairer comparison between competing systems is obtained if they are both subjected to the same experimental conditions. Assigning the same random number streams or seeds to each system means that the influence of randomness is similar for both systems and the observed differences in performance are due to differences in the systems, not in the pseudorandom numbers.

The goal of synchronization is to guarantee that each pseudorandom number is used *for the same purpose* in the simulation of each system. The effect of CRN can be greatly enhanced by synchronizing the pseudorandom numbers. Synchronization is achieved through the random number stream assignments to the input processes.

Simulations contain one or more input processes, which are frequently i.i.d. sequences of random variables (see Section 4 for the definition of simulation inputs). For example, in the inventory simulation there is one input process, the sequence of demands in each period. In the license-renewal simulation there are two input processes, the successive times between arrivals of applications and the successive processing times for applications.

One of the best ways to synchronize is to dedicate a distinct random number stream or seed to each input process and then to use the same stream assignment for all simulated systems. In the license-renewal simulation, assigning different random number streams to the two input processes guarantees that exactly the same sequence of application arrival times is experienced by all systems and that the processing times will be positively correlated for all processing rates, μ. In the inventory simulation, CRN guarantees that each inventory policy experiences exactly the same sequence of demands. Synchronization is the primary reason for having more than one random number stream in a simulation language.

Table 8 illustrates the effect of CRN on the inventory simulation when the goal is to estimate $\theta^{(1)} - \theta^{(2)}$, the expected difference between the cost per period of inventory policies 1 and 2. The experiment design is the same one described in Section 9, so the basic data for each inventory policy are $k = 20$ approximately i.i.d. normal batch means (for the purposes of this illustration they can be thought of as k i.i.d. replications). The table gives the point estimate, estimated standard error, and a 95% confidence interval for the expected difference.

The estimated correlation between outputs when using CRN was 0.58, which is positive as desired. Notice that the estimated standard error and the width of the confidence interval are reduced relative to the experiment with independent runs (different random number streams for each policy).

More critically, the point estimate derived without CRN is positive, indicating that policy 2 yields the smallest expected cost, while the point estimate derived with CRN is negative, indicating that policy 1 is superior. For this simple model it can be shown that policy 1 does have the smaller expected cost, so the use of CRN leads to the correct decision. However, in both experiments the 95% confidence interval for the difference contains 0, so it cannot be stated conclusively that policy 1 is best based on the data. Additional batches are needed to reduce the error even further.

TABLE 8 Estimated Difference in Expected Cost With and Without CRN

Design	D	Standard Error	95% Confidence Interval
Independent	0.3	0.57	(−0.85, 1.54)
CRN	−0.3	0.31	(−0.98, 0.35)

ACKNOWLEDGEMENTS

CHAPTER 96

Virtual Reality for Industrial Engineering: Applications for immersive Virtual Environments

HANS-JÖRG BULLINGER
RALF BREINING
MARTIN BRAUN
Fraunhofer Institute of Industrial Engineering

1. OVERVIEW

This chapter focuses on virtual reality (VR) applications in the fields of engineering and industrial engineering. It gives definitions of the main keywords for the field of engineering and describes the hardware and software and the specific human–computer interaction aspects for virtual environments (VE). Some typical applications are specified that show the field-tested use of VR, and the basics for the integration of such applications in the development process are described.

1.1. Virtual Reality in General

By means of VR, an intuitive working environment can be created in which the multiple aspects of human intelligence are addressed. With sufficient perception and interaction qualities to give the user a feeling of intuitive handling of virtual objects, the following VR principles can be attained.

- Visualization, evaluation, and design of 3D objects
- Advancement of creative abilities by free design and communication of imagined objects
- Interactive demonstration of objects and events
- Mediation of (abstract) knowledge based on the user's experiences (e.g., exploring a molecular structure)
- Mediation of skills and training of behavior in dangerous situations and environments
- Knowledge mediation beyond human physical limitations (e.g., exploring how a gasoline engine functions by opening up the combustion chamber)
- Exploration of distant places or past epochs

1.2. Field of Use for VR in Engineering and Science

The main application area for VE is the simulation of objects and processes. This suggests that VE can be used as a presentational simulation technique. Aside from the presentation of perceptible sensory objects, a special use is in the expression of nonmaterial and invisible objects or in the saving of physical products. The presentation can rely on a static scene as well as on a dynamic process. With a pure presentational simulation, the degree of interaction is limited because the emphasis is on the presentation of knowledge. However, with control simulation by means of VE, the user takes a more intensive part in the events, while the qualities of presentation have been preserved. Apart from the use of control simulation for entertainment purposes, uses are in handling critical situations, controlling devices in inaccessible areas, and working with meager resources. The third application type is particularly characterized by its interaction forms, where the virtual objects are not just moved but also used for design simulation. These applications support decision making in the product-development process.

In addition to process simulation, VE systems can be used as mediators for other, generally real, objects. The purpose of presentation of any object is communication. Furthermore, VE can be used as a medium for human–machine interaction. Communication with an unreal object, such as another

virtual representation, is possible. Finally, it is possible to integrate virtual information within a real environment.

A third dimension of possible VE use is telepresence applications, which include simulations that do not take place at the application location, as well as communication. These applications are founded on real spatial distances. Application areas are differentiated into two areas: telepresence, which is a spatially distanced presentational simulation, and teleoperation, which is a type of simulation for a manipulation or design purpose.

1.2.1. Virtual Prototyping

Among other things, the duration of the development process is determined by the number of the physical prototypes that are required for evaluation of the desired product properties. Virtual prototypes are defined as a computer-based simulation of a technical system or subsystem with a degree of functional behavior that is comparable to corresponding physical prototypes (Haug et al. 1993).

The visualization of virtual prototypes calls for the processing of the data with dependence on the visualization techniques. Apart from purely realistic visualization, complexity-reducing models and symbolic visualization are used as well. Mixed models of both methods are most widely spread. Metaphors for visualization of simulation results, for example, are used in FEM analysis (overlaying of paint leveling) or the representation of paint coat thickness in robot simulation (Brown 1996).

Research activities for the evaluation of virtual prototypes with techniques of VR are encountered in the investigation of flow response of flying objects (Bryson et al. 1997) and automobile chassis. The geometry model is overlaid with the results of flow simulation such as isosurfaces or as paint particles. The user can freely move cutting planes or virtual trails of smoke. Investigation of the capability for assembling components is also found in aircraft construction and vehicle construction, including the evaluation of the free construction room available, accessibility, and the ergonomic design of manual assembly workplaces.

Apart from the evaluation of the product properties, a further-reaching use of virtual prototypes also requires consideration of the production processes of the products.

Aspects of asynchronous and synchronous object management in a distributed environment and the data models for the manipulation of lead time have thus far been in the foreground in systems for designing objects in a virtual work environment. Here, the data models are oriented by existing CAD standards or they focus on application protocols for the product data model STEP, with these protocols still to be developed. These systems are also not fully immersive, but they are monitor based in connection with relevant 3D input tools (e.g., space mouse, trackball). Handling aspects of virtual prototypes in an immersive VE have been studied, for example, at the University of Wisconsin-Madison (Dani and Gadh 1996).

1.2.2. 3D Representation of Complex Data

The 3D representation of complex data is applied to the examination of comprehensive geometry data records, such as in architecture or in the scientific visualization field, the representation of mathematically computed data. In the visualization of building data in architecture, the architect would like to walk through the virtual building together with the customer and detect design errors. Research and development work is conducted at a large number of research institutions and enterprises. The visualization of mathematically computed data has the goal of rendering simulation results visible, audible, or tactile. Outstanding work on this subject has been done by NASA Ames Research (Bryson et al. 1997). For evaluation of the outside shape of flying objects, they simulate the flow response in a virtual wind tunnel.

1.2.3. Simulation of Work Sequences and Activities

A near-reality perception (immersion) in a virtual environment is used to plan and investigate work sequences and activities. Immersion is achieved by 3D representation of information in real time by integrating several human senses, with the user perceiving himself or herself as part of the scene. The interaction differs from the input devices used so far in that direct intervention in the 3D space is possible (Durlach 1997). The goal is to adapt the work environment to human responses and physical capabilities. Simulation of the work environment and human interaction with work surroundings is necessary to produce a near-reality perception. Ergonomic investigations can be conducted with subjects without a physical test setup.

1.2.4. Substitution of Complex Physical Prototypes and Tools

Physical prototypes are used for testing and evaluation of product properties in the early development stages of product development. VR permits testing and evaluation to be conducted in virtual prototypes. The objective is to avoid physical prototypes if possible. Research is being conducted in the automotive and aerospace industries (Leston et al. 1996). Apart from purely design-oriented tasks, efforts are also being made to conduct physical materials tests, such as crash tests, in virtual proto-

types. Additional approaches deal with the production engineering view of prototypes and products up to the planning of production facilities and production plants. These also include approaches to the substitution of complex resources for the support of production, such as in the production of cable harnesses in the aerospace industry (Ellis et al. 1997).

1.2.5. Modeling and Control of Business and Production Processes

Apart from product- and production-oriented spheres of application, VR technologies are also used in product modeling and control. Research approaches can also be encountered in information technology, for the analysis and maintenance of communication networks, and in the modeling of production engineering processes.

1.2.6. Cooperation in Virtual Work Environments

In addition to spoken language, human communication is based on expression by the body (gestures) and the face (miming). Research in near-reality virtual work environments investigates human communication in immersive VR environments. This research is focused on computer-supported cooperative work (CSCW) (Pandzic et al. 1996), the mapping of human gestures and movement, and the realization of synthetic behavior of virtual human beings (Shawver 1997).

1.3. Virtual Reality in the Product-Development Process

The use of computer-based tools and methods in the development process is essential with respect to quality, time, and costs. The general business conditions are similar worldwide: product life cycles are declining drastically, and technological leadership of the highest possible quality is required in order to react to constantly increasing innovation dynamics. Engineers have to decrease the time for construction and evaluation of the prototypes. The mainly computer-based development of products using 3D CAD systems offers many advantages in optimization of time, costs, and quality, but it leads quickly to a restricted, reduced perception of the product during the development process. Therefore, digital models require an immersive VR-based working environment to improve the perception of the computer-based models.

Another factor is that new processes like rapid product development (RPD) focus on the short time between the final determination of the construction and the start of sale. Although the complexity of most products and of the product development process is growing, the first sketches must be more detailed and the basis for valid decisions should be guaranteed. Therefore, the use of VE has two main goals: to enhance the degree of freedom of predefinition and to achieve a higher level of elaboration in the early development phases for better decision support.

Therefore, the use of immersive projection technology (IPT) has two main goals: to enhance the degree of freedom of the construction constraints and to achieve a higher level of elaboration in the early development phases for better decision support. Figure 1 shows how these goals are benefitted by the use of VE.

Tools and methods that are used in VE and that permit information to be obtained about the product in the early development phases offer attractive optimization potentials (time, costs, quality) in engineering. Among other things, in the foreground here are product aspects and features that essentially permit qualitative information to be obtained (e.g., formal aspects) and can be primarily assessed by evaluation (e.g., motion spaces in connection with capability of assembly). Human interaction with the virtual prototypes and human perception and immersion in the VE is decisive for handling the tasks on hand (Figure 2). The verification of qualitative information has normally been possible so far only on the basis of real, physical prototypes.

2. DEFINITIONS

2.1. Virtual Environment

An application-orientated definition that might state the most accurate minimal demand describes VE systems as a combination of computer-based display and interaction techniques.

Ellis (1995) defines a virtual environment as a synthetic, interactive, illusory environment perceived when a user wears or inhabits an appropriate apparatus, providing a coordinated presentation of sensory information in imitation of a physical environment.

All VE applications are founded on the generation, perception, and manipulation of naturalistic or abstract virtual worlds without any physical equivalent. Objects existing within virtual worlds can possess various qualities and behaviors. Examples are graphics, sound, and force feedback. By multiple addressing of the human senses, the attempt is made to generate the greatest possible intuitiveness of virtual environments; VE can be experienced through visualization, marked out by 3D object representations and real-time-orientated interaction modes.

To distinguish VE from the multitude of computer-based visual simulation techniques, the following minimal requests must be fulfilled:

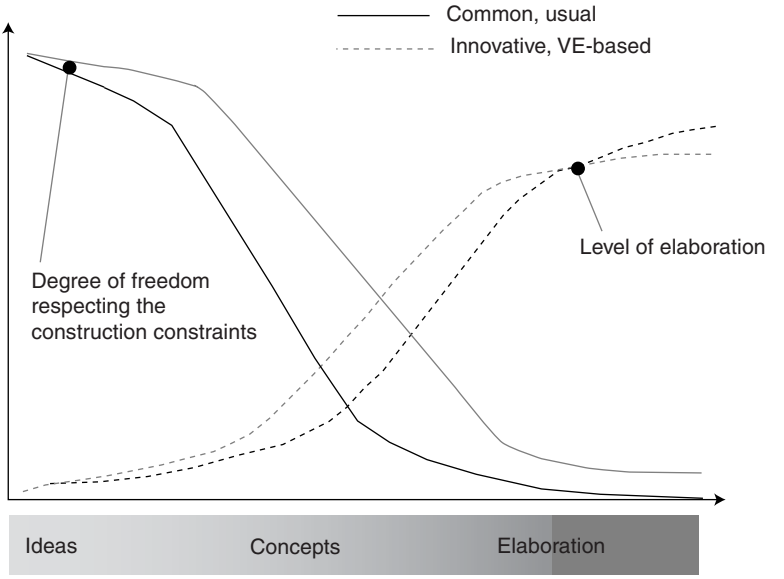

Figure 1 Benefits of use of VE in the Development Process.

- Graphical display dependent on the position and orientation of the user.
- 360° visualization complies with all three coordinate axes
- Realistic 3D behavior of the modeled objects
- The most possible intuitive interaction modes with objects, adapting to human experiences and behavior
- Object manipulation in all real or requested degrees of freedom
- Quasi-real-time-orientated object response

VE systems can be defined as computer-based information technologies for interactive, real-time orientated simulation and multisensory representation of objects, processes, and their results. With

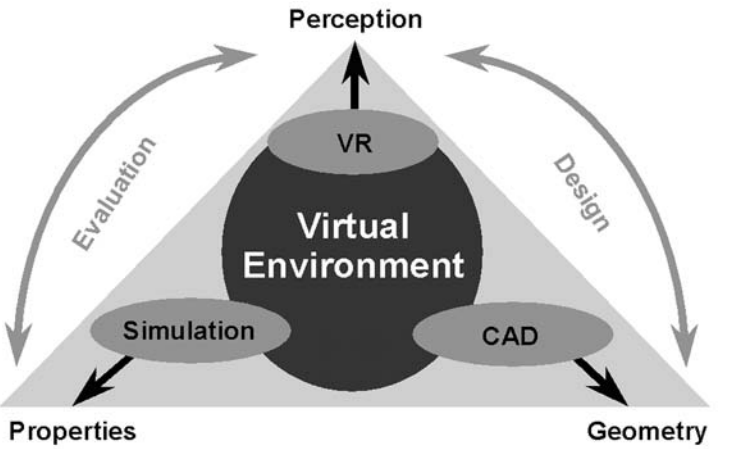

Figure 2 System for Evaluating and Designing Virtual Prototypes.

the surmounting of conventional input and output interaction forms, the user should be given the impression that he or she is situated in a virtual environment. The human's central cognitive abilities, such as the interpretation of visual data and the recognition of complex structures, are thus supported.

To describe computer-generated worlds, terms in addition to *virtual environment* have been established, such as *virtual reality, artificial reality, telepresence,* and *cyberspace*. Generally accepted is the use of *virtual reality* as an umbrella term for computer-generated, interactive 3D scenes, *cyberspace* as a place of communication connecting several users together, and *telepresence* for an experience that overcomes space and time. *Virtual reality* tends to suggest the perception of a meticulously detailed computer-generated duplicate of a natural environment. In contrast, *virtual environment* stresses the secluded nature of the application, whose abstract representations depend more on the user's ideas than on real models. *Virtual reality* suggests utopian visions, and hence for reasons of precise description, experts prefer *virtual environment*.

The degree of immersion indicates the extent to which a user is tied to a virtual environment. Immersion can be described as an opportunity for real-time-orientated perception and interaction. Immersion is characterized by the believability of the environment. Immersion has a technical dimension, a content-representative dimension, and an individual–psychic dimension. These dimensions each contribute to an immersive experience.

2.2. Digital Mock-up

Digital mock-up (DMU) is a digital product description for development, design, and manufacturing. The aim at present is to enhance the DMU in order to replace physical mock-ups with a digital one that will require only one verification prototype at the end of the design process. DMU is based on the management of a complete product model. DMU functions for the assembly, fitting, and operation of a virtual product, simulation of tolerances, ergonomics, and flexible parts will be available. In parallel, DMU checks the virtual product with regulation constraints. DMU is required to be an integral part of design systems, available from any location and from any activity point of view. Virtual reality techniques will be used for the stereoscopic visualization of the DMU.

2.3. Virtual Prototypes

Virtual prototypes are defined as a computer-based simulation of a technical system or subsystem with a degree of functional behavior that is comparable to corresponding physical prototypes. The visualization of virtual prototypes calls for the processing of the data in dependence on the visualization techniques. Apart from purely realistic visualization, complexity-reducing models and symbolic visualization are used as well. Mixed models of both methods are widespread.

2.4. Rapid Product Development

Rapid product development (RPD) shortens the feedback control cycles concerned with product data generation and the associated management processes. RPD exploits the potential of modern information and communication tools in order to support the necessary dynamic cooperation structures. Development times are systematically shortened by means of a holistic integration of man, organization, and technology. The learning processes can be systematically relocated to early product development phases. As a result of generative methods of production and virtual reality, physical and virtual prototypes can be made quickly available.

2.5. Augmented Reality

Augmented reality (AR) combines real worlds/objects with virtual worlds/objects. AR is a novel approach to the interaction between human and machine. It is possible, for example, to view information using a head-mounted display. The information is displayed context sensitive, which means that it depends on the observed objects, such as a part of an assembly. The engineer can now display job-related assembly data while viewing the real object.

3. VIRTUAL ENVIRONMENT HARDWARE AND SOFTWARE

3.1. Structure of VE Systems

In order to be able to design and use effective VE systems, it is necessary to understand the technical concepts related to virtual environments, to be aware of the limitations of the available technology, and know the design approaches that lead to the creation of successful virtual environments. Although there are many VE systems in use, areas open for research are not just the system and device design, but also the ground use concepts. The basic functioning of a VE system is shown in Figure 3.

3.2. Hardware

To create immersive experiences in VEs, VE systems integrate a combination of several hardware technologies. These technologies can be grouped under the following categories:

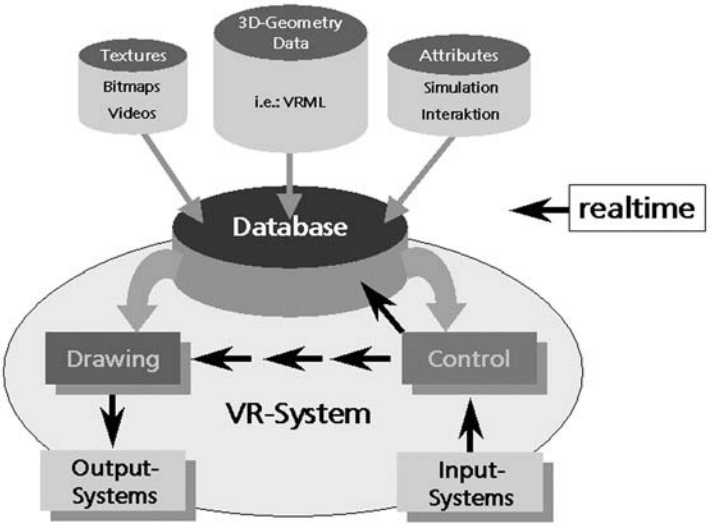

Figure 3 Basic Structure of a VR System.

- *Display systems:* present the virtual environment to the user.
- *Position and orientation systems:* track the user's position and orientation in the virtual environment. They are also used for interaction purposes.
- *Interaction and manipulation systems:* provide manipulation of the virtual environment.
- *Computation systems:* perform the computations required for the generation of a virtual environment.
- *Networks:* allow integration of several distributed user systems in one common environment.

3.2.1. Display Systems

The main elements of VE interfaces are displays that mediate visual, acoustic, and tactile sense stimuli. Of essential significance are visual and acoustic displays.

Visual displays are devices that present the virtual environments to the user. The degree of immersion given by a particular VE system depends greatly on the visual interface display. Several kinds of visual displays are currently available: monitors, head-mounted displays (HMDs), head-coupled displays (HCDs), and projection systems. All of these systems are capable of producing wide-angle stereoscopic views of the scene, although in some cases monoscopic vision is also used.

HMDs, which are the most broadly used visual displays in immersive VE systems, and HCDs place a pair of display screens directly in front of the user's eyes. In HMDs, the screens are mounted on a helmet that the user wears while staying in virtual environments. The HCD is like a pair of binoculars freely attached to a flexible swivel-arm construction, which can be easily handled by the hand through open space. Both HMDs and HCDs are coupled with a tracking system to determine the viewer's position in space. The virtual environment is displayed in stereo from the user's point of view, which serves a high degree of immersion; users are completely surrounded by the virtual environment. Other kinds of visual displays are projection-based systems. In such systems the user's position and actions are tracked and the corresponding virtual scene is projected onto large screens.

Acoustic displays can be used to provide feedback concerning the virtual environment. Sound plays an important role in localization and interaction. Due to the application of simple audio in many other areas outside of VE, it is known as a mature technology. Synthesizers creating, mixing, and reproducing sounds and systems for speech in- and output have been made available.

3.2.2. Position and Orientation Systems

Tracking is a critical component of an immersive environment. Tracking includes the measurement of the user's head position and orientation as well as the measurement of other body parts, such as the user's hand and fingers. The continuous measurement of the user's head position and orientation is of high importance because it is used to produce the correct environmental view from the user's

point of view, which is critical to obtaining a high degree of immersion. Tracking of body parts and movements allows interaction with and control of the virtual environment to take place.

In principle, tracking is suitable for any technology. Thus, the three-dimensional position and orientation of an object can be determined as free of delay and reliable. Electromagnetic, kinematics, acoustic, optical, image work processing, and inertial procedures find use for tracking tasks. Currently available body-tracking systems fall into two classes (Bryson 1993):

- *Position tracking:* devices that detect the absolute position and usual orientation of a tracker in 3D space
- *Angle measurement:* devices that detect the angle of bend of some body part; usually found in data gloves to measure the angle of finger joints

3.2.3. Interaction and Manipulation Systems

Interaction and manipulation systems are devices that allow manual exploration of the virtual environment and the manipulation of virtual objects. These devices, functionally based on a tracking system, measure the position and forces of the user's hand and other body parts and can apply forces to the user to produce the sensation that the virtual objects are real (Cruz-Neira 1993).

Interaction and manipulation devices have been classified as:

- Pointing and selection devices
- Force and torque feedback devices
- Tactile devices
- Devices to produce stimulus, such as temperature

The best-known interaction device is the data glove. After having been calibrated to the user, the data glove allows the computer to determine the user's hand gesture, such as fist, open hand, or pointing. Often the hand's physical position in a 3D space is also determined. The glove's coordinates are overlaid into the virtual environment, where the physical glove position controls a 3D virtual hand in this environment. The virtual hand can be used to pick up virtual objects, push virtual buttons, and so on (Iovine 1994). Numerous interface devices also exist, such as the free-flying joystick and spaceball, which were developed into 3D devices from conventional interface devices, as well as systems for tactile and force feedback.

Another interface technology for effective control and interaction in VEs is speech control. Speech control in virtual environments will facilitate tasks and exploration. Not tied to tapping onto a keyboard or moving, a control device will free the user's hands and add to the feeling of immersion (Iovine 1994).

3.2.4. Computation Systems

Computation systems are the computer hardware used to control the overall operation of a virtual environment. Computer hardware has to handle several tasks: generation of graphics for the scene, computation of the state of the environment, and control of input and output devices. In a VE system, all these tasks have to be integrated and synchronized.

3.2.5. Networks

Networks are used to exchange data between different virtual environments. They lay the foundations for distributed VE systems. Distributed VE systems make it possible to connect people located in different places to let them take part in a joint communication and design process. With the appropriate tools, such systems can be powerful platforms for interdisciplinary work, independent of location. This is known as computer-supported cooperative work (CSCW).

3.3. Software

An internal computer functional hierarchy exists for processing information input and generating appropriate output. Essential functions of this hierarchy are represented by the modules of modeling, simulation control, and rendering. Built onto appropriate hardware structures, this functionality is realized by software technology.

3.3.1. Modeling

The virtual world of an application is constructed principally through modeling. As a rule, object data are converted from CAD data and completed through color and surface data. In addition to geometric description, modeling also includes function modeling, beyond the CAD applications, in which the total number of functions and the geometric free degrees of a respective object are determined.

The structure of geometric objects can be described through parameters (object data). The sum of the computer-stored object data produces the internal computer representation of real objects. The mathematical model of a real object is composed not only from data structures but also from algorithms that operate on these structures. It forms the base for all built-up modules, such as simulation control and rendering.

3.3.2. Simulation Control

During VE application, the arrangement of objects is constantly calculated by putting the contents of the databases in relation with the interaction instructions of the user or the behavioral parameters of autonomous objects. Simulation control is closely linked to the communication of the data processing. The basis for coordinated running is real-time management.

Simulation requires the determination of certain functions. Therefore, interaction parameters or collision identification have to be defined. Complex simulations require very high computing performance, which may lead to bottlenecks within real-time management.

3.3.3. Communication

Communication includes data transformation, that is, the coordination of data transfer between input/output devices and simulation control as well as data exchange between users and units involved in a multiuser system.

With the data transformation, the transformation software interprets the interaction instructions of the user and passes the input commands to the simulation control, where the real-time orientated computation of the virtual environment occurs. Additionally, the data representing the virtual environment are reconverted by the transformation software into appropriate interface signals and presented as simulation output. Thus, the data transformation primarily functions to transfer data between the user interfaces and the simulation control.

Within a multiuser application, the communication coordinates the data exchange between the active participants and units involved in a network. The real-time-oriented data exchange informs all participants about relevant interaction processes as well as the actualization of the databases.

3.3.4. Rendering

The term *rendering* or *drawing* includes different procedures of the transformation of parametric data models into discrete images and sounds. Therefore, rendering is part of the communication within data processing, but due to its complexity and importance in VE it is specially dealt with. The performance requirements of real-time rendering are high. In VE applications the performance bottleneck is mostly in rendering, both visual and acoustic.

The visual presentation normally occurs with a pair of images, which must be rendered with a minimum frame rate of 20 frames/sec in order to avoid picture disturbance.

Image generation is based on lighting models, which are divided into two types: local and global. Local models take into account the reflections from single surfaces, independent of the environmental lighting situation. Global models take into account the independence of lighting and reflections and therefore seem more realistic, but they are more difficult to generate.

The acoustic presentation within a virtual environment orients itself towards the geometry and surface formation of the room being modeled. Acoustic simulation is suitable for two methods. First is the image source method, which calculates virtual sound inclusive of the reflection behavior of the surfaces being modeled. From this, the sound energy coming towards the receiver can be defined. Second, with the particle-tracing method, the transmitted sound impulses are registered by detectors, where the impulse response can be measured.

4. HUMAN–COMPUTER INTERACTION FOR VE

4.1. Visualization Basics

The light transmitted from a source reflected by an object is sent to the eyes. By refraction and collection, the light is concentrated on the retina, where the photoreceptors are embedded. The nerves are then aroused, and the signal is escorted along the optical track and analyzed by the brain. The eye accommodates itself to the distance of the object being seen. By adapting to dark and light, the eyes are able to change their acuity within a wide range. Color vision results from the stimulation of the retina by light of various wavelengths in the range of 400–780 nm.

When a 3D object is seen, a separate 2D image is projected onto each retina. The two images are converted into impulse patterns in the brain, where they are united to create a 3D object. The convergence angle between the eyes' axis and the accommodation is used to determine the distance of an object from the eye.

Visual perception is the most important for feedback in a virtual environment. Optical information is presented by optical displays. Along with the application, display devices with various inserted

performance profiles are used, making it possible to create anything from simple monochrome graphics and line models to a photorealistic rendering. The specifications of the visualization technologies, which can be varied in depending to the application, are discussed below.

4.1.1. Resolution

Optical resolution is the angular size of an object that can be individually resolved. Resolution is defined as the angular size of a picture element. Resolution increases as the angular size of the picture element decreases. Optical resolution is closely related to screen resolution, the number of pixels on a screen, which in turn determines picture element resolution. The effective optical resolution is determined not only by the picture element resolution of the screen devices but also by the optics through which the screen is viewed (Bryson 1993).

Eye resolution depends on many factors, including color, brightness, contrast, and length of exposure. On the axis, resolutions of around 5 arcmin are required to reach the region of peak sensitivity. Acuity increases rapidly as the object moves outside the central 2° region. It is principally sufficient only to provide the central field of vision with detailed pictures because the natural resolution of the eye in the periphery strongly decreases. At 10° off-axis eccentricity, acuity drops around 10 arcmin (Helman 1993).

However, the marginal areas are particularly sensitive to low light intensities and movement. To achieve natural resolution capabilities, screens with 6000 picture lines are suitable. For a convincing visual display with a field of view of 150°/60° at a distance of 250 mm, a resolution of, ideally, 9000 $\times$ 3600 pixels is recommended.

4.1.2. Stereoscopic Visualization and Depth

Stereoscopic visual presentation usually takes place using a pair of pictures with a slightly shifting convergence angle. The limit of stereo vision typically occurs at a binocular disparity of 12 arcsec. The methods of stereoscopic visual presentation can be divided into time parallels (both-eye simultaneous visual presentation) and time-multiplexed systems (non-perceptible alternating visual presentation). Time parallel stereoscopic systems produce the displacement of the optical convergence axis either by different monitors for each eye or by two half pictures differentiating in color and perspective, which are looked at through toned or polarized 3D glasses. Time-multiplexed systems insert optical or mechanical called shutter systems for the viewing of alternating pictures displayed on a monitor.

Three-dimensional visual perception through object-differentiated accommodation cannot occur with an HMD, because the monitor has a flat surface. When the eyes look at stereoscopic computer-generated imagery, their accommodation and convergence often do not match because they must focus on the screen or the image plane defined by the optics of an HMD with an angle for stereoscopic view dictated by the rendered images. Without proper calibration (or a monoscopic system), neither focus nor convergence may reflect the actual position of the virtual object relative to the viewer. Because of these inconsistencies, many users of stereoscopic systems have trouble fusing stereo images. To place the images at infinity, thereby making convergence and focus match closely for distance vision, collimated optics can be used. Computer graphics applications that do not need to depict the depth of scale acurately can artificially adjust the parallax to allow more comfortable viewing. For virtual environments requiring close-up manipulation of objects or accurate registration of virtual objects with the physical world, all variables affecting stereo viewing should be considered. Size, image distance, and overlap of the system must be chosen carefully to match the task and operation distance.

However, other solution approaches try to realize the adaptation of depth with changing of the focus. The eye's focus is measured by means of a laser beam reflected by the retina, and in consequence the depth of focus is followed by image visualization (Aukstakalnis and Blatner 1992).

4.1.3. Field of View (FOV)

Each eye has approximately a 150° FOV horizontally and 120° FOV vertically. The binocular overlap when focused at infinity is approximately 120°. With VE display devices, a wide field of view is very desirable for conveying a feeling of immersion. For HMDs a 120° horizontal and 60° vertical FOV is minimally recommended. The trade-offs for higher FOV are lower effective resolution and usually more distortion in the periphery of the picture. Distortion can be avoided by using complex optics. However, distortion is a big problem with see-through HMDs because the world provides a reference for ''straightness''. With the relatively small FOVs of HMDs, large overlaps of more than 50% have been found useful.

4.1.4. Brightness and Luminance

Including dark adaptation, the eye has a dynamic range of around seven orders of magnitude, far greater than any current display device. The eye is sensitive to ratios of intensities rather than to

absolute differences. At high illuminations the eye can detect differences in luminance as small as 1%. Brightness is a basic precondition for the perception of objects.

Brightness is the available luminance for each picture element. A typical HMD based on a cathode ray tube (CRT) can display no more than about 400 perceptible luminance levels. Sufficient brightness is particularly a problem for liquid crystal displays (LCD).

In order to minimize disturbing light conditions and differences of contrasts between the physical environment and the virtual simulation, high brightness is especially important for see-through HMDs.

4.1.5. Contrast

Contrast is the dynamic range of the luminance that the display supports. Contrast is important to the perception of structure in an image. Low-contrast systems are difficult to interpret. Low-contrast and low-brightness displays do not serve a high degree of immersion. With use of screen displays, a 5:1 contrast ratio for scenery and 25:1 for light points is recommended.

With LCDs, the display brightness and contrast depend greatly on the viewing angle. The display viewing angle is characterized as the angle between the normal to the display surface and the line between the center of the display and the user's eye. For high image quality, the viewing angle should be as small as possible.

4.1.6. Color Saturation

Color is a significant feature of visual images. The quality of color can be characterized in terms of the decomposition of a color signal into three primary components. Usually these components will be red, green, and blue, the primary colors, measured by their luminance. Alternatively, color components could include the hue, luminance, and value components.

In display systems, color is usually attained by grouping pixels into sets of color components. For example, a red pixel, blue pixel, and green pixel are grouped into a triple that comprises one full-color picture element. While this method works when the optical pixel resolution is very high, in wide-field displays the individual component pixels are easily individually visible. Another method of attaining color, called time-multiplexed color, is to use a monochromatic display screen with three rotating colored filters, one for each primary color. According to the activated filter, the monochromatic image with the illumination of the correspondent colored filter is displayed.

The quality of the color signal depends on several aspects, such as quality of color component pixels. The dynamic range of the luminance value for each component will determine the full range of colors that can be achieved.

Apart from color displays, monochrome displays are in use for several purposes. In general, monochrome displays offer higher resolution for an equivalent price.

4.1.7. Masking

A display quality issue closely related to color is the problem of masking, or nonabutting pixels, which occurs when the pixels are separated by a blank space. Masking is a problem because wide-field optics magnify the display screen and so magnify the space between the pixel elements. To avoid the problem of visible pixel elements and masking, the image in wide-field displays is often intentionally degraded, which is usually done by a diffusion screen that blurs the pixel.

4.1.8. Performance

In order to avoid picture disturbance, the frame rate must at the least be 20 frames per second. The frequency at which modulation is no longer perceptible varies from 15 Hz up to around 70 Hz for high illumination levels. Bright displays with large FOV can require frame rates up to 85 Hz. In order to minimize movement dizziness, the perceptional latency must be below 0.1 seconds.

4.1.9. Refresh Rate

The refresh rate is the time required for the picture elements to change state (on or off). These times need not be the same. Typically, a pixel takes longer to go off than to go on. If the refresh time of a pixel is too long, ghosting effects will occur in rapidly changing images.

4.2. Visualization Systems

Depending on the grade of immersion and the extent of the interactions, graded concepts from fully immersive VEs down to extended reality can be realized. VE applications for entertainment purposes are intended principally to simulate secluded fantasy worlds. Although development at the beginning relied almost exclusively on fully immersive concepts, today, because of the shortcomings of those concepts, an increasing number of partly immersive VE system applications are being developed.

4.2.1. Fully Immersive VE

With a fully immersive VE, the user wears a head-mounted display (HMD) equipped with headphones and a visual stereo display directly in front of the eyes. The user is visually and acoustically sealed off from the physical environment and primarily perceives impressions the virtual environment.

HMD fully immersive display is made up of two color monitors that project the image directly in front of the eyes and a lens system that widens the image to the natural field of view. Because the convergence angles, the screen arrangement presents a certain appearance of depth.

4.2.2. Projection VE

With projection VE, stereo pictures are projected by means of a special projection system onto surrounding walls. Projection VE systems allow the user a higher degree of free movement because 3D glasses are the only device that has to be worn. Such a system make it possible to link up several users within a VE application. However, orientation and interaction within the virtual environment is more difficult because of the system's low grade of immersion.

For an example of projection VE, see Cruz-Neira et al. (1992), who describe the CAVE system (Audio Visual Experience Automatic Virtual Environment).

4.2.3. Augmented Reality

With augmented reality, semitransparent data glasses are used, which make it possible for computer-generated objects and information to be linked by superimposing them with the perception of the physical environment. Parts of the physical environment remain perceptible at the same time that virtual elements contribute to an enrichment of information.

4.2.4. Monitor VR

In contrast to immersive VE systems, monitor VR portrays a low-priced alternative for 3D visualization of virtual worlds. As with projection VE, the user wears 3D glasses, which give him or her a steroscopic view of the virtual world on a monitor. The user's head movements are measured by a tracking system. The tracking data are acquired by the computation of the orientation-dependent displayed vision. Monitor VR makes the viewing of virtual objects from different directions and distances possible. A decided advantage of monitor VR over fully immersive VE is the possibility of simultaneous interaction with the physical environment. In addition, in contrast to head-mounted displays, present monitors make substantially higher visual resolution available. Because monitor VR is limited to a visual frame, only a slight feeling of immersion is possible.

4.2.5. Responsive Workbench

Responsive workbenches enable direct interaction with virtual objects appearing in physical environments. At a responsive workplace, several users move around a table with a glass top. By means of stereoscopic visual projection from the under side of the table, 3D virtual objects are constructed that appear to the users as if they were resting on the workbench. The users perceive the virtual object and the workbench as well as the individual person and colleagues. Responsive workbench applications are used in medicine and architecture (Krüger and Fröhlich 1994).

4.3. Methods for Human–Computer Interaction

Foley and Silbert (1989) define a human–computer interface as the determination of all user inputs into a computer, the determination of all computer outputs to the user, and the determination of sequences of inputs/outputs made accessible to the user.

The fundamental design principle of VE interfaces is to support human mental processes through an extensive communication and interaction environment and therefore increase the range of human handling and decision making. Following from these principles is the reduction of the degree of enforced handling sequences and the use of a computer for establishment and expression of relations. According to Brooks (1988), from these principles the following differentiated design criteria for the development of user interfaces and computer-based tools comply with ergonomic system design can be derived:

- Three-dimensionality of the modeled objects
- Direct manipulative and intuitive interaction instead of formal interaction
- Interactivity rather than sequence professed routines
- Multisensory stimulation rather than purely visual perception

These requirements derive from the basic idea that human–computer interaction should be comparable to human communication by means of speech, gestures, or body movements. For human access to a computer, all the human sensory channels should be included in the interaction, if possible.

The principal technical challenge in the design of interactive VE systems is in the development of human–computer interfaces, which make it possible to convert internal data structures into sensory-perceptible representations that possess consistent and (for the user) understandable behavior. In the same way, development of devices that translate human movements into computer commands.

In the context of VEs, generic modes of human–computer interaction can be classified into formal language interaction, natural language interaction, direct manipulative interaction, and gesture interaction. These interaction modes are complemented by combined interaction.

4.3.1. Formal Language Interaction

Formal interaction languages are classified into programming languages, command languages, and formal query languages. With command languages, the meanings are predominantly laid down in the vocabulary. An accurate, distinguished volume of available commands and parameters exists. The meaning of a command arises from the sequence and the relative position within an expression. Interactions based on formal languages are technically effective but are unfamiliar to most users. Because formal languages must be learned before they can be used, they are suitable only for a limited number of users. Programming languages are established for system implementation and form the basis of all other interaction languages.

4.3.2. Natural Language Interaction

Natural language systems can use conventional methods of electronic data processing or interfere with knowledge-based systems. In the framework of human–computer interaction, natural language is an adequate means for expressing references to objects, actions, and abstract facts. Natural language offers possibilities of expressing things that can be expressed by other forms of interaction only incompletely or with a large expenditure. The use of natural language in user interfaces increases the number of possible users considerably, particularly unpracticed users. Spoken language, however, changes quickly and cannot be called up in format as written language can. When analyzed, natural language proves inefficient and inaccurate and is manipulable and applicable only with selected dialogs.

Natural speech interaction occurs by means of appropriate input/output speech devices. The technical precondition for speech input/output is voice recognition. Voice recognition systems are classified into speaker-dependent and speaker-independent systems. Speaker-dependent systems, which are capable of achieving a high command count, are trained by the individual who uses the system. The most common drawback of this approach is that the system responds accurately only to the individual who trained the system. A speaker-independent system is trained to respond to a word, regardless of who is speaking. Therefore, the system must respond to a large variety of speech patterns of the target word. The command word count is usually lower than the speaker-dependent word count (Iovine 1994).

Special hardware and software for speech output exists that enables one great amounts of acoustic information to be efficiently stored and reproduced. As yet, the quality of synthetic speech is insufficient because the generation of correctly accentuated and pronounced speech has not been satisfactory achieved.

4.3.3. Direct Manipulative Interaction

Direct manipulative interaction techniques, which are applied with graphical user interfaces, make use of familiar metaphors of daily life. The dialogue of direct manipulative interaction techniques is based on a permanent visual presentation of all relevant objects and function undertaking by single-stage reversible operations. The impacts of actions on the relevant objects are received on a direct visual feedback. Direct manipulative systems make easy learning, use, and extension of system functions possible. The syntax of direct manipulation shows a clear, standardized structure of objects, functions, and attributes. The steps of dialogue with direct manipulation are slight in their complexity and range, as with natural or command languages. Disadvantages of direct manipulative systems are high implementation expenditures and the impossibility of activating objects that are nonvisible on a graphical user interface.

4.3.4. Gesture Interaction

Gesture interaction can be defined as a command-based tool kit that allows the user to interact through nonverbal, nonsymbolic commands and instructions, using gestures, hand signals, and movements. A special kind of gesture interaction is manual interaction. Manual interaction forms are distinguished by grips and movements of virtual objects, corresponding to a physical environment. With the application of natural and intuitive gesture interaction modes, improvement of efficiency of human–computer interaction is aimed at.

The naturalism of gesture interaction forms results from the inclusion of human sensory characteristics and abilities as well as the integration of gestures, which have been culturally conditioned. The quality of a gesture, in particular manual interaction, is orientated towards maximal usability of adaptability and dexterity of the human hand. Consequent allocation of hand movements and accompanying actions contributes to the understanding of gesture interaction.

Gesture interaction makes the specification of certain commands and parameters with high expressive abilities possible—for example, pointing out directions, gripping objects, controlling complex kinematics movements, and parameterizing object qualities. Trivial gesture interaction is easy to learn and does not assume linguistic knowledge. A further advantage is the directness of gesture interaction, in that the hand serves as an immediate medium.

With gesture interaction, every command must be represented by a certain hand gesture clearly distinguishable from other gestures. Particularly for complex commands and control processes, not enough gestures are available, so that gesture interactions based on arbitrary gestures are inefficient. Discrete values and vague expressions are scarcely. Complex gesture interaction, such as for shaping and design applications, has proven somewhat inaccurate and applicable only with selected commands.

In addition, for gesture interaction within the control process, sensory feedback is an essential decision-making criterion.

4.3.5. Combined Interaction

Combined forms of interaction do not represent generic interaction modes, but rather an application-oriented combination of existing interaction modes, primarily gesture, direct manipulative, and speech input.

The isolated use of some interaction modes often leads to a one-sided application and performance profile. With the symbiosis of gesture-based, natural language and direct manipulative forms of interaction, the scope of human–computer interaction and the functionality of the information input can be increased, making it possible to maximize usability and efficiency.

The interaction modes applied within virtual environments in the historical context of human communication are not new. In fact, the tendency to limit communication to screen and keyboard, driven during the last decades by computer technology, will be reversed and communication will be shifted back to a human standard.

5. VR APPLICATIONS

5.1. Virtual Prototyping

Prototyping includes numerous technical, methodical, and organizational measures, from concept formulation to a finished draft. In the face of increasing task complexity and shorter innovation cycles, the various requirements, design areas, methods, and planning participants can however only be integrated in a common development, design, and communication process with considerable computer support. For this task, computer-based planning and design tools are needed that possess a high degree of stimulation at their human–machine interface. VE technologies are well suited as the methodical foundation for the prototyping.

5.1.1. Immersive Design Review

3D CAD systems generate continuous surface and volume descriptions often referred to as solids. VR rendering systems deal with polygons or, in some cases, voxels. The process of converting CAD data to VR data is called tessellation. Tessellators exist for all major CAD formats, including the neutral formats IGES, VDAFS, and STEP. Different problems occur with this conversion:

- Insufficient model quality (wrong-side normals, cracks through not considering topology, LODs too coarse)
- Unneeded model complexity (wrong SAG values, improper algorithms, tessellation of invisible details, LODs too fine)
- Poor image-rendering performance (poor culling structure, missing LODs, unneeded model complexity)
- Missing data structure (loss of logical structure, trade-off to culling structure)
- Typical CAD conversion problems with neutral formats such as IGES or VDAFS.

Data exchange properties other than geometrical ones (surface description, constraints, kinematics, etc.) is by no means standardized. Importing those properties into a VR system currently requires a proprietary interface. However, for consistent and efficient work, all properties considered need to be imported and altered definitions need to be sent back to the CAD system.

Performance problems with complex model data will likely be handled by intelligent software algorithms (occlusion culling, motion LODs) in the near future.

One example of CAD data visualization is the virtual design review, which is used to evaluate, compare, and optimize exterior car designs in very early stages of the development process. The benefits gained are clear: saving physical design models can dramatically reduce time and costs. In Figure 4, a picture of a nonexistent car can be seen. Key factors for the designers in this type of application are very realistic rendering, especially of surface properties (in this case SGI′s ClearCoat technology), and the ability to render a very high number of polygons.

Scaling accuracy and high resolution for good visual perception are another must. This example was created using the Fraunhofer IAO software Lightning (Blach et al. 1998). The application properties and demands here are:

- *Goal:* evaluation of design/surface/proportions
- *Data:* surface geometry (very complex), surface appearance (very realistic)
- *Visualization:* highest possible projection quality, 1:1 scale, medium field of view power wall or CAVE (especially for interior models)
- *Graphics power:* highest possible
- *Application level:* basic

Of course, it is not possible to replace all physical design prototypes with virtual ones, but even saving of one physical prototype represents a great success for the first generation of virtual design

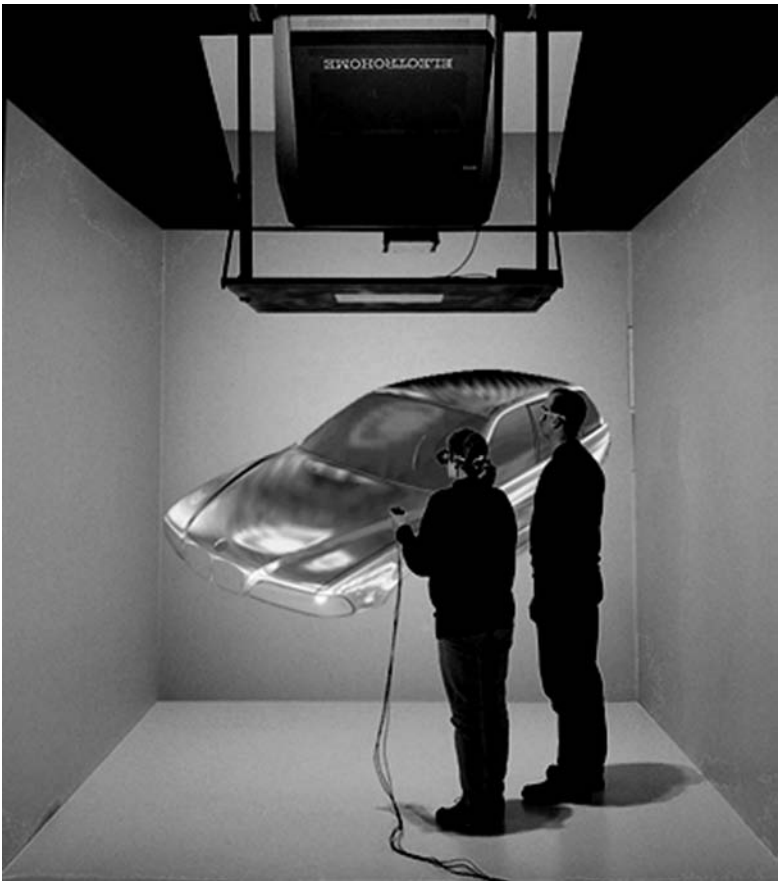

Figure 4 Example of Immersive Design Review.

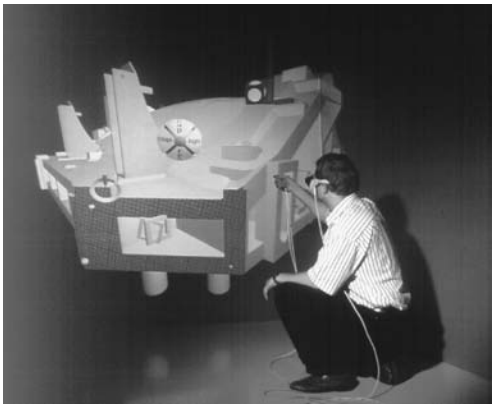

Figure 5 Tool Evaluation.

review tools. High-resolution power walls matching a 1:1 scale model seem to be the best output device here.

5.1.2. Tool Evaluation

The main task in this application example was to give specialized engineers a tool for improving the construction and evaluation process with sheet metal forms. The application was developed by Fraunhofer IAO for BMW:

- *Goal:* evaluation of CAD data
- *Data:* surface geometry (medium sized, CATIA solids), surface appearance (simple)
- *Visualization:* medium field of view, 1:1 scale, medium projection quality, single-wall rear projection or multiwall rear projection
- *Graphics power:* medium
- *Application level:* complex

The evaluation of tools can, in some cases, be greatly simplified by completely replacing the physical prototype with a virtual one.

Automatically creating a VR data set from the CAD solids reduces the preparation time for a tool review session to minutes. The required level of image-rendering speed and projection quality in this special application is medium, so the actual IPT system is moderate in price.

Special care has been given to creating an easy-to-learn, easy-to-use, and therefore simple interface for end users working with the application up to six hours a day. The main functionality of the application is as follows:

- Cutting of the data to explore collisions, etc.
- Annotation function to mark critical areas
- Snapshot function for automatic documentation (creating HTML pages for the intranet)
- Movie player for animating FEA data
- Virtual light source with dimmer function
- Measurement of sizes and angles

5.1.3. Immersive Postprocessing

The field of simulation (mostly FEM and CFD) deals with engineering and the natural sciences, which in many cases are to complex to be discussed exclusively on the basis of numerical values or texts. Multidimensional data sets need adequate visualization and presentation. An interdisciplinary discussion of simulation results is supported by a spatial, multidimensional representation of the data using VR-based techniques. An example of an industrial VR-based postprocessing application can be seen in Figure 6, where the thermal comfort in a car cabin is analyzed by examining the results of a stationary fluid flow simulation (using STAR CD).

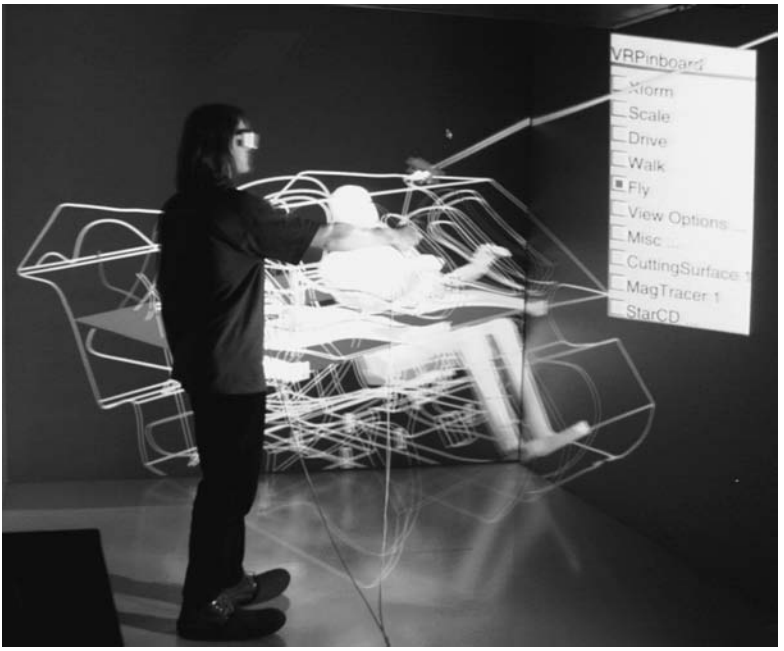

Figure 6 Fluid Dynamic Visualization in a VE. (*Source:* HLRS and Fraunhofer IPA)

- *Goal:* visualization of simulation results
- *Data:* surface geometry (simulation meshes), surface appearance (simple), visual appearance of simulation data (high resolution, medium quality)
- *Visualization:* high field of view, variable scale, medium projection quality CAVE
- *Graphics power:* high
- *Application level:* complex

The software used, COVISE (Rantzau and Lang 1998), is in principle based on a data flow paradigm found in visualization packages. In contrast to most pure data flow packages, COVISE uses the concept of data and function objects (modules) that can be arbitrarily distributed across machines. The data objects are transferred between hosts using special request broker modules (one for each host). A central controller module is responsible for proper synchronization and execution of a module network constructed beforehand in a visual application builder.

5.2. Process Simulation/Factory Planning

Near-reality perception (immersion) in virtual environment is used to plan and investigate work sequences and activities. Immersion is achieved through 3D representation of information in real time by integrating several human senses, with the user perceiving himself or herself as part of the scene. The interaction differs from input devices used so far in the possibility of direct intervention in the 3D space. The goal is to adapt the work environment to human responses and physique. The simulation of the work environment and the interaction of humans with their work surroundings is necessary to produce a near-reality perception. It is possible in the surroundings to conduct ergonomic investigations with subjects without a physical test setup.

Figure 7 shows a snapshot of a robot simulation for an automotive welding cell, DaimlerChrysler A-Class manufacturing plant in Rastatt, Germany. This application is based on the Fraunhofer IAO software Lightning attached to a kinematics simulation package from Fraunhofer IPA:

- *Goal:* visualization of the production process
- *Data:* surface geometry (medium), surface appearance (medium), logistic data kinematics
- *Visualization:* highest possible field of view, 1:1 scale, medium projection quality CAVE
- *Graphics power:* high

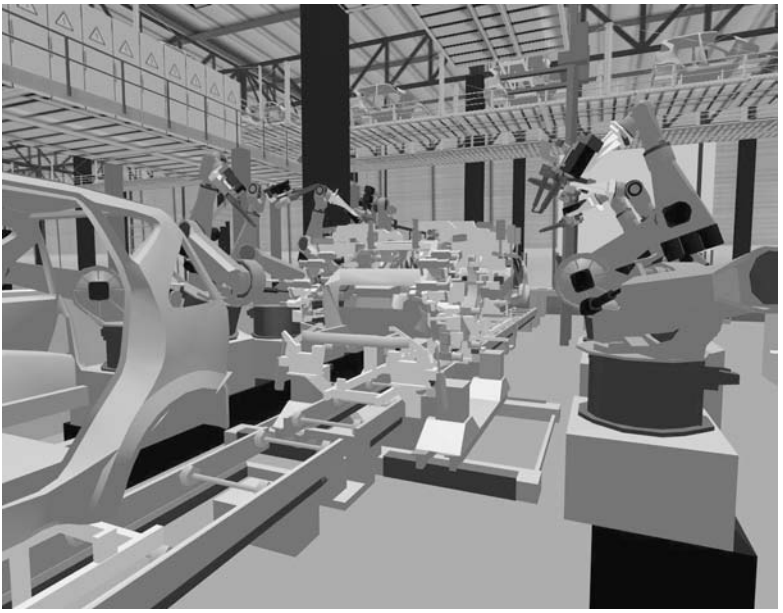

Figure 7 Robot Welding Cell of a Production System. (*Source:* HLRS and Fraunhofer IPA)

- *Application level:* advanced

The immersive visualization of production and workflow simulations greatly increases the clearness of the production cycles and helps to identify problem areas quickly. Therefore, a large field of view is essential. The ideal IPT system used here is a CAVE-like multiwall projection system. Currently, most of these applications are used for presentation purposes only. Offline teaching of robots in VR poses a number of problems, most involving accuracy and usability.

5.3. Education and Training

By means of virtual environments a learning context can be created where the multiple aspects of human intelligence are addressed. With sufficient perception and interaction qualities to give the learner a feeling of intuitive handling of virtual objects to the learner, the following VE applications are possible in the area of apprenticeship.

- Interactive demonstration of objects and events
- Mediation of (abstract) knowledge based on the user's experience (e.g., exploring a molecular structure)
- Mediation of skills and training of behavior in dangerous situations and environments
- Knowledge mediation beyond humans physical limitations (e.g., exploring how a gasoline engine functions by opening up the combustion chamber)
- Exploring distant places or past epochs
- Advancement of creative abilities by free design and impart of imagined objects

The use of VE systems in teaching, education, and training can be very effective because it agrees with the psychological and pedagogical knowledge, which is that the greatest success in learning can result from the practical application of educational programs and case studies. The success of learning can be increased by parallel addressing which means frequently changing the sensory channels, and by the inclusion of the learner's own actions. Concentration and learning success increase when thinking structures are fixed in the imagination or the ideas of a third person are made intelligible.

Particularly in the artistic field, VE should contribute to supporting students' creativity. In addition to this, when VE is is used in language education, the simulation of a suitable environment will make the learning of a foreign language more intensive and therefore more effective.

5.4. Scientific Visualization

The 3D representation of complex data is applied to the examination of comprehensive geometry data records and, especially in the scientific visualization field, the representation of mathematically computed data. The visualization of mathematically computed data has the goal of rendering simulation results visible, audible, or tactile.

6. PROCESS INTEGRATION OF VR APPLICATIONS

VE must be integrated in the development process with respect to the available 3D geometry database, the communication structure between departments, and the specific characteristics of the product.

The use of VE-based tools in a virtual immersive work environment with real-time capability speeds up finding and reviewing concepts in the early stages of the development process. Product aspects and features of prototypes can be examined in the virtual environment that so far have been verifiable only in real, physical prototypes (Figure 8). For this purpose, product aspects and features can be represented directly or indirectly by means of metaphors. In a passenger car, for example, the shape and the room required by individual units are directly presentable product aspect and features, in contrast to the dynamic load of the chassis (which is indirectly presentable by means of metaphors). Connecting these steps in the early development with quality, time, and cost management will create several advantages.

6.1. Analyzing Engineering Tasks for VE Applications

The field of engineering, apart from planning tasks, above all handles complex contents of engineering and the natural sciences, which will be discussed in the global engineering network on the basis of CSCW in the future. Unlike planning tasks, engineering and the natural sciences can in many cases not be discussed exclusively on the basis of numerical values or texts. Frequently they involve complex, multidimensional problem scopes. Therefore, a discussion of these subjects is supported by a spatial, multidimensional representation of the contents.

The major weak point of the computer-assisted simulation and design tools that have been available so far is that ideas of 3D geometry and/or functions are handled by 2D input/output media. This disadvantage is intensified by the growing complexity and multidimensionality of the problem at hand. A thoroughly interdisciplinary discussion of the scope of the problem is hampered by the existing tools, which are usually very specialized, whereas the multisensory and immersive systems of virtual reality (VR) support quick and interdisciplinary visualization of contents.

The use of conventional computer systems in such complex processes as the design of product shapes or the evaluation of assembly processes requires the user to have a great ability to think in abstract terms. To provide more intuitive access to these problem scopes, the problems can be handled in a VE.

Virtual prototypes (VP) are defined as a computer-based simulation of a technical system or subsystem with a degree of functional behavior which is comparable to corresponding physical pro-

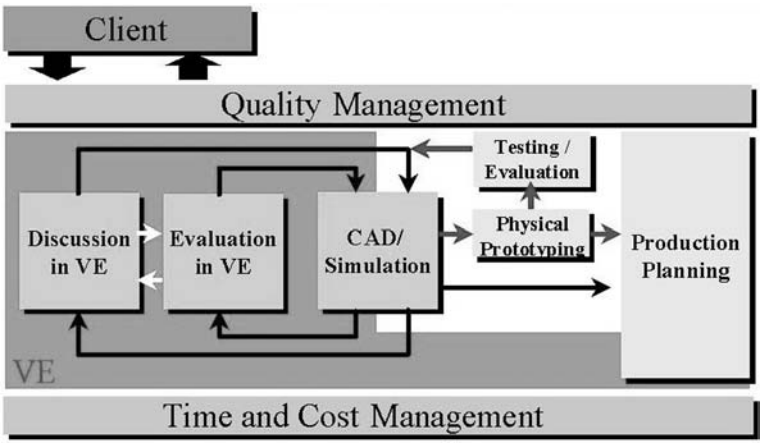

Figure 8 Use of VE in the Development Process.

totypes (Haug et al. 1993). Practically speaking, VP is a 3D graphical representation of an object that can be manipulated in its geometry, surface, behavior, and other degrees of freedom in real time. The source of the information can be parts from the traditional design process, such as hand-made models and drawings that are digitized in all their features, such as by 3D laser scanners with videocapture capabilities for catching surface information. Another option is the use of digital databases, which can store nearly everything from CAD files on materials and colors up to rules and standards for the generation of a new virtual prototype. Because all the data used inside the virtual prototype are digital, changes to the virtual prototype can be reflected quickly in the digital model without physical effort. This same model can be used in different ways to get feedback on various aspects of the design and its performance.

Are there any specific characteristics of the tasks that guarantee a maximum benefit when using immersive VR systems, or rather an IPT system? If we analyze engineering tasks focusing on the use of immersive projection environments, we should do so with regard to aspects of the following areas:

1. Representation of the product (model, prototype) and the user
2. Communication between users about the engineering task
3. The Engineering task itself

In addition, we have to check our requirements for costs, quality, and time. For costs, key words are investment, the costs for physical models, the assessment of earlier time-to-market, decision support through more realistic models, and checking of customer acceptance of reduction of risks. The quality can be enhanced through more variants (digital mock-ups), the integration of implicit know-how (as well as experience) by assessing the digital models, and the reduction of bugs early in the development process. This can also be a relevant factor in shortening the time of the whole development process, in addition to there being fewer real prototypes necessary and the digital manufacturing process needing less time to achieve the final quality of the series.

Most tasks can be done by transferring the tasks in immersive VR systems. Therefore, the user can choose different IPT systems based on the tables above. But each task has its own specific characteristics and has its specific benefits. Below are some typical tasks based on examples and experiences regarding benefits:

- Visual evaluation of the form
- Visual evaluation of the position of different parts
- Visual evaluation of proportions
- Assessment of surface quality
- Evaluation of color concepts
- Evaluation of colors
- Modification of geometry
- Modification of colors/textures/material appearance

TABLE 1 Ranking of IPT Task Requirements

		CAVE-Like	Power Wall	Benches	HMD	HCD
Scale	micro	+	0	+	+	+
	1:1	++	+	0	+	+
	macro	++	++	−	+	+
Simulation of human activities by the user		++	0	0	+	−
Immersion of the user in the VE		++	+	−−	+	+
Immersion of the user in the product		++	0	−−	+	+

−−: not possible
−: not suitable
0: possible
+: suitable
++ : very suitable

- Assessment of kinematics
- Auditory evaluation

Tasks that allow visual spatial perception for a subjective assessment of product characteristics are especially convenient for the use of immersive projection environments. Tasks with high complexity (especially in spatial aspects) that have to be discussed in an interdisciplinary team also have interesting advantages for using VR.

Because we use visual perception especially in immersive projection technology (IPT), we have to ask which product characteristics we can assess there. The product characteristics for which we can achieve reliable assessment differ between the real world and a virtual environment. Therefore, Table 2 ranks characteristics and their relative usefulness for direct representation and assessment in the different IPT systems.

The goal of digital mock-ups is the assessment of products early stage in the development process. For direct assessment, the digital mock-up should have nearly the same characteristics as the final product. But if we think only in such a direct way of assessment we get only a small part of the possibilities and advantages of digital mock-ups. As in other fields of science and technology, we have to learn to think of assessment in an indirect way. That means that it is not possible to measure or assess a specific parameter or characteristic of the product, but it is possible to measure or assess a number of other parameters or characteristics from which we can derive the specific characteristic. With the less useful ranked characteristics in Table 1 we should try this strategy of substitution or indirect assessment. Therefore, we have to look for adequate metaphors.

6.2. Requirements from the Engineering Side

For a quick development process, the definition of geometry must be, in principle, closely linked to the evaluation of particular product features that are influenced through geometry. For this reason, design and evaluation form iteration loops that reach a higher level of design of the prototype after each iteration step. The tools necessary for executing of the described tasks in the virtual environment are being researched, conceived, and developed within the scope of the subproject. In addition to the tools for design and evaluation, communication and cooperation in the virtual environment are primary requirements. Within this subproject, the fundamentals of the representation of the actor are researched. The representation model, which is based on the above-mentioned fundamentals, is integrated into the virtual working environment. The tools for design and evaluation are the basis for an interdisciplinary project by experts on the basis of CSCW in a virtual working environment. A user guidance system adapted to this environment has to be developed for system control.

The advantages of VE are:

- 1:1 scale
- Immersion

TABLE 2 Ranking of Product Characteristics with Respect to Representation in IPT

		CAVE-Like	Power Wall	Benches	HMD[a]	HCD
Geometry	Form	++	+	+	+	+
	Continuity of the surface	+	+	++	+	+
	Proportion	++	+	0	0	0
Material	Color	0	0	0	+	++
	Surface structure		+	0	+	++
	Haptic characteristics	−−	−−	−−	0[b]	0[b]
Kinematics		++	+	+	+	+
Acoustics		++	+	+	+	+
Functionality	User interface	+[c]	0[c]	0[c]	−	−−
	Physical effects	−	−	−	+[d]	0[d]

−−: not possible
−: not suitable
0: possible
+: suitable
++: very suitable
[a] Especially LCD-based HMD in comparison to CRT-based BOOM/PUSH.
[b] In combination with a force feedback device (i.e., PHANTOM).
[c] In an augmented reality environment.
[d] In combination with special systems for physical effects (i.e., temperature device).

- Interactivity
- Intuitiveness

3D visualization from the individual line of sight and the most varied interaction possibilities through gestures, speech input, and new input/output media are still to be developed. As a result of the free positioning and scaling of the user inside and outside the object to be planned, it will be possible for a large number of persons to work simultaneously on an object. The object will not have to be broken down into its elements.

Taking advantage of a new process chain the whole process of product development and product improvement can benefit, like other fields of work, from VE-based tools:

- Reduction of cost and time for building prototypes, making it possible to test and evaluate more variants,
- Faster testing and evaluation through virtual testbeds
- Scalable test persons
- Online changes of parameters
- Enhancement of quality and effectiveness of project drawing and design performance
- Improvement of the product quality, e.g., by integrating the customer earlier and getting better feedback from the customer
- Better ecological balance through saving resources during iteration cycles

6.3. Data Requirements

3D CAD data consist of continuous area and volume description and can therefore not be used directly as a VR database. The data have to be transformed in a polygonal database by a process called tessellation. For most of the current proprietary CAD formats there are one or more data filters, called tessellators, that can also be used for generic formats such as IGES, VDA-FS, and STEP. But the best way in general is as close as possible to the generated data from CAD or other modeling tools.

Aspects of the VR database include:

- *Geometry:* continuous (CAD, STEP, IGES, etc.), discrete (polygons, voxels, STL, VRML, etc.)
- *Surfaces:* textures, reflection properties, acoustic properties
- *Kinematics*
- *Material properties*

The most important guideline for tessellation is variation of the chordal height. This value indicates the maximum permissible variation of polygon data from CAD data. However, this guideline does not fix the tessellation. There are many tessellation algorithms that can guarantee such a maximum variation. From a VR point of view, the quality assessment of the data produced concentrates on the following criteria:

- The number and kind of the produced polygons are directly linked with the frame rates achieved by visualization.
- The maintenance of the topology of CAD objects guarantees the avoidance of cracks and other inconsistencies in the VR database.
- Only the indication of correct normals in every point of polygon representation enables the correct assessment of the tessellated surface.

Most tessellators are applications within the CAD system and not independent data filters on the demand line. The reasons are as follows:

- Some relevant information is stored in proprietary CAD data only as a reference in library data of the CAD system. The tessellator must have access to these data.
- The same CAD systems on different basic programs may produce different data with the same geometric information (e.g., codepage problem with CATIA)

Tessellators of generic data formats such as IGES and VDA-FS can work on a stand-alone basis because all necessary information is contained in these data.

6.3.1. Partitioning of VR-Data Preparation

The preparation of the database (especially the 3D Geometry-inclusive attributes for surfaces, kinematics, etc.) should be distributed to the departments where the data are generated. This means that every user of the IPT system is responsible for its own VR data. The know-how for generating VR data must first be taught.

Usually there are several strategies for generating VR data, and a compromise should be made regarding the visual quality (degree of detail of the objects) and the performance of the application. This decision could best be optimized by the users who are responsible for the results.

Apart from pure geometrical information (points, polygons, normals) detailed surface information such as color, material (in the understanding of VR), and texture are needed in order to visualize CAD data close to reality. Many CAD systems already offer the possibility of defining such properties in a CAD record. However, in construction this is often ignored. The evaluation of such information, if available, is not carried through by every tesselator.

6.3.2. Material: Color, Textures

To deposit geometric data with color and material qualities is not a difficult problem and can be automated if the parameters are known. Because with every CAD construction the material in use is determined, it would be relatively simple to construct a valid databank that can link VR material qualities with material or equipment. The information needed could then be extracted from this databank, in principle. The challenge is integration in a PDM system. Therefore, the data structure of the VR objects should be designed to be flexible and modular.

The use of textures offers the possibility of reproducing surface qualities such as roughness in a VR system. How far this process can be automated must be examined. Probably it does not make sense to replace CAD geometry as low LOD stage by textures.

6.3.3. Performance Optimization

There are several aspects of performance optimization. In the construction process the tessellation of the CAD data is one example. The number of polygons produced determines the speed of real-time visualization. The finer the tessellation, the worse the graphic performance.

One problem in controlling the complexity is the goal in tessellating. In general, it is not possible to set the number of polygons that have to be produced (= complexity of VR databases) in advance but a quality criterion, namely the variation of the chordal height, is set in advance. This is ideal from the user's point of view. The estimation of a resulting polygon number from only the variation of the chordal height is extremely unreliable. In order to use the complexity as a line function, the tessellator has to be iterated until the desired complexity is reached.

However, the tessellation algorithm used has an even stronger influence on the complexity than the variation of the chordal height. If one follows the argument of the developers of OpenGL Optimizer (SGI), huge differences in complexity of the variation of the chordal height are possible. It is therefore not unrealistic to minimize the database to 20% by determining the CAD topology and total analysis of CAD surfaces. The challenge here is also integration in a PDM system where different models for high-end IPTs, desktop visualization, video-based animation, printing quality, and so on can be managed.

6.3.4. The Training Concept

It is well known that CAD requires a great deal of training, especially 3D CAD. Although the functionality of the current IPT-based tools is less complex, their handling must be taught.

Table 3 gives a brief overview of the migration from existing applications. Because a migration strategy depends very strongly on the available products, we show here only a very abstract version of migration.

7. CONCLUSIONS

The development of products mainly will base on virtual prototypes in future. Many of the virtual prototype characteristics can only be evaluated in a VE, which can provide developer or customer with an adequate perception. Changes to the virtual prototype can be quickly reflected in the digital model without physical effort—a great advantage for the engineering process. This same model can be used in different ways to get feedback on various aspects of the design and its performance. VE-based tools are being used as a vehicle for clear communication and understanding, such as in seeing how assemblies will fit together without a real physical prototype.

Immersive projection technology (IPT) is ready for productive applications. Despite the complexity of such systems, it is possible to provide them as a productive tool. Analysis and understanding of the special requirements is necessary to deliver the most appropriate system. An intuitive user

TABLE 3 Migration of Data from Existing Model

Type of Application	Type of Data	Migration
3D CAD/modeler	Free-form surfaces, parametric geometry, trim curves, surface/material properties, assembly information	Tessellation (static dynamic), data reduction (LOD), surface properties −> textures, materials, reflection mapping
Prototypes	3D scanning data sets, surface reconstruction −> CAD data sets	Data repair, data reduction, color information −> texture
Simulation (FEM/GEM, etc.)	Geometry, additional simulation data, temporal changes	Geometrical representation of simulation data, intelligent structures
Functionality	Interaction human–model, operating/behavior	Description language, feedback, intuitive user interaction

interface is very important for user productivity and acceptance. The design of 3D user interfaces is clearly progressing, at least special-purpose user interfaces created for very specific tasks. This, together with careful VR workplace design, is dramatically increasing user productivity and acceptance.

While the return on investment can be calculated immediately in some cases, in other cases will only see some excited engineers playing with the new technology.

Migration and integration of IPT and VE in standard engineering processes is a part of the second principal stream. This includes plug-ins for established VR software as well as the support of data transfer and translation of data from legacy applications. This work will depend on available standards. On the other hand, there will be a trend toward the integration of VR functionality into existing CAD/CAE packages.

All innovative media of the future will contain three major components: interactivity, co-operation, and new possibilities in receiving experience by including several senses at once. The further development of virtual reality (and all technologies included under it, such as IPT systems) must be carried out on the basis of an user-centered approach—that is, the problems and limits of a person working in an immersive VE must be considered. This is how the necessary user acceptance can be achieved.

Cutting Edge Optimization

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. INTRODUCTION

Linear programming (LP) defines a particular class of optimization problems that meet the following two conditions:

1. The objective function to be optimized can be described by a linear function of the decision variables.
2. The operating rules or constraints governing the process (e.g., limited resources) can be expressed as a set of linear equations or inequalities.

LP techniques are widely used to solve a number of military, economic, industrial, and social problems.

1. A large variety of problems in diverse fields can be represented (within reasonable accuracy) as LP models.
2. Efficient techniques for solving LP problems are available.
3. Data variation (sensitivity analysis) can be handled with ease through LP models.

2. FORMULATION OF LINEAR MODELS

2.1. Basic Steps in Formulation

The three basic steps in constructing an LP model are:

Step 1: Identify the unknown variables to be determined (design or decision variables) and represent them in terms of algebraic symbols.

Step 2: Identify all the restrictions or constraints in the problem and express them as linear equations or inequalities, which are linear functions of the unknown variables.

Step 3: Identify the objective or criterion and represent it as a linear function, which is to be maximized or minimized.

The following example illustrates these basic steps.

2.2. Product-Mix Problem (Ravindran et al. 1987)

2.2.1. Example 1 (Product Mix Problem)

A company manufactures three products that require three resources—labor, material, and administration. The company's production engineering department has furnished the following data:

	Products		
	1	2	3
Labor (hr/unit)	1	1	1
Material (lb/unit)	10	4	5
Administration (hr/unit)	2	4	6
Profit ($/unit)	10	6	4

The supply of raw material is restricted to 600 lb/day. The daily availability of manpower is 100 hr. There are 300 hr of administration. Formulate a linear programming model to determine the daily production levels of the various products in order to maximize the total profit.

The formulation is as follows:

Step 1. Identify the decision variables. The unknown activities to be determined are the daily rates of production on the three products. Represented by algebraic symbols, they are

x_1 = daily production of product 1
x_2 = daily production of product 2
x_3 = daily production of product 3

Step 2. Identify the constraints. In this problem the constraints are the limited availability of the three resources—labor, material, and administration. Product 1 requires 1 hr of labor for each unit,

and its production quantity is x_1. Hence the requirement of labor for product 1 alone will be x_1 hr (assuming a linear relationship). Similarly, products 2 and 3 will require x_2 and x_3 hr, respectively. Thus, the total requirement of labor will be $x_1 + x_2 + x_3$ which should not exceed the available 100 hr. So the labor constraint becomes

$$x_1 + x_2 + x_3 \leq 100$$

The raw material requirements will be $10x_1$ lb for product 1, $4x_2$ lb for product 2, and $5x_3$ lb for product 3. Thus, the raw material constraint is given by

$$10x_1 + 4x_2 + 5x_3 \leq 600$$

Similarly, the constraint for administration becomes

$$2x_1 + 2x_2 + 6x_3 \leq 300$$

In addition, we restrict the variables x_1, x_2, and x_3 to having only nonnegative values. This is called the nonnegativity constraint, which the variables must satisfy. Most practical LP problems will have this nonnegative restriction on the decision variables.

Step 3. Identify the objective. The objective is to maximize the total profit from sales. Assuming that a perfect market exists for the products such that all that is produced can be sold, the total profit from sales becomes

$$Z = 10x_1 + 6x_2 + 4x_3$$

Thus, the LP model for our product mix problem is to find numbers x_1, x_2, x_3 that will maximize

$$Z = 10x_1 + 6x_2 + 4x_3$$

subject to the constraints

$$\begin{aligned} x_1 + x_2 + x_3 &\leq 100 \\ 10x_1 + 4x_2 + 5x_3 &\leq 600 \\ 2x_1 + 2x_2 + 6x_3 &\leq 300 \\ x_1 \geq 0 \quad x_2 \geq 0 \quad x_3 &\geq 0 \end{aligned}$$

3. BASIC ASSUMPTIONS OF LINEAR MODELS

The LP approach to modeling a system under study is to decompose the system into its elementary functions, or ''activities.'' In Example 1 there were three activities—manufacture of one unit of product 1, manufacture of one unit of product 2, and manufacture of one unit of product 3. The decision variables merely define the levels at which these activities are to be carried out. Of course, the aim of the LP model is to determine the optimal activity levels. To change the activity level, the input and output flows into each activity have to be changed. These flows are called ''items.'' In Example 1 the input flows were labor, material, and administration, and the output was profit in dollars.

There are two basic assumptions in the formulation of all LP models: proportionality and additivity.

3.1. Proportionality

This guarantees that the flow of items into and out of an activity is directly proportional to its activity level. If one unit of product 1 requires 1 hr of labor, 10 lb of material, and 2 hr of administration, then to make x units of product 1 will require x hr of labor, $10x$ lb of material, and $2x$ hr of administration for any x. Similarly, the unit profit from selling product 1 is always \$10, irrespective of how many units are sold.

3.2. Additivity

This assumption implies that the total usage of an item is equal to the sum of the item usages of each individual activity at its specified level. In Example 1 the total material consumption was equal to the sum of the material consumed by the individual products.

For a more detailed discussion on the input–output approach to modeling and LP assumptions. the reader is referred to Dantzig 1963. The proportionality and additivity assumptions imply that all the constraints of the LP problem can be expressed as linear equations or inequalities and that the objective is a linear function of the decision variables. It is common to find some practical problems violating one or more LP assumptions. In such cases, by using clever formulations or good approximations, one could still use LP. Some of these are discussed in the next section.

4. HANDLING NONLINEARITIES BY LINEAR PROGRAMMING (Ravindran, et al., 1987; and Murty 1995)

Nonlinearities can arise in a number of ways in optimization problems in either the objective function or the constraints. Some of the nonlinearities can be handled by LP methods, whereas the rest have to be solved by specialized nonlinear programming methods.

4.1. Piecewise Linear Functions

A piecewise linear function arises when the per-unit contribution (cost) depends on the level of sales (production). For example, consider a product whose profit contribution is \$10/unit for the first 40 units, \$8/unit for the next 60 units, and \$5/unit for the rest. The nonlinearity of the profit function is apparent if a graph is plotted between total profit and quantity sold. This is illustrated by Figure 1, which is called a piecewise linear function since it is linear in the region (0, 40), (40, 100), and (100,∞). Partitioning the quantity sold into three activities means that the profit function could be expressed as a linear function as follows:

x_1 = quantity sold at \$10/unit profit
x_2 = quantity sold at \$8/unit profit
x_3 = quantity sold at \$5/unit profit

The amount of product sold is $x_1 + x_2 + x_3$, and the objective function is to maximize $Z = 10x_1 + 8x_2 + 5x_3$. Since there is a limit on how many units can be sold for a certain profit, we need the following constraints:

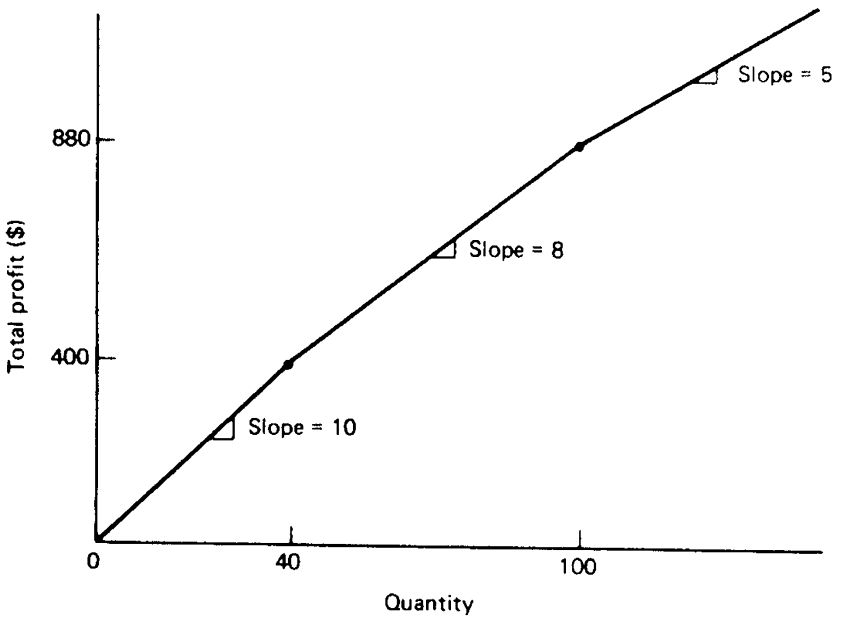

Figure 1 Example of a Piecewise Linear Function.

$$0 \le x_1 \le 40 \quad 0 \le x_2 \le 60 \quad 0 \le x_3$$

When the objective function is maximized, it is easy to see that x_2 will not become positive until x_1 reaches its limit of 40. Similarly, x_3 cannot be positive until $x_1 = 40$ and $x_2 = 60$.

One could extend this idea to handle smooth nonlinear profit functions by approximating them into piecewise linear functions. It is important to realize that LP methods can be used successfully to handle piecewise linear functions as long as the following hold:

1. In a maximization problem the piecewise linear function must have decreasing slope or be a concave function (i.e., the per-unit contribution must be decreasing or at least nonincreasing).
2. In a minimization problem the function must have increasing slope or be a convex function (i.e., the per unit cost must be increasing or at least nondecreasing).

If these properties do not hold, then one has to use the more complicated integer programming formulations.

4.2. Max-Min Problems

In some optimization problems one may encounter a nonlinear objective that is to maximize the minimum of several variables or functions. Consider an assembly made up of three different parts. Let x_1, x_2 and x_3 be the decision variables denoting the number of parts 1, 2, and 3 produced, respectively. If management wishes to maximize the number of assemblies, then the objective function becomes

$$\text{Maximize [minimum of } (x_1, x_2, x_3)]$$

Even though this is a nonlinear function, it can be linearized as follows: Let y denote the number of assemblies made. Then the linear objective function is

$$\text{Maximize } y \tag{1}$$

Since y is the minimum of x_1, x_2, x_3, we get the three additional constraints

$$y \le x_1 \tag{2}$$

$$y \le x_2 \tag{3}$$

$$y \le x_3 \tag{4}$$

The inequalities (2), (3), and (4) in conjunction with (1) are equivalent to maximizing the minimum of x_1, x_2 and x_3.

4.3. Handling Absolute Value Functions

Absolute value sign in the constraint can be handled by replacing it by two constraints. For example, a nonlinear constraint of the type

$$|x_1 - x_2| \le 30 \tag{5}$$

is equivalent to the following two linear constraints:

$$x_1 - x_2 \le 30$$

$$-x_1 + x_2 \le 30$$

Nonlinear constraints of the type given in inequality (5) occur frequently in machine balancing. If x_1 represents the daily utilization of machine 1 in minutes and x_2 is the utilization for machine 2, then inequality (5) is equivalent to the machine balancing constraint that no machine run more than 30 min/day longer than the other machine.

5. SIMPLEX ALGORITHM

The simplex algorithm as developed by G. B. Dantzig in 1947 is an iterative procedure for solving LP problems. The theory of the simplex algorithm and its many computational refinements are fully

presented in several outstanding textbooks (Dantzig 1963; Murty 1995; Ravindran et al. 1987; Gass 1975) The intent of this section is to describe briefly the basic principles of the simplex method.

5.1. Basic Principles

5.1.1. Example 2

Consider the following LP problem (Ravindran et al. 1987):

$$\begin{aligned} \text{Minimize } Z &= 40x_1 + 36x_2 \\ \text{Subject to} \quad & x_1 \le 8 \\ & x_2 \le 10 \\ & 5x_1 + 3x_2 \ge 45 \\ & x_1 \ge 0 \qquad x_2 \ge 0 \end{aligned}$$

In this problem we are interested in determining the values of the variables x_1 and x_2 that will satisfy all the restrictions and give the least value for the objective function. As a first step in solving this problem, we want to identify all possible values of x_1 and x_2 that are nonnegative and that satisfy the constraints. For example, a solution $x_1 = 8$ $x_2 = 10$ is positive and satisfies all the constraints. Such a solution is called a feasible solution. The set of all feasible solutions is called the feasible region. Solution of a linear program is nothing but finding the best feasible solution in the feasible region. The best feasible solution is called an optimal solution to the linear programming problem. In our example an optimal solution is a feasible solution that minimizes the objective function $40x_1 + 36x_2$. The value of the objective function corresponding to an optimal solution is called the optimal value of the linear program.

To represent the feasible region in a graph, every constraint may be plotted, and all values of x_1, x_2 that will satisfy these constraints can be identified. The nonnegativity constraints imply that all feasible values of the two variables will lie in the first quadrant. The constraint $5x_1 + 3x_2 \ge 45$ requires that any feasible solution (x_1, x_2) to the problem should be above the straight line $5x_1 + 3x_2 = 45$ (see Figure 2). Similarly, the constraints $x_1 \le 8$ and $x_2 \le 10$ are plotted. The feasible region is given by the shaded region *ABC* as shown in Figure 2. Obviously there are an infinite number of feasible points in this region. Our objective is to identify the feasible point with the lowest value of *Z*. The feasible points *A, B,* and C are called the comer points of the feasible region.

Observe that the objective function given by $Z = 40x_1 + 36x_2$ represents a straight line if the value of Z is fixed a priori. Changing the value of Z essentially translates the entire line to another straight line parallel to itself. To determine an optimal solution, the objective function line is drawn for a convenient value of *Z* such that it passes through one or more points in the feasible region. Initially *Z* is chosen as 600. By moving this line closer to the origin, the value of *Z* is further decreased (Figure 2). The only limitation on this decrease is that the straight line $40x_1 + 36x_2 = Z$ contain at least one point in the feasible region *ABC*. This clearly occurs at the comer point *A* given by $x_1 = 8$, $x_2 = 5/3$. This is the best feasible point giving the lowest value of *Z* as 380. Hence $x_1 = 8$, $x_2 = 5/3$ is an *optimal solution* and $Z = 380$ is the *optimal value* for the linear program.

In our example one of the comer points of the feasible region (namely, *A*) was an optimal solution. As a matter of fact, the following property is true for any LP problem: if there exists an optimal solution to an LP problem, then at least one of the corner points of the feasible region will always qualify to be an optimal solution.

This is the fundamental property on which the simplex method for solving LP problems is based. Even though the feasible region of an LP problem contains an infinite number of points, an optimal solution can be determined by merely examining the finite number of comer points in the feasible region. In LP terminology the comer point feasible solutions are known as basic feasible solutions.

Hence the simplex method for solving general LP problems is simply an orderly procedure for generating and examining different basic feasible solutions. In problems involving just two variables, one can easily draw the feasible region in a graph and identify the comer points that are basic feasible solutions. In practice, the LP problems involve hundreds of constraints and several thousand variables, and we need an algebraic procedure for generating the basic feasible solutions. The simplex method uses the classical Gauss-Jordan elimination scheme for generating the basic feasible solution. The Gauss–Jordan elimination can be represented by a sequence of vector–matrix operations and hence easily implemented on a digital computer.

5.2. General Steps

The general steps of the matrix-based simplex method are as follows:

1. Start with an initial basic feasible solution.

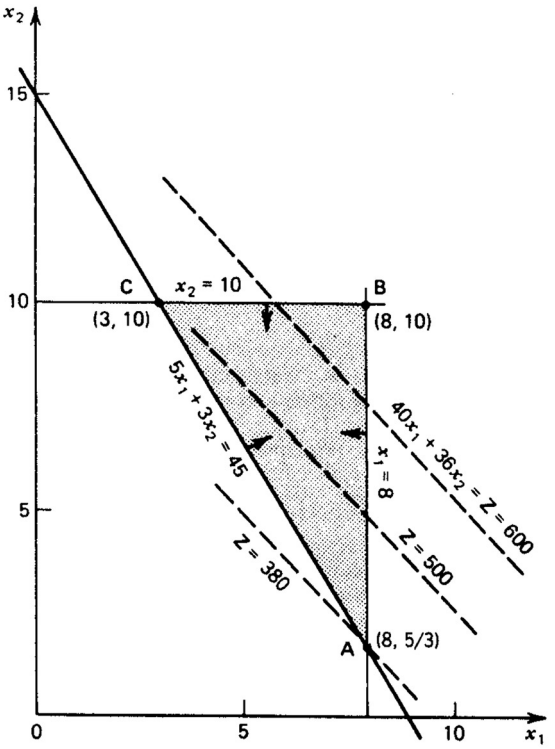

Figure 2 Graphical Solution of Example 2.

2. Improve the initial solution, if possible, by finding another basic feasible solution with a better objective function value. At this step the simplex method implicitly eliminates from consideration all those basic feasible solutions whose objective function values are worse than the present one. This makes the procedure more efficient than the naive approach, which would examine all the basic feasible solutions.
3. Continue to find better basic feasible solutions, improving the objective function values. When a particular basic feasible solution cannot be improved further, it becomes an optimal solution and the simplex method terminates.

Finding an initial basic feasible solution can be accomplished by temporarily loosening the definition of "feasible" in such a way that the origin becomes feasible. In Example 2, the simplex algorithm would start at the origin, make its first step to the temporarily feasible point D, and make its second step to the truly feasible and optimal point A. (The fact that the first truly feasible point is optimal is coincidental.)

5.3. Computational Efficiency of the Simplex Method

The computational efficiency of the simplex method depends on (1) the number of iterations (basic feasible solutions) to go through before reaching the optimal solution and (2) the total computer time to solve the problem. Much effort has been spent in studying the computational efficiency with regard to the number of constraints and the decision variables in the problem.

Empirical experience with thousands of practical problems shows that the number of iterations of a standard linear program with m constraints and n variables varies between m and $3m$, the average being $2m$. A practical upper bound for the number of iterations is $2(m + n)$. (Occasionally some problems have violated this bound.)

If every decision variable had a nonzero coefficient in every constraint, then the computational time would increase approximately in relation to the cube of the number of constraints, m^3. In practical large-scale models, however, typically fewer than 1% of the matrix coefficients are nonzero.

The use of sparse matrix techniques makes computation times unpredictable but far better than the m^3 would suggest.

It is to be noted that the computational efficiency of the simplex method is more sensitive to the number of constraints than to the number of variables. Hence the general recommendation is to keep the number of constraints as small as possible by avoiding unnecessary or redundant constraints in the formulation of the LP problem.

6. INTERIOR POINT METHOD

In 1984, a new and very different way of solving linear programs was introduced (Karmarkar 1984). Announced with much fanfare by Karmarkar's employer, AT&T Bell Laboratories, the new method was claimed to be 50 times faster than the simplex method. By 1990, Karmarkar's seminal work had spawned hundreds of research papers and a large class of what are now called interior point methods. It has become clear that while the initial claims were somewhat overenthusiastic, interior point methods dominate the simplex method for very large problems and for certain special classes of problems that have always been particularly difficult for the simplex method. Two such classes are highly degenerate problems (in which many different algebraic basic feasible solutions correspond to the same geometric comer point) and multiperiod problems that involve decisions in successive time periods that are linked together by inventory transfers. For both of these classes, the number of iterations taken by the simplex method can far exceed the $2m$ rule of thumb.

The definition of the class of very large problems for which interior point methods dominate is changing almost daily as computer implementations of the interior point method become more and more efficient. However, since 1984 there have been dramatic improvements in the computer implementations of the simplex method as well, largely spurred by the competition between the two methods. As a result, there is not currently much reason to prefer either method for LP models with a few hundred constraints. Beyond a few thousand constraints, however, the interior point method leaves the simplex method further and further behind as problem size grows.

Karmarkar's derivation was quite original, but it has since become clear that the whole family of interior point methods is equivalent to some classical ideas from the field of nonlinear programming (Gill et al. 1986). We shall present here a brief introduction to the current framework for these methods. A more detailed tutorial can be found in Marsten et al. 1990.

The classical building blocks that we need are Newton's method (Newton 1687) for unconstrained optimization, Lagrange's method (Lagrange 1788) for optimization with equality constraints, and Fiacco and McCormick's barrier method (Fiacco and McCormick 1968) for optimization with inequality constraints. Let us review these. A good general reference is Bazarra and Shetty 1979.

6.1. Newton's Method

One of the foundations of numerical mathematics is Newton's method for finding a zero of a function of a single variable: $f(x) = 0$. Given an initial estimate x^0, we compute a sequence of trial solutions.

$$x^{k+1} = x^k - \frac{f(x^k)}{f'(x^k)}$$

for $k = 0, 1, 2, \ldots$, stopping when $|f(x^k)| < \varepsilon$ where ε is some stopping tolerance, for example, $\varepsilon = 10^{-8}$.

Suppose we have n equations in n variables: $f(x) = 0$, where

$$f(x) = \begin{pmatrix} f_1(x) \\ \vdots \\ f_n(x) \end{pmatrix} \text{ and } x = \begin{pmatrix} x_1 \\ \vdots \\ x_n \end{pmatrix}$$

The Jacobian at the point x, $J(x)$, is defined as the matrix with (i, j) component

$$\frac{\partial f_i}{\partial x_j}(x)$$

and Newton's method looks like

$$x^{k+1} = x^k - [J(x^k)]^{-1} f(x^k)$$

Or, if we let

$$dx = x^{k+1} - x^k$$

denote the displacement vector and move the Jacobian matrix to the other side

$$J(x^k)dx = -f(x^k) \tag{6}$$

Newton's method can be applied to the unconstrained minimization problem as well: to minimize $g(x)$, take $f(x) = g'(x)$ and use Newton's method to search for a zero of $f(x)$. Each step of the method can be interpreted as constructing a quadratic approximation of $g(x)$ and stepping directly to the minimum of this approximation.

If g is a real valued function of n variables, a local minimum of g will satisfy the following system of n equations in n variables:

$$\frac{\partial g}{\partial x_1}(x) = 0$$

$$\frac{\partial g}{\partial x_n}(x) = 0$$

In this case the Newton iteration (6) looks like

$$\nabla^2 g(x^k)dx = -\nabla g(x^k)$$

where ∇g is the gradient of g and $\nabla^2 g$ is the Hessian of g, that is, the matrix with (i, j) component

$$\frac{\partial^2 g}{\partial x_i \partial x_j}(x)$$

If g is convex, then any local minimizer is also a global minimizer. If x^* is a local minimizer of $g(x)$, that is, $\nabla g(x^*) = 0$, and if $\nabla^2 g(x^*)$ has full rank, then Newton's method will converge to x^* if started sufficiently close to x^*.

6.2. Lagrange Multiplier Method

Lagrange discovered how to transform a constrained optimization problem, with equality constraints, into an unconstrained problem. To solve the problem

$$\text{Minimize } f(x)$$
$$\text{Subject to } g_i(x) = 0 \quad \text{for } i = 1, \ldots, m$$

form a Lagrange function

$$L(x, y) = f(x) - \sum_{i=1}^{m} y_i g_i(x)$$

and then minimize the unconstrained function $L(x, y)$ by solving the system of $(n + m)$ equations in $(n + m)$ variables:

$$\frac{\partial L}{\partial x_j} = \frac{\partial f}{\partial x_j}(x) - \sum_{i=1}^{m} y_i \frac{\partial g_i}{\partial x_j}(x) = 0 \quad \text{for } j = 1, \ldots, n$$

$$\frac{\partial L}{\partial y_i} = -g_i(x) = 0 \quad \text{for } i = 1, \ldots, m$$

These equations can be solved by Newton's method.

6.3. Fiacco and McCormick Algorithm

General inequality constraints can be converted to equations by adding nonnegative slack (or surplus) variables. So the only essential inequalities are the nonnegativity conditions: $x \geq 0$. The idea of the barrier function approach is to start from a point in the strict interior of the inequalities ($x_j^0 > 0$ for all j) and construct a barrier that prevents any variable from reaching the boundary ($x_j^0 = 0$).

For example, adding $-\log(x_j)$ to the objective function will cause the objective to increase without bound x_j as approaches 0. Of course, if the constrained optimum is on the boundary (i.e., some $x_j^* = 0$ that is always true for linear programming), then the barrier will prevent us from reaching it. The solution is to use a barrier parameter that balances the contribution of the true objective function against that of the barrier function.

A minimization problem with nonnegativity conditions can be converted into a sequence of unconstrained minimization problems in the following way. The problem

$$\begin{aligned} &\text{Minimize } f(x) \\ &\text{Subject to } x \geq 0 \end{aligned}$$

is replaced by the family of unconstrained problems

$$\text{Minimize } B(x|\mu) = f(x) - \mu \sum_{j=1}^{n} \log(x_j)$$

which is parameterized on the positive barrier parameter μ. Let $x(\mu)$ be the minimizer of Fiacco and McCormick show that $x(\mu) \rightarrow x^*$ the constrained minimizer, as $\mu \rightarrow 0$. The set of minimizers is called the central trajectory.

As a simple example, consider the problem

$$\begin{aligned} &\text{Minimize } (x_1 + 1)^2 + (x_2 + 1)^2 \\ &\text{Subject to } x_1 \geq 0 \quad x_2 \geq 0 \end{aligned}$$

The unconstrained minimum would be at $(-1, -1)$, but the constrained minimum is at the origin $(x_1^*, x_2^*) = (0,0)$. For any $\mu > 0$:

$$B(x|\mu) = (x_1 + 1)^2 + (x_2 + 1)^2 - \mu \log(x_1) - \mu \log(x_2)$$

$$\frac{\partial B}{\partial x_1} = 2(x_1 + 1) - \frac{\mu}{x_1} = 0$$

$$\frac{\partial B}{\partial x_2} = 2(x_2 + 1) - \frac{\mu}{x_2} = 0$$

$$x_1(\mu) = x_2(\mu) = -\frac{1}{2} + \frac{1}{2}\sqrt{1 + 2\mu}$$

which approaches (0,0) as $\mu \rightarrow 0$.

In general, we cannot get a closed-form solution for the central trajectory, but can use the following algorithm.

1. Choose $\mu_0 > 0$, set $k = 0$.
2. Find $x^k(\mu_k)$, the minimizer of $B(x|\mu_k)$.
3. If $\mu_k < \varepsilon$, stop. Otherwise, choose $\mu_{k+1} < \mu_k$.
4. Set $k = k + 1$ and go to step 2.

Then as $x^k(\mu_k) \rightarrow x^*$ as $\mu \rightarrow 0$.

In step 2 we can find $x(\mu)$ by using Newton's method to solve the system of n equations in n variables:

$$\frac{\partial B}{\partial x_j}(x|\mu) = \frac{\partial f(x)}{\partial x_j} - \frac{\mu}{x_j} = 0 \quad \text{for } j = 1, \ldots, n$$

In practice, we do not have to compute $x(\mu)$ very accurately before reducing μ.

6.4. Application to Linear Programming

The classical ideas reviewed can be applied to LP in the following way. If nonnegative slack and/or surplus variables have been used to convert inequalities into equations, then the general LP problem can be written as

$$\begin{aligned} &\text{Minimize} && c^T x \\ &\text{Subject to} && Ax = b \\ & && x \geq 0 \end{aligned}$$

where A is $m \times n$. Let A_j denote column j of A, for $j = 1, \ldots, n$. We can replace the nonnegativity conditions with a barrier function:

$$\begin{aligned} &\text{Minimize } c^T x - \mu \sum_{j=1}^{n} \log(x_j) \\ &\text{Subject to } Ax = b \end{aligned}$$

This is now a problem with equality constraints, so we can use Lagrange's method. The Lagrangian function is

$$L(x, y) = c^T x - \mu \log(x_j) - y^T (Ax - b)$$

and the partial derivatives are

$$\frac{\partial L}{\partial x_j} = c_j - \frac{\mu}{x_j} - A_j^T y = 0 \quad j = 1, \ldots, n$$

$$\frac{\partial L}{\partial y} = -(Ax - b) = 0$$

The first set of equations gives

$$c_j - A_j^T y = \frac{\mu}{x_j} > 0$$

since $\mu > 0$ and $x_j > 0$. If we define

$$z_j = c_j - A_j^T y \quad \text{for } j = 1, \ldots, n$$

and require $z \geq 0$, then the system of equations that need to be solved is

$$(*) \begin{cases} Ax = b \\ A^T y + z = c \\ x_j z_j = \mu \quad \text{for } j = 1, \ldots, n \end{cases}$$

So we have $(m + 2n)$ equations in $(m + 2n)$ variables. Notice that the last n equations are nonlinear.

Starting from any point x^0, y^0, z^0 that satisfies $x^0 > 0$ and $z^0 > 0$, the idea is now to use Newton's method to solve the *nonlinear* system (*) for a given $\mu > 0$, and then reduce μ. In fact μ could be reduced after some fixed number of Newton steps (perhaps only one!). Various methods will differ in how many Newton steps are taken before reducing μ and in how much μ is reduced.

Forming the Jacobian of (*), we see that making a single Newton step requires the solution of the *linear* system of equations:

$$(**) \begin{bmatrix} A & 0 & 0 \\ 0 & A^T & I \\ Z & 0 & X \end{bmatrix} \begin{bmatrix} dx \\ dy \\ dz \end{bmatrix} = \begin{bmatrix} b - Ax^0 \\ c - A^T y^0 - z^0 \\ \mu e - xZe \end{bmatrix}$$

where

$$\begin{aligned} X &= \text{diag}(x_1^0, \ldots, x_n^0) \\ Z &= \text{diag}(z_1^0, \ldots, z_n^0) \\ e &= (1, \ldots, 1)^T \end{aligned}$$

The iteration count for the interior method is the total number of Newton steps, that is, the number of times the *linear* system (**) is solved.

The interior point method sketched here, which is simply an application of the classical nonlinear barrier method to LP, was actually tried in the late 1960s. At that time it was not even close to being competitive with the simplex method. The reason was that the efficient numerical linear algebra for solving (**) had not yet been developed. This was done during the 1970s and early 1980s for the purpose of solving large-scale finite-element problems. One way to solve (**) involves the Cholesky factorization of the symmetric positive-definite matrix: $AZ^{-1}XA^T$. Factoring large, sparse, symmetric, positive-definite matrices is the central computational core of finite-element methods. See George and Liu (1981) and Duff et al. (1987).

6.5. Computational Efficiency of the Interior Point Method

The truly remarkable thing about the interior point method is that the number of iterations (Newton steps) is almost independent of problem size. For all models solved to date, the number of iterations has been less than 100, and is usually between 20 and 40. (Note, however, that one Newton step involves much more computation than one simplex step.) There are theoretical and empirical reasons to believe that the number of iterations increases with the log of the number of variables, $\log(n)$. Indeed, Marsten et al. (1990) report a family of problems with from 35,000 to 2,000,000 variables for which a regression of iterations vs. $\log(n)$ gave an $R^2 = 0.979$.

Given this surprising behavior, the computation time depends on how efficiently the individual steps can be executed. This is a very active area of research and one that is exploring new parallel and vector computer architectures. (As with the simplex method, if the A matrix were completely dense, the computation time would increase with the cube of the number of constraints, but sparse matrix techniques make this rather meaningless.)

To give some comparison between the interior point method and the simplex method, consider the following set of multiperiod oil refinery planning models. The number of periods is the number of days in the planning horizon. This is a class of problems, as mentioned earlier, that becomes particularly hard for the simplex method as the number of periods increases. In Table 1, OB1 is an implementation of the interior point method and XMP is an implementation of the simplex method. They were both written entirely in FORTRAN by the same programmer and run on the same computer, a DECstation 3100.

One surprising consequence of the independence between iteration count and problem size is the fact that it takes about 20 Newton steps to solve even very small problems. For Example 2, the interior method takes 18 steps to obtain eight digits of accuracy, while the simplex method takes only 2 steps! The interior point method has to converge to the vertex, while the simplex method, being essentially combinatorial, hops exactly (within machine precision) onto the vertex. The sequence of trial solutions generated by the interior method, rounded to three decimal places, are given in Table 2. Steps 14 to 18 are required for eight digits of accuracy and are omitted. Recall that the solution is at (8, 5/3).

7. COMPUTER SOLUTION OF LINEAR PROGRAMS

7.1. Evolution of Commercial Packages for LP

The discovery of the simplex method and the birth of the digital computer occurred at about the same time, in the late 1940s. Because of the prodigious amount of computation required to solve all but the smallest problems, the simplex method would be of no practical use without the digital computer. Solving large LP models has always been one of the most challenging computational tasks for each new generation of computers. This remains true today, as the meaning of ''large'' expands with the capabilities of each new computer. It is interesting that the interior point method appeared at about the same time as the widespread availability of vector and parallel computers, since it seems much better suited to these new architectures than the simplex method.

TABLE 1 OB1 vs. XMP on Multiperiod Refinery Models

	Number of Time Periods in the Model					
	1	2	3	4	8	16
Equation	442	883	1,255	1,659	3,275	6,507
Variables	1,032	1,945	2,644	3,506	6,874	13,610
Nonzeros	7,419	14,280	19,494	25,727	50,659	100,253

7.2. PC Software for LP

Up until the mid-1980s, almost all industrial LP models were solved on mainframe computers, with software provided by the computer manufacturers or by a very small number of specialty LP software companies. In the late 1980s, the situation changed drastically. LP models with a few hundred constraints can now be solved on personal computers (PCs using Intel Pentium chips). This has expanded the use of LP dramatically. There are even LP solvers that can be invoked directly from inside spreadsheet packages. For example, Microsoft Excel and Microsoft Office for Windows contain a general purpose optimizer for solving small linear, integer, and nonlinear programming problems. The LP optimizer is based on the simplex algorithm. There are now at least a hundred companies marketing LP software for personal computers. They can be found in any issue of *OR/MS Today,* a publication of the Institute for Operations Research and Management Science. For a 1999 survey of LP software, see Fourer (1999). A web version of the survey can be reached via Fourer's home page at http://iems.nwu.edu/~4er/.

7.3. High-End LP Software

As we entered the 1990s, another dramatic change became apparent. The workstation class of machines offered mainframe speed at a fraction of the mainframe cost. The result is that virtually all currently used LP models can now be solved on workstations.

We now have the capability to solve truly enormous LP models using interior point methods on supercomputers, but at the moment users are just beginning to realize this and to think of larger models. For example, an oil company that has been solving single-period production planning models for each refinery can start to piece together a multiperiod, multirefinery model that incorporates distribution as well as production planning. Another sure source of very large LP models is stochastic programming, which attempts to deal with uncertainty in the context of optimization.

In 1989, three new high-end LP software systems were introduced that dominated all earlier systems and redefined the state of the art. The first is OSL from IBM. OSL incorporates both the simplex method and the interior point method. The simplex part is a very substantial improvement over IBM's earlier LP software. The second is CPlex, a simplex code written by Robert Bixby of Rice University and marketed by CPlex Optimization. The third is OB1, an interior point code written by Roy Marsten and David Shanno and marketed by XMP Software.

7.4. LP Modeling Languages

During the 1980s, there was also great progress in the development of computer tools for building LP models. The old mainframe LP systems had matrix generator languages that provided some assistance in constructing LP coefficient matrices out of collections of data tables. The focus was on the matrix, however, rather than on the algebraic form of the model. The matrix is a very large, very concrete object that is of little real interest to the human model builder.

There are now modeling languages that allow the user to express a model in a very compact algebraic form, with whole classes of constraints and variables defined over index sets. Models with thousands of constraints and variables can be defined in a couple of pages, in a syntax that is very close to standard algebraic notation. The algebraic form of the model is kept separate from the actual data for any particular instance of the model. The computer takes over the responsibility of trans-

forming the abstract form of the model and the specific data into a specific coefficient matrix. This has greatly simplified the building, and even more the changing, of LP models. Several modeling languages are available for PCs. The two high-end products are GAMS (General Algebraic Modeling System) and AMPL (A Mathematical Programming Language). GAMS is marketed by GAMS Development. For a reference on GAMS, see Brooke et al. (1988). AMPL is marketed by AT&T. For a general introduction to modeling languages, see Fourer (1983), and for an excellent discussion of AMPL see Fourer et al. (1990).

7.5. LP Software on the Internet

A complete list of optimization software available for LP problems is available at the following NEOS website: http://www.mcs.anl.gov/home/otc. This site not only provides access to the software guide but also to the other optimization related sites that are continually updated. The NEOS guide on optimization software is based on More and Wright (1993), an excellent resource for those interested in a broad review of the various optimization methods and their computer codes. The book is divided into two parts. Part I has an overview of algorithms for different optimization problems, categorized as unconstrained optimization, nonlinear least squares, nonlinear equations, linear programming, quadratic programming, bound-constrained optimization, network optimization, and integer programming. Part II includes product descriptions of 75 software packages that implement the algorithms described in Part I. Much of the software described in this book is in the public domain and can be obtained through the Internet.

8. SENSITIVITY ANALYSIS IN LINEAR PROGRAMMING

8.1. Reasons for Sensitivity Analysis

In all linear programming models, the coefficients of the objective function and the constraints are supplied as input data or as parameters to the model. The optimal solution obtained by the simplex method is based on the values of these coefficients. In practice, the values of these coefficients are seldom known with absolute certainty because many of the coefficients are functions of some uncontrollable parameters. For instance, the future demands, the cost of raw materials, or the cost of energy resources cannot be predicted with complete accuracy before the problem is solved. Hence the solution of a practical problem is not complete with the mere determination of the optimal solution.

Each variation in the values of the data coefficients changes the linear programming problem, which may in turn affect the optimal solution found earlier. To develop an overall strategy to meet the various contingencies, one has to study how the optimal solution will change as a result of changes in the input (data) coefficients. This is sensitivity analysis or postoptimality analysis. Other reasons for performing a sensitivity analysis are as follows:

1. There may be some data coefficients or parameters of the linear program that are controllable, for example, availability of capital, raw material, or machine capacities. Sensitivity analysis enables one to study the effects of changing these parameters on the optimal solution. If it turns out that the optimal value (profit/cost) changes (in our favor) by a considerable amount for a small change in the given parameters, then it may be worthwhile to implement some of these changes. For example, if increasing the availability of labor by allowing overtime contributes to a greater increase in the maximum return as compared to the increased cost of overtime labor, then one might want to allow overtime production.
2. In many cases the values of the data coefficients are obtained by statistical estimation procedures on past figures, as in the case of sales forecasts, price estimates, and cost data. These estimates, in general, may not be very accurate. If we can identify which of the parameters affect the objective value most, then we can obtain better estimates of these parameters. This will increase the reliability of our model and the solution.

8.2. Practical Uses

Example 1, discussed at the beginning of this chapter, can be used to help illustrate the practical uses of sensitivity analysis. A computer output of the solution of this problem is given in Table 3. Note from the optimal solution that the optimal product mix is to produce products 1 and 2 only at levels 33.33 and 66.67 units, respectively.

The shadow prices give the net impact on the maximum profit if additional units of certain resources can be obtained. Labor has the maximum impact, providing a \$3.33 increase in profit per every hour of increase in labor. Of course, the shadow prices on the resources apply as long as their variations stay within the prescribed ranges on right-hand side (RHS) constants given in Table 3. In other words, a \$3.33/hr increase in profit is achievable as long as the labor hours are not increased beyond 150 hr. Suppose it is possible to increase the labor hours by 25% by scheduling overtime that incurs an additional labor cost of \$50. To see whether it is profitable to schedule overtime, we

TABLE 3 Computer Solution of Example 1

Optimal solution	$x_1 = 33.33, \quad x_2 = 66.67, \quad x_3 = 0$
Optimal value	Maximum profit = \$733.33
Shadow prices	For row 1 = \$3.33, for row 2 = \$0.67, for row 3 = 0
Opportunity costs	For $x_1 = 0$, for $x_2 = 0$, for $x_3 = 2.67$

Ranges on Objective Function Coefficients

Variable	Lower Limit	Present Value	Upper Limit
x_1	6	10	15
x_2	4	6	10
x_3	$-\infty$	4	6.67

Ranges on RHS Constants

Row	Lower Limit	Present Value	Upper Limit
1	60	100	150
2	400	600	1000
3	200	300	∞

first determine the net increase in maximum profit due to 25 hr of overtime as (25) (3.33) = \$83.25. Since it is more than the total cost of overtime, it is economical to schedule overtime. It is important to note that, when any of the RHS constants is changed, the optimal solution will change. However, the optimal product mix will be unaffected as long as the RHS constant varies within the specified range. In other words, we will still be making products 1 and 2 only, but their quantities may change.

The ranges on the objective function coefficients given in Table 3 exhibit the sensitivity of the optimal solution with respect to changes in the unit profits of the three products. It shows that the optimal solution will not be affected as long as the unit profit of product 1 stays between \$6 and \$15. Of course, the maximum profit will be affected by the change. For example, if the unit profit on product 1 increases from \$10 to \$12, the optimal solution will be the same, but the maximum profit will increase to \$733.33 + (12 − 10) (33.33) = 799.99.

Note that product 3 is not economical to include in the optimal product mix. Hence a further decrease in its profit contribution will not have any impact on the optimal solution or maximum profit. Also, the unit profit on product 3 must increase to \$6.67 (present value + opportunity cost) before it becomes economical to produce.

8.3. Simultaneous Variations in Parameters (Bradley et al., 1977)

The sensitivity analysis output on profit and RHS ranges is obtained by varying only one of the parameters and holding all other parameters fixed at their current values. However, it is possible to use the sensitivity analysis output when several parameters are changed simultaneously. This is done with the help of the 100% rule.

8.3.1. 100% Rule for Objective Function Coefficients

The 100% rule for the objective function coefficients is given by

$$\sum_j \frac{\delta c_j}{\Delta c_j} \leq 1 \tag{7}$$

where δc_j is the actual increase (decrease) in the objective function coefficient of variable x_j and Δc_j is the maximum increase (decrease) allowed by sensitivity analysis. As long as inequality (7) is satisfied, the optimal solution to the LP problem will not change. For example, suppose the unit profit on product 1 decreases by \$1, but increases by \$1 for both products 2 and 3. This simultaneous variation satisfies the 100% rule, since $\delta c_1 = -1$, $\Delta c_1 = -4$, $\delta c_2 = 1$, $\Delta c_2 = 4$, $\delta c_3 = 1$, $\Delta c_3 = 2.67$, and

$$\frac{-1}{-4} + \frac{1}{4} + \frac{1}{2.67} = 0.875 < 1$$

Hence the optimal solution will not change, but the maximum profit will change by $(-1)(3.33) + 1(66.67) + 1(0) = 33.34$.

8.3.2. 100% Rule for RHS Constants

The 100% rule for the RHS constants is given by

$$\sum_j \frac{\delta b_i}{\Delta b_i} \leq 1 \tag{8}$$

where δb_1 is the actual increase (decrease) in the RHS constant of the ith constraint and Δb_i is the maximum increase (decrease) allowed by sensitivity analysis. If inequality (8) is satisfied, then the optimal product mix remains the same and the shadow prices apply, but the optimal solution and maximum profit will change. Of course, the net change in the maximum profit ran be obtained using the shadow prices.

Warning: The failure of the 100% rule does not automatically imply that the LP solution will be affected.

9. APPLICATIONS OF LINEAR PROGRAMMING

Linear programming models are widely used to solve a number of military, economic, industrial, and social problems. The oil companies have been and still are one of the foremost users of very large LP models in petroleum refining, distribution, and transportation. The number of LP applications has grown so much in the last 20 years that it would be impossible to survey all the different applications. Instead, the reader is referred to two excellent textbooks, Gass (1970) and Salkin and Saha (1975) which are devoted solely to LP applications in such diverse areas as defense, industry, commercial-retail, agriculture, education, and the environment. Many of the applications also contain a discussion of the experiences in using the LP models in practice.

An excellent bibliography on LP applications is available in Gass (1975). It contains a list of references arranged by area (e.g., agriculture, industry, military, production, transportation). In the area of industrial application, the references have been further categorized by industry (e.g., chemical, coal, airline, iron and steel, paper, petroleum, railroad). For additional bibliographies on LP applications, readers may refer to a survey by Gray and Cullinan-James (1976). For more recent applications of LP in practice, readers should check the recent issues of *Interfaces, AIIE Transactions, Decision Sciences, European Journal of Operational Research, Management Science, Operations Research, Operational Research* (United Kingdom), *Naval Research Logistics Quarterly,* and *Op-Search* (India).

CHAPTER 98
Nonlinear Optimization

TOM M. CAVALIER
Pennsylvania State University

1. INTRODUCTION

Nonlinear programming and nonlinear optimization are generally considered synonymous terms, where in this context the term *programming* refers to the process of determining an optimum program or solution. Optimization can be thought of as a very broad extension of the simple calculus problem of finding the extrema of a given function. This process of finding the ''best'' solution to a mathematical model of some real-world system has a wealth of practical applications (see, e.g., Bracken and McCormick 1968.)

The basic elements of a mathematical program are *decision variables,* an *objective function,* and *constraints* or restrictions. To help fix ideas, consider the simple problem of finding the dimensions of a rectangle that has maximum area and whose perimeter is at most 4. This problem can be posed as the following mathematical program:

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

Example 1

$$\text{maximize } f(\mathbf{x}) = x_1x_2 \tag{1}$$

$$\text{subject to } g_1(\mathbf{x}) = 2x_1 + 2x_2 - 4 \leq 0 \tag{2}$$

$$g_2(\mathbf{x}) = -x_1 \leq 0 \tag{3}$$

$$g_3(\mathbf{x}) = -x_2 \leq 0 \tag{4}$$

where $\mathbf{x} = (x_1, x_2)^t \in E_2$, Euclidean 2-space. (The notation $\mathbf{v}^t$ represents the *transpose* of the vector $\mathbf{v}$.) The decision variables in this case are x_1 and x_2, which represent the length and width of the rectangle, respectively. The objective function is $f(\mathbf{x}) = x_1x_2$, which represents the area of the rectangle. $g_1(\mathbf{x}) \leq 0$ is the perimeter constraint, whereas $g_1(\mathbf{x}) \leq 0$ and $g_1(\mathbf{x}) \leq 0$ represent nonnegativity restrictions on the variables. These nonnegativity restrictions, as well as simple bounds on the variables, are handled implicitly by some mathematical programming techniques (e.g., the simplex algorithm for linear programming). Here it is assumed that they are included as explicit constraints.

In general, a mathematical program can be represented in the generic form:

$$\text{(P) optimize } f(\mathbf{x}) \tag{5}$$

$$\text{subject to } g_i(\mathbf{x}) \leq 0 \text{ for } i = 1, \ldots, m \tag{6}$$

$$h_j(\mathbf{x}) = 0 \text{ for } j = 1, \ldots, p \tag{7}$$

where $\mathbf{x} = (x_1, x_2, \ldots, x_n)^t \in E_n$, Euclidean n-space, and f, g_i, h_j: $E_n \rightarrow E_1$. Generally, throughout much of this chapter, "optimize" will be taken to mean "minimize," since maximization problems can be addressed using the simple transformation, maximize $f(\mathbf{x}) = -$minimize $(-f(\mathbf{x}))$.

If all of the functions f, g_i, h_j are linear functions of $\mathbf{x}$, then (P) is called a *linear program*. Otherwise (P) is a *nonlinear program*. Note that Example 1 is a nonlinear program since the objective function (1) is a nonlinear function. Actually, as will be seen later, this problem can be classified as a *quadratic program* since the objective function is a quadratic function and the constraints are all linear functions.

The region in E_n defined by constraints (6) and (7) is referred to as the *feasible region*; the feasible region for Example 1 is illustrated in Figure 1. The *objective function contours* (or level curves) are also identified in Figure 1, and it is clear that the point, $\mathbf{x}^* = (x_1^*, x_2^*)^t = (1, 1)^t$, where the objective contour is tangent to the boundary of the feasible region, is the global optimal solution. The constraint $g_1(\mathbf{x}) \leq 0$ is said to be *binding* (tight or active) at the optimal solution since $g_1(\mathbf{x}^*) = 0$, whereas $g_2(\mathbf{x}) \leq 0$ and $g_3(\mathbf{x}) \leq 0$ are *nonbinding* (loose or inactive) at the optimal solution.

Unlike linear programming, in which an optimum, if one exists, can be found at an extreme point of the feasible region, solutions of nonlinear programming problems can occur at any feasible point. Whereas Figure 1 shows an example where the optimum lies on the boundary of the feasible region, Figure 2 illustrates a case where the optimum is an interior point of the feasible region. In the latter

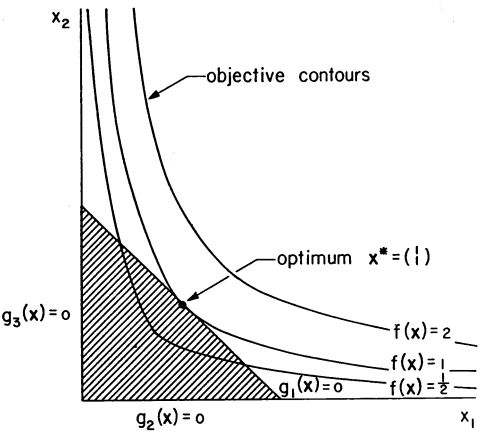

Figure 1 Graphical Solution of Example 1.

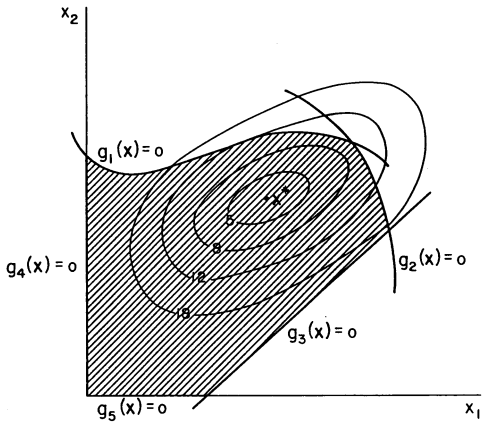

Figure 2 Example of a Nonlinear Programming Solution—No Active Constraints.

case, the constraints have no influence on the optimal solution, that is, the unconstrained optimum is also the constrained optimum.

This is just one of the difficulties encountered in nonlinear optimization. In contrast to linear programming, no single method is suitable for all types of nonlinear programs. And generally, it is only practical to obtain a *local minimum* that is not guaranteed to be a *global minimum*. (See Figure 3.)

Generally speaking, optimization methods can be divided into direct and indirect methods. Classical optimization methods are frequently referred to as *indirect methods* since these methods rely on analytic techniques for determining the optimal solution. This indirect approach does not involve a direct search for a particular solution but rather specifies a set of general conditions that must be satisfied by all solutions to the problem. As such, these methods do not lend themselves to computer implementations; however, they form the foundation for many of the computer-oriented direct methods. *Direct methods* of optimization seek to find a particular solution to a specified problem in a direct, iterative manner. The iterative nature of these procedures allows for effective computer implementations. Since real-world problems may involve many variables and constraints, the major challenge of nonlinear programming has been the development of efficient computational and algorithmic techniques. Although many algorithms have been developed, only a relative few have enjoyed continued success in real-world applications.

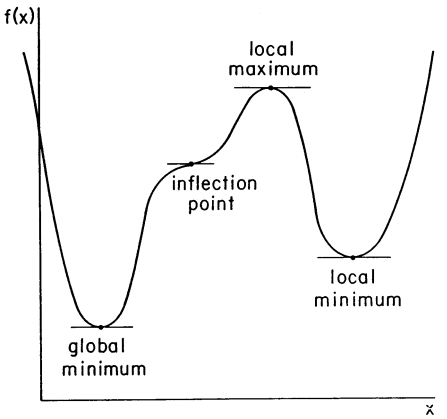

Figure 3 Local and Global Extrema.

This chapter outlines the fundamentals of nonlinear optimization. A review of some basic concepts and convexity is followed by a section addressing unconstrained optimization. This section presents classical optimization results as well as several direct search algorithms for solving univariate and multivariate problems. Next, constrained optimization problems are addressed. A review of Lagrange multipliers and the Karush–Kuhn–Tucker conditions precedes the presentation of several algorithms for solving different classes of nonlinear programming problems. There are a multitude of direct search algorithms in the literature, and the author has selected several representative methods to review. This is by no means an exhaustive review. It is simply an attempt to expose the reader to a cross-section of algorithmic methods. Finally, a listing of some nonlinear programming codes and some online resources is provided.

2. CONVEXITY

As indicated previously, nonlinear programming algorithms can generally only find a local optimal solution. Under these conditions, it becomes very important to know when a local minimum is actually guaranteed to be a global minimum over a given feasible region. One set of conditions that ensures such an outcome is that the feasible region is a convex set and the objective function is a convex function. Such a problem is called a *convex program*.

A *convex set* satisfies the following property: if $\mathbf{x}_1, \mathbf{x}_2 \in S$, then $\bar{\mathbf{x}} = \lambda\mathbf{x}_1 + (1 - \lambda)\mathbf{x}_2 \in S$ for all $\lambda \in [0, 1]$. $\bar{\mathbf{x}}$ is referred to as a *convex combination* of $\mathbf{x}_1$ and $\mathbf{x}_2$. Geometrically, the above property simply means that if $\mathbf{x}_1, \mathbf{x}_2 \in S$, then the line segment joining $\mathbf{x}_1$ and $\mathbf{x}_2$ is also contained in S. An *extreme point* of a convex set S is any point in S that cannot be written as a strict convex combination (i.e. $\lambda \in (0, 1)$) of two distinct points in S. Figure 4 illustrates a convex and a nonconvex set. A set is *closed* if it contains all of its boundary points.

A function $f : S \rightarrow E_1$ defined on a convex set $S \subset E_n$ is a *convex function* if $f(\bar{\mathbf{x}}) \leq \lambda f(\mathbf{x}_1) + (1 - \lambda)f(\mathbf{x}_2)$ for all $\mathbf{x}_1, \mathbf{x}_2 \in S$ and $\lambda \in [0, 1]$. This property is illustrated geometrically in Figure 5(*a*) and means that the line segment joining the points $(\mathbf{x}_1, f(\mathbf{x}_1))$ and $(\mathbf{x}_2, f(\mathbf{x}_2))$ lies above the graph of $f(\mathbf{x})$. Also, f is a *strictly convex function* if $f(\bar{\mathbf{x}}) < \lambda f(\mathbf{x}_1) + (1 - \lambda)f(\mathbf{x}_2)$ for all $\mathbf{x}_1, \mathbf{x}_2 \in \mathbf{S}$, $\mathbf{x}_1 \neq \mathbf{x}_2$, and $\lambda \in [0, 1]$. Similarly, $g : S \rightarrow E_1$ is (*strictly*) *concave* if $-g$ is (strictly) convex.

As a special case, if the feasible region of a linear program with nonnegative variables is nonempty, the feasible region is always a convex polyhedral set with a finite number of extreme points. If an optimal solution exists, an optimal extreme point among this finite set can be found quite efficiently using either the simplex algorithm, which was developed by Dantzig in 1947, or, more recently, by Karmarkar's interior point algorithm (Karmarkar 1984). An analogous approach is not possible with general nonlinear programs, since the feasible region cannot readily be reduced to a finite set of candidate solutions and a global optimal solution cannot necessarily be found by relying only on local information, as in the simplex method. The effects of convexity on the outcome of different mathematical programming problems can be summarized as follows.

1. *Minimizing an unconstrained convex objective function:* In this case, any local minimum will also be a global minimum. Furthermore, if the objective function is differentiable, any stationary point (i.e., a point at which all the first-order derivatives vanish) will be a global minimum.
2. *Maximizing an unconstrained concave objective function:* Any stationary point will be a global maximum, and any local maximum will also be a global maximum.
3. *Minimizing a convex objective function over a closed convex feasible region:* Again, any local minimum will be a global minimum. As mentioned earlier, this class of problems is labeled convex programming problems, and a global minimum, if one exists, may occur at either an interior point or a boundary point of the feasible region.

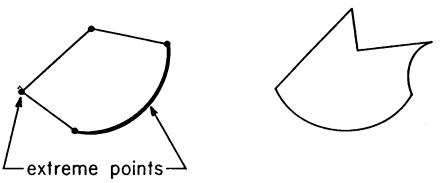

Figure 4 Examples of (*a*) Convex Set and (*b*) Nonconvex Set.

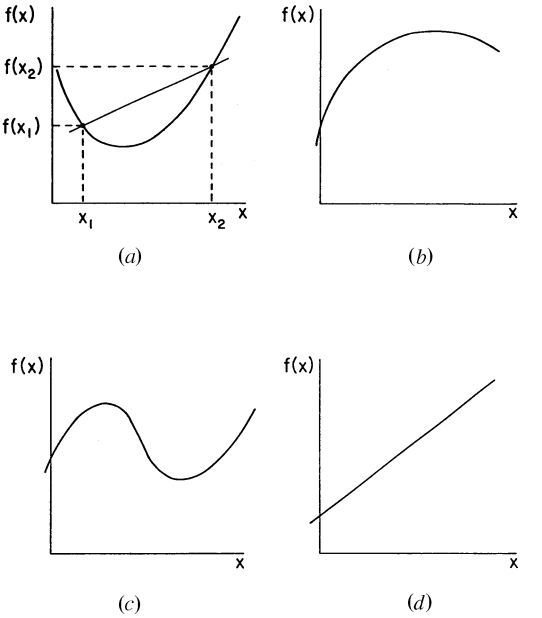

Figure 5 Examples of (*a*) Convex function, (*b*) Concave function, (*c*) Neither convex nor concave, (*d*) Both convex and concave.

4. *Maximizing a convex objective function over a closed bounded convex feasible region:* In this case, a maximum, if one exists, will be found at an extreme point of the feasible region. However, a local maximum need not be a global maximum.
5. *Maximizing a concave objective function over a closed convex feasible region:* This case is similar to case 3. That is, a local maximum is a global maximum.
6. *Minimizing a concave objective function over a closed bounded convex feasible region:* This case is analogous to case 4 and does not guarantee that a local minimum is a global minimum. However, a global minimum, if one exists, will occur at an extreme point of the feasible region.
7. *Maximizing or minimizing an objective function over a nonconvex set:* This is a difficult case that may produce a local minimum or maximum that is not also a global solution. Figure 6 illustrates that this can occur even in the simple case when the objective function is linear. Observe that extreme point **B** is a local minimum since all feasible points near **B** have an objective value that is greater than that at **B**.

In general, the task of proving that an arbitrary subset of E_n is convex can be quite difficult. However, the feasible region of problem (P) will be a convex set if each function $g_i(\mathbf{x})$ is a convex function and each function $h_j(\mathbf{x})$ is a linear function. Actually, these conditions on the functions $g_i(\mathbf{x})$, $h_j\mathbf{x})$ can be relaxed somewhat using the concepts of generalized convexity. A nice summary of generalized convexity is provided by Avriel (1976).

Verifying the convexity of an arbitrary function $f : E_n \rightarrow E_1$ can also be a difficult task. In the case when f is twice differentiable, however, the concept of quadratic form is useful for investigating the convexity or concavity of f.

A *quadratic form* $q(\mathbf{x})$ is defined by

$$q(\mathbf{x}) = \mathbf{x}^t\mathbf{A}\mathbf{x} \tag{8}$$

where $\mathbf{x} \in E_n$ and $\mathbf{A}$ is an $n \times n$ real symmetric matrix. The matrix $\mathbf{A}$ is said to be:

1. *Positive definite* if and only if $\mathbf{x}^t\mathbf{A}\mathbf{x} > 0$ for all $\mathbf{x} \neq \mathbf{0}$
2. *Negative definite* if $\mathbf{x}^t\mathbf{A}\mathbf{x} < 0$ and only if for all $\mathbf{x} \neq \mathbf{0}$

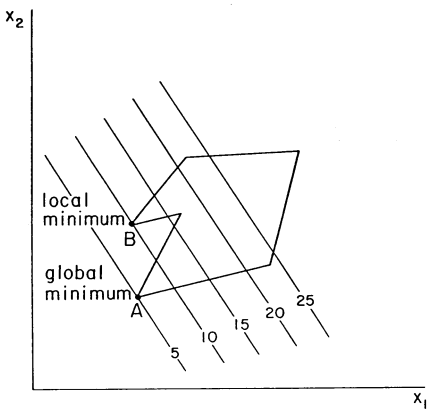

Figure 6 Minimizing a Linear Objective over a Nonconvex Set.

3. *Positive semidefinite* if and only if $\mathbf{x}^t\mathbf{A}\mathbf{x} \geq 0$ for all $\mathbf{x}$
4. *Negative semidefinite* if and only if $\mathbf{x}^t\mathbf{A}\mathbf{x} \leq 0$ for all $\mathbf{x}$
5. *Indefinite* if $\mathbf{x}^t\mathbf{A}\mathbf{x} > 0$ for some $\mathbf{x}$ and $\mathbf{x}^t\mathbf{A}\mathbf{x} < 0$ for some $\mathbf{x}$

Example 2. Consider the 2×2 symmetric matrix $\mathbf{A} = \begin{pmatrix} 1 & -3 \\ -3 & 11 \end{pmatrix}$. $\mathbf{A}$ is positive definite since

$$q = \mathbf{x}^t\mathbf{A}\mathbf{x} = (x_1, x_2)\begin{pmatrix} 1 & -3 \\ -3 & 11 \end{pmatrix}\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = x_2^2 - 6x_1x_2 + 11x_2^2 = (x_1 - 3x_2)^2 + 2x_2^2 > 0 \text{ for all } \mathbf{x} \neq \mathbf{0}$$

Positive and negative definiteness can also be checked using the leading principal minor test, although semidefiniteness cannot be verified in this manner. Using standard matrix notation, let

$$\mathbf{A} = \begin{pmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{pmatrix} \tag{9}$$

Define

$$A_1 = a_{11}, A_2 = \begin{vmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{vmatrix}$$

with $A_3, \ldots, A_n$ defined similarly. Note that $A_n = |\mathbf{A}|$, that is, A_n is the determinant of $\mathbf{A}$. A_i is called the ith *leading principal minor* of $\mathbf{A}$. The results of the *leading principal minor test* can be summarized as follows:

1. If $A_i > 0$ for all $i = 1, \ldots, n$, then $\mathbf{A}$ is positive definite.
2. If A_i, $i = 1, \ldots, n$, alternate in sign with $A_1 < 0$, then $\mathbf{A}$ is negative definite.
3. If 1 and 2 are not satisfied and $A_i \neq 0$ for all $i = 1, \ldots, n$, then $\mathbf{A}$ is indefinite.
4. If $A_i = 0$ for some i, then the test fails.

In Example 2, $A_1 = 1 > 0$ and $A_2 = 2 > 0$, therefore $\mathbf{A}$ is positive definite. A more comprehensive polynomial-time algorithm for checking both definiteness and semidefiniteness is presented in Bazaraa et al. (1994, pp. 96–97). The algorithm uses Gauss–Jordan reduction and works toward systematically reducing the matrix to upper triangular form until a conclusion is reached. Definiteness and semidefiniteness can also be determined by examining the eigenvalues of the matrix.

2.1. Convexity and the Hessian Matrix

Let $f : E_n \rightarrow E_1$ be a twice differentiable function and define the *Hessian matrix,* $\mathbf{H}(\mathbf{x})$, to be the matrix of second partial derivatives, $f_{ij}(\mathbf{x}) = \partial^2 f(\mathbf{x}) / \partial x_i \partial x_j$.

$$\mathbf{H}(\mathbf{x}) = \begin{pmatrix} f_{11}(\mathbf{x}) & f_{12}(\mathbf{x}) & \dots & f_{1n}(\mathbf{x}) \\ f_{21}(\mathbf{x}) & f_{22}(\mathbf{x}) & \dots & f_{2n}(\mathbf{x}) \\ \vdots & \vdots & \ddots & \vdots \\ f_{n1(}\mathbf{x}) & f_{n2}(\mathbf{x}) & \dots & f_{nn}(\mathbf{x}) \end{pmatrix} \tag{10}$$

Let $\bar{\mathbf{x}} \in E_n$. Then by examining the nature of the quadratic form of $\mathbf{H}(\mathbf{x})$, it is possible to determine local characteristics of the function f.

1. If $\mathbf{H}(\bar{\mathbf{x}})$ is positive definite, then f is locally convex at $\bar{\mathbf{x}}$.
2. If $\mathbf{H}(\bar{\mathbf{x}})$ is negative definite, then f is locally concave at $\bar{\mathbf{x}}$.
3. If $\mathbf{H}(\mathbf{x})$ is positive semidefinite for all $\mathbf{x}$, then f is a convex function.
4. If $\mathbf{H}(\mathbf{x})$ is negative semidefinite for all $\mathbf{x}$, then f is a concave function.

If f is a univariate function, that is, $f : E_1 \rightarrow E_1$, then the Hessian matrix simply reduces to the scalar, $f''(x)$ and the above conditions simplify to the following:

1. If $f''(\bar{x}) > 0$, then f is locally convex at $\bar{x}$.
2. If $f''(\bar{x}) < 0$, then f is locally concave at $\bar{x}$.
3. If $f''(x) \geq 0$ for all x, then f is a convex function.
4. If $f''(x) \leq 0$ for all x, then f is a concave function.

These conditions are used in the following section to develop optimality conditions in unconstrained optimization.

3. UNCONSTRAINED OPTIMIZATION

An unconstrained mathematical programming problem is a problem of the form: minimize $f(\mathbf{x})$ where $f : E_n \rightarrow E_1$. This is the type of problem that is typically addressed in a first course in calculus, and this class of problems has many applications, including maximum-likelihood or least-squares estimation problems in statistics. The classical fundamentals and algorithmic techniques used to solve these problems are often used as a basis for constructing efficient procedures for solving more general problems. This section presents some fundamental classical results, as well as algorithmic strategies for finding the solution of unconstrained optimization problems.

3.1. Classical Unconstrained Results

Classical methods of optimization are based on differential calculus, and it is generally assumed that the function to be optimized is continuous and differentiable (smooth). For a function of one variable, $f : E_1 \rightarrow E_1$, a *necessary condition* for a local extremum (either a local maximum or local minimum) to occur at a point $x^* \in E_1$ is that the first derivative vanishes at x^*, that is,

$$f'(x^*) = 0 \tag{11}$$

However, a local extremum does not necessarily occur at every point that satisfies (11); that is, (11) is not a *sufficient condition* for optimality. In practice, necessary conditions are used to identify *stationary points,* which are candidate extrema, whereas sufficient conditions are used to classify the stationary points as local maxima, local minima, or saddle points (inflection points in E_2). Once all local extrema are found, the global extrema can be found by selecting the absolute maximum or minimum. The necessary and sufficient conditions for determining and classifying the stationary points of a function of one variable are summarized in Table 1. These conditions are easily derived using a Taylor series expansion.

As indicated in the previous section, the sufficiency conditions in Table 1 are essentially examining the local properties of the function f. For example, $f''(\bar{x}) > 0$ indicates that the function is convex at the point $\bar{x}$, and thus, if $f'(\bar{x}) = 0$, a local minimum occurs at $\bar{x}$. Similarly, if $f''(\bar{x}) < 0$, then f is concave at $\bar{x}$.

To illustrate the use of the results presented in Table 1 consider the following simple problem.

Example 3. Find the extrema of the function $f(x) = x^3 (3x - 8) + 20$. First, the stationary points are identified by finding the roots of $f'(x) = 12x^2 (x - 2) = 0$. Clearly $x = 0, 2$ are the only stationary points. Next, these candidate points are classified by examining higher-order derivatives. In particular,

TABLE 1 Necessary and Sufficient Conditions for Local Extrema of a Univariate Function

	Necessary Condition	Sufficient Condition
Local minimum at $\bar{x}$	$f'(\bar{x}) = 0$	$f^{(i)}(\bar{x}) = 0$, $i = 1, \ldots, m-1$, $f^{(m)}(\bar{x}) > 0$ and m is even
Local maximum at $\bar{x}$	$f'(\bar{x}) = 0$	$f^{(i)}(\bar{x}) = 0$, $i = 1, \ldots, m-1$ $f^{(m)}(\bar{x}) < 0$ and m is even
Inflection point at $\bar{x}$	$f'(\bar{x}) = 0$	$f^{(i)}(\bar{x}) = 0$, $i = 1, \ldots, m-1$ $f^{(m)}(\bar{x}) \neq 0$ and m is odd

for this example, it is necessary to determine $f''(x) = 36x^2 - 48x$ and $f'''(x) = 72x - 48$. A local minimum occurs at $x = 2$ since $f''(2) = 48 > 0$ and $m = 2$ is even. Also, $f''(0) = 0$ and $f'''(0) = -48$. Therefore, an inflection point occurs at $x = 0$ since $f'''(0) < 0$ and $m = 3$ is odd. In addition, upon graphing, it can be seen that the local minimum at $x = 2$ is also a global minimum, even though the function f is not convex.

For a function of n variables, $f : E_n \rightarrow E_1$, a necessary condition for an extremum to occur at a point $\mathbf{x}^* \in E_n$ is that the gradient vector, $\nabla f(\mathbf{x})$, the vector of first partial derivatives, vanishes at $\mathbf{x}^*$. Thus, in this case, the task of finding the stationary points is more difficult, in that it is necessary, in general, to solve a system of n simultaneous nonlinear equations in n unknowns,

$$\frac{\partial f(\mathbf{x})}{\partial x_i} = 0 \quad \text{for } i = 1, \ldots, n \tag{12}$$

Sufficiency conditions are determined by examining the Hessian matrix $\mathbf{H}(\mathbf{x})$, the matrix of second partial derivatives. Based on the discussion in Section 2, Table 2 gives the necessary and sufficiency conditions for identifying and classifying stationary points in the multivariate case. In the event that the sufficiency conditions are not satisfied, higher-order derivative information must be used.

Example 4. Find the extrema of the function $f(\mathbf{x}) = x_1^3 - 6x_1x_2 + 24x_1 + x_2^2$. First, obtain first and second order derivative information.

$$\nabla f(\mathbf{x}) = \begin{pmatrix} 3x_1^2 - 6x_2 + 24 \\ -6x_1 + 2x_2 \end{pmatrix} \tag{13}$$

$$\mathbf{H}(\mathbf{x}) = \begin{pmatrix} 6x_1 & -6 \\ -6 & 2 \end{pmatrix} \tag{14}$$

Setting $\nabla f(\mathbf{x}) = 0$, the stationary points are $\mathbf{x}_1 = (2, 6)^t$ and $\mathbf{x}_2 = (4, 12)^t$. From Table 2, $\mathbf{x}_1$ is a saddle point since $H_1(\mathbf{x}_1) = 12$ and $H_2(\mathbf{x}_1) = -12$, that is, $\mathbf{H}(\mathbf{x}_1)$ is indefinite. Similarly, $H_1(\mathbf{x}_2) = 24$ and $H_2(\mathbf{x}_2) = 12$ implies that $\mathbf{H}(\mathbf{x}_2)$ is positive definite and thus, a local minimum occurs at $\mathbf{x}_2$.

3.2. Line Search Techniques

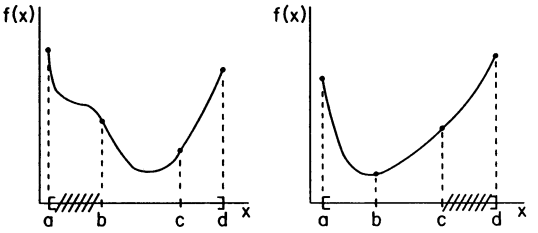
There are several direct search techniques for minimizing a function of one variable. The methods generally start from an initial estimate and sequentially move toward the minimum. Univariate or line search techniques play a major role in solving subproblems in more complex direct search algorithms.

3.2.1. Golden Section Method

An example of a line search technique that does not use derivatives is the golden section method, which seeks to find the minimum of a function $f(x)$ on an interval $[a, d]$. The interval $[a, d]$ is called

TABLE 2 Necessary and Sufficient Conditions for Local Extrema of a Multivariate Function

	Necessary Condition	Sufficient Condition
Local minimum at $\bar{\mathbf{x}}$	$\nabla f(\bar{\mathbf{x}}) = \mathbf{0}$	$\mathbf{H}(\bar{\mathbf{x}})$ is positive definite
Local maximum at $\bar{\mathbf{x}}$	$\nabla f(\bar{\mathbf{x}}) = \mathbf{0}$	$\mathbf{H}(\bar{\mathbf{x}})$ is negative definite
Saddle point at $\bar{\mathbf{x}}$	$\nabla f(\bar{\mathbf{x}}) = \mathbf{0}$	$\mathbf{H}(\bar{\mathbf{x}})$ is indefinite



(*a*) (*b*)

Figure 7 Narrowing the Interval of Uncertainty.

the *interval of uncertainty,* and the basic strategy of the method is to successively decrease the length of the interval, assuming that the function is unimodal, that is, the function has only one minimum on the interval $[a, d]$.

Let $b, c \in [a, d]$ such that $a < b < c < d$ and compute $f(b)$ and $f(c)$. Since f is unimodal on $[a, d]$, it is possible to narrow the interval of uncertainty by comparing $f(b)$ and $f(c)$. That is, if $f(b) > f(c)$, then the true minimum cannot lie on the interval $[a, b]$ [Figure 7(*a*)], and if $f(b) < f(c)$, the minimum cannot lie on the interval $[c, d]$ [Figure 7(*b*)]. Thus, in either case, the length of the interval of uncertainty is reduced and the entire process can be repeated until some desired accuracy is achieved.

Let $a_k < b_k < c_k < d_k$, where $[a_k, d_k]$ is the interval of uncertainty at iteration k and assume that $[a_1, d_1] = [a, d]$. Since functional evaluations are the most expensive step in the process, the golden section method reduces the amount of overall work by intelligently choosing symmetric points b_k and c_k so that they can be reused on successive iterations, as illustrated in Figure 8. This is achieved by using the relationships $b_k = \lambda a_k + (1 - \lambda)d_k$ and $c_k = (1 - \lambda)a_k + \lambda d_k$, where $\lambda = 0.618$. Observe that b_k and c_k are simply expressed as convex combinations of a_k and d_k. A summary of the *golden section algorithm* follows:

1. Choose a tolerance $\varepsilon > 0$ for the length of the final interval of uncertainty. Choose an initial interval of uncertainty $[a_1, d_1]$ and set the iteration counter $k = 1$. Compute $b_1 = \lambda a_1 + (1 - \lambda)d_1$ and $c_1 = (1 - \lambda)a_1 + \lambda d_1$.
2. If $d_k - a_k < \varepsilon$, stop; the interval $[a_k, d_k]$ contains the minimum. Otherwise, continue with step 3.
3. If $f(b_k) > f(c_k)$, go to step 4. Otherwise go to step 5.
4. Let $a_{k+1} = b_k$, $b_{k+1} = c_k$, $d_{k+1} = d_k$ [see Figure 8(*a*)]. Compute $c_{k+1} = (1 - \lambda)a_{k+1} + \lambda d_{k+1}$. Replace k by $k + 1$ and go to step 2.
5. Let $a_{k+1} = a_k$, $c_{k+1} = b_k$, $d_{k+1} = c_k$. [see Figure 8(*b*)]. Compute $b_{k+1} = \lambda a_{k+1} + (1 - \lambda)d_{k+1}$. Replace k by $k + 1$ and go to step 2.

Other line search methods that involve only function evaluations, that is, no derivative calculations, are the dichotomous search, the Fibonacci search (Kiefer 1957), and the quadratic fit line search. The Fibonacci search is the most efficient derivative-free line search technique in the sense that it requires the fewest function evaluations to attain a prescribed degree of accuracy. The quadratic fit method

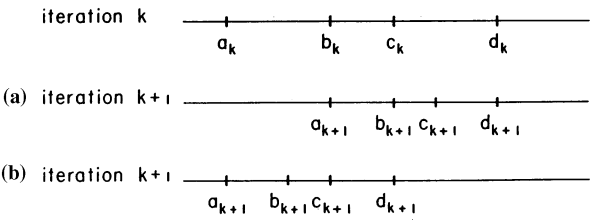


Figure 8 Successive Iterations of the Golden Section Method.

fits a quadratic function to three points on the function and then finds the unique minimizing point of the resulting quadratic function. A new interval of uncertainty is determined and the process is repeated until convergence is achieved (see, e.g., Bazaraa et al. 1994, pp. 279–281). Examples of line search techniques that utilize derivative information are the bisection search method and Newton's method. The more general multivariate version of Newton's algorithm will be discussed in the next section. In practice, a line search is typically used to find the step length during an iterative step of a more general algorithm. As such, it may be impractical to try to find the exact minimum point and it may be appropriate to apply an inexact method such as Armijos' rule (Armijo 1966) or simply to terminate the line search procedure before it has converged.

3.3. Multidimensional Search Techniques

This section is a natural extension of the previous section and addresses the problem of minimizing a function of several variables, that is, minimize $f(\mathbf{x})$ where $f : E_n \rightarrow E_1$. The general process behind multidimensional search techniques may be expressed as follows: Given a current point $\mathbf{x}_k$, determine a direction $\mathbf{d}_k$ and a step size α_k to yield a new point,

$$\mathbf{x}_{k+1} = \mathbf{x}_k + \alpha_k \mathbf{d}_k \tag{15}$$

The step size α_k is determined by either solving the line search problem in the variable α,

$$\text{Minimize } f(\mathbf{x}_k + \alpha \mathbf{d}_k) \tag{16}$$

where typically $\alpha \in E_1$, $\alpha \in [0, \infty)$, or $\alpha \in [a, b]$, or by taking prescribed discrete steps along the search directions. The strategy for choosing the search directions and the step sizes determines the different methods.

3.3.1. Multidimensional Search Techniques without Using Derivatives

The *cyclic coordinate search* method successively uses search directions that are parallel to the coordinate axes along with line search problems to determine the step sizes. This method is conceptually simple, but the sequence of iterates generated by this method tend to zigzag if the optimal solution lies in a valley.

To help overcome this problem, the method of Hooke and Jeeves (1961) involves both exploratory moves and pattern moves (acceleration moves) with discrete steps along the search directions. The discrete steps eliminate the need for a line search. In the exploratory move phase, starting at a point $\mathbf{x}_k$, a modified cyclic coordinate search is performed in which, if possible, the objective function is reduced once along each of the coordinate directions using a prescribed discrete step length. This leads to a new point $\mathbf{x}_{k+1}$ and establishes a direction of improvement. A pattern move is then performed in the direction $\mathbf{x}_{k+1} - \mathbf{x}_k$, leading to an intermediate point $\mathbf{y}$. Now, starting from $\mathbf{y}$, another exploratory move yields the point $\mathbf{x}_{k+2}$. If $f(\mathbf{x}_{k+2} < f(\mathbf{x}_{k+1})$, then an improvement has been found and the process is continued with a pattern move in the direction $\mathbf{x}_{k+2} - \mathbf{x}_{k+1}$. Otherwise, $\mathbf{x}_{k+1}$ is considered the new initial point and the process is begun anew. In the instance when no improving exploratory step can be made, the discrete step size is reduced and the process is repeated. When the step size becomes smaller than some prescribed tolerance, the search terminates. A graphical interpretation of the algorithm is presented in Figure 9.

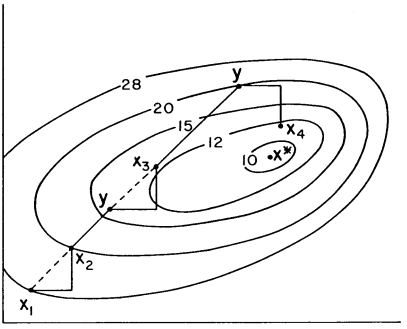

Figure 9 The Method of Hooke and Jeeves.

Other methods of multidimensional search without using derivatives include Rosenbrock's method (1960) and the simplex method of Spendley et al. (1962), which was later modified by Nelder and Meade (1974). Although it has the same name, this simplex method is not the same algorithm as that used for linear programming; it is a polytope algorithm that requires only functional evaluations and requires no smoothness assumptions.

3.3.2. Multidimensional Search Techniques Using Derivatives

In this section, optimization techniques are discussed that use derivative information in determining the search directions. As in the preceding discussion, a basic step in the algorithmic process consists of choosing a direction $\mathbf{d}_k$ and a step length α_k to arrive at a new point,

$$\mathbf{x}_{k+1} = \mathbf{x}_k + \alpha_k \mathbf{d}_k \tag{17}$$

Recall from calculus that the gradient, $\nabla f(\mathbf{x})$, of a differentiable function $f : E_n \rightarrow E_1$ provides local information concerning the rate of change of the function. In fact, given a point $\bar{\mathbf{x}}$, the gradient of f evaluated at $\bar{\mathbf{x}}$, $\nabla f(\bar{\mathbf{x}})$, is the direction of steepest ascent at $\bar{\mathbf{x}}$ and $-\nabla f(\bar{\mathbf{x}})$ is the direction of steepest descent at $\bar{\mathbf{x}}$. This fundamental result leads to the following algorithm.

3.3.2.1. The Method of Steepest Descent This is one of the most basic procedures for minimizing an unconstrained differentiable function, and the process is defined by simply specifying $\mathbf{d}_k = -\nabla f(\mathbf{x}_k)$ in Eq. (17) to get

$$\mathbf{x}_{k+1} = \mathbf{x}_k - \alpha_k \nabla f(\mathbf{x}_k) \tag{18}$$

where α_k is determined by solving the line search problem

$$\underset{\alpha \geq 0}{\text{Minimize}}\ f(\mathbf{x}_k - \alpha \nabla f(\mathbf{x}_k)) \tag{19}$$

The path generated by the algorithm for an example problem is illustrated in Figure 10. Note that successive directions are orthogonal and at each point $\mathbf{x}_k$, $\nabla f(\mathbf{x}_k)$ is normal to the objective contour at $\mathbf{x}_k$. A typical stopping rule is when the Euclidean norm of $\nabla f(\mathbf{x}_k)$, $(\|\nabla f(\mathbf{x}_k)\|)$, is less than some prescribed small positive number. The performance of the method of steepest descent is quite good during early iterations, but the convergence tends to slow excessively during later iterations and exhibits zigzagging tendencies near stationary points. Thus, it is not well used in practice.

3.3.2.2. Newton's Method The classical Newton's method is a technique that instead of specifying a step length at each iteration uses the inverse of the Hessian matrix, $\mathbf{H}(\mathbf{x})^{-1}$, to deflect the direction of steepest descent. The method assumes that $f(\mathbf{x})$ may be approximated locally by a second order Taylor approximation and is derived quite easily by determining the minimum point of this quadratic approximation. Assuming that $\mathbf{H}(\mathbf{x}_k)$ is nonsingular, then the algorithmic process is defined by

$$\mathbf{x}_{k+1} = \mathbf{x}_k - \mathbf{H}(\mathbf{x}_k)^{-1} \nabla f(\mathbf{x}_k) \tag{20}$$

The classical method does not require a line search at each iteration, but it does require second order derivative information and a matrix inversion, or equivalently, the solution of a system of linear

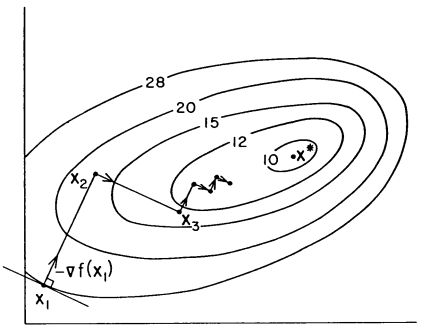

Figure 10 The Steepest Descent Method.

equations. In general, the performance of Newton's method is quite erratic and the sequence of points generated may not converge. Thus, it is not well suited for general use. However, Newton's method performs quite well if the initial point is sufficiently close to the optimal solution. This is because near an optimal solution, the local contours of the approximating quadratic function are usually a good approximation of those of the function.

Another interesting feature is that the method is not a true descent procedure, since the objective function is not guaranteed to decrease at each iteration. However, the direction, $-\mathbf{H}(\mathbf{x}_k)^{-1}\nabla f(\mathbf{x}_k)$, is guaranteed to be a descent direction if $\mathbf{H}(\mathbf{x}_k)$ is positive definite. Thus, adding a line search to control the step size means the objective will improve at each iteration provided that $\mathbf{H}(\mathbf{x}_k)$ is positive definite. In the case when $\mathbf{H}(\mathbf{x}_k)$ is indefinite, some other corrective action must be taken. One alternative is to give the Newton search direction a bias towards the steepest descent direction as suggested by Levenberg (1944) and Marquardt (1963). Another method, suggested by Fiacco and McCormick (1990, pp. 167–169), involves computing a negative curvature descent direction when $\mathbf{H}(\mathbf{x}_k)$ is indefinite. For further discussion of these methods, see, for example, McCormick (1983).

Example 5. Use classical Newton's method to minimize $f(\mathbf{x}) = (x_1^2 - x_2)^2 + (1 - x_1)^2$. Clearly, since $f(\mathbf{x}) \geq 0$ for all $\mathbf{x}$, a unique minimum occurs at $\mathbf{x}^* = (1, 1)^t$. First, compute the gradient vector, $\nabla f(\mathbf{x})$, and the Hessian matrix, $\mathbf{H}(\mathbf{x})$.

$$\nabla f(\mathbf{x}) = \begin{pmatrix} 4x_1^3 - 4x_1x_2 + 2x_1 - 2 \\ -2x_1^2 + 2x_2 \end{pmatrix} \tag{21}$$

$$\mathbf{H}(\mathbf{x}) = \begin{pmatrix} 12x_1^2 - 4x_2 + 2 & -4x_1 \\ -4x_1 & 2 \end{pmatrix} \tag{22}$$

Choosing $\mathbf{x}_1 = (-1, 1)^t$, then from (20),

$$\mathbf{x}_2 = \begin{pmatrix} -1 \\ 1 \end{pmatrix} - \begin{pmatrix} 10 & 4 \\ 4 & 2 \end{pmatrix}^{-1} \begin{pmatrix} -4 \\ 0 \end{pmatrix} = \begin{pmatrix} 1 \\ -3 \end{pmatrix} \tag{23}$$

$$\mathbf{x}_3 = \begin{pmatrix} 1 \\ -3 \end{pmatrix} - \begin{pmatrix} 26 & -4 \\ -4 & 2 \end{pmatrix}^{-1} \begin{pmatrix} 16 \\ -8 \end{pmatrix} = \begin{pmatrix} 1 \\ 1 \end{pmatrix} \tag{24}$$

Observe that $f(\mathbf{x}_1) = 4$, $f(\mathbf{x}_2) = 16$, and $f(\mathbf{x}_3) = 0$. That is, even though the minimum was found in two iterations, the objective function did not improve from iteration 1 to iteration 2.

3.3.2.3. Quasi-Newton Methods In some sense, quasi-Newton methods are an attempt to combine the best features of the steepest descent method with those of Newton's method. Recall that the steepest descent method performs well during early iterations and always decreases the value of the function, whereas Newton's method performs well near the optimum but requires second order derivative information. Quasi-Newton methods are designed to start like the steepest descent method and finish like Newton's method while using only first order derivative information. The basic idea was originally proposed by Davidon (1959) and subsequently developed by Fletcher and Powell (1963). An additional feature of quasi-Newton methods is that the minimum of a convex quadratic function $f : E_n \rightarrow E_1$ can be found in at most n iterations if exact line searches are used. The basic step of the algorithm is

$$\mathbf{x}_{k+1} = \mathbf{x}_k - \alpha_k \mathbf{D}_k \nabla f(\mathbf{x}_k) \tag{25}$$

where $\mathbf{D}_k$ is a deflection matrix requiring only first order derivative information and α_k is determined using a line search. The method of Davidon–Fletcher–Powell can be summarized as follows:

1. Choose a small positive number $\varepsilon > 0$ to test convergence and choose an initial point $\mathbf{x}_1$. Let the initial deflection matrix $\mathbf{D}_1 = \mathbf{I}$ and set the iteration counter $k = 1$.
2. Compute $\nabla f(\mathbf{x}_k)$. If $\|\nabla f(\mathbf{x}_k)\| < \varepsilon$, stop with $\mathbf{x}_k$ as the optimal solution. Otherwise, set $\mathbf{d}_k = -\mathbf{D}_k \nabla f(\mathbf{x}_k)$ and continue with step 3.
3. Let $\alpha = \alpha_k$ be a solution to the univariate problem, $\underset{\alpha \geq 0}{\text{minimize}}\ f(\mathbf{x}_k + \alpha \mathbf{d}_k)$.
4. Compute $\mathbf{x}_{k+1} = \mathbf{x}_k + \alpha_k \mathbf{d}_k$.
5. Find the updated deflection matrix $\mathbf{D}_{k+1}$ using

$$\mathbf{D}_{k+1} = \mathbf{D}_k + \frac{\mathbf{u}_k \mathbf{u}_k^t}{\mathbf{u}_k^t \mathbf{v}_k} - \frac{\mathbf{D}_k \mathbf{v}_k \mathbf{v}_k^t \mathbf{D}_k}{\mathbf{v}_k^t \mathbf{D}_k \mathbf{v}_k} \tag{26}$$

where $\mathbf{u}_k = \alpha_k \mathbf{d}_k$ and $\mathbf{v}_k = \nabla f(\mathbf{x}_{k+1}) - \nabla f(\mathbf{x}_k)$. Replace k by $k + 1$ and go to step 2.

Since $\mathbf{D}_1 = \mathbf{I}$, the initial iteration is a steepest descent step. Also, if f is a convex quadratic function, it can be shown that at termination $\mathbf{D}_k$ is the inverse of the Hessian matrix.

There are several other methods for updating $\mathbf{D}_k$ in step 5. Another important method is based on the BFGS formula, which was developed by Broyden (1970), Fletcher (1970), Goldfarb (1970), and Shanno (1970) and is given by

$$\mathbf{D}_{k+1} = \mathbf{D}_k + \left(1 + \frac{\mathbf{v}_k^t \mathbf{D}_k \mathbf{v}_k}{\mathbf{u}_k^t \mathbf{v}_k}\right) \frac{\mathbf{u}_k \mathbf{u}_k^t}{\mathbf{u}_k^t \mathbf{v}_k} - \frac{\mathbf{u}_k \mathbf{v}_k^t \mathbf{D}_k + \mathbf{D}_k \mathbf{v}_k \mathbf{u}_k^t}{\mathbf{u}_k^t \mathbf{v}_k} \tag{27}$$

The BFGS formula is generally preferred to (26) since computational results have shown that it requires considerably less effort, especially when inexact line searches are used. Quasi-Newton methods, also referred to as variable metric methods, are much more widely used than either the steepest descent or Newton's method. For additional details and computational comparisons, see Fletcher (1987, pp. 44–74).

Example 6. Find the minimum of $f(\mathbf{x}) = x_1^2/2 - x_1 x_2 + x_2^2 - x_1 - x_2$ using the method of Davidon–Fletcher–Powell. Choose an initial point $\mathbf{x}_1 = (0, 0)^t$, an initial deflection matrix $\mathbf{D}_1 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$, and determine the gradient vector,

$$\nabla f(\mathbf{x}) = \begin{pmatrix} x_1 - x_2 - 1 \\ -x_1 + 2x_2 - 1 \end{pmatrix} \tag{28}$$

Next, compute $\nabla f(\mathbf{x}_1) = (-1, -1)^t$, and as in step 3, solve the line search problem:

$$\underset{\alpha \geq 0}{\text{minimize}}\ f\left(\begin{pmatrix} 0 \\ 0 \end{pmatrix} - \alpha \begin{pmatrix} -1 \\ -1 \end{pmatrix}\right) = \alpha^2/2 - 2\alpha \tag{29}$$

to find $\alpha_1 = 2$. Therefore, from (25),

$$\mathbf{x}_2 = \begin{pmatrix} 0 \\ 0 \end{pmatrix} - 2 \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} -1 \\ -1 \end{pmatrix} = \begin{pmatrix} 2 \\ 2 \end{pmatrix} \tag{30}$$

Now compute the updated deflection matrix as in (26).

$$\mathbf{D}_2 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + \frac{\begin{pmatrix} 2 \\ 2 \end{pmatrix}(2 \quad 2)}{(2 \quad 2)\begin{pmatrix} 2 \\ 2 \end{pmatrix}} - \frac{\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}\begin{pmatrix} 0 \\ 2 \end{pmatrix}(0 \quad 2)\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}}{(0 \quad 2)\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}\begin{pmatrix} 0 \\ 2 \end{pmatrix}} = \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix} \tag{31}$$

Then,

$$\mathbf{x}_3 = \begin{pmatrix} 2 \\ 2 \end{pmatrix} - 1 \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix} \begin{pmatrix} -1 \\ 1 \end{pmatrix} - \begin{pmatrix} 3 \\ 2 \end{pmatrix} \tag{32}$$

Since $\nabla f(\mathbf{x}_3) = 0$, the algorithm terminates with $\mathbf{x}^* = (3, 2)^t$. Note that $\mathbf{D}_2$ is precisely the inverse of the Hessian matrix, $\mathbf{H}(\mathbf{x}) = \begin{pmatrix} 1 & -1 \\ -1 & 2 \end{pmatrix}$, of the convex quadratic objective function $f(\mathbf{x})$.

3.4. Conjugate Gradient Methods

The nonzero vectors $\mathbf{d}_1, \ldots, \mathbf{d}_k$ are said to be *conjugate* with respect to the positive definite matrix $\mathbf{H}$ if they are linearly independent and $\mathbf{d}_i^t \mathbf{H} \mathbf{d}_j = 0$ for $i \neq j$. A method that generates such directions when applied to a quadratic function with Hessian matrix $\mathbf{H}$ is called a *conjugate direction method*. These methods will locate the minimum of a quadratic function in a finite number of iterations, and they can also be applied iteratively to optimize nonquadratic functions.

The algorithm proposed by Fletcher and Reeves (1964), is probably the best-known example of a conjugate gradient algorithm. Starting at some initial point $\mathbf{x}_1$, the algorithm begins like the steepest descent method by searching in the direction $\mathbf{d}_1 = -\nabla f(\mathbf{x}_1)$ to determine $\mathbf{x}_2$. Subsequent directions are computed using the expression

$$\mathbf{d}_{k+1} = -\nabla f(\mathbf{x}_{k+1}) + \alpha_k \mathbf{d}_k \tag{33}$$

where

$$\alpha_k = \frac{\nabla f(\mathbf{x}_{k+1})^t \nabla f(\mathbf{x}_{k+1})}{\nabla f(\mathbf{x}_k)^t \nabla f(\mathbf{x}_k)} \tag{34}$$

Note from (33) that the method actually deflects the current direction of steepest descent by adding on a positive multiple of the direction vector used in the previous step. In fact, it is easily shown that $\mathbf{d}_{k+1}$ is essentially a convex combination of $-\nabla f(\mathbf{x}_{k+1})$ and $\mathbf{d}_k$.

Quasi-Newton methods are generally preferable to conjugate gradient methods because they have been shown to be more efficient. However, conjugate gradient methods have the advantage of requiring no matrix operations and having minimal storage requirements for computer implementation.

4. CONSTRAINED OPTIMIZATION

In this section, methods for addressing constrained optimization problems are discussed. First the classical method of Lagrange multipliers is presented, followed by the Karush–Kuhn–Tucker conditions. Both of these techniques are indirect methods, and general optimality conditions are presented. Then several algorithmic strategies are presented for addressing specific classes of nonlinear programming problems.

4.1. Lagrange Multipliers

The method of Lagrange multipliers is a classical indirect method for solving nonlinear programming problems in which the objective is to optimize a differentiable function subject to a set of equality constraints comprised of differentiable functions. The basic technique involves transforming the constrained nonlinear problem into an unconstrained nonlinear problem by forming what is called the Lagrangian function. Consider the mathematical programming problem with equality constraints,

$$\text{(NLPE) Minimize } f(\mathbf{x}) \tag{35}$$

$$\text{Subject to } h_j(\mathbf{x}) = 0 \text{ for } j = 1, \ldots, p \tag{36}$$

The *Lagrangian function,*

$$L(\mathbf{x}, \mathbf{v}) = f(\mathbf{x}) + \sum_{j=1}^{p} v_j h_j(\mathbf{x}) \tag{37}$$

is formed by introducing a vector of Lagrange multipliers, $\mathbf{v} = (v_1, \ldots, v_p)^t$. v_j is referred to as the Lagrange multiplier, dual multiplier, or dual variable for constraint $h_j(\mathbf{x}) = 0$. Since each feasible point $\mathbf{x}$ must satisfy $h_j(\mathbf{x}) = 0$ for all $j = 1, \ldots, p$, the addition of the term $\Sigma_{j=1}^{p} v_j h_j(\mathbf{x})$ to the objective function $f(\mathbf{x})$ does not change the value of the function. As in section 3, a necessary condition for a stationary point is that the partial derivatives with respect to x_i for $i = 1, \ldots, n$ and v_j for $j = 1, \ldots, p$, equal zero. That is,

$$\frac{\partial L(\mathbf{x}, \mathbf{v})}{\partial x_i} = \frac{\partial f(\mathbf{x})}{\partial x_i} + \sum_{j=1}^{p} v_j \frac{\partial h_j(\mathbf{x})}{\partial x_i} = 0 \quad \text{for } i = 1, \ldots, n \tag{38}$$

$$\frac{\partial L(\mathbf{x}, \mathbf{v})}{\partial v_j} = h_j(\mathbf{x}) = 0 \quad \text{for } j = 1, \ldots, p \tag{39}$$

A stationary point for a general Lagrangian function may or may not be a local extremum. If, as described in Section 2, suitable convexity conditions hold, then the method of Lagrange multipliers will yield a global minimum.

Example 7

$$\text{Minimize } f(\mathbf{x}) = x_1^2 + 2x_2^2 + 4x_1x_2 - 12x_1 - 15x_2 \tag{40}$$

$$\text{Subject to } h_1(\mathbf{x}) = 2x_1 - x_2 - 5 = 0 \tag{41}$$

First, form the Lagrangian function,

$$L(\mathbf{x}, \mathbf{v}) = x_1^2 + 2x_2^2 + 4x_1x_2 - 12x_1 - 15x_2 + v_1(2x_1 - x_2 - 5) \tag{42}$$

Then, using (38) and (39),

$$\frac{\partial L(\mathbf{x}, \mathbf{v})}{\partial x_1} = 2x_1 + 4x_2 - 12 + 2v_1 = 0 \tag{43}$$

$$\frac{\partial L(\mathbf{x}, \mathbf{v})}{\partial x_2} = 4x_1 + 4x_2 - 15 - v_1 = 0 \tag{44}$$

$$\frac{\partial L(\mathbf{x}, \mathbf{v})}{\partial v_1} = 2x_1 - x_2 - 5 = 0 \tag{45}$$

Solving the system of linear equations, (43) through (45), yields $x_1 = 3$, $x_2 = 1$, and $v_1 = 1$. Thus, the optimal solution is $\mathbf{x}^* = (3, 1)^t$.

4.2. Karush–Kuhn–Tucker Conditions

Consider the general nonlinear programming problem,

$$\text{(NLP) Minimize } f(\mathbf{x}) \tag{46}$$

$$\text{Subject to } g_i(\mathbf{x}) \leq 0 \text{ for } i = 1, \ldots, m \tag{47}$$

$$h_j(\mathbf{x}) = 0 \text{ for } j = 1, \ldots, p \tag{48}$$

where f, g_i, $h_j : E_n \rightarrow E_1$ are continuously differentiable functions. The *Karush–Kuhn–Tucker (*KKT*) conditions* are essentially an extension of the method of Lagrange multipliers to problems involving inequality constraints. The results were derived independently by Karush (1939), and Kuhn and Tucker (1951). Although these necessary conditions are not typically used to derive an optimal solution, they do provide insight into solution behavior and form the basis for many nonlinear programming algorithms. They can also be used to verify that a given solution is a candidate for an optimal solution.

4.2.1. KKT Necessary Conditions

If $\mathbf{x}^*$ is a local minimum of problem (NLP) and some constraint qualification holds (e.g. the vectors $\nabla g_i(\mathbf{x}^*)$ for all i such that $g_i(\mathbf{x}^*) = 0$, and $\nabla h_j(\mathbf{x}^*)$ for $j = 1, \ldots, p$, are linearly independent), then there exists vectors $\mathbf{u} = (u_1, \ldots, u_m)^t$ and $\mathbf{v} = (v_1, \ldots, v_p)^t$ such that

$$g_i(\mathbf{x}^*) \leq 0 \text{ for } i = 1, \ldots, m \tag{49}$$

$$h_j(\mathbf{x}^*) = 0 \text{ for } j = 1, \ldots, p \tag{50}$$

$$\frac{\partial f(\mathbf{x}^*)}{\partial x_k} + \sum_{i=1}^{m} u_i \frac{\partial g_i(\mathbf{x}^*)}{\partial x_k} + \sum_{j=1}^{p} v_j \frac{\partial h_j(\mathbf{x}^*)}{\partial x_k} = \text{ for } k = 1, \ldots, n \tag{51}$$

$$u_i \geq 0 \text{ for } i = 1, \ldots, m \tag{52}$$

$$u_i g_i(\mathbf{x}^*) = 0 \text{ for } i = 1, \ldots, m \tag{53}$$

Conditions (49) and (50) are called *primal feasibility,* conditions (51) and (52) are called *dual feasibility,* and condition (53) is called *complementary slackness*. To interpret these results geometrically, it is helpful to rewrite (51) in a more compact notation using gradients,

$$-\nabla f(\mathbf{x}^*) = \sum_{i=1}^{m} u_i \nabla g_i(\mathbf{x}^*) + \sum_{j=1}^{p} v_j \nabla h_j(\mathbf{x}^*) \tag{54}$$

Given a point $\mathbf{x}^*$, condition (53) asserts that the dual variable u_i will be zero if $g_i(\mathbf{x}^*) < 0$ (i.e., the constraint $g_i(\mathbf{x}) \leq 0$ is nonbinding at $\mathbf{x}^*$). Thus, from (53) and (54), the KKT conditions are specifying that, at an optimal solution, $-\nabla f(\mathbf{x}^*)$ can be written as a linear combination of the gradients of the binding constraints (i.e., those constraints satisfied as equalities). In the case involving only constraints of the form $g_i(\mathbf{x}) \leq 0$, $-\nabla f(\mathbf{x}^*)$ must lie in the cone spanned by the gradients of the binding constraints since $u_i \geq 0$ for $i = 1, \ldots, m$. This geometric interpretation is illustrated in Figure 11 using the following example.

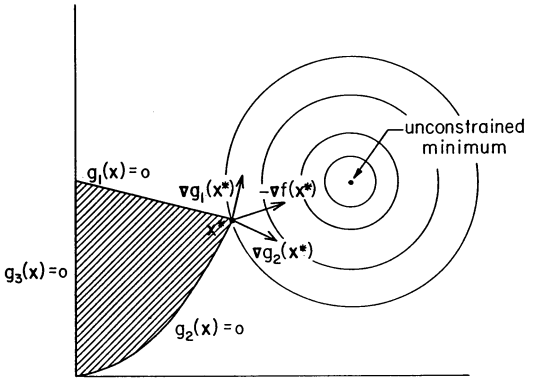

Figure 11 Graphical Solution of Example 8 Illustrating the KKT Conditions.

Example 8

$$\text{Minimize } f(\mathbf{x}) = (x_1 - 14)^2 + (x_2 - 12)^2 \tag{55}$$

$$\text{Subject to } g_1(\mathbf{x}) = x_1 + 4x_2 - 40 \leq 0 \tag{56}$$

$$g_2(\mathbf{x}) = x_1^2 - 8x_2 \leq 0 \tag{57}$$

$$g_3(\mathbf{x}) = -x_1 \leq 0 \tag{58}$$

The KKT conditions for this problem can be written as follows:

$$x_1 + 4x_2 - 40 \leq 0 \tag{59}$$

$$x_1^2 - 8x_2 \leq 0 \tag{60}$$

$$-x_1 \leq 0 \tag{61}$$

$$\begin{pmatrix} 2x_1 - 28 \\ 2x_2 - 24 \end{pmatrix} + u_1 \begin{pmatrix} 1 \\ 4 \end{pmatrix} + u_2 \begin{pmatrix} 2x_1 \\ -8 \end{pmatrix} + u_2 \begin{pmatrix} -1 \\ 0 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix} \tag{62}$$

$$u_i \geq 0 \text{ for } i = 1, 2, 3 \tag{63}$$

$$u_1(x_1 + 4x_2 - 40) = 0 \tag{64}$$

$$u_2(x_1^2 - 8x_2) = 0 \tag{65}$$

$$u_3(-x_1) = 0 \tag{66}$$

The reader can verify that $\mathbf{x}^* = (8, 8)^t$ and $\mathbf{u}^* = (28/9, 5/9, 0)^t$ satisfy (59) through (66) and thus, as illustrated in Figure 11, the negative gradient of the objective at $\mathbf{x}^*$, $-\nabla f(\mathbf{x}^*)$, lies in the cone spanned by $\nabla g_1(\mathbf{x}^*)$ and $\nabla g_2(\mathbf{x}^*)$.

It should also be pointed out that if f and g_i for $i = 1, \ldots, m$ are convex functions and h_j for $j = 1, \ldots, p$ are linear functions, then the KKT conditions are also sufficient for optimality. This is the case in Example 8. In fact, these assumptions can be somewhat relaxed using the concepts of generalized convexity. For a detailed discussion of first- and second-order KKT conditions, see, for example, Fiacco and McCormick (1990, pp. 17–34).

The following section discusses a solution procedure that is a direct application of the KKT conditions.

4.3. Quadratic Programming

Quadratic programming problems are an important class of linearly constrained problems having the following form:

$$\text{(QP) Minimize } \mathbf{c}^t\mathbf{x} + 1/2\mathbf{x}^t\mathbf{H}\mathbf{x} \tag{67}$$

$$\text{Subject to } \mathbf{A}\mathbf{x} \leq \mathbf{b} \tag{68}$$

$$\mathbf{x} \geq \mathbf{0} \tag{69}$$

where $\mathbf{H}$ is an $n \times n$ symmetric matrix, $\mathbf{A}$ is an $m \times n$ matrix, $\mathbf{c} = (c_1, \ldots, c_n)^t$, $\mathbf{b} = (b_1, \ldots, b_m)^t$ and the decision vector is $\mathbf{x} = (x_1, \ldots, x_n)^t$. The following method is based on the Karush–Kuhn–Tucker conditions and reduces the quadratic programming problem to what is referred to as a linear complementarity problem.

Let $\mathbf{u} = (u_1, \ldots, u_m)^t$ and $\mathbf{v} = (v_1, \ldots, v_n)^t$ be the dual multipliers for constraints $\mathbf{A}\mathbf{x} \leq \mathbf{b}$ and $-\mathbf{x} \leq \mathbf{0}$, respectively. Then, using matrix notation, the KKT conditions for (QP) can be expressed as follows:

$$\mathbf{A}\mathbf{x} + \mathbf{s} = \mathbf{b} \tag{70}$$

$$-\mathbf{A}^t\mathbf{u} - \mathbf{H}\mathbf{x} + \mathbf{v} = \mathbf{c} \tag{71}$$

$$\mathbf{x}, \mathbf{v} \geq \mathbf{0}, \mathbf{s}, \mathbf{u} \geq \mathbf{0} \tag{72}$$

$$\mathbf{x}^t\mathbf{v} = 0, \mathbf{u}^t\mathbf{s} = 0 \tag{73}$$

If $\mathbf{H}$ is positive semidefinite, then problem (QP) is a convex program. Thus, the KKT conditions are sufficient in this case, and any solution to this system will yield a global optimal solution to (QP). When $\mathbf{H}$ is indefinite, then local optimal solutions which are not global optimal solutions may occur.

The system (70)–(73) can be expressed in the form

$$\mathbf{w} - \mathbf{M}\mathbf{z} = \mathbf{q} \tag{74}$$

$$\mathbf{w} \geq \mathbf{0}, \mathbf{z} \geq \mathbf{0} \tag{75}$$

$$\mathbf{w}^t\mathbf{z} = 0 \tag{76}$$

where $\mathbf{M} = \begin{pmatrix} \mathbf{0} & -\mathbf{A} \\ \mathbf{A}^t & \mathbf{H} \end{pmatrix}$, $\mathbf{q} = \begin{pmatrix} \mathbf{b} \\ \mathbf{c} \end{pmatrix}$, $\mathbf{w} = \begin{pmatrix} \mathbf{s} \\ \mathbf{v} \end{pmatrix}$, $\mathbf{Z} = \begin{pmatrix} \mathbf{u} \\ \mathbf{x} \end{pmatrix}$.

Written in this form, (74)–(76) are an example of a *linear complementarity problem,* which also has applications in game theory. In this context, (76) is referred to as the *complementarity condition,* and all w_i, z_i pairs are said to be *complementary variables*. A method for finding a solution to this system is the complementary pivoting algorithm credited to Lemke (1968). Under certain assumptions on the matrix $\mathbf{M}$, the algorithm determines a solution or finds a direction indicating unboundedness in a finite number of iterations.

Other solution procedures for quadratic programming problems include conjugate gradient methods and the Dantzig–Wolfe method (see Dantzig 1963), which uses a modification of the simplex algorithm for linear programming.

4.4. Separable Programming

Separable programming is a procedure for obtaining an approximate solution to a nonlinear programming problem in which the objective function and constraint functions can be expressed as the sum of univariate functions. A separable programming problem has the following form:

$$\text{(SP) Minimize } f(\mathbf{x}) = \sum_{j=1}^{n} f_j(x_j) \tag{77}$$

$$\text{Subject to } \sum_{j=1}^{n} g_{ij}(x_j) \leq b_i \text{ for } i, \ldots, m \tag{78}$$

$$x_j \geq 0 \text{ for } j = 1, \ldots, n \tag{79}$$

Here, for example, $f(\mathbf{x})$ may represent the total cost whereas $f_j(x_j)$ represents the cost contribution of variable x_j.

The solution technique involves approximating each of the functions $f_j(x_j)$ and each of the functions $g_{ij}(x_j)$ by piecewise linear functions on their respective intervals of interest. Before presenting the resulting mathematical programming formulation, it is informative to review the idea of a linear approximation.

A *piecewise linear approximation* of a univariate function $h(x)$ on an interval of interest $[a, b]$ is illustrated in Figure 12. The interval $[a, b]$ is partitioned using t grid points, $a = x_1, x_2, \ldots, x_t = b$. Then the linear approximation, $l_k(x)$, on subinterval $[x_k, x_{k+1}]$ can be written as follows using the concept of a convex combination.

$$l_k(x) = \lambda h(x_k) + (1 - \lambda)h(x_{k+1}) \tag{80}$$

where

$$x = \lambda x_k + (1 - \lambda)x_{k+1} \tag{81}$$

$$\lambda \in [0, 1] \tag{82}$$

Generalizing, the piecewise linear approximation of $h(x)$ on the interval $[a, b]$ is given by

$$l(x) = \sum_{k=1}^{t} \lambda_k h(x_k) \tag{83}$$

$$\sum_{k=1}^{t} \lambda_k = 1 \tag{84}$$

$$\lambda_k \geq 0 \quad \text{for } k = 1, \ldots, t \tag{85}$$

where, at most, two adjacent λ_ks are positive. This last restriction arises because if nonadjacent λ_ks are positive, the resulting approximation will not lie on the piecewise linear approximating function. The accuracy of this approximation improves as the number of grid points increases, but, increasing the number of grid points increases the number of variables in the approximating problem.

Denoting the grid points for variable x_j by x_{kj} for $k = 1, \ldots, t_j$, the approximating problem is

$$\text{Minimize} \sum_{j=1}^{n} \sum_{k=1}^{t_j} \lambda_{kj} f_j(x_{kj}) \tag{86}$$

$$\text{Subject to} \sum_{j=1}^{n} \sum_{k=1}^{t_j} \lambda_{kj} g_{ij}(x_{kj}) = b_i \quad \text{for } i = 1, \ldots, m \tag{87}$$

$$\sum_{k=1}^{t_j} \lambda_{kj} = 1 \quad \text{for } j = 1, \ldots, n \tag{88}$$

$$\lambda_{kj} \geq 0 \quad \text{for } k = 1, \ldots, t_j; \quad j = 1, \ldots, n \tag{89}$$

$$\text{At most, two adjacent } \lambda_{kj}\text{s are positive for } j = 1, \ldots, n \tag{90}$$

Except for constraint (90), this is a linear programming problem in the variables λ_{kj}, which can be solved by the simplex method provided a restricted basis entry rule is used which enforces (90). However, in the case when each f_j is strictly convex and each g_{ij} is convex, constraint (90) can be

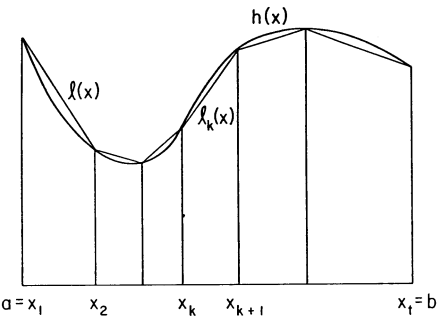

Figure 12 Piecewise Linear Approximation, $l(x)$, of a Function, $h(x)$.

neglected since it will be satisfied automatically by a solution generated by the simplex method. For additional details, see Miller (1963), and Wolfe (1963).

4.5. Geometric Programming

As has been shown in the two previous sections, it is sometimes possible to find the solution of a problem by transforming it into a simpler problem. This is also the case with geometric programming problems, another important class of nonlinear programming problems. The motivation for addressing this class of problems originated with work in engineering design. Geometric programming problems have the following general form:

$$\text{(GP) Minimize } g_0(\mathbf{x}) = \sum_{k=1}^{t_0} c_{0k} \prod_{j=1}^{n} (x_j)^{a_{0jk}} \tag{91}$$

$$\text{Subject to } g_i(\mathbf{x}) = \sum_{k=1}^{t_i} c_{ik} \prod_{j=1}^{n} (x_j)^{a_{ijk}} \leq 1 \text{ for } i = 1, \ldots, m \tag{92}$$

$$x_j > 0 \text{ for } j = 1, \ldots, n \tag{93}$$

where the coefficients c_{ik}, $i = 0, \ldots, m$ must be positive. Although each of the functions $g_i(\mathbf{x})$ for $i = 0, \ldots, m$ is not a true polynomial since the exponents a_{ijk} are not restricted to be integers, they are generally referred to as *posynomials* or positive generalized polynomials.

Problem (GP) has a nonlinear objective function and nonlinear constraints and, as such, is quite difficult to solve. However, geometric programming problems belong to a class of problems whose dual problems involve only linear constraints. Let δ_{ik} be the dual variable associated with the term $c_{ik}\prod_{j=1}^{n} (x_j)^{a_{ijk}}$. Then the dual problem for problem (GP) can be written as follows:

$$\text{Minimize } v(\boldsymbol{\delta}, \boldsymbol{\lambda}) = \prod_{i=0}^{m} \prod_{k=1}^{t_i} \left(\frac{c_{ik}}{\delta_{ik}}\right)^{\delta_{ik}} \prod_{i=1}^{m} (\lambda_i)^{\lambda_i} \tag{94}$$

$$\text{Subject to } \sum_{i=0}^{m} \sum_{k=1}^{t_i} a_{ijk}\delta_{ik} = 0 \text{ for } j = 1, \ldots, n \tag{95}$$

$$\sum_{k=1}^{t_0} \delta_{0k} = 1 \tag{96}$$

$$\sum_{k=1}^{t_i} \delta_{0k} = \lambda_i \text{ for } i = 1, \ldots, m \tag{97}$$

$$\boldsymbol{\delta} \geq \mathbf{0} \tag{98}$$

This dual problem has $t = \sum_{i=0}^{m} t_i$ variables, and at best, in the case when $t - n - 1 = 0$, determining the solution simply involves solving a square system of linear equations in nonnegative variables. The quantity $t - n - 1$ is referred to as the *degree of difficulty*. Although the dual objective function as written in (94) is neither convex nor concave, by using a natural logarithm transformation, the resulting function can be shown to be a concave function. In fact, by taking the logarithm, the objective function becomes separable and the dual problem can be cast as a separable programming problem. Thus, at worst, solving the dual problem involves maximizing a nonlinear concave objective function subject to linear constraints. As such, any local solution to the dual problem is a global solution. Even so, the advantage of solving the dual problem is offset by the fact that it can be difficult to find the optimal primal variables given the optimal dual variables and the optimal objective value.

Example 9

$$\text{Minimize } g_0(\mathbf{x}) = 4x_1x_2^3 + 20x_1^{-2} \tag{99}$$

$$\text{Subject to } g_1(\mathbf{x}) = x_1x_2^{-1} \leq 1 \tag{100}$$

$$x_1, x_2 > 0 \tag{101}$$

Letting δ_{01}, δ_{02}, and δ_{11} be the dual variables for the terms $4x_1x_2^3$, $20x_1^{-2}$, and $x_1x_2^{-1}$, respectively, then the dual problem becomes

$$\text{Maximize } v(\boldsymbol{\delta}, \boldsymbol{\lambda}) = \left(\frac{4}{\delta_{01}}\right)^{\delta_{01}} \left(\frac{20}{\delta_{02}}\right)^{\delta_{02}} \left(\frac{1}{\delta_{11}}\right)^{\delta_{11}} (\lambda_1)^{\lambda_1} \tag{102}$$

$$\text{Subject to } \delta_{01} - 2\delta_{02} + \delta_{11} = 0 \tag{103}$$

$$3\delta_{01} - \delta_{11} = 0 \tag{104}$$

$$\delta_{01} + \delta_{02} = 1 \tag{105}$$

$$\delta_{11} = \lambda_1 \tag{106}$$

$$\delta_{01}, \delta_{02}, \delta_{11} > 0 \tag{107}$$

Condition (103) is derived from the exponents of x_1 in the respective terms of the primal. Similarly, (104) is derived from the exponents of x_2. These are referred to as the *orthogonality conditions,* whereas (105) is termed the *normality condition*. In this case $t - n - 1 = 3 - 2 - 1 = 0$ and the dual problem can be solved by finding the solution of the linear system of equations, (103)–(105). Thus, $\delta_{01}^* = 1/3$, $\delta_{02}^* = 2/3$, $\lambda_1^* = \delta_{01}^* = 1$, with $g_0(\mathbf{x}^*) = v(\boldsymbol{\delta}^*, \boldsymbol{\lambda}^*) = 12^{1/3}30^{2/3}$.

The optimal values of the primal variables can be recovered by utilizing the following condition:

$$\delta_{ok}^* = \frac{c_{0k}}{g_0(\mathbf{x}^*)} \prod_{j=1}^{n} (x_j^*)^{a_{0jk}} \text{ for } k = 1, \ldots, t_0 \tag{108}$$

Substituting into (108) yields

$$\frac{1}{3} = \frac{4}{12^{1/3}30^{2/3}} x_1 x_2^3 \tag{109}$$

$$\frac{2}{3} = \frac{20}{12^{1/3}30^{2/3}} x_1^{-2} \tag{110}$$

Now solving (109) and (110) gives $x_1^* = x_2^* = (5/2)^{1/6}$.

For a complete discussion of geometric programming, the interested reader is referred to Duffin et al. (1967), and Beighter and Phillips (1976). Reviews of software for solving geometric programming problems are provided in Dembo (1976) and Rijckaert and Walraven (1985).

4.6. Methods of Feasible Directions

Consider the following nonlinear programming problem:

$$\text{Minimize } f(\mathbf{x}) \tag{111}$$

$$\text{Subject to } \mathbf{x} \in S \subseteq E_n \tag{112}$$

Conceptually, methods of feasible directions operate in a manner similar to unconstrained multidimensional search techniques. That is, the basic idea is, given a feasible point $\mathbf{x}_k$, determine a direction $\mathbf{d}_k$ and a step length α_k that yield the new point $\mathbf{x}_{k+1} = \mathbf{x}_k + \alpha_k \mathbf{d}_k$. In the constrained case, however, care must to taken to choose a direction $\mathbf{d}_k$ that not only produces a point $\mathbf{x}_{k+1}$ that improves the objective function, but also maintains the feasibility of $\mathbf{x}_{k+1}$. For a differentiable objective function $f(\mathbf{x})$, an *improving feasible direction* $\mathbf{d}_k$ at the point $\mathbf{x}_k \in S$, has the following two properties (see Figure 13):

1. $\nabla f(\mathbf{x}_k)^t \mathbf{d}_k < 0$, that is, the *directional derivative* at $\mathbf{x}_k$ in the direction $\mathbf{d}_k$ is negative, resulting in a reduction in objective value. Geometrically, this means that $\mathbf{d}_k$ forms an acute angle with $-\nabla f(\mathbf{x}_k)$.
2. $\mathbf{x}_{k+1} = \mathbf{x}_k + \alpha \mathbf{d}_k \in S$ for some $\alpha > 0$, that is, a feasible move is possible in the direction $\mathbf{d}_k$.

Thus, methods of feasible directions operate by determining an improving feasible direction and then solving a line search problem to determine the step length in that direction. This process is repeated until some stopping rule is satisfied. Since the sequence of points generated is feasible to the primal problem, these are often called *primal methods*. The way in which the directions are generated and the step sizes are computed determines the various methods.

One such method that can be applied to a nonlinear programming problem with a linear constraint set is the method of reduced gradient, originally proposed by Wolfe (1963). It operates in a manner

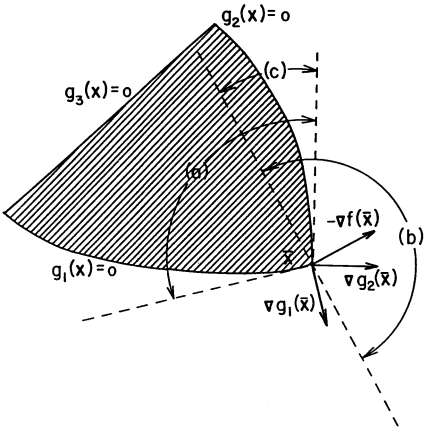

Figure 13 Illustration of (*a*) Feasible direction set at $\bar{\mathbf{x}}$, (*b*) Improving direction set at $\bar{\mathbf{x}}$, and (*c*) Improving feasible direction set at $\bar{\mathbf{x}}$.

similar to the simplex method for linear programming by using a set of independent variables to reduce the dimensionality of the problem. The reduced gradient is the gradient with respect to these independent variables. This method was generalized to handle nonlinear constraints by Abadie and Carpentier (1969) and is called the generalized reduced gradient method (GRG). There are several other methods of feasible directions, including those proposed by Zoutendijk (1960), the gradient projection method of Rosen (1961), and the convex simplex method of Zangwill (1967).

4.7. Sequential Unconstrained Minimization Techniques

In this section, methods for converting a general constrained nonlinear programming problem into an equivalent unconstrained problem are discussed. Once this conversion has been made, algorithms for unconstrained optimization can be applied. Unfortunately, there are computational difficulties associated with this process, and instead of solving a single unconstrained problem, it is usually necessary to solve a sequence of unconstrained problems. Although penalty functions methods were originally introduced by Courant (1943), the sequential unconstrained minimization technique (SUMT) was primarily developed by Fiacco and McCormick (1964). There are two basic approaches, both of which add a penalty term to the objective function. In the *penalty function method* (or exterior penalty function method), the optimal solution is approached by a sequence of infeasible points. That is, the optimum is approached from the exterior of the feasible region. In the second approach, known as the *barrier function method* (or interior penalty function method), the sequence of points generated converges to the optimum from within the feasible region.

4.7.1. Penalty Function Methods

Consider the following problem:

$$\text{Minimize } f(\mathbf{x}) \tag{113}$$

$$\text{Subject to } \mathbf{x} \in S \subseteq E_n \tag{114}$$

The basic idea is to approximate this problem with an unconstrained problem by adding a penalty function to the objective function that prescribes a high cost for violation of the constraint set S. This new unconstrained *auxiliary problem* is of the form

$$\text{Minimize } f(\mathbf{x}) + rP(\mathbf{x}) \tag{115}$$

where r is a positive constant, and $P(\mathbf{x})$ is chosen as a continuous penalty function such that (1) $P(\mathbf{x}) \geq 0$ for all $\mathbf{x}$, and (2) $P(\mathbf{x}) = 0$ if and only if $\mathbf{x} \in S$. For large r, the optimal solution of (115) will be in a region where $P(\mathbf{x})$ is small. However, if r is chosen too large, then the unconstrained problem becomes ill-conditioned and difficult to solve. Thus, a sequence of problems is solved in which r is increased from problem to problem. A sequence of problems that could be used for solving the general nonlinear programming problem (NLP), (46)–(48), is

$$\text{Minimize } f(\mathbf{x}) + r_k \left(\sum_{i=1}^{m} [\max\{0, g_i(\mathbf{x})\}]^q + \sum_{j=1}^{p} |h_j(\mathbf{x})|^q \right) \tag{116}$$

where q is a positive integer and r_k represents a strictly increasing sequence of positive numbers such that $r_k \to \infty$.

4.7.2. Barrier Function Methods

Barrier function methods are very similar to penalty function methods except that they start at an interior point of the feasible region and set a barrier against leaving the feasible region. In this case, the feasible region must have an interior, so this method is generally restricted to inequality constraints. Consider the nonlinear problem with inequality constraints,

$$\text{(NLPI) Minimize } f(\mathbf{x}) \tag{117}$$

$$\text{Subject to } g_i(\mathbf{x}) \leq 0 \text{ for } i = 1, \ldots, m \tag{118}$$

Ideally, a barrier function, $B(\mathbf{x})$, would assume the value zero for $\mathbf{x} \in \{\mathbf{x}: g_i(\mathbf{x}) < 0 \text{ for } i = 1, \ldots, m\}$ and the value ∞ on the boundary of the feasible region. $B(\mathbf{x})$ is usually defined such that (1) $B(\mathbf{x})$ is continuous and nonnegative on the interior of the feasible region, and (2) $B(\mathbf{x}) \to \infty$ on the boundary of the feasible region. A typical barrier function is

$$B(\mathbf{x}) = \sum_{i=1}^{m} [-1/g_i(\mathbf{x})] \tag{119}$$

This would result in the sequence of auxiliary problems

$$\text{Minimize } f(\mathbf{x}) + t_k \sum_{i=1}^{m} [-1/g_i(\mathbf{x})] \tag{120}$$

where t_k is a strictly decreasing sequence of positive numbers such that $t_k \to 0$.

4.7.3. Augmented Lagrangian Methods

In an attempt to avoid the ill-conditioning that occurs in the regular penalty and barrier function methods, Hestenes (1969) and Powell (1969) independently developed a multiplier method for solving nonlinearly constrained problems. This multiplier method was originally developed for equality constraints and involves optimizing a sequence of unconstrained augmented Lagrangian functions. It was later extended to handle inequality constraints by Rockafellar (1973).

Consider the mathematical programming problem

$$\text{(NLPE) Minimize } f(\mathbf{x}) \tag{121}$$

$$\text{Subject to } h_j(\mathbf{x}) = 0 \text{ for } j = 1, \ldots, p \tag{122}$$

The *augmented Lagrangian* function,

$$L_r(\mathbf{x}, \mathbf{v}) = f(\mathbf{x}) + \sum_{j=1}^{p} v_j h_j(\mathbf{x}) + r \sum_{j=1}^{p} (h_j(\mathbf{x}))^2 \tag{123}$$

is formed by introducing a multiplier vector, $\mathbf{v} = (v_1, \ldots, v_p)^t$ and a positive penalty parameter r. Note that $L_r(\mathbf{x}, \mathbf{v})$ in (123) is the Lagrangian function (37) augmented with the term $r \sum_{j=1}^{p} (h_j(\mathbf{x}))^2$. Thus, instead of a single penalty parameter, as in regular penalty function methods, the augmented Lagrangian requires estimates of the Lagrange multipliers. Using these multiplier estimates, which are updated from iteration to iteration, reduces the ill-conditioning of the unconstrained problems. Assuming that at iteration k, estimates $\mathbf{x}_k$, $\mathbf{v}_k$, and penalty parameter r_k are available, the problem minimize $L_{r_k}(\mathbf{x}, \mathbf{v}_k)$ is solved to find the local unconstrained solution $\mathbf{x}_{k+1}$. The updated vector $\mathbf{v}_{k+1}$ is then found using the relationship

$$\mathbf{v}_{k+1} = \mathbf{v}_k + 2r_k \mathbf{h}(\mathbf{x}_{k+1}) \tag{124}$$

where $\mathbf{h}(\mathbf{x}) = (h_1(\mathbf{x}), \ldots, h_p(\mathbf{x}))^t$. Upon selecting $r_{k+1} \geq r_k$, the process is repeated until $\mathbf{x}_{k+1}$ is sufficiently close to a local solution of (NLPE).

A summary of basic penalty function techniques, as well as exact penalty functions and multiplier methods are discussed in Fletcher (1987, pp. 277–304). For a complete discussion of multiplier methods, the interested reader is referred to Bertsekas (1982).

4.8. Successive Linear Programming

Successive (or sequential) linear programming (SLP) algorithms were introduced by Griffith and Stewart (1961) and have been used in a number of application areas, especially the oil and gas industry. SLP algorithms solve nonlinear optimization problems by using a sequence of linear programs, and computational results have shown they are particularly efficient on problems that are highly constrained. Consider the following nonlinear programming problem:

$$\text{(NLP1) Minimize } f(\mathbf{x}) + \mathbf{c}^t\mathbf{y} \tag{125}$$

$$\text{Subject to } \mathbf{g}(\mathbf{x}) + \mathbf{A}\mathbf{y} = \mathbf{b} \tag{126}$$

$$\mathbf{D}\mathbf{x} + \mathbf{E}\mathbf{y} = \mathbf{e} \tag{127}$$

$$\mathbf{l} \le \mathbf{x} \le \mathbf{u} \tag{128}$$

$$\mathbf{s} \le \mathbf{y} \le \mathbf{t} \tag{129}$$

where $\mathbf{A}$ is an $m \times p$ matrix, $\mathbf{D}$ is $q \times n$, $\mathbf{E}$ is $q \times p$, $\mathbf{c, s, t} \in E_p$, $\mathbf{l, u} \in E_n$, $\mathbf{b} \in E_m$, $\mathbf{e} \in E_q$, $f : E_n \to E_1$, and $\mathbf{g} : E_n \to E_m$, that is, $\mathbf{g}(\mathbf{x}) = (g_1(\mathbf{x}), \ldots, g_m(\mathbf{x}))^t$. Note that the decision variables have been partitioned into the nonlinear variables $\mathbf{x} \in E_n$, and the variables $\mathbf{y} \in E_p$, which appear only linearly. Similarly, the constraints are divided into nonlinear constraints (126) involving the vector of nonlinear differentiable functions $\mathbf{g}(\mathbf{x})$, and the linear constraints (127). The nonlinear variables $\mathbf{x}$ appear in the objective function (125) via the nonlinear differentiable function f.

The basic idea is, given a base point $\bar{\mathbf{x}}$, the nonlinear functions, f, $\mathbf{g}$, are linearized using first order Taylor series approximations. That is, $f(\mathbf{x})$ is replaced by $f(\bar{\mathbf{x}}) + \nabla f(\bar{\mathbf{x}})^t\mathbf{d}$ where $\mathbf{d} = \mathbf{x} - \bar{\mathbf{x}}$. Similarly, $g_i(\mathbf{x})$ for $i = 1, \ldots, m$, is replaced by $g_i(\bar{\mathbf{x}}) + \nabla g_i(\bar{\mathbf{x}})^t\mathbf{d}$. It is assumed that these linear approximations are accurate on some interval $-\boldsymbol{\delta} \le \mathbf{d} \le \boldsymbol{\delta}$ where $\boldsymbol{\delta} \in E_n$, $\boldsymbol{\delta} > \mathbf{0}$. Substituting these results into (NLP1) yields the linear program

$$\text{(LP}(\bar{\mathbf{x}}, \boldsymbol{\delta})\text{) Minimize } \nabla f(\bar{\mathbf{x}})^t\mathbf{d} + \mathbf{c}^t\mathbf{y} \tag{130}$$

$$\text{Subject to } \mathbf{J}(\bar{\mathbf{x}})\mathbf{d} + \mathbf{A}\mathbf{y} = \mathbf{b} - \mathbf{g}(\bar{\mathbf{x}}) \tag{131}$$

$$\mathbf{D}\mathbf{d} + \mathbf{E}\mathbf{y} = \mathbf{e} - \mathbf{D}\bar{\mathbf{x}} \tag{132}$$

$$\max(\mathbf{l} - \bar{\mathbf{x}}, -\boldsymbol{\delta}) \le \mathbf{d} \le \max(\mathbf{u} - \bar{\mathbf{x}}, \boldsymbol{\delta}) \tag{133}$$

$$\mathbf{s} \le \mathbf{y} \le \mathbf{t} \tag{134}$$

where $\mathbf{J}(\bar{\mathbf{x}})$ is the Jacobian matrix whose jth column is $\nabla g_j(\bar{\mathbf{x}})$.

Assuming a feasible solution exists, LP($\bar{\mathbf{x}}$, $\boldsymbol{\delta}$) is solved to find the solution $\bar{\mathbf{y}}$, $\bar{\mathbf{d}}$ that results in the candidate solution ($\bar{\mathbf{x}} + \bar{\mathbf{d}}$, $\bar{\mathbf{y}}$). If this solution is acceptable, then the bounds $\boldsymbol{\delta}$ may be increased and the process repeated. Otherwise, the bounds $\boldsymbol{\delta}$ are decreased and LP($\bar{\mathbf{x}}$, $\boldsymbol{\delta}$) is resolved. The process terminates when $\|\bar{\mathbf{d}}\|$ is sufficiently small.

Details of SLP algorithms along with computational results are contained in Palacios-Gomez et al. (1982), Baker and Lasdon (1985), and Zhang et al. (1985).

4.9. Successive Quadratic Programming

Successive quadratic programming (SQP) algorithms are an important class of methods that has shown much promise in solving general nonlinear programming problems. The methods are also referred to as Wilson–Han–Powell-type methods (Wilson 1963; Han 1976; Powell 1978) as well as Lagrange–Newton methods. SQP algorithms essentially determine a Karush–Kuhn–Tucker point by applying Newton's method to find a stationary point of the Lagrangian function. For a discussion of SQP algorithms, see, for example, Stoer (1985) and Fletcher (1987, pp. 304–317).

4.10. Nonsmooth Optimization

Nonsmooth or nondifferentiable optimization plays an important role in large-scale programming and addresses mathematical programming problems in which the functions involved have discontinuous first derivatives. Thus, classical methods that rely on gradient information fail to solve these problems, and alternative nonstandard approaches must be used. These alternative methods include subgradient methods and bundle methods. The interested reader is referred to Shor (1985), Zowe (1985), and Fletcher (1987, pp. 357–414).

5. ONLINE SOURCES OF INFORMATION ON OPTIMIZATION

There is a wealth of information on mathematical programming available on the World Wide Web. The resources range from electronic books on optimization to libraries of source code for optimization problems to test data archives for mathematical programming. The following is a listing of a few of the more comprehensive optimization sites. Many of the sites also provide links to other related sites.

- Center for Advanced Modeling and Optimization (CAMO)
  http://www.ici.ro/camo/
- Mathematical Optimization (Computational Science Education Project)
  http://csep1.phy.ornl.gov/mo/mo.html
- The Optimization Technology Center and The Network Enabled Optimization System (NEOS)
  http://www-fp.mcs.anl.gov/otc/
- Nonlinear Programming FAQ (Optimization Technology Center)
  http://www-unix.mcs.anl.gov/otc/Guide/faq/nonlinear-programming-faq.html
- Mathematical Programming Glossary (Harvey J. Greenberg)
  http://www.cudenver.edu/~hgreenbe/glossary/glossary.html

6. NONLINEAR PROGRAMMING CODES

Due to advances in computer technology and algorithmic techniques, mathematical programming codes have made significant progress in recent years. Below is a partial listing of some of the nonlinear programming software that is available to the industrial engineering practitioner. For a detailed discussion of software packages, the interested reader is referred to Moré and Wright (1993). Several online sites also provide listings and reviews of available optimization software. See, for example,

- Decision Tree for Optimization Software (H. D. Mittelmann and P. Spellucci)

6.1. Optimization Software

CONOPT
Problem Type: Nonlinear programs with sparse nonlinear constraints
Method: Generalized reduced gradient
Author: Arne S. Drud, ARKI Consulting and Development A/S, Denmark
Contact: ARKI Consulting and Development A/S, Email: info@arki.dk

DONLP2
Problem Type: Smooth nonlinear functions subject to smooth constraints
Method: Sequential quadratic programming
Author: Peter Spellucci, Technical University Darmstadt, Germany
Contact: http://www.mathematik.tu-darmstadt.de/ags/ag8/spellucci/

EA3
Problem Type: Nonlinear programs
Method: Ellipsoid algorithm
Authors: J. G. Ecker, M. Kupferschmid, Rensselaer Polytechnic Institute, NY
Contact: J. G. Ecker, Department of Mathematical Sciences; M. Kupferschmid, Alan M. Voorhees Computing Center, Rensselaer Polytechnic Institute, Troy, NY 12181

FSQP
Problem Type: Multiple linear/nonlinear objective functions with linear/nonlinear constraints
Method: Sequential quadratic programming
Authors: Eliane R. Panier, Andre Tits, Jian Zhou, Craig Lawrence, University of Maryland

Contact: http://www.isr.umd.edu/Labs/CACSE/FSQP/fsqp.html

GRG2
Problem Type: Nonlinear programs
Method: Generalized reduced gradient
Author: Prof. Leon Lasdon, The University of Texas at Austin
Contact: http://www.optimalmethods.com/

LANCELOT
Problem Type: Large-scale optimization problems
Method: Penalty method
Authors: Andy Conn, IBM T. J. Watson Research Center, NY, Nick Gould, Rutherford Appleton Laboratory, UK, Philippe Toint, Facultés Universitaires Notre Dame de la Paix, Belgium
Contact: http://www.cse.clrc.ac.uk/Activity/LANCELOT+165

LSGRG2
Problem Type: Large-scale nonlinear programs
Method: Generalized reduced gradient
Author: Prof. Leon Lasdon, The University of Texas at Austin
Contact: http://www.optimalmethods.com/

MINOPT
Problem Type: Linear, mixed-integer, nonlinear, dynamic, and mixed-integer nonlinear programs
Method: Generalized benders decomposition, outer approximation and variants, generalized cross decomposition
Authors: C. Schweiger, Christodoulos A. Floudas, Princeton University
Contact: http://titan.princeton.edu/MINOPT/minopt.html

MINOS
Problem Type: Large-scale linear and nonlinear programs
Method: Projected Lagrangian
Authors: Bruce A. Murtagh, University of New South Wales, Australia, Michael A. Saunders, Stanford University
Contact: http://www.stanford.edu/~saunders/brochure/brochure.html

NIMBUS
Problem Type: Differentiable/nondifferentiable multiobjective/single objective optimization problems with nonlinear/linear constraints
Method: Nondifferentiable interactive multiobjective bundle-based optimization
Authors: Kaisa Miettinen, University of Jyväskylä, Finland
Contact: http://nimbus.mit.jyu.fi/

NLPQL
Problem Type: Nonlinear programs
Method: Sequential quadratic programming
Authors: K. Schittkowski, University of Bayreuth, Germany
Contact: http://www.uni-bayreuth.de/departments/math/~kschittkowski/nlpql.htm

NLPQLB
Problem Type: Smooth nonlinear programming with many constraints
Method: Sequential quadratic programming
Authors: Schittkowski, University of Bayreuth, Germany
Contact: http://www.uni-bayreuth.de/departments/math/~kschittkowski/nlpqlb.htm

NPSOL
Problem Type: Dense linear and nonlinear programs
Method: Sequential quadratic programming
Authors: Philip Gill, University of California, San Diego; Walter Murray, Michael A. Saunders, Stanford University; Margaret H. Wright, AT&T Bell Laboratories
Contact: http://www.stanford.edu/~saunders/brochure/brochure.html

OPTIMA Library
Problem Type: Unconstrained and constrained nonlinear optimization
Method: Various methods
Authors: M. C. Bartholomew-Biggs, University of Hertfordshire, United Kingdom
Contact: Dr. M. C. Bartholomew-Biggs, Numerical Optimisation Center, Hatfield, Hertfordshire AL10 9AB, United Kingdom

SNOPT
Problem Type: Large-scale linear and nonlinear programs
Method: Sparse sequential quadratic programming
Authors: Philip Gill, University of California, San Diego; Walter Murray, Michael A. Saunders, Stanford University
Contact: http://www.stanford.edu/~saunders/brochure/brochure.html

SOLVOPT
Problem Type: Nonlinear programs
Method: Exact penalty method
Authors: Alexei V. Kuntsevich, Karl-Franzens Universität Graz, Austria, Franz Kappel
Contact: http://bedvgm.kfunigraz.ac.at:8001/alex/solvopt/

SPENBAR
Problem Type: Nonlinear programs
Method: Modified penalty method
Authors: Neculai Andrei, Research Institute for Informatics, Romania
Contact: Neculai Andrei, Research Institute for Informatics, 8-10, Bdl. Maresal Averescu, 71316 Bucharest, Romania, E-mail: nandrei@u3.ici.ro

TRON
Problem Type: Large bound-constrained optimization problems
Method: Trust region Newton method
Authors: Chih-Jen Lin,National Taiwan University; Jorge Moré, Argonne National Laboratory
Contact: http://www-unix.mcs.anl.gov/~more/tron/

CHAPTER 99
Network Optimization

RICHARD T. WONG
Telcordia Technologies

1. NETWORK MODELS: INTRODUCTION

Network flow models constitute a special class of linear programming problems. Historically, the useful special structure of networks sparked much of the initial interest and enabled the design of special-purpose algorithms that made network models much easier to solve than general linear programming problems. In addition, networks have a number of representational features that enhance their attractiveness for application in areas of industrial engineering such as manufacturing, production, and supply chain management or logistics and distribution systems. Network models can be especially useful in analyzing systems with spatial or temporal relationships. In network models, the nodes can represent entities such as geographic locations or space-time locations and the arcs can represent allowable ways of going from one node to another. One application scenario might be where the goal is to find the shortest travel route (set of roads) between a dispatching depot and a customer in need of a special delivery. The nodes correspond to intersections of roads, and the arcs correspond to sections of roads connecting the intersections. Another example of networks arises in modeling a flexible manufacturing system (Kumar and Kroll 1987) where a node might represent the location of a machine or a storage area. The arcs would correspond to connections between various system locations via a conveyor system or an automated guided vehicle system.

Network models offer a number of desirable characteristics, including:

Flexibility: Network models can accommodate a large number of different situations.

Versatility as a subproblem: Even in situations where linear network flow models do not apply, such as when there are nonlinear elements in the system, network models often arise usefully as subproblems for the more general model.

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

Ease of explanation: Since many network models can be depicted in a very easy-to-understand way, network models and their results are generally easy to explain and motivate to nontechnical managers.

Ease of Solution: There are a variety of computer codes (running on computers ranging from mainframes to personal computers) capable of solving large-scale models that might arise in practice; these limited computational requirements also facilitate "what-if" analysis that can be useful in performing sensitivity and scenario analyses on a model.

The remainder of this chapter gives more information concerning the formulation, solution and application of network flow models. Section 2 details some of the principal network models. Sections 3 and 4 discuss solution procedure concepts and give information concerning available software for solving network flow models. Section 5 discusses some examples of network applications.

2. CLASSES OF NETWORK MODELS

All of the network flow models presented in this section can be viewed in terms of a single general model—the minimum cost flow problem. However, there are many important problem subclasses whose structures are particularly suggestive for potential applications and that can be solved with special-purpose solution algorithms. This section gives an overview of various types of network flow models.

2.1. Minimum Cost Flow Problem

The minimum cost flow problem is the most general network flow model. It arises in applications such as the efficient distribution of a single product from a set of source (production) sites to a set of demand sites over a given distribution network. The product may be shipped directly from a source site to a demand site, or it may pass through one or more intermediate points in the distribution network before reaching its final destination.

In the network model, the nodes represent source sites, demand sites, or other (intermediate) nodes that are neither source nor demand sites. The net supply at node i is denoted as b_i (for source sites b_i is positive, for demand sites b_i is negative, and for all other nodes b_i is zero). To simplify our discussion, it is assumed that the total amount produced at the source sites is exactly equal to the total amount required at the demand sites. An arc connecting two nodes represents a transportation link. Associated with each arc (i, j) is an upper bound (arc capacity) u_{ij} limiting the total amount of goods that can flow on it. (In more complex models, there may also be a specific lower bound ij on the total flow on the arc. However, to simplify the discussion in this chapter, it is assumed that all lower bounds are zero.) An uncapacitated arc is one that has no upper bound on the amount of flow it can carry. There is a unit transportation flow cost c_{ij}. The minimum cost flow problem can be represented as the following linear program:

$$\text{Minimize} \sum_{(i,j)} c_{ij}x_{ij} \tag{1}$$

$$\text{Subject to:} \sum_{j} x_{ij} - \sum_{j} x_{ji} = b_i \text{ for all nodes } i \tag{2}$$

$$x_{ij} \leq u_{ij} \tag{3}$$

$$x_{ij} \geq 0 \text{ for all arcs } (i, j) \tag{4}$$

The objective is to find the minimum cost routing of the flows through the network such that all source and demand node constraints (2) and all arc capacity constraints (3) are satisfied.

Figure 1 gives an example of an eight node network that represents a distribution system between factories and retailers. Nodes 1 and 2 are factories whose production capacities (net supplies) are 6 and 9. Nodes 3, 4, and 5 are warehouses (intermediate nodes) whose net supplies are zero. Nodes 6, 7, and 8 correspond to the retailers, whose net supplies are -3, -5, and -7. Each arc is labeled with its unit transportation cost and its upper bound. In this example, there are only arcs between source nodes and intermediate nodes and between intermediate nodes and sink nodes. In a general minimum cost flow model there can be arcs between any two nodes in the network.

In many application situations we may wish to restrict the arc flows to be integer valued. The minimum cost flow problem has the interesting property that if all of the net supplies b_i, and arc upper bounds u_{ij} are integer valued, then whenever there is an optimal solution, there is always an integer-valued optimal solution.

The minimum cost flow problem, besides having many useful applications, also contains a number of special cases that arise in a variety of application scenarios. We will now discuss some of these special cases.

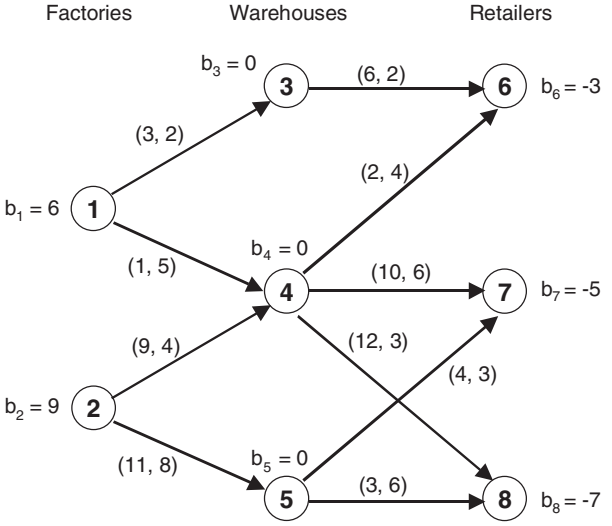

Figure 1 Example of Minimum Cost Flow Problem.

2.2. Transportation Problem

In this subclass of problems there are only source and demand sites (no intermediate nodes are included), and shipments can only be made directly between source and demand sites. The source node i has a supply of s_i and demand node j has demand of d_j (or a net supply of $-d_j$). The transportation problem can be formulated as the following linear programming model:

$$\text{Minimize} \quad \sum_{(i,j)} c_{ij}x_{ij} \tag{5}$$

$$\text{Subject to} \quad \sum_{j} x_{ij} = s_i \text{ for all source nodes } i \tag{6}$$

$$\sum_{i} - x_{ij} = d_j \text{ for all destination nodes } j \tag{7}$$

$$x_{ij} \leq u_{ij} \tag{8}$$

$$x_{ij} \geq 0 \text{ for all arcs } (i,j). \tag{9}$$

Constraints (6) and (7) regulate the net supply for the nodes, and constraint (8) enforces the upper bounds on arc flows. Transportation problems can arise in areas such as logistics inventory control and production planning.

Consider the following example of a production planning problem (Bowman 1956). Production must be scheduled over the next three quarters where the demands are predicted to be 40, 30, and 60, respectively. In each quarter, items may be produced on a regular shift at a cost of \$10 per item. During the regular shift there is a capacity restriction limiting production to 45 items per quarter. A maximum of 20 items can also be produced during an overtime shift, at a cost of \$12 per item. Finally, items can be held in inventory at a cost of \$0.50 per unit per month.

This type of planning problem can be formulated as a transportation model, and the corresponding network is given in Figure 2. Each production shift corresponds to a source node, and the node supply represents the production shift capacity. There are six source nodes since each quarter i can have a regular shift (denoted by node r_i) and an overtime shift (denoted by o_i). For each quarter j there is a demand node j, and finally, there is a dummy demand node DUMMY, which is included to ensure that the total demand equals the total supply. The cost coefficient for arc (g, h) represents the unit cost of supplying demand node h from supply node g. For example, the unit cost of supplying demand node 3 from node o_1, the overtime shift in quarter 1, is (\$12.00 + (2 × \$0.50) = \$13.00). Note that the costs of all arcs incident to the DUMMY node are zero since these flows do not represent any actual production.

This transportation model can also be formulated as the following linear programming problem:

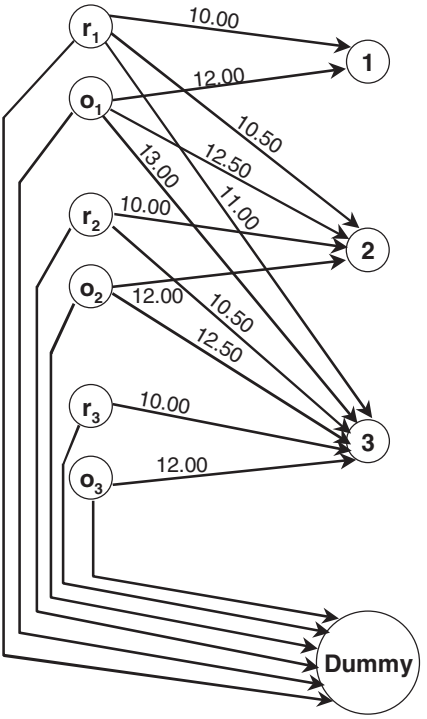

Figure 2 Transportation Problem Representation of Production Planning Example.

$$\begin{aligned}
\text{Minimize } & 10.00\,x_{r1,1} + 10.50\,x_{r1,2} + 11.00\,x_{r1,3} + 12.00\,x_{o1,1} + 12.50\,x_{o1,2} \\
& + 13.00\,x_{o1,3} + 10.00\,x_{r2,2} + 10.50\,x_{r2,3} + 12.00\,x_{o2,2} \\
& + 12.50\,x_{o2,3} + 10.00\,x_{r3,3} + 12.00\,x_{o3,3}
\end{aligned}$$

$$\begin{aligned}
\text{Subject to: } & x_{r1,1} + x_{r1,2} + x_{r1,3} + x_{r1,dummy} = 45 \\
& x_{o1,1} + x_{o1,2} + x_{o1,3} + x_{o1,dummy} = 20 \\
& x_{r2,2} + x_{r2,3} + x_{r2,dummy} = 45 \\
& x_{o2,2} + x_{o2,3} + x_{o2,dummy} = 20 \\
& x_{r3,3} + x_{r3,dummy} = 45 \\
& x_{o3,3} + x_{o3,dummy} = 20 \\
& -x_{r1,1} - x_{o1,1} = -40 \\
& -x_{r1,2} - x_{r2,2} - x_{o1,2} - x_{o2,2} = -30 \\
& -x_{r1,3} - x_{r2,3} - x_{r3,3} - x_{o1,3} - x_{o2,3} - x_{o3,3} = -60 \\
& -x_{r1,dummy} - x_{o1,dummy} - x_{r2,dummy} - x_{o2,dummy} - x_{r3,dummy} - x_{o3,dummy} = -65 \\
& x_{ij} \geq 0 \text{ for all arcs } (i,j).
\end{aligned}$$

Notice that every variable appears in exactly two equations—once with a coefficient of $+1$ and once with a coefficient of -1. For example, the variable $x_{r1,1}$ appears in the first equation with a $+1$ coefficient and in the seventh equation with a -1 coefficient. This special property for the variable coefficients holds for any transportation problem and more generally for ANY general minimum cost flow problem. This special structure is also the key to many of the specialized solution approaches for network flow problems.

2.3. Assignment Problem

A special case of the transportation problem is the assignment problem where there are exactly n source nodes that all have a supply of 1 and n demand nodes that all have a demand of 1 (net supply of -1). Thus, each source node must be assigned to a unique demand node. The cost of assigning source node i to demand node j is c_{ij} and all arcs are uncapacitated. The assignment problem can be represented in the following way:

$$\text{minimize} \quad \sum_{(i,j)} c_{ij}x_{ij} \tag{10}$$

$$\text{subject to:} \quad \sum_{j} x_{ij} = 1 \text{ for all sources nodes } i \tag{11}$$

$$\sum_{i} x_{ij} = 1 \text{ for all demand nodes } j \tag{12}$$

$$x_{ij} \geq 0 \text{ for all arcs } (i,j) \tag{13}$$

Constraints (11) and (12) enforce the supply and demand restrictions.

The assignment problem can arise in a manufacturing system when we view the source nodes as jobs and the demand nodes as machines that can perform the jobs. In the next time cycle, each job must be assigned to a unique machine. The coefficient c_{ij} represents the cost of assigning job i to machine j during this time cycle. The optimal solution assigns the jobs to machines so that the total cost during the next time cycle is minimized.

2.4. Shortest Path Problem

Another special case of the uncapacitated minimum cost flow problem is when there is a single source site and a single demand site and all arcs are uncapacitated. The problem reduces to finding the shortest (minimum cost) path from the source node s to the sink node (demand site) t. As discussed in Section 1, one application of this model might be where we wish to find the best travel route for a truck traveling between a depot and a special customer. Another important application is the routing of information packets in the Internet. A shortest path-routing model is used to determine the path traversed by information packets sent over the Internet (Sackett and Metz 1997). The shortest path problem can be formulated as the following linear programming model:

$$\text{minimize} \quad \sum_{(i,j)} c_{ij}x_{ij} \tag{14}$$

$$\text{subject to:} \quad \sum_{j} x_{ij} - \sum_{j} x_{ji} = \begin{cases} 1 & i = s \\ -1 & i = t \\ 0 & \text{otherwise} \end{cases} \tag{15}$$

$$x_{ij} \geq 0 \text{ for all arcs } (i,j) \tag{16}$$

The objective function minimizes the travel costs and constraint (14) ensures that there is a path from node s to node t.

2.5. Longest Path Problem

The longest path problem is identical to the shortest path problem except that the goal is to find the longest path from a source node to a sink node. An important application of this problem is in the area of project scheduling (Elmaghraby 1977), where there are precedence constraints that specify some tasks cannot be completed until other tasks are done. Each arc represents a task and its length is the task duration. Each node indicates a precedence relationship. The tasks corresponding to outgoing nodes cannot be started until all of the tasks corresponding to the incoming nodes are completed. The source and sink nodes represent the overall start and completion of the entire project. The length of the longest path between the source and sink nodes represents the time required to complete the entire project even if unlimited resources are available to perform tasks that could be performed in parallel. The precedence constraints would generally restrict what tasks could be performed in parallel. The arcs on the longest path indicate the ''bottleneck'' tasks whose reduction in task duration would result in an overall reduction of the project duration.

The linear programming formulation of the longest path problem is identical to that of the shortest path problem except that the objective function must be maximized instead of minimized.

2.6. Maximum Flow Problem

The typical maximum flow problem has a network where there are arc upper bounds and a designated source node s and a designated sink node t. The objective is to find the flow pattern that maximizes

the total flow v from the source to the sink node. The maximum flow problem can be formulated as the following linear programming model:

$$\text{minimize} \quad v \tag{17}$$

$$\text{subject to:} \quad \sum_j x_{ij} - \sum_j x_{ji} = \begin{cases} v & i = s \\ -v & i = t \\ 0 & \text{otherwise} \end{cases} \tag{18}$$

$$x_{ij} \leq u_{ij} \tag{19}$$

$$x_{ij} \geq 0 \text{ for all arcs } (i,j) \tag{20}$$

One application of this model is in the area of emergency evacuation of a facility (such as a building or subway station). The source node represents the location of workers in the facility and the sink node represents a safety area. The arcs can correspond to the various links from one part of the facility to another (stairways, corridors, etc.) and the arc capacity indicates the maximum number of people who could traverse a link per unit time. The maximum flow represents the maximum rate at which people could be evacuated from the facility (see Chalmet et al. 1982 for a more elaborate model).

2.7. Additional Models

There are a number of more advanced models that are beyond the scope of this chapter. For example, there are many network flow models that have additional side constraints. The general linear constraints could correspond to tarriff constraints or other restrictions that cannot be directly incorporated into the basic network flow model. There are some advanced network-based solution procedures that can accommodate linear side constraints (Glover and Klingman 1985). These procedures have been incorporated into available computer software. Another useful generalization of the minimum cost flow problem is when there is more than one type of flow in the network. These situations arise frequently in applications where there may be more than one type of product that is being processed by a distribution network or more than one type of material that is flowing through a materials handling facility or supply chain system. Multicommodity flow models, although they can model a wide range of situations, are usually considerably more complicated to solve than comparably sized (single-commodity) network flow models (McBride 1998; Ali et al. 1984).

Other network models incorporate features such as fixed setup costs or nonlinear flow costs. For example, in a production scheduling environment, the amount of flow on an arc could correspond to the number of units assigned to be processed on a machine. There could be a setup cost incurred if there is a nonzero number of units scheduled on the machine. In a transportation network, there could be a fixed construction cost for opening up a transportation link and a variable operating cost that would depend on the traffic flow through the link. The usual modeling procedure for setup and fixed costs is to introduce 0–1 (binary integer) variables and to create a mixed integer programming model.

Another advanced mixed integer programming network model is the traveling salesman problem, which determines the minimum cost or length tour that passes through each node of the network exactly once. Note that such a tour can also be viewed as the sequence of nodes to visit. From this perspective, the traveling salesman problem has applications in machine scheduling where the sequencing of a set of jobs to be run on a machine must be determined. The arc cost for arc (i,j), c_{ij}, corresponds to the setup or changeover cost on the machine from job i to job j. The tour can also be viewed as the travel route of a delivery vehicle that starts out at a depot and then must visit every other node to make deliveries and then return to the depot. In this context, the cost c_{ij} represents the travel cost of going from the customer at node i to the customer at node j. Finally, the traveling salesman problem also arises in the manufacture of printed circuit boards with a robotic assembly unit (Chan and Mercier 1989). There is a given set of locations at which components must be inserted. The term c_{ij} now corresponds to the cost of inserting the component at location j immediately after inserting the component at location i.

Nonlinear costs could arise when the production cost function exhibits economies of scale and is concave. Another example of nonlinear flow costs is in the area of transportation and distribution planning. Models for analyzing the traffic congestion on a road network usually have arc travel costs that are convex functions of the arc flow in order to represent congestion effects on the network. These models also generally have multiple commodities to represent the various origin–destination characteristics of the network users.

3. NETWORK MODEL SOLUTION TECHNIQUES

The current solution technology for network models is quite powerful and is capable of solving large-scale models that can arise in practice. Also, the continually increasing computational power of

computers guarantees that the size of network models that can be solved will continue to grow. Specialized solution procedures are available on a wide spectrum of machines, ranging from personal computers and workstations to mainframe machines. Some tests have indicated that specialized network codes can be one to two orders of magnitude faster than general linear programming codes in solving network flow models. This section gives a brief overview of some basic concepts for network flow problem-solution procedures. The next section discusses some available computer software for solving network flow models.

Over the past 50 years, there have been several periods of evolutionary development in the field of network algorithms. In the 1950s and 1960s, many classical results and algorithms were developed (Ford and Fulkerson 1962). In the 1970s, many researchers began to recognize and emphasize the role of computer data structures in the efficient implementation of algorithms. With these new and powerful implementations, a number of large-scale applications of network models were successfully completed.

Starting in the 1970s and continuing into the 1980s and 1990s, researchers began to design and evaluate algorithms according to a worst-case computation time criterion (Ahuja et al 1993). That is, the speed of a solution procedure was evaluated according to the maximum number of solution procedure steps required as a function of the problem size. For example, a shortest path algorithm A with worst-case computation time of $4n^2$ is a procedure that when applied to a problem with n nodes requires no more than $4n^2$ steps. It is widely believed that the rate of worst-case computation growth (for algorithm A, the n^2 term) is more important in evaluating algorithms than the constant (for algorithm A, the factor of 4). So the worst-case computation time of algorithm A is usually described as $O(n^2)$ (pronounced ''order n squared''). That is, the worst-case computation time grows as the square of the number of nodes in the network and the exact rate of growth with the constant is not specified. Although the worst-case criterion is mainly a theoretical measure, there is some empirical evidence that indicates that some of the recently developed network solution methods with good worst-case computational performance also perform well relative to other solution procedures.

The following subsections highlight some useful concepts for solving various classes of network flow problems.

3.1. Minimum Cost Flow and Transportation Problems

One of the most effective algorithms for these classes of network problems has been a specialized implementation of the simplex algorithm for linear programming. This type of approach uses special data structures to exploit the special properties of the network models and accelerate the steps of the simplex algorithm. For example, for these network flow models (and all of the other related subclasses discussed in this chapter), the set of basic variables corresponds to a set of arcs that form a spanning tree for the underlying network. Computing such items as the current values for the dual multipliers is easily done with a specialized procedure that exploits the basis tree structure (Ahuja et al. 1993).

3.2. Shortest Path Problem

Dynamic programming and a specialized algorithm due to Dijkstra (Ahuja et al. 1993) are the two most widely used shortest path procedures. Dijkstra's algorithm iteratively labels the nodes with their shortest path distance from the origin node. All nodes are initially unlabeled except for the origin node, which has a label of 0. At each iteration the algorithm labels the unlabeled node that has the minimum shortest path distance from the origin node. The procedure terminates when the destination node is labeled. Dijkstra's algorithm is an $O(n^2)$ algorithm, where n is the number of nodes in the network.

The fastest shortest path codes use either dynamic programming or Dijkstra's algorithm in conjunction with sophisticated data structures that reduce the amount of time spent searching for required problem information.

3.3. Maximum Flow Problem

For the maximum flow problem, the classical solution concept has been the augmenting path. Given a feasible flow pattern, an augmenting path procedure then attempts to find a path from the source node to the sink node such that we can increase the flow along this path and thus increase the total flow from the source node to the sink node. The general augmenting path algorithm iteratively performs a series of path augmentations where each augmentation increases the flow on the selected path as much as possible subject to the arc capacity constraints.

The example in Figure 3*a* shows how a judicious selection of augmenting paths can accelerate the performance of the augmenting path algorithm. In the example, the arc labels are the arc capacities. Nodes s and t are the source and sink nodes, respectively. The initial solution starts with zero flow on all of the arcs. The procedure starts by augmenting the flow on path s–1–2–t by one unit to obtain the flow pattern in Figure 3*b*. Next the procedure augments the flow on path s–2–1–t by one unit to obtain the flow pattern in Figure 3*c*. Iteratively augmenting the flows on these two paths would require a total of 1000 path augmentations. Notice that the optimal solution can be reached

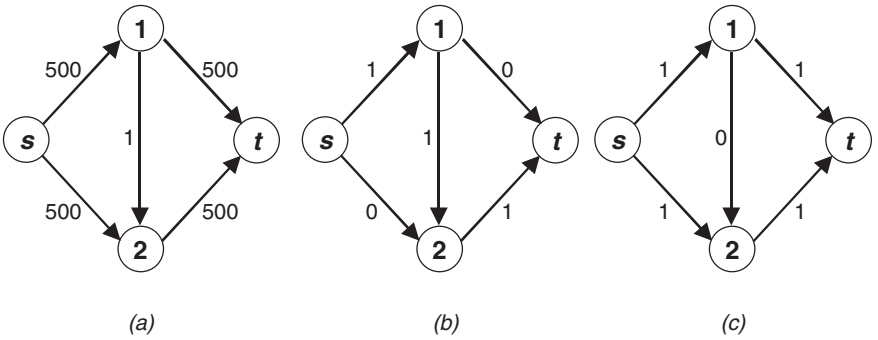

Figure 3 (*a*) Four-Node Example of Maximum Flow Problem (*b*) Example Flow Pattern after One Flow Augmentation (*c*) Example Flow Pattern after Two Flow Augmentations.

from the initial solution in just two augmentations (augment paths *s*–1–*t* and *s*–2–*t* by 500 units each)! Research in the 1970s highlighted the value of judiciously selecting the augmenting paths used and demonstrated that the augmenting path with the minimum number of arcs, the shortest augmenting path, should be chosen (in our example, the paths *s*–1–*t* and *s*–2–*t* would be selected before the path *s*-1-2-*t* since they have fewer arcs). Thus, the maximum flow problem can be approached by solving a series of shortest path problems. This procedure can be improved by saving information about the shortest path computation from one iteration to the next in order to reduce the work required to solve each shortest path problem (Goldfarb and Grigoriadis 1988).

4. COMPUTER SOFTWARE FOR NETWORK FLOW MODELS

A considerable amount of computer software is available for solving network flow problems. During the latter part of the 1990s, the use of the World Wide Web on the Internet has greatly facilitated the dissemination of information and software for solving network flow models.

For personal computers, a number of packages are available which have modules for solving various classes of network flow problems (see Oberstone 1990, chaps. 7, 8 for additional information). The CPLEX (www.cplex.com), OSL (www.6.software.ibm.com/es/oslvZ/features/lib.htm), SAS/OR (www.sas.com), and LINDO (www.lindo.com) commercial systems have network flow modules and run on machines ranging from mainframes to workstations and personal computers. Also, Michael Trick (mat.gsia.cmu.edu/companies.html) has assembled a set of World Wide Web links to a variety of companies that offer OR software including network optimization routines.

There are also a number of codes available for solving network flow models. See Kennington and Helgason (1980), Simeone et al. (1988), and Bertsekas (1991), which all give listings of some network flow codes. More and Wright (1993) contains some discussion of network optimization and available software routines. Also, Michael Trick (see mat.gsia.cmu.edu/resource.html, under Software Packages and Descriptions) has assembled a set of World Wide Web links to a variety of OR software packages (including network optimization routines) that are available for little or no cost.

The field of project management, which includes applications of the longest path problem, has spawned a number of software packages for both commercial and educational use. See Oberstone (1990, chaps. 13, 16) and Wasil and Assad (1988) for a discussion and comparison of some of these packages. It has been estimated that at one time there were over 200 different products on the market (see Scheduling Software, www.buildersnet.org/cpmtutor/html/schedulingsoftware.html). See Microsoft Project (www.microsoft.com/office/project/default.htm) and Job Boss (engineering.software-directory.com/software-2.cdprod1/009/683.Job.Boss.sthml) for two examples of such systems.

5. ADDITIONAL NETWORK FLOW EXAMPLES

This section gives further examples of applications that can be cast as network flow models. These examples also help illustrate the types of situations that can be formulated as network flow problems. In many other applications, the network model structure is often hidden and can require considerable ingenuity to identify and formulate.

5.1. An Example of Dynamic Network Flow: A Material-Handling System

Network flow models can represent temporal as well as spatial relationships. Consider the four-node dynamic maximum flow network example depicted in Figure 4. For each arc the two labels represent

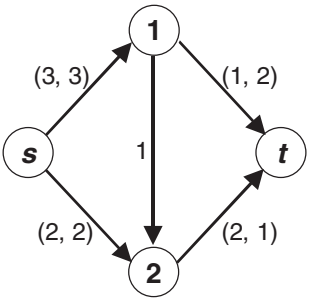

Figure 4 Four-Node Example of Dynamic Network Flow Model.

the arc capacity and the time required to traverse the arc. The dynamic network model can be expanded and represented by an equivalent static model as depicted in Figure 5. In this expanded network, each node represents a specific location at a particular point in time. Such a network could be used, for example, to compute the maximum flow possible between the source and sink node within a given interval of time. By adding arc costs and node demands, the network model could be reformulated as a minimum cost flow problem.

This type of dynamic network flow model can be used to model certain types of material-handling systems (Maxwell and Wilson 1981). The necessary modeling assumptions include that both time and space can be represented by discrete points and that there be only a single type of material which flows through the system. These dynamic network flow models could be useful in evaluating and optimizing preliminary material-handling system configurations and analyzing where system bottlenecks could occur due to storage or processing rate limitations. Maxwell and Wilson (1981) also discuss the role of other methodologies such as simulation (see Chapters 93–96 of this Handbook) in the overall design and evaluation of material-handling systems.

5.2. Personnel Assignment

The assignment of personnel to jobs is an often-cited application area for network flow models. Consider the classical assignment problem where the model represents the assignment of n people to n jobs. There is one source node for each person available and one demand node for each job. One possible objective function would be to assign people to jobs in order to minimize the relocation costs.

More elaborate network flow models for the personnel assignment problem are also possible (Liang and Thompson 1987). Suppose there are more people available then there are jobs but each

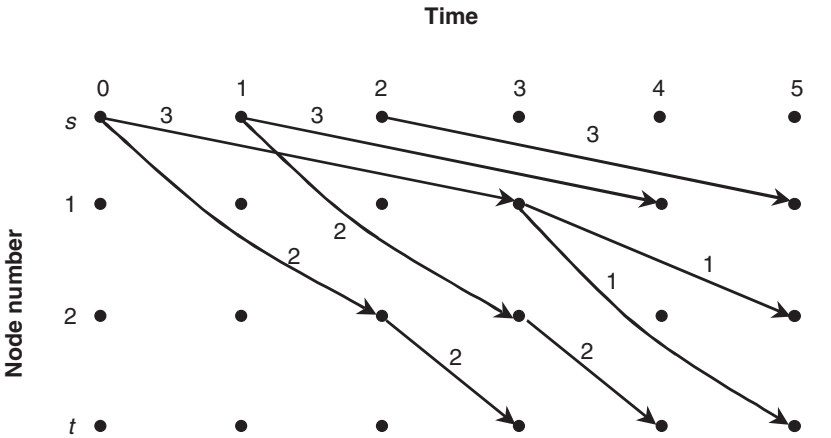

Figure 5 Static Equivalent of Four-Node Dynamic Network Flow Model.

job can be filled by only one person. In particular, consider an example where six people and four different jobs are available. This type of personnel assignment problem can be represented by the minimum cost network flow model in Figure 6. Every node in the layer of nodes (P_1, P_2, . . . , P_6) represents an available person and has a supply of 1. Node t has a net supply of -6. Every node in the layer of nodes (J_1, J_2, J_3, J_4) corresponds to an available job and along with node s are all intermediate nodes whose net supply is zero. All arcs in the network have a capacity of one. In the network flow problem solution, person P_i is assigned to job J_j if there is a flow of one unit on the arcs (P_i, J_j) and (J_j, t). Since arc (J_j, t) has a flow capacity of one, the total flow into node J_j can be at most one and so job j can be assigned to at most one person. Person P_i is not assigned to a job if there is a flow on the arcs (P_i, s) and (s, t). Note that for each personnel node P_i, all of the possible arcs to the job nodes are not included, since a person may only be qualified for a subset of the available jobs.

This type of network flow model can be further expanded by adding another layer of nodes, as depicted in Figure 7. Every job is associated with a particular branch location. In this example there are two branch locations represented by the nodes B_1 and B_2. The total flow between a location node and node t is the total number of jobs at that location that are filled. This information can be useful in enforcing preferences or restrictions concerning the staffing levels at various locations. The staffing preferences can be incorporated by attaching the appropriate arc costs to the arcs incident to node t. As for the restrictions, suppose that company policy specifies a restriction that at most k new jobs at location B_1 will be filled. The model can incorporate this constraint by setting the arc flow capacity on arc (B_1, t) to be k.

This additional layer of nodes illustrates how other preferences or constraints can be added to a network flow model without destroying the special network flow structure. Such modeling techniques are quite useful since network models can be solved much more efficiently than general linear programs.

There is another personnel assignment question for which a network model may be useful. There is a set of jobs and a set of people where for each person there is a list of the jobs that the person is qualified for. The objective is to Maximize the total number of jobs that can be filled with qualified people. This question can be modeled as a maximum flow problem, as shown in Figure 8. All arcs in the network have a capacity of one. The objective function is to maximize the flow between nodes s and t. An arc connecting nodes P_i and J_j indicates that person i is qualified for job j. In the optimal flow pattern, person i is assigned to job j if the flows on arcs (P_i, J_j), (s, P_i) and (J_j, t) are all one. Since every arc (J_j, t) has a flow capacity of one, the total flow into node J_j can be at most one and so job j can be assigned to at most one person. For this model, there are no direct considerations of cost but instead the objective is to maximize the number of jobs filled by qualified people.

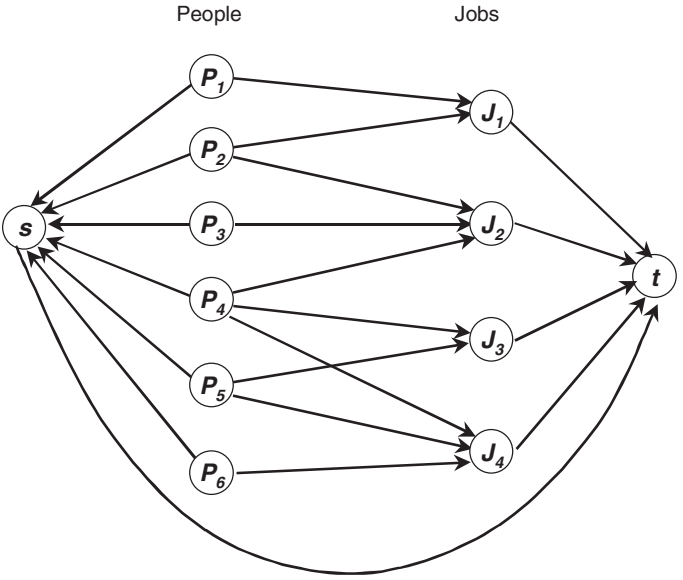

Figure 6 Minimum Cost Network Flow Model of Personnel Assignment Example.

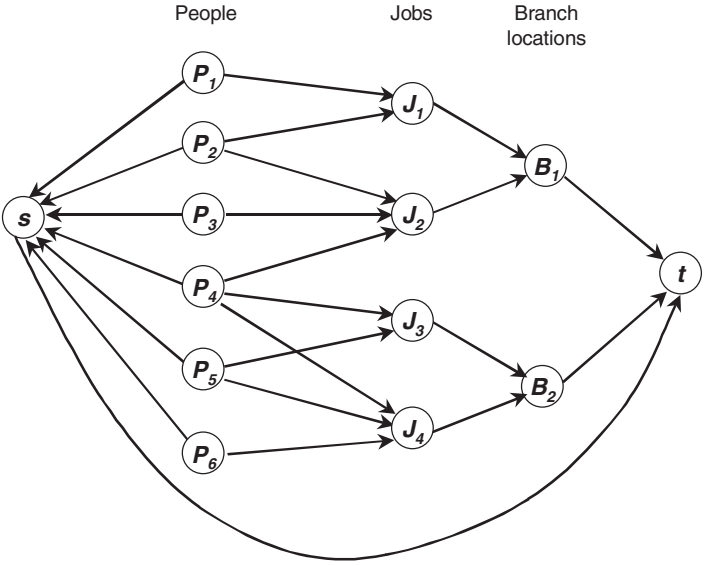

Figure 7 Expanded Minimum Cost Network Flow Model of Personnel Assignment Example.

5.3. Equipment Replacement

Network models can also be useful for the decisions related to replacing equipment over a fixed time horizon. For example, a manufacturing center has just installed a new $20,000 cutting machine at the start of year 1. At the start of each of the next four years, the firm has the option to continue operating the current machine for an additional year or to trade in the current machine for a new machine. The operating costs for the machine grow with the age of the machine, while the trade-in value of a machine decreases with age. The operating costs and trade in values are given below:

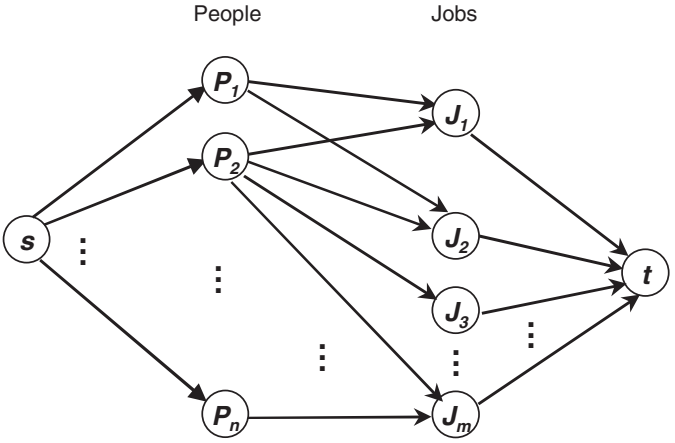

Figure 8 Maximum Flow Model of Alternative Version of the Personnel Assignment Example.

Number of Years Used	Salvage Value	Operating Cost During Last Year
1	$15,000	$1,000
2	$10,000	$2,000
3	$8,000	$4,000
4	$7,000	$8,000

The firm must decide the optimal equipment replacement strategy over the next four years. Figure 9 gives a shortest path network model for determining the optimal replacement strategy. Each of the first five layers of nodes represents the start of a new year. The last layer, which consists of the sink node t, represents the end of the planning horizon. The nodes within each layer represent the status (the age or the number of years the machine has been in use) of the current machine at the start of the year. Each arc represents a decision that can be made at the start of a year. For example, the arc from node Year 3–Age 2 to node Year 4–Age 1 corresponds to having a two-year-old cutting machine at the start of year 3 and then trading it in to buy a new machine so that at the start of year 4 the current cutting machine is one year old. The arc cost of $11,000 corresponds to the cost of buying the new cutting machine ($20,000) minus the trade in value of the two-year-old machine ($10,000) plus the operating cost during year 3 ($1,000). The arcs incident to node t correspond to the final action of trading in the current machine at the end of the planning horizon. The negative arc cost corresponds to the trade-in (salvage) value of the cutting machine. The arcs on the shortest path from nodes s to node t will represent the least-cost machine-replacement strategy over the four-year time horizon.

5.4. Reliability

In many engineering systems for areas such as telecommunications and transportation, the issue of system reliability can arise. A telecommunications system can be modeled as a network where the arcs correspond to communication links and the nodes correspond to switching machines. Figure 10 gives an example of such a representation. The system is designed to send messages from node s to node t where failures may remove an arc (communication link) from service. Assume that the nodes (switching machines) do not fail (or are much less likely to fail than the links). One question of interest is to compute the number of arc disjoint paths between nodes s and t. The answer provides some measure of the redundancy of the network and its resilience to communication link failures. This question can be answered with a maximum flow network model where each arc has a capacity

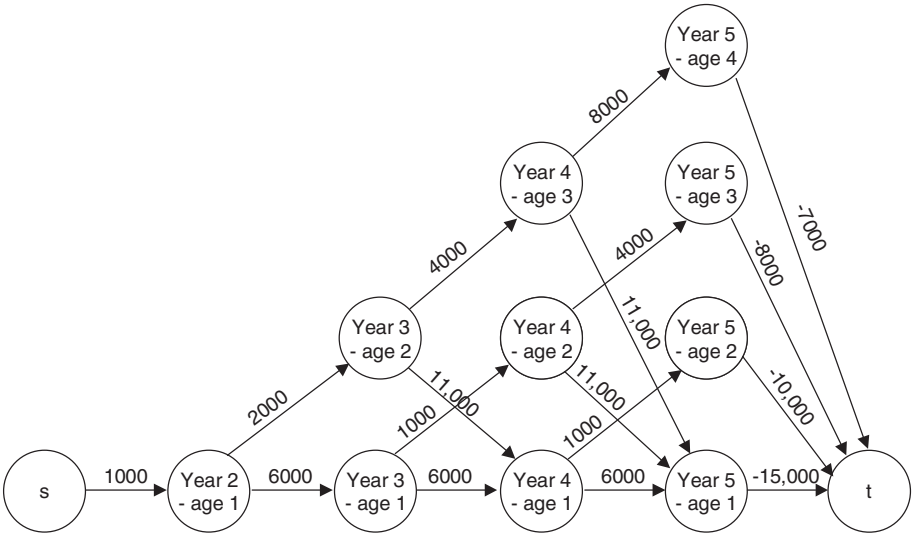

Figure 9 Shortest Path Model of Equipment Replacement Example.

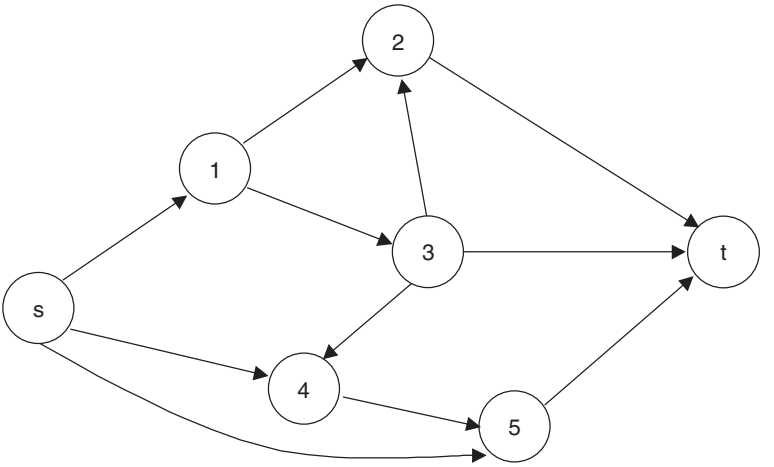

Figure 10 Network Reliability Example.

of one and the maximum flow between s and t is the number of arc disjoint paths between s and t. Since each arc has a capacity of one, every arc disjoint path between s and t can carry one unit of flow and every arc can only belong to at most one flow carrying path, so the maximum flow between these two nodes will equal the (maximum) number of arc disjoint paths between s and t.

CHAPTER 100
Discrete Optimization

RONALD L. RARDIN
Purdue University

Optimization is the process of selecting a solution from among available decision alternatives so that it conforms to all problem constraints and (at least approximately) maximizes or minimizes one or more objective/criterion functions. *Discrete optimization* is the branch confronting the vast array of problems having decisions of a logical or countable nature. Instead of, say, selecting an operating temperature, which is a decision that can pick any value in a *continuous* interval, discrete decisions are those with only specified list of options: turn left or turn right, build or do not build a plant, undertake job *A* before job *B* or *B* before *A*. If all decisions of a problem are discrete, the problem is termed *pure;* otherwise (e.g., if decisions include both whether to setup a process and what temperature to operate it at), the problem is *mixed*. The Appendix to this chapter presents many specific discrete optimization models. Other names for discrete optimization are *combinatorial optimization, integer programming,* and *mixed-integer programming*. A good introduction is provided in Rardin (1998, chaps. 9–12). More advanced books include Wolsey (1988), Parker and Rardin (1988), and Nemhauser and Wolsey (1988). Other standard sources are Schrijver (1986), Papadimitriou and Steiglitz (1982), and Lawler (1976).

1. MODELING

Modeling is the process of mathematically representing a problem in a form conducive to analysis and solution. The logical nature of discrete optimization—especially pure discrete optimization—invites a variety of quite different representations. Many problems can usefully be modeled in terms of logical predicates, objects and sets, graphs, or numerous other constructs.

The format that has proved most useful, and the focus of this chapter, is *numerical representation*—formulation of the problem in terms of numerically valued decision variables. Discrete decision options are encoded as specific numerical variable values. For example, variable $y_j = 1$ may mean plant j is selected for construction and $y_j = 0$ that it is not.

TABLE 1 Representing Discrete Phenomena with Numerical Variables

Phenomena	Representation
At least K decisions j of subset J must be taken.	$y_j \triangleq 1$ if j is in the solution, 0 otherwise $\Sigma_{j\in J}\, y_j \geq K$
Exactly K decisions j of subset J must be taken.	$y_j \triangleq 1$ if j is in the solution, 0 otherwise $\Sigma_{j\in J}\, y_j = K$
At most K decisions j of subset J can be taken.	$y_j \triangleq 1$ if j is in the solution, 0 otherwise $\Sigma_{j\in J}\, y_j \leq K$
At most K variables z_j with j in subset J can be positive in a solution.	$y_j \triangleq 1$ if $z_j > 0$, 0 otherwise $\Sigma_{j\in J}\, y_j \leq K$ $z_j \leq M\, y_j$ for all $j \in J$
Decision j is allowed only if all decisions $i_1, \ldots, i_n$ are taken.	$y_{ik} \triangleq 1$ if decision i_k is taken, 0 otherwise $y_j \triangleq 1$ if decision j is taken, 0 otherwise $y_j \leq y_{i_k}$ for all $k = 1, \ldots, n$
Decision j is allowed only if some decision $i_1, \ldots, i_n$ is taken.	$y_{i_k} \triangleq 1$ if decision i_k is taken, 0 otherwise $y_j \triangleq 1$ if decision j is taken, 0 otherwise $y_j \leq \Sigma_{k=1}^{n}\, y_{i_k}$
Decision j is implied if all decisions $i_1, \ldots, i_n$ are taken.	$y_{i_k} \triangleq 1$ if decision i_k is taken, 0 otherwise $y_j \triangleq 1$ if decision j is taken, 0 otherwise $\Sigma_{k=1}^{n}\, y_{i_k} \leq (n-1) + y_j$
Decision j is implied if any decision $i_1, \ldots, i_n$ is taken.	$y_{i_k} \triangleq 1$ if decision i_k is taken, 0 otherwise $y_j \triangleq 1$ if decision j is taken, 0 otherwise $y_{i_k} \leq y_j$ for all $k = 1, \ldots, n$
Nonnegative fixed cost F_j is incurred whenever variable z_j is positive.	$y_j \triangleq 1$ if z_j positive, 0 otherwise min $\ldots + F_j y_j + \ldots$ $z_j \leq M\, y_j$
If decision i is taken and decision j is taken, cost C_{ij} is incurred.	$y_i \triangleq 1$ if decision i is taken, 0 otherwise $y_j \triangleq 1$ if decision j is taken, 0 otherwise min $\ldots + C_{ij} y_i y_j + \ldots$
Either task i of duration T_i done before task j of duration T_j or vice versa.	$z_i \triangleq$ task i start time; $z_j \triangleq$ task j start time $y_{ij} \triangleq 1$ if task i before j, 0 otherwise $0 \leq z_i + T_i \leq z_j - M\,(1 - y_{ij})$ $0 \leq z_j + T_j \leq z_i - M\, y_{ij}$
Function $\theta(p) = \Theta_1, \ldots, \Theta_n$ at $p = P_1 < \ldots < P_n$, with linear interpolation between P_j's.	$y_j \triangleq 1$ if j left interpolation point, 0 otherwise $\theta \triangleq$ interpolated value $z_j \triangleq$ weight on point j $p = \Sigma_{j=1}^{n}\, P_j z_j$; $\theta = \Sigma_{j=1}^{n}\, \Theta_j z_j$ $\Sigma_{j=1}^{n-1}\, y_j = 1$; $\Sigma_{j=1}^{n}\, z_j = 1$ $0 \leq z_1 \leq y_1$; $0 \leq z_n \leq y_{n-1}$ $0 \leq z_j \leq y_j + y_{j-1}$ for all $j = 2, \ldots, n-1$
Quantity q is a nonnegative integer variable with value less than or equal to positive integer U.	$y_j \triangleq 1$ if the 2^j bit in the binary representation of q is "on," 0 otherwise $N \triangleq \lfloor \log_2 U \rfloor$ $q = \Sigma_{j=0}^{N}\, 2^j y_j$ $q \leq U$

Although numerical modeling of discrete problems requires more abstraction than some other approaches, it offers a host of advantages. First, objective and constraint functions involving weighted sums and the like are easily expressed in terms of numerically valued variables. Second, methods and encodings evolved for pure problems extend naturally to mixed cases. Most important, however, is the fact that the available methods for continuous optimization are generally more effective than those for discrete problems (see Chapters 97 and 98). Embedding a discrete problem in a continuous environment makes it possible to exploit continuous approximations in the analysis.

Table 1 shows the standard modeling of a variety of discrete notions in terms of numerical decision variables. Throughout, y denotes discrete variables restricted to 0 and 1 values, z represents continuous variables, and M is a large positive constant.

2. SOLUTIONS

In optimization, a solution (choice of values for decision variables) is termed *feasible* if it satisfies all problem constraints and *optimal* if it is feasible and as good as any other feasible solution in objective function value. Models that have no feasible solutions are *infeasible*.

The goal of all discrete optimization analysis is to find feasible solutions with good objective function values. It is rarely important to know a mathematically optimal solution to a model, since the model is itself only an approximation to the underlying problem. However, it is desirable to have a sharp bound on the objective function value that might be obtained by any feasible solution. Then, for example, if a feasible solution to a maximize problem is known with objective function value \$92, and other analysis establishes that no feasible solution can produce better that \$100, one can accept the \$92 solution with confidence that it is no more $(100 - 92)/100 = 8\%$ suboptimal. The attraction of mathematically optimal solutions is that they provide good feasible solutions with zero-error bounds.

Many search methods for discrete optimization move through a sequence of *partial solutions* that assign specific values to some decision variables in a model, leaving others *free* or undetermined. A *completion* of a partial solution is an assignment of specific values to any remaining free variables. Of course, the definition of a partial solution includes the possibility that there are no free variables, in which case the solution is *complete*.

Each change in solution as a search proceeds is termed a *move,* and the collection of partial solutions reachable in one move from the current solution constitutes its *neighborhood*. Moves may change the value of a decision variable already assigned a value in the partial solution, or they may give a value to a previously free decision variable.

To illustrate, consider a pure discrete model with four decision variables y_1, y_2, y_3, y_4. One partial solution is $(y_1, y_2, y_3, y_4) = (1, 0, \#, \#)$, where # denotes a free value. Here only y_1 and y_2 have been assigned a specific value. Assume moves may either increase a single fixed variable from 0 to 1; or decrease a single fixed variable from 1 to 0; or assign the value 0 to a single free variable; or assign the value 1 to a single free variable. The neighborhood of the present solution is then the six partial solutions $(y_1, y_2, y_3, y_4) = (1, 1, \#, \#)$, $(0, 0, \#, \#)$, $(1, 0, 0, \#)$, $(1, 0, 1, \#)$ $(1, 0, \#, 0)$, and $(1, 0, \#, 1)$, reachable in one move.

3. TOTAL ENUMERATION

When there are only a few discrete-valued decision variables in a model, the most effective method of analysis is usually the most direct one: *total enumeration* of all the possibilities. For example, a model with only eight 0–1 variables could be enumerated by trying all $2^8 = 256$ combinations of values for the different variables. If the model is pure discrete, it is only necessary to check whether each possible assignment of values to discrete variables is feasible and to keep track of the feasible solution with best objective function value. For mixed models the process is more complicated because each choice of discrete values yields a residual optimization problem over the continuous variables. Each such continuous problem must be solved or shown infeasible to establish an optimal solution for the full mixed problem.

Although attractive for problems with only a few discrete decisions, enumeration becomes impractical as the number of discrete variables grows to even modest size. Each new 0–1 variable doubles the number of cases that must be considered. In the range of 100–150 discrete decisions, one can compute that this explosive number of cases could occupy the fastest imaginable computer longer than the estimated life of the universe.

4. RELAXATION

When dealing with difficult discrete optimization problems, it is natural to search for related, but easier optimization models that can aid in the analysis. *Relaxations* are auxiliary optimization problems of this sort formed by weakening either the constraints or the objective function of the main problem. Specifically, an optimization problem $(\tilde{P})$ is said to be a *constraint relaxation* of another optimization problem (P) if every solution feasible to (P) is also feasible for $(\tilde{P})$. Similarly, maximize problem (respectively minimize problem) $(\tilde{P})$ is an *objective relaxation* of another maximize (respectively minimize) problem (P) if the two problems have the same feasible solutions and the objective function value in $(\tilde{P})$ of any feasible solution is $\geq$ (respectively $\leq$) the objective function value of the same solution in (P).

To illustrate, consider the discrete optimization problem

$$
\begin{aligned}
&\min\ -2y_1 + 3y_2 + 6z_1 \\
(P)\ &\text{s.t. } y_1 + y_2 = 1 \\
&\qquad z_1 - 10y_1 \leq 0 \\
&\qquad y_1, y_2 = 0 \text{ or } 1,\ z_1 \geq 0
\end{aligned}
$$

Table 2 shows a variety of relaxations.

TABLE 2 Examples of Relaxations

Relaxation ($\tilde{P}$)	Reason
min $-2y_1$ s.t. $y_1 + y_2 = 1$ $z_1 - 10y_1 \leq 0$ $y_1, y_2 = 0$ or 1, $z_1 \geq 0$	Objective relaxation. New objective underestimates at feasible y_1, y_2, z_1.
min $-2y_1 + 3y_2 + 6z_1$ s.t. $y_1 + y_2 = 1$ $y_1, y_2 = 0$ or 1, $z_1 \geq 0$	Constraint relaxation. Second main constraint deleted.
min $-2y_1 + 3y_2 + 6z_1$ s.t. $y_1 + y_2 = 1$ $z_1 - 10y_1 \leq 0$ $1 \geq y_1, y_2 \geq 0, z_1 \geq 0$	Constraint relaxation. Feasible 0–1 values satisfy $1 \geq y_1, y_2 \geq 0$.
min $-2y_1 + 3y_2 + 6z_1$ $+100(z_1 - 10y_1)$ s.t. $y_1 + y_2 = 1$ $y_1, y_2 = 0$ or 1, $z_1 \geq 0$	Objective relaxation by term $100(z_1 - 10y_1) \leq 0$ at feasible solutions. Then constraint relaxation dropping $z_1 - 10y_1 \leq 0$.

Relaxations of discrete optimization problems aid in both the good solution finding and the bounding tasks of model analysis.

- An optimal solution to a relaxation can often be rounded or otherwise manipulated in a straightforward way to obtain a satisfactory solution for the main problem.
- The objective function value of an optimal solution to a relaxation bounds the optimal objective function value of the main problem. Specifically, relaxation optima provide lower bounds for minimize problems and upper bounds for maximize problems.
- An optimal solution to a relaxation is an optimal solution to the main problem if (1) it is feasible in the main problem and (2) its objective value in the main problem is the same as that in the relaxation.
- If a relaxation is infeasible, the main problem is infeasible.

4.1. Linear Programming Relaxations

An expression is *linear* if it consists of a weighted sum of variables + or − a constant. Most of the discrete modeling illustrated in Table 1 consists of linear objective functions and constraints. In follows that a great many discrete optimization problems can be effectively modeled as *integer linear programs* of the general form

$$\begin{aligned} &\min \text{ or } \max \sum_{j=1}^{n} C_j x_j \\ (ILP)\ \text{s.t.}\quad &\sum_{j=1}^{n} A_{ij} x_j \begin{Bmatrix} \geq B_i \\ = B_i \\ \leq B_i \end{Bmatrix} \quad \text{for all } i = 1, \ldots, m \\ &x_j \geq 0 \qquad\qquad \text{for all } j \notin J \\ &x_j = 0 \text{ or } 1 \qquad \text{for all } j \in J \end{aligned}$$

Here the C_j are given objective function coefficients, the A_{ij} are given coefficients of the m linear constraints, the B_i are constant terms of the linear constraints, and J is the subset of subscripts $j = 1, \ldots n$ indexing the 0–1 variables.

The *linear programming relaxation* of problem (*ILP*), denoted ($\overline{ILP}$), is the linear program obtained when the last 0–1 system of constraints is replaced by

$$1 \geq x_j \geq 0 \text{ for all } j \in J$$

The third relaxation of Table 2 provides an example.

Because linear programs are the best solved of all optimization problems (see Chapter 97), linear programming relaxations can be optimized for very large models. For this reason, (*ILP*)s are by far the most commonly employed relaxations, and they form the core of most commercial software for discrete optimization.

Not all linear programming relaxations are close approximations of the discrete problem of interest. Because very complex criterion functions and constraints can be modeled by the linear part of an *ILP,* however, it is often the case that an optimal solution to the relaxation (*ILP*) provides a sound starting point for construction of a good feasible solution to the discrete problem. Such constructions may loosely be termed *rounding*.

Let an optimal solution to LP relaxation (*ILP*) be denoted by $\bar{x}_j$, $j = 1, \ldots, n$. The easiest case of rounding, yet one that still applies in many models, is where the model permits fractional $\bar{x}_j$ that should be integer (i.e., $j \in J$) to be simply rounded up to the next integer (often denoted $\lceil \bar{x}_j \rceil$) or rounded down to the next integer ($\lfloor \bar{x}_j \rfloor$). General-purpose rounding algorithms are also available, notably Balas and Martin's (1980), pivot and complement procedure. For most cases, however, the methods are dependent on the form of the model.

In a number of very important cases, (*ILP*)s have properties that guarantee there will always be an optimal solution to the corresponding (*ILP*) with integer values for variable x_j with $j \in J$. That is, the full model (*ILP*) can be solved optimally by solving the linear relaxation (*ILP*) because its only relaxed constraints (x_j integer for $j \in J$) are automatically satisfied by an LP optimum.

The most common of these exact cases are optimization problems that can be modeled as single-commodity *network flows* (see Chapter 99). Equivalently, these are the (*ILP*)s that can be written so that for each variable x_j, at most one constraint coefficient A_{ij} equals 1, at most one A_{ij} equals -1, and all other A_{ij} equal 0. Such (*ILP*)'s are *totally unimodular* in that any submatrix formed by the $\{A_{ij}\}$ associated with a collection of rows i and a like-sized collection of variables j has determinant 0, 1 or -1. This is enough to ensure optimal basic solutions to (*ILP*) (produced, for example, by the simplex algorithm for linear programming) are integer whenever right-hand-side coefficients B_i are all integer.

Another important class of (*ILP*)'s with integer optimal solutions to their linear relaxations is those that are *totally dual integer* (TDI). An (*ILP*) with integer constraint coefficients A_{ij} is TDI if its linear programming dual (see Chapter 97) has an integer optimal solution for every integer choice of objective function coefficients C_j. Models that are TDI will have integer optimal solutions to their linear programming relaxations if all right-hand-side constants B_i are integer.

When linear programming relaxations are not exact, it is important to make them as sharp an approximation as possible. Different formulations of discrete models as (*ILP*)s can produce quite different linear programming relaxations, even though the models have the same discrete solutions.

To illustrate, consider a problem to

$$\begin{aligned} \min \quad & 30z_1 + 60z_2 - 100z_3 \\ \text{s.t.} \quad & (z_3 = 1 \textit{ only if } z_1 = z_2 = 1) \\ & z_1, z_2, z_3 = 0 \text{ or } 1 \end{aligned}$$

If the specified logical requirement is modeled as $z_1 + z_2 \geq 2z_3$ the optimal solution to the linear programming relaxation is $z_1 = 1$, $z_2 = 0$, $z_3 = 1/2$ with objective function value -20. An equivalent (*ILP*) with a sharper (*ILP*) comes from modeling the requirement as $z_1 \geq z_3$, $z_2 \geq z_3$. In this format, an optimal solution to the linear programming relaxation is $z_1 = z_2 = z_3 = 1$ with objective value -10. The latter form is stronger because the relaxation solution obtained is both more nearly feasible for the discrete problem and the source of a more exact bound. (In fact, the second modeling yields an optimal solution for this instance.)

Because of the importance of using formulations with sharp linear programming relaxations, a great deal of research in the recent decades has been addressed to various aspects of that issue. One broad area of opportunity for sharpening linear programming relaxation comes in choosing constraint coefficients more carefully. Assume that each linear inequality of the formulation is rearranged to $\geq$ format with only the constant term on the right-hand side. Each inequality is then of the form $\sum_{j=1}^{n} A_{ij}x_j \geq B_i$. Recalling that we also assume all variables are subject to nonnegativity constraints, it is easy to see that this constraint will cut off more LP-feasible points if either B_i can be increased or at least one of the A_{ij} can be decreased.

A classic example relates to large-integer "big M" constants in (*ILP*) formulations. For example, suppose continuous variable z_1 is subject to constraints $0 \leq z_1 \leq 10$ and corresponding 0–1 variable y_1 is to be 1 whenever z_1 is positive. The latter requirement is modeled $My_1 - z_1 \geq 0$, where M is any positive constant at least 10. However, the modeling with the strongest linear programming relaxation will be the one that makes M as small as possible (i.e., $M = 10$).

A second common method of improving linear programming relaxations is to add new valid inequality constraints. An inequality is *valid* for an (*ILP*) if it is satisfied by every (integer) feasible

solution to (*ILP*). Technically all the original constraints of (*ILP*) are valid inequalities. However, the term usually refers to added constraints that are not needed for a correct integer linear programming formulation but do sharpen the corresponding linear programming relaxation. The strongest such valid inequalities—ones that are unavoidable if the sharpened LP relaxation is to be exact—are called *facet-inducing, facetial,* or simply *facets*.

It is easy to find valid inequalities for discrete optimization formulations but difficult to find ones strong enough to materially improve the LP relaxation. Most of the families of such inequalities that have proved useful are highly problem specific.

One fairly general case is the family of valid inequalities employed by Crowder et al. (1983), when the original (*ILP*) formulation includes a constraint $\Sigma_{j\in L} A_{ij}x_j \leq B_i$ where nonzero coefficients occur only on integer subscripts in $L \subseteq J$, all coefficients A_{ij} and B_i are positive, and the A_{ij} are not just ones. For any $K \subseteq L$ with $\Sigma_{j\in K} A_{ij} > B_i$, it is easy to see the following inequality is valid $\Sigma_{j\in K} x_j \leq |K| - 1$ ($|K|$ denotes the number of subscripts in K). Furthermore, the smaller we can make K while satisfying its defining requirement, the sharper the revised linear programming relaxation. Choosing minimal K, that is, K that cannot be further reduced, produces a useful family of valid inequalities.

One difficulty with using families of strong valid inequalities to sharpen linear programming relaxations is that the number of inequalities in such families is usually exponentially large. It would be impossible actually to enumerate all such inequalities and add them to the formulation submitted to a linear programming code. Instead, successful applications have employed *separation* subroutines. Such subroutines heuristically select a small subfamily of inequalities that are likely to improve the current formulation. After solving the linear programming relaxation with the selected inequalities added, if the approximation is still not sharp enough, the separation routine may be reinvoked to generate further inequalities.

A third approach to sharpening linear programming relaxations has been to introduce an extended (larger) set of variables (see Martin 1999). Such extra variables are not necessary for a correct (*ILP*) formulation. Still, their presence in the model makes it possible to write new constraints that sharpen the linear programming relaxation.

To illustrate, consider a fixed charge network flow problem with two candidate locations for \$50 thousand facilities, each with a demand for 10 thousand units of the commodity to be provided by the facilities. If there is a \$1 per unit shipping charge between the facilities, a textbook formulation is

$$\begin{aligned} \min \quad & z_{12} + z_{21} + 50y_1 + 50y_2 \\ \text{s.t.} \quad & z_1 = z_{12} + 10,\ z_2 = z_{21} + 10 \\ & z_1 \leq 20y_1,\ z_2 \leq 20y_2 \\ & z_1, z_2, z_{12}, z_{21} \geq 0;\ y_1, y_2 = 0 \text{ or } 1 \end{aligned}$$

Here z_i is the total supplied at facility i, z_{ij} represents the number of thousands of units shipped to the other facility, and y_i decides whether facility i is built. This model has LP relaxation optimal solution $\bar{z}_1 = \bar{z}_2 = 10$, $\bar{z}_{12} = \bar{z}_{21} = 0$, $\bar{y} = \bar{y}_2 = 1/2$ and value \$50 thousand.

The extended form of Rardin and Wolsey (1993) introduces new variables that subdivide flows z_1 and z_2 according to whether they are directed to the facility site or to its companion site. Specifically,

$$\begin{aligned} z_1 &= w_{11} + w_{12},\ z_2 = w_{21} + w_{22} \\ z_{12} &= w_{12},\ z_{21} = w_{21} \\ 0 &\leq w_{11} \leq 10y_1,\ 0 \leq w_{12} \leq 10y_1 \\ 0 &\leq w_{21} \leq 10y_2,\ 0 \leq w_{22} \leq 10y_2 \end{aligned}$$

With this extended system, the LP relaxation yields a discrete optimum of value \$60 thousand.

4.2. Lagrangean Relaxations

Linear programming relaxations of integer linear programs produce an easier problem by deleting difficult integrality requirements on variables x_j with $j \in J$. This makes them as widely applicable as integer linear programming itself, but they are not always very good approximations.

Lagrangean relaxations are an alternative appropriate where some of the linear constraints are treated as the complications in an otherwise manageable discrete model. Integrality requirements are explicitly retained in relaxations, and complicating linear constraints are *dualized,* that is, taken to the objective function with appropriate Lagrange multipliers.

The fourth relaxation of Table 2 illustrates the principle of Lagrangean relaxation, but most of the success with Lagrangean relaxation has derived from problem-specific structures. Its power is better illustrated by a classic application.

Generalized assignment problems involve optimal arranging of objects $i = 1, \ldots, m$ of known size S_i into locations $j = 1, \ldots, n$ of known capacity K_j. An (*ILP*) formulation is

$$\begin{aligned} \min \quad & \sum_{i=1}^{m}\sum_{j=1}^{n} C_{ij}y_{ij} \\ (GA)\ \text{s.t.} \quad & \sum_{j=1}^{n} y_{ij} = 1 \qquad \text{for all } i = 1, \ldots, m \\ & \sum_{i=1}^{m} S_i y_{ij} \le K \quad \text{for all } j = 1, \ldots, n \\ & y_{ij} = 0 \text{ or } 1 \quad \text{for all } i = 1, \ldots, m;\ j = 1, \ldots, n \end{aligned}$$

where C_{ij} is the cost of assigning object i to location j.

Either of the main systems of constraints in (*GA*) might be thought of as complicating because deletion of either leaves an easier model where each variable appears in only one constraint. Thus, either system might be first dualized and then dropped. Corresponding Lagrangean relaxations are

$$\begin{aligned} \min \quad & \sum_{i=1}^{m}\sum_{j=1}^{n} C_{ij}y_{ij} + \sum_{j=1}^{n} u_j\left(\sum_{i=1}^{m} S_i y_{ij} - K_j\right) \\ (GA_u)\ \text{s.t.} \quad & \sum_{j=1}^{n} y_{ij} = 1 \text{ for all } i = 1, \ldots, m \\ & y_{ij} = 0 \text{ or } 1 \text{ for all } i = 1, \ldots, m;\ j = 1, \ldots, n \end{aligned}$$

and

$$\begin{aligned} \min \quad & \sum_{i=1}^{m}\sum_{j=1}^{n} C_{ij}y_{ij} + \sum_{i=1}^{m} v_i\left(\sum_{j=1}^{n} y_{ij} - 1\right) \\ (GA_v)\ \text{s.t.} \quad & \sum_{i=1}^{m} S_i y_{ij} \le K_j \text{ for all } j = 1, \ldots, n \\ & y_{ij} = 0 \text{ or } 1 \text{ for all } i = 1, \ldots, m;\ j = 1, \ldots, n \end{aligned}$$

The effect of dualizing constraints is to enforce them partially by penalizing violating solutions in the objective function. However, care must be taken to ensure that a valid relaxation results. In (GA_u), the dualized constraints are inequalities. Terms weighted by u_j will be negative or zero at feasible solutions. Thus, in order to have a proper objective relaxation, multipliers must satisfy

$$u_j \ge 0 \text{ for all } j = 1, \ldots, n$$

Furthermore, an optimal solution to a relaxation (GA_u) may not be optimal in (*GA*) even if it satisfies the relaxed constraints. Since the objective function values in (*GA*) and (GA_u) may differ, *complementary slackness* conditions

$$u_j\left(\sum_{i=1}^{m} S_i y_{ij} - K_j\right) = 0 \text{ for all } j = 1, \ldots, n$$

must also be satisfied if a relaxation optimum is to be optimal in (*GA*).

In (GA_v), the situation is much easier because dualized constraints are equalities. Terms weighted by v_i will be zero at feasible solutions. Thus, no sign restrictions on Lagrange multipliers are needed for a proper relaxation, and complementary slackness is not an issue for (*GA*) optimality.

Any valid choice of multipliers on dualized constraints produces a Lagrangean relaxation, and like all relaxations the optimal objective function value in the relaxation bounds the optimal value of the main problem. However, some choices of constraints to dualize may give rather weak bounds; others may yield very strong bounds (see Parker and Rardin 1988, chap. 5 for a full discussion).

For any fixed dualization strategy, good bounds depend on good multipliers. Successful use of Lagrangean relaxation requires a search where a sequence of Lagrangean relaxations is solved with different multipliers. Results of one relaxation suggest ways to change the multipliers for the next.

The simplest, *subgradient search,* is effective in many settings. Assume the given discrete problem has been expressed as a minimize (*ILP*) with all inequalities $\leq$, $I^{=}$ the collection of dualized equality row numbers, $I^{\leq}$ the collection of dualized ($\leq$) inequalities, and $\{u_i : i \in I^{=} \cup I^{\leq}\}$ the Lagrange multipliers. Then subgradient search updates multipliers:

$$u_i \leftarrow u_i + \alpha \left(\sum_{j=1}^{n} A_{ij}\hat{x}_j - B_i \right) \text{ for all } i \in I^{=} \cup I^{\leq}$$

$$u_i \leftarrow \max\{u_i, 0\} \text{ for all } i \in I^{\leq}$$

where $\hat{x}_j$ denotes the most recent relaxation optimum and α is a stepsize.

5. HEURISTIC SEARCH

When a discrete model has too many decisions for total enumeration and no convenient relaxation that is sharp enough to give sound approximations, the principal remaining approach is to organize a search through a series of solutions (or partial solutions) until a satisfactory feasible solution is isolated.

Sometimes a practical method is available for computing an exact optimum (see Section 6). More commonly, however, only a *heuristic* or *approximate optimum* can be obtained in reasonable computation time. Such solutions are feasible, but there is no guarantee they are optimal. Often it is not even possible to bound the error in the heuristic optima produced.

Implementations of heuristic search in discrete optimization are usually classified according to whether they focus on partial or complete solutions. *Constructive searches* begin with an all-free partial solution and fix one or more components at each move until a complete solution is obtained. *Improving searches* work their way through a sequence of complete solutions, striving at each move to find a complete solution in the neighborhood that is either less infeasible, better in objective value than the current solution, or both. Of course, the strategies can be combined by, for example, using a constructive search to build a first complete solution and then applying an improving search to make it better.

5.1. Constructive or Solution-Building Search

Constructive searches are often called *greedy* or *myopic* because they usually choose variables and values to fix on the basis of estimates of immediate or short-term gain. The main issue in design of such procedures is to choose an informative measure of efficiency or gain on which to base selections.

For certain maximizing models on combinatorial structures called *matroids* (see e.g., Parker and Rardin 1988, chap. 3), an exact optimal solution results from the most naive possible greedy choice rule. Moves iteratively make $=1$ the remaining free variable with greatest objective function coefficient, subject only to the requirement that this choice does not produce infeasibility. The *spanning tree problem* (see the Appendix) is the most famous example of this matroid structure where a greedy algorithm is optimal.

Constructive searches based on more complicated efficiency ratios are much more common than the pure greedy notion of considering only objective coefficient magnitudes. One example is Dobson's (1982), heuristic for *generalized covering* problems of the form

$$\begin{aligned} \min \quad & \sum_{j=1}^{n} C_j y_j \\ \text{s.t.} \quad & \sum_{j=1}^{n} A_{ij} y_j \geq B_i \quad \text{for all } i = 1, \ldots, m \\ & y_j = 0 \text{ or } 1 \quad \text{for all } j = 1, \ldots, n \end{aligned}$$

where all A_{ij} and B_i are nonnegative integers. Dobson's algorithm starts with the all free solution and iteratively chooses a new $y_{\tilde{j}}$ to make $= 1$ where $\tilde{j}$ is the free index with $\min\{C_j / \Sigma_{i=1}^{m} \min\{A_{ij}, \tilde{B}_i\}\}$ and $\tilde{B}_i = \max\{0, B_i - \Sigma_{j \text{ fixed } 1} A_{ij}\}$. The denominator of this ratio is the total overall constraints of the amount variable j could contribute toward resolving remaining infeasibility. Thus, the algorithm is choosing on the basis of least cost per unit improvement in infeasibility. The process terminates (making any remaining free variables $= 0$) when the current partial solution is feasible in every main constraint.

The fact that constructive heuristics usually terminate as soon as the first feasible solution is found makes them an attractive choice where solution time is critical, such as in near real-time control. Still, results obviously depend critically on the early decisions taken, so the quality of the heuristic optimum produced tends to deteriorate rapidly with the number of discrete variables in the model.

5.2. Improving or Solution-Enhancing Search

Improving searches begin from a complete solution and apply moves that either improve the objective function value or reduce infeasibility. All or a large part of the complete solutions in the neighborhood are evaluated, and the search advances to the one found most attractive. One example is the *parallel processor* problem:

$$\begin{aligned} \min \quad & z \\ \text{s.t.} \quad & y_{i1} + y_{i2} = 1 \quad \text{for all } i = 1, \ldots, m \\ & \sum_{i=1}^{m} T_i y_{ip} \le z \quad \text{for all } p = 1, 2 \\ & y_{ip} = 0 \text{ or } 1 \quad \text{for all } i = 1, \ldots, m;\ p = 1, 2 \end{aligned}$$

Here tasks $i = 1, \ldots, m$ of time duration T_i must be scheduled on one of two processors p. Decision variables $y_{ip} = 1$ if task i is assigned to processor p and $= 0$ otherwise. Continuous variable z measures the completion time of all tasks.

An improving search would begin from any feasible choice of values for the discrete variables (each task is assigned to some processor). A major algorithm-design question is what other solutions should be considered neighbors, or equivalently, what set of moves to apply.

One obvious family of moves consists of switching one task from its current processor to the other. Whichever of these changes most improved the objective function would provide the move to be taken.

A neighborhood allowing pairs of tasks to be interchanged between the two processors could yield better results. However, the computational effort per step would increase because there are only m reassignments of one task to a different processor, but more like $m^2/4$ pairwise swaps (assuming about half the tasks will be on each processor).

Still another neighborhood might employ moves that delete or add a single task to one of the processors. Such moves could create infeasibility because a task might be assigned to both processors, or it might not be assigned at all. The difficulty in this case is how to balance improvement in solution value with reduction in infeasibility as the next solution is chosen. A common approach is to add a penalty term in the objective function to discourage infeasibility without prohibiting it. In the parallel processor example above, this penalty term would have the form

$$\alpha \sum_{i=1}^{m} |y_{i1} + y_{i2} - 1|$$

where $\alpha > 0$ is the weight applied to infeasibility.

5.3. Local Optima

Although heuristic search has proved useful on some problems, natural definitions of neighborhoods often lead to poor *local optima,* that is, final feasible solutions that cannot be improved in the neighborhood. Of course, a richer family of allowed moves would make it possible to reach stronger local optima, but the cost of examining the neighborhood at each iteration rapidly becomes prohibitive.

One standard solution to this dilemma, known as *multistart,* is to employ a limited neighborhood but restart the search several times. Each time, the search begins with a randomly chosen starting solution and continues to a local optimum. The best of these local optima is kept as an heuristic optimum.

5.4. Tabu, Simulated Annealing, and Genetic Algorithms

An alternative that has generated much recent research interest is to liberate neighborhood search from the obligation to improve at each step. That is, moves are sometimes adopted that do not improve the objective function (or reduce infeasibility). Comprehensive books on the topic include Reeves (1993), Aarts and Lenstra (1997), and Glover and Laguna (1998).

The immediate difficulty with nonimproving moves is that they can make the search loop. For example, suppose that no improving move is available and a nonimproving move is adopted to change y_{27} from $= 1$ to $= 0$. Assuming some symmetry in the move set, there will certainly be an improving

move at the next step: changing y_{27} back from = 0 to = 1. The algorithm could loop infinitely between the two.

Tabu algorithms of Glover and others deal with repeats by keeping list of moves that are temporarily "tabu" or forbidden. The best improving (or least nonimproving) non-tabu move is adopted at each step of the procedure. For example, in the above case where y_{27} is switched from = 1 to = 0, any move involving y_{27} might be placed on the tabu list for say the next 5–10 steps and then freed. Solutions can still repeat under tabu, but computational experience has shown promise in a number of applications.

From this simple beginning, tabu methods have developed in a variety of directions. Once a data structure must be maintained to limit moves, it can be used to guide other aspects of the search in a variety of creative ways. For example, moves that have proved useful in the past may be given some preference, or moves that have not been used in the most recent part of the search might be tried. Glover and Laguna (1998) develop a host of alternatives.

A second approach is the stochastic one of *simulated annealing* (see, e.g., Kirkpatrick et al. (1983); Aarts and Lenstra (1998)). With simulated annealing, a move is selected randomly from the available neighborhood at each iteration. If the selected move would result in an improvement, it is adopted and the search advances to the indicated solution. If the move would degrade the solution, it may or may not be adopted, depending on a probability that decreases with the magnitude of the degradation.

A common rule is to accept a nonimproving move with probability $e^{-d/T}$, where d is the amount by which the solution degrades the objective function value and T is a control parameter called the *temperature*. Typically T is started relatively large so that the search can range widely in the early stages. Then T is slowly decreased as the procedure settles into the region of a good feasible solution.

As with tabu, solutions can repeat, but simulated annealing's use of probabilities ensures the search will advance to better solutions if any exist, although it may take a long time. Experience has shown simulated annealing to be a reliable and easy-to-implement way to compute good heuristic solutions in a wide variety of applications. However, comparatively long running times are often required.

Genetic algorithms (see Holland 1975; Goldberg 1989) offer still another approach to dealing with local optima. Instead of keeping just a single current solution at each move, these methods retain a whole *population* of solutions. At each update or *generation,* some or all of these solutions will be replaced by improved ones.

Any of the normal manipulations of neighborhood search can be employed to construct the new solutions, but *crossover* moves, which interchange parts of solutions in the current population, are the most popular. For example, crossover of "parent" solutions (0,1,0,0,1,1) and (1,1,0,1,0,1) by cutting after the third component would produce "offspring" (0,1,0,1,0,1) and (1,1,0,0,1,1). These new solutions would be evaluated and the better ones preserved in the next generation.

Genetic algorithms have become the method of choice in difficult engineering design circumstances where complex feasibility limitations and massive nonlinearity make it difficult to employ neighborhood-based methods. However, other methods usually give better performance on classic combinatorial optimization problems—especially (*ILP*)'s and cases with linear constraints.

6. BACKTRACKING SEARCH AND BRANCH AND BOUND

Heuristic searches usually guarantee neither a global optimal solution nor a bound on the error when computation stops because they make *preemptive* moves—moves for which there are viable alternatives that are not explored. In order to carry out a more exhaustive search, such moves must be taken as *provisional*. That is, a record must be retained of the alternatives not yet pursued, and search must *backtrack* to those alternatives, pursuing them until they prove incapable of producing an satisfactory solution. As the search encounters a particular partial solution, it either *terminates* that solution, that is, finds it to admit no improving move, or *branches* it, that is, extends it by one applicable move. The best feasible solution encountered is recorded as the *incumbent solution*. Thus, if the search exhausts all open alternatives, the incumbent solution is a global optimum.

6.1. Tree Representation

One essential element of backtracking search is a record of provisional moves and alternatives not yet explored. The most convenient format for such a record is a tree like the one in Figure 1. *Nodes* of that tree represent states of the search. *Branches* show the selected and alternative moves available in a state. Search proceeds from the first node or *root* of the tree toward the bottom. A node is numbered when it is actually visited by the search; ones still to be considered are left unnumbered. A backtrack occurs thenever the search skips to an open alternative instead of an extension of the current state.

The example of Figure 1 represents a search that has already completed 6 nodes. Successive moves from the root=1 fixed y_5, then y_{11}, then y_3 to 1. The last produced a feasible solution and node 4, which is terminated. The search now backtracks to one of the three unexplored alternatives

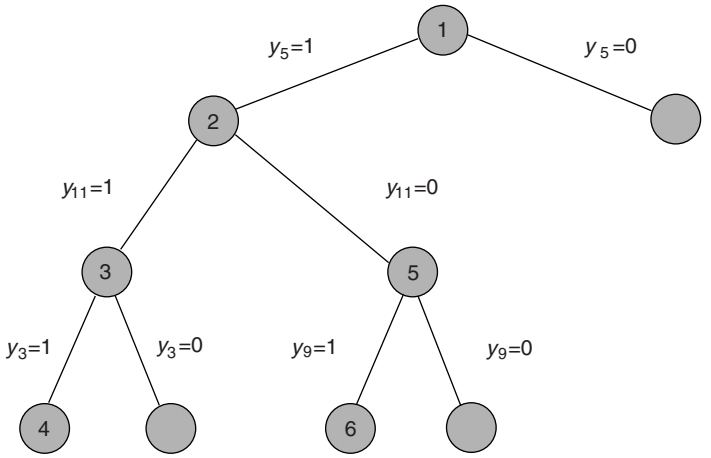

Figure 1 Backtracking Search Tree.

to the moves taken. Here the choice was to adopt move $y_{11} = 0$ to the node marked 5. Moves $y_9 = 1$ and $y_9 = 0$ were now available at this node, so it was branched and the first of these moves was selected.

6.2. Branch and Bound

Branch and bound procedures combine backtracking search with the power of relaxations. Any partial solution in a search that has variables still free defines a *candidate problem,* that is, a discrete optimization problem over the free variables subject to limits imposed by the fixed decisions. Instead of pursuing partial solutions until no further moves are available, branch and bound solves a relaxation of the corresponding candidate problems. If the relaxation optimum satisfies requirements to be optimal for the candidate problem, the partial solution can be terminated immediately; its best completion has been identified. If the relaxation proves infeasible, the partial solution can also be terminated; no completion exists. When neither of these cases occurs, the value of the relaxation optimal solution provides a bound on the value of the candidate problem. That is, it yields a bound on the quality of any completion. If that bound is already worse than the incumbent solution, no completion can improve on the incumbent; the node can be terminated. In any event, the best such bound across all unexplored nodes provides a global bound on the optimal value of the full discrete model.

Any reasonable set of branching moves can be combined with any convenient relaxation to produce a branch and bound procedure. Still, the great majority of successful applications and all commercial codes for discrete optimization use implementations of branch and bound on integer linear programs (*ILP*), with linear programming relaxations. The main ideas of such an algorithm can be outlined as follows:

ILP branch and bound (minimize):
initialize $CAND \leftarrow \{(ILP)\}$; $INCUM \leftarrow \infty$; $k \leftarrow 0$
while $CAND \neq \emptyset$ **do**
  $k \leftarrow k + 1$
  select a member of $CAND$ as (ILP_k)
  attempt to solve relaxation $(\overline{ILP_k})$ for value VAL_k
  if $(\overline{ILP_k})$ is infeasible or $VAL_k \geq INCUM$
    then delete (ILP_k) from $CAND$
    elseif the $(\overline{ILP_k})$ optimum is feasible in (ILP)
      then $INCUM \leftarrow \min\{INCUM, VAL_k\}$
        delete any member of $CAND$ with stored bound $\geq INCUM$
        delete (ILP_k) from $CAND$
    else choose binary free x_p fractional in $(\overline{ILP_k})$
      replace (ILP_k) in $CAND$ by extensions with $x_p = 0$
        and $x_p = 1$, both with stored bound VAL_k
end

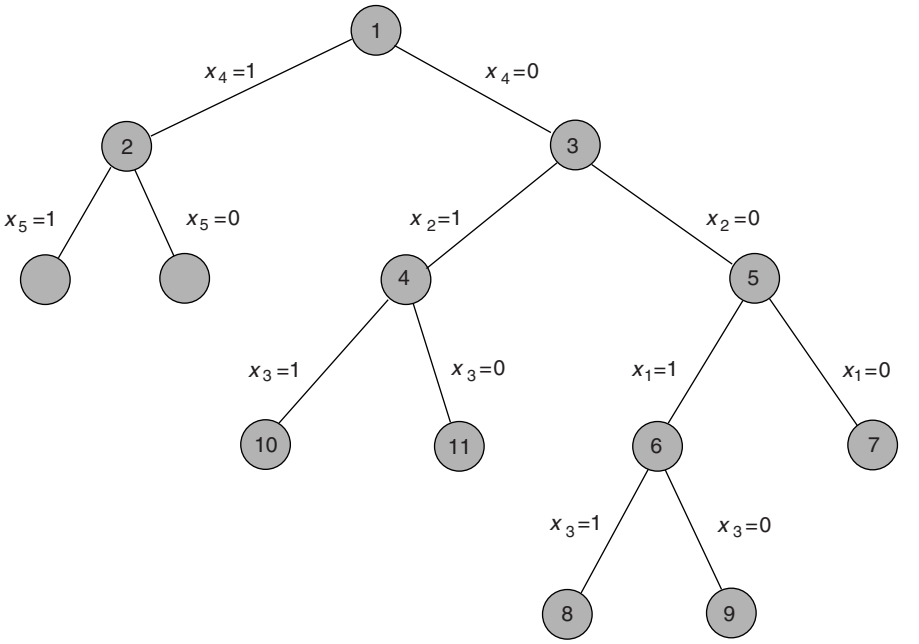

Figure 2 Branch and Bound Example.

In this statement, *CAND* represents a list of the candidate problems associated with active nodes of the search. *Stored bounds* are maintained with members of *CAND* to show the best-known lower bound on the value of an optimal solution to the candidate.

To illustrate this (*ILP*) form of branch and bound, consider the example

$$\begin{aligned} \min \quad & 7x_1 + 12x_2 + 7x_3 + 14x_4 + x_5 + 25x_6 \\ \text{s.t.} \quad & 3x_1 + 6x_2 + 5x_3 + 16x_4 + x_6 \geq 7 \\ & 5x_1 + 4x_2 + 4x_3 + 5x_4 \geq 2 \\ & 3x_1 + 3x_2 + 3x_3 + 10x_5 \leq 3 \\ & x_1, \ldots, x_5 = 0 \text{ or } 1;\ 0 \leq x_6 \leq 3 \end{aligned}$$

Figure 2 shows the search tree for this example, and Table 3 describes processing of each node.

A complete implementation of branch and bound in even the (*ILP*) form given above involves many heuristic rules. The primary ones are (1) which free variable to fix in branching node k and (2) which active node (member of *CAND*) to choose at each iteration k. For the simple example above, corresponding rules were (1) choose the fractional-valued free variable closest to 0.0 and (2) choose the active node with least stored bound, breaking ties in favor of the last fixed variable = 1.

A desirable feature of branch and bound is that a bound on the value of a global optimal solution is always available, so that the algorithm need not be run to termination in order to bound the error of accepting the incumbent solution as approximately optimal. The best stored bound of *CAND* (least for minimize problems, highest for maximize problems) always provides such a bound. Thus, for example, after node 8 is processed in the example of Figure 2, it is certain that any solution to the full (*ILP*) will cost at least $\min\{12.6,13.4\} = 12.6$. Stopping at that point with the incumbent solution of value 14 would produce at most $(14 - 12.6)/12.6 = 11.1\%$ error.

7. GUIDELINES AND LIMITS

Discrete optimization problems abound in all phases of industrial engineering, and ones with important economic implications easily justify formal modeling and systematic analysis. However, there are no general-purpose methods appropriate for dealing with all or even most models. This concluding

TABLE 3 Processing for Branch and Bound Example

Node	Fixed	LP Relaxation	*VAL*	Processing
1	none	(0,0,0,0.44,0.3,0)	6.42	branch on x_4
2	$x_4 = 1$	(0,0,0,1,0.3,0)	14.30	branch on x_5
3	$x_4 = 0$	(0,0.33,1,0,0,0)	11	branch on x_2
4	$x_4 = 0, x_2 = 1$	(0,1,0.2,0,0,0)	13.4	branch on x_3
5	$x_4 = 0, x_2 = 0$	(0.67,0,1,0,0,0)	11.67	branch on x_1
6	$x_4 = 0, x_2 = 0, x_1 = 1$	(1,0,0.8,0,0,0)	12.6	branch on x_3
7	$x_4 = 0, x_2 = 0, x_1 = 0$	(0,0,1,0,0,2)	57	new incumbent; *INCUM* ← 57; terminate solved
8	$x_4 = 0, x_2 = 0, x_1 = 1, x_3 = 1$	(1,0,1,0,0,0)	14	new incumbent; *INCUM* ← 14; delete extensions of Node 2; terminate solved
9	$x_4 = 0, x_2 = 0, x_1 = 1, x_3 = 0$	infeasible	—	terminate infeasible
10	$x_4 = 0, x_2 = 1, x_3 = 1$	(0,1,1,0,0,0)	19	terminate bound $\geq$ 14
11	$x_4 = 0, x_2 = 1, x_3 = 0$	(0.33,1,0,0,0,0)	14.33	terminate bound $\geq$ 14; incumbent solution optimal

section reviews theory and accumulated wisdom delimiting which of the approaches treated in previous sections are appropriate for a given model.

7.1. Computational Complexity Theory

The formal theory of problem difficulty classification is called *computational complexity theory* (see Garey and Johnson 1979; Papadimitriou 1994; Parker and Rardin 1988, chap. 2). Complexity theory terms a *problem* any collection of related *instances* distinguished only by their size and numerical constants. For example, (*ILP*) is a problem with instances distinguished by counts m and n, discrete variable list J, and constants C_j, A_{ij}, and B_i. The *size* of an instance is the length of the symbol string required to encode it for a computer.

The objective of complexity theory is to classify problems according to how efficiently instances can be solved relative to their size. Bounds on the required computation are expressed as *computational orders,* denoted $O(\ )$. For example, if every instance of a problem can be solved in a number of elementary calculations bounded by the square of its size s, the problem is $O(s^2)$ solvable. More generally, a problem is said to be *polynomially solvable* if there is a constant k such that every instance of size s is solvable in $O(s^k)$ effort. Specifically, $O(s^4)$, $O(s\sqrt{s})$, and $O(s^2 \log s)$ computations are polynomial (the last because $s^2 \log s \leq s^3$). $O(2^s)$ and $O(s!)$ are not polynomial.

One of the most important theoretical achievements of discrete optimization research has been to isolate polynomial solvability as the defining characteristic of truly tractable discrete problems. Every one of the discrete models for which a generally effective algorithm or an exact (polynomially solvable) relaxation has been discovered belongs to the polynomially solvable class.

Across what seems to be a cosmic boundary in mathematics lies the alternative *NP-hard* class, to which almost all discrete optimization models belong that lack such tractable characteristics. *NP*-hard problems are not (yet) provably outside the reach of polynomial solvability, but neither are they just problems for which research has so far failed. Class *NP* is a vast collection of ''Does there exist . . .'' problems in discrete mathematics and computer science, some of which have been studied for centuries without much progress. No discrete optimization problem actually belongs to *NP* because none is of this existence form. Still, each *NP*-hard discrete optimization problem (*H*) is as difficult as any in *NP* in the sense that a polynomial algorithm for (*H*) would provide one for every member of *NP*. Thus, to seek such an algorithm for any *NP*-hard problem is simultaneously to attack the enormous variety of challenging problems in *NP*. Success is most unlikely. Similar logic establishes that exact relaxations and strong duality theories are also highly improbable for most *NP*-hard problems, although additional technical issues make general statements more difficult.

The fundamental importance of the polynomially solvable vs. *NP*-hard distinction makes it a high-priority matter to try to determine on which side of the boundary any given discrete optimization application falls (theory indicates there may be problems that belong to neither category, but few realistic candidates are known). Polynomial solvability is almost always established by showing the given model is a special case of one of the classic polynomial time models detailed in the Appendix,

or inventing some simple enumeration over cases solvable as one of those models. On the other hand, one shows a problem is *NP*-hard by demonstrating that some known *NP*-hard problem can be viewed as a special case (several *NP*-hard models are included in the Appendix, and Garey and Johnson 1979 provides a much bigger list). For example, generalized assignment (*GA*) is known to be *NP*-hard. This is enough to establish that integer linear programming (*ILP*) is *NP*-hard because every instance of (*GA*) is an instance of (*ILP*).

7.2. Choosing a Strategy

When a discrete optimization problem is in the polynomially solvable complexity category, it is usually clear how to proceed with its analysis. A clever and efficient algorithm is at hand. Often an exact linear programming formulation is also known, and a strong duality theory is available for sensitivity studies. Very complete analysis should be possible, unless limits on the time available for solution (e.g., in a real-time setting) mandate quicker methods.

In the far more typical case where the given discrete optimization is *NP*-hard, more care should be exercised in choosing avenues of analysis. Figure 3 offers some very approximate guidelines in terms of two critical characteristics: the number of binary decisions in the model vs. the error of the best available relaxation bound.

For small numbers of decisions, say up to 10–15, total enumeration is recommended, regardless of relaxation quality. As the number of binary decisions increases, models subdivide into three regions. In the outermost, relaxations are too poor to assist in analysis. The only practical strategy is some form of heuristic search lacking even a bound on the suboptimality of results obtained.

The innermost region shows where branch and bound methods may be effective. Relatively strong relaxations are required, and the needed sharpness increases rapidly with the number of binary decisions.

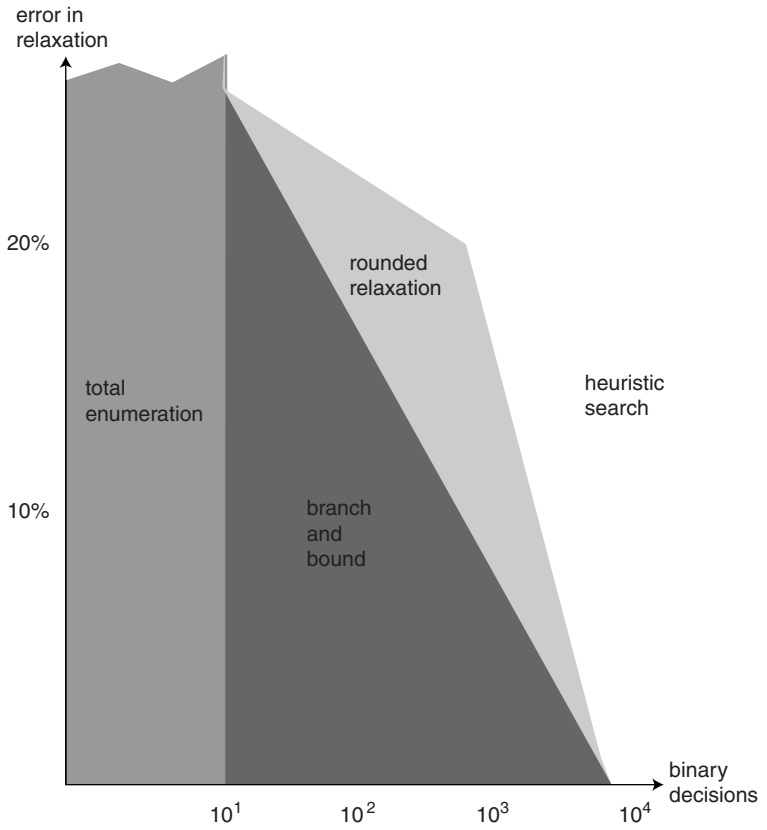

Figure 3 Guidelines for NP-Hard Problems.

Between these two extremes lies a region where relaxations may be helpful but branch and bound is unlikely to be effective. Here, bounds from relaxations at least delimit the suboptimality of solutions found through heuristic search or other means. Relaxation may also provide a good source of feasible discrete solutions when the problem admits easy rounding of relaxation optima.

As with any broad guidelines, the boundaries in Figure 3 are very fuzzy. In particular, it is often too simple to take the number of binary decisions in a model to equal the number of 0–1 variables in an (*ILP*) formulation. A generalized assignment model, for example, with m objects and n locations has mn 0–1 variables. However, each belongs to $\Sigma_j y_{ij} = 1$ multiple-choice set. Thus, there are really only n choices in each of these subsets, or $m \log_2 n$ total binary decisions in the model.

Application of the guidelines in Figure 3 also requires, of course, information about the likely quality of available relaxations. Each family of examples has different behavior, but there are characteristic attributes of relaxations with little promise:

- Nonlinear objective functions or constraints
- Either–or constraints that can only be placed in (*ILP*) format through the use of large positive constants (''big *M*'s'')
- Massive symmetry introducing numerous feasible alternatives of nearly the same objective function value

Any relaxation possessing such attributes is likely to require strengthening if it is to be of practical use with even moderately large applications.

APPENDIX

This appendix briefly describes and formulates a variety of standard discrete optimization models. Throughout, y denotes 0–1 discrete variables, z represents continuous variables, $D(N, A)$ indicates a directed network or graph with nodes in N and arcs in A, and $G(N, E)$ denotes an undirected network or graph with nodes in N and edges in E. Capital letters are used to denote input and lower case to show decision variables. The size of set S is indicated by $|S|$.

Assignment: Maximum utility pairing of objects from two given sets S and T; $\triangleq$ family of allowed pairs (i, j), $i \in S$, $j \in T$; $C_{ij} \triangleq$ value of pair (i, j).

$$
\begin{aligned}
y_{ij} \triangleq\ & 1 \text{ if pair } (i, j) \text{ is chosen, else } 0 \\
\max\ & \Sigma_{(i,j)\in E}\, C_{ij} y_{ij} \\
\text{s.t.}\ & \Sigma_{j\in T}\, y_{ij} = 1,\ i \in S \\
& \Sigma_{i\in S}\, y_{ij} = 1,\ j \in T \\
& y_{ij} = 0 \text{ or } 1,\ (i, j) \in E
\end{aligned}
$$

Polynomially solvable by combinatorial algorithms. Special case of both Matching and Network Flows. LP relaxation is totally unimodular.

Capital Budgeting: Maximum value subset of objects or projects j to pack within given capacity or resource limits B_i; $A_{ij} \triangleq$ (nonnegative) consumption of resource i by project j; $C_j \triangleq$ value of project j.

$$
\begin{aligned}
y_j \triangleq\ & 1 \text{ if project } j \text{ is chosen, else } 0 \\
\max\ & \Sigma_j\, C_j y_j \\
\text{s.t.}\ & \Sigma_j\, A_{ij} \le B_i \quad \text{for all } i \\
& y_j = 0 \text{ or } 1 \quad \text{for all } j
\end{aligned}
$$

NP-hard. LP relaxation rounds down and can be strengthened with the inequalities discussed in the Valid Inequalities section above. Solution-building heuristics based on ratios of C_j to weighted sums of A_{ij} are common.

Facilities Location: Minimum cost subset of facilities i with capacity U_i, considering both construction, setup, etc. cost $F_i \ge 0$ of the facility; plus variable travel, service cost C_{ij} of serving customers j from facility i; $D_j \triangleq$ demand at j.

$z_{ij} \triangleq$ flow from i to j
$y_i \triangleq$ 1 if i is opened, else 0
min $\Sigma_{i,j}\, C_{ij}z_{ij} + \Sigma_i\, F_i y_i$
s.t. $\Sigma_i\, z_{ij} = D_j$ for all j
$\Sigma_j\, z_{ij} \le U_i y_i$ for all i
$0 \le z_{ij} \le D_j y_i$ for all i, j
$y_i = 0$ or 1 for all i

NP-hard. LP relaxation of the stated form is strong, but weak if the third system of constraints is deleted. Special case of Fixed Charge Network Flows.

Fixed Charge Network Flows: Minimum variable plus fixed cost flow in directed graph $D(N, A)$ with net demands D_k at nodes $k \in N$, and capacities U_{ij} on arc $(i, j) \in A$; $C_{ij} \triangleq$ unit cost of (i, j) flow; $F_{ij} \triangleq$ fixed cost (nonnegative) of using arc (i, j) at all.

$z_{ij} \triangleq$ flow in arc (i, j)
$y_{ij} \triangleq$ 1 if $z_{ij} > 0$, else 0
min $\Sigma_{(i,j)\in A}\, C_{ij}z_{ij} + \Sigma_{(i,j)\in A}\, F_{ij}y_{ij}$
s.t. $\Sigma_{(i,k)\in A}\, z_{ik} - \Sigma_{(k,j)\in A}\, z_{kj} = D_k,\ k \in N$
$0 \le z_{ij} \le U_{ij}y_{ij},\ (i, j) \in A$
$y_{ij} = 0$ or 1, $(i, j) \in A$

NP-hard. LP relaxation is poor unless capacities are tight. For other cases much improved *multicommodity* extended LP relaxation is obtained by introducing separate variables z^{st}_{ij} recording the (i, j) flow originating at supply s and bound for demand t.

Generalized Assignment: Minimum cost assignment of objects i to capacitated locations, plants, vehicles, etc.; $S_i \triangleq$ size of object i; $K_j \triangleq$ capacity of location j; C_{ij} cost of assigning i to j.

$y_{ij} \triangleq$ 1 if i assigned to j, else 0
min $\Sigma_{i,j}\, C_{ij}y_{ij}$
s.t. $\Sigma_j\, y_{ij} = 1$ for all i
$\Sigma_i\, S_i y_{ij} \le K_i$ for all j
$y_{ij} = 0$ or 1 for all i, j

NP-hard. Excellent bounds are obtained from Lagrangean relaxations dualizing $=1$ constraints to leave a series of Knapsack problems.

Generalized Covering: Minimum cost subset of patterns j to cover given requirements B_i; $A_{ij} \triangleq$ (nonnegative) contribution to requirement i by pattern j; $C_j \triangleq$ cost of pattern j.

$y_j \triangleq$ 1 if pattern j is chosen, else 0
max $\Sigma_j\, C_j y_j$
s.t. $\Sigma_j\, A_{ij}y_j \ge B_i$ for all i
$y_j = 0$ or 1 for all j

NP-hard. LP relaxation rounds up. Solution building heuristics based on ratios of C_j to weighted sums of A_{ij} are common.

Job Shop Scheduling: Sequence a collection of jobs j with steps $s = 1, \ldots, S_j$ on processors p to minimize the time to complete all jobs; processor sequence for any job is fixed; $T_{js} \triangleq$ duration of step s; $P_{js} \triangleq$ processor of step s.

$z \triangleq$ completion time of all tasks
$z_{js} \triangleq$ start time of job j, step s
min z
s.t. $z_{j1} \ge 0$ for all j
$z_{js} \ge z_{j,s-1} + T_{j,s-1}$,
for all j; $s = 2, \ldots, S_j$
$z \ge z_{jS_j} + T_{jS_j}$ for all j
$z_{js} \ge z_{j's'} + T_{j's'}$ or $z_{j's'} \ge z_{js} + T_{js}$,
for all j, s, j', s' with $P_{js} = P_{j's'}$

NP-hard. LP relaxation formed with big M as in Table 1 is poor. Both solution-building and solution-enhancing heuristics are common.

Knapsack: Maximum value subset of objects or projects j to pack within a given capacity or budget B; $A_j \triangleq$ size of object j; $C_j \triangleq$ value of object j.

$$
\begin{aligned}
y_j \triangleq\ & 1 \text{ if object } j \text{ is chosen, else } 0 \\
\max\ & \Sigma_j C_j y_j \\
\text{s.t.}\ & \Sigma_j A_j y_j \leq B \\
& y_j = 0 \text{ or } 1 \quad \text{for all } j
\end{aligned}
$$

NP-hard. LP relaxation rounds down and is near optimal in many cases. Heuristics can come arbitrarily close to optimal in polynomial time.

B+ Leontief Flows: Minimum cost flow through state nodes in N of directed hyperarcs or composition operators (I, j) combining positive integer multiples A^i_{Ij} of inputs $i \in I \subseteq N$ to produce one unit at node j; $C_{Ij} \triangleq$ unit cost of (I, j) flow; $B_k \geq 0$ is the nonnegative net requirement at node N.

$$
\begin{aligned}
z_{Ij} \triangleq\ & \text{flow in hyperarc } (I, j) \\
\min\ & \Sigma_{(I,j)} C_{Ij} z_{Ij} \\
\text{s.t.}\ & \Sigma_{(I,k)}\ z_{Ik} - \Sigma_{(K,j),K \ni k}\ A^{k\ j}_{K,\ \ } z_{Kj} \\
& \quad = B_k,\ k \in N \\
& z_{Ij} \geq 0, \quad \text{for all } (I, j)
\end{aligned}
$$

Polynomially solvable by combinatorial algorithms. LP relaxation is TDI so has integer optima if all B_k are integer.

Matching: Maximum utility nonoverlapping collection of pairs of objects from a given set N; $E \triangleq$ family of allowed pairs (i, j), $i < j$; $C_{ij} \triangleq$ value of pair (i, j).

$$
\begin{aligned}
y_{ij} \triangleq\ & 1 \text{ if pair } (i, j) \text{ is chosen, else } 0 \\
\max\ & \Sigma_{(i,j)\in E}\ C_{ij} y_{ij} \\
\text{s.t.}\ & \Sigma_{(i,k)\in E}\ y_{ik} + \Sigma_{(k,j)\in E}\ y_{kj} \leq 1,\ k \in N \\
& y_{ij} = 0 \text{ or } 1,\ (i, j) \in E
\end{aligned}
$$

Polynomially solvable by combinatorial algorithms. An exact (TDI) linear programming relaxation is also known.

Network Flows: Minimum cost flow in directed graph $D(N, A)$ with net demands D_k at nodes $k \in N$, and capacities U_{ij} on arc $(i, j) \in A$; $C_{ij} \triangleq$ unit cost of (i, j) flow.

$$
\begin{aligned}
z_{ij} \triangleq\ & \text{flow in arc } (i, j) \\
\min\ & \Sigma_{(i,j)\in A}\ C_{ij} z_{ij} \\
\text{s.t.}\ & \Sigma_{(i,k)\in A}\ z_{ik} - \Sigma_{(k,j)\in A}\ z_{kj} = D_k,\ k \in N \\
& 0 \leq z_{ij} \leq U_{ij},\ (i, j) \in A
\end{aligned}
$$

Polynomially solvable by combinatorial algorithms. LP relaxation is totally unimodular so has integer optima if demands and capacities are integer. Special cases include Assignment, Shortest Path, Maximum Flow, and Minimum Cut (see Chapter 99).

Parallel Processor Scheduling: Assign tasks i of duration T_i to one of several processors p so that the time to complete all tasks (*makespan*) is minimized.

$$
\begin{aligned}
y_{ip} \triangleq\ & 1 \text{ if task } i \text{ assigned to } p, \text{ else } 0 \\
z \triangleq\ & \text{completion time of all tasks} \\
\min\ & z \\
\text{s.t.}\ & \Sigma_i\ T_i y_{ip} \leq z \quad \text{for all } p \\
& \Sigma_p\ y_{ip} = 1 \quad \text{for all } i \\
& y_{ip} = 0 \text{ or } 1 \quad \text{for all } i, p
\end{aligned}
$$

NP-hard. Closely related to Generalized Assignment. Both solution-building and solution-enhancing heuristics are common.

Quadratic Assignment: Minimum cost assignment of objects $i \in S$ to locations, times $j \in T$, where value is measurable only after pairs of assignments; $E \triangleq$ family of allowed pairs (i, j), $i \in S$, $j \in T$; $V_{ik} \triangleq$ the shared activity of i and k; $C_{jl} \triangleq$ unit cost or distance of activity between locations j and l.

$$
\begin{aligned}
y_{ij} &\triangleq 1 \text{ if pair } (i, j) \text{ is chosen, else } 0 \\
\min \quad & \Sigma_{(i,j)\in E} \Sigma_{(k,l)\in E} (V_{ik}C_{jl})y_{kl} \\
\text{s.t.} \quad & \Sigma_{j\in T} y_{ij} = 1,\ i \in S \\
& \Sigma_{i\in S} y_{ij} = 1,\ j \in T \\
& y_{ij} = 0 \text{ or } 1.\ (i, j) \in E
\end{aligned}
$$

NP-hard. No effective relaxations are available for even moderate-sized problems. Local improvement by pairwise exchange of assignments is common.

Set Covering: Finite list of patterns, routes, workers, etc. j that must span a collection of customers, hours, districts, jobs i (duplication allowed); $A_{ij} \triangleq 1$ if pattern j covers i, else 0; $C_j \triangleq$ cost of pattern j.

$$
\begin{aligned}
y_j &\triangleq 1 \text{ if pattern } j \text{ is chosen, else } 0 \\
\min \quad & \Sigma_j C_j y_j \\
\text{s.t.} \quad & \Sigma_j A_{ij} y_j \geq 1 \quad \text{for all } i \\
& y_j = 0 \text{ or } 1 \quad \text{for all } j
\end{aligned}
$$

NP-hard. LP relaxation rounds up and is near optimal in many cases. LP relaxations often numerically difficult.

Set Packing: Finite list of patterns, routes, workers, etc. j that must not overlap in customers, hours, districts, jobs i; $A_{ij} \triangleq 1$ if pattern j uses i, else 0; $C_j \triangleq$ value of pattern j.

$$
\begin{aligned}
y_j &\triangleq 1 \text{ if pattern } j \text{ is chosen, else } 0 \\
\max \quad & \Sigma_j C_j y_j \\
\text{s.t.} \quad & \Sigma_j A_{ij} y_j \leq 1 \quad \text{for all } i \\
& y_j = 0 \text{ or } 1 \quad \text{for all } j
\end{aligned}
$$

NP-hard. LP relaxation rounds down and is near optimal in many cases. For others many valid inequalities are known. LP relaxations often numerically difficult.

Set Partitioning: Finite list of patterns, routes, workers, etc. j that must span a collection of customers, hours, districts, jobs i without duplication; $A_{ij} \triangleq 1$ if pattern j covers i, else 0; $C_j \triangleq$ cost of pattern j.

$$
\begin{aligned}
y_j &\triangleq 1 \text{ if pattern } j \text{ is chosen, else } 0 \\
\min \quad & \Sigma_j C_j y_j \\
\text{s.t.} \quad & \Sigma_j A_{ij} y_j = 1 \quad \text{for all } i \\
& y_j = 0 \text{ or } 1 \quad \text{for all } j
\end{aligned}
$$

NP-hard. LP relaxation gives good bounds in many cases but difficult to round. LP relaxations often numerically difficult.

Spanning Tree: Maximum total weight subset of edges in a connected undirected graph $G(N, E)$ containing exactly one path between each pair of nodes; $C_{ij} \triangleq$ value of edge (i, j), $i < j$.

$$
\begin{aligned}
y_{ij} &\triangleq 1 \text{ if edge } (i, j) \text{ is chosen, else } 0 \\
\max \quad & \sum_{(i,j)\in E} C_{ij} y_{ij} \\
\text{s.t.} \quad & \sum_{(i,j)\in E} C_{ij} y_{ij} \geq |N| - 1 \\
& \sum_{i,j\in S} y_{ij} \leq |S| - 1,\ S \subseteq N \\
& y_{ij} = 0 \text{ or } 1,\ (i, j) \in E
\end{aligned}
$$

Polynomially solvable by the greedy algorithm. LP relaxation is Totally Dual Integer.

Steiner Tree: Minimum cost collection of edges of a graph $G(N, E)$ providing a path between vertices in subset $S \subseteq N$; $C_{ij} \triangleq$ (nonnegative) cost of edge $(i, j) \in E$, $i < j$.

$$
\begin{aligned}
y_{ij} &\triangleq \text{ 1 if edge } (i, j) \text{ is chosen, else 0} \\
\min \quad & \Sigma_{(i,j)\in E}\, C_{ij} y_{ij} \\
\text{s.t.} \quad & \sum_{i\in Q, j\in N\setminus Q} y_{ij} + \sum_{j\in Q, i\in N\setminus Q} y_{ij} \geq 1, \\
& \quad Q \subset N,\ Q \cap S \neq \emptyset,\ S \setminus Q \neq \emptyset \\
& y_{ij} = 0 \text{ or } 1,\ (i, j) \in E
\end{aligned}
$$

NP-hard. LP relaxation easily rounded up then enhanced by deleting unnecessary edges. Numerous valid inequalities are known to strengthen the LP relaxation.

Traveling Salesman: Minimum total weight route or sequence visiting each object, job, customer in N exactly once. Represent on a graph with nodes N and edges for allowed i to j transitions; $C_{ij} \triangleq$ cost of transition (i, j), $i < j$.

$$
\begin{aligned}
y_{ij} &\triangleq \text{ 1 if transition } (i, j) \text{ is chosen, else 0} \\
\max \quad & \Sigma_{i,j}\, C_{ij} y_{ij} \\
\text{s.t.} \quad & \Sigma_{i<k}\, y_{ik} + \Sigma_{j>k}\, y_{kj} = 2,\ k \in N \\
& \Sigma_{i,j\in S}\, y_{ij} \leq |S| - 1,\ S \subset N \\
& y_{ij} = 0 \text{ or } 1,\ (i, j) \in E
\end{aligned}
$$

NP-hard. The best-researched problem in discrete optimization. LP relaxation of the given form is strong but requires a separation procedure. Numerous effective solution building and solution enhancing heuristics exist, especially for the *triangular cost* case with $C_{ik} \leq C_{ik} + C_{kj}$.

CHAPTER 101
Multicriteria Optimization

1. INTRODUCTION

All animals have multiple goals to fulfill in their lives. They want to survive, to perpetuate their own species (including sex), to dominate, and so on. If you kick a dog, the dog will fight back or run away. Humans are no exception. We want to have a good life, which may mean more wealth, power, respect, and time for ourselves, together with good health and a successful next generation, and so on. We want food to taste, smell, and look good and be nutritious. Ever since Adam, human beings have been continuously confronted with multiple-criteria decision problems.

Although there have been abundant records of decision analyses based on multiple criteria in human history, putting the analyses in a formal mathematical setting is fairly new. Though still young, the literature of such mathematical treatments has exploded during the last three decades. The interested reader is referred to Stadler (1979, 1981), Steuer et al (1996) for surveys and historic notes.

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

In this chapter, we will report on six basic concepts of multicriteria optimization. Just as the three primary colors (red, yellow, and blue) can produce an infinite number of pictures and the seven basic notes of the musical scale (do, re, mi, etc.) can produce an infinite number of songs, the six basic concepts we will describe should allow the reader to generate an infinite number of models to solve the complex multiple-criteria decision problems. The six basic concepts are:

1. *Preferences as binary relations,* in which mathematical functional relations are generalized to represent revealed preferences and some basic solution concepts of MCDM (multiple-criteria decision making) will be introduced (Section 2).
2. *Value functions,* in which preferences are represented by powerful numerical ordering and multicriteria optimization problems are reduce to single-criterion optimization (Section 3).
3. *Satisficing, goal programming, and compromise solutions,* in which we model the preferences in terms of human goal-seeking behavior and introduce goal programming (which is well known). Again in this framework multicriteria problems are reduced to single-criterion ones (Section 4).
4. *Domination structures,* in which the preferences are represented in terms of multidimensional comparisons (in contrast to 2 and 3, which are of single-dimensional comparison) and solution concepts and methods to obtain the solutions are introduced (Section 5).
5. *MC²-simplex method for linear cases,* in which powerful computation method for linear cases are introduced (Section 6).
6. *Fuzzy multicriteria optimization,* is sketched in Section 7.

In Section 8, we offer further comments on multicriteria optimization.

2. PREFERENCES

Given any pair of decision outcomes y^1 and y^2, one and only one of the following can occur:

1. We are convinced that y^1 is better than or preferred to y^2, denoted by $y^1 \succ y^2$.
2. We are convinced that y^1 is worse than or less preferred to y^2, denoted by $y^1 \prec y^2$.
3. We are convinced that y^1 is equivalent to or equally preferred to y^2, denoted by $y^1 \sim y^2$; or
4. We have no sufficient evidence to say either 1, 2, or 3, denoted by $y^1 \; ? \; y^2$. Thus, the preference relation between y^1 and y^2 is indefinite or not yet clarified.

Note that each of the above statements involves a comparison or relation between a pair of outcomes. Let Y denote the set of all possible outcomes. Any revealed preference information, accumulated or not, can be represented by a subset of the Cartesian product $Y \times Y$, or by a so-called binary relation. We have the following definition.

Definition 2.1. A binary relation R on Y is a subset of the Cartesian product $Y \times Y$. Binary relation R is

1. *Reflexive* if $(y, y) \in R$ for all $y \in y$
2. *Symmetric* if $(y^1, y^2) \in R$ implies that $(y^2, y^1) \in R$ for all $y^1, y^2 \in y$
3. *Transitive* if $(y^1, y^2) \in R$ and $(y^2, y^3) \in R$ imply that $(y^1, y^3) \in R$, for all $y^1, y^2, y^3 \in Y$
4. *C*omplete if $(y^1, y^2) \in R$ or $(y^2, y^1) \in R$ for all $y^1, y^2 \in y$ and $y^1 \neq y^2$
5. An *equivalence* if R is reflexive, symmetric, and transitive

Definition 2.2.

1. A preference based on $\succ$ (respectively $\prec$, $\sim$, or ?) is a binary relation on Y, denoted by $\{\succ\}$ (respectively $\{\prec\}$, $\{\sim\}$, or $\{?\}$), so that whenever $(y^1, y^2) \in \{\succ\}$ (respectively $\{\prec\}$, $\{\sim\}$, or $\{?\}$) $y^1 \succ y^2$ (respectively $y^1 \prec y^2$, $y^1 \sim y^2$, or $y^1 ? \; y^2$).
2. For convenience, we also define $\{\succ \sim\} = \{\succ\} \cup \{\sim\}; \{\succ ?\} = \{\succ\} \cup \{?\}$, $\{\prec \sim ?\} = \{\prec \sim\} \cup \{?\}$, etc.

By a preference (or revealed preference) structure we mean the collection of all the above preferences. Because such structures are uniquely determined by $\{\succ\}$, $\{\sim\}$ and $\{?\}$, a preference structure will be denoted by $\mathcal{P}(\{\succ\}, \{\sim\}, \{?\})$, or simply by $\mathcal{P}$.

Remark 2.1. Note that the larger {?} is, the less the revealed preference is clarified, which will usually cloud the decision process. Sometimes it may take discipline and/or new information for the decision maker to clarify his or her preference in order to reach the final solution. The concept of *pseudo-orders* (Roy and Vincke 1987) may help in resolving some of the problems.

Example 2.1 (*Pareto preference*). Let greater values be more preferred for each component y_i and assume that no other information on the preference is available or established. Then Pareto preference is defined by $y^1 > y^2$ if and only if $y_i^1 \geq y_i^2$ for all i and $y^1 \neq y^2$. Therefore,

$$\begin{aligned}\{>\} &= \{(y^1, y^2) |\ y_i^1 \geq y_i^2 \text{ for all } i \text{ and } y^1 \neq y^2\}\\ \{\sim\} &= \{(y, y) | y \in Y\}\\ \{?\} &= \{(y^1, y^2) | \text{there exist } i \text{ and } j \text{ such that } y_i^1 > y_i^2,\ y_j^1 < y_j^2\}\end{aligned}$$

Example 2.2 (*value function*). A value function v is a real-valued function which is defined on Y, the set of decision outcomes, such that $v(y^1) > v(y^2)$ if and only if y^1 is preferred to y^2 and $v(y^1) = v(y^2)$ if and only if y^1 is indifferent to y^2. It is easy to see that

$$\begin{aligned}\{>\} &= \{(y^1, y^2) \in Y \times Y | v(y^1) > v(y^2)\}\\ \{\sim\} &= \{(y^1, y^2) \in Y \times Y | v(y^1) = v(y^2)\}\\ \{?\} &= \varnothing\end{aligned}$$

Example 2.3 (*a lexicographic ordering*). Let $y = (y_1, y_2, \ldots, y_q)$ be indexed so that the kth component is overwhelmingly more important than the $(k + 1)$th component for $k = 1, 2, \ldots, q - 1$. A lexicographic ordering preference is defined as follows: the outcome $y^1 = (y_1^1, y_2^1, \ldots, y_q^1)$ is preferred to $y^2 = (y_1^2, y_2^2, \ldots, y_q^2)$ if and only if $y_1^1 > y_1^2$, or there is some k so that $y_k^1 > y_k^2$ and $y_j^1 = y_j^2$ for $j = 1, 2, \ldots, k - 1$. We see that

$$\begin{aligned}\{>\} &= \{(y^1, y^2) \in Y \times Y | y^1 \text{ is lexicographically preferred to } y^2\}\\ \{\sim\} &= \{(y, y) \in Y \times Y\}\\ \{?\} &= \varnothing\end{aligned}$$

Definition 2.3. Given a preference and a point $y^0 \in Y$, we define the *better, worse, equivalent,* and *indefinite* sets with respect to (*w.r.t.*) y^0 as:

1. $\{y^0 <\} = \{y \in Y | y^0 \prec y\}$ (the better set *w.r.t* y^0)
2. $\{y^0 >\} = \{y \in Y | y^0 \succ y\}$ (the worse set *w.r.t* y^0)
3. $\{y^0\sim\} = \{y \in Y | y^0 \sim y\}$ (the equivalent set *w.r.t* y^0)
4. $\{y^0?\} = \{y \in Y | y^0 ? y\}$ (the indefinite set *w.r.t* y^0)
5. $\{y^0>\sim\} = \{y^0 >\} \cup \{y^0\sim\}$
6. $\{y^0>?\} = \{y^0 >\} \cup \{y^0?\}$
7. $\{y^0>\sim?\} = \{y^0 >\sim\} \cup \{y^0?\}$

Now we can define various solution concepts as follows.

Definition 2.4. Given a preference structure $\mathcal{P}(\{>\}, \{\sim\}, \{?\})$ defined on the outcome space Y, we define:

1. $y^0 \in Y$ is an $N[<]$-solution (point) if and only if $\{y^0 <\} \cap Y = \varnothing$; the collection of all such solutions is denoted by $N[<]$.
2. $y^0 \in Y$ is an $N[<\sim]$-solution if and only if $\{y^0<\sim\} \cap Y = \{y^0\}$; the collection of all such solutions is denoted by $N[<\sim]$.
3. $y^0 \in Y$ is an $N[<?]$-solution if and only if $\{y^0?<\} \cap Y = \varnothing$; the collection of all such solutions is denoted by $N[?]$.
4. $y^0 \in Y$ is an $N[<\sim?]$-solution if and only if $\{y^0 <\sim?\} \cap Y = \{y^0\}$; the collection of all such solutions is denoted by $N[<\sim?]$.

The following can be easily established (Chien 1987; Chien et al. 1990):
Theorem 2.1.

1. $N[\prec\sim?] \subseteq N[\prec?] \subseteq N[\prec]$
2. $N[\prec\sim?] \subseteq N[\prec\sim] \subseteq N[\prec]$
3. $N[\prec\sim?]$ contains at most one point

Remark 2.2. In application, we may first try to locate $N[\prec]$, then $N[\prec ?]$ or $N[\prec \sim]$, and finally $N[\prec \sim?]$, which, if nonempty, will contain only one clear superior solution, and no alternative optimals would occur.

3. VALUE FUNCTIONS

3.1. Revealed Preferences and Value Functions

Numerical systems have a prevailing impact on our culture and thinking. It is natural and important for us to ask, Is it possible to express our preference over the outcomes in terms of numbers so that the larger the number the stronger the preference, and if it is, how do we do it?

Suppose that our preference structure $\mathcal{P}$ can be represented by a value function $v: Y \rightarrow R$ so that $v(y^1) > v(y^2)$ if and only if y^1 is preferred to y^2 and $v(y^1) = v(y^2)$ if and only if y^1 is indifferent to y^2 and that Y is convex and v is continuous on Y. We immediately can obtain the following properties for $\mathcal{P}$ (see Example 2.2).

1. $\{?\} = \varnothing$
2. $\{\succ\}$ and $\{\succ \sim\}$ are transitive.
3. Let $\mathcal{Y}$ be the collection of all isovalued curves (or surfaces) of v in Y. Note that different isovalued curves never intersect. Since Y is convex and v is continuous, $V = v[Y]$ is an interval which contains dense countable rational numbers. Their corresponding isovalued curves are thus countable and dense in $\mathcal{Y}$.
4. $\{y \prec\}$ and $\{y \succ\}$ are open sets in Y for every $y \in Y$, if Y is open.

We summarize some important results on value functions in the following remark.

Remark 3.1. (a) Property 1 of the above is essential. If $\{?\} \neq \varnothing$, then value function representation cannot offer meaningful numerical ordering; (b) Properties 1 and 2 together mean that $\mathcal{P}$ is a weak order in literature; (c) Properties 1–3 conversely ensure the existence of value function representation; (d) Properties 1–2 and 4 conversely ensure the existence of *continuous* value function representation. The reader is referred to Fishburn (1970), Debreu (1954, 1960), Keeney and Raiffa (1976), Yu (1985), Gorman (1968), Yu and Takeda (1987), and others for further detailed discussion on the existence condition of value functions and their forms.

3.2. Methods of Constructing Value Functions

Assuming that the existence conditions are satisfied, we are interested in methods of constructing value functions to approximate the revealed preferences. Let us first roughly classify the existing methods before we illustrate some popular methods.

One large class of techniques for constructing value functions is a direct application of calculus. These methods are usually based on the construction of approximate indifference curves. This class includes methods using trade-off ratios, tangent planes, gradients, and line integrals. Some of these methods are discussed in Yu (1985).

A second class has specifically been developed for the case of additive value functions. One of the well-known methods in this class is the midvalue method (Keeney and Raiffa 1976; Yu 1985), which is based on the pairwise information of $\{\sim\}$ and $\{\succ\}$.

A third class takes into account the fact that usually the revealed preference contains conflicting information, making it a virtually impossible task to construct a consistent value function. The conflicting nature of the information may be due to an unclear perception on the part of the DM of his true preference structure or to imperfect and/or incorrectly used interaction techniques. The objective of these methods is to find a value function and/or ideal point that minimizes the inconsistencies. Some of the techniques, such as regression analysis, are based on statistical theory, others on mathematical programming models, such as least distance and minimal inconsistency methods (using some appropriate l_p-norm). Included are methods based on weight ratios, pairwise preference information, or the distance from a (perhaps unknown) idea/target point (see Yu 1985, Section 6.3.4 and the citations therein). Another group of methods in this class is that of eigenweight vectors (see, e.g., Saaty 1980; Cogger and Yu 1985; Yu 1985, Section 6.3.3.). Yet another group uses holistic assessment utilizing the orthogonal design of statistical experiment (see Yu 1985, Section 6.3.3.2 and citations therein).

Each method has its strengths and weaknesses. The selection of the best/correct method is truly an art and poses a challenge for the analyst and decision maker. Assume that there are q criteria under consideration and that more is better for each y_k (k = l, 2, . . . , q) with y_k taking values in the interval $[a_k, b_k]$. Thus, the outcome space is the rectangle $[a_1, b_1] \times [a_2, b_2] \times \ldots \times [a_q, b_q]$. Assume that the value function is additive as follows:

$$v(y) = w_1 v_1(y_1) + w_2 v_2(y_2) + \ldots + w_q v_q(y_q)$$

where $v_k(y_k)$, $k = 1, 2, \ldots, q$ are the individual components and $(w_1, w_2, \ldots, w_q)$ is the weight distribution. Without loss of generality, we can assume that $v_k(a_k) = 0$ and $v_k(b_k) = 1$. To assess individual $v_k(y_k)$, there are several methods. For details, see Yu (1985, chap. 5).

Assume that we have successfully generated the individual function v_k (k = l, 2, . . . , q). We want to determine the weights $w_1, w_2, \ldots, w_q$ so that we can obtain the overall value function

$$v(y) = w_1 v_1(y_1) + w_2 v_2(y_2) + \ldots + w_q v_q(y_q)$$

by aggregating the individual components. There are many ways to assess the weights (see, e.g., Hwang and Masu 1979; Hwang and Yoon 1981; Yu 1973). Being limited by space, we shall discuss only two popular methods for different situations.

Method 1. Recall that $v_k(a_k) = v_k(y_k^0) = 0$ and $v_k(b_k) = v_k(y_k^1) = 1$. Set $y^0 = (y_1^0, \ldots, y_q^0)$ and $y^1 = (y_1^1, \ldots, y_q^1)$. Denote

$$(y_k^1, y_k^0) = (y_1^0, \ldots, y_{k-1}^0, y_k^1, y_{k+1}^0, \ldots, y_q^0)$$

then

$$v((y_k^1, y_k^0)) = w_k v_k(y_k^1) = w_k$$

This simply means that we need only to know the value of the value function at point (y_k^1, y_k^0) to know w_k. If this is difficult to accomplish, we can alternatively identify $q - 1$ pairs of indifferent points, then, using the additive form of the value function, we can obtain $q - 1$ equations for the q unknowns $(w_1, w_2, \ldots, w_q)$. After normalizing, we obtain a unique solution.

Example 3.1. Assume that there are three criteria under consideration and that $Y_1 = Y_2 = Y_3 = [0, 2]$. Suppose that we have obtained the individual functions as

$$v_1(y_1) = (5/6)y_1 - (1/6)\, y_1^2$$
$$v_2(y_2) = y_2 - (1/4)\, y_2^2$$
$$v_3(y_3) = (3/4)\, y_3 - (1/8)\, y_3^2$$
$$(1, 2, 0) \sim (1, 0, 2)$$
$$(1, 0, 1) \sim (0, 2, 0)$$

Using the additive form of the value function, we obtain

$$v((1, 2, 0)) = w_1 v_1(1) + w_2 v_2(2) + w_3 v_3(0) = (2/3)w_1 + w_2$$
$$v((1, 0, 2) = w_1 v_1(1) + w_2 v_2(0) + w_3 v_3(2) = (2/3)w_1 + w_3$$

Therefore, (l, 2, 0) $\sim$ (l, 0, 2) implies that $w_2 = w_3$. Similarly, from (l, 0, l) $\sim$ (0, 2, 0), we have $(2/3)w_1 + (5/8)w_3 = w_2$. Combined with $w_1 + w_2 + w_3 = 1$, we obtain the weights

$$w_1 = \frac{9}{41},\ w_2 = \frac{16}{41},\ w_3 = \frac{16}{41}$$

Therefore, the overall value function is given by

$$v(y) = \left(\frac{15}{82}\right) y_1 - \left(\frac{3}{82}\right) y_1^2 + \left(\frac{16}{41}\right) y_2 - \left(\frac{4}{41}\right) y_2^2 + \left(\frac{12}{41}\right) y_3 - \left(\frac{2}{41}\right) y_3^2$$

Method 2. Saaty's Eigenweight Vector Method (Saaty 1980). Suppose that the value function is of the form

$$v(y) = w_1y_1 + w_2y_2 + \ldots + w_qy_q$$

Thus, the value function is determined if the weights are known. Without losing generality, we can assume that $w_k > 0$ ($k = 1, 2, \ldots, q$).

If weights are given, we can define the weight ratio by

$$w_{ij} = \frac{w_i}{w_j}$$

Then the weight ratio matrix $W = [w_{ij}]_{q\times q}$ is *consistent* in the sense that for any i, j, and k,

$$w_{ij} = w_{ji}^{-1}$$
$$w_{ik} = w_{ij}w_{jk}$$

On the other hand, given a consistent matrix, we can find the weight vector that generates it.

Theorem 3.1. Let $w_{q\times q}$ be any consistent matrix. Then

1. The maximum eigenvalue for W is q and all the other eigenvalues are 0.
2. The eigenvector corresponding to the maximum eigenvalue, which is unique after normalizing, is the weight vector $w = (w_1, w_2, \ldots, w_q)$, which generates W by $w_{ij} = w_i/w_j$.

Therefore, to find the weights $w_1, w_2, \ldots, w_q$, we need only to find the weight ratios w_{ij} ($i, j = 1, 2, \ldots, q$). Saaty proposed the following procedure:

Step 1: For $i < j$, estimate or elicit the weight ratio w_{ij}, by a_{ij}. Let $a_{ii} = 1$ for all i and $a_{ij} = a_{ij}^{-1}$ for $i > j$. Denote $A = [a_{ij}]_{q\times q}$.

Step 2: Since A is found as an approximation for W, when the consistency conditions are "almost" satisfied for A, one would expect that the normalized eigenvector corresponding to the maximum eigenvalue of A, denoted by $\lambda_{\max}$, will be close to w. Thus, w can be approximated by the normalized eigenvector corresponding to $\lambda_{\max}$.

Here the problem is, however, that the estimated weight ratios are generally not consistent, especially when criteria are not few, since human perception and judgment are subject to change when the information input or psychological state of the decision maker change. The using of the above procedure is partially justified by the following theorem.

Theorem 3.2 (Saaty 1980).

1. Let $\overline{w} = (\overline{w_1}, \overline{w_2}, \ldots, \overline{w_q})$ be the normalized eigenvector corresponding to $\lambda_{\max}$ of A. Then $\overline{w_i} > 0$ for all i.
2. Given i and k, if $a_{ij} \geq a_{kj}$ for all j, then $\overline{w_i} \geq \overline{w_k}$.

Example 3.2 (Saaty 1980). Three criteria are under consideration. Assume that the following estimations of weight ratios are obtained:

$$a_{12} = 9,\ a_{13} = 7,\ a_{23} = 1/5$$

We construct the following matrix:

$$A = \begin{bmatrix} 1 & 9 & 7 \\ 1/9 & 1 & 1/5 \\ 1/7 & 5 & 1 \end{bmatrix}$$

To find $\lambda_{\max}$, we solve $\det[A - \lambda\, \mathrm{I}] = 0$, or $(1 - \lambda)^3 - (1 - \lambda) + 9/35 + 35/9 = 0$. The maximum solution is $\lambda_{\max} \approx 3.21$. Then we find the corresponding normalized eigenweight vector $\overline{w}$ with

$$\overline{w_1} = 0.77,\ \overline{w_2} = 0.05,\ \overline{w_3} = 0.17$$

The value function is therefore given by

$$v(y) = 0.77y_1 + 0.05y_2 + 0.17\, y_3$$

Remark 3.2. In Saaty's method, one needs to solve a nonlinear equation to find the maximum eigenvalue. Cogger and Yu (1985) proposed another eigenweight vector method that can be applied to find the eigenweight vector easily by using the deductive formula. The weights determined by the latter method are different from those determined by the former. It is important to note that there is no need to have all a_{ij}, $i < j$, in order to apply the above method. For such exploration, the reader is referred to Takeda and Yu (1995).

Many other methods have been developed that we cannot discuss here due to limited space. The interested reader is referred to Yu (1985), Yu and Takeda (1987, 1995), Hwang and Masud (1979), Hwang and Yoon (1981), and Yu (1973) and quotes therein. It should also be stressed that all these methods are approximation methods. When inconsistencies occur, we may wish to represent the decision maker's preference in ways other than value functions. This will be discussed shortly.

4. SATISFICING AND COMPROMISE SOLUTIONS

Each human being has a set of ideal goals to achieve and maintain (see Yu 1990, 1995, and 1985, chap. 9 and citations therein). When a perceived state (or value) has unfavorably deviated from its targeted or ideal state (or value), a charge (tension or pressure) will be produced to prompt an action to reduce or eliminate the deviation. The behavior of taking actions, including adjustment of the ideal values to move the perceived states to the targeted ideal states is called *goal-seeking behavior*.

This goal-seeking behavior has an important and pervasive impact on human decision making. In this section, we shall focus on two concepts that model human goal-seeking behavior. These are satisficing goal programming and compromise models.

4.1. Satisficing Models

Example 4.1. Consider the problem of selecting an athlete for a basketball team. Assume that quickness, f_1, and accuracy of shooting, f_2, of the player are the main concerns. Let both f_1 and f_2 be indexed from 0 to 10, where the higher indices, the better the player. Assume that a player, x, will be selected with satisfaction if $f_1(x) \geq 9$ or $f_2(x) \geq 9$, or $f_1(x) + f_2(x) \geq 15$. Let $f = f(x) = (f_1(x), f_2(x))$ be the score vector of x and $G_1(f) = f_1 - 9$, $G_2(f) = f_2 - 9$, and $G_3(f) = f_1 + f_2 - 15$. If an athlete's score vector is in at least one of the sets , $S_i = \{f|G_i(f) \geq 0\}$, $i = 1, 2, 3$, then he or she is to be selected with satisfaction. Note that these sets are defined in terms of the scores (outcomes) instead of the candidates (decision alternatives). Here S_i, $i = 1, 2, 3$, so defined, are called satisficing sets.

Note that the specifying of lower bounds 9, 9, and 15 in the above example is an act of *goal setting*. Goal setting for satisficing models is defined as the procedure of identifying a satisficing set S such that whenever the decision outcome is an element of S, the decision maker will be happy and satisfied and is assumed to have reached the optimal solution. When S contains only a single point, the point is called the goal or target point.

Let our MCDM problem be specified by the criteria $f = (f_1, f_2, \ldots, f_q)$ and the feasible set is $X = \{x \in R^n | g(k) \leq 0\}$, where $g = (g_1, g_2, \ldots, g_m)$. Note that the outcome of a decision x is specified by $y(x) = f(x)$.

To specify S, one can start with each individual f_i and find its satisficing or acceptable intervals. One can then consider two or more criteria simultaneously for their corresponding trade-off. In a general form, in the final satisficing set S can be defined as the union of

$$S_k = \{f|G_k(f) \geq 0\},\ k = 1, 2, \ldots, r$$

where G_k is a vector function that reflects the trade-off over f. Note that when the union contains a single set (i.e., $r = 1$), S is defined by a system of inequalities.

Once S, the satisficing set, has been determined, finding a satisficing solution x^0, such that $f(x^0) \in S$, is a mathematical programming problem.

Since $S = \cup \{S_k | k = 1, 2, \ldots, r\}$, $Y \cap S \neq \varnothing$ if and only if there is an S_k such that $Y \cap S_k \neq \varnothing$. Because we need only one point of $Y \cap S$ when it is nonempty, we can verify individually if $Y \cap S_k \neq \varnothing$, $k = 1, 2, \ldots, r$, and find one point from the nonempty intersections.

To verify whether or not $Y \cap S_k \neq \varnothing$ is empty and to find a point in $Y \cap S_k$, if it is nonempty, we can use the following mathematical program. First rewrite each satisficing set as

$$S_k = \{f(x)|G_{kj}(f(x)) \geq 0, j = 1, 2, \ldots, J_k\}$$

where G_{kj}, $j = 1, 2, \ldots, J_k$, are components of G_k, and J_k is the number of components of G_k.

Program 4.1. $V_k = \min d_1 + d_2 + \ldots + d_{J_k}$

$$\text{s.t. } G_{kj}(f(x)) + d_j \geq 0,\ j = 1, 2, \ldots, J_k$$

$$x \in X,\ d_j \geq 0,\ j = 1, 2, \ldots, J_k$$

It is readily verified that $Y \cap S_k \neq \varnothing$ if and only if $V_k = 0$. We thus have:

Theorem 4.1. Let $S = \cup [S_k | k = 1, 2, \ldots, r\}$. Then a satisficing solution exists if and only if there is at least one $k \in \{1, 2, \ldots, r\}$ such that Program 4.1 yields $V_k = 0$.

Observe that when one satisficing solution is found, the decision problem is solved, at least temporarily. Otherwise the decision maker can activate either positive problem solving or negative problem avoidance to restructure the problem. The former will enable careful restudy and restructuring of the problem so as to find a solution, perhaps a new one, that lies in the satisficing set. The latter will try to reduce the aspiration levels or play down the importance of making a good decision, thus, lowering the satisficing set to have a nonempty intersection with Y. While the psychological attitude in problem solving and in problem avoidance may be different (see Yu 1990, 1995, 1985, chap. 9 for further discussion), the consequences are the same. That is, eventually the newly structured problem enables the decision maker to have $Y \cap S \neq \varnothing$. The following provides some helpful information for decision maker for restructing S and Y.

1. Depending on the formation of S, if Program 4.1 is used to identify a satisficing solution, one can produce x^k, $k = 1, 2, \ldots, r$, which solves Program 4.1 with S_k as the satisficing set. One then can compute $f(x^k)$, $G_k(f(x^k))$, the distance between $f(x^k)$ and S_k, and the trade-off among the $G_{kj}(f(x))$, $j = 1, 2, \ldots, J_k$, at x^k. All of these can be helpful for the decision maker to reframe S_k.
2. Suppose that it has been revealed or established that more is better for each criterion and that the revealed preference contains at least the Pareto preference. One can then generate (a) all or some representatives of the $N[\prec]$ points, the corresponding $f(x)$, and optimal weights $\Lambda(x)$ for the $N[\prec]$ points (see Sections 5 and 6 for further discussion); (b) the value $f_k^* = \max \{f_k(x) | x \in X\} (k = 1, 2, \ldots, q)$, which gives the best value of $f(x)$ over X. This information can help the decision maker to restructure his or her S. Relaxing of the target goal with reference to the ideal point $(f_1^*, f_2^*, \ldots, f_q^*)$ sequentially and interactively with the decision maker, until a satisficing solution is obtained, is certainly an art. It is especially useful when X and f are fairly fixed and not subject to change.
3. If possible (for instance, in bicriteria cases), displaying Y and S, even if only partially, can help the decision maker conceptualize where Y and S are, to make it easier to restructure the problem.

One must keep in mind that with X, $f(x)$, and S, one can generate as much information as one wishes, just as one can generate as many statistics from sample values as one wants. However, relevant information (e.g., useful statistics) that can positively affect the problem solving may not be too much. Irrelevant information can become a burden for decision analysis and decision making.

Example 4.2. Consider a sample production problem. Let the resource constraints in the amount produced, x_1 and x_2, be given as follows:

$$\begin{aligned} g_1(x) &= 3x_1 + x_2 - 12 \leq 0 \\ g_2(x) &= 2x_1 + x_2 - 9 \leq 0 \\ g_3(x) &= x_1 + 2x_2 - 12 \leq 0 \\ x_1 &\geq 0,\ x_2 \geq 0 \end{aligned}$$

The following two objective functions are related to gross output and net profit respectively:

$$\begin{aligned} y_1 &= f_1(x) = x_1 + x_2 \\ y_2 &= f_2(x) = 10x_1 - x_1^2 + 4x_2 - x_2^2 \end{aligned}$$

Assume that the decision maker specifies his or her satisficing set as

$$S = \{(y_1, y_2) | y_1 \geq 10,\ y_2 \geq 30\}$$

Then, using Program 4.1, we solve the problem of

$$
\begin{aligned}
V = \min\ & d_1 + d_2 \\
\text{s.t.}\ & x_1 + x_2 + d_1 \geq 10 \\
& 10x_1 - x_1^2 + 4x_2 - x_2^2 + d_2 \geq 30 \\
& 3x_1 + x_2 \leq 12 \\
& 2x_1 + x_2 \leq 9 \\
& x_1 + 2x_2 \leq 12 \\
& x_1 \geq 0,\ x_2 \geq 0
\end{aligned}
$$

It turns out that $V > 0$, thus S $\cap$ Y = $\varnothing$. To find a satisficing solution, we must restructure X, f, and/or S. If X and f are fairly fixed, we may offer the information that $f_1^* = 7$ and $f_2^* = 26.5$, which simply means that any outcome y with $y_1 > 7$ or $y_2 > 26.5$ is unobtainable. Thus, the goals $y_1 > 10$ and $y_2 > 30$ must come down to allow a satisficing solution. The restructuring of S will continue until a satisficing solution is found.

4.2. Compromise and Goal Programming Solutions

Assume that each criterion $f_i (i = 1, 2, \ldots, q)$ is characterized by "more is better." Let $y^* = (y_1^*, y_2^*, \ldots, y_q^*)$ where $y_i^* = \sup\{ f_i(x) | x \in X \}$ with X the feasible set. The point y^* is called *ideal* (or *utopia*) *point* because it is usually unattainable even though y_i^* may individually be attainable.

Example 4.3. Consider the following maximization problem with two criteria:

$$
\begin{aligned}
\max\ & y_1 = f_1(x) = 6x_1 + 4x_2 \\
\max\ & y_2 = f_2(x) = x_1 \\
\text{s.t.}\ & g_1(x) = x_1 + x_2 \leq 100 \\
& g_2(x) = 2x_1 + x_2 \leq 150 \\
& x_1, x_2 \geq 0
\end{aligned}
$$

To find y_1^*, we solve

$$
\begin{aligned}
\max\ & y_1 = f_1(x) = 6x_1 + 4x_2 \\
\text{s.t.}\ & x_1 + x_2 \leq 100 \\
& 2x_1 + x_2 \leq 150 \\
& x_1, x_2 \geq 0
\end{aligned}
$$

The solution is $x_1^* = x_2^* = 50$. Thus, $y_1^* = f_1(x^*) = 500$. Similarly, we find $y_2^* = 75$. Therefore, the ideal point is $y^* = (500, 75)$. Note that y^* is not attainable.

In group decision problems, if each criterion represents a player's payoff, then y^*, if attainable, would make each player happy because it would simultaneously maximize each player's payoff. Even if one is a dictator, he cannot do better than y^* for himself. As y^* is usually not attainable, a compromise is needed if no other alternative is available to dissolve the group conflict. This offers a natural explanation of why the solution to be introduced is called a *compromise solution* (Yu 1973). The reader can extend this explanation easily to multiple-criteria problems.

Now given $y \in Y$, the outcome space, the *regret* of using y instead of obtaining the *ideal* point y^* may be approximated by the distance between y and y^*. Thus, we define the (group) regret of using y by

$$r(y) = \| y - y^* \|$$

where $\| y - y^* \|$ is the distance between y and y^* according to some specific norm. Typically, the l_p-norm will be used in our discussion because it is easy to understand, unless otherwise specified. To make this more specific, define for $p \geq 1$,

$$r(y; p) = \| y - y^* \|_p = \left[\sum | y_i - y_i^* |^p \right]^{1/p}$$

and

$$r(y; \infty) = \max \{ | y_i - y_i^* |, i = 1, 2, \ldots, q \}$$

Then $r(y; p)$ is a measurement of regret from y to y^* according to the l_p-norm.

Definition 4.1. The compromise solution with respect to the l_p-norm is $y^p \in Y$, which minimizes $r(y; p)$ over Y, or is $x^p \in X$, which minimizes $r(f(x); p)$ over X. When the ideal point y^* is replaced by a specific goal or target point, the resulting compromise solution is called the goal programming solution with respect to the goal point.

Remark 4.1. In group decision problems, $r(y; p)$ may be interpreted as group regret and the compromise solution y^p, is the one which minimizes the group regret in order to maintain a cooperative group spirit. As the parameter p varies, the solution y^p can change.

Note that $r(y; p)$ treats each $|y_i^* - y_i|$ as having the same importance in forming the group regret and the multiple criteria problems. If the criteria have different degrees of importance, then a weight vector may be assigned to signal the different degrees of importance. The regret function $r(y; p)$ can be modified in a natural way (Yu 1985). Observe that using weights in the regret function has the effect of changing the scale of each criterion. Conversely, the scale can be adjusted so that the regret function is reduced to that of equal weight. Thus, in studying the properties of compromise solutions, without loss of generality, one may focus on the equal weight case. We shall assume the equal weight case from now on, unless specified otherwise.

Remark 4.2. Observe that the compromise solution is not scale *independent*. Scale independence, an important criterion in group decision problems, can prevent players from artificially changing the scale to obtain a better arbitration for themselves. Note that when the scale of $f_i(x)$ or y_i is changed and the weight of importance of each criterion is changed, so is the compromise solution.

Remark 4.3. Compromise solutions with proper assumptions enjoy a number of properties, such as feasibility, least group regret, no dictatorship, Pareto optimality, uniqueness, symmetry, independence of irrelevant alternatives, continuity, monotonicity, and boundedness. In terms of parameter p (associated with p-norms), we may say that when $p = 1$, the sum of the group utility is mort emphasized, and when $p = \infty$, the individual regret of the group is mort emphasized. For the details and further exploration, see Yu (1985, 1973) and Freimer and Yu (1976).

4.3. Computing Compromise Solutions and Goal Programming Solutions

Now we turn to the computation of compromise solutions. We first consider the case when the target point is the ideal point, then the general case.

4.3.1. The Ideal Point as the Target Point

To find a compromise solution when the ideal point is the target point, we have to solve $q + 1$ mathematical programming problems. The first q problems are to find the utopia or ideal point where $y^* = (y_1^*, y_2^*, \ldots, y_q^*)$, where $y_i^* = \sup\{f_i(x) | x \in X\}$. The last one is to find the compromise solution y^p. Suppose that X contains only countable points. We will have $q + 1$ integer programming problems. Otherwise, if X is a region, we will have $q + 1$ nonlinear programming problems.

If X and $f_i(x)$, $i = 1, 2, \ldots, q$ have some special structure, then more efficient computational techniques are available. For instance, if X is a convex set and each $f_i(x)$ is concave, then we first have q concave programming and then a convex programming (because $r(f(x); p)$ is convex under the assumptions). If X is a polyhedron defined by a system of linear inequalities and each $f_i(x)$ is linear, then the ideal points y^* can be found by q simple linear programming problems. Furthermore, the compromise solutions of y^1 and y^∞ can be found by a linear programming problem (the other compromise solutions, y^p, $1 < p < \infty$, can be found by convex programming) (Yu 1985).

Example 4.4. Reconsider Example 4.3. The ideal point is (500, 75). Now we show how to find compromise solutions y^1, y^2, and y^∞.

1. To find the y^1 compromise solution, we solve

$$\begin{aligned} \min \quad & \{[500 - (6x_1 + 4x_2)] + [75 - x_1]\} \\ \text{s.t.} \quad & x_1 + x_2 \le 100 \\ & 2x_1 + x_2 \le 150 \\ & x_1, x_2 \ge 0 \end{aligned}$$

We obtain $x_1^* = 50$, $x_2^* = 50$ and the compromise solution is then $y^1 = (500, 50)$.

2. Similar to (l), we obtain compromise solution $y^2 = (490, 55)$.

3. For the y^∞ compromise solution, we solve

$$\begin{aligned} \min \max \quad & \{500 - (6x_1 + 4x_2),\ 75 - x_1\} \\ \text{s.t.} \quad & x_1 + x_2 \le 100 \\ & 2x_1 + x_2 \le 150 \\ & x_1, x_2 \ge 0 \end{aligned}$$

This problem can be simplified as

$$\begin{aligned} \min \quad & v \\ \text{s.t.} \quad & v \ge 500 - (6x_1 + 4x_2) \\ & v \ge 75 - x_1 \\ & x_1 + x_2 \le 100 \\ & 2x_1 + x_2 \le 150 \\ & x_1, x_2 \ge 0 \end{aligned}$$

Note that this is a linear program. We can obtain the solution easily as $x_1^* = 58.33$, $x_2^* = 33.33$, and $y^\infty = (483.33, 58.33)$.

4.3.2. General Target Points and Goal Programming

The computation for the compromise solution with general target point can be slightly more complicated. This is due to the possibility that $y_i^* \ge y_i$ for all $y \in Y$ and $i = 1, 2, \ldots, q$ no longer hold. In this case, we need some transformation of variables.

Let d_i^+ and d_i^- be respectively the positive and negative pairs of $y_i - y_i^*$, i.e., $d_i^+ = y_i - y_i^*$ if $y_i > y_i^*$ and 0 if otherwise, and $d_i^- = y_i^* - y_i$ if $y_i \le y_i^*$ and 0 if otherwise. Now given a target point y^*, the compromise solution with l_p-norm can be found by solving the following (Yu 1985):

Program 4.2.

$$\begin{aligned} \min \quad & \sum (d_i^+ + d_i^-)^p \\ \text{s.t.} \quad & y_i^* - f_i(x) = d_i^- - d_i^+,\ i = 1, 2, \ldots, q \\ & d_i^+, d_i^- \ge 0,\ i = 1, 2, \ldots, q \\ & g(x) \le 0 \end{aligned}$$

Remark 4.4.

1. Suppose that all $f_i(x)$, $i = 1, 2, \ldots, q$, and $g(x)$ are linear. Then Program 4.2 for l_1-compromise solutions reduces to a linear program typically known as (linear) *goal programming*. By adding weights to or imposing lexicographical ordering on the criteria, one can generalize the concept discussed here to a variety of goal programming formats. Goal programming and compromise solutions are closely related. The major advantages of goal programming and l_1-compromise solutions are that they are easily understood and can be easily computed by linear programs.
2. When all $f_i(x)$, $i = 1, 2, \ldots, q$, and $g(x)$ are linear, Program 4.2 for l_2-compromise solutions becomes a quadratic program. The program can be solved without major difficulty.
3. When all $f_i(x)$, $i = 1, 2, \ldots, q$, and $g(x)$ are linear, Program 4.2 for l_∞-compromise solutions becomes a linear program.

4.3.3. Interactive Methods of Compromise and Goal Programming Models

For nontrivial decision problems, an optimal decision usually cannot be reached by applying the compromise solution only once. The following interactive method, according to Figure 1, may be helpful.

Box (1): Identifying X, f, and y^* is an art that requires careful observation and conversation with the decision maker. The target point y^*, weight vector w, and p for l_p-norm may be more difficult to specify precisely. However, one can use the ideal point as the first step of approximation for y^*, select some representative weights for w, and let $p = 1$, 2, or ∞ to begin.

Box (2): One can locate compromise solutions according to Program 4.2 for the specified values of y^*, w, and p.

Box (3): All relevant information obtained in Box (1) and (2) can be presented to the decision maker. These include X, f, Y, ideal points y_i^*, $i = 1, 2, \ldots, q$, the optimal vector value that maximizes the ith criterion, and the compromise solutions y^1, y^2, and y^* with their weights and norms.

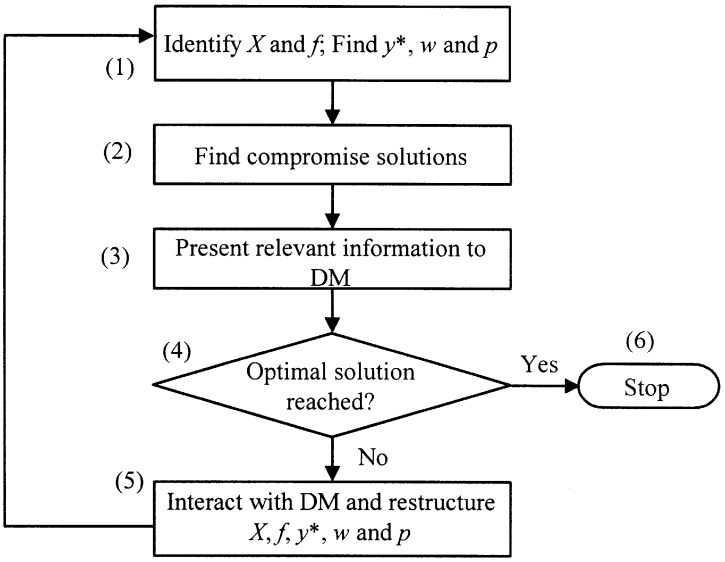

Figure 1 An Interactive Method for Compromise Solutions.

Boxes (4) and (6): If an optimal solution is reached in Box (3) and the decision maker is satisfied, the process is terminated at Box (6); otherwise, we go to Box (5) to obtain more information.

Box (5): Through conversation, we may obtain new information on X, f, y^*, weight vector w, and norm parameter p. Note that each of these five elements may change with time. To help the decision maker locate or change the target point, the "one-at-a-time method may be used. That is, only one value of f_i, or y_i, $i = 1, 2, \ldots, q$, is to be changed and the rest remain unchanged. One may ask the decision maker, "Since no satisfactory solution is obtained with the current target point y^*, would it be possible to decrease (or increase) the value of y_i^*? And, if so, by how much?" This kind of suggestive question may help the decision maker to think carefully of possible changes in the target points. The other method is called the pairwise trade-off method. We first select two criteria, say f_i and f_j, and then ask: "To maintain the same degree of satisfaction for the target point everything else being equal, how many units of f_j must be increased in order to compensate a one-unit decrease in f_i?" Again, this kind of suggestive question can help the decision maker to think carefully of the possible changes in the target points. Finally, we recall that the target point may be regarded as the satisficing set containing a single satisficing solution. Thus, by locating the satisficing set, we may locate the target point.

Example 4.5. Let us use Example 4.3 to illustrate the interactive method.

Step 1: Identify X, f, y^*, w, and p. The decision space X is given by

$$g_1(x) = x_1 + x_2 \leq 100$$
$$g_2(x) = 2x_1 + x_2 \leq 150$$
$$x_1, x_2 \geq 0$$

and the objective functions are

$$y_1 = f_1(x) = 6x_1 + 4x_2$$
$$y_2 = f_2(x) = x_1$$

Through conversation with the decision maker, assume that the ideal point will be used as the approximation for the target point. The ideal point (y_1^*, y_2^*) is (500, 75). We also assume that the two criteria are of the same weights. We shall use $p = 1$, 2, and ∞ for l_p-norm.

Step 2: Find compromise solutions. The computation of compromise solutions for $p = 1$, 2, and ∞ was illustrated in Example 4.4. The compromise solutions are $y^1 = (500, 50)$, $y^2 = (490, 55)$, and $y^\infty = (483.33, 58.33)$.

Step 3: Present relevant information to DM. All relevant information obtained in steps 1 and 2 will be presented to the decision maker. This includes X, f, Y, ideal points and the compromise solutions y^1, y^2, and y^∞ with their weights (w) and norms (p).

Step 4: Optimal solution reached? Suppose the decision maker is not satisfied with the compromise solutions presented. Assume that he or she is not satisfied with the target point (y^*) and the weight vector (w). The decision maker prefers to have the target point a little bit closer to the set Y and also feels that more weight should be given to the first criterion (f_1) rather than having equal weights.

Step 5: Through conservation with the decision maker, new relevant information on the target point (y^*) and the weight vector (w) will be obtained. Assume that the information on X, f, and p remains the same and that the new y^* is (450, 75) and the new w is (2/3, 1/3). With this new information compromise solutions y^1, y^2, and y^∞ can be recalculated and the new solutions will be presented to the decision maker. If the decision maker is satisfied with the new solutions, the procedure will be terminated; otherwise, more information from the decision maker on X, f, y^*, w, and p will be needed. We go to Box 5 and the process continues.

4.4. Further Comments

Utilizing human goal-seeking behavior, we have described the main concepts of satisficing and compromise solutions. In the real world, although specifying the satisficing set or the target point is not trivial, we can always start with the ideal point and then interact with the decision maker to gradually reach the final decision. For more details see Yu (1985, chap. 4).

There is a rich literature related to satisficing and compromise models. For instance, for goal programming see Charnes (1975), Ignizio (1976), Lee (1972) and those quoted therein; for different kinds of norms or penalty functions see Hwang and Yoon (1981), Gearhart (1979), Pascoletti and Serafini (1984), and the citations therein; for restructuring ideal points see Zeleny (1975).

Finally, observe that methods of this and the previous section are called methods of one-dimensional comparison, which tries to convert the preferences into a single-criterion numerical ordering. Other methods, such as Elimination et Choice Translating Reality (ELECTRE) (see Roy 1971 for further details) also belong to this class.

5. DOMINATION STRUCTURES

As mentioned in the introduction, preferences may be represented by one-dimensional comparison, which we discussed in the previous two sections, or in terms of multidimensional comparison, which we will discuss in this and the following section. Note that in one-dimensional comparison, we implicitly or explicitly assume that $\{?\} = \emptyset$ and that no ambiguity exists in preference. Once the value function or proper regret function is determined, MCDM becomes a one-dimensional comparison or a mathematical programming problem. In this section we shall tackle the problems with $\{?\} \neq \emptyset$.

Recall Definition 2.3 and $\{y^0\prec\}$, $\{y^0\succ\}$, $\{y^0 \sim\}$, and $\{y^0?\}$ are respectively the sets of points in Y that are better (preferred), worse (less preferred), equivalent and indefinite to y^0. For simplicity, we rewrite:

$$\{y^0\prec\} = y^0 + P(y^0)$$
$$\{y^0\succ\} = y^0 + D(y^0)$$
$$\{y^0\sim\} = y^0 + I(y^0)$$
$$\{y^0?\} = y^0 + U(y^0)$$

where $P(y^0)$, $D(y^0)$, $I(y^0)$, and $U(y^0)$ are respectively the sets of preferred, dominated, indifferent (equivalent), and unclarified (indefinite) factors.

Example 5.1

1. In Pareto preference (Example 2.1), for each y, $P(y) = \Lambda^{\geq} = \{d \in R^q | d_i \geq 0$ for all i and $d \neq 0\}$, $D(y) = \Lambda^{\leq} = \{d \in R^q | d_i \leq 0$ for all i and $d \neq 0\} = -P(y)$, $I(y) = \{0\}$, $U(y) = R^q \backslash (\Lambda^{\geq} \cup \Lambda^{\leq} \cup \{0\})$.
2. If the preference is represented by a concave differentiable value function $v(y)$, then $D(y)$ contains $\{d | \nabla v(y) \cdot d < 0\}$ which is a "half" space no matter what the dimensionality of Y is. Except linear $v(y)$, $D(y)$ is a function of y and in general $D(y) \neq -P(y)$. Note that in general $D(y)$ and $P(y)$ are not convex cones. Nevertheless, if we use the *tangent* cones of $\{y\succ\}$ and

$\{y<\}$ at y to represent the local sets of the preferred and dominated factors, denoted by $LD(y)$ and $LP(y)$, respectively, then $LD(y)$ and $LP(y)$ can be convex cones and $LD(y) = -LP(y)$. For a detail of such treatment, see Yu (1985, chap. 7).

In order to simplify our presentation, we shall assume the following throughout this section.

Assumption 5.1. For each $y \in Y$, $D(y)$ and $P(y)$ are convex cones. Furthermore, $D(y) = -P(y)$.

Remark 5.1. Pareto preference (Example 5.l number 1) satisfies Assumption 5.l, so does the preference represented by a linear value function. As indicated in Example 5.l, number 2, one can use $LD(y)$ and $LP(y)$ to replace $D(y)$ and $P(y)$ respectively when the assumption does not hold. If we do so, our results stated in this section are still valid, but only in a local sense (local optimal vs. global optimal). For the details of such treatment and conditions for the local results to be valid as the global results refer to Yu (1985, chap. 7).

Definition 5.1. A point $y^0 \in Y$ is a *nondominated point* or *N*-points if $y^0 N[<]$, where $N[<]$ is as defined in Definition 2.4.

In Section 5.1, we discuss some basic properties of *N*-points when $D(y)$ is constant. In Section 5.2, we explore the case when $D(y)$ varies with y.

5.1. Constant Cone Domination Structures and Solutions

For simplicity, when $D(y) = \Lambda$ for all y, we shall call Λ the dominated cone and denote the set of all nondominated points or (*N*-points) by $N(Y, \Lambda)$. In this subsection we shall discuss two sets of conditions that characterize *N*-points. To facilitate our discussion, let us introduce the following concepts:

Definition 5.2

1. Y is Λ-convex if $Y + \Lambda$ is a convex set.
2. The polar cone of Λ is defined by $\Lambda^* = \{\lambda | \lambda \cdot d \leq 0 \text{ for all } d \in \Lambda\}$; interior is denoted by int Λ^*.
3. Given $\lambda \in \Lambda^*$, $\lambda \neq 0$, the set of all maximum points in Y with respect to linear functional $\lambda \cdot y$ is denoted by $Y^0(\lambda)$.

For further discussion on cone convexity, see Yu (1974, 1985).

Theorem 5.1

1. $\cup \{Y^0(\lambda) | \lambda \in \text{int } \Lambda^*, \lambda \neq 0\} \subseteq N(Y, \Lambda)$
2. If Y is Λ-convex and Λ is pointed (that is, $\Lambda \cap (-\Lambda) = \{0\}$), then

$$N(Y, \Lambda) \subseteq \cup \{Y^0(\lambda) | \lambda \in \Lambda^*, \lambda \neq 0\}$$

Note that the theorem states that conditions for *N*-points to be found by maximizing a linear function over Y; 1 is a sufficient condition and 2 a necessary condition. If one is interested in the entire set of *N*-points, then the theorem serves as an approximation for the set; 1 is the inner approximation and 2 the outer approximation for $N(Y, \Lambda)$. The results are derived in Yu (1974, 1985); their further refinement can be found in Hartley (1978).

A cone that is a closed polyhedron is called a *polyhedral cone*. If Λ is a polyhedral cone, so is Λ^*. In this case, there are a finite number of vectors $\{H^1, H^2, \ldots, H^p\}$ so that Λ^* is the cone generated by $\{H^1, H^2, \ldots, H^p\}$. That is,

$$\Lambda^* = \{a_1 H^1 + a_2 H^2 + \ldots + a_p H^p | a_i \in R^1, a_1 \geq 0, i = 1, 2, \ldots, p\}$$

$\{H^1, H^2, \ldots, H^p\}$ will be called a *generator* of Λ^*. From now on, unless otherwise specified, whenever Λ is a polyhedral cone, we shall assume that $\{H^1, H^2, \ldots, H^p\}$ is a generator for Λ^*.

Let $r(j)$ be the vector in R_k^{p-1} representing $\{r_k \in R^1 | k \in \{1, 2, \ldots, p\} \backslash \{j\}\}$. Define $Y(r(j)) = \{y \in Y | H^k \cdot y \geq r_k, k \in \{1, 2, \ldots, p\} \backslash \{j\}\}$. Note that r_k may be regard as an aspiration level or satisfying level for $H^k \cdot y$.

Theorem 5.2 (Yu 1974). Let $\Lambda' = \Lambda \cup \{0\}$ be a polyhedral cone. Then $y^0 \in N(Y, \Lambda)$ if and only if for any arbitrary $j \in \{1, 2, \ldots, p\}$, there is $r(j)$ such that y^0 uniquely maximizes $H^j \cdot y$ over $Y(r(j))$.

This theorem essentially says that in search of $N(Y, \Lambda)$ by mathematical programming, constraints and objective functions are interchangeable.

5.2. Variable Cone Domination Structures and Methods for Seeking Good Solutions

In this subsection we describe a convergent method and a heuristic method to locate $N(Y, D(\cdot))$. To begin, let us assume that each $D(y)$ contains $\Lambda^{\leq}$. Define $\Lambda^0 = \cap \{D(y) | y \in Y\}$ and set $Y^0 = Y$. Note that $\Lambda^{\leq} \subseteq \Lambda^0$. Recursively, let us define, for $n = 0, 1, 2, \ldots$

$$\Lambda^n = \cap \{D(y) | y \in Y^n\} \text{ and } Y^{n+1} = N(Y^n, \Lambda^n)$$

Then

$$Y^{n+1} \subseteq Y^n \text{ and } \Lambda^n \subseteq \Lambda^{n+1}$$

It follows that the sequences converge. Denote by $\lim Y^n$ and $\lim \Lambda^n$ the limits. It can be shown (Yu 1985) that for each n, $N(Y, D(\cdot)) \subseteq Y^n$ and $N(Y, D(\cdot)) \subseteq \lim Y^n$. This observation allows us to locate the N-points according to Flowchart 1 (method 1) of Figure 2.

Flowchart 1 is self-explanatory. Although the method guarantees a convergent set containing the N-points, it may not be effective and efficient. The following heuristic method according to Flowchart 2 (method 2) can be more efficient in reaching the final decision at the risk of missing some N-points. Let us explain Flowchart 2.

Box (*0*): We first explore the relationship among the criteria and locate some plausible aspiration levels and trade-offs among the criteria. Then we use Theorem 5.1 or 5.2 to locate a set of initial "good" alternatives corresponding to different aspiration levels and trade-offs, using mathematical programming if necessary. One can also start with the points that respectively maximize the individual criteria. This initial set is denoted by Z^0.

Box (*1*): We should first estimate $D(y)$ for some representative points in Z^n and find their intersection for Λ^n. The more representative points considered, the smaller is Λ^n and the less chance there is to miss N-points; but it may take longer to find the final solutions. In estimate $D(y)$, we can use the definition to locate it directly, or we can use the bounds of trade-off ratios to locate it indirectly. For further discussion, see Yu (1985).

Box (*2*): Here we can use Theorem 5.1 or 5.2 to locate the entire set of Z^{n+1} or to locate a representative set for Z^{n+1}, depending on how much we want to avoid missing some N-points.

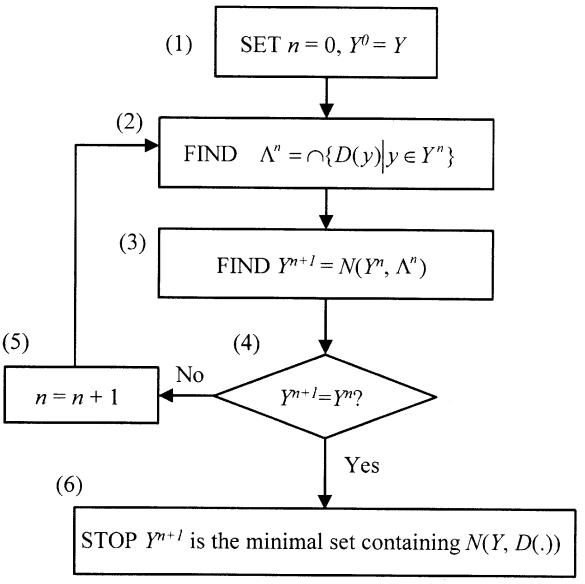

Figure 2 Flowchart 1: The First Method for Nondominated Solutions.

Boxes (*3*) *and* (*4*): Box (3) is a comparison to see if the process has reached a steady state. If not, the process will continue to Box (4), which is to eliminate those dominated points in Z^{n+1}. Here $\hat{D}(Z^{n+1})$ denotes estimated dominated points in Z^{n+1}, and W^{n+1} will be the remaining "good" alternatives after the elimination.

Boxes (*5*) *and* (*6*): Box (5) is a comparison to see if the elimination in Box (4) is effective if $W^{n+1} = Z^{n+1}$, then Z^{n+1} can be a set of *N*-points and the process can reach its steady state. Box (6) is to replace Z^{n+1} by W^{n+1} for the next iteration.

Boxes (*7*)–(*10*): Z^{n+1} is stable if no element in Z^{n+1} is dominated by any other element in Z^{n+1} and every element outside of Z^{n+1} is dominated by some element in $Z^{n+1} = N(Z^{n+1}, D(\cdot))$. If this condition is satisfied, Z^{n+1} can probably be the set of all *N*-points. In Box (9), nondominance is verified either by Theorem 5.1 or 5.2. If Z^{n+1} is the set of all *N*-points, the process is stopped at Box (10) with Z^{n+1} as the set for the final decision. Otherwise, the process should be repeated again from Box (0). If Z^{n+1} is not stable, then Z^{n+1} contains some dominated points or there are *N*-points not contained in Z^{n+1}. We shall accordingly either eliminate the dominated points from Z^{n+1} or add new *N*-points into Z^{n+1}. This adjustment on Z^{n+1} is performed at Box (8).

Box (11): This step is obvious for changing the step variable in the process.

For examples of applying the two methods described in this subsection, the interested reader is referred to Yu (1985).

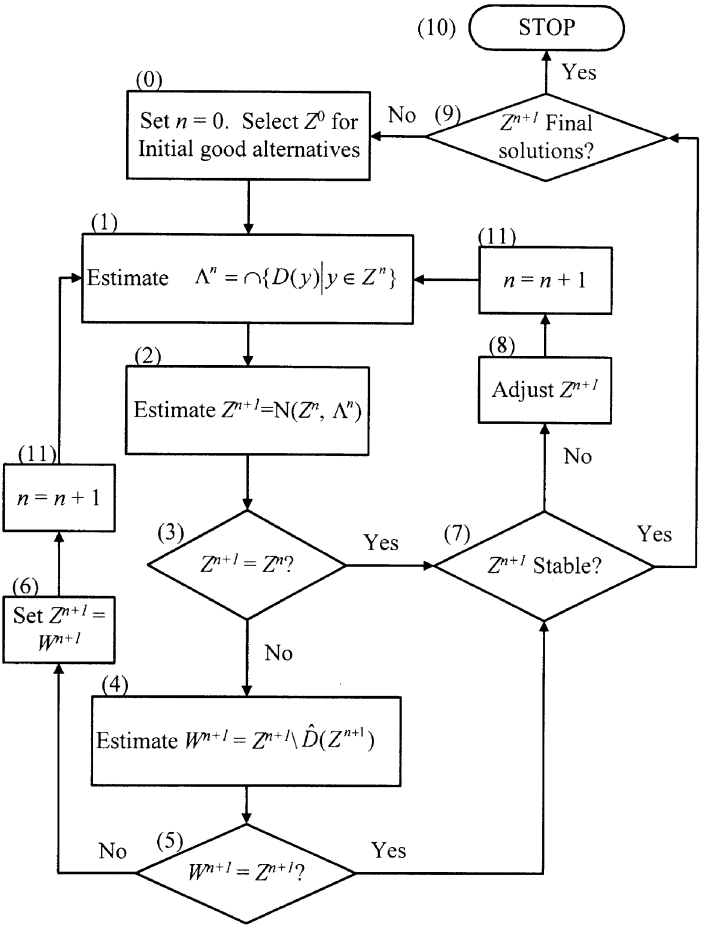

Figure 3 Flowchart 2: The Second Method for Nondominated Solutions.

6. MC²-SIMPLEX METHOD FOR LINEAR CASES

Linear function is the best function in analysis and application because it is easy to understand and compute. Because of these traits of linear functions, linear programming is popular and powerful. In this section we shall extend the linear programming with single criterion to that with multiple criteria and multilevel constraints of the resource. Instead of the simplex method with single criterion, we shall discuss the multicriteria (MC) simplex method and the multicriteria multiconstraint-level (MC²) simplex method to help resolve the difficulty of decision problems.

Algebraically, the MC²-simplex method can be represented by

$$\begin{array}{ll} \max & Cx \\ \text{s.t.} & Ax \leq D,\ x \geq 0 \end{array} \tag{1}$$

where $C = C_{q\times n}$, $A = A_{m\times n}$, and $D = D_{m\times k}$ are matrices. Note that if $k = 1$, then D is a vector and (1) becomes the MC simplex problem; if $q = 1$, then C is a vector and (1) becomes the ordinary simplex problem.

The MC²-simplex formulation can arise in many ways. Recall that Theorem 5.2 implies that to find N-points, the constraints and the objective functions in mathematical programming formulation are interchangeable. One may put some criteria in constraints with multiple levels, and thus the result will be a MC²-simplex form. Another case is in the design of optimal systems, in which one wishes to design a system that is optimal over all contingencies rather than find an optimal point within a given system (see Seiford and Yu 1979; Yu 1985, chap. 8 for further discussion). Alternatively, one may view the constraint level as occurring according to a random rule or influenced by some uncertain factor but contained within a set. In multiple-person decision making, the resource levels may reflect the views of different coalitions of the players.

6.1. Nondominated Solutions

The following result (Yu and Zeleny 1974) connects the relationship between N-points and the MC-simplex method.

Theorem 6.1. When D is a column vector, x^0 is an N-point in X with respect to $D(y) = \Lambda^{\leq}$ (i.e., $Cx^0 \in N(Y, \Lambda^{\leq})$) if and only if there exists some $\lambda > 0$ such that x^0 solves

$$\begin{array}{ll} \max & \lambda Cx \\ \text{s.t.} & Ax \leq D_{m\times 1},\ x \geq 0 \end{array} \tag{2}$$

Thus, by varying over λ over $\Lambda^{>} = \{\lambda | \lambda > 0\}$, we can locate all possible nondominated extreme points (N_{ex}-points) of X. Indeed, there are only a finite number of N_{ex}-points in X, and they are connected. (That is, by simplex pivoting, one can always arrive at any N_{ex}-point from other N_{ex}-point without leaving the bases of N_{ex}-points.) Locating all N_{ex}-points is in fact computationally feasible. Once all N_{ex}-points are located, they can be used to locate the entire N-points. (See Yu 1985, Yu and Zeleny 1974 for further discussion.)

To find N_{ex}-points, one can use the MC-simplex method, which appends multiple-criteria rows to the simplex tableaus. Because the MC-simplex method is a special case of the MC²-simplex method, we shall only describe the MC² simplex method in the next subsection.

Now suppose $\Lambda' = \Lambda \cup \{0\}$ is a general pointed polyhedral cone with $(H^1, H^2, \ldots, H^p)$ as a generator for Λ^*. One can define $C' = HC$, where H is the matrix with H^j as its jth row. Then $Cx^0 \in N(Y, \Lambda)$ if and only if there is $\lambda_{1\times p} > 0$ so that x^0 is a solution of (2) with C' replacing C. (See Yu 1985; Yu and Zeleny 1974 for further discussion.) This result suggests that in locating N_{ex}-points for a general polyhedral dominated cone Λ one can first convert the objective coefficient C into C', and then it becomes a problem of locating N_{ex}-points with dominated cone $\Lambda^{\leq}$. Thus, unless specified, we shall assume $D(y) = \Lambda^{\leq}$ for all y throughout the remainder of this subsection.

6.2. Potential Solutions and MC²-Simplex Method

Returning to (1), we generalize the concept of nondominated solutions into that of a potential solution by defining: A basis J is a potential basis (without confusion we also call J a potential solution) for the MC² problem (1) if there are $\lambda > 0$ and $\gamma > 0$ such that J is an optimal basis for

$$\begin{array}{ll} \max & \lambda Cx \\ \text{s.t.} & Ax \leq D\gamma,\ x \geq 0 \end{array} \tag{3}$$

Note that if D is a vector, $\gamma \in R^1$. By normalization, we can set $\gamma = 1$ and (3) reduces to (2). Then Theorem 6.1 ensures that a potential solution with D being a vector is indeed an N_{ex}-point. Thus, the concept of potential solutions is a generalization of that of nondominated solutions.

Note that the simplex tableau of (3) can be written as:

A	I	$D\gamma$ (4)
$-\lambda C$	0	0 (5)

Let B be the basis matrix associated with J. Since each set of basic vectors J is uniquely associated with a column index set, we shall, without confusion, let J be this set of indices and J' the set of non-basic columns. The simplest tableau associated with J is

$B^{-1}A$	B^{-1}	$B^{-1}D\gamma$ (6)
$\lambda C_B B^{-1}A - \lambda C$	$\lambda C_B B^{-1}$	$\lambda C_B B^{-1} D\gamma$ (7)

where (6) $= B^{-1} \cdot$ (4) (i.e., premultiply (4) by B^{-1} on both sides of the equation), (7) $= \lambda C_B \cdot$ (6) + (5), and C_B is the submatrix of criteria columns associated with the basis vectors.

Dropping γ and λ, we obtain the MC^2 tableau associated with basis J:

$B^{-1}A$	B^{-1}	$B^{-1}D$ (8)
$C_B B^{-1}A - C$	$C_B B^{-1}$	$C_B B^{-1} D$ (9)

which we write as

Y	W
Z	V

where $Y = [B^{-1}A, B^{-1}]$, $W = B^{-1}D$, $Z = [C_B B^{-1}A - C, C_B B^{-1}]$ and $V = C_B B^{-1} D$.

Let $W(J)$ and $Z(J)$ be the submatrices of the tableau associated with basis J Define:

$$\Gamma(J) = \{\gamma > 0 | W(J)\gamma \geq 0\},\ \Lambda(J) = \{\lambda > 0 | \lambda Z(J) \geq 0\}$$

Note that, because of (6) and (8), the basis is feasible for all $\gamma \in \Gamma(J)$; and because of (7) and (9), the basis is also optimal for all $\lambda \in \Lambda(J)$. Immediately, we have (Yu 1985; Seiford and Yu 1979):

Theorem 6.2.

1. J is a potential solution if and only if $\Lambda(J) \times \Gamma(J) \neq \varnothing$.

2. Given basis J, $\Gamma(J) \neq \varnothing$ if and only if $w_{\max} = 0$ for

$$\begin{array}{ll} \max & w = e_1 + e_2 + \ldots + e_q \\ \text{s.t.} & Z(J)x + e = 0 \\ & x \geq 0,\ e \geq 0, \text{ where } e \in R^q \end{array}$$

3. Given basis J, $\Gamma(J) \neq \varnothing$ if and only if $w_{\max} = 0$ for

$$\begin{array}{ll} \max & w = d_1 + d_2 + \ldots + d_k \\ \text{s.t.} & yW(J)x + d = 0 \\ & y \geq 0,\ x \geq 0, \text{ where } d \in R^k \end{array}$$

There are practical ways to verify whether a basis is a potential solution. It can be shown (Yu 1985; Seiford and Yu 1979) that the set of all potential bases is connected (that is, using pivoting, one can arrive at any potential solution without leaving the potential bases). This result makes locating all potential solutions feasible.

Given a potential basis, its corresponding sets of weights $\Lambda(J)$ and $\Gamma(J)$ on criteria and constraint levels can be specified. Even if we do not know the precise weights λ and γ, as long as $\lambda \in \Lambda(J)$ and $\gamma \in \Gamma(J)$), we know that J is the optimal basis and the decision process terminates at J for the solution. Since there are only a finite number of potential bases, finding them and identifying their corresponding weight sets can greatly simplify the difficulty in finding the final solution.

Suppose that we have $N = \{1, \ldots, n\}$ opportunities or products, from which we want to choose a subset to undertake or produce as to maximize profit. We can formulate the problem as in (3). We want to maximize the objective $\lambda\ Cx$ with constraint and $Ax \le D\lambda$ and $x \ge 0$. Here λ and γ are uncertain. In this way we have a system design problem with multiple-criteria and multiple-resource availability levels. We can use MC^2-simplex method to identify a set of potentially good systems as candidates for the optimal system. Here, each potentially good system is a subset of a given opportunity set, each of which optimizes the objective when the parameters of contribution coefficients and that of resource availability levels fall in certain region. For further discussion along this line and applications, see Lee et al. (1990), Shi (1998a, b).

7. FUZZY MULTICRITERIA OPTIMIZATION

In addition to the above methods, we could imbed fuzzy set theory into multiple-criteria linear programming. Bellman and Zadeh (1970) propose the concept of fuzzy set, and Zimmermann (1978) first propose this idea. In fuzzy set theory, there is a membership function $\mu(x)$ indicating each element x the degree of membership for x to belong to a set. Fuzzy multiple-objective linear programming formulates the objectives and the constraints as fuzzy sets, characterized by their individual linear membership functions. The decision set is defined as the intersection of all fuzzy sets and the set defined by relevant hard constraints. A crisp (nonfuzzy) solution is generated by selecting the solution that has the highest degree of membership in the decision set. For further discussions, the reader is referred to Zimmermann (1978), Werners (1987), Martinson (1993), and Lee and Li (1993).

The fuzzy multiple objectives linear programming (f-MOLP) usually has the following format:

$$\begin{aligned}
\max\ & \tilde{z}_k = \sum_{j=1}^{n} \tilde{c}_{kj} x_k,\ k = 1, 2, \ldots, q_1 \\
\min\ & \tilde{w}_k = \sum_{j=1}^{n} \tilde{c}_{kj} x_j,\ k = q_1 + 1, \ldots, q \\
\text{s.t.}\ & \sum_{j=1}^{n} \tilde{a}_{ij} x_j \le \tilde{b}_i,\ i = 1, 2, \ldots, m_1 \\
& \sum_{j=1}^{n} \tilde{a}_{ij} x_j \ge \tilde{b}_i,\ i = m_1 + 1, \ldots, m_2 \\
& \sum_{j=1}^{n} \tilde{a}_{ij} x_j = \tilde{b}_i,\ i = m_2 + 1, \ldots, m \\
& x_j \ge 0,\ j = 1, 2, \ldots, n
\end{aligned} \tag{10}$$

where $\tilde{c}_{kj}$ is the jth coefficient of kth objective, $\tilde{a}_{ij}$ is jth coefficient of ith constraint, and $\tilde{b}_i$ is the right-hand side (RHS) of ith constraint. Note that $\tilde{c}_{kj}$, $\tilde{a}_{ij}$, and $\tilde{b}_i$ are fuzzy numbers. The f-MOLP problem (10) can be solved by transferring it into crisp MOLP (c-MOLP), shown as (11).

$$\begin{aligned}
\max\ & (z_k)_a = \sum_{j=1}^{n} (c_{kj})_a^U x_j,\ k = 1, 2, \ldots, q_1 \\
\min\ & (w_k)_a = \sum_{j=1}^{n} (c_{kj})_a^L x_j,\ k = q_1 + 1, \ldots, q \\
\text{s.t.}\ & \sum_{j=1}^{n} (a_{ij})_a^L x_j \le (b_i)_a^U,\ i = 1, 2, \ldots, m_1, m_2 + 1, \ldots, m \\
& \sum_{j=1}^{n} (a_{ij})_a^U x_j \ge (b_i)_a^L,\ i = m_1 + 1, \ldots, m \\
& x_j \ge 0,\ j = 1, 2, \ldots, n
\end{aligned} \tag{11}$$

where $(c_{kj})_a^U$ and $(c_{kj})_a^L$, $(a_{ij})_a^U$ and $(a_{ij})_a^L$ and $(b_i)_a^U$ and $(b_i)_a^L$ are upper and lower bound of fuzzy number $\tilde{c}_{kj}$, $\tilde{a}_{ij}$ and $\tilde{b}_i$, respectively, by taking α-level cut. Problem (11) can be solved by a fuzzy algorithm interactively. For details, see Zimmermann (1978) and Lee and Li (1993). For applications and extensions along this line, see Sakawa et al. (1994, 1995), Shibano et al. 1996), Shih et al. (1996), Ida and Gen (1997), and Shih and Lee (1999) and those quoted therein.

8. EXTENSIONS AND CONCLUDING REMARKS

We have briefly sketched six important topics of MCDM problems. Many more topics, such as interactive methods including adapted gradient search method, surrogate-worth trade-off methods (Haimes and Hall 1974), the Zionts–Wallenius method (Zionts and Wallenius 1976), the paired com-

parison simplex method (Malakooti and Ravindran (1986), the bireference procedure (Michalowski and Szapiro 1992), the paired comparison method (Shin and Allen 1994), preference over uncertain outcomes, and second-order games can be found in Yu (1985, chap. 10 and the citations therein). For multiple-criteria dynamic optimization problems, refer to Li and Haimes (1989), Yu and Seiford (1981), Yu and Leitmann (1974) and those quoted therein. The reader who is interested in decision aid and MCDM in abstract spaces is referred to Roy (1977) and Dauer and Stadler (1986) respectively, and the citations therein. For other mathematical analysis on multiple criteria optimization, see Metev and Yordanova-Markova (1997), Ehrgott and Klamroth (1997), and Gal and Hanne (1999).

There are a number of computer programs to solve multiple-criteria decision making (MCDM) problems. Because many MCDM problems are reformulated and solved by converting them into single-criterion optimization problems (as discussed in the previous sections), many computer programs for mathematical programming are adopted in MCDM computer software. Since the problem domains of MCDM are rich and complex, so are the computer software programs. Space limitations make it difficult to list and discuss them here. However, interested readers can refer to www.cba.uga.edu/mcdm.html, the website of the International Society on Multiple Criteria Decision Making, for MCDM software listing.

With creative thinking and practicing, the basic concepts of MCDM described above can generate an infinite number of concepts and be applied to an infinite number of multicriteria problems. Rigid habitual ways of thinking usually are the stumbling blocks to creativity. In solving nontrivial problems, we need not only the mastery of the mathematical tools but also a good understanding of human behavior and the habitual domains of the decision makers (see Yu 1990, 1995 for a detailed discussion). At the least, we should not become so overenthusiastic about one particular concept or method that, so to speak, we cut our feet to fit the already-made shoes.

CHAPTER 102
Stochastic Optimization

ANTON J. KLEYWEGT
ALEXANDER SHAPIRO
Georgia Institute of Technology

1. INTRODUCTION

Decision makers often have to make decisions in the presence of uncertainty. Decision problems are often formulated as optimization problems, and thus in many situations decision makers wish to solve optimization problems that depend on parameters which are unknown. Typically, it is quite difficult to formulate and solve such problems, both conceptually and numerically. The difficulty already starts at the conceptual stage of modeling. Often there are a variety of ways in which the uncertainty can be formalized. In the formulation of optimization problems, one usually attempts to find a good trade-off between the realism of the optimization model, which affects the usefulness and quality of the obtained decisions, and the tractability of the problem, so that it can be solved analytically or numerically. As a result of these considerations, there are a large number of different approaches for formulating and solving optimization problems under uncertainty. It is impossible to give a complete survey of all such methods in one article. Therefore, this chapter aims only to give a flavor of prominent approaches to optimization under uncertainty.

2. OPTIMIZATION UNDER UNCERTAINTY

To describe some issues involved in optimization under uncertainty, we start with a static optimization problem. Suppose we want to maximize an objective function $G(x, \omega)$, where x denotes the decision

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

to be made, χ denotes the set of all feasible decisions, ω denotes an outcome that is unknown at the time the decision has to be made, and Ω denotes the set of all possible outcomes.

There are several approaches for dealing with optimization under uncertainty. Some of these approaches are illustrated next in the context of an example.

Example 1 (Newsvendor problem). Many companies sell seasonal products, such as fashion articles, airline seats, Christmas decorations, magazines, and newspapers. These products are characterized by a relatively short selling season, after which the value of the products decreases substantially. Often a decision has to be made how much of such a product to manufacture or purchase before the selling season starts. Once the selling season has started, there is not enough time remaining in the season to change this decision and implement the change, so that at this stage the quantity of the product is given. During the season the decision maker may be able to make other types of decisions to pursue desirable results, such as to change the price of the product as the season progresses and sales of the product take place. Such behavior is familiar in many industries. Another characteristic of such a situation is that the decisions have to be made before the eventual outcomes become known to the decision maker. For example, the decision maker has to decide how much of the product to manufacture or purchase before the demand for the product becomes known. Thus, decisions have to be made without knowing which outcome will take place.

Suppose that a manager has to decide how much of a seasonal product to order. Thus, the decision variable x is a nonnegative number representing the order quantity. The cost of the product to the company is c per unit of the product. During the selling season the product can be sold at a price (revenue) of r per unit of the product. After the selling season, any remaining product can be disposed of at a salvage value of s per unit of the product, where typically $s < r$. The demand D for the product is unkown at the time the order decision x has to be made. If the demand D turns out to be greater than the order quantity x, then the whole quantity x of the product is sold during the season, and no product remains at the end of the season, so that the total revenue and the profit turn out to be rx and $rx - cx = (r - c)x$, respectively. If the demand D turns out to be less than the order quantity x, then quantity D of the product is sold during the season, and the remaining amount of product at the end of the season is $x - D$, so that the total revenue and the profit turn out to be $rD + s(x - D)$ and $rD + s(x - D) - cx = (s - c)x + (r - s)D$, respectively. Thus, the profit is given by

$$G(x, D) = \begin{cases} (s - c)x + (r - s)D & \text{if } x \geq D \\ (r - c)x & \text{if } x < D \end{cases} \tag{1}$$

The manager would like to choose x to maximize the profit $G(x, D)$, but the dilemma is that D is unknown, or in other words is uncertain, at the time the decision should be made.

Note that if $r \leq c$ and $s \leq c$, then the company can make no profit from buying and selling the product, so that the optimal order quantity is $x^* = 0$, irrespective of what the demand D turns out to be. Also, if $s \geq c$, then any unsold product at the end of the season can be disposed of at a value at least equal to the cost of the product, so that it is optimal to order as much as possible, irrespective of what the demand D turns out to be. These, of course, are obvious cases. Therefore, we assume in the remainder of this example that $s < c < r$. Under this assumption, for any given $D \geq 0$, the function $G(\cdot, D)$ is a piecewise linear function with positive slope $r - c$ for $x < D$ and negative slope $s - c$ for $x > D$. Therefore, if the demand D is known at the time the order decision has to be made, then the best decision is to choose order quantity $x^* = D$.

However, if D is not known, then the problem becomes more difficult. Sometimes a manager may want to hedge against the worst possible outcome. Suppose the manager thinks that the demand D will turn out to be some number in the interval $[a, b]$ with $a < b$, that is, the lower and upper bounds for the demand are known to the manager. In that case, in order to hedge against the worst possible scenario, the manager will choose the value of x that gives the best profit under the worst possible outcome. That is, the manager will maximize the function $g(x) \equiv \min_{D \in [a,b]} G(x, D)$ over $x \geq 0$. This leads to the following max-min problem:

$$\max_{x \geq 0} \min_{D \in [a,b]} G(x, D) \tag{2}$$

It is not difficult to see that $g(x) = G(x, a)$, and hence $x^* = a$ is the optimal solution from the point of view of the worst-case scenario. Clearly, in many cases this will be an overly conservative decision.

Sometimes a manager may want to make the decision that under the worst possible outcome will still appear as good as possible compared with what would have been the best decision with hindsight, that is, after the outcome becomes known. For any outcome of the demand D, let

$$g^*(D) \equiv \max_{x \geq 0} G(x, D) = (r - c)D$$

denote the optimal profit with hindsight, also called the optimal value with perfect information. The optimal decision with perfect information, $x^* = D$, is sometimes called the wait-and-see solution. Suppose the manager chose to order quantity x, so that the actual profit turned out to be $G(x, D)$. The amount of profit that the company missed out on because of a suboptimal decision is given by $g^*(D) - G(x, D)$. This quantity is often called the absolute regret. The manager may want to choose the value of x that minimizes the absolute regret under the worst possible outcome. For any decision x, the worst possible outcome is given by $\max_{D \in [a,b]} [g^*(D) - G(x, D)]$. Since the manager wants to choose the value of x that minimizes the absolute regret under the worst possible outcome, this leads to the following min-max problem:

$$\min_{x \geq 0} \max_{D \in [a,b]} [g^*(D) - G(x, D)] \tag{3}$$

The optimal solution of this problem is $x^* = [(c - s)a + (r - c)b]/(r - s)$. Note that x^* is a convex combination of a and b, and thus $a < x^* < b$. The larger the salvage loss per unit $c - s$, the closer x^* is to a, and the larger the profit per unit $r - c$, the closer x^* is to b. That seems to be a more reasonable decision than $x^* = a$.

It was assumed in both variants of the worst-case approach discussed above that no a priori information about the demand D was available to the manager except the lower and upper bounds for the demand. In some situations this may be a reasonable assumption and the worst-case approach could make sense if the range of the demand is known and is not too large.

Another approach to decision making under uncertainty, different from the worst-case approaches described above, is the stochastic optimization approach, on which we focus in the remainder of this article. Suppose that the demand D can be viewed as a *random variable*. This means that the probability distribution of D is known, or at least can be estimated, by using historical data and/or a priori information available to the manager. Let $F(w) \equiv \mathbb{P}(D \leq w)$ be the corresponding cumulative distribution function (cdf) of D. Then one can try to optimize the objective function on *average*, that is, to maximize the expected profit $\mathbb{E}[G(x, D)] = \int_0^\infty G(x, w)\, dF(w)$. This leads to the stochastic program

$$\max_{x \geq 0} \{g(x) \equiv \mathbb{E}[G(x, D)]\} \tag{4}$$

In the present case it is not difficult to solve the above optimization problem in a closed form. For any $D \geq 0$, the function $G(\cdot, D)$ is concave (and piecewise linear). Therefore, the expected value function $g(\cdot)$ is also concave. Suppose for a moment that $F(\cdot)$ is continuous at a point $x > 0$. Then

$$g(x) = \int_0^x [(s - c)x + (r - s)w]\, dF(w) + \int_x^\infty (r - c)x\, dF(w)$$

Using integration by parts it is possible to calculate that

$$g(x) = (r - c)x - (r - s) \int_0^x F(w)\, dw \tag{5}$$

The function $g(\cdot)$ is concave, and hence continuous, and therefore Eq. (5) holds even if $F(\cdot)$ is discontinuous at x. It follows that $g(\cdot)$ is differentiable at x iff $F(\cdot)$ is continuous at x, in which case

$$g'(x) = r - c - (r - s)F(x) \tag{6}$$

Consider the inverse $F^{-1}(\alpha) \equiv \min\{x : F(x) \geq \alpha\}$ function of the cdf F, which is defined for $\alpha \in (0, 1)$. ($F^{-1}(\alpha)$ is called the α-quantile of the cdf F.) Since $g(\cdot)$ is concave, a necessary and sufficient condition for $x^* > 0$ to be an optimal solution of problem (4), is that $g'(x^*) = 0$, provided that $g(\cdot)$ is differentiable at x^*. Note that because $s < c < r$, it follows that $0 < (r - c)/(r - s) < 1$. Consequently, an optimal solution of (4) is given by

$$x^* = F^{-1}\left(\frac{r - c}{r - s}\right) \tag{7}$$

This holds even if $F(\cdot)$ is discontinuous at x^*.

Clearly the above approach explicitly depends on knowledge of the probability distribution of the demand D. In practice, the corresponding cdf $F(\cdot)$ is never known exactly and can be approximated (estimated) at best. Nevertheless, often the obtained optimal solution is robust with respect to perturbations of the cdf $F(\cdot)$.

Another point worth mentioning is that by solving (4), the manager tries to optimize the profit on average. However, the realized profit $G(x^*, D)$ could be very different from the corresponding expected value $g(x^*)$, depending on the particular realization of the demand D. This may happen if $G(x^*, D)$, considered as a random variable, has a large variability that could be measured by its variance $\mathrm{Var}[G(x^*, D)]$. Therefore, if the manager wants to hedge against such variability, he may consider the following optimization problem

$$\max_{x \geq 0} \{g_\beta(x) \equiv \mathbb{E}[G(x, D)] - \beta \, \mathrm{Var}[G(x, D)]\} \tag{8}$$

The coefficient $\beta \geq 0$ represents the weight given to the conservative part of the decision. If β is large, then the above optimization problem tries to find a solution with minimal profit variance, while if $\beta = 0$, then problem (8) coincides with problem (4). Note that since the variance $\mathrm{Var}[G(x, D)] \equiv \mathbb{E}[(G(x, D) - \mathbb{E}[G(x, D)])^2]$ is itself an expected value, from a mathematical point of view, problem (8) is similar to the expected value problem (4). Thus, the problem of optimizing the expected value of an objective function $G(x, D)$ is very general—it could include the means, variances, quantiles, and almost any other aspects of random variables of interest.

The following deterministic optimization approach is also often used for decision making under uncertainty. The random variable D is replaced by its mean $\mu = \mathbb{E}[D]$, and then the following deterministic optimization problem is solved:

$$\max_{x \geq 0} G(x, \mu) \tag{9}$$

A resulting optimal solution $\bar{x}$ is sometimes called an expected value solution. Of course, this approach requires that the mean of the random variable D be known to the decision maker. In the present example, the optimal solution of this deterministic optimization problem is $\bar{x} = \mu$. Note that the mean solution $\bar{x}$ can be very different from the solution x^* given in (7). It is well known that the quantiles are much more stable to variations of the cdf F than the corresponding mean value. Therefore, the optimal solution x^* of the stochastic optimization problem is more robust with respect to variations of the probability distributions than an optimal solution $\bar{x}$ of the corresponding deterministic optimization problem. This should be not surprising, since the deterministic problem (9) can be formulated in the framework of the stochastic optimization problem (4) by considering the trivial distribution of D being identically equal to μ.

Also note that, for any x, $G(x, D)$ is concave in D. As a result, it follows from Jensen's inequality that $G(x, \mu) \geq \mathbb{E}[G(x, D)]$, and hence

$$\max_{x \geq 0} G(x, \mu) \geq \max_{x \geq 0} \mathbb{E}[G(x, D)]$$

Thus, the optimal value of the deterministic optimization problem is biased upward relative to the optimal value of the stochastic optimization problem.

One can also try to solve the optimization problem

$$\max_{x \geq 0} G(x, D) \tag{10}$$

for different realizations of D, and then take the expected value of the obtained solutions as the final solution. In the present example, for any realization D, the optimal solution of (10) is $x = D$, and hence the expected value of these solutions, and final solution, is $\bar{x} = \mathbb{E}[D]$. Note that this approach does not have a clear rationale, and moreover, in many optimization problems it may not make sense to take the expected value of the obtained solutions. This is usually the case in optimization problems with discrete solutions, for example, when a solution is a path in a network, there does not seem to be a useful way to take the average of several different paths. Therefore, we do not discuss this approach further.

3. STOCHASTIC PROGRAMMING

The discussion of the above example motivates us to introduce the following model optimization problem, referred to as a *stochastic programming* problem:

$$\min_{x \in \chi} \{g(x) \equiv \mathbb{E}[G(x, \omega)]\} \tag{11}$$

(We consider a minimization rather than a maximization problem for the sake of notational convenience.) Here $\chi \subset \mathbb{R}^n$ is a set of permissible values of the vector x of decision variables and is referred to as the feasible set of problem (11). Often χ is defined by a (finite) number of smooth (or even linear) constraints. In some other situations the set χ is finite. In that case problem (11) is called a *discrete* stochastic optimization problem (this should not be confused with the case of discrete probability distributions). Variable ω represents random (or stochastic) aspects of the problem. Often ω can be modeled as a finite dimensional random vector, or in more involved cases as a random process. In the abstract framework we can view ω as an element of the probability space $(\Omega, \mathcal{F}, P)$ with the known probability measure (distribution) P.

It is also possible to consider the following extensions of the basic problem (11).

- One may need to optimize a function of the expected value function $g(x)$. This happened, for example, in problem (8), where the manager wanted to optimize a linear combination of the expected value and the variance of the profit. Although important from a modeling point of view, such an extension usually does not introduce additional technical difficulties into the problem.
- The feasible set can also be defined by constraints given in a form of expected value functions. For example, suppose that we want to optimize an objective function subject to the constraint that the event $\{h(x, W) \geq 0\}$, where W is a random vector with a known probability distribution and $h(\cdot, \cdot)$ is a given function, should happen with a probability not bigger than a given number $p \in (0, 1)$. Probability of this event can be represented as the expected value $\mathbb{E}[\psi(x, W)]$, where

$$\psi(x, w) \equiv \begin{cases} 1 & \text{if} \quad h(x, w) \geq 0 \\ 0 & \text{if} \quad h(x, w) < 0 \end{cases}$$

Therefore, this constraint can be written in the form $\mathbb{E}[\psi(x, W)] \leq p$. Problems with such probabilistic constraints are called *chance constrained* problems. Note that even if the function $h(\cdot, \cdot)$ is continuous, the corresponding indicator function $\psi(\cdot, \cdot)$ is discontinuous unless it is identically equal to zero or one. Because of that, it may be technically difficult to handle such a problem.

- In some cases the involved probability distribution P_θ depends on parameter vector θ, whose components also represent decision variables. That is, the expected value objective function is given in the form

$$g(x, \theta) \equiv \mathbb{E}_\theta[G(x, \omega)] = \int_\Omega G(x, \omega)\, dP_\theta(\omega) \tag{12}$$

By using a transformation it is sometimes possible to represent the above function $g(\cdot)$ as the expected value of a function, depending on x and θ, with respect to a probability distribution that is independent of θ. We shall discuss such likelihood ratio transformations in Section 3.4

The above formulation of stochastic programs is somewhat too general and abstract. In order to proceed with a useful analysis we need to identify particular classes of such problems that on one hand are interesting from the point of view of applications and on the other hand are computationally tractable. In the following sections we introduce several classes of such problems and discuss various techniques for their solution.

3.1. Stochastic Programming with Recourse

Consider again problem (4) of the newsvendor example. We may view that problem as a two-stage problem. At the first stage a decision should be made about the quantity x to order. At this stage the demand D is not known. At the second stage a realization of the demand D becomes known and, given the first stage decision x, the manager makes a decision about the quantities y and z to sell at prices r and s, respectively. Clearly the manager would like to choose y and z in such a way as to maximize the profit. It is possible to formulate the second stage problem as the simple linear program

$$\max_{y,z} ry + sz \quad \text{subject to } y \leq D,\ y + z \leq x,\ y \geq 0,\ z \geq 0 \tag{13}$$

The optimal solution of the above problem (13) is $y^* = \min\{x, D\}$, $z^* = \max\{x - D, 0\}$, and its

optimal value is the profit $G(x, D)$ defined in (1). Now at the first stage, before a realization of the demand D becomes known, the manager chooses a value for the first-stage decision variable x by maximizing the expected value of the second-stage optimal profit $G(x, D)$.

This is the basic idea of a two-stage stochastic program with recourse. At the first stage, before a realization of the random variables ω becomes known, one chooses the first-stage decision variables x to optimize the expected value $g(x) \equiv \mathbb{E}[G(x, \omega)]$ of an objective function $G(x, \omega)$ that depends on the optimal second stage objective function.

A *two-stage stochastic linear program with fixed recourse* is a two-stage stochastic program of the form

$$\begin{aligned} &\min_x c^T x + \mathbb{E}[Q(x, \xi)] \\ &\text{s.t. } Ax = b,\ x \geq 0 \end{aligned} \tag{14}$$

where $Q(x, \xi)$ is the optimal value of the second-stage problem

$$\begin{aligned} &\min_y q(\omega)^T y \\ &\text{s.t. } T(\omega)x + Wy = h(\omega),\ y \geq 0 \end{aligned} \tag{15}$$

The second-stage problem depends on the data $\xi(\omega) \equiv (q(\omega), h(\omega), T(\omega))$, elements of which can be random, while the matrix W is assumed to be known beforehand. The matrices $T(\omega)$ and W are called the *technology* and *recourse* matrices, respectively. The expectation $\mathbb{E}[Q(x, \xi)]$ is taken with respect to the random vector $\xi = \xi(\omega)$, whose probability distribution is assumed to be known. The above formulation originated in the works of Dantzig (1955) and Beale (1955).

Note that the optimal solution $y^* = y^*(\omega)$ of the second-stage problem (15) depends on the random data $\xi = \xi(\omega)$ and therefore is random. One can write $Q(x, \xi(\omega)) = q(\omega)^T y^*(\omega)$.

The next question is how one can solve the above two-stage problem numerically. Suppose that the random data have a *discrete* distribution with a finite number K of possible realizations $\xi_k = (q_k, h_k, T_k)$, $k = 1, \ldots, K$, (sometimes called *scenarios*), with the corresponding probabilities p_k. In that case, $\mathbb{E}[Q(x, \xi)] = \sum_{k=1}^K p_k Q(x, \xi_k)$, where

$$Q(x, \xi_k) = \min \{q_k^T y_k : T_k x + W y_k = h_k,\ y_k \geq 0\}$$

Therefore, the above two-stage problem can be formulated as one large linear program:

$$\begin{aligned} &\min\ c^T x + \textstyle\sum_{k=1}^K p_k q_k^T y_k \\ &\text{s.t. } Ax = b \\ &\qquad T_k x + W y_k = h_k \\ &\qquad x \geq 0,\ y_k \geq 0,\ k = 1, \ldots, K \end{aligned} \tag{16}$$

The linear program (16) has a certain block structure that makes it amenable to various decomposition methods. One such decomposition method is the popular L-shaped method developed by Van Slyke and Wets (1969). We refer the interested reader to the recent books by Kall and Wallace (1994) and Birge and Louveaux (1997) for a thorough discussion of stochastic programming with recourse.

The above numerical approach works reasonably well if the number K of scenarios is not too large. Suppose, however, that the random vector ξ has m independently distributed components, each having just three possible realizations. Then the total number of different scenarios is $K = 3^m$. That is, the number of scenarios grows exponentially fast in the number m of random variables. In that case, even for a moderate number of random variables, say $m = 100$, the number of scenarios becomes so large that even modern computers cannot cope with the required calculations. It seems that the only way to deal with such exponential growth of the number of scenarios is to use sampling. Such approaches are discussed in Section 3.2.

It may also happen that some of the decision variables at the first or second stage are integers, such as binary variables representing "yes" or "no" decisions. Such integer (or discrete) stochastic programs are especially difficult to solve, and only very moderate progress has been reported so far. A discussion of two-stage stochastic integer programs with recourse can be found in Birge and Louveaux (1997). A branch and bound approach for solving stochastic discrete optimization problems was suggested by Norkin et al. (1998). Schultz et al. (1998) suggested an algebraic approach for solving stochastic programs with integer recourse by using a framework of Gröbner basis reductions. For a recent survey of mainly theoretical results on stochastic integer programming see Klein Haneveld and Van der Vlerk (1999).

Conceptually the idea of two-stage programming with recourse can be readily extended to *multistage* programming with recourse. Such an approach tries to model the situation where decisions

are made periodically (in stages) based on currently known realizations of some of the random variables. An H-stage stochastic linear program with fixed recourse can be written in the form

$$\begin{aligned} &\min c^1x^1 + \mathbb{E}\{\min c^2(\omega)x^2(\omega) + \ldots + \mathbb{E}[\min c^H(\omega)x^H(\omega)]\} \\ &\text{s.t. } W^1x^1 = h^1 \\ &\quad T^1(\omega)x^1 + W^2x^2(\omega) = h^2(\omega) \\ &\qquad \ldots\ldots \\ &\quad T^{H-1}(\omega)x^{H-1}(\omega) + W^Hx^H(\omega) = h^H(\omega) \\ &\quad x^1 \geq 0,\ x^2(\omega) \geq 0,\ \ldots,\ x^H(\omega) \geq 0 \end{aligned} \tag{17}$$

The decision variables $x^2(\omega), \ldots, x^H(\omega)$ are allowed to depend on the random data ω. However, the decision $x^t(\omega)$ at time t can only depend on the part of the random data that is known at time t (these restrictions are often called nonanticipativity constraints). The expectations are taken with respect to the distribution of the random variables whose realizations are not yet known.

Again, if the distribution of the random data is discrete with a finite number of possible realizations, then problem (17) can be written as one large linear program. However, it is clear that even for a small number of stages and a moderate number of random variables the total number of possible scenarios will be astronomical. Therefore, a current approach to such problems is to generate a reasonable number of scenarios and solve the corresponding (deterministic) linear program, hoping to catch at least the flavor of the stochastic aspect of the problem. The argument is that the solution obtained in this way is more robust than the solution obtained by replacing the random variables with their means.

Often the same practical problem can be modeled in different ways. For instance, one can model a problem as a two-stage stochastic program with recourse, putting all random variables whose realizations are not yet known at the second stage of the problem. Then, as realizations of some of the random variables become known, the solutions are periodically updated in a two-stage rolling horizon fashion, every time by solving an updated two-stage problem. Such an approach is different from a multistage program with recourse, where every time a decision is to be made, the modeler tries to take into account that decisions will be made at several stages in the future.

3.2. Sampling Methods

In this section we discuss a different approach that uses Monte Carlo sampling techniques to solve stochastic optimization problems.

Example 2. Consider a stochastic process I_t, $t = 1, 2, \ldots$, governed by the recursive equation

$$I_t = [I_{t-1} + x_t - D_t]^+ \tag{18}$$

with initial value I_0. Here D_t are random variables and x_t represent decision variables. (Note that $[a]^+ \equiv \max\{a, 0\}$.) The above process I_t can describe the waiting time of the tth customer in a $G/G/1$ queue, where D_t is the interarrival time between the $(t-1)$th and tth customers and x_t is the service time of $(t-1)$th customer. Alternatively, I_t may represent the inventory of a certain product at time t, with D_t and x_t representing the demand and production (or ordering) quantities, respectively, of the product at time t.

Suppose that the process is considered over a finite horizon with time periods $t = 1, \ldots, T$. Our goal is to minimize (or maximize) the expected value of an objective function involving $I_1, \ldots, I_T$. For instance, one may be interested in maximizing the expected value of a profit given (Albritton et al. 1999);

$$\begin{aligned} G(x, W) &\equiv \Sigma_{t=1}^{T} \{\pi_t \min[I_{t-1} + x_t, D_t] - h_tI_t\} \\ &= \Sigma_{t=1}^{T} \pi_tx_t + \Sigma_{t=1}^{T-1} (\pi_{t+1} - \pi_t - h_t)I_t + \pi_1I_0 - (\pi_T + h_T)I_T \end{aligned} \tag{19}$$

Here $x = (x_1, \ldots, x_T)$ is a vector of decision variables, $W = (D_1, \ldots, D_T)$ is a random vector of the demands at periods $t = 1, \ldots, T$, and π_t and h_t are nonnegative parameters representing the marginal profit and the holding cost, respectively, of the product at period t.

If the initial value I_0 is sufficiently large, then with probability close to one, variables $I_1, \ldots, I_T$ stay above zero. In that case $I_1, \ldots, I_T$ become linear functions of the random data vector W, and hence components of the random vector W can be replaced by their means. However, in many practical situations the process I_t hits zero with high probability over the considered horizon T. In such cases the corresponding expected value function $g(x) \equiv \mathbb{E}[G(x, W)]$ cannot be written in a closed

form. One can use a Monte Carlo simulation procedure to evaluate $g(x)$. Note that for any given realization of D_t, the corresponding values of I_t, and hence the value of $G(x, W)$, can be easily calculated using the iterative formula (18).

That is, let $W^i = (D_1^i, \ldots, D_T^i)$, $i = 1, \ldots, N$, be a random (or pseudorandom) sample of N independent realizations of the random vector W generated by computer, that is, there are N generated realizations of the demand process D_t, $t = 1, 2, \ldots, T$, over the horizon t. Then for any given x the corresponding expected value $g(x)$ can be approximated (estimated) by the sample average

$$\hat{g}_N(x) \equiv \frac{1}{N} \sum_{i=1}^{N} G(x, W^i) \tag{20}$$

We have that $\mathbb{E}[\hat{g}_N(x)] = g(x)$, and by the law of large numbers, that $\hat{g}_N(x)$ converges to $g(x)$ with probability one (w.p.1) as $N \to \infty$. That is, $\hat{g}_N(x)$ is an *unbiased* and *consistent* estimator of $g(x)$.

Any reasonably efficient method for optimizing the expected value function $g(x)$, say by using its sample average approximations, is based on estimation of its first (and maybe second) order derivatives. This has an independent interest and is called *sensitivity* or *perturbation* analysis. We will discuss that in Section 3.3. Recall that $\nabla g(x) \equiv (\partial g(x)/\partial x_1, \ldots, \partial g(x)/\partial x_T)$ is called the gradient vector of $g(\cdot)$ at x.

It is possible to consider a stationary distribution of the process I_t (if it exists) and to optimize the expected value of an objective function with respect to the stationary distribution. Typically, such a stationary distribution cannot be written in a closed form and is difficult to compute accurately. This introduces additional technical difficulties into the problem. Also, in some situations the probability distribution of the random variables D_t is given in a parametric form whose parameters are decision variables. We will discuss dealing with such cases later.

3.3. Perturbation Analysis

Consider the expected value function $g(x) \equiv \mathbb{E}[G(x, \omega)]$. An important question is under which conditions the first order derivatives of $g(x)$ can be taken inside the expected value, that is, under which conditions the equation

$$\nabla g(x) \equiv \nabla \mathbb{E}[G(x, \omega)] = \mathbb{E}[\nabla_x G(x, \omega)] \tag{21}$$

is correct. One reason why this question is important is the following. Let $\omega^1, \ldots, \omega^N$ denote a random sample of N independent realizations of the random variable with common probability distribution P, and let

$$\hat{g}_N(x) \equiv \frac{1}{\mathrm{N}} \sum_{i=1}^{N} G(x, \omega^i) \tag{22}$$

be the corresponding sample average function. If the interchangeability equation (21) holds, then

$$\mathbb{E}[\nabla \hat{g}_N(x)] = \frac{1}{N} \sum_{i=1}^{N} \mathbb{E}[\nabla_x G(x, \omega^i)] = \frac{1}{N} \sum_{i=1}^{N} \nabla \mathbb{E}[G(x, \omega^i)] = \nabla g(x) \tag{23}$$

and hence $\nabla \hat{g}_N(x)$ is an unbiased and consistent estimator of $\nabla g(x)$.

Let us observe that in both examples 1 and 2 the function $G(\cdot, \omega)$ is piecewise linear for any realization of ω, and hence is not everywhere differentiable. The same holds for the optimal value function $Q(\cdot, \xi)$ of the second-stage problem (15). If the distribution of the corresponding random variables is discrete, then the resulting expected value function is also piecewise linear and hence is not everywhere differentiable.

On the other hand, expectation with respect to a continuous distribution typically smoothes the corresponding function and in such cases Eq. (21) often is applicable. It is possible to show that if the following two conditions hold at a point x, then $g(\cdot)$ is differentiable at x and Eq. (21) holds:

1. The function $G(\cdot, \omega)$ is differentiable at x w.p.1.
2. There exists a positive valued random variable $K(\omega)$ such that $\mathbb{E}[K(\omega)]$ is finite and the inequality

$$|G(x_1, \omega) - G(x_2, \omega)| \leq K(\omega)\|x_1 - x_2\| \tag{24}$$

holds w.p.1 for all x_1, x_2 in a neighborhood of x.

If the function $G(\cdot, \omega)$ is not differentiable at x w.p.1 (i.e., for P-almost every $\omega \in \Omega$), then the right-hand side of Eq. (21) does not make sense. Therefore, clearly the above condition (1) is necessary for (21) to hold. Note that condition (1) requires $G(\cdot, \omega)$ to be differentiable w.p.1 at the given (fixed) point x and does not require differentiability of $G(\cdot, \omega)$ everywhere. The second condition (ii) requires $G(\cdot, \omega)$ to be continuous (in fact Lipschitz continuous) w.p.1 in a neighborhood of x.

Consider, for instance, function $G(x, D)$ of example 1 defined in 1. For any given D, the function $G(\cdot, D)$ is piecewise linear and differentiable at every point x except at $x = D$. If the cdf $F(\cdot)$ of D is continuous at x, then the probability of the event $\{D = x\}$ is zero and hence the interchangeability equation (21) holds. Then $\partial G(x, D)/\partial x$ is equal to $s - c$ if $x > D$, and is equal to $r - c$ if $x < D$. Therefore, if $F(\cdot)$ is continuous at x, then $G(\cdot, D)$ is differentiable at x and

$$g'(x) = (s - c)\mathbb{P}(D < x) + (r - c)\mathbb{P}(D > x)$$

which gives the same equation as (6). Note that the function $\partial G(\cdot, D)/\partial x$ is discontinuous at $x = D$. Therefore, the second order derivative of $\mathbb{E}[G(\cdot, D)]$ cannot be taken inside the expected value. Indeed, the second order derivative of $G(\cdot, D)$ is zero whenever it exists. Such behavior is typical in many interesting applications.

Let us calculate the derivatives of the process I_t, defined by the recursive equation (18), for a particular realization of the random variables D_t. Let τ_1 denote the first time that the process I_t hits zero, that is, $\tau_1 \geq 1$ is the first time $I_{\tau_1 - 1} + x_{\tau_1} - D_{\tau_1}$ becomes less than or equal to zero, and hence $I_{\tau_1} = 0$. Let $\tau_2 > \tau_1$ be the second time that I_t hits zero, etc. Note that if $I_{\tau_1 + 1} = 0$, then $\tau_2 = \tau_1 + 1$, and so on. Let $1 \leq \tau_1 < \ldots < \tau_n \leq T$ be the sequence of hitting times. (In queueing terminology, τ_i represents the starting time of a new busy cycle of the corresponding queue.) For a given time $t \in \{1, \ldots, T\}$, let $\tau_{i-1} \leq t < \tau_i$ Suppose that the events $\{I_{\tau - 1} + x_\tau - D_\tau = 0\}$, $\tau = 1, \ldots, T$, occur with probability zero. Then, for almost every W, the gradient of I_s with respect to the components of vector x_t can be written as follows:

$$\nabla_{x_t} I_s = \begin{cases} 1 & \text{if } t \leq s < \tau_i \text{ and } t \neq \tau_{i-1} \\ 0 & \text{otherwise} \end{cases} \tag{25}$$

Thus, by using Eqs. (19) and (25), one can calculate the gradient of the sample average function $\hat{g}_N(\cdot)$ of example (2), and hence one can consistently estimate the gradient of the expected value function $g(\cdot)$.

Consider the process I_t defined by the recursive equation (18) again. Suppose now that variables x_t do not depend on t, and let x denote their common value. Suppose further that D_t, $t = 1, \ldots,$ are independently and identically distributed with mean $\mu > 0$. Then for $x < \mu$ the process I_t is stable and has a stationary (steady-state) distribution. Let $g(x)$ be the steady-state mean (the expected value with respect to the stationary distribution) of the process $I_t = I_t(x)$. By the theory of regenerative processes it follows that for every $x \in (0, \mu)$ and any realization (called sample path) of the process D_t, $t = 1, \ldots,$ the-long run average $\hat{g}_T(x) \equiv \Sigma_{t=1}^T I_t(x)/T$ converges w.p.1 to $g(x)$ as $T \to \infty$. It is possible to show that $\nabla \hat{g}_T(x)$ also converges w.p.1 to $\nabla g(x)$ as $T \to \infty$. That is, by differentiating the long-run average of a sample path of the process I_t we obtain a consistent estimate of the corresponding derivative of the steady-state mean $g(x)$. Note that $\nabla I_t(x) = t - \tau_{i-1}$ for $\tau_{i-1} \leq t < \tau_i$, and hence the derivative of the long-run average of a sample path of the process I_t can be easily calculated.

The idea of differentiation of a sample path of a process in order to estimate the corresponding derivative of the steady-state mean function by a single simulation run is at the heart of *infinitesimal perturbation analysis*. We refer the interested reader to Glasserman (1991) and Ho and Cao (1991) for a thorough discussion of that topic.

3.4. Likelihood Ratio Method

The Monte Carlo sampling approach to derivative estimation introduced in Section 3.3 does not work if the function $G(\cdot, \omega)$ is discontinuous or if the corresponding probability distribution also depends on decision variables. In this section we discuss an alternative approach to derivative estimation known as the *likelihood ratio* (or *score function*) method.

Suppose that the expected value function is given in the form $g(\theta) \equiv \mathbb{E}_\theta[G(W)]$, where W is a random vector whose distribution depends on the parameter vector θ. Suppose further that the distribution of W has a probability density function (pdf) $f(\theta, w)$. Then for a chosen pdf $\phi(w)$ we can write

$$\mathbb{E}_\theta[G(W)] = \int G(w) f(\theta, w)\, dw = \int G(w) \frac{f(\theta, w)}{\phi(w)} \phi(w)\, dw$$

and hence

$$g(\theta) = \mathbb{E}_{\phi}[G(Z)L(\theta, Z)] \tag{26}$$

where $L(\theta, z) \equiv f(\theta, z)/\phi(z)$ is the so-called likelihood ratio function, $Z \sim \phi(\cdot)$ and $\mathbb{E}_{\phi}[\cdot]$ means that the expectation is taken with respect to the pdf ϕ. We assume in the definition of the likelihood ratio function that $0/0 = 0$ and that the pdf ϕ is such that if $\phi(w)$ is zero for some w, then $f(\theta, w)$ is also zero, that is, we do not divide a positive number by zero.

The expected value in the right-hand side of (26) is taken with respect to the distribution ϕ, which does not depend on the vector θ. Therefore, under appropriate conditions ensuring interchangeability of the differentiation and integration operators, we can write

$$\nabla g(\theta) = \mathbb{E}_{\phi}[G(Z)\nabla_{\theta}L(\theta, Z)] \tag{27}$$

In particular, if for a given θ_0 we choose $\phi(\cdot) \equiv f(\theta_0, \cdot)$, then $\nabla_{\theta}L(\theta, z) = \nabla_{\theta}f(\theta, z)/f(\theta_0, z)$, and hence $\nabla_{\theta}L(\theta_0, z) = \nabla_{\theta}\ln[f(\theta_0, z)]$. The function $\nabla_{\theta}\ln[f(\theta, z)]$ is called the score function; thus the name of this technique.

Now by generating a random sample $Z^1, \ldots, Z^N$ from the pdf $\phi(\cdot)$, one can estimate $g(\theta)$ and $\nabla g(\theta)$ by the respective sample averages

$$\tilde{g}_N(\theta) \equiv \frac{1}{N}\sum_{i=1}^{N} G(Z^i)L(\theta, Z^i) \tag{28}$$

$$\nabla \tilde{g}_N(\theta) \equiv \frac{1}{N}\sum_{i=1}^{N} G(Z^i)\nabla_{\theta}L(\theta, Z^i) \tag{29}$$

This can be readily extended to situations where function $G(x, W)$ also depends on decision variables.

Typically, the density functions used in applications depend on the decision variables in a smooth and even analytic way. Therefore, usually there is no problem in taking derivatives inside the expected value in the right-hand side of (26). When applicable, the likelihood ratio method often also allows estimation of second and higher order derivatives. However, note that the likelihood ratio method is notoriously unstable and a bad choice of the pdf ϕ may result in huge variances of the corresponding estimators. This should not be surprising since the likelihood ratio function may involve divisions by very small numbers, which of course is a very unstable procedure. We refer to Glynn (1990) and Rubinstein and Shapiro (1993) for a further discussion of the likelihood ratio method.

As an example consider the optimal value function of the second stage problem (15). Suppose that only the right-hand-side vector $h = h(\omega)$ of the second-stage problem is random. Then $Q(x, h) = G(h - Tx)$, where $G(\chi) \equiv \min\{q^T y : Wy = \chi, y \geq 0\}$. Suppose that the random vector h has a pdf $f(\cdot)$. By using the transformation $z = h - Tx$, we obtain

$$\mathbb{E}_f[Q(x, h)] = \int G(\eta - Tx)f(\eta)\, d\eta = \int G(z)f(z + Tx)\, dz = \mathbb{E}_{\phi}[G(Z)L(x, Z)] \tag{30}$$

Here ϕ is a chosen pdf, z is a random vector having pdf ϕ, and $L(x, z) \equiv f(z + Tx)/\phi(z)$ is the corresponding likelihood ratio function. It can be shown by duality arguments of linear programming that $G(\cdot)$ is a piecewise linear convex function. Therefore, $\nabla_x Q(x, h)$ is piecewise constant and discontinuous, and hence second order derivatives of $\mathbb{E}_f[Q(x, h)]$ cannot be taken inside the expected value. On the other hand, the likelihood ratio function is as smooth as the pdf $f(\cdot)$. Therefore, if $f(\cdot)$ is twice differentiable, then the second order derivatives can be taken inside the expected value in the right-hand side of (30), and consequently the second order derivatives of $\mathbb{E}_f[Q(x, h)]$ can be consistently estimated by a sample average.

3.5. Simulation-Based Optimization Methods

There are basically two approaches to the numerical solution of stochastic optimization problems by using Monte Carlo sampling techniques. One approach is known as the *stochastic approximation* method and originated in Robbins and Monro (1951). The other method was discovered and rediscovered by different researchers and is known under various names.

Suppose that the feasible set χ is convex and that at any point $x \in \chi$ an estimate $\hat{\gamma}(x)$ of the gradient $\nabla g(x)$ can be computed, say by a Monte Carlo simulation method. The stochastic approximation method generates the iterates by the recursive equation

$$x_{\nu+1} = \Pi_{\chi}(x_{\nu} - \alpha_{\nu}\hat{\gamma}(x_{\nu})) \tag{31}$$

where $\alpha_{\nu} > 0$ are chosen step sizes and Π_{χ} denotes the projection onto the set χ, that is, $\Pi_{\chi}(x)$ is the point in χ closest to x. Under certain regularity conditions the iterates x_{ν} converge to a locally

optimal solution of the corresponding stochastic optimization problem, that is, to a local minimizer x^* of $g(x)$ over χ. Typically, in order to guarantee this convergence the following two conditions are imposed on the step sizes: (1) $\Sigma_{\nu=1}^{\infty} \alpha_\nu = \infty$, and (2) $\Sigma_{\nu=1}^{\infty} \alpha_\nu^2 < \infty$. For example, one can take $\alpha_\nu \equiv c/\nu$ for some $c > 0$.

If the exact value $\gamma_\nu \equiv \nabla g(x_\nu)$ of the gradient is known, then $-\gamma_\nu$ gives the direction of steepest descent at the point x_ν. This guarantees that if $\gamma_\nu \neq 0$, then moving along the direction $-\gamma_\nu$ the value of the objective function decreases, that is, $g(x_\nu - \alpha\gamma_\nu) < g(x_\nu)$ for $\alpha > 0$ small enough. The iterative procedure (31) tries to mimic that idea by using the estimates $\hat{\gamma}(x_\nu)$ of the corresponding "true" gradients. The projection Π_χ is needed in order to enforce feasibility of the generated iterates. If the problem is unconstrained, that is, the feasible set χ coincides with the whole space, then this projection is the identity mapping and can be omitted from (31). Note that $\hat{\gamma}(x_\nu)$ does not need to be an accurate estimator of $\nabla g(x_\nu)$.

Kushner and Clark (1978) and Benveniste et al. (1990) contain expositions of the theory of stochastic approximation. Applications of the stochastic approximation method, combined with the infinitesimal perturbation analysis technique for gradient estimation, to the optimization of the steady-state means of single-server queues were studied by Chong and Ramadge (1992) and L'Ecuyer and Glynn (1994).

An attractive feature of the stochastic approximation method is its simplicity and ease of implementation in those cases in which the projection $\Pi_\chi(\cdot)$ can be easily computed. However, it also has severe shortcomings. The crucial question in implementations is the choice of the step sizes α_ν. Small step sizes result in very slow progress towards the optimum while large step sizes make the iterates zigzag. Also, a few wrong steps in the beginning of the procedure may require many iterations to correct. For instance, the algorithm is extremely sensitive to the choice of the constant c in the step size rule $\alpha_\nu = c/\nu$. Therefore, various step size rules were suggested in which the step sizes are chosen adaptively (see Ruppert 1991 for a discussion of that topic).

Another drawback of the stochastic approximation method is that it lacks good stopping criteria and often has difficulties with handling even relatively simple linear constraints.

Another simulation-based approach to stochastic optimization is based on the following idea. Let $\hat{g}_N(x)$ be the sample average function defined in (22), based on a sample of size N. Consider the optimization problem

$$\min_{x \in \chi} \hat{g}_N(x) \tag{32}$$

We can view the above problem as the sample average approximation of the "true" (or expected value) problem (11). The function $\hat{g}_N(x)$ is random in the sense that it depends on the corresponding sample. However, note that once the sample is generated, $\hat{g}_N(x)$ becomes a deterministic function whose values and derivatives can be computed for a given value of the argument x. Consequently, problem (32) becomes a deterministic optimization problem and one can solve it with an appropriate deterministic optimization algorithm.

Let $\hat{v}_N$ and $\hat{x}_N$ denote the optimal objective value and an optimal solution of the sample average problem (32), respectively. By the law of large numbers we have that $\hat{g}_N(x)$ converges to $g(x)$ w.p.1 as $N \to \infty$. It is possible to show that under mild additional conditions, $\hat{v}_N$ and $\hat{x}_N$ converge w.p.1 to the optimal objective value and an optimal solution of the true problem (11), respectively. That is, $\hat{v}_N$ and $\hat{x}_N$ are consistent estimators of their "true" counterparts.

This approach to the numerical solution of stochastic optimization problems is a natural outgrowth of the Monte Carlo method of estimation of the expected value of a random function. The method is known by various names, and it is difficult to point out who was the first to suggest this approach. In the recent literature a variant of this method, based on the likelihood ratio estimator $\bar{g}_N(x)$, was suggested in Rubinstein and Shapiro (1990) under the name *stochastic counterpart method* (also see Rubinstein and Shapiro 1993 for a thorough discussion of such a likelihood ratio–sample approximation approach). In Robinson (1996) such an approach is called the *sample path method*. This idea can also be applied to cases in which the set χ is finite, that is, to stochastic discrete optimization problems (Kleywegt and Shapiro 1999).

Of course, in a practical implementation of such a method, one has to choose a specific algorithm for solving the sample average approximation problem (32). For example, in the unconstrained case, one can use the steepest descent method. That is, iterates are computed by the procedure

$$x_{\nu+1} = x_\nu - \alpha_\nu \nabla \hat{g}_N(x_\nu) \tag{33}$$

where the step size α_ν is obtained by a line search, such as $\alpha_\nu \equiv \arg\min_\alpha \hat{g}_N(x_\nu - \alpha \nabla \hat{g}_N(x_\nu))$. Note that this procedure is different from the stochastic approximation method (31) in two respects. Typically a reasonably large sample size N is used in this procedure, and, more importantly, the step sizes are calculated by a line search instead of being defined a priori. In many interesting cases

$\hat{g}_N(x)$ is a piecewise smooth (and even piecewise linear) function and the feasible set is defined by linear constraints. In such cases bundle-type optimization algorithms are quite efficient (see Hiriart-Urruty and Lemarechal 1993 for a discussion of the bundle method).

A well-developed statistical inference of the estimators $\hat{v}_N$ and $\hat{x}_N$ exists (Rubinstein and Shapiro 1993). That inference aids in the construction of stopping rules, validation analysis, and error bounds for obtained solutions and, furthermore, suggests variance reduction methods that may substantially enhance the rate of convergence of the numerical procedure. For a discussion of this topic and an application to two-stage stochastic programming with recourse, we refer to Shapiro and Homem-de-Mello (1998).

If the function $g(x)$ is twice differentiable, then the above sample path method produces estimators that converge to an optimal solution of the true problem at the same asymptotic rate as the stochastic approximation method, provided that the stochastic approximation method is applied with the *asymptotically optimal* step sizes (Shapiro 1996). On the other hand, if the underlying probability distribution is discrete and $g(x)$ is piecewise linear and convex, then w.p.1 the sample path method provides an exact optimal solution of the true problem for N large enough, and moreover the probability of that event approaches one exponentially fast as $N \to \infty$ (Shapiro and Homem-de-Mello 1999).

4. DYNAMIC PROGRAMMING

Dynamic programming (DP) is an approach for the modeling of dynamic and stochastic decision problems, the analysis of the structural properties of these problems, and the solution of these problems. Dynamic programs are also referred to as Markov decision processes (MDP). Slight distinctions can be made between DP and MDP, such as that in the case of some deterministic problems the term *dynamic programming* is used rather than *Markov decision processes*. The term *stochastic optimal control* is also often used for these types of problems. We shall use these terms synonymously.

Dynamic programs and multistage stochastic programs deal with essentially the same types of problems, namely dynamic and stochastic decision problems. The major distinction between dynamic programming and stochastic programming is in the structures that are used to formulate the models. For example, in DP, the so-called state of the process, as well as the value function, that depends on the state, are two structures that play a central role, but these concepts are usually not used in stochastic programs. Section 4.1 provides an introduction to concepts that are important in dynamic programming.

Much has been written about dynamic programming. Some books in this area are Bellman (1957), Bellman (1961), Bellman and Dreyfus (1962), Nemhauser (1966), Hinderer (1970), Bertsekas and Shreve (1978), Denardo (1982), Ross (1983), Puterman (1994), Bertsekas (1995), and Sennott (1999).

The dynamic programming modeling concepts presented in this chapter are illustrated with an example, which is both a multiperiod extension of the single-period newsvendor problem of Section 2 as well as an example of a dynamic pricing problem.

Example 3 (Revenue management problem). Managers often have to make decisions repeatedly over time regarding how much inventory to obtain for future sales as well as how to determine the selling prices. This may involve inventory of one or more products, and the inventory may be located at one or more locations, such as warehouses and retail stores. The inventory may be obtained from a production operation that is part of the same company as the decision maker, and such a production operation may be a manufacturing operation or a service operation, such as an airline, hotel, or car rental company, or the inventory may be purchased from independent suppliers. The decision maker may also have the option to move inventory between locations, such as from warehouses to retail stores. Often the prices of the products can be varied over time to attempt to find the most favorable balance between the supply of the products and the dynamically evolving demand for the products. Such a decision maker can have several objectives, such as to maximize the expected profit over the long run. The profit involves both revenue, which is affected by the pricing decisions, as well as cost, which is affected by the inventory replenishment decisions.

In Section 4.1 examples are given of the formulation of such a revenue management problem with a single product at a single location as a dynamic program.

4.1. Basic Concepts in Dynamic Programming

In this section the basic concepts used in dynamic programming models are introduced.

4.1.1. Decision Times

A dynamic programming model should distinguish between the decisions made at different points in time. The major reason for this is that the information available to the decision maker is different at different points in time—typically more information is available at later points in time (in fact, many people hold this to be the definition of time).

A second reason why distinguishing decision points is useful is that for many types of DP models it facilitates the computation of solutions. This seems to be the major reason why dynamic programming is used for deterministic decision problems. In this context, the time parameter in the model does not need to correspond to the notion of time in the application. The important feature is that a solution is decomposed into a sequence of distinct decisions. This facilitates computation of the solution if it is easier to compute the individual decisions and then put them together to form a solution than it is to compute a solution in a more direct way.

The following are examples of ways in which the decision points can be determined in a DP model:

- Decisions can be made at predetermined discrete points in time. In the revenue management example, the decision maker may make a decision once per day regarding what prices to set during the day, as well as how much to order on that day.
- Decisions can be made continuously in time. In the revenue management example, the decision maker may change prices continuously in time (which is likely to require a sophisticated way of communicating the continuously changing prices).
- Decisions can be made at random points in time when specific events take place. In the revenue management example, the decision maker may decide on prices at the random points in time when customer requests are received and may decide whether to order and how much to order at the random points in time when the inventory changes.

A well-formulated DP model specifies the way in which the decision points in time are determined.

Most of the results presented in this article are for DP models where decisions are made at predetermined discrete points in time, denoted by $t = 0, 1, \ldots, T$, where T denotes the length of the time horizon. DP models with infinite time horizons are also considered. DP models such as these are often called discrete-time DP models.

4.1.2. States

A fundamental concept in DP is that of a state, denoted by s. The set $\mathbb{S}$ of all possible states is called the state space. The decision problem is often described as a controlled stochastic process that occupies a state $S(t)$ at each point in time t.

Describing the stochastic process for a given decision problem is an exercise in modeling. The modeler has to determine an appropriate choice of state description for the problem. The basic idea is that the state should be a sufficient, and efficient, summary of the available information that affects the future of the stochastic process. For example, for the revenue management problem, choosing the state to be the amount of the product in inventory may be an appropriate choice. If there is a cost involved in changing the price, then the previous price should also form part of the state. Also, if competitors' prices affect the demand for the product, then additional information about competitors' prices and behavior should be included in the state.

Several considerations should be taken into account when choosing the state description, some of which are described in more detail in later sections. A brief overview is as follows. The state should be a sufficient summary of the available information that affects the future of the stochastic process in the following sense. The state at a point in time should not contain information that is not available to the decision maker at that time, because the decision is based on the state at that point in time. (There are also problems, called partially observed Markov decision processes, in which what is also called the state contains information that is not available to the decision maker. These problems are often handled by converting them to Markov decision processes with observable states. This topic is discussed in Bertsekas [1995].) The set of feasible decisions at a point in time should depend only on the state at that point in time, and maybe on the time itself, and not on any additional information. Also, the costs and transition probabilities at a point in time should depend only on the state at that point in time, the decision made at that point in time, and maybe on the time itself, and not on any additional information. Another consideration is that often one would like to choose the number of states to be as small as possible since the computational effort of many algorithms increase with the size of the state space. However, the number of states is not the only factor that affects the computational effort. Sometimes it may be more efficient to choose a state description that leads to a larger state space. In this sense the state should be an efficient summary of the available information.

The state space $\mathbb{S}$ can be a finite, countably infinite, or uncountable set. This article addresses dynamic programs with finite or countably infinite, also called discrete, state spaces $\mathbb{S}$.

4.1.3. Decisions

At each decision point in time, the decision maker has to choose a decision, also called an action or control. At any point in time t, the state s at time t, and the time t, should be sufficient to determine

the set $\mathfrak{A}(s, t)$ of feasible decisions, that is, no additional information is needed to determine the admissible decisions. (Note that the definition of the state of the process should be chosen in such a way that this holds for the decision problem under consideration.) Sometimes the set of feasible decisions depends only on the current state s, in which case the set of feasible decisions is denoted by $\mathfrak{A}(s)$. Although most examples have finite sets $\mathfrak{A}(s, t)$ or $\mathfrak{A}(s)$, these sets may also be countably or uncountably infinite.

In the revenue management example, the decisions involve how much of the product to order, as well as how to set the price. Thus, decision $a = (q, r)$ denotes that quantity q is ordered and that the price is set at r. Suppose the supplier requires that an integer amount between a and b be ordered at a time. Also suppose that the state s denotes the current inventory, and that the inventory may not exceed capacity Q at any time. Then the order quantity may be no more than $Q - s$. Also suppose that the price can be set to be any real number between r_1 and r_2. Then the set of feasible decisions is $\mathfrak{A}(s) = \{a, a + 1, a + 2, \ldots, \min\{Q - s, b\}\} \times [r_1, r_2]$.

The decision maker may randomly select a decision. For example, the decision maker may roll a die and base the decision on the outcome of the die roll. This type of decision is called a randomized decision, as opposed to a nonrandomized, or deterministic, decision. A randomized decision for state s at time t can be represented by a probability distribution on $\mathfrak{A}(s, t)$ or $\mathfrak{A}(s)$. The decision at time t is denoted by $A(t)$.

4.1.4. Transition Probabilities

The dynamic process changes from state to state over time. The transitions between states may be deterministic or random. The presentation here is for a dynamic program with discrete time parameter $t = 0, 1, \ldots$, and with random transitions.

The transitions have a memoryless, or Markovian, property, in the following sense. Given the history $H(t) \equiv (S(0), A(0), S(1), A(1), \ldots, S(t))$ of the process up to time t, as well as the decision $A(t) \in \mathfrak{A}(S(t), t)$ at time t, the probability distribution of the state that the process is in at time $t + 1$ depends only on $S(t)$, $A(t)$, and t, that is, the additional information in the history $H(t)$ of the process up to time t provides no additional information for the probability distribution of the state at time $t + 1$. (Note that the definition of the state of the process should be chosen in such a way that the probability distribution has this memoryless property.)

Such memoryless random transitions can be represented in several ways. One representation is by transition probabilities, which are denoted by $p[s'|s, a, t] \equiv \mathbb{P}[S(t + 1) = s'|H(t), S(t) = s, A(t) = a]$. Another representation is by a transition function f, such that given $H(t)$, $S(t) = s$, and $A(t) = a$, the state at time $t + 1$ is $S(t + 1) = f(s, a, t, \omega)$, where ω is a random variable with a known probability distribution. The two representations are equivalent, and in this article we use mostly transition probabilities. When the transition probabilities do not depend on the time t beside depending on the state s and decision a at time t, they are denoted by $p[s'|s, a]$.

In the revenue management example, suppose the demand has probability mass function $\tilde{p}(r, d) \equiv \mathbb{P}[D = d|\text{price} = r]$ with $d \in \{0, 1, 2, \ldots\}$. Also suppose that a quantity q that is ordered at time t is received before time $t + 1$, and that unsatisfied demand is back-ordered. Then $\mathbb{S} = \{\ldots, -2, -1, 0, 1, 2, \ldots\}$, and the transition probabilities are as follows.

$$p[s'|s, (q, r)] = \begin{cases} \tilde{p}(r, s + q - s') & \text{if } s' \leq s + q \\ 0 & \text{if } s' > s + q \end{cases}$$

If a quantity q that is ordered at time t is received after the demand at time t, and unsatisfied demand is lost, then $\mathbb{S} = \{0, 1, 2, \ldots\}$, and the transition probabilities are as follows:

$$p[s'|s, (q, r)] = \begin{cases} \tilde{p}(r, s + q - s') & \text{if } q < s' \leq s + q \\ \sum_{d=s}^{\infty} \tilde{p}(r, d) & \text{if } s' = q \\ 0 & \text{if } s' < q \text{ or } s' > s + q \end{cases}$$

4.1.5. Rewards and Costs

Dynamic decision problems often have as objective to maximize the sum of the rewards obtained in each time period, or equivalently, to minimize the sum of the costs incurred in each time period. Other types of objectives sometimes encountered are to maximize or minimize the product of a sequence of numbers resulting from a sequence of decisions, or to maximize or minimize the maximum or minimum of a sequence of resulting numbers.

In this article we focus mainly on the objective of maximizing the expected sum of the rewards obtained in each time period. At any point in time t, the state s at time t, the decision $a \in \mathfrak{A}(s, t)$ at time t, and the time t, should be sufficient to determine the expected reward $r(s, a, t)$ at time t.

(Again, the definition of the state should be chosen so that this holds for the decision problem under consideration.) When the rewards do not depend on the time t beside depending on the state s and decision a at time t, they are denoted by $r(s, a)$.

Note that even if in the application the reward $\tilde{r}(s, a, t, s')$ at time t depends on the state s' at time $t + 1$, in addition to the state s and decision a at time t, and the time t, the expected reward at time t can still be found as a function of only s, a, and t, because

$$r(s, a, t) = \mathbb{E}[\tilde{r}(s, a, t, s')] = \sum_{s' \in \mathcal{S}} \tilde{r}(s, a, t, s') p[s' | s, a, t]$$

In the revenue management example, suppose unsatisfied demand is back-ordered and that an inventory cost/shortage penalty of $h(s)$ is incurred when the inventory level is s at the beginning of the time period. Then $\tilde{r}(s, (q, r'), s') = r'(s + q - s') - h(s)$ with $s' \leq s + q$. Thus,

$$r(s, (q, r')) = \sum_{d=0}^{\infty} \tilde{p}(r', d) r' d - h(s)$$

If unsatisfied demand is lost, then $\tilde{r}(s, (q, r'), s') = r'(s + q - s') - h(s)$ with $q \leq s' \leq s + q$. Thus,

$$r(s, (q, r')) = \sum_{d=0}^{s-1} \tilde{p}(r', d) r' d + \sum_{d=s}^{\infty} \tilde{p}(r', d) r' s - h(s)$$

In finite horizon problems, there may be a salvage value $v(s)$ if the process terminates in state s at the end of the time horizon t. Such a feature can be incorporated in the previous notation by letting $\mathcal{A}(s, T) = \{0\}$, and $r(s, 0, T) = v(s)$ for all $s \in \mathcal{S}$.

Often the rewards are discounted with a discount factor $\alpha \in [0, 1]$, so that the discounted expected value of the reward at time t is $\alpha^t r(s, a, t)$. Such a feature can again be incorporated in the previous notation by letting $r(s, a, t) = \alpha^t \bar{r}(s, a, t)$ for all s, a, and t, where $\bar{r}$ denotes the undiscounted reward function. When the undiscounted reward does not depend on time, it is convenient to denote explicitly the discounted reward by $\alpha^t r(s, a)$.

4.1.6. Policies

A policy, sometimes called a strategy, prescribes the way a decision is to be made at each point in time, given the information available to the decision maker at the point in time. Therefore, a policy is a solution for a dynamic program.

There are different classes of policies of interest, depending on which of the available information the decisions are based on. A policy can base decisions on all the information in the history of the process up to the time the decision is to be made. Such policies are called history-dependent policies. Given the memoryless nature of the transition probabilities, as well as the fact that the sets of feasible decisions and the expected rewards depend on the history of the process only through the current state, it seems intuitive that it should be sufficient to consider policies that base decisions only on the current state and time, and not on any additional information in the history of the process. Such policies are called memoryless, or Markovian, policies. If the transition probabilities, sets of feasible decisions, and rewards do not depend on the current time, then it also seems intuitive that it should be sufficient to consider policies that base decisions only on the current state, and not on any additional information in the history of the process or on the current time. (However, this intuition may be wrong, as shown by counterexample in Section 4.1.7). Under such policies, decisions are made in the same way each time the process is in the same state. Such policies are called stationary policies.

The decision maker may also choose to use some irrelevant information to make a decision. For example, the decision maker may randomly select a decision by rolling a die or drawing a card from a deck of cards. Policies that allow such randomized decisions are called randomized policies, and policies that do not allow randomized decisions are called nonrandomized or deterministic policies.

Combining the above types of information that policies can base decisions on, the following types of policies are obtained: the class Π^{HR} of history dependent randomized policies, the class Π^{HD} of history dependent deterministic policies, the class Π^{MR} of memoryless randomized policies, the class Π^{MD} of memoryless deterministic policies, the class Π^{SR} of stationary randomized policies, and the class Π^{SD} of stationary deterministic policies. The classes of policies are related as follows: $\Pi^{SD} \subset \Pi^{MD} \subset \Pi^{HD} \subset \Pi^{HR}$, $\Pi^{SD} \subset \Pi^{MD} \subset \Pi^{MR} \subset \Pi^{HR}$, $\Pi^{SD} \subset \Pi^{SR} \subset \Pi^{MR} \subset \Pi^{HR}$.

For the revenue management problem, an example of a stationary deterministic policy is to order quantity $q = s_2 - s$ if the inventory level $s < s_1$, for chosen constants $s_1 \leq s_2$, and to set the price at level $r = \check{r}(s)$ for a chosen function $\check{r}(s)$ of the current state s. An example of a stationary randomized policy is to set the price at level $r = \check{r}_1(s)$ with probability $p_1(s)$ and at level $r = \check{r}_2(s)$

with probability $1 - p_1(s)$ for chosen functions $\check{r}_1(s)$, $\check{r}_2(s)$, and $p_1(s)$ of the current state s. An example of a memoryless deterministic policy is to order quantity $q = s_2(t) - s$ if the inventory level $s < s_1(t)$, for chosen functions $s_1(t) \leq s_2(t)$ of the current time t, and to set the price at level $r = \check{r}(s, t)$ for a chosen function $\check{r}(s, t)$ of the current state s and time t.

4.1.7. Example

In this section an example is presented that illustrates why it is sometimes desirable to consider more general classes of policies, such as memoryless and/or randomized policies, instead of stationary deterministic policies, even if the sets of feasible solutions, transition probabilities, and rewards are stationary. More such examples may be found in Ross (1970), Ross (1983), Puterman (1994), and Sennott (1999).

The examples are for dynamic programs with stationary input data and objective to minimize the long-run average cost per unit time, $\lim \sup_{T\to\infty} \mathbb{E}[\sum_{t=0}^{T-1} r(S(t), A(t))|S(0)]/T$. For any policy π, let

$$V^{\pi}(s) \equiv \limsup_{T\to\infty} \frac{1}{T} \mathbb{E}^{\pi} \left[\sum_{t=0}^{T-1} r(S(t), A(t)) \middle| S(0) = s \right]$$

denote the long-run average cost per unit time under policy π if the process starts in state s, where $\mathbb{E}^{\pi}[\cdot]$ denotes the expected value if policy π is followed.

A policy π^* is called optimal if $V^{\pi^*}(s) = \inf_{\pi\in\Pi^{HR}} V^{\pi}(s)$ for all states s.

Example 4. This example shows that even if the dynamic program has stationary input data, it does not always hold that for any policy $\tilde{\pi}$, and any $\epsilon > 0$, there exists a stationary deterministic policy π that has value function V^{π} within ϵ of the value function $V^{\tilde{\pi}}$ of policy $\tilde{\pi}$.

The state space $\mathcal{S} = \{0, 1, 1', 2, 2', 3, 3', \ldots\}$. Feasible decision sets are $\mathcal{A}(0) = \{a\}$, $\mathcal{A}(i) = \{a, b\}$, and $\mathcal{A}(i') = \{a\}$ for each $i \in \{1, 2, 3, \ldots\}$. When in state $i \in \{0, 1, 2, \ldots\}$, a cost of 2 is incurred, otherwise there is no cost. That is, the costs are $r(0, a) = 2$, $r(i, a) = r(i, b) = 2$, and $r(i', a) = 0$. The transition probabilities are as follows:

$$p[0|0, a] = 1,\ p[i + 1|i, a] = 1,\ p[i'|i, b] = 1 - p[0|i, b] = p_i \qquad \text{for all } i$$

$$p[1|1', a] = 1, \text{ and } p[(i - 1)'|i', a] = 1 \qquad \text{for all } i \geq 2$$

The values p_i can be chosen to satisfy

$$p_i < 1 \text{ for all } i, \text{ and } \prod_{i=1}^{\infty} p_i = \frac{3}{4}$$

Suppose the process starts in state 1. The idea is simple: we would like to go down the chain i', $(i - 1)', \ldots, 1'$ as much as possible. To do that, we also need to go up the chain $1, 2, \ldots, i$, and then go from state i to state i' by making decision b. When we make decision b in state i, there is a risk $1 - p_i > 0$ of making a transition to state 0, which is very bad.

A stationary deterministic policy π that chooses decision a for each state i, has long-run average cost per unit time of $V^{\pi}(1) = 2$, which is as bad as can be. The only other possibility for a stationary deterministic policy π is to choose decision b for the first time in state j. In that case, each time state j is visited, there is a positive probability $1 - p_j > 0$ of making a transition to state 0. It follows that the mean time until a transition to state 0 is made is less than $2j/(1 - p_j) < \infty$, and the long-run average cost per unit time is $V^{\pi}(1) = 2$. Thus, $V^{\pi}(1) = 2$ for all stationary deterministic policies π.

Consider the memoryless deterministic policy $\tilde{\pi}$ that on its jth visit to state 1, chooses decision a, $j - 1$ times, and then chooses decision b. With probability $\Pi_{i=1}^{\infty} p_i = 3/4$, the process never makes a transition to state 0 and the long-run average cost per unit time is 1. Otherwise, with probability $1 - \Pi_{i=1}^{\infty} p_i = 1/4$, the process makes a transition to state 0 and the long-run average cost per unit time is 2. Hence, the expected long-run average cost per unit time is $V^{\tilde{\pi}}(1) = 3/4 \times 1 + 1/4 \times 2 = 5/4$. Thus, there is no ε-optimal stationary deterministic policy for $\varepsilon \in (0, 3/4)$. In fact, by considering memoryless deterministic policies $\tilde{\pi}_k$ that on their jth visit to state 1, choose decision a, $j + k$ times and then choose decision b, one obtains policies with expected long-run average cost per unit time $V^{\tilde{\pi}_k}(1)$ arbitrarily close to 1 for sufficiently large values of k. It is clear that $V^{\pi}(1) \geq 1$ for all policies π, and thus $V^*(1) = 1$, and there is no ε-optimal stationary deterministic policy for $\varepsilon \in (0, 1)$.

4.2. Finite Horizon Dynamic Programs

In this section we investigate dynamic programming models for optimization problems with the form

$$\max_{(A(0),A(1),\ldots,A(T))} \mathbb{E}\left[\sum_{t=0}^{T} r(S(t), A(t), t)\right] \tag{34}$$

where $T < \infty$ is the known finite horizon length and decisions $A(t)$, $t = 0, 1, \ldots, T$, have to be feasible and may depend only on the information available to the decision maker at each time t, that is, the history $H(t)$ of the process up to time t, and possibly some randomization. For the presentation we assume that $\mathcal{S}$ is countable and r is bounded. Similar results hold in more general cases, subject to regularity conditions.

4.2.1. Optimality Results

From the memoryless properties of the feasible sets, transition probabilities, and rewards, it is intuitive that it should be sufficient to consider memoryless deterministic policies. This can be shown to be true for finite horizon problems of the form (34).

The value function V^π of a memoryless policy π is defined by

$$V^\pi(s, t) \equiv \mathbb{E}^\pi\left[\sum_{\tau=t}^{T} r(S(\tau), A(\tau), \tau) \middle| S(t) = s\right] \tag{35}$$

Then, because it is sufficient to consider memoryless deterministic policies, the optimal value function V^* is given by

$$V^*(s, t) \equiv \sup_{\pi \in \Pi^{MD}} V^\pi(s, t) \tag{36}$$

It is easy to see that the value function V^π of a memoryless policy π satisfies the following inductive equation:

$$V^\pi(s, t) = r(s, \pi(s, t), t) + \sum_{s' \in \mathcal{S}} p[s'|s, \pi(s, t), t)]V^\pi(s', t + 1) \tag{37}$$

(Recall that $\pi(s, t)$ denotes the decision under policy π if the process is in state s at time t. If π is a randomized policy, then the understanding is that the expected value is computed with the decision distributed according to probability distribution $\pi(s, t)$. Also, even history-dependent policies satisfy a similar inductive equation, except that the value function depends on the history up to time t.) Similarly, the optimal value function V^* satisfies the following inductive optimality equation:

$$V^*(s, t) = \sup_{a \in \mathcal{A}(s,t)} \left\{r(s, a, t) + \sum_{s' \in \mathcal{S}} p[s'|s, a, t]V^*(s', t + 1)\right\} \tag{38}$$

4.2.2. Finite Horizon Algorithm

Solving a finite horizon dynamic program usually involves using (38) to compute V^* with the following backward induction algorithm. An optimal policy $\pi^* \in \Pi^{MD}$ is then obtained using (40), or an ε-optimal policy $\pi^*_\varepsilon \in \Pi^{MD}$ is obtained using (41).

Finite horizon backward induction algorithm.

0. Set $V^*(s, T + 1) = 0$ for all $s \in \mathcal{S}$.

1. For $t = T, \ldots, 1$, repeat steps 2 and 3.

2. For each $s \in \mathcal{S}$, compute

$$V^*(s, t) = \sup_{a \in \mathcal{A}(s,t)} \left\{r(s, a, t) + \sum_{s' \in \mathcal{S}} p[s'|s, a, t]V^*(s', t + 1)\right\} \tag{39}$$

3. For each $s \in \mathcal{S}$, choose a decision

$$\pi^*(s, t) \in \arg \max_{a \in \mathcal{A}(s,t)} \left\{ r(s, a, t) + \sum_{s' \in \mathcal{S}} p[s'|s, a, t] V^*(s', t + 1) \right\} \tag{40}$$

if the maximum on the right hand side is attained. Otherwise, for any chosen $\varepsilon > 0$, choose a decision $\pi^*_\varepsilon(s, t)$ such that

$$\begin{aligned} r(s, \pi^*_\varepsilon(s, t), t) + \sum_{s' \in \mathcal{S}} p[s'|s, \pi^*_\varepsilon(s, t), t] V^*(s', t + 1) + \frac{\varepsilon}{T + 1} \\ > \sup_{a \in \mathcal{A}(s,t)} \left\{ r(s, a, t) + \sum_{s' \in \mathcal{S}} p[s'|s, a, t] V^*(s', t + 1) \right\} \end{aligned} \tag{41}$$

The value function V^π of a policy π can be calculated with a similar algorithm, except that (37) is used instead of (39), that is, the maximization on the right-hand side of (39) is replaced by the decision under policy π, and step 3 is omitted.

4.2.3. Structural Properties

Dynamic programming is useful not only for the computation of optimal policies and optimal expected values, but also for determining insightful structural characteristics of optimal policies. In fact, for many interesting applications the state space is too big to compute optimal policies and optimal expected values exactly, but dynamic programming can still be used to establish qualitative characteristics of optimal quantities. Some such structural properties are illustrated with examples.

Example 5 (inventory replenishment). A business purchases and sells a particular product. A decision maker has to decide regularly, say once every day, how much of the product to buy. The business does not have to wait to receive the purchased product. In contrast to the newsvendor problem, here product that is not sold on a particular day can be kept in inventory for the future. The business pays a fixed cost K plus a variable cost c per unit of product each time product is purchased. Thus, if a units of product are purchased, then the purchasing cost is $K + ca$ if $a > 0$, and it is 0 if $a = 0$. In addition, if the inventory level at the beginning of the day is s, and a units of product is purchased, then an inventory cost of $h(s + a)$ is incurred, where h is a convex function. The demand for the product on different days are independent and identically distributed. If the demand D is greater than the available inventory $s + a$, then the excess demand is backlogged until additional inventory is obtained, at which time the backlogged demand is filled immediately. Inventory remaining at the end of the time horizon has no value. The objective is to minimize the expected total cost over the time horizon. This problem can be formulated as a discrete-time dynamic program. The state $S(t)$ is the inventory at the beginning of day t. The decision $A(t)$ is the quantity purchased on day t, and the single-stage cost $r(s, a) = (K + ca) I_{\{a>0\}} + h(s + a)$. The transitions are given by $S(t + 1) = S(t) + A(t) - D(t)$. Dynamic programming can be used to show that the following policy is optimal. If the inventory level $S(t) < \sigma^*(t)$, where $\sigma^*(t)$ is called the optimal reorder point at time t, then it is optimal to purchase $\Sigma^*(t) - S(t)$ units of product at time t, where $\Sigma^*(t)$ is called the optimal order-up-to point at time t. If the inventory level $S(t) \geq \sigma^*(t)$, then it is optimal not to purchase any product. Such a policy is often called an (s, S)-policy, or a (σ, Σ)-policy. Similar results hold in the infinite horizon case, except that σ^* and Σ^* do not depend on time t anymore.

Example 6 (resource allocation). A decision maker has an amount of resource that can be allocated over some time horizon. At each discrete point in time, a request for some amount of resource is received. If the request is for more resource than the decision maker has available, then the request has to be rejected. Otherwise, the request can be accepted or rejected. A request must be accepted or rejected as a whole—the decision maker cannot allocate a fraction of the amount of resource requested. Rejected requests cannot be recalled later. If the request is accepted, the amount of resource available to the decision maker is reduced by the amount of resource requested and the decision maker receives an associated reward in return. The amounts of resource and the rewards of future requests are unknown to the decision maker, but the decision maker knows the probability distribution of these. At the end of the time horizon, the decision maker receives a salvage reward for the remaining amount of resource. The objective is to maximize the expected total reward over the time horizon. Problems of this type are encountered in revenue management and the selling of assets such as real estate and vehicles. This resource-allocation problem can be formulated as a dynamic program. The state $S(t)$ is the amount of resource available to the decision maker at the beginning of time period t. The decision $A(t)$ is the rule that will be used for accepting or rejecting requests during time period t. If a request for amount Q of resource with an associated reward R is accepted in time period t, then the single-stage reward is R and the next state is $S(t + 1) = S(t) - Q$. If the request

is rejected, then the next state is $S(t + 1) = S(t)$. It is easy to see that the optimal value function $V^*(s, t)$ is increasing in s and decreasing in t. The following threshold policy, with reward threshold function $x^*(q, s, t) = V^*(s, t + 1) - V^*(s - q, t + 1)$, is optimal. Accept a request for amount Q of resource with an associated reward R if $Q \leq S(t)$ and $R \geq x^*(Q, S(t), t)$, and reject the request otherwise. If each request is for the same amount of resource (say 1 unit of resource), and the salvage reward is concave in the remaining amount of resource, then the optimal value function $V^*(s, t)$ is concave in s and t, and the optimal reward threshold $x^*(1, s, t) = V^*(s, t + 1) - V^*(s - 1, t + 1)$ is decreasing in s and t. These intuitive properties do not hold in general if the requests are for different amounts of resource.

Structural properties of the optimal value functions and optimal policies of dynamic programs have been investigated for many different applications. Some general structural results are given in Serfozo (1976), Topkis (1978), and Heyman and Sobel (1984).

4.3. Infinite Horizon Dynamic Programs

In this section we present dynamic programming models with an infinite time horizon. Although an infinite time horizon is a figment of the imagination, these models often are useful for decision problems with many decision points. Many infinite horizon models also have the desirable feature that there exist stationary deterministic optimal policies. Thus, optimal decisions depend only on the current state of the process and not on the sometimes artificial notion of time, as in finite horizon problems. This characteristic makes optimal policies easier to understand, compute, and implement, which is desirable in applications.

We again assume that $\mathbb{S}$ is countable and r is bounded. Similar results hold in more general cases, subject to regularity conditions. We also assume that the sets $\mathbb{A}(s)$ of feasible decisions depend only on the states s, the transition probabilities $p[s'|s, a]$ depend only on the states s, s', and decisions a, and the rewards $r(s, a)$ depend only on the states s and decisions a, and not on time, as in the finite horizon case.

In this article we focus on dynamic programs with total discounted reward objectives. As illustrated in the example of Section 4.1.7, infinite horizon dynamic programs with other types of objectives, such as long-run average reward objectives, may exhibit undesirable behavior. A proper treatment of dynamic programs with these types of objectives requires more space than we have available here, and therefore we refer the interested reader to the references. Besides, in most practical applications, rewards and costs in the near future are valued more than rewards and costs in the more distant future, and hence total discounted reward objectives are preferred for applications.

4.4. Infinite Horizon Discounted Dynamic Programs

In this section we investigate dynamic programming models for optimization problems with the form

$$\max_{(A(0),A(1),\ldots)} \mathbb{E}\left[\sum_{t=0}^{\infty} \alpha^t r(S(t), A(t))\right] \tag{42}$$

where $\alpha \in (0, 1)$ is a known discount factor. Again, decisions $A(t)$, $t = 0, 1, \ldots$ have to be feasible and may depend only on the information available to the decision maker at each time t, that is, the history $H(t)$ of the process up to time t, and possibly some randomization.

4.4.1. Optimality Results

From the stationary properties of the feasible sets, transition probabilities, and rewards, one would expect that it should be sufficient to consider stationary deterministic policies. This can be shown to be true for infinite horizon discounted problems of the form (42).

The value function V^π of a stationary policy π is defined by

$$V^\pi(s) \equiv \mathbb{E}^\pi\left[\sum_{t=0}^{\infty} \alpha^t r(S(t), A(t)) \middle| S(0) = s\right] \tag{43}$$

Then, because it is sufficient to consider stationary deterministic policies, the optimal value function V^* is given by

$$V^*(s) \equiv \sup_{\pi \in \Pi^{SD}} V^\pi(s) \tag{44}$$

Again motivated by the stationary input data, it is intuitive, and can be shown to be true, that the value function V^π of a stationary policy π satisfies an equation similar to (37) for the finite horizon case, that is,

$$V^{\pi}(s) = r(s, \pi(s)) + \alpha \sum_{s' \in \mathbb{S}} p[s'|s, \pi(s)] V^{\pi}(s') \tag{45}$$

Similarly, the optimal value function V^* satisfies the following optimality equation:

$$V^*(s) = \sup_{a \in \mathbb{A}(s)} \left\{ r(s, a) + \alpha \sum_{s' \in \mathbb{S}} p[s'|s, a] V^*(s') \right\} \tag{46}$$

4.4.2. Infinite Horizon Algorithms

Solving an infinite horizon discounted dynamic program usually involves computing V^*. An optimal policy $\pi^* \in \Pi^{SD}$ or an ε-optimal policy $\pi^*_\varepsilon \in \Pi^{SD}$ can then be obtained, as shown in this section.

Unlike the finite horizon case, V^* is not computed directly using backward induction. An approach that is often used is to compute a sequence of approximating functions V_i, $i = 0, 1, 2, \ldots$, such that $V_i \to V^*$ as $i \to \infty$.

Approximating value functions provide good policies, as motivated by the following result. Suppose V^* is approximated by $\hat{V}$ such that $\|V^* - \hat{V}\|_\infty \leq \varepsilon$. Consider any policy $\hat{\pi} \in \Pi^{SD}$ such that

$$r(s, \hat{\pi}(s)) + \alpha \sum_{s' \in \mathbb{S}} p[s'|s, \hat{\pi}(s)] \hat{V}(s') + \delta \geq \sup_{a \in \mathbb{A}(s)} \left\{ r(s, a) + \alpha \sum_{s' \in \mathbb{S}} p[s'|s, a] \hat{V}(s') \right\}$$

for all $s \in \mathbb{S}$, that is, decision $\hat{\pi}(s)$ is within δ of the optimal decision using approximating function $\hat{V}$ on the right-hand side of the optimality equation (46). Then

$$V^{\hat{\pi}}(s) \geq V^*(s) - \frac{2\alpha\varepsilon + \delta}{1 - \alpha} \tag{47}$$

for all $s \in \mathbb{S}$, that is, policy $\hat{\pi}$ has value function within $(2\alpha\varepsilon + \delta)/(1 - \alpha)$ of the optimal value function.

4.4.2.1. Value Iteration One algorithm based on a sequence of approximating functions V_i is called value iteration, or successive approximation. The iterates V_i of value iteration correspond to the value function $V^*(s, T + 1 - i)$ of the finite horizon dynamic program with the same problem parameters. Specifically, starting with initial approximation $V_0(s) = 0 = V^*(s, T + 1)$ for all s, the ith approximating function $V_i(s)$ is the same as the value function $V^*(s, T + 1 - i)$ of the corresponding finite horizon dynamic program, that is, the value function for time $T + 1 - i$ that is obtained after i steps of the backward induction algorithm.

Value iteration algorithm

0. Choose initial approximation V_0 and stopping tolerance ε. Set $i \leftarrow 0$.

1. For each $s \in \mathbb{S}$, compute

$$V_{i+1}(s) = \sup_{a \in \mathbb{A}(s)} \left\{ r(s, a) + \alpha \sum_{s' \in \mathbb{S}} p[s'|s, a] V_i(s') \right\} \tag{48}$$

2. If $\|V_{i+1} - V_i\|_\infty < (1 - \alpha)\varepsilon/2\alpha$, then go to step 3. Otherwise, set $i \leftarrow i + 1$ and go to step 1.

3. For each $s \in \mathbb{S}$, choose a decision

$$\pi^*_\varepsilon(s) \in \arg\max_{a \in \mathbb{A}(s)} \left\{ r(s, a) + \alpha \sum_{s' \in \mathbb{S}} p[s'|s, a] V_{i+1}(s') \right\}$$

if the maximum on the right-hand side is attained. Otherwise, for any chosen $\delta > 0$, choose a decision $\pi^*_\delta(s)$ such that

$$r(s, \pi^*_\delta(s)) + \alpha \sum_{s' \in \mathbb{S}} p[s'|s, \pi^*_\delta(s)] V_{i+1}(s') + (1 - \alpha)\delta > \sup_{a \in \mathbb{A}(s)} \left\{ r(s, a) + \alpha \sum_{s' \in \mathbb{S}} p[s'|s, a] V_{i+1}(s') \right\}$$

It can be shown, using the contraction property provided by the discount factor α, that $V_i \to V^*$ as $i \to \infty$ for any initial approximation V_0. Also, the convergence is geometric with rate α. Specifically,

for any V_0, $\|V_i - V^*\|_\infty \leq \alpha^i \|V_0 - V^*\|_\infty$. That implies that the convergence rate is faster if the discount factor α is smaller.

When the value iteration algorithm stops, the final approximation V_{i+1} satisfies $\|V_{i+1} - V^*\|_\infty < \varepsilon/2$. Furthermore, the chosen policy π_ε^* is an ε-optimal policy, and the chosen policy π_δ^* is an $(\varepsilon + \delta)$-optimal policy.

There are several versions of the value iteration algorithm. One example is Gauss–Seidel value iteration, which uses the most up-to-date approximation $V_{i+1}(s)$ on the right-hand side of (48) as soon as it becomes available, instead of using the previous approximation $V_i(s')$ as shown in (48). Gauss–Seidel value iteration has the same convergence properties and performance guarantees given above, but in practice it usually converges faster.

There are several other algorithms for solving infinite horizon discounted dynamic programs. One of these is policy iteration, which computes a sequence of policies π_i, and their value functions V^{π_i}. Another algorithm is modified policy iteration, which is a generalization of both value iteration and policy iteration. With correct choice of algorithm parameters, modified policy iteration often performs much better than value iteration and policy iteration. There are also several variations on these algorithms, obtained with different choices of algorithm control methods, such as adaptive control, as well as parallel versions. Most books on dynamic programming in the References discuss one or more of these algorithms.

4.5. Approximation Methods

For many interesting applications the state space $\mathcal{S}$ is too big for any of the algorithms discussed so far to be used. This is usually due to the ''curse of dimensionality''—the phenomenon that the number of states grows exponentially in the number of dimensions of the state space. When the state space is too large, not only is the computational effort required by these algorithms excessive, but storing the value function and policy values for each state is impossible with current technology.

Recall that solving a dynamic program usually involves using (38) in the finite horizon case or (46) in the infinite horizon case to compute the optimal value function V^*, and an optimal policy π^*. To accomplish this, the following major computational tasks are performed:

1. Estimation of the optimal value function V^* on the right-hand side of (38) or (46).
2. Estimation of the expected value on the right-hand side of (38) or (46). For many applications, this is a high-dimensional integral that requires a lot of computational effort to compute accurately.
3. The maximization problem on the right hand side of (38) or (46) has to be solved to determine the optimal decision for each state. This maximization problem may be easy or hard, depending on the application. The first part of this article discusses several methods for solving such stochastic optimization problems.

Approximation methods usually involve approaches to perform one or more of these computational tasks efficiently, sometimes by sacrificing optimality.

For many applications, the state space is uncountable and the transition and cost functions are too complex for closed form solutions to be obtained. To compute solutions for such problems, the state space is often discretized. Discretization methods and convergence results are discussed in Wong (1970a), Fox (1973), Bertsekas (1975), Chow and Tsitsiklis (1991), and Kushner and Dupuis (1992).

For many other applications, such as queueing systems, the state space is countably infinite. Computing solutions for such problems usually involves solving smaller dynamic programs with finite state spaces, often obtained by truncating the state space of the original DP, and then using the solutions of the smaller DPs to obtain good solutions for the original DP. Such approaches and their convergence are discussed in Fox (1971), White (1980a, b, 1982), White (1982), Cavazos-Cadena (1986), Van Dijk (1991), and Sennott (1997).

Even if the state space is not infinite, the number of states may be very large. A natural approach is to aggregate states, usually by collecting similar states into subsets, and then to solve a related DP with the aggregated state space. Aggregation and aggregation/disaggregation methods are discussed in Mendelssohn (1982), Chatelin (1984), Schweitzer et al. (1985), Bean et al. (1987), and Bertsekas and Castanon (1989).

Another natural approach for dealing with a large-scale DP is to decompose the DP into smaller related DPs, which are easier to solve, and then to use the solutions of the smaller DPs to obtain a good solution for the original DP. Decomposition methods are presented in Wong (1970b), Collins and Lew (1970), Courtois (1977), and Kleywegt et al. (1999).

Some general state space-reduction methods that include many of the methods mentioned above are analyzed in Whitt (1978, 1979a, b), Hinderer (1976, 1978), Hinderer and Hübner (1977), and Haurie and L'Ecuyer (1986). Surveys are given in Morin (1978) and Rogers et al. (1991).

Another natural and quite different approach for dealing with DPs with large state spaces is to approximate the optimal value function V^* with an approximating function $\hat{V}$. It was shown in Section

4.4.2 that good approximations $\hat{V}$ to the optimal value function V^* lead to good policies $\hat{\pi}$. Polynomial approximations, often using orthogonal polynomials such as Legendre and Chebychev polynomials, have been suggested by Bellman and Dreyfus (1959), Chang (1966), and Schweitzer and Seidman (1985). Approximations using splines have been suggested by Daniel (1976), and approximations using regression splines by Chen et al. (1999). Estimation of the parameters of approximating functions for infinite horizon discounted DPs have been studied in Tsitsiklis and Van Roy (1996), Van Roy and Tsitsiklis (1996), and Bertsekas and Tsitsiklis (1996). Some of this work was motivated by methods proposed for reinforcement learning; see Sutton and Barto (1998) for an overview.
